Preface

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research papers in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues. The first MFCS conference was organized in 1972 in Jablonna (near Warsaw, Poland). Since then, the conference traditionally moved between the Czech Republic, Slovakia, and Poland. A few years ago, the conference started traveling around Europe: in 2013 it was held in Austria, in 2014 in Hungary, in 2015 in Italy, and most recently, in 2016, the conference returned to Poland and then in 2017 was organized in Denmark. This year the conference has been visiting the United Kingdom for the first time and was organized in Liverpool.

Over 210 abstracts were submitted, of which 185 materialized as papers, of which 84 were finally accepted. The authors of the submitted papers represent nearly 40 countries. The authors first registered their papers' abstracts (by the 20th of April, 2018) and only then their content (by the 24th of April, 2018). This division in two stages has helped with the assignment of the papers to the PC members. Each paper was assigned to three PC members, who reviewed and discussed them thoroughly over a period of nearly six weeks. As the co-chairs of the program committee, we would like to express our deep gratitude to all the committee members for their hard, dedicated work. The quality of the submitted papers was very high and many good papers had to be rejected. The conference featured five invited talks, by Christel Baier (TU Dresden, Germany)m Olivier Bournez (LIX, France), Herbert Edelsbrunner (IST, Austria), Leslie Ann Goldberg (University of Oxford, UK) and Christos H. Papadimitriou (Columbia University, USA):

Christel Baier - On energy conditions and stochastic shortest path problems for Markov Decision Processes
Abstract: Markov decision processes (MDP) are widely used to formalize algorithmic problems where the task is to find a policy for traversing a weighted probabilistic graph structure in a somehow optimal way. Examples are the stochastic shortest-path problem where the goal is to minimize the expected accumulated weight until reaching a target or decision problems for MDPs with energy constraints that, e.g., aims to ensure that almost surely a target will be reached while the accumulated weight ("energy") meets a given bound. The talk will discuss solutions for such and related problems for MDPs with integer weights. These rely on a new classification of so-called end components of MDPs according to their limiting behavior with respect to the accumulated weights. This classification will be used to show that the stochastic shortest path problem is solvable in polynomial time for arbitrary finite-state MDPs, generalizing previous results for sub-classes of MDPs. Furthermore, it will be used to provide algorithms for deciding the existence of a policy ensuring that a weight-bounded (repeated) reachability condition or holds almost surely or with positive probability, and the analogous problems for universal rather than existential quantification over policies.

Olivier Bournez - Descriptive Mathematics and Computer Science with Polynomial Ordinary Differential Equations
Abstract: We will see that many continuous and discrete concepts from mathematics and computer science can be presented using ordinary differential equations. Basically, we will start from the following observation: if you know what 0, 1, -1 are, as well as what an

addition and a multiplication are, and if you remember what an ordinary differential equation is, then you can define and program many concepts from Mathematics and Computer Science. In particular we will present/rediscover descriptive complexity, computability and complexity using polynomial ordinary differential equations only. A title for this talk could also be "Programming with Ordinary Differential Equations", as these questions also relate to analog models of computations, and in particular to the 1941 General Purpose Analog Computer of Claude Shannon. In some way, we are rediscovering the forgotten art of their programming, and we are only starting to understand the true power of these very old models.

Herbert Edelsbrunner - Tri-partition of a simplicial complex
Abstract: We prove that for every simplicial complex, K, and every dimension, p, there is a partition of the p-simplices into a maximal p-tree, a maximal p-cotree, and the remaining p-simplices defining the p-th homology of K. Given a monotonic order of the simplices, this tri-partition is unique and can be computed by matrix reduction. Collecting the sets over all monotonic orders, we get matroids over the set of p-simplices (Joint work with Katharina Oelsboeck).

Leslie Ann Goldberg - Computational Complexity and the Independence Polynomial
Abstract: The independence polynomial is one of the most well-studied graph polynomials, arising in combinatorics and computer science. It is also known in statistical physics as the "partition function of the hard-core model". After describing the polynomial, I will tell you something about the complexity of approximating this polynomial, including the now-classical breakthrough results of Weitz and Sly, incursions into the complex plane by Harvey, Srivastava, and Vondrák and by Patel and Regts and finally more recent work using tools from complex analysis by Peters and Regts and also in joint work with Bezakova, Galanis, and Stefankovic.

Christos H. Papadimitriou - A computer scientist thinks about the Brain
Abstract: How does the Brain give rise to the Mind? How do neurons and synapses, molecules and genes, evolution and development, give rise to behavior and cognition, language and intelligence? Despite lightning progress in recording and molecular technology and a deluge of experimental data, we do not seem to get closer to an answer. This is a talk about admiring and appreciating the problem, and proposing a new approach based on a recognized but little studied intermediate level of Brain computation carried out by the synchronous firing of large and highly interconnected sets of neurons called assemblies. We show that assemblies give rise to a novel computational system, and we speculate that they may instrument higher cognitive functions, such as language and math.

We would like to thank them deeply for their contributions and their time. This is the third time that the MFCS proceedings are published in the Dagstuhl/LIPIcs series. We would like to particularly thank Marc Herbstritt and the LIPIcs team for all the help and support. We believe that the cooperation between MFCS and Dagstuhl/LIPIcs in the future will continue to be as seamless and fruitful as ours.

Abstract

The parameterised complexity of consensus string problems (Closest String, Closest Substring, Closest String with Outliers) is investigated in a more general setting, i. e., with a bound on the maximum Hamming distance *and* a bound on the sum of Hamming distances between solution and input strings. We completely settle the parameterised complexity of these generalised variants of Closest String and Closest Substring, and partly for Closest String with Outliers; in addition, we answer some open questions from the literature regarding the classical problem variants with only one distance bound. Finally, we investigate the question of polynomial kernels and respective lower bounds.

2012 ACM Subject Classification Theory of computation → Problems, reductions and completeness, Theory of computation → Fixed parameter tractability, Theory of computation → W hierarchy

Keywords and phrases Consensus String Problems, Closest String, Closest Substring, Parameterised Complexity, Kernelisation

Digital Object Identifier 10.4230/LIPIcs.MFCS.2018.1

1 Introduction

Consensus string problems have the following general form: given input strings $S = \{s_1, \ldots, s_k\}$ and a distance bound d, find a string s with distance at most d from the input strings. With the Hamming distance as the central distance measure for strings, there are two obvious types of distance between a single string and a set S of strings: the maximum distance between s and any string from S (called *radius*) and the sum of all distances between s and strings from S (called *distance sum*). The most basic consensus string problem is Closest String, where we get a set S of k length-ℓ strings and a bound d, and ask whether there exists a length-ℓ *solution string* s with radius at most d. This problem is NP-complete (see [16]), but fixed-parameter tractable for many variants (see [17]), including the parameterisation by d, which in biological applications can often be assumed to be small (see [12, 18]). A classical extension is Closest Substring, where the strings of S have length *at most* ℓ, the solution string must have a given length m and the radius bound d is w. r. t. some length-m substrings of the input strings. A parameterised complexity analysis (see [13, 14, 20]) has shown Closest Substring to be harder than Closest String. If we bound the distance sum instead of the radius, then Closest String collapses to a trivial problem, while Closest Substring, which is then called Consensus Patterns, remains

NP-complete. Closest String with Outliers is a recent extension, which is defined like Closest String, but with the possibility to ignore a given number of t input strings.

The main motivation for consensus string problems comes from the important task of finding similar regions in DNA or other protein sequences, which arises in many different contexts of computational biology, e. g., universal PCR primer design [9, 18, 19, 23], genetic probe design [18], antisense drug design [8, 18], finding transcription factor binding sites in genomic data [25], determining an unbiased consensus of a protein family [3], and motif-recognition [18,21,22]. The consensus string problems are a formalisation of this computational task and most variants of them are NP-hard. However, due to their high practical relevance, it is necessary to solve them despite their intractability, which has motivated the study of their approximability, on the one hand, but also their fixed-parameter tractability, on the other (see the survey [6] for an overview of the parameterised complexity of consensus string problems). This work is a contribution to the latter branch of research.

Problem Definition. Let Σ be a finite alphabet, Σ^* be the set of all strings over Σ, including the empty string ε and $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. For $w \in \Sigma^*$, $|w|$ is the length of w and, for every i, $1 \leq i \leq |w|$, by $w[i]$, we refer to the symbol at position i of w. For every $n \in \mathbb{N} \cup \{0\}$, let $\Sigma^n = \{w \in \Sigma^* \mid |w| = n\}$ and $\Sigma^{\leq n} = \bigcup_{i=0}^{n} \Sigma^i$. By $\preceq$, we denote the *substring relation* over the set of strings, i. e., for $u, v \in \Sigma^*$, $u \preceq v$ if $v = xuy$, for some $x, y \in \Sigma^*$. We use the concatenation of sets of strings as usually defined, i. e., for $A, B \subseteq \Sigma^*$, $A \cdot B = \{uv \mid u \in A, v \in B\}$.

For strings $u, v \in \Sigma^*$ with $|u| = |v|$, $\mathsf{d_H}(u, v)$ is the *Hamming distance* between u and v. For a multi-set $S = \{u_i \mid 1 \leq i \leq n\} \subseteq \Sigma^\ell$ and a string $v \in \Sigma^\ell$, for some $\ell \in \mathbb{N}$, the *radius of S (w. r. t. v)* is defined by $\mathsf{r_H}(v, S) = \max\{\mathsf{d_H}(v, u) \mid u \in S\}$ and the *distance sum of S (w. r. t. v)* is defined by $\mathsf{s_H}(v, S) = \sum_{u \in S} \mathsf{d_H}(v, u)$.[1] Next, we state the problem (r, s)-Closest String in full detail, from which we then derive the other considered problems:

(r, s)-Closest String
Instance: Multi-set $S = \{s_i \mid 1 \leq i \leq k\} \subseteq \Sigma^\ell$, $\ell \in \mathbb{N}$, and integers $d_r, d_s \in \mathbb{N}$.
Question: Is there an $s \in \Sigma^\ell$ with $\mathsf{r_H}(s, S) \leq d_r$ and $\mathsf{s_H}(s, S) \leq d_s$?

For (r, s)-Closest Substring, we have $S \subseteq \Sigma^{\leq \ell}$ and an additional input integer $m \in \mathbb{N}$, and we ask whether there is a multi-set $S' = \{s'_i \mid s'_i \preceq s_i, 1 \leq i \leq k\} \subseteq \Sigma^m$ with $\mathsf{r_H}(s, S') \leq d_r$ and $\mathsf{s_H}(s, S') \leq d_s$. For (r, s)-Closest String with Outliers (or (r, s)-Closest String-wo for short) we have an additional input integer $t \in \mathbb{N}$, and we ask whether there is a multi-set $S' \subseteq S$ with $|S'| = k - t$ such that $\mathsf{r_H}(s, S') \leq d_r$ and $\mathsf{s_H}(s, S') \leq d_s$. We also call (r, s)-Closest String the *general variant* of Closest String, while (r)-Closest String and (s)-Closest String denote the variants, where the only distance bound is d_r or d_s, respectively; we shall also call them the (r)- and (s)-*variant* of Closest String. Analogous notation apply to the other consensus string problems. The problem names that are also commonly used in the literature translate into our terminology as follows: Closest String = (r)-Closest String, Closest Substring = (r)-Closest Substring, Consensus Patterns = (s)-Closest Substring and Closest String-wo = (r)-Closest String-wo.

[1] Note that we slightly abuse notation with respect to the subset relation: for a multi-set A and a set B, $A \subseteq B$ means that $A' \subseteq B$, where A' is the set obtained from A by deleting duplicates; for multi-sets A, B, $A \subseteq B$ is defined as usual. Moreover, whenever it is clear from the context that we talk about multi-sets, we also simply use the term *set*.

The motivation for our more general setting with respect to the bounds d_r and d_s is the following. While the distance measures of radius and distance sum are well-motivated, they have, if considered individually, also obvious deficiencies. In the distance sum variant, we may consider strings as close enough that are very close to some, but totally different to the other input strings. In the radius variant, on the other hand, we may consider strings as too different, even though they are very similar to all input strings except one, for which the bound is exceeded by only a small amount. Using an upper bound on the distance per each input string and an upper bound on the total sum of distances caters for these cases.[2]

For any problem K, by $K(p_1, p_2, \ldots)$, we denote the variant of K parameterised by the parameters $p_1, p_2, \ldots$. For unexplained concepts of parameterised complexity, we refer to the textbooks [7, 10, 15].

Known Results. In contrast to graph problems, where interesting parameters are often hidden in the graph structure, string problems typically contain a variety of obvious, but nevertheless interesting parameters that could be exploited in terms of fixed-parameter tractability. For the consensus string problems these are the number of input strings k, their length ℓ, the radius bound d_r, the distance sum bound d_s, the alphabet size $|\Sigma|$, the substring length m (in case of (r,s)-Closest Substring), the number of *outliers* t and *inliers* $k-t$ (in case of (r,s)-Closest String-wo). This leads to a large number of different parameterisations, which justifies the hope for fixed-parameter tractable variants.

The parameterised complexity (w. r. t. the above mentioned parameters) of the radius as well as the distance sum variant of Closest String and Closest Substring has been settled by a sequence of papers (see [13, 14, 16, 17, 20] and, for a survey, [6]), except (s)-Closest Substring with respect to parameter ℓ, which has been neglected in these papers and mentioned as an open problem in [24], in which it is shown that the fixed-parameter tractability results from (r)-Closest String carry over to (r)-Closest Substring, if we additionally parameterise by $(\ell - m)$. The parameterised complexity analysis of the radius variant of Closest String with Outliers has been started more recently in [5] and, to the knowledge of the authors, the distance sum variant has not yet been considered.

The parameterised complexity of the general variants, where we have a bound on both the radius and the distance sum, has not yet been considered in the literature. While there are obvious reductions from the (r)- and (s)-variants to the general variant, these three variants describe, especially in the parameterised setting, rather different problems.

Our Contribution. In this work, we answer some open questions from the literature regarding the (r)- and (s)-variants of the consensus string problems, and we initiate the parameterised complexity analysis of the general variants.

We extend all the FPT-results from (r)-Closest String to the general variant; thus, we completely settle the fixed-parameter tractability of (r,s)-Closest String. While for some parameterisations, this is straightforward, the case of parameter d_r follows from a non-trivial extension of the known branching algorithm for (r)-Closest String(d_r) (see [17]).

For (r,s)-Closest Substring, we classify all parameterised variants as being in FPT or W[1]-hard, which is done by answering the open question whether (s)-Closest Substring(ℓ) is in FPT (see [24]) in the negative (which also settles the parameterised complexity of (s)-Closest Substring) and by slightly adapting the existing FPT-algorithms.

[2] To the knowledge of the authors, optimising both the radius and the distance sum has been considered first in [1], where algorithms for the special case $k = 3$ are considered.

Regarding (r,s)-Closest String-wo, we solve an open question from [5] w. r. t. the radius variant, we show W[1]-hardness for a strong parameterisation of the (s)-variant, we show fixed-parameter tractability for some parameter combinations of the general variant and, as our main result, we present an FPT-algorithm (for the general variant) for parameters d_r and t (which is the same algorithm that shows (r,s)-Closest String$(d_r) \in$ FPT mentioned above). Many other cases are left open for further research.

Finally, we investigate the question whether the fixed-parameter tractable variants of the considered consensus string problems allow polynomial kernels; thus, continuing a line of work initiated by Basavaraju et al. [2], in which kernelisation lower bounds for (r)-Closest String and (r)-Closest Substring are proved. Our respective main result is a cross-composition from (r)-Closest String into (r)-Closest String-wo.

Due to space constraints, proofs for results marked with $(*)$ are omitted.

2 Closest String and Closest String-wo

In this section, we investigate (r,s)-Closest String and (r,s)-Closest String-wo (and their (r)- and (s)-variants) and we shall first give some useful definitions.

It will be convenient to treat a set $S = \{s_i \mid 1 \leq i \leq k\} \subseteq \Sigma^\ell$ as a $k \times \ell$ matrix with entries from Σ. By the term *column of* S, we refer to the transpose of a column of the matrix S, which is an element from Σ^k; thus, the introduced string notations apply, e. g., if c is the i^{th} column of S, then $c[j]$ corresponds to $s_j[i]$. A string $s \in \Sigma^\ell$ is a *majority string* (*for a set* $S \subseteq \Sigma^\ell$) if, for every i, $1 \leq i \leq \ell$, $s[i]$ is a symbol with majority in the i^{th} column of S. Obviously, $\mathsf{s_H}(s,S) = \min\{\mathsf{s_H}(s',S) \mid s' \in \Sigma^\ell\}$ if and only if s is a majority string for S. We call a string $s \in \Sigma^\ell$ *radius optimal* or *distance sum optimal* (*with respect to a set* $S \subseteq \Sigma^\ell$) if $\mathsf{r_H}(s,S) = \min\{\mathsf{r_H}(s',S) \mid s' \in \Sigma^\ell\}$ or $\mathsf{s_H}(s,S) = \min\{\mathsf{s_H}(s',S) \mid s' \in \Sigma^\ell\}$, respectively.

It is a well-known fact that (r)-Closest String allows FPT-algorithms for any of the single parameters k, d_r or ℓ, and it is still NP-hard for $|\Sigma| = 2$ (see [17]). While the latter hardness result trivially carries over to (r,s)-Closest String (by setting $d_s = k\,d_r$), we have to modify the FPT-algorithms for extending the fixed-parameter tractability results to (r,s)-Closest String. We start with parameter k, for which we can extend the ILP-approach that is used in [17] to show (r)-Closest String$(k) \in$ FPT.

▶ **Theorem 1 (*).** (r,s)-Closest String$(k) \in$ FPT.

Next, we consider the parameter d_r. For the (r)-variant of (r,s)-Closest String, the fixed-parameter tractability with respect to d_r is shown in [17] by a branching algorithm, which proved itself as rather versatile: it has successfully been extended in [5] to (r)-Closest String-wo(d_r,t) and in [24] to (r)-Closest Substring$(d_r,(\ell-m))$.

We propose an extension of the same branching algorithm, that allows for a bound d_s on the distance sum; thus, it works for (r,s)-Closest String(d_r). In fact, we prove in Theorem 7 an even stronger result, where we also extend the algorithm to exclude up to t outlier strings from the input set S, i. e., we extend it to the problem (r,s)-Closest String-wo(d_r,t). Since Theorem 3 can therefore be seen as a corollary of this result by taking $t = 0$, we only give an informal description of a direct approach that solves (r,s)-Closest String(d_r) (and refer to Theorem 7 for a formal proof).

The core idea is to apply the branching algorithm starting with the majority string for the input set S, instead of any random string from S. Then, as in [17], the algorithm would replace some characters of the current string with characters of the solution string. This way, it can be shown that the distance sum of the current string is always a lower bound of the

Table 1 Results for (r,s)-Closest String.

distance sum of the optimal string, which allows to cut any branch where the distance sum goes beyond the threshold d_s. We prove the following lemma, which allows to bound the depth of the search tree (and shall also be used in the proof of Theorem 7 later on):

▶ **Lemma 2 (*).** *Let $S \subseteq \Sigma^\ell$, $s \in \Sigma^\ell$ such that $\mathsf{r}_\mathsf{H}(s,S) \leq d_r$, and let s_m be a majority string for S. Then $\mathsf{d}_\mathsf{H}(s_m,s) \leq 2d_r$.*

▶ **Theorem 3.** (r,s)-Closest String$(d_r) \in$ FPT.

Obviously, we can assume $d_r \leq \ell$ and we can further assume that every column of S contains at least two different symbols (all columns without this property could be removed), which implies $\mathsf{s}_\mathsf{H}(s_i,S) \geq \ell$ for every $s \in \Sigma^\ell$; thus, we can assume $\ell \leq d_s$. Consequently, we obtain the following corollary:

▶ **Corollary 4.** (r,s)-Closest String$(\ell) \in$ FPT, (r,s)-Closest String$(d_s) \in$ FPT.

This completely settles the parameterised complexity of (r,s)-Closest String with respect to parameters k, d_r, d_s, $|\Sigma|$ and ℓ; recall that the (r)-variant is already settled, while the (s)-variant is trivial.

2.1 (r, s)-Closest String-wo

We now turn to the problem (r,s)-Closest String-wo and we first prove several fixed-parameter tractability results for the general variant; in Sec. 2.2, we consider the (r)- and (s)-variants separately.

First, we note that solving an instance of (r,s)-Closest String-wo(k) can be reduced to solving $f(k)$ many (r,s)-Closest String(k)-instances, which, due to the fixed-parameter tractability of the latter problem, yields the fixed-parameter tractability of the former.

▶ **Theorem 5 (*).** (r,s)-Closest String-wo$(k) \in$ FPT.

If the number $k-t$ of inliers exceeds d_s, then an (r,s)-Closest String-wo-instance becomes easily solvable; thus, $k-t$ can be bounded by d_s, which yields the following result:

▶ **Theorem 6 (*).** (r,s)-Closest String-wo$(d_s,t) \in$ FPT.

The algorithm introduced in [17] to prove (r)-Closest String$(d_r) \in$ FPT has been extended in [5] with an additional branching that guesses whether a string s_j should be considered an outlier or not; thus, yielding fixed-parameter tractability of (r)-Closest String-wo(d_r,t). We present a non-trivial extension of this algorithm, with a carefully selected starting string, to obtain the fixed-parameter tractability of (r,s)-Closest String-wo(d_r,t) (and, as explained in Section 2, also of (r,s)-Closest String(d_r)):

▶ **Theorem 7.** (r,s)-Closest String-wo$(d_r,t) \in$ FPT.

Figure 1 Example for Algorithm 1 on an instance of (r, s)-Closest String-wo. The shown steps correspond to one branch that yields a correct solution. The algorithm starts with the majority string where disputed characters are replaced by ◇. At each step, the algorithm either inserts a character from an input string at maximal distance from s' (note that even non-disputed characters may be replaced), or removes one such string. When $t = 0$, it is checked whether the completion s'' of s' is a correct solution. At step 7, we return a solution with $\mathsf{r_H}(s'', S') = 5$ and $\mathsf{s_H}(s'', S') = 14$.

Proof. Let (S, d_s, d_r, t) be a positive instance of (r, s)-Closest String-wo(d_r, t) with $k \geq 5t$ (otherwise k can be considered as a parameter). A character x is *frequent in column i* if it has at least as many occurrences as the majority character minus t (thus, for any $S' \subseteq S$, $|S'| \geq |S| - t$, all majority characters for S' are frequent characters). A column i is *disputed* if it contains at least two frequent characters. Let D be the number of disputed columns.

Let (S^*, s^*) be a solution for this instance. In a disputed column i, no character occurs more than $\frac{k+t}{2}$ times, hence, among the $k - t$ strings of S^*, there are at least $(k-t) - \frac{k+t}{2} = \frac{k-3t}{2}$ mismatches at position i. The disputed columns thus introduce at least $D\frac{k-3t}{2}$ mismatches. Since the overall number of mismatches is upper-bounded by $d_r(k-t)$, we have $D \leq \frac{2d_r(k-t)}{k-3t} = 2d_r\left(1 + \frac{2t}{k-3t}\right)$, and, with $k \geq 5t$, the upper-bound $D \leq 4d_r$ follows.

We introduce a new character $\diamond \notin \Sigma$. A string $s' \in (\Sigma \cup \{\diamond\})^\ell$ is a *lower bound* for a solution s^*, if, for every i such that $s'[i] \neq s^*[i]$, either i is a disputed column and $s'[i] = \diamond$, or i is not disputed and $s'[i]$ is the majority character for column i of S^* (which is equal to the majority character for column i of S). Intuitively speaking, whenever a character $s'[i]$ differs from $s^*[i]$, it is the majority character of its column (except for disputed columns in which we use an "undecided" character $\diamond$). Finally, the *completion for S'* of a string $s' \in (\Sigma \cup \{\diamond\})^*$ is the string obtained by replacing each occurrence of $\diamond$ by a majority character of the corresponding column in S'.

We now prove that Algorithm 1 solves (r, s)-Closest String-wo in time at most $O^*((d_r+1)^{6d_r}2^{6d_r+t})$, using the following three claims (see Figure 1 for an example).

Claim 1. Any call to Solve Closest String-wo(S', t, s', d) always returns after a time $O^*((d_r+1)^d 2^{d+t})$.

ALGORITHM 1: Solve Closest String-wo.

Input : $S' \subseteq S$, $t \in \mathbb{N}$, $s' \in (\Sigma \cup \{\diamond\})^\ell$, $d \in \mathbb{N}$
Output : a pair (S^*, s^*) or the symbol ∇

1 **if** $t = 0$ **then**
2 $s'' =$ completion of s' in S';
3 **if** $\mathsf{s_H}(s'', S') \leq d_s$, and $\mathsf{r_H}(s'', S') \leq d_r$ **then** return (S', s'');
4 **if** $d = 0$ **then** return ∇;
5 Let $s_j \in S'$ be such that $\mathsf{d_H}(s', s_j)$ is maximal;
6 **if** $t > 0$ **then**
7 $sol =$ Solve Closest String-wo$(S' \setminus \{s_j\}, t-1, s', d)$;
8 **if** $sol \neq \nabla$ **then** return sol;
9 **if** $d > 0$ **then**
10 Let $I \subseteq \{1, \ldots, \ell\}$ contain $d_r + 1$ indices i s. t. $s'[i] \neq s_j[i]$ (or all indices if $\mathsf{d_H}(s_j, s') \leq d_r$);
11 **for** $i \in I$ **do**
12 $s'' = s'$, $s''[i] = s_j[i]$;
13 $sol =$ Solve Closest String-wo$(S', t, s'', d-1)$;
14 **if** $sol \neq \nabla$ **then** return sol;
15 return ∇;

Proof of Claim 1. We prove this running time by induction: if $d = t = 0$, then the function returns in Line 3 or 4; thus, it returns after polynomial time. Otherwise, it performs at most d_r+1 recursive calls with parameters $(d-1, t)$, and one recursive call with parameters $(d, t-1)$. By induction, the complexity of this step is $O^*((d_r+1)(d_r+1)^{d-1}2^{d+t-1} + (d_r+1)^d 2^{d+t-1}) = O^*((d_r+1)^d 2^{d+t})$. ◀

A tuple (S', t', s', d) is *valid* if $|S'| - t' = |S| - t$, there exists an optimal solution (S^*, s^*) for which $S^* \subseteq S'$, $|S^*| = |S'| - t'$, $\mathsf{d_H}(s', s^*) \leq d$, and s' is a lower bound for s^*. A call of the algorithm is *valid* if its parameters form a valid tuple, its *witness* is the pair (S^*, s^*).

Claim 2. Any valid call to Solve Closest String-wo either directly returns a solution or performs at least one recursive valid call.

Proof of Claim 2. Let $S' \subseteq \Sigma^\ell$, $t' \geq 0$, $s' \in (\Sigma \cup \{\diamond\})^\ell$, and $d \geq 0$. Consider the call to Solve Closest String-wo(S', t', s', d). Assume it is valid, with witness (S^*, s^*).

Case 1. If $d = t' = 0$, then $s^* = s'$ and $S^* = S'$. The completion s'' of s' is exactly s', and since (S', s') is a solution, it satisfies the conditions of Line 3 and is returned on Line 3.

Case 2. If $t' = 0$ and $\forall s \in S' : \mathsf{d_H}(s, s') \leq d_r$. Then $S^* = S'$ and s' is a lower bound for s^*. Let s'' be the completion of s'. We show that $\mathsf{s_H}(s'', S') \leq \mathsf{s_H}(s^*, S') \leq d_s$. Indeed, consider any column i with $s''[i] \neq s^*[i]$. Either $s'[i] = \diamond$, in which case $s''[i]$ is the majority character for column i of S', or $s'[i] \neq \diamond$, in which case by the definition of lower bound, i is not a disputed column and $s'[i] = s''[i]$ contains the only frequent character of this column, which is the majority character for S'. In both cases, $s''[i]$ is a majority character for S' in any column where it differs from s^*; thus, it satisfies the upper-bound on the distance sum. Since it also satisfies the distance radius (by the case hypothesis: $\mathsf{d_H}(s, s'') \leq \mathsf{d_H}(s, s') \leq d_r$ for all $s \in S'$), it satisfies the conditions of Line 3; thus, solution (S', s'') is returned on Line 3.

In the following cases, we can thus assume that the algorithm reaches Line 5. Indeed, if it returns on Line 3 then it returns a solution, and if it returns on Line 4 then we have $d = t' = 0$, which is dealt in Case 1 above (the algorithm may not return on this line when it has a valid input). We can thus define s_j to be the string selected in Line 5.

Case 3. $s_j \in S' \setminus S^*$. Then in particular $t' > 0$; and since $S^* \subseteq S' \setminus \{s_j\}$, the recursive call in Line 7 is valid, with the same witness (S^*, s^*).

Case 4. $s_j \in S^*$, $d = 0$ and $t' > 0$. Then $s' = s^*$, let s'_j be any string of $S' \setminus S^*$, and $S^+ = S^* \setminus \{s'_j\} \cup \{s_j\}$. Then the pair (S^+, s^*) is a solution, since $\mathsf{d_H}(s^*, s'_j) \leq \mathsf{d_H}(s^*, s_j)$ by definition of s_j. Thus the recursive call on Line 7 is valid, with witness (S^+, s^*).

Case 5. $s_j \in S^*$, $d > 0$ and $\mathsf{d_H}(s_j, s') > d_r$. Consider the set I defined in Line 10. I has size $d_r + 1$, hence there exists $i_0 \in I$ such that $s_j[i_0] = s^*[i_0]$. Then the recursive call with parameters $(S', t, s'', d-1)$ in Line 13 with $i = i_0$ is valid with the same witness (S^*, s^*). Indeed, s'' is obtained from s' by setting $s''[i_0] = s^*[i_0] \neq s'[i_0]$, hence, all mismatches between s'' and s^* already exist between s' and s^*, which implies that s'' is still a lower bound for s^*. Moreover, $\mathsf{d_H}(s'', s^*) = \mathsf{d_H}(s', s^*) - 1 \leq d - 1$.

From now on, we can assume that $d > 0$ and $t' > 0$. Indeed, $d = 0$ is dealt with in cases 1, 3 and 4, and $t' = 0, d > 0$ is dealt with in cases 2 and 5. Moreover, with cases 3 and 5, we can assume that $s_j \in S^*$ and $\mathsf{d_H}(s_j, s') \leq d_r$ (i.e. $\mathsf{d_H}(s, s') \leq d_r$ for all $s \in S^*$).

Case 6. There exists i_0 such that $s_j[i_0] = s^*[i_0] \neq s'[i_0]$. Then again consider the set I defined in Line 10. Since $\mathsf{d_H}(s_j, s') \leq d_r$, we have $i_0 \in I$, and, with the same argument as in Case 5, there is a valid recursive call in Line 13 when $i = i_0$.

Case 7. For all i, $s_j[i] \neq s'[i] \Rightarrow s_j[i] \neq s^*[i]$. In this case no character from s_j can be used to improve our current solution, so the character switching procedure Line 13 will not improve the solution, but still s_j is part of our witness set S^*, so it is not clear a priori that we can remove s_j from our current solution, i.e. that the recursive call on Line 7 is valid.

We handle this situation as follows. Let s^+ be obtained from s' by filling the $\diamond$-positions of s' with the corresponding symbols of s^*. We now show that (S^*, s^+) is a solution. To this end, let $s \in S^*$. For every i, $1 \leq i \leq \ell$, if $s[i] \neq s^+[i]$, then either $s'[i] = \diamond$ or $s'[i] \in \Sigma$ with $s'[i] = s^+[i]$. In both cases, we have $s[i] \neq s'[i]$, which implies $\mathsf{d_H}(s, s^+) \leq \mathsf{d_H}(s, s') \leq d_r$, i. e., the radius is satisfied. Regarding the distance sum, we note that if $s^+[i] \neq s^*[i]$, then, since occurrences of $\diamond$ of s' have been replaced by the corresponding symbol from s^*, $s'[i] \neq \diamond$, which, by the definition of lower bound, implies that $s^+[i] = s'[i]$ is the majority character for column i of S^*. Consequently, $\sum_{s \in S^*} \mathsf{d_H}(s^+[i], s[i]) \leq \sum_{s \in S^*} \mathsf{d_H}(s^*[i], s[i])$, which implies $\mathsf{s_H}(s^+, S^*) \leq \mathsf{s_H}(s^*, S^*) \leq d_s$.

Having defined a new solution string s^+ (with respect to S^*), we now prove that s^+ is also a solution string with respect to $S^+ = (S^* \setminus \{s_j\}) \cup \{s'_j\}$, where s'_j is any string of $S' \setminus S^*$. To this end, we prove that $\mathsf{d_H}(s'_j, s^+) \leq \mathsf{d_H}(s_j, s^+)$; together with the fact that $\mathsf{d_H}(s'_j, s') \leq d_r$, this implies that (S^+, s^+) is a solution. For two strings $s_1, s_2 \in \Sigma^\ell$, let $d_\diamond(s_1, s_2)$ be the number of mismatches between s_1 and s_2 at positions i such that $s'[i] = \diamond$, and $d_\Sigma(s_1, s_2)$ be the number of mismatches at other positions. Clearly $\mathsf{d_H}(s_1, s_2) = d_\diamond(s_1, s_2) + d_\Sigma(s_1, s_2)$. Comparing strings s_j and s'_j to s', we have $d_\diamond(s_j, s') = d_\diamond(s'_j, s')$ (both distances are equal to the number of occurrences of $\diamond$ in s'). Since $\mathsf{d_H}(s_j, s')$ is maximal, we have $d_\Sigma(s'_j, s') \leq d_\Sigma(s_j, s')$. Consider now s^+. Since s^+ is equal to s' in every non-$\diamond$ characters, we have $d_\Sigma(s'_j, s^+) \leq d_\Sigma(s_j, s^+)$. Finally, for any i such that $s'[i] = \diamond$, by hypothesis of this case we have $s_j[i] \neq s^*[i] = s^+[i]$, hence $d_\diamond(s_j, s^+)$ is equal to the number of occurrences of $\diamond$ in s', which is an upper bound for $d_\diamond(s'_j, s^+)$. Overall, $d(s'_j, s^+) \leq d(s_j, s^+)$, and (S^+, s^+) is a solution.

Thus, (S^+, s^+) is a solution such that $S^+ \subseteq S' \setminus \{s_j\}$, s' is a lower bound for s^+, and $\mathsf{d_H}(s', s^+) \leq d$, hence the recursive call in Line 7 is valid. ◀

It follows from the claim above that any valid call to Solve Closest String-wo returns a solution. Indeed, if it does not directly return a solution, then it receives a solution of a more constrained instance from a valid recursive call, which is returned on Line 8 or 14.

Claim 3. Let s' be the majority string for S where for every disputed column i, $s'[i] = \diamond$. Then Solve Closest String-wo$(S, t, s', 2d_r + D)$ is a valid call.

Proof of Claim 3. Consider a solution (S^*, s^*). We need to check whether $\mathsf{d_H}(s^*, s') \leq 2d_r + D$, and whether s' is a lower bound of s^*. The fact that s' is a lower bound follows from the definition, since $\diamond$ is selected in every disputed column, and the majority character is selected in the other columns. String s^* can be seen as a solution of (r, s)-Closest String over S^*, d_r, d_s, thus, we can use Lemma 2: the distance between s^* and the majority string of S^* is at most $2d_r$. Hence there are at most $2d_r$ mismatches between s' and s^* in non-disputed columns (since in those columns, the majority characters are identical in S and S^*). Adding the D mismatches from disputed columns, we get the $2d_r + D$ upper bound. ◀

◀

2.2 The (r)- and (s)-Variants of Closest String-wo

In [5], the fixed-parameter tractability of (r)-Closest String-wo w. r. t. parameter k and w. r. t. parameters $(|\Sigma|, d_r, k-t)$ are reported as open problems. Since Theorem 5 also applies to (r)-Closest String-wo, the only open cases left for the (r)-variant are the following:

▶ **Open Problem 8.** *What is the fixed-parameter tractability of* (r)-Closest String-wo *with respect to* $(|\Sigma|, k-t)$, $(|\Sigma|, d_r)$ *and* $(|\Sigma|, d_r, k-t)$*?*

Next, we consider the (s)-variant of Closest String-wo. We recall that replacing the radius bound by a bound on the distance sum turns (r)-Closest String into a trivial problem, while (s)-Closest Substring remains hard. The next result shows that Closest String-wo behaves like Closest Substring in this regard. For the proof, we use Multi-Coloured Clique (which is W[1]-hard, see [11]), which is identical to the standard parameterisation of Clique, but the input graph $G = (V, E)$ has a partition $V = V_1 \cup \ldots \cup V_{\mathrm{k_c}}$, such that every V_i, $1 \leq i \leq \mathrm{k_c}$, is an independent set (we denote the parameter by $\mathrm{k_c}$ to avoid confusion with the number of input strings k).

▶ **Theorem 9.** (s)-Closest String-wo$(d_s, \ell, k-t)$ *is* W[1]*-hard.*

Proof. Let $G = (V_1 \cup \ldots \cup V_{\mathrm{k_c}}, E)$ be a Multi-Coloured Clique-instance. We assume that, for some $q \in \mathbb{N}$, $V_i = \{v_{i,1}, v_{i,2}, \ldots v_{i,q}\}$, $1 \leq i \leq \mathrm{k_c}$, i. e., each vertex has an index depending on its colour-class and its rank within its colour-class. Let $\Sigma = V \cup \Gamma$, where Γ is some alphabet with $|\Gamma| = |E|(\mathrm{k_c} - 2)$. For every $e = (v_{i,j}, v_{i',j'}) \in E$, let $s_e \in \Sigma^{\mathrm{k_c}}$ with $s_e[i] = v_{i,j}$, $s_e[i'] = v_{i',j'}$ and all other non-defined positions are filled with symbols from Γ such that each $x \in \Gamma$ has exactly one occurrence in the strings s_e, $e \in E$. We set $S = \{s_e \mid e \in E\}$, $t = |E| - \binom{\mathrm{k_c}}{2}$ (i. e., the number of inliers is $\binom{\mathrm{k_c}}{2}$) and $d_s = \binom{\mathrm{k_c}}{2}(\mathrm{k_c} - 2)$.

Let K be a clique of G of size $\mathrm{k_c}$, let $s \in \Sigma^{\mathrm{k_c}}$ be defined by $\{s[i]\} = K \cap V_i$, $1 \leq i \leq \mathrm{k_c}$, and let $S' = \{s_e \mid e \subseteq K\}$. Since $\mathsf{d_H}(s, s') = \mathrm{k_c} - 2$, for every $s' \in S'$, $\mathsf{s_H}(s, S') = d_s$. Consequently, S' and s is a solution for the (s)-Closest String-wo-instance S, t, d_s.

Now let $s \in \Sigma^{\mathrm{k_c}}$ and $S' \subseteq S$ with $|S'| = \binom{\mathrm{k_c}}{2}$ be a solution for the (s)-Closest String-wo-instance S, t, d_s. If, for some $s'_1 \in S'$, $\mathsf{d_H}(s'_1, s) \geq \mathrm{k_c} - 1$, then there is an $s'_2 \in S'$ with $\mathsf{d_H}(s'_2, s) \leq \mathrm{k_c} - 3$. Thus, for some i, $1 \leq i \leq \mathrm{k_c}$, $s[i] = s'_2[i]$ and $s'_2[i] \in \Gamma$, which implies that replacing $s[i]$ by $s'_1[i]$ does not increase $\mathsf{s_H}(s, S')$. Moreover, after this modification, $\mathsf{d_H}(s'_1, s)$ has decreased by 1, while $\mathsf{d_H}(s'_2, s) \leq \mathrm{k_c} - 2$. By repeating such operations, we can transform s such that $\mathsf{d_H}(s', s) \leq \mathrm{k_c} - 2$, $s' \in S'$. Next, assume that, for some i, $1 \leq i \leq \mathrm{k_c}$, there is an $S'' \subseteq S'$ with $|S''| = \mathrm{k_c}$ and, for every $s' \in S''$, $s[i] = s'[i]$. Since $\mathsf{d_H}(s', s) \leq \mathrm{k_c} - 2$ for every

$s' \in S''$, pigeon-hole principle implies that there are $s'_1, s'_2 \in S''$ with $s'_1[i'] = s'_2[i'] = s[i']$, for some i', $1 \leq i' \leq \mathrm{k_c}$, and $i' \neq i$, which, by the structure of the strings of S, is a contradiction. Consequently, for every i, $1 \leq i \leq \mathrm{k_c}$, s matches with at most $\mathrm{k_c}-1$ strings from S' at position i. Since there are at least $2\binom{\mathrm{k_c}}{2} = \mathrm{k_c}(\mathrm{k_c}-1)$ matches, we conclude that, for every i, $1 \leq i \leq \mathrm{k_c}$, $s[i]$ matches exactly $k_c - 1$ times with the i^{th} position of a string from S'. Hence, $s[i] \in V_i$, $1 \leq i \leq \mathrm{k_c}$, i. e., $s = v_{1,r_1} v_{2,r_2} \dots v_{\mathrm{k_c},r_{\mathrm{k_c}}}$, for some $r_j \in \{1, 2, \dots, q\}$, $1 \leq j \leq \mathrm{k_c}$. Let $K = \{v_{1,r_1}, v_{2,r_2}, \dots, v_{\mathrm{k_c},r_{\mathrm{k_c}}}\}$. For every $s' \in S'$, by definition of the strings s_e, we have $\mathsf{d_H}(s, s') \geq \mathrm{k_c}-2$, combining with the lower-bound proved ealier, we conclude $\mathsf{d_H}(s, s') = \mathrm{k_c}-2$, for every $s' \in S$. Now let $e = (v_{i,j}, v_{i',j'}) \in E$ be such that $s_e \in S'$. From $\mathsf{d_H}(s, s_e) = \mathrm{k_c}-2$ its follows that $s[i] = v_{i,j}$ and $s[i'] = v_{i',j'}$, which implies $e \subseteq K$. Since $|S| = \binom{\mathrm{k_c}}{2}$, there are $\binom{\mathrm{k_c}}{2}$ edges connecting vertices from K; thus, K is a clique. ◀

Setting $d_r = \mathrm{k_c}-2$ instead of $d_s = \binom{\mathrm{k_c}}{2}(\mathrm{k_c}-2)$ in the reduction of Theorem 9 leads to a simpler proof for the W[1]-hardness of (r)-Closest String-wo$(d_r, \ell, k-t)$ shown in [5] (on the other hand, the reduction of [5] does not work for (s)-Closest String-wo$(d_s, \ell, k-t)$). The results obtained in this section are summarized in Table 2.

3 Closest Substring

In this section, we consider the problem (r, s)-Closest Substring and, as done in Section 2 for (r, s)-Closest String, we classify all parameterisations of (r, s)-Closest Substring (and its (r)- and (s)-variants) with respect to the parameters ℓ, k, m, d_r, d_s and $|\Sigma|$ into either fixed-parameter tractable or W[1]-hard. Of course, many of those questions are already solved in the literature, but, unlike for (r, s)-Closest String, not all cases of the (r)- and (s)-variants are settled, i. e., the status of (s)-Closest Substring(ℓ) is unknown, which is mentioned as open problem in [24]. We shall first close this gap by defining a reduction from Multi-Coloured Clique to (s)-Closest Substring.

Let $G = (V_1 \cup \dots \cup V_{\mathrm{k_c}}, E)$ be a Multi-Coloured Clique-instance. We assume that, for some $q \in \mathbb{N}$, $V_i = \{v_{i,1}, v_{i,2}, \dots v_{i,q}\}$, $1 \leq i \leq \mathrm{k_c}$, i. e., each vertex has an index depending on its colour-class and its rank within its colour-class. Let $\Sigma = V \cup \{\$, \diamond\}$. For every j, $1 \leq j \leq q$, we list all j^{th} elements of the colour-classes as a string $\mathcal{V}_j = \$v_{1,j} v_{2,j} \dots v_{\mathrm{k_c},j}$. For every edge $e = (v_{i,j}, v_{i',j'})$ with $i < i'$, we define a string $\mathcal{E}_e = \$\diamond^i v_{i,j} \diamond^{i'-i-1} v_{i',j'} \diamond^{\mathrm{k_c}-i'-1}$. Note that $\mathcal{E}_e = \$\diamond\mathcal{E}'_e$, where $|\mathcal{E}'_e| = \mathrm{k_c}$, the positions i and i' of $\mathcal{E}'_e$ are $v_{i,j}$ and $v_{i',j'}$, respectively, and all remaining positions are $\diamond$. The (s)-Closest Substring-instance is now defined as follows. Let S contain $N = |E|(\mathrm{k_c}+2)+1$ occurrences of each $\mathcal{V}_j$, $1 \leq j \leq q$, and one occurrence of each $\mathcal{E}_e$, $e \in E$, and let $m = \mathrm{k_c}+1$. We note that $\ell = \mathrm{k_c}+2$. See Figure 2 for an example.

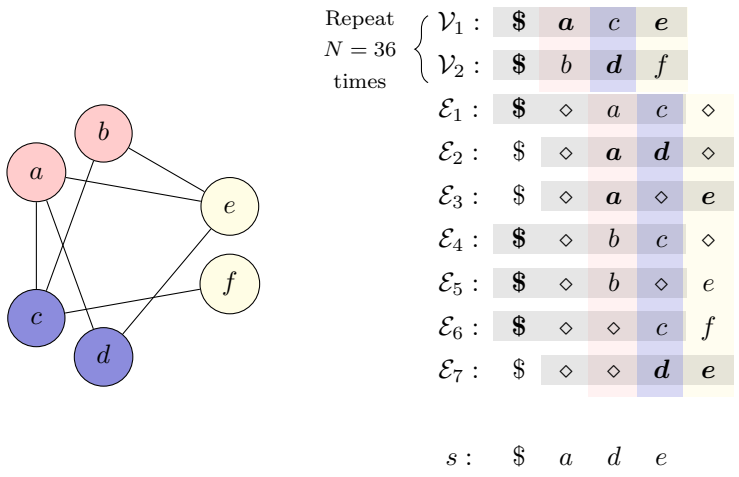

Figure 2 Illustration of the parameterized reduction from a Multi-Coloured Clique-instance to (s)-Closest Substring. The colour-classes of the graph are $V_1 = \{a, b\}$ (red), $V_2 = \{c, d\}$ (blue) and $V_1 = \{e, f\}$ (yellow), the occurrences of symbols from V in the strings $\mathcal{V}_j$ and $\mathcal{E}_i$ are coloured according to their colour-classes. The string $s = \$ade$ is an optimal solution with respect to the substrings emphasised with grey background (positions producing a match are in bold). Note that vertices $\{a, d, e\}$ form a clique in G.

In the following, we extend the notation of *radius optimal* and *distance sum optimal* to sets $S \subseteq \Sigma^{\leq \ell}$ and strings $s \in \Sigma^m$ in the natural way by taking all sets S' of length-m substrings of the string in S into account. The next lemma shows that distance sum optimal strings (with respect to S and m) are basically lists of vertices from each colour-class.

▶ **Lemma 10 (*).** *If $s \in \Sigma^{k+1}$ is distance sum optimal w. r. t. S, then $s \in \{\$\} \cdot V_1 \cdot V_2 \cdot \ldots \cdot V_k$.*

Now let s be distance sum optimal with respect to S and m. From Lemma 10, we can conclude that $s = \$v_{1,r_1} v_{2,r_2} \ldots v_{k_c,r_{k_c}}$, for some $r_j \in \{1, 2, \ldots, q\}$, $1 \leq j \leq k_c$. Let K be the corresponding set of vertices, i. e., $K = \{v_{1,r_1}, v_{2,r_2}, \ldots, v_{k_c,r_{k_c}}\}$.

▶ **Lemma 11 (*).** *Let $e \in E$. The optimal distance between s and a length-$(\mathrm{k_c}+1)$ substring of $\mathcal{E}_e$ is $\mathrm{k_c}-1$ if $e \subseteq K$, and $\mathrm{k_c}$ otherwise.*

Using the lemmas from above, we can now show the correctness of the reduction.

▶ **Theorem 12.** *(s)-Closest Substring(ℓ, m) is W[1]-hard.*

Proof. Let $s \in \Sigma^{\mathrm{k_c}+1}$ be distance sum optimal with respect to S and m, and let K be the corresponding set of vertices. We first note that the total distance from s to the N copies of the strings $\mathcal{V}_j$, $1 \leq j \leq q$, is exactly $Nq\,\mathrm{k_c}$. According to Lemma 11, for every $e \in E$, the optimal distance sum between s and the respective substring of $\mathcal{E}_e$ is $\mathrm{k_c}-1$ if $e \subseteq K$, and $\mathrm{k_c}$ otherwise. Hence, the total distance sum from s to the respective substrings of $\mathcal{E}_e$, $e \in E$, is $|E|\,\mathrm{k_c} - r$, where $r = \{e \in E \mid e \subseteq K\}$, and the total distance sum between s and S is therefore $Nq\,\mathrm{k_c} + |E|\,\mathrm{k_c} - r$. This implies that the distance sum between s and S is $Nq\,\mathrm{k_c} + |E|\,\mathrm{k_c} - \frac{\mathrm{k_c}(\mathrm{k_c}-1)}{2}$ if and only if $r = \frac{\mathrm{k_c}(\mathrm{k_c}-1)}{2}$ if and only if K is a clique of size $\mathrm{k_c}$. Consequently, the above reduction, with the addition of $d_s = Nq\,\mathrm{k_c} + |E|\,\mathrm{k_c} - \frac{\mathrm{k_c}(\mathrm{k_c}-1)}{2}$, is a parameterised reduction from Multi-Coloured Clique to (s)-Closest Substring(ℓ, m). ◀

As illustrated by Table 3, Theorem 12 together with known results from the literature completely settle the parameterised complexity of (s)-Closest Substring.

Moving on to the problem (r, s)-Closest Substring, we first observe that reducing (s)-Closest Substring to (r, s)-Closest Substring by setting $d_r = m$ is a parameterised reduction from (s)-Closest Substring(ℓ, m) to (r, s)-Closest Substring(ℓ, m, d_r), which implies the following corollary:

▶ **Corollary 13.** *(r, s)-Closest Substring(ℓ, m, d_r) is W[1]-hard.*

Next, we consider several fixed-parameter tractable variants of (r, s)-Closest Substring.

▶ **Theorem 14 (*).** *(r, s)-Closest Substring$(x) \in$ FPT, for every $x \in \{(m, |\Sigma|), (\ell, k), (\ell, |\Sigma|), (\ell, d_s)\}$.*

It remains to observe that all remaining parameterisations of (r, s)-Closest Substring are W[1]-hard. More precisely, it is known that (r)-Closest Substring is W[1]-hard for parameterisations $(k, d_r, |\Sigma|)$ (see [20]) and (k, m, d_r) (see [14]). Hence, the obvious reduction from (r)-Closest Substring to (r, s)-Closest Substring, i. e., setting $d_s = k\, d_r$, shows that (r, s)-Closest Substring is W[1]-hard for parameterisations $(k, d_r, d_s, |\Sigma|)$ and (k, m, d_r, d_s). As can be checked with the help of Table 4, this now classifies all parameterised variants of (r, s)-Closest Substring.

4 Kernelisation

Neither (r)-Closest String$(d_r, \ell, |\Sigma|)$ nor (r)-Closest Substring(k, m, d_r) admit polynomial kernels unless coNP $\subseteq$ NP/Poly (see [2]), and (r)-Closest String(k, d_r) has a kernel of size $\mathrm{O}(k^2 d_r \log k)$ (see [17]). From these results, we can conclude the following:

▶ **Proposition 15** (*).

- (r, s)-Closest String$(d_r, \ell, |\Sigma|)$ *has no polynomial kernel unless* coNP $\subseteq$ NP/Poly.
- (r, s)-Closest String(k, d_r) *has a kernel of size* $\mathrm{O}(k^2 d_r \log k)$.
- (r, s)-Closest String(d_s) *has a kernel of size* $\mathrm{O}((d_s)^3 \log d_s)$.

This only leaves the case open, where only k (or k and $|\Sigma|$, which, due to the dependency $|\Sigma| \leq k$ (see [17]), is the same question) is a parameter (regarding this case, note that for (r)-Closest String(k) no combinatorial kernel or combinatorial FPT-algorithm is known).

▶ **Proposition 16** (*).

- (r, s)-Closest Substring$(k, m, d_r, d_s, |\Sigma|)$ *has no polynomial kernel unless* coNP $\subseteq$ NP/Poly.
- (r, s)-Closest Substring(ℓ, k) *and* (r, s)-Closest Substring(ℓ, d_s) *have kernels of size* $\mathrm{O}(\ell k)$ *and* $\mathrm{O}(\ell d_s)$*, respectively.*

This almost settles the (r, s)-variant, for which only the parameterisation $(\ell, |\Sigma|)$ is open. For the (r)-variant, the parameterisations ℓ, (ℓ, d_r) and $(\ell, |\Sigma|)$, and for the (s)-variant, the parameterisations $(m, |\Sigma|)$ and $(d_s, |\Sigma|)$ are open.

For (r)-Closest String-wo no kernelisation lower bounds are known so far. However, the following can be concluded from [2]:

▶ **Proposition 17** (*). (r)-Closest String-wo$(d_r, \ell, t, |\Sigma|)$ *has no polynomial kernel unless* coNP $\subseteq$ NP/Poly.

By a cross-composition[3] from (r)-Closest String into (r)-Closest String-wo, we can rule out a polynomial kernel for the parameterisation $(d_r, d_s, \ell, (k-t), |\Sigma|)$.

To this end, we define a polynomial equivalence relation $\sim$ over the (r)-Closest String-instances as follows. For $j \in \{1, 2\}$, let $S_j = \{s_{j,i} \mid 1 \leq i \leq k_j\} \subseteq \Sigma^{\ell_j}$ and $d_{r,j} \in \mathbb{N}$. Then $(S_1, d_{r,1}) \sim (S_2, d_{r,2})$ if $k_1 = k_2$, $\ell_1 = \ell_2$ and $d_{r,1} = d_{r,2}$. Now let $(S_1, d_r), (S_2, d_r), \ldots, (S_q, d_r)$ be $\sim$-equivalent (r)-Closest String-instances, where, for the sake of convenience, $S_i = \{s_{i,1}, s_{i,2}, \ldots, s_{i,k}\} \subseteq \Sigma^{\ell}$, $1 \leq i \leq q$. For every i, $1 \leq i \leq q$, let B_i denote the binary representation of i with exactly $\lceil \log(q) \rceil$ bits, and let $C_i = (B_i)^{2d_r+1}$. Moreover, for every i, $1 \leq i \leq q$, let $S'_i = \{s'_{i,1}, s'_{i,2}, \ldots, s'_{i,k}\}$, where, for every j, $1 \leq j \leq k$, $s'_{i,j} = s_{i,j} C_i$. Finally, let the (r, s)-Closest String-wo-instance be (S', d'_r, d'_s, t) with $S' = \bigcup_{i=1}^{q} S'_i$, $d'_r = d_r$, $d'_s = k d_r$ and $t = (q-1)k$.

▶ **Theorem 18** (*). (r, s)-Closest String-wo$(d_r, d_s, \ell, (k-t), |\Sigma|)$ *does not admit a polynomial kernel unless* coNP $\subseteq$ NP/Poly.

5 Conclusions

The parameterised complexity of the (r)-, (s)- and general variant of Closest String and Closest Substring with respect to $\ell, k, m, d_r, d_s, |\Sigma|$ is now completely settled. For (r, s)-Closest Substring, where positive results are less abundant, it might be worthwhile to identify other parameters that yield fixed-parameter tractability. For (r, s)-Closest String, it should be pointed out that the FPT-algorithms with respect to k are based on ILP and are most likely practically not relevant; direct combinatorial FPT-algorithms are still unknown. For the outlier variant of (r, s)-Closest String, many cases are left open, most prominently, the ones with $|\Sigma|$ as parameter, and we expect those to be challenging. Moreover, for several FPT-variants, the existence of polynomial kernels is not yet answered.

Abstract

In this paper we analyze the notion of "stopping time complexity", the amount of information needed to specify when to stop while reading an infinite sequence. This notion was introduced by Vovk and Pavlovic [9]. It turns out that plain stopping time complexity of a binary string x could be equivalently defined as (a) the minimal plain complexity of a Turing machine that stops after reading x on a one-directional input tape; (b) the minimal plain complexity of an algorithm that enumerates a prefix-free set containing x; (c) the conditional complexity $\mathrm{C}(x\,|\,x*)$ where x in the condition is understood as a prefix of an infinite binary sequence while the first x is understood as a terminated binary string; (d) as a minimal upper semicomputable function K such that each binary sequence has at most 2^n prefixes z such that $K(z) < n$; (e) as $\max \mathrm{C}^X(x)$ where $\mathrm{C}^X(z)$ is plain Kolmogorov complexity of z relative to oracle X and the maximum is taken over all extensions X of x.

We also show that some of these equivalent definitions become non-equivalent in the more general setting where the condition y and the object x may differ, and answer an open question from Chernov, Hutter and Schmidhuber [3].

1 Introduction: stopping time complexity

Imagine that you explain to someone which exit on a long road she should take. You can just say "Nth exit"; for that you need $\log N$ bits. You may also say something like "the first exit after the first bridge", and this message has bounded length even if the bridge is very far away.[3]

More formally, consider a machine with one-directional read-only input tape that contains bits $x_0, x_1, \ldots x_n, \ldots$. We want to program the machine in such a way that it stops after reading bits $x_0, \ldots, x_{n-1}$ (and never sees x_n and the subsequent bits). Obviously, the complexity of this task does not depend on the values of $x_n, x_{n+1}, \ldots$, because the machine never sees them, so this complexity should be a function of a bit string $x = x_0 x_1 \ldots x_{n-1}$. It can be called the "stopping time complexity" of x.

Such a notion was introduced recently by Vovk and Pavlovic [9]. In their paper an "interactive" version of stopping time complexity is considered where even (x_{2n}) and odd (x_{2n+1}) terms are considered differently, but this is just a special case, so we do not consider this setting. It turns out that the stopping time complexity is a special case of conditional Kolmogorov complexity with structured conditions. (In this paper we consider the plain version of stopping time complexity and postpone similar questions for prefix versions.)

The Kolmogorov complexity was introduced independently by Solomonoff, Kolmogorov, and Chaitin to measure the "amount of information" in a finite object (say, in a binary string). One can also consider the *conditional* version of complexity where some other object (a *condition*) is given "for free". Later different versions of Kolmogorov complexity appeared (plain, prefix, a priori, monotone complexities). We assume that the reader is familiar with basic notions of algorithmic information theory, see, for example, [6] for a short introduction and [7] for a detailed exposition.

For the plain version of stopping time complexity we prove the equivalence between five different definitions (Section 2). First, we show that it can be equivalently defined as (1) the minimal plain complexity of a machine with one-way read-only input tape that stops after reading x, or (2) the minimal enumeration complexity of a prefix-free set that contains x. Then we show how the stopping time complexity can be expressed in terms of plain conditional complexity that is monotone with respect to conditions. Namely, we prove that (3) the stopping time complexity equals $\mathrm{C}(x \mid x*)$ where x is used both as an object and a condition. Of course, according to standard definitions, the complexity $\mathrm{C}(x \mid x)$ is $O(1)$, but now we treat these two strings x differently (and use a star in the notation to stress this). One may say that the topologies in the space of objects and the space of conditions are different. The first x (object to be described) is considered as an isolated object (terminated string). The second x (in the condition) is considered as a prefix of an infinite sequence. In [7, Section 6.3] this approach is described in general (see also [5] for even more general setting); to make this paper self-contained, we give all necessary definitions for our special case. We call this version of complexity "monotone-conditional complexity" since this function is monotone with respect to the condition. Then we provide a characterization of stopping time complexity in quantitative terms proving that (4) stopping time complexity is the minimal upper semicomputable function satisfying some restrictions (no more than 2^n prefixes of any given sequence could have complexity at most n). Finally, we point out the connections with the relativized version $\mathrm{C}^A(x)$ of plain complexity and prove that (5) the

[3] We do not allow, however, the description "the last exit before the bridge", since it uses information that is unavailable at the moment when we have to take the exit.

stopping time complexity of a binary string x is the maximal value of $C^A(x)$ for all oracles (infinite bit sequences) A that have prefix x.

Having such a robust definition for plain stopping time complexity, one may ask whether similar characterizations can be obtained for a more general notion of $C(y|x*)$ where x and y are arbitrary strings. Unfortunately, here the situation is much worse, and we prove mostly negative results (Section 3). We show that while $C(y|x*)$ can be defined as a minimal plain complexity of a prefix-stable program that maps x to y (Theorem 12), it cannot be defined as a minimal plain complexity of a prefix-free program that maps some prefix of x to y (Theorem 13; this result answers a question posed in [3]). Then we show that the attempt to define $C(y|x*)$ by quantitative restrictions also fails: we get another function that may be up to two times less (Theorem 14).

2 Equivalent definitions

2.1 Machines and prefix-free sets

Consider a Turing machine M that has one-directional read-only input tape with binary alphabet, and a work tape with arbitrary alphabet (or many work tapes). Let x be a binary string. We say that *M stops at x* if M, being started with the input tape x (and an empty work tape, as usual), reads all the bits of x and stops without trying to read more bits. (We assume that initially the input head is on the left of x, so it needs to move right before seeing the first bit of x.) For a given x, we may consider the *minimal plain Kolmogorov complexity of a machine M that stops at x*. This quantity is independent (up to $O(1)$-additive term) of the details of the definition (work tape alphabet, number of work tapes, etc.) since computable conversion algorithms exist, and a computable transformation may increase complexity only by $O(1)$. We arrive at the following definition:

▶ **Definition 1.** The *plain stopping time complexity* of x is the minimal plain Kolmogorov complexity of a Turing machine that stops at x.

Here is a machine-independent equivalent characterization of the plain stopping time complexity.

▶ **Theorem 2.** *Plain stopping time complexity of x equals (up to an $O(1)$ additive term) the minimal complexity of a program that enumerates some prefix-free set containing x.*

(A set of strings is called *prefix-free* if it does not contain a string and its proper prefix at the same time.)

Proof. One direction is simple: For a Turing machine M of the type described the set $\{x\colon M \text{ stops at } x\}$ is enumerable (we may simulate all runs) and prefix-free (if M stops at some x, then for every extension y of x the machine M will behave in the same way on tapes x and y, so M with input y stops after reading x and never reads the rest of y). This computable conversion (of a machine into an enumeration program) increases complexity at most by $O(1)$.

The other direction is a bit more complicated. Imagine that we have a program that enumerates some prefix-free set U of strings. How can we construct a machine that stops exactly at the strings in U? Initially no bits of x are read. Enumerating U, we wait until some element u of U appears. (If this never happens, the machine never stops, and this is OK.) If u is empty, machine stops. In this case U cannot contain non-empty strings (being prefix-free), so the machine's behavior is correct. If u is not empty, we know that empty

string is not in U (since U is prefix-free), so we may read the first bit of x without any risk, and get some one-bit string v. Then we wait until v or some extension of v appears in U (it may have already happened if u is an extension of v). If v itself appears, the computation stops; if a proper extension of v appears, then v is not in U and we can safely read the next bit, etc. It is easy to check that indeed this machine stops at some x if and only if x belongs to U. ◀

2.2 Monotone-conditional complexity

In this section we show how the stopping time complexity can be obtained as a special case of some general scheme [5, 8, 7]. This scheme can be used to define different versions of Kolmogorov complexity. We consider *decompressors*, called also *description modes*. In our case decompressor is a subset D of the set

$$(\text{descriptions}) \times (\text{conditions}) \times (\text{objects}).$$

Here descriptions, conditions, and objects are binary strings. If $(p, x, y) \in D$, we say that p *is a description of y given x as condition*, and define the *conditional complexity of y given x* (with respect to the description mode D) as the length of the shortest description. The different versions of complexity correspond to different topologies on the spaces involved, and imply different restrictions on description modes. This is explained in [8] or [7, Chapter 6], and we do not go into technical details here. Let us mention only that descriptions and objects can be considered as isolated entities (terminated strings, natural numbers) or prefixes of an infinite sequence (extension of a string provides more information than the string itself). In this way we get four classical versions of complexity:

	isolated descriptions	descriptions as prefixes
isolated objects	plain complexity	prefix complexity
objects as prefixes	decision complexity	monotone complexity

As noted in [7], one can also consider different structures on the condition space, thus getting eight versions of complexity instead of four in the table. In this paper we use only one of them: objects and descriptions are isolated objects, and conditions are considered as prefixes. (Vovk and Pavlovic [9] consider also another version of stopping time complexity that corresponds to the other topology on the description space, but we do not consider this version now.)

To make this paper self-contained, let us give the definitions tailored to the special case we consider (the plain version of monotone-conditional complexity). In this case the set D is called a *description mode* if it satisfies the following requirements:

- D is (computably) enumerable;
- for every p and x there exists at most one y such that $(p, x, y) \in D$;
- if $(p, x, y) \in D$ and x is a prefix of some x', then $(p, x', y) \in D$.

The last requirement reflects the idea that x is considered as a known prefix of a yet unknown infinite sequence; if x' extends x, then x' contains more information than x and can be used instead of x. To stress this kind of monotonicity, we use $*$ in the notation suggested by the following definition.

▶ **Definition 3.** For a given description mode D, we define the function

$$\mathrm{C}_D(y \,|\, x*) = \min\{|p| \colon (p, x, y) \in D\}$$

and call it *monotone-conditional complexity of y with condition x with respect to description mode D*.

By definition, if x is a prefix of some x', the same description can be used, so $\mathrm{C}_D(y\,|\,x'*) \le \mathrm{C}_D(y\,|\,x*)$. Therefore, this function is indeed monotone with respect to the condition in a natural sense.

One could also use a name *plain monotone-conditional complexity* to distinguish this notion from prefix monotone-conditional complexity that can be defined in a similar way by adding the monotonicity restriction along the p-coordinate.

▶ **Proposition 4** (Solomonoff–Kolmogorov's optimality theorem)**.** *There exists a description mode D that makes C_D minimal up to $O(1)$ additive term in the class of all functions $\mathrm{C}_{D'}$ for all description modes D'.*

Proof. As usual, we first note that description modes can be effectively enumerated. This enumeration is obtained as follows. We generate all enumerable sets of triples and then modify them in such a way that the modified set becomes a description mode and is left unchanged if it already was a description mode. Namely, when a triple (p, x, y) appears in the enumeration, we add this triple and all triples (p, x', y) for all extensions x' of x, unless the second condition would be violated after that; in the latter case we ignore (p, x, y).

Let U_n be the nth set in this enumeration. The optimal set U can be constructed as

$$U = \{(0^n 1 p, x, y) \colon (p, x, y) \in U_n\};$$

the standard argument shows that $\mathrm{C}_U \le \mathrm{C}_{U_n} + n + 1$ as required. ◀

▶ **Definition 5.** Fix some optimal description mode D provided by Proposition 4. The function $\mathrm{C}_D(y\,|\,x*)$ is denoted by $\mathrm{C}(y\,|\,x*)$ and called the (plain) *monotone-conditional complexity of y given x*, or the (plain) *conditional complexity of y given x as a prefix.*

If we omit the third requirement for description modes, we get the standard conditional complexity $\mathrm{C}(y\,|\,x)$ in the same way. The notation we use (placing $*$ after the condition) follows [3] though a different version of monotone-conditional complexity is considered there. In general, $\mathrm{C}(y\,|\,x*)$ is greater than the standard conditional complexity $\mathrm{C}(y\,|\,x)$ since we have more requirements for the description modes. One may say also that the condition now is weaker than in $\mathrm{C}(y\,|\,x)$ since we do not know where x terminates. It is easy to show that the difference is bounded by $O(\log |x|)$, since we need at most $O(\log |x|)$ bits to specify how many bits should be read in the condition x. Difference of this order is possible: for example, $\mathrm{C}(n\,|\,0^n) = O(1)$, but $\mathrm{C}(n\,|\,0^n*) = \mathrm{C}(n) + O(1)$ (the condition 0^n is a prefix of a computable sequence $000\ldots$, so it does not help at all).

The following simple result shows that the plain stopping time complexity (Definition 1) is a special case of this definition when $x = y$ (so we do not need a separate notation for the stopping time complexity).

▶ **Theorem 6.** *The complexity $\mathrm{C}(x\,|\,x*)$ is equal (up to $O(1)$ additive term) to the plain stopping time complexity of x.*

Proof. Let D be a description mode. Then for every p we may consider the set S_p of strings x such that $(p, x, x) \in D$. This set is prefix-free: if (p, x, x) and (p, x', x') belong to D and x is a prefix of x', then $(p, x', x) \in D$ according to the third condition, and then $x = x'$ according to the second condition. The algorithm enumerating S_p can be constructed effectively if p is known, so its complexity is bounded by the length of p (plus $O(1)$, as usual). Choosing the shortest p such that $(p, x, x) \in D$, we conclude that the minimal complexity of an algorithm enumerating a prefix-free set containing x does not exceed $\mathrm{C}(x\,|\,x*) + O(1)$.

Going in the other direction, consider an optimal decompressor $U(\cdot)$ that defines the (plain Kolmogorov) complexity of programs enumerating sets of strings. A standard trimming argument shows that we may modify U in such a way that all algorithms $U(p)$ enumerate only prefix-free sets of strings (not changing the sets there were already prefix-free). Then consider a set D of triples

$$(p, x, y) \in D \Leftrightarrow y \text{ is a prefix of } x \text{ and } y \text{ is enumerated by } U(p).$$

This set in obviously enumerable; the second requirement is satisfied since $D(p)$ enumerates a prefix-free set; the third requirement is true by construction, so D is a description mode. If p is the shortest description of a program that enumerates a set containing x, then $(p, x, x) \in D$, so $\mathrm{C}_D(x \,|\, x*) \leq |p|$. Switching to the optimal description mode, we get similar inequality with $O(1)$ additive term, as required. ◀

Another simple observation shows that indeed this complexity may be called the *stopping time* complexity.

▶ **Proposition 7.** *If x has length n, then* $\mathrm{C}(x \,|\, x*) = \mathrm{C}(n \,|\, x*) + O(1)$.

Proof. If D is the optimal description mode used to define $\mathrm{C}(y \,|\, x*)$, we may consider a new set $D' = \{(p, u, |x|) \colon (p, u, x) \in D\}$ that also is a description mode, and then note that $\mathrm{C}_{D'}(n \,|\, x*) \leq \mathrm{C}_D(x \,|\, x*)$. For the other direction, we consider $D' = \{(p, u, z) \colon \exists n\, [(p, u, n) \in D, |u| \geq n, \text{ and } z = (n\text{-bit prefix of } u)]\}$. ◀

▶ Remark. If $a_0 a_1 a_2 \ldots$ is a computable sequence, then

$$\mathrm{C}(a_0 \ldots a_{n-1} \,|\, a_0 \ldots a_{n-1}*) = \mathrm{C}(n \,|\, a_0 \ldots a_{n-1}*) = \mathrm{C}(n)$$

with $O(1)$-precision (the constant depends on the computable sequence, but not on n), so the stopping time complexity can be considered as a generalization of the plain complexity (of a natural number n).

2.3 Quantitative characterization

There is a well known characterization (see, e.g., [8, Section 1.1, Theorem 8]) for plain complexity in terms of upper semicomputable functions that satisfy some properties. Recall that a function is called *upper semicomputable* if it is a pointwise limit of a decreasing sequence of uniformly computable total functions. (Now we need this notion for integer-valued functions; in this case we may assume without loss of generality that the total computable functions used in the definition are also integer-valued; in the general case one needs to consider rational-valued functions.) An equivalent definition of a semicomputable natural-valued function $S(x)$ requires the set $\{(n, x) \colon S(x) < n\}$ to be enumerable.

Plain complexity function $\mathrm{C}(x)$ is upper semicomputable; we know also that

$$\#\{x \colon \mathrm{C}(x) < n\} < 2^n \qquad (*)$$

since there are less than 2^n programs of length less than n. The characterization that we mentioned says that there exist a minimal (up to $O(1)$ additive term) upper semicomputable function that satisfies the requirement $(*)$, and it coincides with the plain complexity function with $O(1)$-precision.

It turns out that this characterization can be generalized to plain stopping time complexity (though the proof becomes more involved). Consider upper semicomputable functions $S(x)$

on strings that have the following property: *for each infinite binary sequence α and for each n there exists less than 2^n prefixes x of α such that $S(x) < n$.* The following statement is true (it appears as Theorem 18 in the extended version of Vovk–Pavlovic's paper [9]).

▶ **Theorem 8.** *There exist a minimal (up to $O(1)$ additive term) function in this class; it coincides with the plain stopping time complexity $C(x\,|\,x*)$ with $O(1)$-precision.*

Proof. The easy part is to show that $C(x\,|\,x*)$ belongs to the class. It is upper semicomputable, since in general the function $C(x\,|\,y*)$ is upper semicomputable (enumerating the set D of triples, we get better and better upper bounds, finally reaching the limit value).

Let α be some infinite sequence. There are less than 2^n algorithms of complexity less than n enumerating prefix-free sets, and each of this prefix-free sets may contain at most one prefix of α. So the second condition is also true.

In the other direction we use some online (interactive) version of Dilworth's theorem (saying that a partially ordered finite set where maximal chain is of length at most k can be partitioned into k antichains) where the set is growing and splitting into antichains should be performed at each stage (and cannot be changed later). The exact statement is as follows.

Consider a game with two players. Alice and Bob alternate. Alice may at each move (irreversibly) mark a vertex of the full binary tree. The restriction is that each infinite branch should contain at most k marked vertices. Bob replies by assigning a color from $1, \ldots, k$ to the newly marked vertex. No vertices of the same color should be comparable (be on the same branch). The colors cannot be changed after they are assigned. Bob loses if he is unable to assign color at some stage (not violating the rules).

▶ **Lemma 9.** *Bob has a computable strategy that prevents him from losing.*

Proof of Lemma 9. This lemma can be proven in different ways. In the extended version of Vovk–Pavlovic's paper [9] the following simple strategy is suggested: Bob assigns the first available color. In other terms, for a new vertex x Bob chooses the first color that is not used for any vertex comparable with x. One needs to check that k colors are always enough. It is not immediately obvious, since more than k vertices could be comparable with x (being its descendants, for example). However, we may note that during the process:

- Colors of comparable vertices are different. (By construction.)
- If a vertex x gets color i, then each smaller color is used either for a predecessor of x or for a descendant of x. (By construction.)
- If x is a vertex (colored or not), T_x is the set of colors used in the subtree rooted at x (including x itself), and P_x is the set of colors used on the path to x (not including x), then T_x and P_x are disjoint and T_x is the initial segment in the complement to P_x. (Indeed, the disjointness is mentioned above. If y appears in T_x, then all smaller colors appear either below y (therefore in P_x or in T_x), or above y (therefore in T_x).
- The sets T_{x0} and T_{x1} for two brother vertices $x0$ and $x1$ are comparable with respect to inclusion. (Indeed, they are two initial segments of the same ordered set, the complement to P_{x0} or P_{x1}; note that $P_{x0} = P_{x1}$.)
- For each x the total number of colors used in T_x is minimal, i.e., this number equals the maximal number of marked vertices on some path in T_x. (Induction using the previous property.)

The last property implies that Bob never uses more than k colors, since by assumption the total number of marked vertices on a path is at most k.

A different description of the same strategy that explains why it is successful is provided in the extended version of this paper [1]. ◀

Now let us show how the lemma is used to finish the proof of Theorem 8. Let S be a function in the class; since S is upper semicomputable, Alice may, given n, enumerate strings x such that $S(x) < n$; we know that there is at most 2^n strings of this type along any branch of the tree, so Alice never violates the restriction for $k = 2^n$. The lemma then says that Bob can assign 2^n colors (represented as n-bit strings) to all the vertices in such a way that compatible vertices (a string and its prefix) never get the same color. We run these games for all n in parallel; if vertex x gets color c, we put x into an enumerable set indexed by c. The rules of the game guarantee that all these sets are prefix-free, and the algorithm enumerating cth set needs only $|c|$ bits of information. So, if $S(x) < n$, there exists an algorithm of complexity $n + O(1)$ that enumerates a prefix-free set containing x. This means that $\mathrm{C}(x\,|\,x*) \leq S(x) + O(1)$ as required. ◀

2.4 Oracles and the stopping time complexity

It is natural to compare the stopping time complexity $\mathrm{C}(x\,|\,x*)$ and the relativized complexity $\mathrm{C}^X(x)$ where X is some oracle (infinite binary sequence) that has x as a prefix. (The relativized complexity $\mathrm{C}^X(x)$ can be naturally defined as a function of two arguments, a binary string x and an infinite binary sequence X, up to $O(1)$ additive term.)

It is easy to see that

$$\mathrm{C}^X(x) \leq \mathrm{C}(x\,|\,x*)$$

for every X that has prefix x: an oracle access to entire sequence X is more powerful than a bit-by-bit sequential access to x without the right to read too much (beyond x). More formally, let D be a set of triples (p, x, y) used to define $\mathrm{C}(y\,|\,x*)$ (Definition 5). Then we say that p is a description of x with oracle X (as the definition of $\mathrm{C}^X(x)$ requires) if $(p, z, x) \in D$ for some z that is a prefix of X. For a given X every string p can be a description of only one x, since D is monotone. If $(p, x, x) \in D$ and X is an extension of x, then p is a description of x, and we get the required inequality.

The "last exit before the bridge" example shows that $\mathrm{C}^X(x)$ can be much smaller than $\mathrm{C}(x\,|\,x*)$ for *some* extensions X of x: we have $\mathrm{C}(0^n\,|\,0^n*) = \mathrm{C}(n) + O(1)$, but $\mathrm{C}^X(0^n) = O(1)$ for $X = 0^n 10^\infty$.

So it is natural to take *maximum* over all oracles X that extend a given string x. Indeed this approach works:

▶ **Theorem 10.**

$$\mathrm{C}(x\,|\,x*) = \max\{\mathrm{C}^X(x) \colon X \textit{ is an infinite extension of } x\} + O(1).$$

Proof. As we have already mentioned, $\mathrm{C}^X(x) \leq \mathrm{C}(x\,|\,x*) + O(1)$ for every infinite extension X of x. This shows that right hand side does not exceed the left hand side.

Before proving the reverse inequality, let us discuss informally its meaning (this discussion is not used in the argument below and can be omitted). The reverse inequality is a minimax-type result that shows that either (1) there exists a short program that produces x given *any* extension of x as an oracle (and never reads bits after x, but this is not so important for us now), or (2) there exists a "hard to use" extension X of x such that *any* program that computes x given X is long. In other words, it is not possible that for every extension X of x there exists a short program that computes x given X as an oracle, but these programs depend on X and only a much longer program works for all extensions.

For the proof of the reverse inequality we use the quantitative characterization of stopping time complexity (Theorem 8). Let $S(x)$ be the value of the right hand side. It is enough to

prove that S is upper semicomputable and that $S(x) < n$ cannot happen for 2^n different prefixes x of some infinite branch X.

The second claim follows directly from the definition. Let $x_1, \ldots, x_k$ be some prefixes of an infinite sequence X such that $S(x_i) < n$ for all $i = 1, \ldots, k$. We need to show that $k < 2^n$. Since $S(x_i)$ is defined as maximum and X is an extension of x_i, we know that $\mathrm{C}^X(x_i) < n$ for all i and the same X. It remains to note that the number of different programs of length less than n is smaller than 2^n (and the same programs with the same oracles give the same results).

To show that $S(x)$ is upper semicomputable, we use the standard compactness argument. As usual, it is enough to show that the binary relation $S(x) < n$ is (computably) enumerable. Indeed, for every x, the set $\{X\colon \mathrm{C}^X(x) < n\}$ is the union, taken over all strings p of length less than n, of the sets

$$\{X\colon p \text{ is a description of } x \text{ with oracle } X\}.$$

Each of these sets is an open set in the Cantor space, since every terminating oracle computation uses only a finite part of the oracle, and the intervals in the Cantor space that form these sets, can be effectively enumerated for all p and x. The inequality $S(x) < n$ means that the union of these intervals for all p of length less than n covers the Cantor space. Now compactness guarantees that this happens already at some finite stage of the enumeration, so the property $S(x) < n$ is indeed enumerable. ◀

3 Non-equivalence results

3.1 Prefix-stable or prefix-free functions?

Looking at the characterization of $\mathrm{C}(x\,|\,x*)$ as the minimal enumeration complexity of a prefix-free set containing x (Theorem 6), one can ask whether a similar characterization works for the general case, i.e., whether $\mathrm{C}(y\,|\,x*)$ can be characterized as a minimal complexity of programs (machines) with some property. The answer is 'yes', but we should be careful choosing a property of programs used in this characterization. Here are the details.

▶ **Definition 11.** A partial function f defined on binary strings is called

- *prefix-free* if its domain is prefix-free (function is never defined on a string and its extension at the same time);
- *prefix-stable* if for every x, if $f(x)$ is defined, then f is defined and has the same value on all (finite) extensions of x.

It is easy to see that the definition of $\mathrm{C}(y\,|\,x*)$ can be reformulated in terms of prefix-stable functions:

▶ **Theorem 12.** *The minimal plain complexity of a program that computes a prefix-stable function mapping x to y is equal to $\mathrm{C}(y\,|\,x*) + O(1)$.*

Proof. A description mode can be considered as a family of prefix-stable functions (indexed by the first argument p). This shows that there exist a program for a prefix stable function mapping x to y of complexity at most $\mathrm{C}(y\,|\,x*) + O(1)$. On the other hand, one can efficiently "trim" all programs to make them prefix-stable; if $\hat{u}$ is the trimmed version of a program u and U is the decompressor used to define plain complexity of programs, then the set $D = \{p, x, \widehat{U(p)}(x)\colon p, x\}$ satisfies the conditions and may be considered as a decompressor in the definition of $\mathrm{C}(y\,|\,x*)$. Using this decompressor, we get the reverse inequality. ◀

More interesting question: is a similar statement true for *prefix-free* functions instead of prefix-stable ones? As we mentioned above, Theorem 6 implies that this is the case when $x = y$. (We spoke about programs that stop at x, but we may assume without loss of generality that the output is also x.) But in the general case it is not true anymore. Let us make this statement more precise. The first idea is to consider the minimal plain complexity of a program computing a prefix-free function mapping x to y. But this quantity does not look reasonable: the complexity of empty string Λ with condition x defined in this way may be arbitrarily large (and is actually the stopping time complexity of the condition x).

A more reasonable approach is to consider function $\mathrm{C}'(y\,|\,x*)$ defined as the minimal complexity of a prefix-free program that maps *some prefix of* x to y. This approach still does not work, as the following result shows.

▶ **Theorem 13.** *The inequality* $\mathrm{C}(y\,|\,x*) \leq \mathrm{C}'(y\,|\,x*)+c$ *holds for some* c *and for all* x, y. *The reverse inequality does not: there exist strings* x_i, y_i *(for* $i = 0, 1, 2, \ldots$*) such that* $\mathrm{C}(y_i\,|\,x_i*)$ *is bounded while* $\mathrm{C}'(y_i\,|\,x_i*)$ *is unbounded.*

Proof. The first part is easy: if an algorithm computing a prefix-free function f is given, we can effectively transform it into an algorithm that computes its prefix-stable extension g such that $g(x) = y$ if $f(u) = y$ for some prefix u of x.

For the second part of the proof (using game arguments in the sense of [4]) see the extended version of this paper [1]. ◀

Theorem 13 implies that the conjecture from [3, p. 254] is false, and the function C_T defined there may exceed C_E more than by $O(1)$ additive term. We do not go into the details of the definition used in [3]; let us mention only that $C_E(y_i\,|\,x_i)$ is bounded while $C_T(y_i\,|\,x_i)$ is not: for every twice prefix machine (as defined in [3, p. 252]) we get a prefix-free function if we fix the first argument (denoted there by p).

3.2 Quantitative characterization of $\mathrm{C}(y\,|\,x*)$ works only up to factor 2

In Section 2.3 we provided a quantitative characterization of stopping time complexity, or $\mathrm{C}(x\,|\,x*)$, with $O(1)$-precision (Theorem 8). The natural question is whether a similar characterization works in the general case, i.e., for $\mathrm{C}(x\,|\,y*)$. As we will see, the answer is negative.

For $\mathrm{C}(x\,|\,y)$ (the standard version of conditional complexity, with no monotonicity requirement) such a characterization is well known: $\mathrm{C}(x\,|\,y)$ is the minimal upper semicomputable function of two arguments $K(x, y)$ such that for every string y and every number n there is at most 2^n different strings x such that $K(x, y) < n$.

The natural approach is to keep this restriction and add the monotonicity requirements:

$$K(x, y0) \leq K(x, y) \text{ and } K(x, y1) \leq K(x, y), \text{ for every } x \text{ and } y.$$

We get some class of functions (that are upper semicomputable, satisfy the cardinality restriction and are monotone in the sense described). Can we characterize $\mathrm{C}(x\,|\,y*)$ as the minimal function in this class? No, as the following theorem shows.

▶ **Theorem 14.**

(a) *Function* $\mathrm{C}(x\,|\,y*)$ *belongs to this class.*

(b) *There exists a minimal (up to* $O(1)$ *additive term) function in this class;*

(c) *Function* $\mathrm{C}(x\,|\,y*)$ *is not minimal in this class: there exist a function* K *in this class, and sequences of strings* x_n *and* y_n *such that* $K(x_n, y_n) \leq n$, *but* $\mathrm{C}(x_n\,|\,y_n*) \geq 2n - c$ *for some* c *and for every* n.

(d) *The factor* 2 *that appears in the previous statement is optimal: if* K *is a function in the class (for example, the minimal one), then* $\mathrm{C}(x\,|\,y*) \leq 2K(x,y) + c$ *for some* c *and for all* x *and* y.

Proof. The statements (a) and (b) are "good news", while the statement (c) is "bad news" showing that our characterization does not work. (It is possible *a priori* that one can get a natural characterization of $\mathrm{C}(x\,|\,y*)$ by adding some other restrictions, but it is quite unclear what kind of restrictions could help here.) Finally, the statement (d) partly saves the situation and shows that the minimal function in the class and $\mathrm{C}(x\,|\,y*)$ differ at most by factor 2.

The statement (a) is obvious; note that $\mathrm{C}(x\,|\,y*)$ is bigger than $\mathrm{C}(x\,|\,y)$, so the cardinality restriction remains true. Other requirements immediately follow from the definition.

The statement (b) can be proved in a standard way. We can enumerate all functions in the class and get a uniformly computable sequence of functions $K_m(x,y)$. For that we enumerate all monotone upper semicomputable functions and then "trim" them by deleting small values that make the cardinality restriction false. Then we construct the minimal function $K(x,y)$ by letting

$$K(x,y) = \min_m (K_m(x,y) + m + 1).$$

It is upper semicomputable and monotone; for every y, the set of x such that $K(x,y) < n$ is the union of sets $\{x\colon K_m(x,y) < n - m - 1\}$ that have cardinality at most 2^{n-m-1}, and $2^{n-1} + 2^{n-2} + \ldots < 2^n$. The function K is minimal, since $K \leq K_m + m + 1$.

For the proofs of statements (c) and (d) see the extended version of this paper [1]. These proofs use game arguments in the sense of [4]. ◀

4 Questions

▶ Question 1. Imagine Turing machines with two read-only input tapes; for such a machine M consider a function f_M such that $f_M(x,y) = z$ if M stops at x and y on first and second tape respectively (reading all bits and not more) and produces z. Could we characterize the functions f_M (called *twice prefix free* in [3, page 242]) or at least their domains? Such a domain is an enumerable set of pairs that does not contain two pairs (x,y) and (x',y') where x is compatible with x' (one is a prefix of the other) and y is compatible with y'. Still this necessary condition is not sufficient, as the following argument shows. Let z_i be a computable sequence of pairwise incompatible strings (say, $z_i = 0^i1$). Let P and Q be two enumerable sets that are inseparable (do not have a decidable separating set). Consider the set of pairs that contains

- (z_i0, z_i0) for all i;
- (z_i, z_i1) for $i \in P$;
- (z_i1, z_i) for $i \in Q$.

This set satisfies the necessary condition above (does not contain two compatible pairs). However, assume that some twice prefix free machine has this set as a domain. Then it should terminate after reading z_i0 on the first tape and z_i0 on the second tape. Consider the last zero bits on both tapes. One of these bits should be read first (if they are read simultaneously, we may choose any of two). If this is the first bit, then $i \in P$ is impossible (since the machine cannot read 1 on the second tape before reading 0 on the first tape). For the same reason, $i \in Q$ is impossible if the second bit is read first. Therefore, a decidable separator exists.

Can we add some conditions to get a characterization of domains of twice prefix free machines? What do we get if we define stopping time complexity for pairs using machines of

this type? Does it have some equivalent description (for example, can it be defined using monotone-conditional complexity with pairs as conditions, Section 2.2)?

▶ Question 2. Do we have $\mathrm{C}(x\,|\,x*) = \max_z \mathrm{C}(x\,|\,z) + O(1)$ where the maximum is taken over all *finite* extensions z of x? (The problem is that the compactness argument does not work anymore.)

▶ Question 3. One may consider the function

$$K(x, y) = \max\{\mathrm{C}^Y(x) \colon Y \text{ is an infinite extension of } y\}$$

We have shown that for $x = y$ it coincides with $\mathrm{C}(x\,|\,x*)$, showing that it does not exceed $\mathrm{C}(x\,|\,x*)$ and satisfies the quantitative restrictions of Theorem 8. Both arguments remain valid (with minimal changes) for the general case, and we conclude that $K(x, y)$ defined in this way does not exceed $\mathrm{C}(x\,|\,y*)$ and also satisfies the cardinality restrictions of Theorem 14, (b). However, now these upper bound and lower bound differ, and we do not know where the function $K(x, y)$ defined as shown above lies. Does it coincide with its upper bound $\mathrm{C}(x\,|\,y*)$ for arbitrary x and y, or with its lower bound, the minimal upper semicomputable function that satisfies the cardinality requirements (see Theorem 14), or neither?

Error-Tolerant Non-Adaptive Learning of a Hidden Hypergraph

Hasan Abasi
Department of Computer Science, Technion, Haifa, 32000, Israel
hassan@cs.technion.ac.il

Abstract

We consider the problem of learning the hypergraph using edge-detecting queries. In this model, the learner is allowed to query whether a set of vertices includes an edge from a hidden hypergraph. Except a few, all previous algorithms assume that a query's result is always correct. In this paper we study the problem of learning a hypergraph where α-fraction of the queries are incorrect. The main contribution of this paper is generalizing the well-known structure CFF (Cover Free Family) to be Dense (we will call it DCFF - Dense Cover Free Family) while presenting three different constructions for DCFF. Later, we use these constructions wisely to give a polynomial time non-adaptive learning algorithm for a hypergraph problem with at most α-fracion incorrect queries. The hypergraph problem is also known as both monotone DNF learning problem, and complexes group testing problem.

1 Introduction

The classical group testing model consists of a set of n items, where s of these items are defective (positive) while others are good (negative) items. The problem is to identify all defective (positive) items with a small number of group tests. A group test is a test with a negative/positive result, where you can choose an arbitrary group $S \subseteq [n]$ and ask whether S contains at least one defective item. The outcome is negative if all the items within the group are good (negative), and positive otherwise (See [13, 12] for more details about group testing).

Torney [20] was the first who generalized the group testing model to the complex group testing model, where we have the same set of n items, as in the first model, but instead of s defective elements, we have s defective groups $M_1, \cdots, M_s$, that are known as positive complexes, where $M_i \subseteq [n]$ and for any $i_1, i_2 \in [s]$ where $i_1 \neq i_2$ $M_{i_1} \not\subseteq M_{i_2}$ and $M_{i_2} \not\subseteq M_{i_1}$. In complex group testing model, a complex group test is a test with a negative/positive result, where you can choose an arbitrary group $S \subseteq [n]$ and ask whether S contains at least one positive complex. The outcome is negative if all the complexes within the group are negative, and positive otherwise. A usual assumption is that each positive complex has at most r items ($|M_i| \leq r$).

This problem is also known as graph testing, where a hypergraph $H = (V, E)$ with s edges and n vertices is given, our objective is to learn the hypergraph by asking edge-detecting queries (denote query function by Q). An edge detecting-query is a test with a negative/positive result, where you can choose an arbitrary group of vertices $S \subseteq [n]$ and ask whether this group of vertices has at least one edge or not. A usual assumption is that each edge has at most r vertices. It is easy to see that this model is equivalent to the complex

group testing model (see [1]). In addition to complex group testing and graph testing, this problem is also known as the learning monotone DNF problem with s monomials, where each monomial contains at most r variables. In this paper, we will use the latter terminology rather than complexes or graphs.

Tests can be *adaptive* (sequential), *non-adaptive* or *multi-stage*. Adaptive tests are tests that may be affected by the outcome of earlier tests. Non-adaptive tests, all tests are executed in parallel without knowledge of any other tests' outcome. Multi-stage tests are divided into stages, and all tests within each stage are executed in parallel, but different stages may be affected by the outcome of earlier stages.

This problem has many applications in chemical reactions, molecular biology and genome sequencing (see [15, 14, 7, 17, 6]). In these types of applications, an experiment corresponding to a group test could take several hours or even several days. Thus, non-adaptive algorithms are most desirable. In addition to the prolonged process, errors in applications are unavoidable. And as the number of tests increases, the number of errors occurring is increased as well. Therefore, it is very important to construct error-tolerant algorithms, where the number of the errors is a fraction of the number of queries. In all of the above applications the size of each term (rank of the hypergraph) is much smaller than the number of terms (edges), and both are much smaller than the number of variables (vertices) n. Therefore, throughout the paper, we will assume that $r < s < n$ (this assumption will be used in the constructions in Section 3) and will denote $d \triangleq r + s$.

Both adaptive and non-adaptive learning of monotone DNF problem are well-known and well-studied. In the Adaptive model, Angluin et al. [5] was the first to present a deterministic optimal adaptive algorithm for learning s-term 2-MDNF (s terms each of size 2). Later, Abasi et al., [1], gave an almost optimal adaptive algorithm for the general s-term r-MDNF case and they proved that any algorithm that learns s-term r-MDNF needs to ask at least

$$\begin{cases} r > s & \Omega\left((r/s)^{s-1} + rs\log n\right) \text{ Queries} \\ r \le s & \Omega\left((2s/r)^{r/2} + rs\log n\right) \text{ Queries} \end{cases}$$

On the non-adaptive side many works studied the s-term r-MDNF. Abasi et al. [2], gave the first deterministic algorithm which runs in polynomial time and non-adaptively learns a hypergraph that asks an almost optimal number of queries. On the other hand, only few algorithms discussed the error-tolerant problems. Stinson and Wei, [18], proved a lower bound

$$0.7c\frac{d\binom{d}{r}}{\log\binom{d}{r}}\log n + \frac{c(z-1)}{2}\binom{d}{r} = s\left(\frac{es}{r}\right)^{r+o(1)}\log n + z\left(\frac{es}{r}\right)^{r+o(1)},$$

where z is constant and the algorithm is tolerant to $z/2$ errors (constant number of errors). In the same paper they proved an upper bound of

$$O\left(z\binom{d}{r}(rs)^{\log^* n}\log n\right) = z\left(\frac{es}{r}\right)^{r+o(1)}(rs)^{\log^* n}\log n.$$

Chen et al., [11], improved the last upper bound to

$$z\left(\frac{d}{r}\right)^{r}\left(\frac{d}{s}\right)^{s}\left(1+\ln\left(\frac{n}{d}+1\right)\right) = z\left(\frac{es}{r}\right)^{r+o(1)}\log n.$$

Lang et al., [16], considered the problem where z errors occur in every m tests. They gave a random algorithm which identifies all the target function's terms with high probability. All

previous algorithms either run in exponential time, are non-deterministic or are tolerant to a constant number of errors.

In this paper we introduce the first algorithm, to the best of our knowledge, that handles α-fraction of incorrect queries which is deterministic and runs in polynomial time. In [2], the authors use the $(n,(s,r))$-cover-free family ($(n,(s,r))$-CFF). This family is a set $A \subseteq \{0,1\}^n$ of assignments such that for every distinct $i_1,\ldots,i_s,j_1,\ldots,j_r \in \{1,\ldots,n\}$, there is an assignment $a \in A$ such that

$$a_{i_1} = \cdots = a_{i_s} = 0 \text{ and } a_{j_1} = \cdots = a_{j_r} = 1.$$

In this paper we extend the definition of $(n,(s,r))$-CFF to be

$$(n,(s,r),\alpha)\text{- } \textbf{Dense CFF (DCFF)},$$

where the DCFF is a CFF with an additional requirement, which is that for every distinct $i_1,\ldots,i_s,j_1,\ldots,j_r \in \{1,\ldots,n\}$, an ***α*-fraction** of the assignments $a \in A$ satisfy the following:

$$a_{i_1} = \cdots = a_{i_s} = 0 \text{ and } a_{j_1} = \cdots = a_{j_r} = 1.$$

Improving techniques that were used in [2], by customizing them to comply with DCFF, results in the needed algorithm. In the improvement process we used what we defined above as DCFF. In order to do so, we present three constructions of DCFF, each of which has an advantage over the other. One of these constructions is superior in terms of density, while the other two have better time complexities. One of them is better when $r < T(s)$, while the other is better when $r \geq T(s)$, where T is a function of s. In addition to the extension described above, we also prove that α in $(n,(s,r),\alpha)$-DCFF cannot exceed

$$DNS(s,r) \triangleq \frac{1}{\binom{r+s}{r}} = \frac{1}{\binom{d}{r}}.$$

It is also known, [19], that any non-adaptive learning algorithm must ask at least

$$\Omega\left(\left(\frac{es}{r}\right)^r \log n\right) = \Omega\left(s^{r(1+o(1))} \log n\right)$$

queries, and therefore any algorithm must run in time $poly\,(n,s^r)$. An algorithm that runs in time $poly\,(n,s^r)$ is called efficient algorithm.

This paper is organized as follows. Section 2 gives some definitions and preliminary results that will be used throughout the paper. Section 3 gives three different algebraic constructions for Dense Cover Free family (see Section 3 for full definition). Section 4 gives an inefficient algorithm by using DCFF directly. Section 5 gives a reduction to reduce any non-linear α-error tolerant algorithm that depends on d variables at most to be linear in $\log n$. And finally in Section 6 we use all the constructions and the reduction to generate an efficient algorithm that asks

$$O\left(r^{11}\,(4s)^{r+7} \log n\right) = O\left(s^{r(1+o(1))} \log n\right)$$

noisy membership queries and runs in $poly\,(n,s^r)$, and handles

$$\Omega\left(DNS(s,r)^{1+o(1)}\right) \text{ fraction of incorrect queries.}$$

1.1 Optimality for $r = 2$ (or any constant r)

The learning problem of a graph (when $r = 2$) has been considered and well-studied. Angluin et al., [4, 5], studied the graph problem for the adaptive, nonadaptive and multistage models. Our construction and algorithm are almost optimal when $r = 2$ (or any constant r) in terms of density and query complexity, where the density in case r is constant is $\Omega\left(DNS(s,r)\right)$.

1.2 Algorithm idea overview

One can easily see that using $(n,(s,r),\alpha)$-DCFF solves the problem of s-term r-MDNF when less than $\alpha/2$-fraction of the queries can be incorrect. That is true because for each subset of s terms there are at least $\alpha/2$-fraction of the DCFF's assignments that satisfy one term (r 1's) and assigns 0 to all other terms ($s-1$ 0's) (see Section 4 for more details).
The problem with using DCFF directly is the time complexity, and that is because we need to find out whether each possible subset of s terms each of size at most r satisfies a given set of conditions or not (again, see Section 4 for more details).
In order to achieve a polynomial time complexity, we use bit-wise conjunction of assignments in each DCFF. The general idea is to create two DCFFs. One of them spreads the set of terms over different sets, and the other is used afterward with other structures and techniques to find each term explicitly (see Section 6 and Section 5 for more details).

2 Definitions and Preliminary Results

2.1 Monotone Boolean Functions

For a vector w, we denote by w_i the ith entry of w. For a positive integer j, we denote by $[j]$ the set $\{1,2,\ldots,j\}$. For two assignments $a,b\in\{0,1\}^n$ we denote by $(a\wedge b)\in\{0,1\}^n$ the bitwise AND assignment. That is, $(a\wedge b)_i = a_i\wedge b_i$ for all $i\in[n]$.

Let $f(x_1,x_2,\ldots,x_n)$ be a Boolean function from $\{0,1\}^n$ to $\{0,1\}$. We say that the variable x_i is *relevant* in f if $f|_{x_i\leftarrow 0}\not\equiv f|_{x_i\leftarrow 1}$. A variable x_i is *irrelevant* in f if it is not relevant in f. We say that the class of functions C is *closed under variable projections* if for every function $f\in C$ and every two variables x_i and x_j, $i,j\leq n$, we have $f|_{x_i\leftarrow x_j}\in C$.

For two assignments $a,b\in\{0,1\}^n$, we write $a\leq b$ if for every $i\in[n]$, $a_i\leq b_i$. A Boolean function $f:\{0,1\}^n\to\{0,1\}$ is said to be *monotone* if for every two assignments $a,b\in\{0,1\}^n$, if $a\leq b$ then $f(a)\leq f(b)$. In other words, there is no negated variables in f. Every monotone Boolean function f has a unique representation as a *reduced monotone* DNF, [3].

An *s-term r-MDNF* is a monotone DNF with at most s monomials, where each monomial contains at most r variables. It is easy to see that the class s-term r-MDNF is closed under variable projections.

For a function $f=M_1\vee\cdots\vee M_s$ that belongs to an s-term r-MDNF class, we say that $b\in\{0,1\}^n$ **separates** a term M_i in f from other terms if $M_i(b)=1$ and $M_j(b)=0$ for any $i\neq j$. In the same way, we say that $b\in\{0,1\}^n$ **separates** the terms $M_{i_1},\ldots,M_{i_k}$ in f from other terms if $M_j(b)=1$ for any $j\in\{i_1,\ldots,i_k\}$, and otherwise $M_j(b)=0$.

2.2 α-Error Tolerant Learning from Noisy Membership Queries

Consider a *teacher* that has a *target function* $f:\{0,1\}^n\to\{0,1\}$ that is an s-term r-MDNF. The teacher can answer *noisy membership queries*. That is, when receiving $a\in\{0,1\}^n$, it returns $\overline{f(a)}=1-f(a)$ for α-fraction of the queries, and $f(a)$ for the rest. This teacher is called *α-Liar Teacher*. An *α-error tolerant learning algorithm* is an algorithm that can

ask the α-*Liar Teacher* noisy membership queries. The goal of the learning algorithm is to *exactly learn* (exactly find) f with a minimum number of noisy membership queries and optimal time complexity.

2.3 Dense Perfect Hash Function, Cover Free Family and Dense Cover Free Family

▶ **Definition 1** (Perfect Hash Family)**.** Let H be a family of functions $h : [n] \to [q]$. For $d \leq q$ we say that H is an $(n, q, d, 1-\epsilon)$- *dense perfect hash family* ($(n, q, d, 1-\epsilon)$-DPHF) if for every subset $S \subseteq [n]$ of size $|S| = d$ there are at least $(1-\epsilon)|H|$ *hash functions* $h \in H$ such that $h|_S$ is injective (one-to-one) on S, i.e., $|h(S)| = d$.

▶ **Lemma 2** ([8])**.** *Let q be a power of prime. If $\epsilon > 4(d(d-1)/2+1)/q$, then there is a $(n, q, d, 1-\epsilon)$-DPHF of size*

$$O\left(\frac{d^2 \log n}{\epsilon \log \frac{\epsilon q}{d^2}}\right),$$

that can be constructed in linear time.

▶ **Definition 3** (Cover Free Family)**.** An $(n, (s, r))$- *cover free family* ($(n, (s, r))$-CFF), is a set $A \subseteq \{0, 1\}^n$, such that for every $1 \leq i_1 < i_2 < \cdots < i_d \leq n$ where $d = s + r$ and every $J \subseteq [d]$ of size $|J| = s$, there is $a \in A$ such that $a_{i_k} = 0$ for all $k \in J$ and $a_{i_j} = 1$ for all $j \in [d]\backslash J$. Denote by $N(n, (s, r))$ the minimum size of such set.

▶ **Definition 4** (Dense Cover Free Family)**.** An $(n, (s, r), \alpha)$- *dense cover free family* ($(n, (s, r), \alpha)$-DCFF), is a set $A \subseteq \{0, 1\}^n$, such that for every $1 \leq i_1 < i_2 < \cdots < i_d \leq n$ where $d = s + r$ and every $J \subseteq [d]$ of size $|J| = s$, the following holds for α-fraction vectors $a \in A$: $a_{i_k} = 0$ for all $k \in J$ and $a_{i_j} = 1$ for all $j \in [d]\backslash J$. Denote by $N(n, (s, r), \alpha)$ the minimum size of such set.

▶ **Lemma 5.** *Let A be an $(n, (s, r), \alpha)$ -DCFF, then $\alpha \leq \frac{1}{\binom{d}{r}} \triangleq DNS(s, r)$.*

Proof. For any $d = r + s$ variables, we must have exactly $\binom{d}{r}$ different assignments to cover all the possible assignments over d variables. Otherwise, one assignments at least will be missed. Denote these assignments by R. If there is at least one assignment $r_0 \in R$ that appears among $(n, (s, r), \alpha)$-DCFF more than $1/\binom{d}{r}$ times, then by pigeonhole principle, there exists at least one assignment $r_1 \in R$, that appears less than $1/\binom{d}{r}$ times. Therefore, α cannot exceed $1/\binom{d}{r}$. ◀

For completeness we show:

▶ **Lemma 6.** *Let H_1 be an $(n, q, d, 1-\epsilon)$-DPHF, and H_0 is a $(q, (r, s), \alpha)$-DCFF, then $DC = \{h_0(h_1)|h_0 \in H_0, h_1 \in H_1\}$ is an $(n, (r, s), \alpha(1-\epsilon))$-DCFF of size $|H_0||H_1|$.*

Proof. We will show that for every $1 \leq i_1 < i_2 < \cdots < i_d \leq n$ where $d = s + r$ and for every $J \subseteq [d]$ of size $|J| = s$ there are $\alpha(1-\epsilon)|H_0||H_1|$ vectors $h \in DC$ such that $h(i_k) = 0$ for all $k \in J$, and $h(i_j) = 1$ for all $j \in [d]\backslash J$.
Since H_1 is $(n, q, d, 1-\epsilon)$-DPHF, then there are $(1-\epsilon)|H_1|$ functions $h_1 \in H$ where $h_1(i_1), \ldots, h_1(i_d)$ are distinct. And since H_0 is a $(q, (r, s), \alpha)$-DCFF, then for each $h_1(i_1), \ldots, h_1(i_d)$ distinct values there are $\alpha|H_0|$ vectors $h_0 \in H_0$, where for every $J \subseteq [d]$ of size $|J| = s$, such that $h_0(h_1(i_k)) = 0$ for all $k \in J$ and $h_0(h_1(i_j)) = 1$ for all $j \in [d]\backslash J$. Accordingly, there are $(1-\epsilon)|H_1| \cdot \alpha|H_0|$ vectors $h \in DC$ where for every $1 \leq i_1 < i_2 < \cdots < i_d \leq n$ where $d = s + r$ and for every $J \subseteq [d]$ of size $|J| = s$, $h(i_k) = 0$ for all $k \in J$ and $h(i_j) = 1$ for all $j \in [d]\backslash J$. ◀

Constr.	Construction Time	Size	Density
I	$O\left(d^{\sqrt{\frac{r}{\log r}}}\left(\frac{d}{r}\right)^r n\log n\right)$	$O\left(d^{\sqrt{\frac{r}{\log r}}}\left(\frac{d}{r}\right)^r \log n\right)$	$\Omega\left(DNS(s,r)d^{-\sqrt{\frac{r}{\log r}}}\right)$
II	$O\left(c^d \cdot d^{2d+6}s^2\left(\frac{es}{r}\right)^{2r} n\log n\right)$	$O\left(d^3 s^2\left(\frac{es}{r}\right)^r \log n\right)$	$\Omega\left(DNS(s,r)\right)$
III	$O\left(d^3\left(\frac{ed^3}{r}\right)^{r+2}(4s)^{2r+4} n\log n\right)$	$O\left(d^3(4s)^{r+2}\log n\right)$	$\Omega\left(\frac{DNS(s,r)}{(c\cdot r)^r}\right)$

3 Explicit Dense Cover Free Family Constructions

In this section we will show three different constructions of $(n,(r,s),\alpha)$-DCFF - each of which has an advantage on the other. Before we introduce the constructions, we will state the results for each construction in **Table** 1.

Note that construction II is the best construction in terms of density. When r is non-constant then construction I and III are much better than construction II in terms of time complexity. Accordingly, when

$$\omega(1) < r < O\left(\frac{\log^2 d}{\log\log d}\right),$$

then we prefer construction III over I. Otherwise we prefer construction I over III.

In our algorithms, we will distinguish between the cases r is constant and r is non-constant. When r is non-constant, we will only deal with the case where $\omega(1) < r < O\left((\log^2 d)/(\log\log d)\right)$, and it can be done similarly for the other case.

3.1 Explicit Construction

Before we start our explicit constructions, we will start with lemmas from [10, 9], that are necessary for our constructions.

▶ **Lemma 7** ([9] - Derandomization lemma). *Let S be a finite sample space with a probability distribution D.*
Let $X_1,\ldots,X_N$ be random variables over S that take values from $\{0,1\}$. Suppose that for every $s \in S = S_1 \times S_2 \times \cdots \times S_n$, the values $X_1(s),\ldots,X_N(s)$ can be computed in $\tilde{O}(N)$[1]. Let

- $N' \leq N, 0 < \epsilon \leq \frac{1}{2}$.
- $\lambda_i = (1-\epsilon)p_i$, *where* $0 < p_i \leq E_{s\sim D}[X_i(s)]$ *for all* $i \in [N'] := \{1,\ldots,N'\}$.
- $\lambda_j = (1+\epsilon)p_j$, *where* $1 > p_j \geq E_{s\sim D}[X_j(s)]$ *for all* $j \in (N',N] := \{N'+1,\ldots,N\}$.
- $\alpha = \min_i \min\left(1/(1-p_i), 1/(1-\lambda_i)\right)$ *and* $m \geq \frac{4\ln N}{\min_i p_i\epsilon^2}$.

If any expectation of the form $E[X_i(x_1,\ldots,x_n)|x_1=\xi_1,\ldots,x_j=\xi_j]$ can be computed in time T, then there is an algorithm that runs in time

$$\tilde{O}\left(T\left(|S_1|+\cdots+|S_n|\right)\cdot Nm^2\log\alpha\right), \text{ and outputs } S' = \{s_1,\ldots,s_{m+1}\} \subseteq S$$

such that for all $i \in [N']$ and $j \in (N',N]$: $E_{s\sim U_{S'}}[X_i(s)] \geq \lambda_i, E_{s\sim U_{S'}}[X_j(s)] \leq \lambda_j$, where $U_{S'}$ is the uniform distribution over S'.

[1] $\tilde{O}(N)$ is $O(N\cdot poly(\log T))$ where T is the time complexity of the construction.

In other words, the lemma says if you have a set of random variables over a big range S, in our case $|S| = 2^n$, then there is a smaller set S' that can replace S while keeping the expectation of each variable the same to the factor of $(1 \pm \epsilon)$. This lemma will help us convert a random algorithm to a deterministic one, since the set S' is "small" and we can go over all possible values in a polynomial time.

▶ **Lemma 8** ([10] - CFF explicit construction). *Fix any integers $r < s < d$ with $d = r+s$, there is an almost optimal $(n, (r, s))$-CFF, i.e., of size $N(r, s)^{1+o(1)} \log n$, where $N(r, s) = \frac{d\binom{d}{r}}{\log\binom{d}{r}}$, that can be constructed in linear time.*

▶ **Corollary 9.** *There is an $\left(n, (r, s), \frac{1}{N(r,s)^{1+o(1)} \log n}\right)$-DCFF of size $N(r, s)^{1+o(1)} \log n$, that can be constructed in linear time.*

3.2 First Construction

From the proof of Lemma 8, we infer that the accurate value of the size is

$$N(n) = t(d) \left(\frac{d}{r}\right)^r \log n.$$

where

$$t(d) = \begin{cases} 2^{O(r \log\log d)} & r > O\left(\frac{\log^2 d}{\log\log d}\right) \\ 2^{O\left(\frac{\sqrt{r}\log d}{\sqrt{\log r}}\right)} & \text{Otherwise} \end{cases}$$

Now we can build the first DCFF by Lemma 2, Lemma 6 and Lemma 8.
Simply choose $\epsilon = 0.01$ (or any small constant) and a prime $q = O(d^3)$. By Lemma 2, there is a $(n, q, d, \Omega(1))$-DPHF of size $O\left(d^2 \log n\right)$. By Corollary 9 and the claim above, for $q = O\left(d^3\right)$, there is

$$\text{an } \left(O\left(d^3\right), r, s, \Omega\left(\frac{DNS(s,r)}{t(d)}\right)\right)\text{-DCFF, that can be constructed in linear time.}$$

By using Lemma 6, we can get

$$\left(n, r, s, \Omega\left(\frac{DNS(s,r)}{t(d)}\right)\right)\text{-DCFF of size } O\left(t(d)\left(\frac{d}{r}\right)^r \log n\right).$$

▶ **Theorem 10.** *There is an $\left(n, (r, s), \Omega\left(\frac{DNS(s,r)}{t(d)}\right)\right)$-DCFF of size $O\left(d^2 \log d N(r, s)^{1+o(1)} \log n\right)$ that can be constructed in linear time.*

3.3 Second Construction

▶ **Theorem 11.** *There is an $(n, (r, s), \Omega\left(DNS(s, r)\right))$-DCFF of size $O\left(s\left(\frac{es}{r}\right)^r \log n\right)$ that can be constructed in poly $\left(n^d\right)$.*

Proof. We define a probability space over the vectors $x = (x_1, \ldots, x_n) \in \{0, 1\}^n$, where

$$x_i = \begin{cases} 0, & \text{with probability } \frac{s}{d} \\ 1, & \text{with probability } \frac{r}{d} \end{cases}$$

For every couple of sets $\{i_1, \ldots, i_r\}$, $\{j_1, \ldots, j_s\}$, we define the random variable $X_{i_1,\cdots,i_r,j_1,\cdots,j_s}$ where

$$X_{i_1,\cdots,i_r,j_1,\cdots,j_s}(x) = \begin{cases} 1, & \text{If } x_{i_1} = \cdots = x_{i_r} = 1, x_{j_1} = \cdots = x_{j_s} = 0. \\ 0, & \text{Otherwise} \end{cases}$$

Note that the number of random variables is $N = \binom{n}{d}\binom{d}{r}$, and that the expectation of each random variable is $E[X_{i_1,\cdots,i_r,j_1,\cdots,j_s}] = \left(\frac{r}{d}\right)^r \left(\frac{s}{d}\right)^s$.
We now use Lemma 7. Note that

$$N' = N, \epsilon = \tfrac{1}{2}, p_{i_1,\cdots,i_r,j_1,\cdots,j_s} = p := \left(\tfrac{r^r s^s}{d^d}\right).$$

$$\lambda_i = \lambda := \tfrac{1}{2}p, \quad m \geq \frac{4\ln\binom{n}{d}\binom{d}{r}}{\frac{p}{4}} = O\left(s\left(\tfrac{es}{r}\right)^r \log n\right).$$

Therefore, according to Lemma 7, there is an algorithm that runs in

$$\tilde{O}(nNm^2\log\alpha) = O\left(n\left(\tfrac{en}{d}\right)^d s^2 \left(\tfrac{es}{r}\right)^{2r}\log^2 n\right) \text{ time, and outputs}$$

$S' = \{s_1,\ldots,s_{m+1}\} \subseteq S$, such that, for all $i = (i_1,\ldots,i_r,j_1\ldots,j_s) \in [n]^d$, holds:
$E_{s\sim U_{S'}}[X_i(s)] \geq \frac{1}{2}\left(\frac{r}{d}\right)^r \left(\frac{s}{d}\right)^s = \Omega\left(DNS(s,r)\right)$ ◀

The size of the construction is almost optimal, while the running time is exponential. In the third construction we will reduce the exponent from d to r.

3.4 Third Construction

▶ **Theorem 12.** *There is an* $\left(n,(r,s),\Omega\left(\frac{DNS(s,r)}{(cr)^r}\right)\right)$*-DCFF of size* $O\left((4s)^{r+2}\log n\right)$ *that can be constructed in poly* (n^r).

Through applying the same technique from the **Second construction** wisely, we reduce the number of random variables this time, leading to a reduced construction time.

Proof. We define a probability space over the vectors $x = (x_1,\ldots,x_n) \in \{0,1\}^n$, where

$$x_i = \begin{cases} 1, & \text{with probability} \frac{1}{4s} \\ 0, & \text{with probability} \frac{4s-1}{4s}. \end{cases}$$

For every couple of sets $\{i_1,\ldots,i_r\}$, $\{j_1,\ldots,j_s\}$, we define the following random variables:

$$X_{i_1,\cdots,i_r,j_1,\cdots,j_s}(x) = \begin{cases} 1, & \text{If } x_{i_1} = \cdots = x_{i_r} = 1, x_{j_1} = \cdots = x_{j_s} = 0. \\ 0, & \text{Otherwise.} \end{cases}$$

$$Y_{i_1,\cdots,i_r,j}(x) = \begin{cases} 1, & \text{If } x_{i_1} = \cdots = x_{i_r} = x_j = 1. \\ 0, & \text{Otherwise.} \end{cases}, j \in \{j_1,\ldots,j_s\}$$

$$Z_{i_1,\cdots,i_r}(x) = \begin{cases} 1, & \text{If } x_{i_1} = \cdots = x_{i_r} = 1. \\ 0, & \text{Otherwise.} \end{cases}$$

Note that we can bound the random variable X, by an expression of Y and Z in the following way:

$$X_{i_1,\cdots,i_r,j_1,\cdots,j_s} \geq Z_{i_1,\cdots,i_r} - \textstyle\sum_{k=1}^{s} Y_{i_1,\cdots,i_r,j_k}$$

The correctness of the above equation follows immediately from the definition.
Note that instead of $\binom{n}{d}$ that we used in the previous construction, now we can do a similar construction by using the following number of random variables

$$N = \tbinom{n}{r+1}(r+1) + \tbinom{n}{r}$$

and the expectation of each random variable is

$$E[X_{i_1,\cdots,i_r,j_1,\cdots,j_s}] \geq E[Z_{i_1,\cdots,i_r}] - \sum_{k=1}^{s} E[Y_{i_1,\cdots,i_r,j_k}] = \frac{3}{4}\frac{1}{(4s)^r}$$

Again we use Lemma 7 for the random variables Z and Y. Note that

1. $N' = \binom{n}{r}$, $\epsilon = \frac{1}{2}$.
2. $p_{i_1,\cdots,i_r} = p_0 := \left(\frac{1}{4s}\right)^r$.
3. $p_{i_1,\cdots,i_r,j} = p_1 := \left(\frac{1}{4s}\right)^{r+1}$.
4. $\lambda_{i_1,\cdots,i_r} = \lambda_0 := \frac{1}{2}p_0$.
5. $\lambda_{i_1,\cdots,i_r,j} = \lambda_1 := \frac{3}{2}p_1$.
6. $m \geq \frac{4\ln\left(\binom{n}{r+1}(r+1)+\binom{n}{r}\right)}{\frac{p_1}{4}} = O\left((4s)^{r+2}\log n\right)$.

Therefore, according to Lemma 7, there is an algorithm that runs

$$\tilde{O}\left(nNm^2\log\alpha\right) = O\left(n\left(\frac{en}{r}\right)^{r+2}(4s)^{2r+4}\log^2 n\right), \text{ and outputs}$$

$$S' = \{s_1,\ldots,s_{m+1}\} \subseteq S,$$

such that for all $i = (i_1,\ldots,i_r) \in [n]^r, j = (j_1,\ldots,j_r,j_{r+1}) \in [n]^{r+1}$:

$$E_{s\sim U_{S'}}[Z_i(s)] \geq \tfrac{1}{2}(\tfrac{1}{4s})^r \text{ and } E_{s\sim U_{S'}}[Y_j(s)] \leq \tfrac{3}{2}(\tfrac{1}{4s})^{r+1}, \text{so}$$

$$E[X_{i_1,\cdots,i_r,j_1,\cdots,j_s}] \geq E[Z_{i_1,\cdots,i_r}] - \sum_{k=1}^{s} E[Y_{i_1,\cdots,i_r,j_k}] \geq \tfrac{1}{2}(\tfrac{1}{4s})^r - s\cdot\tfrac{3}{2}(\tfrac{1}{4s})^{r+1}$$

$$E[X_{i_1,\cdots,i_r,j_1,\cdots,j_s}] \geq \tfrac{1}{8}(\tfrac{1}{4s})^r$$ ◀

Note that we can apply Lemma 2 and Lemma 6 on the second and third constructions, the same way we did in the first construction to get the needed results.

4 Direct Usage of DCFF: α-Error Tolerant Algorithm

In this section we discuss and explain the intuition behind using DCFF, and show how we can use it directly to present an α-error tolerant algorithm of a hidden hypergraph. Unfortunately though, the time complexity of the algorithm will not be polynomial. The issue of the time complexity will be solved in the following sections by wise use of the DCFF combined with other algebraic structures.

We assume our function is $f = M_1 \vee \cdots \vee M_{s'}$, $s' \leq s$, and each M_i is of size at most r. For simplicity we assume that $s' = s$ and each term is of size exactly r. Denote $S_{terms} = \{x_{i_1}\cdots x_{i_r} | 1 \leq i_1 < \ldots < i_r \leq n \text{ and } x_{i_1}\cdots x_{i_r} \notin \{M_1,\ldots,M_s\}\}$.
In order to find M_1 we need a set of assignments A_{M_1} such that:

1. $\exists a \in A_{M_1}$ such that $M_1(a) = 1, M_i(a) = 0$ $(1 < i \leq s)$.
2. $\forall t \in S_{terms}$ $\exists a \in A_{M_1}$ where $t(a) = 1$ and $f(a) = 0$.

If all the above is satisfied, then we can find M_1 simply by trying all the possible terms of size r. One can easily see that any $(n,(s,r),\alpha)$-DCFF(CFF) has a subset that satisfies all the above requirements. To satisfy the first requirement we need r $1's$ (to satisfy M_1) and $s-1$ $0's$ (to falsify $M_i, 1 < i \leq s$), and to satisfy the second requirement we need s $0's$ (to falsify $M_i, 1 \leq i \leq s$) and r $1's$ (to satisfy a given term $t \in S_{terms}$).
Now we present the details of the algorithm:

We construct an $(n,(s,r),\beta)$-DCFF A, where $\beta = 2\alpha + \frac{1}{|A|}$. Denote by $A'(M)$ the set $\{a \in A | M(a) = 1 \text{ and } Q'(a) = 1\}$. Now, take every monomial M of size at most r where $|A'(M)| \leq \alpha|A|$. The disjunction of all such monomials is equivalent to the target function.

This follows from the following two facts: (1) for any monomial M' such that $M' \not\Rightarrow f$, there are at least $\left(\alpha + \frac{1}{|A|}\right)|A|$ assignments $a \in A$ such that $Q'(a) = 0$ and $M'(a) = 1$ (2) for any monomial $M' \Rightarrow f$, there are at least $\left(\alpha + \frac{1}{|A|}\right)|A|$ assignments $a \in A$ such that $Q'(a) = 1$ and $M'(a) = 1$. Since only $\alpha|A|$ queries can be incorrect, and there are $\beta|A|$ assignments where $M'(a) = 1$ and $Q(a) = 0$ for each $M' \not\Rightarrow f$, then there are more than $\alpha|A|$ assignments $a \in A$ where $Q(a) = 0$ and $M'(a) = 1$. Similarly, for each $M' \Rightarrow f$ there are at most $\alpha|A|$ assignments $a \in A$ where $Q(a) = 0$ and $M'(a) = 1$.

▶ **Lemma 13.** *If an* $\left(n, (s, r), 2\alpha + \frac{1}{|A|}\right)$*-DCFF* A *of size* N *can be constructed in time* T*, then there is an algorithm that learns the class* s*-term* r*-MDNF with* N *noisy membership queries in time*

$$O\left(T + Nr\sum_{r'=0}^{r}\binom{n}{r'}\right).$$

Correctness and time complexity of the algorithm follows from the above explanation and from the correctness of the error-free folklore algorithm [2].

5 α-Error Tolerant Reduction

In this section, we give a reduction to reduce the query complexity of any α-error tolerant algorithm that depends on d variables to become linear in $\log n$. The idea behind this is to map the n-dimensional variables space to $g(d)$-dimensional space, where g is a polynomial function of d. Then we run the original algorithm over the new space. The main challenge here is to recover the original function efficiently (in terms of time complexity), while keeping the algorithm $\Omega(\alpha)$-error tolerant. This can be done by using PHF in the following way: by the definition of PHF, it contains a function h such that h maps each variable of MDNF to a distinct variable. After finding this h, we use it to reduce the variables space from n-dimensional to $g(d)$-dimensional. Here is the main theorem of this section:

▶ **Theorem 14.** *Let* H *be a class of boolean functions that is closed under variable projection. And suppose there is an algorithm that, given* $f \in H$ *as an input, finds the relevant variables of* f *in time* $R(n)$*.*

If H *is non-adaptively learnable in time* $T(n)$ *with* $Q'(n)$ *noisy membership queries, and* $\alpha Q'(n)$*-errors might occur, then* H *is non-adaptively learnable in time*

$$O\left(\frac{d^2 n\log n}{\epsilon\log(\epsilon q/d^3)} + \frac{d^2\log n}{\epsilon\log(\epsilon q/d^3)}(T(q) + Q'(q)n + R(q))\right), \text{ with}$$

$$Q_{new}(n) = O\left(\frac{d^2 Q'(q)}{\epsilon\log(\epsilon q/d^3)}\log n\right)$$

noisy membership queries where less than $\frac{1-\epsilon}{2}\alpha Q_{new}(n)$ *errors might occur, and* d *is an upper bound on the number of relevant variables in* $f \in C$ *and* q *is any integer such that* $q \geq 2(d+1)^2$*.*

Consider the algorithm in Figure 1.

Let $\mathcal{A}(n, \alpha)$ be a non-adaptive algorithm that learns H in $T(n)$ time with $Q'(n)$ noisy membership queries, where $\alpha Q'(n)$ errors might occur. Let $f \in H_n$ be the target function. Consider the $(n, q, d+1, 1-\epsilon)$-DPHF P that was constructed in Lemma 2 (Step 1 in the algorithm).

The following lemma follows from the fact that H is closed under variable projection:

Reduction
$\mathcal{A}(n,\alpha)$ is a non-adaptive α error tolerant learning algorithm for H.
1) Construct an $(n, q, d+1, (1-\epsilon))$-DPHF P.
2) For each $h \in P$
    Run $\mathcal{A}(q,\alpha)$ to learn $f_h := f(x_{h(1)}, \ldots, x_{h(n)})$.
    Let $f'_h \in H$ be the output of $\mathcal{A}(q,\alpha)$.
3) For each $h \in P$
    $V_h \leftarrow$ the relevant variables in f'_h
4) $G(h) = |\{h' || V_{h'}| = |V_h|, h' \in P\}|$, $H' = \{h \in H | G(h) \geq \frac{1-\epsilon}{2}|P|\}$
    $d_{max} \leftarrow \max_{h \in H'} |V_h|$.
5) $X \leftarrow \{x_1, x_2, \ldots, x_n\}$.
6) For each $i \in [n]$, $W(i) = |\{h \in H | x_{h(i)} \notin V_h, |V_h| = d_{max}\}|$
    If $W(i) \geq \frac{1-\epsilon}{2}|P|$, then $X \leftarrow X \backslash \{x_i\}$
7) Take all $h \in H$ with $|V_h| = d_{max}$
8) Replace each relevant variable x_i in f'_h by $x_j \in X$ where $h(j) = i$.
9) Output the function that appears at least $\frac{1-\epsilon}{2}|P|$ times from step (8).

Figure 1 Reduction.

▶ **Lemma 15.** *For every $h \in P$, the function $f_h := f(x_{h(1)}, \ldots, x_{h(n)})$ is in H_q.*

▶ **Lemma 16.** *The total number of queries after the reduction is $Q_{new} = |P|Q'(q)$.*

Proof. For each $h \in P$, we run $\mathcal{A}(q,\alpha)$ to learn f_h. It is known that $\mathcal{A}(q,\alpha)$ generates $Q'(q)$ queries, so overall we have $|P|Q'(q)$ queries. ◀

▶ **Lemma 17.** *(Step 2 in the algorithm) Let f'_h be the output of algorithm $\mathcal{A}(q,\alpha)$ when it runs on f_h, and let $K = \{h | h \in P \text{ and } f'_h \not\equiv f_h\}$, then $K < \frac{1-\epsilon}{2}|P|$.*

Proof. The lemma follows from the fact that the number of times when $\alpha Q'(q)$ errors appear while running $A(q,\alpha)$ is less than $\frac{1-\epsilon}{2}|P|$. Otherwise, the number of errors will be at least $\frac{1-\epsilon}{2}\alpha|P|Q'(q) = \frac{1-\epsilon}{2}\alpha Q_{new}(n)$. ◀

(Step 3 in the algorithm) Note that if the number of errors when running $A(q,\alpha)$ is less than $\alpha Q'(q)$-errors, then the algorithm finds the correct relevant variables of f'_h, by the definition of $A(q,\alpha)$.

▶ **Lemma 18.** *(Step 4 in the algorithm) Suppose $x_{i_1}, \ldots, x_{i_{d'}}$, $d' \leq d$ are the relevant variables in the target function f, then $d_{max} = d'$.*

Proof. Let V_h be the set of relevant variables of f'_h and let $d_{max} = \max_{h \in H'} |V_h|$. By the definition of P there are at least $(1-\epsilon)|P|$ maps $h' \in P$ such that $h'(i_1), \ldots, h'(i_{d'})$ are distinct, and since more than $\alpha Q'(q)$ errors might occur in less than $\frac{1-\epsilon}{2}|P|$ functions $h \in H$ (as mentioned above), then there are at least $(1-\epsilon)|P| - \frac{1-\epsilon}{2}|P| = \frac{1-\epsilon}{2}|P|$ functions $h' \in P$ where $h'(i_1), \ldots, h'(i_{d'})$ are distinct and their $V_{h'}$ equals d'. Such h' satisfies $G(h') \geq \frac{1-\epsilon}{2}|P|$, so $h' \in H'$. Stemming from the same fact, there are less than $\frac{1-\epsilon}{2}|P|$ functions $h \in P$ where the learned function f'_h can have number of relevant variables greater than d'. Such h satisfies $G(h) < \frac{1-\epsilon}{2}|P|$, so $h \notin H'$. And therefore, $d_{max} = d'$. ◀

▶ **Lemma 19.** *(Step 6 in the algorithm) If x_i is an irrelevant variable, then for at least $\frac{1-\epsilon}{2}|P|$ maps $h \in P$ $|V_h| = d_{max}$ and $x_{h(i)} \notin V_h$.*

Learn(f_{MDNF})
1) Construct an $(n,(1,r),\alpha_1)$-DCFF A and an $(n,(s-1,r),\alpha_2)$-DCFF B.
2) Ask noisy membership queries for all $a \wedge b$, $a \in A$ and $b \in B$.
3) For every $b \in B$.
4) $\quad T_b \leftarrow 1$.
5) $\quad$ For every $i \in [n]$.
6) $\quad\quad$ If for at most $\beta_1|A|$ assignments $a \in A$, $(a \wedge b)_i < Q'(a \wedge b)$
7) $\quad\quad\quad$ then $T_b \leftarrow T_b \wedge x_i$.
8) $\quad \mathcal{T} \leftarrow \mathcal{T} \cup \{T_b\}$.
9) Remove from $\mathcal{T}$ all the terms that appear at most $\beta_2|B|$-times.
10) Remove from $\mathcal{T}$ the term $\wedge_{i\in[n]}x_i$
$\quad$ and all subterms of a larger term.

Figure 2 An algorithm for learning s term r MDNF.

Proof. Consider any irrelevant variable $x_j \notin \{x_{i_1},\ldots,x_{i_{d'}}\}$. Since P is $(n,q,d+1,1-\epsilon)$-DPHF, there are $(1-\epsilon)|P|$ functions $h'' \in P$ such that $h''(j)$ and $h''(i_1),\ldots,h''(i_{d'})$ are distinct. Again since αQ_{new} errors might occur, then $f'_{h''}$ depends on $x_{h''(i_1)},\ldots,x_{h''(i_{d'})}$, and not on $x_{h''(j)}$ and $|V_h| = d_{max}$ for at least $\frac{1-\epsilon}{2}|P|$ functions $h'' \in P$. ◀

This way the irrelevant variables can be eliminated. Since the above is true for every irrelevant variable, the set X contains only the relevant variables of f, after Step 6 in the algorithm. Then in Steps 7 and 8, we find all functions f for which the number of relevant variables is d'. The target function appears at least $\frac{1-\epsilon}{2}|P|$ times, and any other function appears less than $\frac{1-\epsilon}{2}|P|$ times. This is Step 9 in the algorithm. The correctness of the algorithm follows immediately from the above lemmas and explanation.

6 Efficient α-Error Tolerant Algorithm

In Section 4 we used DCFF directly to present a non-polynomial algorithm. In order to improve the time complexity we will now use two DCFFs. One of them is used to spread the set of terms over different sets, and the other is used afterwards to find each term explicitly. The complexity of this process is the bit-wise conjunction of assignments in each DCFF is $f(r,s)\log^2 n$, where $f(r,s)$ is a monotone function of s and r. In order to make our algorithm linear in $\log n$, we use the reduction from the previous section.

▶ **Theorem 20.** *Let A be an $(n,(1,r),\alpha_1)$-DCFF and B be an $(n,(s-1,r),\alpha_2)$-DCFF, and let $\beta_1 \triangleq \frac{\alpha_1}{2} - \frac{1}{|A|}, \beta_2 \triangleq \frac{\alpha_2}{2} - \frac{1}{|B|}$. There is a non-adaptive α-error tolerant learning algorithm for s-term r-MDNF that asks all the queries $A \wedge B$ and finds the target function, when $\alpha = \beta_1\beta_2$.*

This gives the algorithm in Figure 2.

▶ **Lemma 21.** *If $b \in B$ **separates** a term T in f from other terms, and at most $\beta_1|A|$ errors can occur, then $T_b = T$.*

Proof. According to the definition of A, for each distinct $i_1,\ldots,i_r$ and j_1 there are $\alpha_1|A|$ assignments $a \in A$, where $a_{i_1} = \cdots = a_{i_r} = 1$ and $a_{j_1} = 0$. Since $\beta_1|A|$ of the queries might have incorrect results, then each $x_i \in T$ can appear as $x_i = 1$ while also $Q = 1$ in at least

$\alpha_1 - \beta_1 > \beta_1$ fraction of the assignments. Each $x_i \notin T$ can appear as $x_i = 0$ while also $Q = 1$ in at least $\alpha_1 - \beta_1 > \beta_1$ fraction of the assignments. So by the definition of T_b, $T_b = T$. ◀

▶ **Lemma 22.** *Let $A_b = \{a \wedge b | a \in A\}$. If $\alpha \triangleq \beta_1\beta_2$ is the fraction of queries that can be incorrect, then for at most $\beta_2|B|$ assignments $b \in B$, A_b contains more than $\beta_1|A|$ errors.*

Proof. If there are more than $\beta_2|B|$ $b \in B$ such that A_b contains more than $\beta_1|A|$ errors, then the fraction of errors is bigger than $\frac{(\beta_2|B|)(\beta_1|A|)}{|A||B|} = \beta_1\beta_2$. ◀

Now we are ready to prove Theorem 20

Proof. Let $f = M_1 \vee M_2 \vee \cdots \vee M_s$ be the target function. For every $b \in B$, let $F_b(i) = \{a | a \in A, (a \wedge b)_i < Q'(a \wedge b)\}$, $A_b = \{a \wedge b | a \in A\}$, $I_b = \{i || F_b(i)| \leq \beta_1|A|\}$, and T_b be the following term: $T_b := \wedge_{i \in I_b} x_i$. We will show:

1. For each T in f, there are more than $\beta_2|B|$ assignments $b \in B$, such that $T_b = T$.
2. Every other term T_b that appears more than $\beta_2|B|$ times, is either equal to $\wedge_{i\in[n]}x_i$ or to a subterm of one of the terms in f.

In case no errors occur, the term that can be learned from each block A_b is either one of the following:

1. In case b separates a term in f then I_b will be the separated term.
2. In case b separates k terms in f then I_b will be a subterm of one of the terms in f (the intersection of the k terms).
3. In case b separates no term in f then I_b will be $\wedge_{i\in[n]}x_i$.
   (For more details see Lemma 13 in [2]).

By Lemma 22, the number of assignments $b \in B$ where A_b has more than $\beta_1|A|$ errors is $\beta_2|B|$, so any term different than a term in f, a subterm of one of the terms in f and $\wedge_{i\in[n]}x_i$ appears at most $\beta_2|B|$ times.

Now we prove that each term T in f appears more than $\beta_2|B|$ times.

Since there are $\alpha_2|B|$ assignments $b \in B$ that separate T from all other terms in f, among which at most $\beta_2|B|$ assignments A_b can have more than $\beta_1|A|$ errors, then by Lemma 21 $(\alpha_2 - \beta_2)|B| > \beta_2|B|$ of A_b will return $T_b = T$. ◀

▶ **Theorem 23.** *Fix any integers $r < s < d$ with $d = r + s$, and let $d \leq n$. There is a non-adaptive proper α error tolerant learning algorithm for s-term r-MDNF that asks $O\left(r^9(4s)^{r+5}\log^2 n\right)$ queries and runs in time $poly(n, s^r)$, with $\alpha = \Omega\left(\frac{1}{r^r}DNS(1,r)DNS(s-1,r)\right)$ -fraction of the queries might be incorrect.*

Proof. By Theorem 11 (**second construction**), we can construct a $(n, (1, r), \alpha_1)$-DCFF, of size $|A| = O\left(r^6 \log n\right)$, where $\alpha_1 = \Omega\left(DNS(1, r)\right)$. And by Theorem 12 (**third construction**), we can construct a $(n, (s-1, r), \alpha_2)$-DCFF of size $|B| = O\left(d^3\,(4s)^{r+2}\log n\right)$, where $\alpha_2 = \Omega\left(\left(\frac{1}{r^r}\right)DNS(s-1,r)\right)$.

The construction of the above DCFFs takes $poly\,(n, |A|, |B|)$ time. By Theorem 20, the learning takes $|A \wedge B| \cdot n = poly\ (n, |A|, |B|)$ time. The number of queries of the algorithm is $|A \wedge B| \leq |A| \cdot |B| = O\left(r^9(4s)^{r+5}\log^2 n\right)$. ◀

We are now ready to prove the main result:

▶ **Theorem 24.** *Fix any integers $r < s < d$ with $d = r + s$, and let $d \leq n$. There is a non-adaptive proper α error tolerant learning algorithm for s-term r-MDNF that asks*

$$O(r^{11}(4s)^{r+7}\log n)$$

queries where $\alpha = \Omega\left(\frac{1}{r^r}DNS(1,r)DNS(s-1,r)\right)$-fraction of the queries might return incorrect result, and runs in time $(n \log n) \cdot poly(s^r)$.

Proof. We use Theorem 14. H is the class of s-term r-MDNF. This class is closed under variable projection. Given f that is s-term r-MDNF, one can find all the relevant variables in $R(n) = O(sr)$ time. The algorithm in the previous section runs in time $T(n) = poly(n, s^r)$ and asks $Q'(n) = O(r^9(4s)^{r+5}\log^2 n)$ queries. The number of variables in the target is bounded by $d = rs$. Let $q = O\left(d^3\right) \geq 2d^2$. By Theorem 14, there is a non-adaptive algorithm that runs in time $O\left(qd^2 n\log n + \frac{d^2\log n}{\log(q/d^2)}(T(q)n + R(q))\right) = (n\log n)poly(s^r)$, and asks $O\left(\frac{d^2Q'(q)}{\log(q/d^2)}\log n\right) = O(r^{11}(4s)^{r+7}\log n)$, noisy membership queries. ◀

Abstract

In this paper we explore hitting distributions, a notion that arose recently in the context of deterministic "query-to-communication" simulation theorems. We show that any expander in which any two distinct vertices have at most one common neighbor can be transformed into a gadget possessing good hitting distributions. We demonstrate that this result is applicable to affine plane expanders and to Lubotzky-Phillips-Sarnak construction of Ramanujan graphs . In particular, from affine plane expanders we extract a gadget achieving the best known trade-off between the arity of outer function and the size of gadget. More specifically, when this gadget has k bits on input, it admits a simulation theorem for all outer function of arity roughly $2^{k/2}$ or less (the same was also known for k-bit Inner Product). In addition we show that, unlike Inner Product, underlying hitting distributions in our new gadget are "polynomial-time listable" in the sense that their supports can be written down in time $2^{O(k)}$, i.e. in time polynomial in size of gadget's matrix.

We also obtain two results showing that with current technique no better trade-off between the arity of outer function and the size of gadget can be achieved. Namely, we observe that no gadget can have hitting distributions with significantly better parameters than Inner Product or our new affine plane gadget. We also show that Thickness Lemma, a place which causes restrictions on the arity of outer functions in proofs of simulation theorems, is unimprovable.

1 Introduction

Assume that we have a Boolean function $f : \{0,1\}^n \to \{0,1\}$ called *outer function* and a Boolean function $g : A \times B \to \{0,1\}$ called *gadget*. Consider a composed function $f \circ g : A^n \times B^n \to \{0,1\}$, defined as follows:

$$(f \circ g)((a_1, \ldots, a_n), (b_1, \ldots, b_n)) = f(g(a_1, b_1), \ldots, g(a_n, b_n)).$$

How can we deal with deterministic communication complexity of $f \circ g$, denoted below by $D^{cc}(f \circ g)$? Obviously, we have the following inequality:

$$D^{cc}(f \circ g) \leq D^{dt}(f) \cdot D^{cc}(g),$$

where $D^{dt}(f)$ stands for deterministic query complexity of f. Indeed, we can transform a decision tree for f making q queries into a protocol of communication cost $q \cdot D^{cc}(g)$ by

[1] Supported in part by RFBR grapnt 16-01-00362 and by the Russian Academic Excellence Project "5-100".

simulating each query to f with $D^{cc}(g)$ bits. It turns out that for some gadgets g and for all f of arity at most some function of g's size this simple protocol is essentially optimal. The first gadget for which this was proved is the Indexing Function

$$\mathsf{IND}_k : \{1, 2, \ldots, k\} \times \{0,1\}^k \to \{0,1\}, \qquad g(x, y) = y_x.$$

More specifically, in 2015 Göös et al. ([4]) proved that for all $n \leq 2^{k^{1/20}}$ and for all $f : \{0,1\}^n \to \{0,1\}$ it holds that

$$D^{cc}(f \circ \mathsf{IND}_k) = \Omega(D^{dt}(f) \log k). \tag{1}$$

Actually, instead of f we can have not only a Boolean function but any relation $R \subset \{0,1\}^n \times C$. The work of Göös et al. was a generalization of the theorem of Raz and McKenzie ([9]), who in 1997 established (1) for a certain class of outer relations, called DNF-Search problems.

Theorems of this kind, called usually *simulation theorems*, can be viewed as a new method of proving lower bounds in communication complexity. Namely, lower bound on communication complexity of a composed function reduces to lower bound on query complexity of an outer function, and usually it is much easier to deal with the latter. As was shown by Raz and McKenzie, this method turns out to be powerful enough to separate monotone NC-hierarchy. Moreover, as was discovered by Göös et al., this method can be quadratically better than the logarithm of the partition number, another classical lower bound method in deterministic communication complexity.

There are simulation theorems not only for deterministic communication and query complexities, but for other models too, see, e.g., [2, 5, 6, 3].

Note that input length of a gadget in (1) is even bigger than input length of an outer function. Göös et al. in [4] asked, whether it is possible to prove a simulation theorem for a gadget which input length is logarithmic in input length of an outer function. This question was answered positively by Chattopadhyay et al. ([1]) and independently by Wu et al. ([12]). Moreover, Chattopadhyay et al. significantly generalized the proof of Göös et al., having discovered a certain property of a gadget $g : A \times B \to \{0,1\}$ which can be used as a black-box to show new simulation theorems: once g satisfies this property, we have a simulation theorem for g. This property can be defined as follows. Let μ be probability distribution over rectangles $U \times V \subset A \times B$. Distribution μ is called (δ, h)-*hitting*, where $\delta \in (0,1)$ and h is a positive integer, if for every $X \subset A$ of size at least $2^{-h}|A|$ and for every $Y \subset B$ of size at least $2^{-h}|B|$ we have that

$$\Pr_{U \times V \sim \mu}[U \times V \cap X \times Y \neq \varnothing] \geq 1 - \delta.$$

It turns out that if for every $b \in \{0,1\}$ there is (δ, h)-hitting distribution over b-monochromatic rectangles of g , then there is a simulation theorem for g. The smaller δ and the bigger h, the better simulation theorem. More precisely, Chattopadhyay et al. proved the following theorem.

▶ **Theorem 1.** *Assume that $\varepsilon \in (0,1)$ and an integer h are such that $h \geq 6/\varepsilon$. Then the following holds. For every (possibly partial) Boolean function $g : A \times B \to \{0,1\}$ that has two $(\frac{1}{10}, h)$-hitting distribution, the one over 0-monochromatic rectangles and the other over 1-monochromatic rectangles, for every $n \leq 2^{h(1-\varepsilon)}$ and $f : \{0,1\}^n \to \{0,1\}$ it holds that*

$$D^{cc}(f \circ g^n) \geq \frac{\varepsilon h}{4} \cdot D^{dt}(f).$$

Further, they showed that Inner Product and Gap Hamming Distance gadgets on k bits have $(o(1), \Omega(k))$-hitting distributions for both kinds of monochromatic rectangles. More precisely, for every constant $\gamma > 0$ and for all large enough k they constructed $(o(1), (1/2 - \gamma)k)$-hitting distributions for k-bit Inner Product (denoted below by IP_k) . Due to Theorem 1 this yields the following simulation theorem for IP_k: for every constant $\gamma > 0$ and for all k large enough

$$D^{cc}(f \circ \mathsf{IP}_k) = \Omega(D^{dt}(f) \cdot k),$$

where f is any Boolean function depending on at most $2^{(1/2-\gamma)k}$ variables. Other gadgets studied until this work do not achieve the same trade-off between the size of outer functions and the size of gadget. Namely, for k-bit Gap Hamming Distance the lower bound $D^{cc}(f \circ \mathsf{GHD}) = \Omega(D^{dt}(f) \cdot k)$ is shown in [1] only for f depending on roughly $2^{0.45k}$ variables or less. For Indexing gadget, as we saw, this trade-off is exponentially worse.

We also touch upon the following question. Theorem 1 transforms a communication protocol for $f \circ g^n$ into decision tree for f (here n is the arity of f). It is an interesting open question whether resulting decision tree can be made efficient, provided that the initial protocol is efficient. More precisely, a decision tree should decide which variable to query in time polynomial in n (provided that messages of the initial protocol can be computed by players in time polynomial in n). Let us note here that we are mostly interested in the regime when n is exponential in k (the size of input to g) and hence in this regime the size of g's matrix is polynomial in n.

Unfortunately, known constructions does not provide this – resulting decision trees work in exponential time. Among other obstacles to resolve this issue there is a particular step in transformation which deals with hitting distributions. Namely, a tree constantly runs a subroutine which, having a family of subrectangles (not necessarily monochromatic) of g's matrix on input, outputs single monochromatic rectangle which intersects most of them. Namely, a subroutine samples rectangle at random from a hitting distribution, which with good probability gives us a correct answer. To derandomize this procedure instead of sampling a rectangle we can just try all the rectangles from the support of hitting distribution. If the support is of size $2^{O(k)}$ (i.e. polynomial in size of g's matrix) and, moreover, the support can be listed in time $2^{O(k)}$, we call a corresponding hitting distribution (or, more precisely, family of distributions) *polynomial-time listable*.

For example, hitting distribution from [1] for k-bit Gap Hamming Distance gadget are polynomial-time listable (roughly speaking, we just have to list all Hamming balls of a certain radius). At the same time, hitting distributions for k-bit Inner Product from [1] are not polynomial-time listable. Namely, their supports are of size $2^{\Omega(k^2)}$ (this number corresponds to the number of $k/2$-dimensional subspaces of $\mathbb{F}_2^k$). Though due to Chernoff bound it is possible to transform any $(0.1, h)$-hitting distribution into , say, $(0.2, h)$-hitting distribution with support size $2^{O(k)}$ (see Proposition 7 below), this does not give explicit construction.

1.1 Our results

We show how to transform any explicit expander satisfying one additional restriction into a gadget with polynomial-time listable hitting distributions. The transformation is as follows. Assume that we have a graph $G = (V, E)$ and a coloring $c : V \to \{0, 1\}$. For $v \in V$ let $\Gamma(v)$ denote the set of all $u \in V$ such that u and v are connected by en edge in G. Assume further that for any two distinct $u, v \in V$ it holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$. Then the following partial

function is well defined:

$$g(G,c) : V \times V \to \{0,1\},$$
$$g(G,c)(u,v) = \begin{cases} 1 & u \neq v \text{ and there is } w \in \Gamma(u) \cap \Gamma(v) \text{ s.t. } c(w) = 1, \\ 0 & u \neq v \text{ and there is } w \in \Gamma(u) \cap \Gamma(v) \text{ s.t. } c(w) = 0, \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Call c balanced if each color is used at least $|V|/3$ times in c. It turns out that if G is a good expander and if c is balanced, then $g(G,c)$ possesses good hitting distributions:

▶ **Theorem 2.** *Assume that $G = (V,E)$ is a (m,d,γ)-spectral expander in which for any two distinct $u,v \in V$ it holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$ and $c : V \to \{0,1\}$ is a balanced coloring of G. Assume also that $m \geq 1/\gamma^2$. Then for any $b \in \{0,1\}$ there is a $\left(\frac{1}{10}, \lfloor 2\log_2(1/\gamma)\rfloor - 100\right)$-hitting distribution μ_b over b-monochromatic rectangles of $g(G,c)$. All the probabilities of μ_b are rational. Moreover, there is a deterministic Turing machine which, having b, G and c on input, in time $m^{O(1)}$ lists all the rectangles from the support of μ_b, together with probabilities μ_b assigns to them.*

Provided that G's adjacency matrix and c's truth table can be computed in time $m^{O(1)}$, from Theorem 2 we obtain polynomial-time listable family of hitting distributions.

In particular, we apply Theorem 2 to the following explicit family of expanders. If q is a power of prime, let AP_q denote a graph in which vertices are pairs of elements of $\mathbb{F}_q$ and in which $(a,b),(x,y) \in \mathbb{F}_q^2$ are connected by an edge if and only if $ax = b + y$. It is known that AP_q is a $(q^2, q, 1/\sqrt{q})$-spectral expander. It can be easily shown that for any two distinct vertices u,v of AP_q it holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$.

▶ **Corollary 3.** *Let q be a power of prime. Then in AP_q for any two distinct vertices u,v it holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$. Moreover, for all $n \leq 2^{\log_2 q - 200}$ and $f : \{0,1\}^n \to \{0,1\}$ the following holds: if c is a balanced coloring of AP_q, then*

$$D^{cc}(f \circ g(AP_q, c)) \geq \frac{\log_2(q/n) - 200}{4} \cdot D^{dt}(f)$$

(in $g(AP_q,c)$ each party receives $2\log_2 q$ bits).

We also give an example of a natural-looking gadget for which Corollary 3 implies a simulation theorem. Our gadget is the following one: Alice gets $a \in \mathbb{F}_{q^2}$ and Bob gets $b \in \mathbb{F}_{q^2}$. Here q is a power of an odd prime. Their goal is to output 1, if $a - b$ is a square in $\mathbb{F}_{q^2}$ (by that we mean that there is $c \in \mathbb{F}_{q^2}$ such that $a - b = c^2$), and 0 otherwise. Let us denote this gadget by SQR^q.

Since $\mathbb{F}_{q^2}$ is a linear space over $\mathbb{F}_q$, we can naturally identify inputs to SQR^q with $\mathbb{F}_q^2$, i.e SQR^q can be viewed as a function of the form $\mathsf{SQR}^q : \mathbb{F}_q^2 \times \mathbb{F}_q^2 \to \{0,1\}$.

▶ **Proposition 4.** *For all large enough q the following holds. If q is a power of an odd prime, then there exists a balanced covering c of AP_q such that $g(AP_q,c)$ is a sub-function of SQR^p, i.e. whenever $g(AP_q,c)(a,b)$ is defined, we have $g(AP_q,c)(a,b) = \mathsf{SQR}^q(a,b)$. A truth table of c can be computed in time $q^{O(1)}$.*

This Proposition implies a simulation theorem for SQR^q, with the same parameters as in Corollary 3 and with polynomial-time listable underlying hitting distributions.

Next we observe that any spectral expander "similar" to AP_q automatically satisfies restrictions of Theorem 2.

▶ **Proposition 5.** *Assume that $G = (V, E)$ is a (m, d, γ)-spectral expander and*

$$2d + 4 > d^2 \left(2\gamma^2 + \frac{4(1-\gamma^2)}{m}\right).$$

Then for any two distinct vertices $u, v \in V$ it holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$.

In particular, all $(m^2, m, 1/\sqrt{m})$-spectral expanders satisfy these restrictions. However, Proposition 5 is by no means a necessary condition. For example, Theorem 2 can be also applied Lubotzky-Phillips-Sarnak construction of Ramanujan graphs ([8]). More specifically, if p, q are unequal primes, $p, q \equiv 1 \pmod 4$ and p is a quadratic residue modulo q, the paper [8] constructs an explicit graph $X^{p,q}$ which, in particular, is a $(q(q^2-1)/2, p+1, 2\sqrt{p}/(p+1))$-spectral expander and in which the shortest cycle is of length at least $2\log_p q$. It can also be easily shown that provided $p < q^2$ there are no self-loops in $X^{p,q}$. Thus if $p < \sqrt{q}$, then any two distinct vertices of $X^{p,q}$ have at most one common neighbor, while inequality from Proposition 5 is false for $X^{p,q}$.

We then obtain some results related to the following question: what is the best possible trade-off between the arity of outer functions and the size of gadget in deterministic simulation theorems? Once again, consider SQR^q. Note that in SQR^q each party receives $k = 2\log_2 q$ bits. Corollary 3 lower bounds $D^{cc}(f \circ \mathsf{SQR}^q)$ whenever arity of f is at most $2^{k/2-O(1)}$. In this regime the lower bound is of the form $\Omega(D^{dt}(f))$ (compare it to the $O(k \cdot D^{dt}(f))$ upper bound). In turn, if the arity of f is at most $2^{(1/2-\Omega(1))k}$, the lower bound becomes tight, namely $\Omega(k \cdot D^{dt}(f))$. Thus SQR^q achieves the same trade-off between the arity of f and the size of a gadget as k-bit Inner Product (while underlying hitting distributions for SQR^q, unlike Inner Product, are polynomial-time listable).

Ramanujan graphs yield gadgets with much worse trade-off. Namely, if p is of order $\sqrt{q}$ and c is a balanced coloring of $X^{p,q}$, then $g(X^{p,q}, c)$ is a gadget on $k \approx 3\log_2 q$ bits which admits a simulation theorem for all outer functions of arity roughly $2^{\log_2 p} = 2^{k/6}$.

This raises the following question: for a given k what is the maximal h such that there is a gadget on k bits having two $(\frac{1}{10}, h)$-hitting distributions, the one over 0-monochromatic rectangles and the other over 1-monochromatic rectangles? Above discussion shows that h can be about $k/2$. In the following Proposition we observe that it is impossible to obtain any constant bigger than $1/2$ before k.

▶ **Proposition 6.** *For every $g : \{0,1\}^k \times \{0,1\}^k \to \{0,1\}$ and for every integer $h \geq 1$ there exists $b \in \{0,1\}$ such that the following holds. For every probability distribution μ over b-monochromatic rectangles of g there are $X, Y \subset \{0,1\}^k$ of size at least 2^{k-h} such that*

$$\Pr_{R \sim \mu}[R \cap X \times Y \neq \varnothing] \leq 2^{k-2h+1}.$$

In addition we show the following simple proposition, studying the minimal possible support size of hitting distributions.

▶ **Proposition 7.** *For every $g : \{0,1\}^k \times \{0,1\}^k \to \{0,1\}$ the following holds*

- *if there is $\left(\frac{1}{20}, h\right)$-hitting distribution over b-monochromatic rectangles of g for some $b \in \{0,1\}$, then there is $\left(\frac{1}{10}, h\right)$-hitting distribution over b-monochromatic rectangles of g which support is of size $2^{O(k)}$.*
- *Assume that for some $\delta < 1$ and $h \in \mathbb{N}$ there are two (δ, h)-hitting distributions μ_0, μ_1, where μ_b is over b-monochromatic rectangles of g. Then the support of μ_b is of size at least 2^h, for every $b \in \{0,1\}$.*

So it is impossible to improve a trade-off between the size of outer functions and the size of gadgets simply by improving hitting distributions. However, until now we only spoke about improving gadgets. What about outer functions? What causes a restriction on the arity of f in Theorem 1? It can be verified that the only place in which arity of f appears in the proof is so-called Thickness Lemma. Let us state this Lemma.

Assume that A is a finite set and X is a subset of A^n. Here n corresponds to the arity of f. Let $X_{[n]/\{i\}}$ denote the projection of X onto all the coordinates except the i-th one. Define the following auxiliary bipartite graph $G_i(X)$. Left side vertices of $G_i(X)$ are taken from A, right side vertices of $G_i(X)$ are taken from $X_{[n]/\{i\}}$. We connect $a \in A$ with $(x_1, \dots, x_{i-1}, x_{i+1}, \dots x_n) \in X_{[n]/\{i\}}$ if and only if

$$(x_1, \dots, x_{i-1}, a, x_{i+1}, \dots x_n) \in X.$$

Clearly, there are $|X|$ edges in $G_i(X)$.

Let $MinDeg_i(X)$ denote the minimal possible degree of a right side vertex of $G_i(X)$. Similarly, let $AvgDeg_i(X)$ denote the average degree of a right side vertex of $G_i(X)$. There are $|X|$ edges and $|X_{[n]/\{i\}}|$ right side vertices, hence it is naturally to define $AvgDeg_i(X)$ as

$$AvgDeg_i(X) = \frac{|X|}{|X_{[n]/\{i\}}|}.$$

Thickness Lemma relates this two measures. Namely, it states that if for every i *average* degree of $G_i(X)$ is big, then there is a large subset $X' \subset X$ such that for every i *minimal* degree of $G_i(X')$ is big. The precise bounds can be found in the following

▶ **Lemma 8** ([9]). *Consider any $\delta \in (0,1)$. Assume that for every $i \in \{1, 2, \dots, n\}$ we have that $AvgDeg_i(X) \geq d$. Then there is $X' \subset X$ of size at least $(1-\delta)|X|$ such that for every $i \in [n]$ it holds that $MinDeg_i(X') \geq \frac{\delta d}{n}$.*

One possible way to improve a trade-off between the arity of f and the size of gadget is to improve Thickness Lemma. For example, if we could replace $\frac{\delta d}{n}$ with $\frac{\delta d}{\sqrt{n}}$ in Lemma 8 , this would mean that k-bit Inner Product and k-bit SQR-gadget admit simulation theorems for all outer functions of arity roughly 2^k (rather than $2^{k/2}$).

However, such an improvement is impossible and the bounds given in Lemma 8 are near-optimal. Note that Thickness Lemma says nothing about whether there even exists a *non-empty* subset $X' \subset X$ such that for all $i \in [n]$ it holds that $MinDeg_i(X')$ is larger, say, by a constant than $\frac{d}{n}$. And indeed, we show that for some X there is no such X' at all. More precisely, we show the following

▶ **Theorem 9.** *For every $\varepsilon > 0$ and for all integer $n \geq 2, s \geq 1$ there exists $m \in \mathbb{N}$ and a non-empty set $X \subset \{0, 1, \dots, m-1\}^n$ such that*

- *for all $i \in [n]$ it holds that $AvgDeg_i(X) \geq s(n-\varepsilon)$;*
- *there is no non-empty $Y \subset X$ such that for all $i \in [n]$ it holds that $MinDeg_i(Y) \geq s+1$.*

1.2 Organization of the paper

The rest of the paper is organized as follows.

In Section 2 we give Preliminaries. In Section 3 we prove Theorem 2 and derive Corollary 3. In Section 4 we prove Proposition 4. In Section 5 we prove Theorem 9. In Section 6 we prove Proposition 5. In section 7 we prove proposition 6. The proof of Proposition 7 is omitted due to space constraints.

2 Preliminaries

2.1 Sets notations

Let $[n]$ be the set $\{1, 2, \ldots, n\}$.

Assume that A is a finite set, X is a subset of A^n and $S = \{i_1, \ldots, i_k\}$, where $i_1 < i_2 < \ldots < i_k$, is a subset of $[n]$. Let X_S denote the following set:

$$X_S = \{(x_{i_1}, \ldots, x_{i_k}) : (x_1, \ldots, x_n) \in X\} \subset A^{|S|}.$$

Given $X \subset A^n$ and $i \in [n]$, consider the following bipartite graph $G_i(X) = (A, X_{[n]\setminus\{i\}}, E)$, where

$$E = \{(x_i, (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)) : (x_1, \ldots, x_n) \in X\}.$$

Vertices of $G_i(X)$ which are from A will be called left vertices. Similarly, vertices of $G_i(X)$ which are from $X_{[n]\setminus\{i\}}$ will be called right vertices.

Define $MinDeg_i(X)$ as minimal d such that there is a right vertex of $G_i(X)$ with degree d. Define $AvgDeg_i(X) = |X|/|X_{[n]\setminus\{i\}}|$.

2.2 Communication and query complexity

For introduction in both query and communication complexities see, e.g., [7]. We will use the following notation.

For a Boolean function $f : \{0,1\}^n \to \{0,1\}$ let $D^{dt}(f)$ denote f's deterministic query complexity, i.e. minimal d such that there is a deterministic decision tree of depth d computing f. For a (possibly partial) Boolean function $g : A \times B \to \{0,1\}$, where A, B are some finite sets, let $D^{cc}(g)$ denote g's deterministic communication complexity, i.e. minimal d such that there is a deterministic communication protocol of depth d, computing g. Let us stress that in the case when g is partial by "deterministic communication protocol computes g" we mean only that a protocol outputs 0 on (a, b) whenever $g(a, b) = 0$ and outputs 1 on (a, b) whenever $g(a, b) = 1$; on inputs on which g is not defined the protocol may output anything.

If f, g are as above, let $f \circ g$ denote the following (possibly partial) function:

$$f \circ g : A^n \times B^n \to \{0,1\},$$
$$(f \circ g)((a_1, \ldots, a_n), (b_1, \ldots, b_n)) = f(g(a_1, b_1), \ldots, g(a_n, b_n)).$$

We can also measure $D^{cc}(f \circ g)$, deterministic communication complexity of $f \circ g$, assuming that Alice's input is $(a_1, \ldots, a_n) \in A^n$ and Bob's input is $(b_1, \ldots, b_n) \in B^n$.

2.3 Hitting distributions

Fix a (possibly partial) Boolean function $g : A \times B \to \{0,1\}$. A set $R \subset A \times B$ is called *rectangle* if there are $U \subset A, V \subset B$ such that $R = U \times V$. If $b \in \{0,1\}$, then we say that rectangle R is b-monochromatic for g if $g(a, b) = b$ whenever $(a, b) \in R$. We stress that if g is partial, then in the definition of b-monochromatic rectangle we require that g is everywhere defined on R.

Let δ be positive real and h be positive integer. A probability distribution μ over rectangles $R \subset A \times B$ is called (δ, h)-hitting if for all $X \subset A, Y \subset B$ such that $|X| \geq 2^{-h}|A|, |Y| \geq 2^{-h}|B|$ it holds that

$$\Pr_{R \sim \mu}[R \cap X \times Y \neq \varnothing] \geq 1 - \delta.$$

In this paper we are focused only on those μ such that there exists $b \in \{0,1\}$ for which all rectangles from the support of μ are b-monochromatic for g. In this case we simply say that μ is over b-monochromatic rectangles of g.

Let $g_t : \{0,1\}^{k_t} \times \{0,1\}^{k_t} \to \{0,1\}$ be family of gadgets and μ_t be family of probability distributions, where μ_t is over rectangles of g_t. We call μ_t polynomial-time listable if the following holds:

- the size of the support of μ_t is $2^{O(k_t)}$;
- all the probabilities of μ_t are rational;
- there is a deterministic Turing machine which, having k_t on input, in time $2^{O(k_t)}$ computes g_t's matrix and lists all the rectangles from the support of μ_t, together with probabilities μ_t assigns to them.

2.4 SQR-gadget

Consider a finite field of size q, denoted below by $\mathbb{F}_q$. We call $a \in \mathbb{F}_q$ a *square* if there is $b \in \mathbb{F}_q$ such that $a = b^2$ in $\mathbb{F}_q$. Let SQR^q denote the following Booelan function:

$$\mathsf{SQR}^q : \mathbb{F}_{q^2} \times \mathbb{F}_{q^2} \to \{0,1\}, \qquad \mathsf{SQR}^q(a,b) = \begin{cases} 1 & \text{if } a-b \text{ is a square in } \mathbb{F}_{q^2}, \\ 0 & \text{if } a-b \text{ is not a square in } \mathbb{F}_{q^2}. \end{cases}$$

2.5 Expanders

We consider undirected graphs which may have parallel edges and self-loops. We assume that a self-loop at vertex v contributes 1 to degree of v. A graph is called d-regular if each its vertex has degree d.

A coloring of a graph $G = (V,E)$ is a function $c : V \to \{0,1\}$. It is called balanced if $|V|/3 \le |c^{-1}(1)| \le 2|V|/3$. For any $A \subset V$ let $\Gamma(A)$ denote the set of all $v \in V$ such that there is $u \in A$ connected with v by an edge of G. If $v \in V$, define $\Gamma(v) = \Gamma(\{v\})$.

Fix graph $G = (V,E)$ and a coloring $c : V \to \{0,1\}$. Assume that for any two distinct $u, v \in V$ it holds that $|\Gamma(u) \cap \Gamma(v)| \le 1$. Then the following partial function is well defined:

$$g(G,c) : V \times V \to \{0,1\},$$
$$g(G,c)(u,v) = \begin{cases} 1 & u \neq v \text{ and there is } w \in \Gamma(u) \cap \Gamma(v) \text{ s.t. } c(w) = 1, \\ 0 & u \neq v \text{ and there is } w \in \Gamma(u) \cap \Gamma(v) \text{ s.t. } c(w) = 0, \\ \text{undefined} & \text{otherwise.} \end{cases}$$

Let M_G be an adjacency matrix of a d-regular graph $G = (V,E)$ with $|V| = m$. Note that d is an eigenvalue of M_G. A graph G is called (m,d,γ)-spectral expander if M_G satisfies the following conditions:

- multiplicity of an eigenvalue d is 1;
- absolute value of any other eigenvalue of M_G is at most γd.

▶ **Proposition 10** ([11], Theorem 4.6). *Assume that a graph $G = (V,E)$ is (m,d,γ)-spectral expander. Then for any $A \subset V$:*

$$\frac{|\Gamma(A)|}{|A|} \ge \frac{1}{\gamma^2 + (1-\gamma^2)\frac{|A|}{m}}.$$

Assume the q is a power of prime. Let AP_q denote the following graph. Vertices of AP_q are pairs of elements of $\mathbb{F}_q$ so that the number of vertices is q^2. We connect (x, y) with (a, b) by an edge if and only if $ax = b + y$ in $\mathbb{F}_q$. It is easy to see that AP_q is q-regular.

▶ **Proposition 11** ([10], Lemma 5.1). *AP_q is $(q^2, q, 1/\sqrt{q})$-spectral expander.*

2.6 k-wise independent hash functions

We will need the following

▶ **Proposition 12** ([11], Corollary 3.34). *For every $n, k \in \mathbb{N}$ there exists a polynomial-time computable function $\psi : \{0,1\}^{kn} \times \{0,1\}^n \to \{0,1\}$ such for all distinct $x_1, \ldots, x_k \in \{0,1\}^n$ and for all $b_1, \ldots, b_k \in \{0,1\}$ the following holds:*

$$\Pr[\psi(s, x_1) = b_1, \ldots, \psi(s, x_k) = b_k] = 2^{-k},$$

where the probability is over uniformly random $s \in \{0,1\}^{kn}$.

2.7 Some useful facts

We will use the following inequality involving binomial coefficients:

▶ **Lemma 13.** *For every k, m the following holds: if $k \leq m/2$, then $\binom{m-k}{k}/\binom{m}{k} \geq 1 - \frac{k^2}{m-k}$.*

Proof. Observe that:

$$\frac{\binom{m-k}{k}}{\binom{m}{k}} = \frac{m-k}{m} \cdot \frac{m-k-1}{m-1} \cdot \ldots \cdot \frac{m-2k+1}{m-k+1} \geq \left(\frac{m-2k}{m-k}\right)^k$$
$$= \left(1 - \frac{k}{m-k}\right)^k \geq 1 - \frac{k^2}{m-k}.$$

The first inequality here is due to the fact that for all positive i we have:

$$\frac{k}{m-k+i} \leq \frac{k}{m-k} \implies 1 - \frac{k}{m-k+i} \geq 1 - \frac{k}{m-k}$$
$$\implies \frac{m-2k+i}{m-k+i} \geq \frac{m-2k}{m-k}.$$

The second inequality here is Bernoulli's inequality. It is legal to apply this inequality because $k \leq m/2$ and hence $\frac{k}{m-k} \leq 1$. ◀

Note that $\mathbb{F}_{q^2}$ contains a subfield of size q. Namely, $\mathbb{F}_q = \{x \in \mathbb{F}_{q^2} : x^q = x\}$.

▶ **Lemma 14.** *Assume that q is a power of an odd prime. Let α be a primitive root of $\mathbb{F}_{q^2}$. Then the following holds:*

- *$0, \alpha^2, \alpha^4, \ldots, \alpha^{q^2-1}$ are the only squares in $\mathbb{F}_{q^2}$;*
- *all the elements of $\mathbb{F}_q$ are squares in $\mathbb{F}_{q^2}$.*

Proof. Let us prove the first statement of the lemma. Assume that $j \in \{1, 2, \ldots, q^2 - 1\}$ is an odd integer. We will show that α^j is not a square. Indeed, assume for contradiction there is a non-zero $y \in \mathbb{F}_{q^2}$ such that $\alpha^j = y^2$. Therefore for some integer i we have that $\alpha^{j-2i} = 1$. Since α is the primitive root of $\mathbb{F}_{q^2}$, this means that $j - 2i$ is divisible by $q^2 - 1$. But $j - 2i$ is odd and $q^2 - 1$ is even.

To show the second statement of the lemma assume that $x = \alpha^k$ is a non-zero root of $x^q = x$. Then we have that $\alpha^{k(q-1)} = 1$. Due to the same argument as above $k(q-1)$ is divisible by $q^2 - 1$. This implies that k is divisible by $q + 1$. Hence k is even and $x = \alpha^k$ is a square. ◀

3 Transforming Expanders into Gadgets

In this section we prove Theorem 2 and derive Corollary 3.

Proof of Theorem 2. Fix $b \in \{0,1\}$ and set $h = \lfloor 2\log_2(1/\gamma) \rfloor - 100$. Let us define a $(\frac{1}{10}, h)$-hitting distribution μ_b over b-monochromatic rectangles of $g(G,c)$. Take $v \in c^{-1}(b)$ uniformly at random. Split $\Gamma(v)$ into two disjoints subsets A, B randomly according to 10-wise independent hash function $\psi : \{0,1\}^{10\cdot\lceil\log_2 m\rceil} \times \{0,1\}^{\lceil\log_2 m\rceil} \to \{0,1\}$ from Proposition 12. Namely, take $s \in \{0,1\}^{10\lceil\log_2 m\rceil}$ uniformly at random. An element $u \in \Gamma(v)$ goes into A if $\psi(s,u) = 0$ and into B if $\psi(s,u) = 1$. By definition $A \times B$ is a b-monochromatic rectangle of $g(G,c)$. Indeed, any two distinct vertices from $\Gamma(v)$ have a common neighbor colored in b. It remains to show that for all $S, T \subset V$ of size at least $2^{-h}m$ with probability at least 0.9 we have that $A \times B \cap S \times T \neq \varnothing$. It is enough to show that $\Pr[A \cap S \neq \varnothing] \geq 0.96$ and $\Pr[B \cap T \neq \varnothing] \geq 0.96$. Let us show that the first inequality holds, the proof of the second inequality is exactly the same. Actually we will show that $\Pr[|\Gamma(v) \cap S| \geq 10] \geq 0.97$. This is enough for our purposes: conditioned on $[|\Gamma(v) \cap S| \geq 10]$ the probability that A is disjoint with S is at most 2^{-10} (due to proposition 12 this is the probability that $\psi(s,\cdot)$ sends 10 fixed points of $\Gamma(v)$ into B). Therefore $\Pr[A \cap S] \geq (1 - 2^{-10}) \Pr[|\Gamma(v) \cap S| \geq 10] \geq 0.999 \cdot 0.97 > 0.96$.

The size of S is at least $2^{100}\gamma^2 m$. Partition S into 10 disjoint subsets $S_1, \ldots, S_{10}$, each of size at least $2000\lfloor\gamma^2 m\rfloor$. Since $m \geq 1/\gamma^2$, we also have $|S_1|, \ldots, |S_{10}| \geq 1000\gamma^2 m$. If $|\Gamma(v) \cap S| < 10$, then $\Gamma(v)$ is disjoint with S_i for some $i \in [10]$. Hence

$$\Pr[|\Gamma(v) \cap S| < 10] \leq \sum_{i=1}^{10} \Pr[\Gamma(v) \cap S_i = \varnothing].$$

If we show for all $i \in [10]$ that $\Pr[\Gamma(v) \cap S_i = \varnothing] \leq 0.003$, we are done. Observe that $\Gamma(v)$ is disjoint with S_i if and only if $v \notin \Gamma(S_i)$. This implies that

$$\Pr[\Gamma(v) \cap S_i = \varnothing] = \frac{|c^{-1}(b) \setminus \Gamma(S_i)|}{|c^{-1}(b)|} \leq \frac{m - |\Gamma(S_i)|}{\frac{m}{3}}. \tag{2}$$

In the last inequality we use the fact that c is balanced. By Proposition 10 we get

$$|\Gamma(S_i)| \geq \frac{|S_i|}{\gamma^2 + \frac{|S_i|}{m}} \geq \frac{|S_i|}{\frac{|S_i|}{1000 \cdot m} + \frac{|S_i|}{m}} \geq \frac{1000 \cdot m}{1001} > 0.999m.$$

Here in the second inequality we use the fact that $|S_i| \geq 1000\gamma^2 m$. Due to (2) this means that $\Pr[\Gamma(v) \cap S_i = \varnothing] \leq 0.003$ and thus the proof that μ_b is $\left(\frac{1}{10}, h\right)$-hitting is finished.

Let us now show that μ_b can be "written down" in time $m^{O(1)}$ from G and c. First of all, note that $g(G,c)$ is a gadget on $k = \lceil\log_2 m\rceil$ bits. To specify a rectangle from a support of μ_b we need to specify a vertex of G and a "seed" s of length $10k$. This shows that the support of μ_b is of size $m^{O(1)} = 2^{O(k)}$. This observation also allows us to list all the rectangles from the support of μ_b in time $2^{O(k)}$ – just go through all vertices from $c^{-1}(b)$ and all seeds. Further, the μ_b-probability of $A \times B$ can be computed as follows:

$$\mu_b(A \times B) = \frac{|\{v \in V : \Gamma(v) = A \cup B\}|}{|c^{-1}(b)|} \cdot \frac{\left|\{s \in \{0,1\}^{10k} : \phi(s,\cdot) \text{ splits } A \cup B \text{ into } A \text{ and } B\}\right|}{2^{10k}}.$$

This probability is rational and can be computed in time $2^{O(k)}$, again by exhaustive search over all vertices and seeds. ◀

Now let us derive Corollary 3. Indeed, AP_q is $(q^2, q, 1/\sqrt{q})$-spectral expander by Proposition 11. Thus theorem 2, applied to AP_q, states that for any balanced coloring c of AP_q and for any $b \in \{0,1\}$ there exists $\left(\frac{1}{10}, \lfloor \log_2(q) \rfloor - 100\right)$-hitting distribution over b-monochromatic rectangles of $g(AP_q, c)$. Apply Theorem 1 to these hitting distributions with $\varepsilon = 1 - \log_2(n)/(\lfloor \log_2(q) \rfloor - 100)$.

We only need to check that in AP_q for any two distinct vertices u, v is holds that $|\Gamma(u) \cap \Gamma(v)| \leq 1$. Assume that (x, y) and (u, v) are distinct vertices of AP_q. Take any $(a, b) \in \Gamma((x, y)) \cap \Gamma((u, v))$. Then

$$\begin{pmatrix} x & -1 \\ u & -1 \end{pmatrix} \cdot \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} y \\ v \end{pmatrix}. \tag{3}$$

If $x \neq u$, then $\det \begin{pmatrix} x & -1 \\ u & -1 \end{pmatrix} \neq 0$ and hence system (3) has exactly one solution. If $x = u$, then $y \neq v$ and system (3) has no solution. Therefore $|\Gamma((x, y)) \cap \Gamma((u, v))| \leq 1$.

4 SQR^q Gadget

In this section we prove Proposition 4.

Fix $w \in \mathbb{F}_{q^2}$ such that $\{1, w\}$ is a basis of $\mathbb{F}_{q^2}$ over $\mathbb{F}_q$. Consider the following coloring of AP_q: set $c((a, b)) = 1$ if and only if $1 + wa$ is a square in $\mathbb{F}_{q^2}$; clearly a truth table of such c can be computed in time $q^{O(1)}$. Note that $g(AP_q, c)((x, y), (u, v))$ is defined if and only if $(x, y), (u, v)$ are distinct and there is $(a, b) \in \Gamma((x, y)) \cap \Gamma((u, v))$. Let us show that for any such $(x, y), (u, v)$ it holds that

$$g(AP_q, c)((x, y), (u, v)) = c((a, b)) = \mathsf{SQR}^q(x + yw, u + vw). \tag{4}$$

Indeed, we have that $ax = b + y, au = b + v$. This means that $y - v = a(x - u)$. Moreover, due to distinctness of $(x, y), (u, v)$ we have that $x \neq u$. Further,

$$x + yw - (u + vw) = (x - u) + w(y - v) = (x - u)(1 + wa).$$

Note that $x - u$ is a non-zero element of $\mathbb{F}_q$. By the second item of Lemma 14 this implies that $x + yw - (u + vw)$ is a square if and only if $1 + wa$ is a square. Hence (4) is true for all $(x, y), (u, v)$ from the domain of $g(AP_q, c)$.

It remains to show that c is balanced. Take $(a, b, \lambda) \in \mathbb{F}_q \times \mathbb{F}_q \times (\mathbb{F}_q \setminus \{0\})$ uniformly at random. Note that $c((a, b)) = 1$ if and only if $1 + wa$ is a square. Thus $|c^{-1}(1)| = q^2 \Pr[1 + wa \text{ is a square}]$. Due to the second item of Lemma 14 we have that $1 + wa$ is a square if and only if $\lambda(1 + wa)$ is a square. Note that $\lambda(1 + wa) = \lambda + \lambda aw$ is distributed uniformly in $\{i + wj : i, j \in \mathbb{F}_q, i \neq 0\}$ (this is because for any λ_0 the distribution of λa given $\lambda = \lambda_0$ is uniform in $\mathbb{F}_q$). Due to the first item of Lemma 14 for all large enough q there are at least $0.4q^2$ squares and at least $0.4q^2$ non-squares in $\{i + wj : i, j \in \mathbb{F}_q, i \neq 0\}$. This means that $1/3 \leq \Pr[\lambda(1 + wa) \text{ is a square}] \leq 2/3$ for all large enough q. Hence $q^2/3 \leq |c^{-1}(1)| \leq 2q^2/3$ and c is balanced.

5 Unimprovability of Thickness Lemma

Consider any set $X \subset \{0, 1, \ldots, m-1\}^n$ and take any $i \in [n]$. Let us say that $x \in X$ is *i-unique in X* if there is no other $x' \in X$ such that

$$x_1 = x'_1, \ldots, x_{i-1} = x'_{i-1}, x_{i+1} = x'_{i+1}, \ldots, x_n = x'_n.$$

Call a set $X \subset \{0,1,\dots,m-1\}^n$ *reducible* if for all non-empty $Y \subset X$ there is $i \in [n]$ such that $MinDeg_i(Y) = 1$. Note that X is reducible if and only if for all non-empty $Y \subset X$ there is $y \in Y$ which is i-unique in Y for some $i \in [n]$.

▶ **Lemma 15.** *For every $\varepsilon > 0$ and for every $n \geq 2$ there exists $m > 0$ and a reducible set $X \subset \{0,1,\dots,m-1\}^n$ such that for all $i \in [n]$ it holds that $AvgDeg_i(X) \geq n - \varepsilon$.*

Proof. Take any $m > 0$. Consider the following sequence of sets $X_2, X_3, \dots$, where X_n is a subset of $\{0,1,\dots,m-1\}^n$:

$$X_2 = \{(j,j) : j \in \{0,1,\dots,m-1\}\} \cup \{(j,j+1) : j \in \{0,1,\dots,m-2\}\},$$

$$X_{\ell+1} = \{(x,j) : x \in X_\ell,\ j \in \{0,1,\dots,m-1\}\} \\ \cup \left\{(y,0) : y \in \{0,1,\dots,m-1\}^\ell / X_\ell\right\}.$$

We have the following relation between the size of $X_{\ell+1}$ and the size of X_ℓ:

$$|X_{\ell+1}| = m \cdot |X_\ell| + m^\ell - |X_\ell| = m \cdot (|X_\ell| - 1) + m^\ell.$$

Let us show by induction on n that $|X_n| \geq nm^{n-1} - n(1 + m + \ldots + m^{n-2})$. Indeed, for $n = 2$ this inequality is true: $|X_2| = 2m - 1 > 2m - 2$. Now, assume that for $n = \ell$ this inequality is proved, i.e. $|X_\ell| \geq \ell m^\ell - \ell(1 + m + \ldots + m^{\ell-2})$. Then

$$\begin{aligned} |X_{\ell+1}| &= m \cdot (|X_\ell| - 1) + m^\ell \\ &\geq m \cdot \left(\ell m^{\ell-1} - \ell(1 + m + \ldots + m^{\ell-2}) - 1\right) + m^\ell \\ &\geq (\ell+1) \cdot m^\ell - (\ell+1) \cdot (1 + m + \ldots + m^{\ell-1}). \end{aligned}$$

This means that for every n and $i \in [n]$ it holds that

$$AvgDeg_i(X_n) = \frac{|X_n|}{|(X_n)_{[n]/\{i\}}|} \geq \frac{nm^{n-1} - n(1 + m + \ldots + m^{n-2})}{m^{n-1}},$$

and the latter tends to n as $m \to \infty$. Thus to show the lemma it is sufficient to show that X_n is reducible. Once again, we will show it by induction on n.

Consider $n = 2$ and take any non-empty $Y \subset X_2$. Let $y \in Y$ be the smallest element of Y in lexicographical order. If $y = (j,j)$, then y is 1-unique in Y and hence $MinDeg_1(Y) = 1$. If $y = (j,j+1)$, then y is 2-unique in Y and hence $MinDeg_2(Y) = 1$.

Further, assume that for $n = \ell$ the statement is proved, i.e. X_ℓ is reducible. Consider any non-empty $Y \subset X_{\ell+1}$. Assume that Y intersects $\left\{(y,0) : y \in \{0,1,\dots,m-1\}^\ell / X_\ell\right\}$ and hence for some $y \notin X_\ell$ it holds that $(y,0) \in Y$. Then $MinDeg_{\ell+1}(Y) = 1$. Indeed, in this case $(y,0)$ is $(\ell+1)$-unique in Y, because if $(y,j) \in Y \subset X_{\ell+1}$ for some $j > 0$, then $y \in X_\ell$, contradiction.

Now assume that Y is a subset of $\{(x,j) : x \in X_\ell,\ j \in \{0,1,\dots,m-1\}\}$. Then for some $j \in \{0,1,\dots,m-1\}$ a set $Y' = \{x \in X_\ell : (x,j) \in Y\}$ is non-empty. Since by induction hypothesis X_ℓ is reducible, there is $y \in Y'$ which is i-unique in Y' for some $i \in [\ell]$. Let us show that (y,j) is i-unique in Y (this would mean that $MinDeg_i(Y) = 1$). Indeed, assume that there is $(y',j') \in Y$ which coincides with (y,j) on all the coordinates except the i^{th} one. Then $j = j'$ and $y' \in Y'$. Due to i-uniqueness of $y \in Y'$ we also have that $y = y'$. ◀

▶ **Definition 16.** Let s, m, n be positive integers and assume that X is a subset of $\{0,1,\dots,m-1\}^n$. Let $In(X,s) \subset \{0,1,\dots,sm-1\}^n$ denote the following set:

$$In(X,s) = \{(sx_1 + r_1, sx_2 + r_2, \dots, sx_n + r_n) : \\ (x_1,\dots,x_n) \in X,\ r_1,\dots,r_n \in \{0,1,\dots,s-1\}\}.$$

Observe that for every $(y_1, \ldots, y_n) \in In(X, s)$ there is exactly one $(x_1, \ldots, x_n) \in X$ such that for some $r_1, \ldots, r_n \in \{0, 1, \ldots, s-1\}$ it holds that

$$y_1 = sx_1 + r_1, \ldots, y_n = sx_n + r_n.$$

▶ **Lemma 17.** *For every $i \in \{1, 2, \ldots, n\}$ it holds that $AvgDeg_i(In(X, s)) = s \cdot AvgDeg_i(X)$.*

Proof. Lemma follows from the following two equalities:

$$|In(X, s)| = s^n \cdot |X|, \qquad |In(X, s)_{[n]/\{i\}}| = s^{n-1} \cdot |X_{[n]/\{i\}}|.$$ ◀

▶ **Lemma 18.** *Assume that $X \subset \{0, 1, \ldots, m-1\}^n$ is reducible. Then for all non-empty $Y \subset In(X, s)$ there is $i \in [n]$ such that $MinDeg_i(Y) \leq s$.*

Proof. Let Y' be the set of all $(x_1, \ldots, x_n) \in X$ for which there are

$$r_1, \ldots, r_n \in \{0, 1, \ldots, s-1\}$$

such that $(sx_1 + r_1, \ldots, sx_n + r_n) \in Y$. Clearly Y' is non-empty. Let $x' = (x'_1, \ldots, x'_n) \in Y'$ be a string which is i-unique in Y'. Let us show that $MinDeg_i(Y) \leq s$. By definition there are $r_1, \ldots, r_n \in \{0, 1, \ldots, s-1\}$ such that $(y'_1, \ldots, y'_n) = (sx'_1 + r_1, \ldots, sx'_n + r_n) \in Y$. It is easy to see that $(y'_1, \ldots, y'_{i-1}, y'_{i+1}, \ldots, y'_n) \in Y_{[n]/\{i\}}$ is connected with at most s left vertices of $G_i(Y)$. More precisely, the only possible neighbors of $(y'_1, \ldots, y'_{i-1}, y'_{i+1}, \ldots, y'_n)$ are

$$sx'_i, sx'_i + 1, \ldots, sx'_i + s - 1.$$

Indeed, otherwise there is $x_i \neq x'_i$ such that $(x'_1, \ldots, x'_{i-1}, x_i, x'_{i+1}, \ldots, x'_n) \in Y$. The latter contradicts the fact that x' is i-unique in Y. ◀

Proof of Theorem 9. Due to Lemma 15 there is a reducible $X' \subset \{0, 1, \ldots, m-1\}^n$ such that for every $i \in [n]$ we have $AvgDeg_i(X') \geq n - \varepsilon$. By Lemma 17, applied to $X = In(X', s)$ for every $i \in [n]$ we have: $AvgDeg_i(X) \geq s(n - \varepsilon)$. Finally, due to Lemma 18, for all non-empty $Y \subset X$ there is $i \in [n]$ such that $MinDeg_i(Y) \leq s$. ◀

6 Expanders Similar to AP_q

In this section we prove Proposition 5. Let us stress that this Proposition is just a slight improvement of Proposition 10 for sets of size 2. Proposition 10 itself is not strong enough to conclude that in all $(m^2, m, 1/\sqrt{m})$-spectral expanders any two distinct vertices have at most 1 common neighbor.

For $S \subset V$ let $\mathbb{I}_S \in \mathbb{R}^{|V|}$ denote characteristic vector of a set S. Assume for contradiction that there are distinct $u, v \in V$ such that $|\Gamma(u) \cap \Gamma(v)| \geq 2$. Then the size of $\Gamma(\{u, v\})$ is at most $2d - 2$. Assume that M is the adjacency matrix of G. Denote $w = \{u, v\}$. Let us show that

$$\|M\mathbb{I}_w\|^2 \leq d^2 \left(2\gamma^2 + \frac{4(1-\gamma^2)}{m}\right). \tag{5}$$

Indeed, observe that $\mathbb{I}_w = \frac{2}{m}\mathbb{I}_V + (\mathbb{I}_w - \frac{2}{m}\mathbb{I}_V)$ and $(\mathbb{I}_w - \frac{2}{m}\mathbb{I}_V)$ is perpendicular to $\mathbb{I}_V$. Since

G is a (m, d, γ)-spectral expander, this implies that

$$\begin{aligned}\|M\mathbb{I}_w\|^2 &= \|M\left(\frac{2}{m}\mathbb{I}_w\right)\|^2 + \|M\left(\mathbb{I}_w - \frac{2}{m}\mathbb{I}_V\right)\|^2 \leq \frac{4d^2}{m} + \gamma^2 d^2 \|\left(\mathbb{I}_w - \frac{2}{m}\mathbb{I}_V\right)\|^2 \\ &= \frac{4d^2}{m} + \gamma^2 d^2\left(2\left(1-\frac{2}{m}\right)^2 + (m-2)\frac{4}{m^2}\right) \\ &= \frac{4d^2}{m} + \gamma^2 d^2\left(2 - \frac{4}{m}\right) = d^2\left(2\gamma^2 + \frac{4(1-\gamma^2)}{m}\right),\end{aligned}$$

and thus (5) is proved.

To obtain a contradiction it is enough to show the following inequality

$$\|M\mathbb{I}_w\|^2 \geq 2d + 4. \tag{6}$$

Assume that there are $t \leq 2d-2$ non-zero coordinates in $M\mathbb{I}_w$. Let $\xi_1, \ldots, \xi_t$ be the values of these coordinates. Their sum is $2d$. We need to show that $\xi_1^2 + \ldots + \xi_t^2 \geq 2d+4$. Observe that $\xi_1 - 1, \ldots, \xi_t - 1$ are non-negative integers and their sum is $2d - t \geq 2$. Clearly this implies that $(\xi_1-1)^2 + \ldots + (\xi_t - 1)^2 \geq 2$. Indeed, otherwise the sum of $\xi_1 - 1, \ldots, \xi_t - 1$ is either 0 or 1. Hence

$$\xi_1^2 + \ldots + \xi_t^2 = (\xi_1 - 1)^2 + \ldots + (\xi_t - 1)^2 + 4d - t \geq 2 + 4d - t \geq 2d + 4.$$

7 Proof of Proposition 6

Denote $s = 2^{k-h}$. Assume that there is a 0-monochromatic rectangle $A \times B$ of g such that $|A| \geq s$ and $B \geq s$. Then clearly the proposition is true for $b = 1$ and $X = A, Y = B$.

Now assume that if $A \times B$ is a 0-monochromatic rectangle of g, then either $|A| < s$ or $B < s$. Take $\mathcal{X}, \mathcal{Y}$ independently and uniformly at random from the set of all s-element subsets of $\{0,1\}^k$. Fix any 0-monochromatic rectangle $A \times B$ of g. Let us show that $\mathcal{X} \times \mathcal{Y}$ intersects $A \times B$ with probability at most 2^{k-2h+1}. Indeed, assume WLOG that $|A| < s$. Then

$$\Pr[\mathcal{X} \times \mathcal{Y} \cap A \times B \neq \varnothing] \leq \Pr[\mathcal{X} \cap A \neq \varnothing] = 1 - \frac{\binom{2^k - |A|}{s}}{\binom{2^k}{s}} \leq 1 - \frac{\binom{2^k - s}{s}}{\binom{2^k}{s}}$$

Since $h \geq 1$, we have that $s \leq 2^k/2$. Applying Lemma 13 we obtain:

$$\Pr[\mathcal{X} \times \mathcal{Y} \cap A \times B \neq \varnothing] \leq \frac{s^2}{2^k - s} \leq \frac{s^2}{2^k/2} = 2^{k-2h+1}.$$

Due to the standard averaging argument this means that for any probability distribution μ over 0-monochromatic rectangles of g it is possible to fix $\mathcal{X} = X, \mathcal{Y} = Y$ in such a way that

$$\Pr_{R \sim \mu}[R \cap X \times Y \neq \varnothing] \leq 2^{k-2h+1}.$$

Balance Problems for Integer Circuits

Titus Dose
Institute of Computer Science, Julius-Maximilians Universität Würzburg, Germany
titus.dose@uni-wuerzburg.de

Abstract

We investigate the computational complexity of *balance problems* for $\{-, \cdot\}$-circuits computing finite sets of natural numbers. These problems naturally build on problems for integer expressions and integer circuits studied by Stockmeyer and Meyer (1973), McKenzie and Wagner (2007), and Glaßer et al. (2010).

Our work shows that the balance problem for $\{-, \cdot\}$-circuits is undecidable which is the first natural problem for integer circuits or related constraint satisfaction problems that admits only one arithmetic operation and is proven to be undecidable.

Starting from this result we precisely characterize the complexity of balance problems for proper subsets of $\{-, \cdot\}$. These problems turn out to be complete for one of the classes L, NL, and NP.

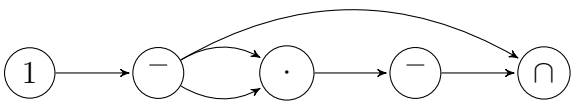
1 Introduction

In 1973, Stockmeyer and Meyer [18] defined and studied membership and equivalence problems for *integer expressions*. They considered expressions built up from single natural numbers by using set operations ($\cup$, $\cap$, $\overline{\ }$), pairwise addition ($+$), and pairwise multiplication ($\cdot$). For example, $\overline{\overline{1} \cdot \overline{1}} \cap \overline{1}$ describes the set of primes $\mathbb{P}$.

The *membership problem for integer expressions* asks whether some given number is contained in the set described by a given integer expression, whereas the *equivalence problem for integer expressions* asks whether two given integer expression describe the same set. Restricting the set of allowed operations results in problems of different complexities.

Wagner [20] studied a more succinct way to represent such expressions, namely *circuits over sets of natural numbers*, also called integer circuits. Each input gate of such a circuit is labeled with a natural number, the inner gates compute set operations and arithmetic operations ($\cup$, $\cap$, $\overline{\ }$, $+$, $\cdot$). The following circuit with only 4 inner gates computes the set of primes.



Starting from this circuit, one can use integer circuits to express fundamental number theoretic questions: thus, a circuit describing the set of all twin primes or the set of all

Sophie Germain primes can be constructed. McKenzie and Wagner [15] constructed a circuit C computing a set that contains 0 if and only if the Goldbach conjecture holds.

Wagner [20], Yang [21], and McKenzie and Wagner [15] investigated the complexity of membership problems for circuits over natural numbers: here, for a given circuit C, one has to decide whether a given number n belongs to the set described by C. Travers [19] and Breunig [2] considered membership problems for circuits over integers and positive integers, respectively. Glaßer et al. [9] studied *equivalence problems for circuits over sets of natural numbers*, i.e., the problem of deciding whether two given circuits compute the same set.

Satisfiability problems for circuits over sets of natural numbers, investigated by Glaßer et al. [11], are a generalization of the membership problems investigated by McKenzie and Wagner [15]: the circuits can have *unassigned input gates* and the question is: on input of a circuit C with gate labels from $\mathcal{O} \subseteq \{\cup, \cap, \bar{}, +, \cdot\}$ and a natural number b, does there exist an assignment of the unassigned input gates with natural numbers such that b is contained in the set described by the circuit?

Barth et al. [1] investigated emptiness problems for integer circuits. Here, for both circuits with unassigned inputs and circuits without unassigned inputs, the question of whether an integer circuit computes the empty set (for some/all assignment(s) if the circuits allow unassigned inputs) is raised and investigated.

Apart from the mentioned research on circuit problems there has been work on related variants like functions computed by circuits [17] and constraint satisfaction problems (csp) over natural numbers [10, 5]. The constraint satisfaction problems by Glaßer, Jonsson, and Martin [10] can be considered as conjunctions of equations of integer expressions with variables standing for singleton sets of natural numbers. Here the question is whether there is an assignment of the variables such that all equations are satisfied. These constraint satisfaction problems have the peculiarity that expressions describe sets of integers whereas variables can only store singleton sets of natural numbers. Dose [5] addressed this and studied constraint satisfaction problems over finite subsets of $\mathbb{N}$, consequently replaced the set complement $\bar{}$ with the set difference $-$, and allowed the variables to describe arbitrary finite subsets of $\mathbb{N}$.

Our Model and Contributions

The definition of the circuits investigated in this paper follows the definition of previous papers such as [15, 9, 11, 1]. Yet there are some differences:

Our circuit problems are about *balanced sets* where a finite and non-empty set $S \subseteq \mathbb{N}$ is balanced if $|S| = |\{0, 1, \ldots, \max(S)\} - S|$. Analogously, S is unbalanced if $|S| \neq |\{0, 1, \ldots, \max(S)\} - S|$. That means, the maximum of a set marks the relevant area and then we ask whether there are as many elements inside the set as outside of it. As the notion of balanced sets only makes sense for finite sets, our circuits should solely compute finite sets. Due to that we replace the commonly used set complement $\bar{}$ with the set difference $-$. Now, as the circuits only work over the domain of finite subsets of $\mathbb{N}$, it suggests itself to also allow the input gates of a circuit to compute arbitrary finite subsets of $\mathbb{N}$ and not only singleton sets (cf. Dose [5] where the analogous step was made for constraint satisfaction problems).

For such circuits we ask: is there an assignment of the unassigned inputs with arbitrary finite subsets of $\mathbb{N}$ under which the circuit computes a balanced set? This problem is denoted by $\mathrm{BC}(\mathcal{O})$, where $\mathcal{O} \subseteq \{\cup, \cap, -, +, \cdot\}$ is the set of allowed operations.

The notion of balance is important in computational complexity. It occurs when considering counting classes [12] like $\mathrm{C_{=}L}$ or $\mathrm{C_{=}P}$ for instance. There, the question is whether for some problem A there is a non-deterministic logarithmic space or polynomial-time machine

M accepting A, where M accepts some input x if and only if the number of accepting paths equals the number of rejecting paths.

Balance problems for integer circuits are interesting for another reason. To our knowledge, there is no natural decision problem for integer circuits or constraint satisfaction problems over sets of natural numbers that allows only one arithmetic operation and is known to be undecidable. In this paper, however, it is shown that $\mathrm{BC}(-,\cdot)$ is undecidable.

Starting from this undecidable problem $\mathrm{BC}(-,\cdot)$, we also investigate $\mathrm{BC}(\mathcal{O})$ for arbitrary proper subsets of $\{-,\cdot\}$ and precisely characterize the complexity of each such problem. It turns out that all these problems are in NP. In detail, we show that $\mathrm{BC}(\cdot)$ is NL-complete, $\mathrm{BC}(-)$ is NP-complete, and $\mathrm{BC}(\emptyset) \in \mathrm{L}$.

2 Preliminaries

Basic Notions

Let $\mathbb{N}$ denote the set of natural numbers. $\mathbb{N}^+ = \mathbb{N} - \{0\}$ is the set of positive naturals. Moreover, the set of primes is denoted by $\mathbb{P}$.

We extend the arithmetical operations $+$ and $\cdot$ to sets of naturals: for $A, B \subseteq \mathbb{N}$ define $A + B = \{a + b \mid a \in A, b \in B\}$ and $A \cdot B = \{a \cdot b \mid a \in A, b \in B\}$. In contrast to previous papers, in this paper the multiplication of sets is not denoted by $\times$ but by $\cdot$. Instead, $\times$ denotes the cartesian product. Furthermore, for arbitrary sets, the operations $\cup$, $\cap$, and $-$ define the union, intersection, and set difference, respectively. The power set of a set M is denoted by $\mathcal{P}(M)$ whereas $\mathcal{P}_{\mathrm{fin}}(M) = \{A \in \mathcal{P}(M) \mid A \text{ finite}\}$. For a finite and non-empty set S let $\max(S)$ (resp., $\min(S)$) denote the maximum (resp., minimum) number of S. Finite intervals $\{x \mid a \leq x \leq b\}$ for $a, b \in \mathbb{Z}$ are denoted by $[a, b]$.

L, NL, and NP denote standard complexity classes [16] and RE is the set of computably enumerable problems.

For problems A and B we say that A is (logarithmic-space) many-one reducible to B if there is some (logarithmic-space) computable function f with $c_A(x) = c_B(f(x))$, where c_X for a set X is the characteristic function of X. We denote this by $A \leq_{\mathrm{m}} B$ (resp., $A \leq_{\mathrm{m}}^{\log} B$).

For pairs (A, B) and (C, D) with $A \cap B = C \cap D = \emptyset$ we say that (A, B) is many-one reducible to (C, D) (denoted as $(A, B) \leq_{\mathrm{m}} (C, D)$) if there is a computable function f with $x \in A \Rightarrow f(x) \in C$ and $x \in B \Rightarrow f(x) \in D$. Note that if $B = \overline{A}$ and $D = \overline{C}$ this coincides with the usual many-one reducibility, i.e., $(A, \overline{A}) \leq_{\mathrm{m}} (C, \overline{C}) \Leftrightarrow A \leq_{\mathrm{m}} C$.

CSAT is the circuit satisfiability problem, i.e., the problem of determining whether a given Boolean circuit has an assignment of the unassigned inputs that makes the output gate true. The problem is $\leq_{\mathrm{m}}^{\log}$-complete for NP via a trivial reduction from SAT which itself can be shown to be $\leq_{\mathrm{m}}^{\log}$-complete for NP via a construction by Cook [3].

Balanced Sets

A finite and non-empty set $S \subseteq \mathbb{N}$ is *balanced* (resp., *unbalanced*) if $|S| = |\{0, 1, \ldots, \max(S)\} - S|$ (resp., $|S| \neq |\{0, 1, \ldots, \max(S)\} - S|$). Intuitively spoken, $\max(S)$ defines the universe $\{0, 1, \ldots, \max(S)\}$ and then S is balanced if it contains the same number of elements as its complement. Note that the notion of balance/unbalance only makes sense if there is some maximum element defining the universe. Hence the empty set is neither balanced nor unbalanced.

The following lemma immediately follows from the definition.

▶ **Lemma 1.** *Let $S \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ be balanced. Then $S \neq \emptyset$ and $\max(S)$ is odd.*

Moreover, we say that S is *subbalanced* if $|S| < (\max(S)+1)/2$ which is equivalent to $|S| \leq \max(S)/2$. As we want to investigate the complexity of balance problems with respect to deterministic logarithmic-space reductions, it is important to see that the test of whether some input set is balanced can be done in deterministic logarithmic space. Define $\mathrm{Bal} = \{S \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N}) \mid S \text{ is balanced}\}$ and the slightly more general problem $\mathrm{Bal}_M = \{S \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N}) \mid M \cdot S \text{ is balanced}\}$ for a non-empty and finite set M. Standard arguments yield the following proposition.

▶ **Proposition 2.** $\mathrm{Bal}_M \in \mathrm{L}$. *In particular,* $\mathrm{Bal} \in \mathrm{L}$.

Circuits and Balance Problems for Circuits

In previous papers such as [1] it was differentiated between completely and partially assigned circuits. As we restrict on partially assigned circuits in this paper, we define circuits in general as partially assigned circuits.

A *circuit* C is a triple (V, E, g_C) where (V, E) is a finite, non-empty, directed, acyclic graph with a designated vertex $g_C \in V$ and a topologically ordered vertex set $V \subseteq \mathbb{N}$, i.e., if $u, v \in V$ are vertices with $u < v$, then there is no edge from v to u. Here, graphs may contain multi-edges and are not necessarily connected. But we require that C is topologically ordered. Note that the test of whether a graph is topologically ordered or not is possible in deterministic logarithmic space. Consequently, we are able to check in deterministic logarithmic space whether an input graph is acyclic. Hence there is a deterministic logarithmic-space algorithm that on input of a graph tests whether the input is a circuit. Therefore, when presenting algorithms for circuits we may always assume that the input is a valid circuit.

Let $\mathcal{O} \subseteq \{\cup, \cap, -, +, \cdot\}$. An *$\mathcal{O}$-circuit* (or *circuit* for short if $\mathcal{O}$ is apparent from the context) is a quintuple $C = (V, E, g_C, \alpha, \beta)$ where (V, E, g_C) is a circuit whose nodes are labeled by the *labeling function* $\alpha : V \to \mathcal{O} \cup \mathcal{P}_{\mathrm{fin}}(\mathbb{N}) \cup \{\square\}$ such that each node has indegree 0 or 2, nodes with indegree 0 have a label from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ (encoded as a list of all the numbers in the set) or from $\{\square\}$, and nodes with indegree 2 have labels from $\mathcal{O}$. Moreover, β is a function $E \to \{\mathrm{l}, \mathrm{r}\}$ and we require that for each node u with predecessors u_1 and u_2 it holds $\{\beta(u_1), \beta(u_2)\} = \{\mathrm{l}, \mathrm{r}\}$. Thus, β marks whether an edge starts in the left or right predecessor of the node it points to.

In the context of circuits, nodes are also called gates. A gate with indegree 0 is called *input gate*, all other nodes are *inner gates*, the designated gate g_C is also called *output gate*. Input gates with a label from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ are *assigned input gates* whereas input gates with label $\square$ are *unassigned input gates*.

$\mathcal{O}$-circuits are also called *integer circuits*. If g is some gate of C with $\alpha(g) = \otimes \in \mathcal{O}$ and with predecessors g' and g'' satisfying $\beta(g') = \mathrm{l}$ and $\beta(g'') = \mathrm{r}$, then we also write $g = g' \otimes g''$.

For an $\mathcal{O}$-circuit C with unassigned input gates $g_1 < \cdots < g_n$ and $X_1, \ldots, X_n \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$, let $C(X_1, \ldots, X_n)$ be the circuit that arises from C by modifying the labeling function α such that $\alpha(g_i) = X_i$ for every $1 \leq i \leq n$.

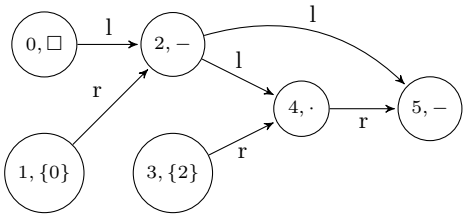
For a circuit $C = (V, E, g_C, \alpha)$ without unassigned input gates we inductively define the set $I(g; C)$ computed by a gate $g \in V$ for $g = 1, \ldots, |V|$ by

$$I(g; C) = \begin{cases} \alpha(g) \subseteq \mathbb{N} & \text{if } g \text{ has indegree 0,} \\ I(g', C) \otimes I(g'', C) & \text{if } g = g' \otimes g''. \end{cases}$$

The set computed by the circuit is denoted by $I(C)$ and defined to be the set computed by the output gate $I(g_C; C)$.

It is convenient to introduce notations for basic constructions of circuits. For $X \in \mathcal{P}_{\text{fin}}(\mathbb{N})$ we use X as an abbreviation for the circuit $(\{1\}, \varnothing, \{1\}, 1 \mapsto X)$. For $\mathcal{O}$-circuits C, C' for some $\mathcal{O}$ and $\otimes \in \{\cup, \cap, , -+, \cdot\}$ let $C \otimes C'$ be the circuit obtained from C' and C'' by feeding their output gates to the new output gate $\otimes$. This is possible in logarithmic space.

As an example, for an unassigned input gate $g = 0$, consider the circuit $C = (g - \{0\}) - ((g - \{0\}) \cdot \{2\})$, which is the following circuit



where each node is given by its number and its label. The node 5 is the output gate and it computes the set $\{1\}$ if and only if $I(2; C)$ is a set of the form $\{2^0, 2^1, 2^2, \ldots, 2^r\}$ for $r \in \mathbb{N}$.

Now we define the problems this paper focuses on.

▶ **Definition 3.** Let $\mathcal{O} \subseteq \{-, \cup, \cap, +, \cdot\}$ and define

$$\text{BC}(\mathcal{O}) = \{C \mid C \text{ is an } \mathcal{O}\text{-circuit with } n \text{ unassigned inputs and there exist } X_1, \ldots, X_n \in \mathcal{P}_{\text{fin}}(\mathbb{N}) \text{ such that } I(C(X_1, \ldots, X_n)) \text{ is balanced}\}.$$

We use the following abbreviations if confusions are impossible: we write g or $I(g)$ for $I(g; C)$, where C is a circuit and g is a gate of C; we write C for $I(C)$, where C is a circuit; we write $\text{BC}(-, \cdot)$ for $\text{BC}(\{-, \cdot\})$ and the like.

3 Set Difference and Multiplication Lead to Undecidability

This section contains our main result: the undecidability of $\text{BC}(-, \cdot)$ which is achieved by a reduction from a famously known RE-complete problem. According to the Matiyasevich-Robinson-Davis-Putnam theorem [14, 4] the problem of determining whether there is a solution for a given Diophantine equation is RE-complete. It can be derived by standard arguments that also the following problem is RE-complete (with regard to $\leq_{\text{m}}$).

$$\text{DE} = \{(p(x_1, \ldots, x_n), q(x_1, \ldots, x_n)) \mid \exists a_1, \ldots, a_n \in \mathbb{N}^+,\ p(a_1, \ldots, a_n) = q(a_1, \ldots, a_n) \text{ for multivariate polynomials } p \text{ and } q \text{ with coefficients from } \mathbb{N}^+\}.$$

▶ **Theorem 4.** $\text{BC}(-, \cdot)$ *is* RE*-complete.*

Let for the remainder of this section $\mathcal{O} = \{-, \cdot\}$ unless stated differently. For the sake of brevity, we make use of intersection gates but note that $A \cap B$ is just an abbreviation for $A - (A - B)$. Further abbreviated notations are $A - \bigcup_{i=1}^{n} B_i$ for $(\ldots((A - B_1) - B_2) - \ldots) - B_n$ and $A - (\bigcup_{i=1}^{n} B_i - \{1\})$ for $(\ldots((A - (B_1 - \{1\})) - (B_2 - \{1\})) - \ldots - (B_n - \{1\})$.

In order to prove Theorem 4 we define a slightly different version of the problem $\text{BC}(-, \cdot)$ which can be reduced to the original version in logarithmic space.

▶ **Definition 5.** Define

$$\text{BC}'(\mathcal{O}) = \{(C, Q) \mid C \text{ is a partially assigned } \mathcal{O}\text{-circuit, } Q \text{ is a subset of the nodes of } C, \text{ and there exist } X_1, \ldots, X_n \in \mathcal{P}_{\text{fin}}(\mathbb{N}^+) \text{ such that } I(C(X_1, \ldots, X_n)) \text{ is balanced and } I(K; C(X_1, \ldots, X_n)) = \{1\} \text{ for all } K \in Q\}.$$

For the sake of simplicity, we call instances of $\text{BC}'(\mathcal{O})$ $\mathcal{O}$-circuits as well.

▶ **Lemma 6.** *1. For $K \in \mathcal{P}_{\text{fin}}(\mathbb{N})$ with $\kappa := \max(K) \geq 3$ it holds $|K \cdot K \cdot K| < \kappa^3/2$.*
2. $\text{BC}'(\mathcal{O}) \leq_{\text{m}}^{\log} \text{BC}(\mathcal{O})$ for $\mathcal{O} = \{-, \cdot\}$.

Proof sketch. We only sketch the proof of statement 2. Let C be a partially assigned $\mathcal{O}$-circuit with output node g_C and let Q be a subset of the nodes of C. Starting with this circuit, we build a new circuit and denote this modified circuit by C':

For each assigned or unassigned input node g, add a node g' of type $-$ which computes the set $g - \{0\}$, replace all edges (g, h) with (g', h), and in case $g \in Q$, remove g from Q and add g'. Then add a new output node $g_{C'} = g_C \cdot \prod_{K \in Q}(K \cdot K \cdot K)$.

Making use of Statement 1, it can be proved that $\text{BC}'(\mathcal{O}) \leq_{\text{m}}^{\log} \text{BC}(\mathcal{O})$ via $C \mapsto C'$. ◀

Before proving Theorem 4 we introduce some $\mathcal{O}$-circuits which will be used extensively as components of circuits expressing Diophantine equations.

▶ **Lemma 7.** *For every finite $P = \{p_1, \ldots, p_n\} \subseteq \mathbb{P}$ with $n = |P| \geq 1$ there is an $\mathcal{O}$-circuit (C_P, Q_P) containing gates $g_P^1, \ldots, g_P^n$ satisfying the following properties:*

1. *For an arbitrary assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ it holds:*
   if $K = \{1\}$ for all $K \in Q_P$, then $\exists_{m \in \mathbb{N}} \, \forall_{i=1,\ldots,n} \, g_P^i = \{1, p_i, \ldots, p_i^m\}$.
2. *For each $m \in \mathbb{N}$ there is an assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ under which $g_P^i = \{1, p_i, \ldots, p_i^m\}$ and $K = \{1\}$ for all $K \in Q_P$.*

Proof sketch. Construct the $\mathcal{O}$-circuit (C_P, Q_P) as follows.

- For each $p \in P$ insert an input gate X_p and gates $h_p = X_p - (X_p \cdot \{p\})$ and $h'_p = (\{1, p\} \cdot X_p) - (X_p - \{1\})$. Put all the nodes h_p into Q_P.
- Similarly, for $k \in \{p_1 \cdot p_2, p_2 \cdot p_3, \ldots, p_{n-1} \cdot p_n\}$ insert an input gate X_k and gates $h_k = X_k - (X_k \cdot \{k\})$ and $h'_k = (\{1, k\} \cdot X_k) - (X_k - \{1\})$. Insert all nodes h_k into Q_P.
- For each $k = p_i \cdot p_{i+1}$ with $i \in \{1, \ldots, n-1\}$ add a node $\gamma_k = h'_k - \big((h'_{p_i} \cdot h'_{p_{i+1}}) - \{1\}\big)$ and let Q_P contain all these nodes.
- Denote $g_P^i = X_{p_i}$.

It can be shown that (C_P, Q_P) satisfies the requirements of the lemma. ◀

By adding nodes of the form $\prod_{j=1}^{i} g_P^j$ for some i we receive the following.

▶ **Lemma 8.** *For every finite $P = \{p_1, \ldots, p_n\} \subseteq \mathbb{P}$ with $n = |P| \geq 1$ there is an $\mathcal{O}$-circuit (D_P, Q_P) with gates $g_P^0, g_P^1, \ldots, g_P^n$ satisfying the following properties:*

1. *For an arbitrary assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ it holds*

$$\forall_{K \in Q_P} \, K = \{1\} \quad \Rightarrow \quad \exists_{m \in \mathbb{N}^+} \forall_{i=0,\ldots,n} \, |g_P^i| = m^i, \; 1 \in g_P^i, \text{ and the prime divisors of numbers in } g_P^i \text{ are all in } P.$$

2. *For each $m \in \mathbb{N}^+$ there is an assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ under which $|g_P^i| = m^i$ and $1 \in g_P^i$ for all i, the prime divisors of numbers in g_P^i are all in P, and $K = \{1\}$ for all $K \in Q_P$.*

Proof of Theorem 4. Due to Lemma 6 it suffices to show $\text{DE} \leq_{\text{m}} \text{BC}'(-, \cdot)$. Instead of showing this reduction directly we define an intermediate problem, the cardinality circuit problem CC given by

$\{(C, Q, s, t) \mid C = (V, E, g_C, \alpha, \beta)$ is a $\{-, \cdot\}$-circuit, $Q \subseteq V$, $s, t \in V$, and there exists an assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ under which

1. $|I(s)| = |I(t)|$
2. $1 \in I(s) \cap I(t)$
3. $I(K) = \{1\}$ for all $K \in Q$
4. $I(s)$ and $I(t)$ only contain numbers whose prime divisors are all $> 3\}$.

Moreover, define

$$\mathcal{C} = \{(C,Q,s,t) \mid C = (V,E,g_C,\alpha,\beta) \text{ is a } \{-,\cdot\}\text{-circuit, } Q \subseteq V,\ s,t \in V, \text{ for all assignments with values from } \mathcal{P}_{\text{fin}}(\mathbb{N}^+) \text{ satisfying } \forall_{K\in Q}\ K = \{1\} \text{ it holds that } s \geq t \text{ and } s \text{ and } t \text{ only contain numbers whose prime divisors are } > 3\},$$

i.e., for all circuits in $\mathcal{C}$ each relevant assignment maps s to a set with higher or equal cardinality than the set it maps t to and each relevant assignment maps s and t to sets that do not contain any numbers with prime divisors ≤ 3. For the sake of simplicity, we also call tuples (C,Q,s,t) $\{-,\cdot\}$-circuits.

The proof will be given in the two steps

1. $(\text{DE}, \overline{\text{DE}}) \leq_{\text{m}} (\text{CC}, \overline{\text{CC}} \cap \mathcal{C})$
2. $(\text{CC}, \overline{\text{CC}} \cap \mathcal{C}) \leq_{\text{m}} (\text{BC}'(-,\cdot), \overline{\text{BC}'(-,\cdot)})$.

Thus the function composition of the two reduction functions shows $\text{DE} \leq_{\text{m}} \text{BC}'(-,\cdot)$.

1. Roughly speaking, the first of the two reductions generates a circuit computing two sets whose cardinalities express the results of two multivariate polynomials.

Let q and q' be multivariate polynomials with variables $x_1,\dots,x_n$. Then for any assignment with positive natural numbers $a_1,\dots,a_n$ it holds $q(a_1,\dots,a_n) = q'(a_1,\dots,a_n)$ if and only if $q(a_1,\dots,a_n)^2 + q'(a_1,\dots,a_n)^2 = 2\cdot q(a_1,\dots,a_n)\cdot q'(a_1,\dots,a_n)$. Observe that here because of $(q(a_1,\dots,a_n) - q'(a_1,\dots,a_n))^2 \geq 0$ we have $q(a_1,\dots,a_n)^2 + q'(a_1,\dots,a_n)^2 \geq 2\cdot q(a_1,\dots,a_n)\cdot q'(a_1,\dots,a_n)$ for any assignment. Due to that we may assume that we are given multivariate polynomials q and q' with variables $x_1,\dots,x_n$ such that $q \geq q'$ for all assignments of the variables with values from $\mathbb{N}^+$. Let

$$q = \sum_{i=1}^{m} a_i \cdot \prod_{j=1}^{n} x_j^{d_{i,j}} \quad \text{and} \quad q' = \sum_{i=1}^{m'} a'_i \prod_{j=1}^{n} x_j^{d'_{i,j}}$$

for positive numbers m, m', a_i, and a'_i and natural numbers $d_{i,j}$ and $d'_{i,j}$. Moreover, for each variable x_j define $e_j = \max(\{d_{1,j},\dots,d_{m,j},d'_{1,j},\dots,d'_{m',j}\})$, i.e., e_j denotes the maximum exponent of the variable x_j occurring in a monomial of q or q'.

We now successively build the output circuit (C,Q,s,t). For the single steps we give intuition which is written italic.

1. For each variable x_j select a set $P_j = \{p_{j,1},\dots,p_{j,e_j}\}$ of primes greater than 3 such that $|P_j| = e_j$ and $P_j \cap P_{j'} = \emptyset$ for $j \neq j'$. Then insert a circuit (C_{P_j}, Q_{P_j}) according to Lemma 8 and for all P_j, insert the nodes of Q_{P_j} into Q.
   We will make use of the notation of Lemma 8, in particular of the nodes $g^0_{P_j},\dots,g^{e_j}_{P_j}$. That means, for any assignment which satisfies $K = \{1\}$ for all $K \in Q \supseteq Q_{P_j}$, it holds $|g^i_{P_j}| = m^i_j$ for $m_j \in \mathbb{N}^+$ and for all $i \leq e_j$. Moreover, in that case all primes dividing some number of $g^i_{P_j}$ are in P_j.
   For intuition, think of the node $g^i_{P_j}$ as a set whose cardinality describes x^i_j.
2. **a.** Choose a prime $p > 3$ not used before and insert gates $h_i = \{1,p,\dots,p^{a_i-1}\}\cdot\prod_{j=1}^{n} g^{d_{i,j}}_{P_j}$ for all $i = 1,\dots,m$.
   Loosely speaking, the cardinality of h_i describes the value of the i-th monomial of q.
   b. For each node h_i choose a prime $p_i > 3$ not used before and insert a node $h'_i = (\{1,p_i\}\cdot h_i) - \big(h_i - \{1\}\big)$.
   As addition is supposed to be simulated by union, we need to make sure that the sets standing for distinct monomials are disjoint. Still, for a technical reason we have to keep 1 in each set. So the idea is to let h'_i consist of 1 and a copy of h_i multiplied with an additional prime factor.

   c. For $i = 1, \dots, m$ add an unassigned input node z_q. Finally add nodes $z_q - \left(\bigcup_{i=1}^{m} h'_i - \{1\}\right)$ and $h'_i - (z_q - \{1\})$ (for $i = 1, \dots, m$) and insert these nodes into Q.
   Roughly speaking, z_q describes the value of $q + 1$ as it is the union of all the h'_i.
3. Do the same as in step 2 but for q'. In particular a node $z_{q'}$ is added.
4. Define $s = z_q$ and $t = z_{q'}$.

First, observe that the function $(q, q') \mapsto (C, Q, s, t)$ is computable. In order to show

$$(q, q') \in \mathrm{DE} \Rightarrow (C, Q, s, t) \in \mathrm{CC} \quad \text{and} \quad (q, q') \notin \mathrm{DE} \Rightarrow (C, Q, s, t) \in \overline{\mathrm{CC}} \cap \mathcal{C}$$

we make the following central observation.

▶ **Claim 9.**

1. *For each $y_1, \dots, y_n \in \mathbb{N}^+$ there is an assignment of the circuit (C, Q) with values from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N}^+)$ such that s (resp., t) consists of $1 + q(y_1, \dots, y_n)$ (resp., $1 + q'(y_1 \dots, y_n)$) numbers whose prime divisors are greater than 3, $1 \in s \cap t$, and $K = \{1\}$ for all $K \in Q$.*
2. *If $K = \{1\}$ for all $K \in Q$ under some assignment with values from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N}^+)$, then there are $y_1, \dots, y_n \in \mathbb{N}^+$ such that $|s| = 1 + q(y_1, \dots, y_n)$ and $|t| = 1 + q'(y_1, \dots, y_n)$ and s and t solely contain numbers whose prime divisors are all greater than 3.*

Proof of Claim 9.

1. Let $y_1, \dots, y_n \in \mathbb{N}^+$. Then according to Lemma 8 the inputs of the circuits (C_{P_j}, Q_{P_j}) can be chosen such that
   - $K = \{1\}$ for all $K \in Q_{P_j}$,
   - $|g^i_{P_j}| = y^i_j$ and $1 \in g^i_{P_j}$ for $i = 1, \dots, e_j$, and
   - all prime divisors of numbers in $g^i_{P_j}$ are in P_j and greater than 3.

   As the set of primes chosen for two different variables are disjoint and in step 2b we select primes not used before, the gate h_i associated with the monomial $a_i \cdot \prod_{j=1}^{n} x_j^{d_{i,j}}$ contains $a_i \cdot \prod_{j=1}^{n} y_j^{d_{i,j}}$ elements that only have prime divisors greater than 3. Furthermore, as $1 \in h_i$ for all i, we have $|h'_i| = 2 \cdot |h_i| - (|h_i| - 1) = |h_i| + 1$. Moreover, observe that $h'_i \cap h'_j = \{1\}$ for arbitrary $i \neq j$.
   For the node z_q choose the assignment $\bigcup_{i=1}^{m} h'_i$. Consequently, $1 \in z_q$ and

$$|z_q| = 1 + \sum_{i=1}^{m} \underbrace{(|h'_i| - 1)}_{=|h_i|} = 1 + \sum_{i=1}^{m} a_i \cdot \prod_{j=1}^{n} x_j^{d_{i,j}} = 1 + q(y_1, \dots, y_n).$$

   Since we do the same for the nodes associated with the polynomial q' we have $|z_{q'}| = 1 + q'(y_1, \dots, y_n)$ and $1 \in z_{q'}$. Observe that the prime divisors of numbers in z_q and $z_{q'}$ are greater than 3.
   It remains to observe that all nodes added into Q in step 2c compute the set $\{1\}$. This holds since z_q was chosen to be $\bigcup_{i=1}^{m} h'_i$.
2. Consider an assignment with $K = \{1\}$ for all $K \in Q$. Then according to Lemma 8 for each variable x_j we have $|g^i_{P_j}| = y^i_j$ for some $y_j \in \mathbb{N}^+$ and $i = 0, \dots, e_j$ and all numbers in these gates solely have prime divisors in P_j. As the P_j are pairwise disjoint and in step 2b we select primes not used before, we obtain $|h_i| = a_i \cdot \prod_{j=1}^{n} y_j^{d_{i,j}}$ and $|h'_i| = |h_i| + 1$. As $h'_i \cap h'_j = \{1\}$ for $i \neq j$ and each h'_i contains 1, it holds $|z_q| = 1 + \sum_{i=1}^{n} a_i \cdot \prod_{j=1}^{n} y_j^{d_{i,j}} = 1 + q(y_1, \dots, y_n)$. Similarly we obtain $|z_{q'}| = 1 + q'(y_1, \dots, y_n)$.
   It remains to argue that under the given assignment s and t do not contain any numbers with prime divisors ≤ 3. Obviously, the assigned inputs only compute sets whose elements solely have prime divisors greater than 3. By our construction and Lemma 8 the same

holds for all nodes $g^i_{P_j}$. As a consequence, all nodes h_i and h'_i have the same property and due to $z_q - \left(\bigcup_{i=1}^m h'_i - \{1\}\right) = \{1\}$ (cf. Step 2c) this also holds for $z_q = s$. An analogous argumentation shows that also t does not contain any numbers with prime divisors ≤ 3. ◀

As it has been argued above that $|q| \geq |q'|$, Claim 9 implies the following two statements: If $(q, q') \in \mathrm{DE}$, then $(C, Q, s, t) \in \mathrm{CC}$. If $(q, q') \notin \mathrm{DE}$, then $(C, Q, s, t) \in \overline{\mathrm{CC}} \cap \mathcal{C}$.

2. Now we show $(\mathrm{CC}, \overline{\mathrm{CC}} \cap \mathcal{C}) \leq_{\mathrm{m}} (\mathrm{BC}'(-,\cdot), \overline{\mathrm{BC}'(-,\cdot)})$. The following algorithm computes the reduction function. The italic comments are supposed to give some intuition.

1. Let a circuit (C, Q, s, t) be given. We construct a circuit (C', Q') by successively updating the given circuit.
2. Add new unassigned input gates X and X'. Insert the following nodes into Q':

$$\{1,2\} \cdot s - (X - \{1\}), \tag{1}$$
$$\{1,2\} \cdot t - (X - \{1\}), \tag{2}$$
$$\{1,2\} \cdot (X - s) - \big((X' \cup (X - s)) - \{1\}\big), \tag{3}$$
$$X' - \{2\} \cdot (X - s). \tag{4}$$

The basic idea is as follows: X is supposed to be an interval containing s and t and X' basically encodes the set $X - s$ where this set is made disjoint to t by multiplying it with $\{2\}$. As $|s| \geq |t|$, the set $X' \cup t$ is subbalanced. But if $|s| = |t|$, then $X' \cup t$ is almost balanced. Adding the element $\max(X')+1$ would make the set balanced. This element is generated in the next step.

3. Let $p_1 = 2$ and $p_2 = 3$. Add a circuit $(C_{\{p_1,p_2\}}, Q_{\{p_1,p_2\}})$ according to Lemma 7. Put all nodes of $Q_{\{p_1,p_2\}}$ into Q'. Add a node $g = \big(g^2_{\{p_1,p_2\}} \cdot \{1,3\}\big) - (g^2_{\{p_1,p_2\}} - \{1\})$.
4. Add a new unassigned input node O and the following nodes which are also added to Q':

$$O - \Big(\big(X' \cup t \cup g\big) - \{1\}\Big), \tag{5}$$
$$X' - (O - \{1\}), \tag{6}$$
$$t - (O - \{1\}), \tag{7}$$
$$g - (O - \{1\}). \tag{8}$$

Thus, roughly speaking, the output set O equals $X' \cup t \cup g$ and is only balanced if $|t| \geq |s|$.

5. Let O be the output node of the circuit (C', Q').

▶ **Claim 10.** *If $(C, Q, s, t) \in \mathrm{CC}$, then $(C', Q') \in \mathrm{BC}'(-,\cdot)$.*

Proof of Claim 10. Let $(C, Q, s, t) \in \mathrm{CC}$. Then there is some assignment with
- $|s| = |t|$,
- $1 \in s \cap t$,
- $K = \{1\}$ for all $K \in Q$, and
- s and t only contain numbers whose prime divisors are all greater than 3.

We now consider the circuit (C', Q') under an assignment satisfying the four conditions just mentioned. Moreover, we choose the input of $C_{\{p_1,p_2\}}$, X, X', and O such that
- $g = \{1, 3^m\}$ for m minimal with $4 \cdot (\max(s \cup t) + 1) < 3^m$ and $4 \mid 3^m - 1$ and all nodes in $Q_{\{p_1,p_2\}}$ compute $\{1\}$ (such an assignment exists by Lemma 7),
- $X = \{x \mid 1 \leq x \leq (3^m - 1)/2\}$,
- $X' = \{1\} \cup \{2\} \cdot (X - s)$, and
- $O = X' \cup t \cup g = \big(\big(\{2\} \cdot (X - s)\big)\big) \cup t \cup \{3^m\}$.

In order to see $K = \{1\}$ for all $K \in Q'$ it remains to consider the nodes added in the steps 2 and 4. Due to the choice of g and X it holds $\max(X) > 2{\cdot}\max(s \cup t)$ and thus the nodes defined in (1) and (2) compute $\{1\}$. The choice of X' immediately implies that the node defined in (4) computes $\{1\}$. Now we argue for the node defined in (3): As $X' = \{1\} \cup \{2\} \cdot (X - s)$ we have $\{1,2\} \cdot (X - s) - \big((X' \cup (X - s)) - \{1\}\big) = \{1,2\} \cdot (X - s) - \big((\{1,2\} \cdot (X - s)) - \{1\}\big) = \{1\}$. The nodes defined in (5), (6), (7), and (8) compute $\{1\}$ by the choice of g, X, X', and O.

As s and t only contain numbers whose prime divisors are > 3, the sets $\{2\} \cdot (X - s)$, t, and $\{3^m\}$ are disjoint. Hence, $|O| = \max(X) - |s| + |t| + 1 = \max(X) + 1 = \frac{\max(O)-1}{2} + 1 = \frac{\max(O)+1}{2}$ and thus O is balanced. ◀

▶ **Claim 11.** *If* $(C, Q, s, t) \in \overline{\mathrm{CC}} \cap \mathcal{C}$*, then* $(C', Q') \in \overline{\mathrm{BC}'(-,\cdot)}$.

Proof of Claim 11. For a contradiction, assume that $(C, Q, s, t) \in \overline{\mathrm{CC}} \cap \mathcal{C}$ and $(C', Q') \in \mathrm{BC}'(-,\cdot)$. As the second circuit is an extended version of the first circuit, both circuits can now be considered under the same assignment. Choose an assignment with values from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N}^+)$ under which O is balanced and all $K \in Q'$ satisfy $K = \{1\}$. As by construction $Q \subseteq Q'$, we have $K = \{1\}$ for $K \in Q$.

As in particular the nodes defined in (1) and (2) compute $\{1\}$, we obtain $1 \in s \cap t$, $X \supseteq \{1,2\} \cdot s \cup \{1,2\} \cdot t$, and in particular $s \subseteq X$ and $\max(X) > \max(s) \geq 1$. As $\{1,2\} \cdot (X - s) - \big((X' \cup (X - s)) - \{1\}\big) = \{1\}$ (cf. (3)), it holds $2 \cdot \max(X) \in X'$. Since the node defined in (4) computes $\{1\}$, we obtain $X' \subseteq \{1\} \cup \{2\} \cdot (X - s)$. In particular, $\max(X') = 2 \cdot \max(X)$.

The fact that the nodes defined in (5), (6), (7), and (8) compute $\{1\}$ implies $1 \in O \cap X' \cap t \cap g$ and $O = X' \cup t \cup g$. Moreover, it follows from Lemma 7 that $g = \{1, 3^m\}$ for some $m \in \mathbb{N}^+$. Thus, as $1 \in t$,

$$O \subseteq \{1\} \cup \big(\{2\} \cdot (X - s)\big) \cup t \cup g = \big(\{2\} \cdot (X - s)\big) \cup t \cup \{3^m\}. \tag{9}$$

As O is balanced, $\max(O)$ is odd by Lemma 1. Since $X \supseteq t$ and $\max(X') = 2 \cdot \max(X)$ is even, $\max(O) = 3^m > \max(X')$. Due to $(C, Q, s, t) \in \mathcal{C}$, under the given assignment $|s| \geq |t|$ and s and t do not contain any numbers with prime divisors ≤ 3. Due to that, since we have seen $1 \in s \cap t$, and as by assumption $(C, Q, s, t) \notin \mathrm{CC}$, it even holds $|s| > |t|$.

Putting things together, as we have proven (9), $|s| > |t|$, $1 \in t$, $s \subseteq X$, $\max(X') = 2 \cdot \max(X)$, and $\max(O) > \max(X')$, we now obtain $|O| \leq \max(X) - |s| + |t| + 1 < \max(X) + 1 = \frac{\max(X')+2}{2} \leq \frac{\max(O)+1}{2}$, which contradicts the fact that O is balanced. ◀

This completes the proof of $(\mathrm{CC}, \overline{\mathrm{CC}} \cap \mathcal{C}) \leq_{\mathrm{m}} (\mathrm{BC}'(-,\cdot), \overline{\mathrm{BC}'(-,\cdot)})$ and thus $\mathrm{BC}'(-,\cdot)$ and $\mathrm{BC}(-,\cdot)$ are $\leq_{\mathrm{m}}$-complete for RE. ◀

4 Smaller Sets of Operations Lead to Problems in NP

In this section it is shown that all problems $\mathrm{BC}(\mathcal{O})$ for $\mathcal{O} \subsetneq \{-,\cdot\}$ are in NP. Each of these problems is proven to be $\leq_{\mathrm{m}}^{\log}$-complete for one of the classes L, NL, and NP.

4.1 The Complexity of the Problem Solely Admitting Multiplication

This section's purpose is to argue for the NL-completeness of $\mathrm{BC}(\cdot)$. Special cases of strong results from the literature [7, 8, 13] essentially yield the following theorem.

▶ **Theorem 12.** *There exists* $\mu \in \mathbb{N}$ *such that for all non-empty sets* $A, B \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ *with* $\max(A) \geq \mu$ *and* $\max(B) \geq \mu$ *the set* $A \cdot B$ *is subbalanced.*

▶ **Theorem 13.** BC(·) *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NL.

Proof. In the following we present an NL-algorithm for BC(·). We make use of the fact that the graph accessibility problem for directed graphs and the modifications of this problem

$$\mathrm{GAP}_{\geq k} = \{(G,s,t) \mid G \text{ is an directed graph, there exist } k \text{ paths from } s \text{ to } t\}$$

and consequently

$$\mathrm{GAP}_{=k} = \{(G,s,t) \mid G \text{ is an directed graph, the number of paths from } s \text{ to } t \text{ is } k\}$$

for $k \in \mathbb{N}^+$ are in NL. We may assume the following for the input circuit C:

1. All gates in C are connected to the output gate g_C. Otherwise, delete all edges not connected to the output, which can be done by an NL-subroutine.
2. No assigned input computes the empty set or the set $\{0\}$. Otherwise, under the assumption of 1 we may reject immediately.
3. There is an assigned input gate a computing a set with maximum ≥ 2. Otherwise: under the assumption of 1 and 2,
   - we may accept if there is an unassigned input or no assigned input computes $\{0,1\}$
   - we may reject if there does not exist an unassigned input and there is an assigned input computing $\{0,1\}$.
4. No assigned input gate but possibly a computes a set containing 0. Otherwise, under the assumptions 1 and 3 we may delete 0 from all assigned inputs and insert 0 into a.
5. There is an assigned input node g_1 computing $\{1\}$.
6. For each set $M \subseteq \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ there is at most one assigned input computing M. Otherwise, select one of the nodes computing M, let all outgoing edges of nodes computing M start in this node, and delete all other nodes computing M and their incident edges.

Assume there is an NL-algorithm P that accepts the set of those circuits C which satisfy the mentioned properties and whose unassigned inputs can be assigned with sets of *positive* naturals such that the output set is balanced. Then the following NL-algorithm accepts BC(·) (on input of a circuit C satisfying the properties listed above).

- If P accepts on C, accept.
- If there is an unassigned input, then add 0 into the set computed by the aforementioned node a and accept if P accepts the modified circuit.
- Reject.

Now we sketch P and argue that it is an NL-algorithm. Let $\mu \geq 2$ be the number mentioned in Theorem 12, i.e., for $A, B \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ with $\max(A) \geq \mu \leq \max(B)$ the set $A \cdot B$ is subbalanced. The algorithm will query the following constant-size problem

$$\Theta = \{(B,k_1,k_2) \mid B \subseteq \{(h,i_h) \mid h \subseteq \{0,1,\ldots,\mu\}, 1 \leq i_h \leq 2\}, |B| \leq \mu, k_1 \leq \mu, k_2 \leq \mu,$$
$$\exists_{E_1,\ldots,E_{k_1},F_1,\ldots,F_{k_2} \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N}^+)} \prod_{(h,i_h)\in B} h^{i_h} \cdot \prod_{i=1}^{k_1} E_i \cdot \prod_{i=1}^{k_2} F_i^2 \text{ is balanced}\}.$$

1. If there are two assigned input gates each containing an element $\geq \mu$, reject.
   If there is an assigned input gate with two paths to g_C containing an element $\geq \mu$, reject.
2. If there are at least μ assigned input gates computing a set with maximum ≥ 2, reject.
3. In case there is an assigned input gate computing a set with maximum ≥ 2 with at least three paths to the output, reject.
4. Let $v_1,\ldots,v_n$ be the nodes of the circuit in topological order. For $i = 1,\ldots,n$, if one of the conditions

- v_i is an unassigned input with at least three paths to g_C.
- v_i is an unassigned input with precisely one path to g_C, such that there are at least μ unassigned inputs $< v_i$ with precisely one path to g_C.
- v_i is an unassigned input with precisely two paths to g_C, such that there are at least μ unassigned inputs $< v_i$ with precisely two paths to g_C.
- g_1 is the only input with a path to v_i.

is satisfied, then delete v_i and let all outgoing edges of v_i start in g_1.
This step can be implemented as a non-deterministic logarithmic-space subroutine.

5. Let n_1 (resp., n_2) be the number of unassigned inputs with 1 path (resp., 2 paths) to g_C. Due to Step 4 we have $\max(n_1, n_2) \leq \mu$. Moreover, let A be a set consisting of all pairs (h, i_h) where h is a set computed by an assigned input with $1 < \max(h) \leq \mu$ and $i_h \in \{1, 2\}$ is the number of paths from h to g_C. Due to Step 2 it holds $|A| \leq \mu$. We have the following cases.

a. In case there is no assigned input gate with an element $\geq \mu$:
If $(A, n_1, n_2) \in \Theta$, then accept. Otherwise reject.
Computing the triple (A, n_1, n_2) is possible in non-deterministic logarithmic space whereas the subsequent test only requires constant time.

b. In case there is one assigned input gate g with an element $\geq \mu$:
Due to Step 1 the node g only has one path to the output.

i. For all $E_1, \ldots, E_{n_1}, F_1, \ldots, F_{n_2} \in \mathcal{P}(\{1, \ldots, \mu\})$ do the following

- Compute the constant-size set

$$M = \prod_{i=1}^{n_1} E_i \cdot \prod_{i=1}^{n_2} F_i^2 \cdot \prod_{(h,i_h)\in A, h\neq g} h^{i_h}.$$

- Test whether $g \in \mathrm{Bal}_M$ and accept in case the answer is "yes".

ii. Reject.

By Proposition 2 this step can be executed in logarithmic space.

In the following we observe that each step of the algorithm P accepts (resp., rejects) if and only if the circuit at the beginning of the execution of the respective step has a (resp., no) balancing assignment with values from $\mathcal{P}_{\mathrm{fin}}(\mathbb{N}^+)$. It suffices to argue for the following steps.

1. If the algorithm rejects in this step, then there are sets A and B with $\max(A) \geq \mu \leq \max(B)$ and a set M such that $g_C = A \cdot B \cdot M$. Then according to Theorem 12 it holds $|(A \cup \{0\}) \cdot B| \leq \max(A) \cdot \max(B)/2$. Hence for each set $M \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ the set $M \cdot A \cdot B \subseteq (A \cup \{0\}) \cdot B \cdot (M - \{0\})$ contains at most $\max(A) \cdot \max(B) \cdot \max(M)/2$ elements and its greatest element is $\max(A) \cdot \max(B) \cdot \max(M)$. Thus, the set is subbalanced.

2. If there are $\geq \mu$ sets with maximum greater 2 connected to the output, then we can interpret these sets as two sets with maxima $\geq \mu$ and argue in the same way as in the step before.

3. If the algorithm rejects in this step, then there are sets A and M with $\max(A) \geq 2$ and $g_C = A \cdot A \cdot A \cdot M$. If $\max(A) = 2$, then Lemma 1 states that the output set is not balanced. Otherwise, $\max(A) \geq 3$ and according to Statement 2 of Lemma 6 the set $A \cdot A \cdot A$ contains less than $\max(A)^3/2$ elements. Hence g_C contains less than $\max(A)^3 \cdot \max(M)/2$ elements and the maximum of this set is $\max(A)^3 \cdot \max(M)$. Thus g_C is subbalanced.

5. At the beginning of the execution of this step we have the following situation: Due to the steps 1, 2, and 3 and because of the assumption we made on the input circuit there

- is at most one assigned input containing an element $> \mu$ and this has at most one path to the output gate.
- are at most μ assigned inputs with maximum ≥ 2 and all these inputs have at most two paths to the output gate.
- is one assigned input with maximum < 2, namely $g_1 = \{1\}$.

Moreover, as observed above, because of Step 4 it holds $\max(n_1, n_2) \leq \mu$ and there are no unassigned inputs with more than 2 paths to the output.

Thus we have to consider two cases. Either there is no assigned input with maximum $> \mu$ or there is one. In the first case the circuit has a balancing assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ if and only if there are $n_1 + n_2$ sets $E_1, \ldots, E_{n_1}, F_1, \ldots, F_{n_2} \in \mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ such that $\prod_{(h,i_h)\in B} h^{i_h} \cdot \prod_{i=1}^{k_1} E_i \cdot \prod_{i=1}^{k_2} F_i^2$ is balanced. This is what the algorithm tests. In the second case, assigning one of the unassigned inputs with a set with maximum $> \mu$ would lead to a subbalanced output with the same argument as was used for Step 1. Thus, only assignments with values from $\mathcal{P}(\{1, \ldots, \mu\})$ have to be considered. Hence, there is a balancing assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ if and only if there are sets $E_1, \ldots, E_{n_1}, F_1, \ldots, F_{n_2} \in \mathcal{P}(\{1, \ldots, \mu\})$ such that $\prod_{i=1}^{n_1} E_i \cdot \prod_{i=1}^{n_2} F_i^2 \cdot \left(\prod_{(h,i_h)\in A, h\neq g} h^{i_h}\right) \cdot g$ is balanced. This is what the algorithm tests.

It remains to observe that the circuit has a balancing assignment with values from $\mathcal{P}_{\text{fin}}(\mathbb{N}^+)$ before the execution of Step 4 if and only if it has afterwards:
In case there are more than μ unassigned inputs with one path (resp., two paths) to the output and more than μ of them are mapped to sets containing elements ≥ 2, then the same arguments as for Step 2 yield that the output is subbalanced. Therefore, all but μ of these nodes can be replaced with g_1.
Let g be an unassigned input with at least three paths to the output (if such a node exists). Assigning this node with a set with maximum ≥ 2 leads to a subbalanced output set with the same arguments as were used for Step 3. Therefore, g can be replaced with g_1.
For each node v_i there exists an input that has a path to v_i. Hence, if no input different from g_1 has a path to v_i, then v_i computes $\{1\}$ and can be replaced with g_1.

By a straightforward reduction from a problem investigated by McKenzie and Wagner [15] one receives the NL-hardness of BC(·). ◀

4.2 The Complexity of the Problems Not Admitting Multiplication

We consider the two remaining problems and prove that BC(−) is $\leq_{\text{m}}^{\log}$-complete for NP and BC(∅) is in L. The NP-hardness of BC(−) can be obtained by a straightforward reduction from CSAT. Hence, for the following theorem it suffices to argue for the membership in NP.

▶ **Theorem 14.** BC(−) *is* $\leq_{\text{m}}^{\log}$*-complete for* NP.

Proof. We sketch an NP-algorithm that accepts BC(−).

1. Input: a circuit C with output node g_C and labeling function α.
2. Go from g_C upwards always taking the left predecessor. Denote the input gate finally reached by g.
3. If g is assigned, then: guess an assignment with values from $\mathcal{P}(\alpha(g))$ and accept if the output set is balanced for this assignment, otherwise reject.
4. Here g is unassigned. Let M be the union of all sets computed by assigned inputs. Let $m = \max(M) + 1$. Guess an assignment such that $I(g) = \{m\}$ and each unassigned input either computes $\{m\}$ or $\emptyset$. If under this assignment g_C contains m, then accept.

5. Guess an assignment of the unassigned inputs such that each of them computes a subset of M. In case g_C is balanced, accept. Otherwise reject.

If the algorithm accepts, then $C \in \mathbf{BC}(-)$: It suffices to consider the 4-th step. If the algorithm accepts in this step, then there is an assignment that maps each unassigned input either to $\{m\}$ or to $\emptyset$ such that m is in the output set. Now change this assignment such that the sets mapped to $\{m\}$ are now mapped to $\{m+1, m+2, \ldots, 2m+1\}$. Then $I(C) = \{m+1, m+2, \ldots, 2m+1\}$ is balanced and $C \in \mathrm{BC}(-)$. Trivially, in case C is accepted in the 5-th step, $C \in \mathrm{BC}(-)$.

If the algorithm rejects, then $C \notin \mathbf{BC}(-)$: If the algorithm rejects, then this happens in step 3 or step 5. We argue for the first case. Here g is an assigned input gate. As the output set is a subset of $\alpha(g)$, it holds $g_c \subseteq \alpha(g)$ for any assignment and hence it suffices to consider assignments that map all unassigned inputs to subsets of $\alpha(g)$. As the algorithm rejects, g_C is not balanced under any of these assignments and thus $C \notin \mathrm{BC}(-)$.

It remains to argue for the case where the algorithm rejects in step 5. In this case, g is an unassigned input and as step 4 did not accept, there is no assignment putting elements outside of M into the circuit's output set. Hence, it is sufficient to consider assignments that solely map to subsets of M. As the algorithm rejects, none of these assignments yields a balanced output set and hence there is no assignment at all under which the output set is balanced. Therefore, $C \notin \mathrm{BC}(-)$. ◀

The following theorem basically follows from Proposition 2.

▶ **Theorem 15.** $\mathrm{BC}(\emptyset) \in \mathrm{L}$.

5 Conclusion and Open Questions

The following table summarizes our results, namely the lower and upper complexity bounds for the complexity of $\mathrm{BC}(\mathcal{O})$ with $\mathcal{O} \subseteq \{-, \cdot\}$.

$\mathrm{BC}(\mathcal{O})$ for $\mathcal{O} =$	$\leq_{\mathrm{m}}^{\log}$-hard for	contained in
$\emptyset$	L	L, Theorem 15
$\{-\}$	NP, Theorem 14	NP, Theorem 14
$\{\cdot\}$	NL, Theorem 13	NL, Theorem 13
$\{\cdot, -\}$	undecidable, Theorem 4	

To our knowledge, in contrast to all results from previous papers on complexty issues concerning decision problems for integer circuits (e.g., [15, 19, 2, 9, 11, 1]) or related constraint satisfaction problems ([10, 5]), a problem *admitting only one arithmetic operation* is shown to be undecidable. Beginning with this problem, namely $\mathrm{BC}(-, \cdot)$, the problems $\mathrm{BC}(\mathcal{O})$ for $\mathcal{O} \subseteq \{-, \cdot\}$ are systematically investigated and for each of these problems the complexity is precisely characterized. It turns out that decreasing the size of the set of allowed operations yields problems that are in NP. In particular, all these problems are $\leq_{\mathrm{m}}^{\log}$-complete for one of the classes L, NL, and NP.

Hence, in some sense the questions of this paper are completely answered. Nevertheless, there arise new questions from our results: Is there a set $\mathcal{O} \subseteq \{-, \cup, \cap\}$ such that $\mathrm{BC}(\mathcal{O} \cup \{+\})$ is undecidable? And if so, for which of the sets this is the case and for which it is not?

Abstract

In this paper, we study rotating $\mathbb{Q}$-automata, which are (memoryless) automata with weights in $\mathbb{Q}$, that can read the input tape from left to right several times. We show that the series realized by valid rotating $\mathbb{Q}$-automata are $\mathbb{Q}$-Hadamard series (which are the closure of $\mathbb{Q}$-rational series by pointwise inverse), and that every $\mathbb{Q}$-Hadamard series can be realized by such an automaton. We prove that, although validity of rotating $\mathbb{Q}$-automata is undecidable, the equivalence problem is decidable on rotating $\mathbb{Q}$-automata. Finally, we prove that every valid two-way $\mathbb{Q}$-automaton admits an equivalent rotating $\mathbb{Q}$-automaton. The conversion, which is effective, implies the decidability of equivalence of two-way $\mathbb{Q}$-automata.

1 Introduction

Rotating automata are a natural model of automata. They were first considered as a restriction of two-way automata [8, 11]. In this model, the automaton reads the input from the left to the right, but when the right end of the input is reached, either the automaton stops, or the tape is rewinded back to the left end of the input. In the Boolean case, rotating automata are as expressive as NFA, but they have been studied since their size can be much smaller [8]. In particular they can compute the intersection of two regular languages with a linear number of states.

In the framework of weighted automata or transducers, rotating automata are more expressive than one-way automata or transducers [9]. In particular, in *rationally additive semirings* [5], they realize Hadamard series, which are the closure of rational series by Hadamard product and Hadamard inverse. This is a sound class of series, and in this framework, algorithms have been defined to convert rotating automata to expressions describing Hadamard series and to synthesize rotating automata from such expressions [4].

Hadamard series over a field have been studied for a long time [12] and it is not surprising that rotating automata can realize them. Nevertheless, fields are not rationally additive semirings, and the potentially infinite number of runs for some input must be handled in a more subtle way to translate rotating automata to Hadamard series. In this paper we prove that the set of Hadamard series over $\mathbb{Q}$ is exactly the behaviour of rotating $\mathbb{Q}$-automata.

We also prove that two-way $\mathbb{Q}$-automata realize the same class of series. This is an extension of the work of Anselmo and Bertoni on probabilistic two-way automata [1]. In contrast, sweeping transducers with unary outputs are equivalent to rotating transducers and they are weaker than two-way transducers [7]. Notice that the algebraic characterization of series realized by weighted two-way automata is in general not achieved.

In Section 2, we briefly recall the definition of rational series and weighted automata. In Section 3, we define Hadamard series, which form a strictly larger class than rational series, and study different ways to describe them as well as the conversions between these descriptions. Finally we show that it is undecidable whether the description of a Hadamard series, called a Hadamard expression, is well defined, but in the case where two expressions actually define a Hadamard series, their equivalence is decidable.

In Section 4, we introduce rotating $\mathbb{Q}$-automata and we prove that they actually realize $\mathbb{Q}$-Hadamard series and that, conversely, a rotating $\mathbb{Q}$-automaton can be synthesized from any expression denoting a Hadamard series. In particular, rotating $\mathbb{Q}$-automata are strictly more expressive than one-way $\mathbb{Q}$-automata.

Finally, in Section 5 we formally define two-way $\mathbb{Q}$-automata and we show that they can be simulated by rotating $\mathbb{Q}$-automata. As a consequence, the equivalence of two-way $\mathbb{Q}$-automata is decidable.

2 Rational series and weighted automata

For every alphabet A, we denote A^* the free monoid generated by A. The set of formal power series over A^* with coefficients in $\mathbb{Q}$ is denoted $\mathbb{Q}\langle\langle A^*\rangle\rangle$. A *series* s in $\mathbb{Q}\langle\langle A^*\rangle\rangle$ is a mapping from A^* into $\mathbb{Q}$; the *coefficient* of a word w in s is denoted $\langle s, w\rangle$, the coefficient of the empty word is the *constant term* of the series, and s itself is denoted as a formal sum:

$$s = \sum_{w \in A^*} \langle s, w\rangle w. \tag{1}$$

The sum $s + t$ of two series is the pointwise sum. The *Cauchy product* is the extension of the usual polynomial product to series; the series 1 (where all the coefficients are 0 except the constant term equal to 1) is neutral for this product. The Cauchy product is associative and distributes over the sum. Hence $(\mathbb{Q}\langle\langle A^*\rangle\rangle, +, \cdot)$ is a semiring.

In a semiring, the *star* of an element is defined as the sum of the powers of the element, if it exists. Hence, in $(\mathbb{Q}\langle\langle A^*\rangle\rangle, +, \cdot)$, the star of s is defined if the constant term belongs to $]-1; 1[$; it is called the *Kleene star* of s and is denoted s^*. In contrast to the case of the Boolean semiring, the Kleene star is not idempotent in $\mathbb{Q}$, neither in series with coefficients in $\mathbb{Q}$.

The *support* of a series s is the set of words w such that $\langle s, w\rangle \neq 0$. A series with a finite support is a *polynomial*; if every word of A^* belongs to the support, we say that the series has a *full support*.

▶ **Definition 1.** The set $\mathbb{Q}\mathrm{Rat}A^*$ of *rational series* is the closure of polynomials in $\mathbb{Q}\langle\langle A^*\rangle\rangle$ under sum, Cauchy product and Kleene star.

Likewise, the set of $\mathbb{Q}_+$-rational series is the closure of polynomials with positive coefficients under sum, Cauchy product and Kleene star.

The *behaviour* of an automaton is the language or series that describes the result of the automaton on every input. For instance, the behaviour of an NFA is the language of accepted words. The behaviour of a $\mathbb{Q}$-automaton is the series which maps every word to the weight of this word in the automaton.

▶ **Definition 2.** A $\mathbb{Q}$-automaton over an alphabet A is a tuple $\mathcal{A} = (Q, E, I, T)$, where
- Q is a finite set of states;
- I and T are, respectively, the initial and the final weight functions from Q into $\mathbb{Q}$;
- E is the transition weight function from $Q \times A \times Q$ into $\mathbb{Q}$.

The set of initial (*resp.* final) states is the support of I (*resp.* T), *i.e.* the states p such that $I(p) \neq 0$ (*resp.* $T(p) \neq 0$). The set of transitions is the support of E.

As usual, a *run* with label $w = w_1 w_2 \dots w_k$ in A^* is a sequence of states $(p_i)_{i \in [\![0;k]\!]}$ such that p_0 is an initial state, p_k is a final state, and for every i in $[\![1;k]\!]$, (p_{i-1}, w_i, p_i) is a transition. The *weight* of the run is equal to $I(p_0).\prod_{i=1}^{k} E(p_{i-1}, x_i, p_i).T(p_k)$. The weight $\mathcal{A}(w)$ of a word w in $\mathcal{A}$ is the sum of all runs with label w. The behaviour of $\mathcal{A}$ is the series $\sum_{w \in A^*} \mathcal{A}(w)w$. We say that $\mathcal{A}$ *realizes* the series s if s is the behaviour of $\mathcal{A}$. Like regular languages are the behaviour of NFA, by the Kleene-Schützenberger Theorem [15], $\mathbb{Q}$-rational series are the behaviour of one-way $\mathbb{Q}$-automata.

In the sequel, it will be useful to consider automata with particular properties.

▶ **Lemma 3.** *Every $\mathbb{Q}$-automaton is equivalent to an automaton with a single initial state with initial weight 1 and such that the weight of every transition is positive.*

Proof. Let $\mathcal{A} = (Q, E, I, T)$ be a $\mathbb{Q}$-automaton. We first show that $\mathcal{A}$ is equivalent to an automaton with a single initial state with initial weight 1. An initial state i is added; for every state q and every letter a, we extend E with $E(i, a, q) = \sum_p I(p).E(p, a, q)$, and T with $T(i) = \sum_p I(p).T(p)$. The automaton $\mathcal{A}' = (Q \cup \{i\}, E, \chi_i, T)$, where χ_i is the characteristic function of i, is then equivalent to $\mathcal{A}$.
We assume now that $\mathcal{A} = (Q, E, \chi_i, T)$ has a single initial state with initial weight 1. We define $\mathcal{B} = (Q \times \{-1, 1\}, E', \chi_{(i,1)}, T')$ such that, for every p, q in Q, every letter a, and every i, j in $\{-1, 1\}$,

$$E'((p,i),a,(q,j)) = \begin{cases} i.j.E(p,a,q) & \text{if } i.j.E(p,a,q) > 0, \\ 0 & \text{otherwise;} \end{cases} \qquad T'(p,i) = iT(p). \tag{2}$$

There is a natural bijection between runs of $\mathcal{A}$ and runs of $\mathcal{B}$ such that corresponding runs have the same weights, hence $\mathcal{B}$ is equivalent to $\mathcal{A}$. ◀

3 Hadamard series

3.1 Hadamard operations

We consider now the Hadamard product of two series: if s and t are two series in $\mathbb{Q}\langle\langle A^* \rangle\rangle$, then for every word w in A^*, $\langle s \odot t, w\rangle = \langle s, w\rangle.\langle t, w\rangle$. This product is also called the pointwise product. The neutral for this product is the series where the coefficient of every word is 1; this series is the characteristic series of A^* and is denoted itself A^*. Like in any commutative semiring, the Hadamard product preserves the rationality of series.

▶ **Proposition 4** ([16])**.** *The Hadamard product of two $\mathbb{Q}$-rational series is a $\mathbb{Q}$-rational series.*

This result is constructive (*cf.* for instance [13]): if two rational series are realized by two $\mathbb{Q}$-automata, their Hadamard product is realized by the *direct product* of the $\mathbb{Q}$-automata. As usual, the Hadamard power of a series can be defined from the Hadamard product. The 0-th Hadamard power of every series is the neutral for the Hadamard product, that is A^*. If

s is a series with each coefficient in $]-1;1[$, then the sum of the Hadamard powers of s is defined; it is called the Hadamard iteration of s and denoted $s^{\circledast}$.

Likewise, if the support of s is full, the Hadamard inverse of s is defined, and for every series t, the Hadamard quotient of t by s is defined as

$$\forall w \in A^*,\ \langle \odot\frac{t}{s}, w\rangle = \frac{\langle t, w\rangle}{\langle s, w\rangle}. \tag{3}$$

With this notation, the *Hadamard inverse* of s is $\odot\frac{A^*}{s}$.

▶ **Definition 5.** The set $\mathbb{Q}\mathrm{Had}A^*$ of Hadamard series over $\mathbb{Q}$ is the set of series which are equal to the Hadamard quotient of two rational series.

The set of Hadamard series is closed under sum and Hadamard product:

$$\odot\frac{t}{s} \odot \odot\frac{t'}{s'} = \odot\frac{t \odot t'}{s \odot s'}, \qquad \odot\frac{t}{s} + \odot\frac{t'}{s'} = \odot\frac{t \odot s' + t' \odot s}{s \odot s'}. \tag{4}$$

If x is a rational number in $]-1;1[$, the sum of powers of x is a rational number $x^* = (1-x)^{-1}$. Since the Hadamard product is a pointwise operation, this extends to formal power series: if every coefficient of a series s is in $]-1;1[$, then

$$s^{\circledast} = \odot\frac{A^*}{A^* - s}. \tag{5}$$

Therefore, series generated from rational series using sum, Hadamard product, and Hadamard iteration are Hadamard series.
Conversely, the Hadamard inverse can also be computed from the Hadamard iteration. To this end, for every rational number λ, we define $\mathsf{Geom}(\lambda)$ as the series over A^* such that, for every word w, $\langle \mathsf{Geom}(\lambda), w\rangle = \lambda^{|w|+1}$.

▶ **Lemma 6.** *Let t be a $\mathbb{Q}$-rational series such that, for every word w, $\langle t, w\rangle > 0$.*[1] *There exists a positive rational number λ such that $t' = A^* - t \odot \mathsf{Geom}(\lambda)$ is a $\mathbb{Q}_+$-rational series where every coefficient is in $[0;1[$.*

Proof. By Lemma 3, there exists a $\mathbb{Q}$-automaton $\mathcal{A} = (Q, E, I, T)$ that realizes t, with a single initial state i with weight 1 and positive transitions.

Let $M = \max(\max_{p,a} \sum_q E(p,a,q), \max_p T(p))$ and $\lambda = 1/M$. We define $\mathcal{B} = (Q \cup \{\bot\}, E', I, T')$, where $\bot$ is a fresh state and, for every p, q in $Q \cup \{\bot\}$ and every letter a,

$$E'(p,a,q) = \begin{cases} E(p,a,q).\lambda & \text{if } p,q \in Q, \\ 1 - \sum_{r \in Q} E(p,a,r).\lambda & \text{if } p \in Q \text{ and } q = \bot, \\ 1 & \text{if } p = q = \bot, \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

Depending on T', the automaton $\mathcal{B}$ may realize different series:

[1] In particular, t has full support.

(a) $T'(p) = T(p).\lambda$ for every p in Q and $T'(\bot) = 0$; then there is a natural bijection between runs of $\mathcal{B}$ and runs of $\mathcal{A}$; the weight of each run with label w in $\mathcal{B}$ is equal to the weight of the corresponding run in $\mathcal{A}$ multiplied by $\lambda^{|w|+1}$. Hence $\langle \mathcal{B}, w\rangle = \langle t, w\rangle.\lambda^{|w|+1}$.

(b) $T'(p) = 1$ for every p in $Q \cup \{\bot\}$; for every letter a and every state p, the sum of weights of outgoing transitions from p with label a is equal to 1. As there is only one initial state with weight 1, the weight of every word in $\mathcal{B}$ is 1.

(c) $T'(p) = 1 - T(p).\lambda$ for every p in Q and $T'(\bot) = 1$. In this case, the behaviour is the difference between the two previous behaviours and $\langle \mathcal{B}, w\rangle = 1 - \langle t, w\rangle.\lambda^{|w|+1}$, which is in $[0; 1[$.

In the last case, every weight in $\mathcal{B}$ is positive; hence $\mathcal{B}$ is a $\mathbb{Q}_+$-automaton which realizes a $\mathbb{Q}_+$-rational series. ◀

▶ **Proposition 7.** *For every $\mathbb{Q}$-rational series s with full support, there exists a positive rational number λ such that the Hadamard iteration of $A^* - s \odot s \odot \mathsf{Geom}(\lambda)$ is defined and*

$$\odot\frac{A^*}{s} = (A^* - s \odot s \odot \mathsf{Geom}(\lambda))^{\circledast} \odot s \odot \mathsf{Geom}(\lambda). \tag{7}$$

Proof. If s is a $\mathbb{Q}$-rational series with full support, $t = s \odot s$ is also rational with positive coefficients. Hence, by Lemma 6, there exists λ such that $1 - \langle s, w\rangle^2.\lambda^{|w|+1}$ is in $[0; 1[$ for every word w, and

$$(A^* - t \odot \mathsf{Geom}(\lambda))^{\circledast} \odot s \odot \mathsf{Geom}(\lambda) = \odot\frac{A^*}{t \odot \mathsf{Geom}(\lambda)} \odot s \odot \mathsf{Geom}(\lambda) = \odot\frac{A^*}{s}. \tag{8}$$

◀

Finally, our definition of Hadamard series is consistent with the definition of [4]:

▶ **Corollary 8.** *$\mathbb{Q}\mathrm{Had}A^*$ is the closure of $\mathbb{Q}\mathrm{Rat}A^*$ under Hadamard product, sum, and Hadamard iteration.*

▶ **Proposition 9.** *There exist $\mathbb{Q}$-Hadamard series which are not rational.*

Proof. Let t be the series such that, for every k in $\mathbb{N}$, $\langle t, a^k\rangle = k + 1$. It is a rational series: $t = a^*.a^*$. Let s be the Hadamard inverse of t: for every k in $\mathbb{N}$, $\langle s, a^k\rangle = \frac{1}{k+1}$. The coefficients of a rational series over one variable satisfy a linear recurrence relation (*cf.* for instance [2]). Therefore s is not rational. ◀

▶ **Proposition 10.** *The set $\mathbb{Q}\mathrm{Had}A^*$ is not closed under Cauchy product.*

Proof. Let s be the series defined in the proof of Proposition 9. We consider the Cauchy product of s with itself; for large integers k, it holds:

$$\langle s.s, a^k\rangle = \frac{2}{k+2}\sum_{i=0}^{k}\frac{1}{i+1} \sim \frac{2\ln k}{k}. \tag{9}$$

If $s.s$ is a Hadamard series, it is the Hadamard quotient of two rational series x and y. If x (*resp.* y) is rational, its coefficients satisfy a linear recurrence relation. The ratio of $\langle x, a^k\rangle$ and $\langle y, a^k\rangle$ can not be equivalent to $\frac{2\ln k}{k}$. ◀

▶ Remark. By Lemma 6, if a series is the Hadamard quotient of two $\mathbb{Q}_+$-rational series, it is also in the closure of $\mathbb{Q}_+\mathrm{Rat}A^*$ under sum, Hadamard product and Hadamard iteration.

Nevertheless, it is unknown whether a series in this closure is always the Hadamard quotient of two $\mathbb{Q}_+$-rational series.

3.2 Validity and equivalence

Rational series over $\mathbb{Q}$ are represented by rational expressions. It is well known that such an expression may be non valid if the star operator is applied to a subexpression whose interpretation is a series s on which the star is not defined. Nevertheless, the star can be applied if and only if the constant term of s is in $]-1;1[$; this condition is decidable on rational expressions; thus it is decidable whether a rational expression is valid.

There are two ways to describe $\mathbb{Q}$-Hadamard series. First, a $\mathbb{Q}$-Hadamard series is a quotient of s by t where s and t are two $\mathbb{Q}$-rational series; hence, it can be described as a pair of rational expressions. Such a representation is valid if and only if both rational expressions are valid and t has full support.

It is undecidable whether a $\mathbb{Q}$-rational series has full support (*cf.* [2, 13]). Notice that it is decidable whether a $\mathbb{Q}_+$-rational series has full support.

▶ **Proposition 11.** *It is undecidable whether the representation of a $\mathbb{Q}$-Hadamard series as a pair of $\mathbb{Q}$-rational series is valid.*
If the denominator series is $\mathbb{Q}_+$-rational, the validity of the representation is decidable.

Another description of $\mathbb{Q}$-Hadamard series consists in the application of pointwise operators (sum, Hadamard product, Hadamard iteration) to $\mathbb{Q}$-rational expressions. This leads to $\mathbb{Q}$-Hadamard expressions as defined in [4]. The validity of $\mathbb{Q}$-Hadamard expressions is undecidable, as well as the validity of $\mathbb{Q}_+$-Hadamard expressions.

▶ **Proposition 12.** *It is undecidable whether a $\mathbb{Q}_+$-Hadamard expression is valid.*

Proof. It is undecidable whether a probabilistic automaton with weights in $\{0; \frac{1}{2}; 1\}$ accepts some word with a probability larger than or equal to $\frac{1}{2}$ [10]. Let s be the $\mathbb{Q}_+$-rational series which is the behaviour of this automaton. It is undecidable whether $(2s)^{\circledast}$ is defined. ◀

Assume now that $h_1 = (s_1, t_1)$ and $h_2 = (s_2, t_2)$ are two valid representations of $\mathbb{Q}$-Hadamard series as pairs of $\mathbb{Q}$-rational series. Then h_1 and h_2 represent the same series if and only if $s_1 \odot t_2 = s_2 \odot t_1$. The Hadamard product of two $\mathbb{Q}$-rational series is a computable $\mathbb{Q}$-rational series (Prop. 4), and the equivalence of $\mathbb{Q}$-rational series is decidable (*cf.* [2, 13]).

If $\mathbb{Q}$-Hadamard series are described by $\mathbb{Q}$-Hadamard expressions, these descriptions can be converted into pairs of $\mathbb{Q}$-rational series. Actually, using Equations (4) and (5), every $\mathbb{Q}$-Hadamard expression can be turned into a pair of expressions which are combinations of $\mathbb{Q}$-rational expressions connected with sum and Hadamard product operators. Each of these expressions denotes a $\mathbb{Q}$-rational series.

▶ **Theorem 13.** *The equivalence of valid descriptions of $\mathbb{Q}$-Hadamard series is decidable.*

3.3 Extension to real and complex numbers

All results presented in this section apply directly to series over $\mathbb{R}$, up to the calculability of operations with real numbers.

To apply them on series over $\mathbb{C}$, we need to consider the complex conjugacy. The conjugacy commutes with rational operations; hence, if s is a $\mathbb{C}$-rational series, its complex conjugacy $\overline{s}$ is also a $\mathbb{C}$-rational series. Thus, Proposition 7 can be extended.

▶ **Proposition 14.** *For every $\mathbb{C}$-rational series s with full support, there exists a positive real number λ such that the Hadamard iteration of $A^* - s \odot \overline{s} \odot \mathsf{Geom}(\lambda)$ is defined and*

$$\odot\frac{A^*}{s} = (A^* - s \odot \overline{s} \odot \mathsf{Geom}(\lambda))^{\circledast} \odot \overline{s} \odot \mathsf{Geom}(\lambda). \tag{10}$$

Actually, $s \odot \overline{s}$ is a $\mathbb{C}$-rational series whose coefficients are positive real numbers, hence, it is a $\mathbb{R}$-rational series [6] and Lemma 6 applies.

4 Weighted rotating automata

A rotating $\mathbb{Q}$-automaton is a $\mathbb{Q}$-automaton that can read its input from left to right several times. To this end, it is endowed with transitions with a special label $\mathbf{r}$, which is not in A.

A run of a rotating $\mathbb{Q}$-automaton is accepting for a word w in A^* if the label of the run is in $(w\mathbf{r})^*w$.

For every word w, if the sum of the weights of the accepting runs for w is defined, the weight $\mathcal{A}(w)$ of w in $\mathcal{A}$ is equal to this sum. The automaton is *valid* if the weight of every word in A^* is defined.

▶ Remark. Every one-way $\mathbb{Q}$-automaton over an alphabet A can be considered as a rotating $\mathbb{Q}$-automaton without any transition with label $\mathbf{r}$. In this case, every run accepting a word w has label w, hence, its behaviour as a rotating $\mathbb{Q}$-automaton is the same as its behaviour as a one-way $\mathbb{Q}$-automaton.

▶ **Proposition 15.** *The behaviour of a valid rotating $\mathbb{Q}$-automaton is a $\mathbb{Q}$-Hadamard series.*

Proof. $\mathbb{Q}_+ \cup \{\infty\}$ is a *rationally additive semiring*: the star of every element is defined. By [9], every rotating $(\mathbb{Q}_+ \cup \{\infty\})$-automaton realizes a Hadamard series. Thus every valid rotating $\mathbb{Q}_+$-automaton realizes a $\mathbb{Q}$-Hadamard series. If $\mathcal{A}$ is a valid rotating $\mathbb{Q}$-automaton, its behaviour s can be split into $s = s_+ - s_-$, where s_+ and s_- are realized by rotating $\mathbb{Q}_+$-automata. This construction is similar to the one described in the proof of Lemma 3. Since s_+ and s_- are $\mathbb{Q}$-Hadamard series, the behaviour of $\mathcal{A}$ is a $\mathbb{Q}$-Hadamard series. ◀

▶ Remark. In the definition of validity, it is not assumed that the potentially infinite sums of weights are in $\mathbb{Q}$ (they might be in $\mathbb{R}$); it appears that these sums can be computed through the rational operations (sum, product and star), hence, if they are defined, they belong to $\mathbb{Q}$.

▶ Remark. Clearly, Proposition 15 extends to $\mathbb{R}$. It also holds for rotating $\mathbb{C}$-automata. Using a construction similar to the construction in the proof of Lemma 3 (with $Q' = Q \times \{-1, 1, i, -i\}$), one shows that every series s with coefficients in $\mathbb{C}$ can be split into four series with positive real coefficients: $s = s_{\mathrm{re}+} - s_{\mathrm{re}-} + i.s_{\mathrm{im}+} - i.s_{\mathrm{im}-}$.

The following proposition is a corollary of Proposition 15 and Theorem 13, since every rotating $\mathbb{Q}$-automaton can be turned into a $\mathbb{Q}$-Hadamard expression.

▶ **Proposition 16.** *The equivalence of valid rotating $\mathbb{Q}$-automata is decidable.*

We prove now that every $\mathbb{Q}$-Hadamard series can be realized by a rotating $\mathbb{Q}$-automaton. If two automata $\mathcal{A}$ and $\mathcal{B}$ respectively realize series s and t, it is straightforward that the union of $\mathcal{A}$ and $\mathcal{B}$ realizes the series $s + t$. Likewise, $s \odot t$ is realized by the automaton $\mathcal{A} \odot \mathcal{B}$ based on the union of $\mathcal{A}$ and $\mathcal{B}$, where

- for every final state p of $\mathcal{A}$ and every initial state q of $\mathcal{B}$ there is a transition with label $\mathbf{r}$ and weight $T_{\mathcal{A}}(p)I_{\mathcal{B}}(q)$;
- the initial function is restricted to states of $\mathcal{A}$ and the final function to states of $\mathcal{B}$.

In order to realize $s^{\circledast}$, a similar construction could be applied to $\mathcal{A}$ by adding transitions with label $\mathbf{r}$ from final states to initial states. This construction may lead to an infinite number of runs accepting a given word w, and, even if the weight of w is in $]-1; 1[$, there is no guarantee that the sum of all these runs is defined. Therefore, we consider that $\mathbb{Q}$-Hadamard series are Hadamard quotients of $\mathbb{Q}$-rational series and we prove that such a quotient can be realized by a rotating $\mathbb{Q}$-automaton.

▶ **Proposition 17.** *Let s be a $\mathbb{Q}$-rational series with full support. There exists a valid rotating $\mathbb{Q}$-automaton $\mathcal{A}$ such that the behaviour of $\mathcal{A}$ is the Hadamard inverse of s.*

Proof. By Lemma 6, there exists a positive rational number λ such that $t = A^* - s \odot s \odot \mathsf{Geom}(\lambda)$ is a series with coefficients in $[0;1[$ that can be realized by a $\mathbb{Q}_+$-automaton $\mathcal{A} = (Q, E, I, T)$. Without loss of generality, we assume that $\mathcal{A}$ has a single initial state i with weight 1. Let $\mathcal{B}$ be the rotating $\mathbb{Q}$-automaton built from $\mathcal{A}$ by:

- adding a transition from each final state p to state i with label $\mathbf{r}$ and weight $T(p)$;
- adding a new state $\perp$, which is initial and final with weight 1, and such that there is a loop on the state with weight 1 for every label except $\mathbf{r}$.

Every run with label w in $\mathcal{B}$ is either a circuit in $\perp$ with weight 1, or a concatenation of runs in $\mathcal{A}$ (glued with $\mathbf{r}$-transitions). The weight of every run in $\mathcal{A}$ is positive and for every word w, the sum of the weights of all runs with label w in $\mathcal{A}$ is smaller than 1. Hence, the weight of w in $\mathcal{B}$ is defined: it is the star of the weight of w in $\mathcal{A}$. Therefore, $\mathcal{B}$ is valid and its behaviour is $(A^* - s \odot s \odot \mathsf{Geom}(\lambda))^{\circledast} = \odot\frac{A^*}{s \odot s \odot \mathsf{Geom}(\lambda)}$. It is then easy to build a rotating automaton that realizes $(A^* - s \odot s \odot \mathsf{Geom}(\lambda))^{\circledast} \odot s \odot \mathsf{Geom}(\lambda) = \odot\frac{A^*}{s}$. ◀

▶ **Theorem 18.** *The set of series which are behaviours of valid rotating $\mathbb{Q}$-automata is the set of $\mathbb{Q}$-Hadamard series.*

Rotating $\mathbb{Q}$-automata and $\mathbb{Q}$-Hadamard expressions are therefore equivalent. Proof of Proposition 11 applies on rotating $\mathbb{Q}$-automata and their validity is therefore undecidable.

▶ **Proposition 19.** *The validity of a rotating $\mathbb{Q}$-automaton is undecidable.*

A sweeping $\mathbb{Q}$-automaton is an automaton that can read its input from left to right and right to left, but can only change the direction of the reading head on one of the endmarkers. Every rotating $\mathbb{Q}$-automaton can be simulated by a sweeping $\mathbb{Q}$-automaton. Conversely, like in any commutative semiring, sweeping $\mathbb{Q}$-automata can be simulated by rotating $\mathbb{Q}$-automata.

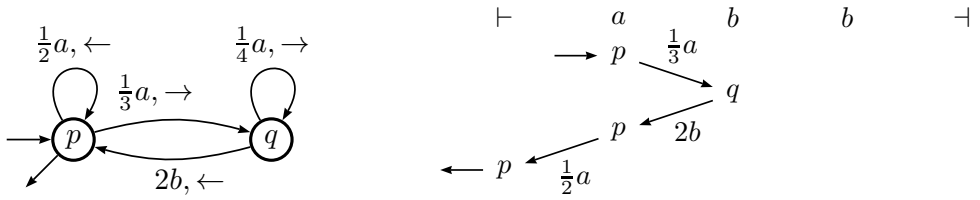
Hence, the validity of sweeping $\mathbb{Q}$-automata is undecidable, but the equivalence of valid sweeping $\mathbb{Q}$-automata is decidable.

5 From two-way to rotating automata

In this section, we formally define two-way $\mathbb{Q}$-automata and we show that they can be simulated by rotating $\mathbb{Q}$-automata. The proof presented here is inspired by the work in [1] on two-way probabilistic automata. Starting with a two-way $\mathbb{Q}$-automaton, for every word w, we define a matrix M_w such that the weight of w in the two-way $\mathbb{Q}$-automaton is an entry of M_w^*, the sum of iterated powers of M_w. We show that since M_w^* is the inverse of $\mathsf{Id} - M_w$, the weight of w can be computed as the ratio of an entry of the matrix of cofactors of $\mathsf{Id} - M_w$ by the determinant of $\mathsf{Id} - M_w$. We prove that both the entry of the matrix of cofactors and the determinant are rational power series (when w spans over A^*), therefore the behaviour of the two-way $\mathbb{Q}$-automaton is the Hadamard quotient of two rational series, *i.e.* a Hadamard series.

5.1 Weighted two-way automata

There are different models of two-way automata. If reading the left and right endmarks is allowed, they are all equivalent; depending on the model, the computation can start (*resp.* stop) at the beginning, the middle or the end of the word, and the move of the reading head can be performed in each state or during each transition traversal.



(a) The automaton $\mathcal{A}_1$. **(b)** A run over the word *abb*.

Figure 1 A two-way automaton and one run over the word *abb*.

For convenience in the conversion from two-way $\mathbb{Q}$-automata to rotating $\mathbb{Q}$-automata, we use in this paper two-way $\mathbb{Q}$-automata where computations start and stop at the left end of the word.

Formally, if A is an alphabet, a two-way $\mathbb{Q}$-automaton over A is a tuple $\mathcal{A} = (Q, E, I, T)$, where

- Q is the finite set of *states*;
- E is the *transition* function: $Q \times (A \cup \{\vdash, \dashv\} \times Q \longrightarrow \mathbb{Q}$;
- I and T are respectively the initial and final functions in $Q \longrightarrow \mathbb{Q}$.

A transition is an element t of $Q \times (A \cup \{\vdash, \dashv\} \times Q$ such that $E(t)$ is different from 0. Likewise a state p is initial if $I(p) \neq 0$; it is final if $T(p) \neq 0$.

The value in $\{-1, +1\}$ on each transition shows the direction of the move of the head of the automaton on the current letter. If it is equal to $+1$, the head moves forward and we can denote it by $\rightarrow$, if it is equal to -1, the head moves backward and it can be denoted $\leftarrow$. There is no transition with backward move and label $\vdash$; likewise, there is no transition with forward move and label $\dashv$.

A *path* compatible with a word $w = w_1 \dots w_k$ in A^* is a sequence of consecutive transitions $\rho = (p_{i-1}, x_i, m_i, p_i)_{i \in [\![1;\ell]\!]}$ such that there exists a function $\mathsf{pos} : [\![0;\ell]\!] \longrightarrow [\![0; k+1]\!]$ satisfying

- for every $i > 0$, $\mathsf{pos}(i) = \mathsf{pos}(i-1) + m_i$;
- for every $i \in [\![1;\ell]\!]$, if $\mathsf{pos}(i-1) = 0$, $x_i = \vdash$, and if $\mathsf{pos}(i-1) = k+1$, $x_i = \dashv$, otherwise $x_i = w_{\mathsf{pos}(i-1)}$.

If furthermore, p_0 is initial, $\mathsf{pos}(0) = 1$, p_ℓ is final, and $\mathsf{pos}(\ell) = 0$, then ρ is a *run* (over w).

The weight of such a run is $I(p_0).\left(\prod_{i=1}^{\ell} E(p_{i-1}, x_i, m_i, p_i)\right).T(p_\ell)$.

Notice that with this model, a run over the empty word w can exist; it contains at least one transition. For instance, if p is an initial state, q a final state and $(p, \dashv, \leftarrow, q)$ is a transition, there is a run over the empty word formed with this single transition.

The *weight* computed by $\mathcal{A}$ on a word w in A^* is the sum (if defined) of the weights of all runs over w. The automaton $\mathcal{A}$ is valid if for every word w, the sum of the weights of runs over w is defined.

▶ **Example 20.** Let $\mathcal{A}_1$ be the two-way automaton of Figure 1a. A run of this automaton over the word *abb* is described in Figure 1b; it is the path $(p, a, \rightarrow, q)(q, b, \leftarrow, p)(p, a, \leftarrow, p)$: it starts at position 1 in an initial state, and ends at position 0 in a final state.

We use a classical extension of the model of adjacency matrices for graphs. We suppose from now that $Q = [\![1; n]\!]$ where n is a positive integer. For every letter a in $A \cup \{\vdash, \dashv\}$ we define $F(a)$ (*resp.* $B(a)$) as the matrix of size $n \times n$ such that $F(a)_{p,q} = E(p, a, \rightarrow, q)$ (*resp.* $B(a)_{p,q} = E(p, a, \leftarrow, q)$).

These matrices represent paths of length 1. In graphs or one-way automata, paths of length k are represented by the k-th power of the adjacency matrix. In the case of a two-way automaton, the position of the head (given by the function pos) must be taken into account, and since there may exist runs with arbitrary large length for a given input, all the powers of the suitable matrix must be considered.

To this end, we define the star of a (square) matrix M as the (infinite) sum of its powers, if it is defined. It satisfies $M^* = \mathsf{Id} + M.M^*$, where Id is the identity matrix, and it can be inductively computed (cf [3]):

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix}^* = \begin{bmatrix} (A^*BD^*C)^*A^* & A^*(BD^*CA^*)^*BD^* \\ D^*C(A^*BD^*C)^*A^* & D^* + D^*CA^*(BD^*CA^*)^*BD^* \end{bmatrix}. \tag{11}$$

We fix from now w as a word with length k: $w = w_1 \dots w_k$. To study paths involved in the runs over w, we consider block matrices with dimension $(k+2) \times (k+2)$ where every entry is itself a $n \times n$ matrix. We assume that indices of blocks are integers in $[\![0; k+1]\!]$. If X is such a matrix, $X_{i,j}$ is a matrix and $(X_{i,j})_{p,q}$ represents some subpaths of runs over w which start in position i and state p, and end in position j and state q.

We first consider the matrix M_w that represents subpaths of runs over w with length 1:

$$M_w = \left[\begin{array}{c|c|ccc} 0 & F(\vdash) & 0 & \dots & 0 \\ \hline B(w_1) & 0 & F(w_1) & \dots & \vdots \\ \hline 0 & B(w_2) & \ddots & \ddots & 0 \\ \vdots & \vdots & \ddots & 0 & F(w_k) \\ \hline 0 & \dots & 0 & B(\dashv) & 0 \end{array}\right]. \tag{12}$$

During the computation, if the automaton reads the letter w_i (in position i) and follows a forward transition, the head moves to position $i+1$. Hence, for every i, the matrix $F(w_i)$ is the block $(i, i+1)$ of M_w; likewise the matrix $B(w_i)$ is the block $(i, i-1)$, $F(\vdash)$ is the block $(0, 1)$, and $B(\dashv)$ is the block $(k+1, k)$.

We show that $(M_w^*)_{i,j}$ represent all the subpaths of runs over w which start in position i and end in position j.

For r in $[\![0; k+1]\!]$, let $C^{(r)}$ be the $(r+1) \times (r+1)$ block matrix where $C^{(r)}_{i,j}$ is a $n \times n$ matrix such that the entry at position (p, q) is the sum of the weights of the paths compatible with w from position i and state p to position j and state q with no position larger than r.

▶ **Lemma 21.** *With the notations above, $M_w^* = C^{(k+1)}$.*

The proof is by induction on k and on the star of the restriction of M_w to the $k+1$ first row blocks and the $k+1$ column blocks.

On a two-way automaton, the initial and final functions can respectively be seen as row and column vectors in $\mathbb{Q}^n$. We let L_i denote the $1 \times (k+1)$ block matrix where every block is null, except the i-th block, which is the identity matrix. Proposition 22 follows then from Lemma 21:

▶ **Proposition 22.** *The weight of w computed by $\mathcal{A}$ is equal to $I.L_2.M_w^*.{}^tL_1.T$.*

If $\mathcal{A}$ is valid, the star of M_w is defined for every word w, hence $\mathsf{Id} - M_w$ is invertible. Otherwise, there would exist a non zero vector v such that $M_w.v = v$; since M_w^* is defined, $M_w^*.v = (\mathsf{Id} + M_w^*.M_w).v = v + M_w^*.v$, and $v = 0$ which is a contradiction. Therefore, for every word w,

$$\langle \mathcal{A}, w\rangle = I.L_2.(\mathsf{Id} - M_w)^{-1}.{}^tL_1.T = \frac{1}{\det(\mathsf{Id} - M_w)} \sum_{p,q\in Q} I_p.(\operatorname{adj}(\mathsf{Id} - M_w))_{n+p,q}.T_q, \quad (13)$$

where $\operatorname{adj}(X)$ is the adjugate matrix of X and $\det(X)$ is the determinant of X. For every p, q in Q, let $\alpha_{p,q}$ be the series defined by $\langle \alpha_{p,q}, w\rangle = (\operatorname{adj}(\mathsf{Id} - M_w))_{n+p,q}$ and let δ be the series defined by $\langle \delta, w\rangle = \det(\mathsf{Id} - M_w)$. We show in the next part that all these series are $\mathbb{Q}$-rational.

5.2 Inductive computation of a determinant of a tridiagonal block matrix

Inductive computations of determinants of tridiagonal block matrices have already been studied [14]. We give here a new presentation of this computation in order to show that it can be realized by a (one-way) $\mathbb{Q}$-automaton.

Let n and k be two positive integers. We consider two families $(A_i)_{i\in[\![1;k]\!]}$ and $(A'_i)_{i\in[\![0;k]\!]}$ of matrices in $\mathbb{Q}^{n\times n}$.

For every r in $[\![0;k]\!]$, we consider the matrix $N^{(r)}$ in $\mathbb{Q}^{(r+1)n\times(r+2)n}$ defined as:

$$N^{(r)} = \begin{bmatrix} A'_r & \mathsf{Id}_n & A_r & & & 0 \\ 0 & A'_{r-1} & \mathsf{Id}_n & A_{r-1} & & \\ & & \ddots & \ddots & \ddots & \\ & & & A'_1 & \mathsf{Id}_n & A_1 \\ 0 & & & & A'_0 & \mathsf{Id}_n \end{bmatrix}, \quad (14)$$

where Id_n is the identity matrix with size n.

We introduce now some notations.

- For every set X and every positive integer i, $\mathcal{P}_iX$ denotes the set of subsets of X with i elements.
- If M is a matrix, the determinant of M is denoted $|M|$.
- If X is a set of indices, $\overline{X}$ is its complementary set, and ΣX is the sum of elements of X.
- If X and Y are two subsets of indices of a matrix M, $M_{X\times Y}$ is the restriction of M to rows in X and columns in Y.
- For every C in $\mathcal{P}_n[\![1;2n]\!]$, we let $G^{(r)}(C)$ denote the square matrix $N^{(r)}_{[\![1;(r+1)n]\!]\times\overline{C}}$.
- For every C, D in $\mathcal{P}_n[\![1;2n]\!]$,

$$K^{(r)}(C,D) = \begin{bmatrix} A'_r & \mathsf{Id}_n & A_r & 0 \\ 0 & A'_{r-1} & \mathsf{Id}_n & A_{r-1} \end{bmatrix}_{[\![1;2n]\!]\times(\overline{C}\cap[\![1;2n]\!])\cup(D+2n)}. \quad (15)$$

▶ **Lemma 23.** *For every $r \in [\![2;k]\!]$, for every C in $\mathcal{P}_n[\![1;2n]\!]$,*

$$\left|G^{(r)}(C)\right| = \sum_{D\in\mathcal{P}_n[\![1;2n]\!]} (-1)^{\mathsf{sig}(D+n)}.\left|K^{(r)}(C,D)\right|.\left|G^{(r-2)}(D)\right| \quad (16)$$

where $\mathsf{sig}(D+n) = \dfrac{n(n+1)}{2} + \Sigma D$.

The proof is an application of the Laplace expansion of the determinant:

$$\forall N \in \mathbb{Q}^{d\times d}, \forall X \subseteq [\![1;d]\!], \qquad |N| = \sum_{Y\in\mathcal{P}_{|X|}[\![1;d]\!]} (-1)^{\Sigma X+\Sigma Y} \, |N_{X\times Y}| \, . \left|N_{\overline{X}\times\overline{Y}}\right| . \tag{17}$$

We apply now Lemma 23 to the computation of the determinant of $\mathsf{Id} - M_w$. For every matrix X, we let ${}^{\circlearrowleft}X$ denote the rotation of X by half-turn; notice that $|X| = |{}^{\circlearrowleft}X|$. For every word $w = w_1 \dots w_k$, we set $A_0 = -{}^{\circlearrowleft}B(\dashv)$, $A'_{k+1} = -{}^{\circlearrowleft}F(\vdash)$, $A_i = -{}^{\circlearrowleft}B(w_i)$, and $A'_i = -{}^{\circlearrowleft}F(w_i)$, for every i in $[\![1;k]\!]$, then $G^{(k+1)}([\![1;n]\!])$ is equal to ${}^{\circlearrowleft}(\mathsf{Id} - M_w)$.

5.3 The transformation automaton

We describe the (one-way) automaton that computes $\det(\mathsf{Id} - M_w)$, based on the induction described in Lemma 23. The set of states is $\{i\} \cup \mathcal{P}_n[\![1;2n]\!] \cup A \times \mathcal{P}_n[\![1;2n]\!]$. The order of the induction is 2; there are two different kinds of initial states, depending on the parity of the length of the input.

- State i is initial with weight 1 and, for every D in $\mathcal{P}_n[\![1;2n]\!]$ and every a in A, there is a transition from i to D with label a and weight

$$\left|\begin{bmatrix} -{}^{\circlearrowleft}F(a) & \mathsf{Id}_n & -{}^{\circlearrowleft}B(a) \\ 0 & -{}^{\circlearrowleft}F(\vdash) & \mathsf{Id}_n \end{bmatrix}_{[\![1;2n]\!]\times\overline{D}}\right| . \tag{18}$$

- For every D in $\mathcal{P}_n[\![1;2n]\!]$, D is initial with weight $\left|\begin{bmatrix} -{}^{\circlearrowleft}F(\vdash) & \mathsf{Id}_n \end{bmatrix}_{[\![1;n]\!]\times\overline{D}}\right|$, and for every a in A, there is a transition from D to (a, D) with label a and weight $(-1)^{\mathsf{sig}(D+n)}$.
- For every C, D in $\mathcal{P}_n[\![1;2n]\!]$ and every a, b in A, there is a transition from (a, D) to C with label b and weight

$$\left|\begin{bmatrix} -{}^{\circlearrowleft}F(b) & I_n & -{}^{\circlearrowleft}B(b) & 0 \\ 0 & -{}^{\circlearrowleft}F(a) & \mathsf{Id}_n & -{}^{\circlearrowleft}B(a) \end{bmatrix}_{[\![1;2n]\!]\times(\overline{C}\cap[\![1;2n]\!])\cup(D+2n)}\right| . \tag{19}$$

- Every state (a, D) is final with weight $\left|\begin{bmatrix} \mathsf{Id}_n & -{}^{\circlearrowleft}B(\dashv) & 0 \\ -{}^{\circlearrowleft}F(a) & \mathsf{Id}_n & -{}^{\circlearrowleft}B(a) \end{bmatrix}_{[\![1;2n]\!]\times([\![1;n]\!]\cup D+n)}\right|$.

By Lemma 23, this automaton computes $\det(\mathsf{Id} - M_w)$ for every word w; it realizes the series δ which is thus $\mathbb{Q}$-rational.

Likewise, for every p, q in $[\![1;n]\!]$, $(\mathrm{adj}(\mathsf{Id} - M_w))_{p+n,q}$ is equal to the determinant of $C_w^{(q,p+n)}$, which is the matrix $\mathsf{Id} - M_w$ where every coefficient of the q-th row and every coefficient of the $p+n$-th column is replaced by 0, except the coefficient in $(q, p+n)$ which is replaced by 1. The determinant of $C_w^{(q,p+n)}$ can be computed with the same induction as for $\det(\mathsf{Id} - M_w)$ with different initial conditions.

Hence, for every p, q in Q, the series $\alpha_{p,q}$ is rational; so is the series $\alpha = \sum_{p,q\in Q} I_p.\alpha_{p,q}.T_p$. Finally, the series realized by the two-way $\mathbb{Q}$-automaton is the Hadamard quotient of two rational series. It is therefore a Hadamard series that can be realized by a rotating $\mathbb{Q}$-automaton.

▶ **Theorem 24.** *The set of series realized by two-way $\mathbb{Q}$-automata is exactly the set $\mathbb{Q}\mathrm{Had}A^*$ of series realized by rotating $\mathbb{Q}$-automata.*

Notice that the conversion of two-way $\mathbb{Q}$-automata to rotating $\mathbb{Q}$-automata is effective, hence the decidability of equivalence of rotating $\mathbb{Q}$-automata extends to two-way $\mathbb{Q}$-automata.

▶ **Theorem 25.** *The equivalence of valid two-way $\mathbb{Q}$-automata is decidable.*

6 Conclusion

The results presented in this paper can be extended to other fields. Section 5 actually shows that the behaviour of a two-way automaton over a field is the Hadamard quotient of two rational series. It extends to any field. Notice that the definition of the behaviour of a two-way automaton involves infinite sums; hence, a structure (topology for instance) is required to handle these sums, and this structure must transfer to matrices to define the star of a matrix.

To show that two-way automata are equivalent to rotating automata, it must be proved that every Hadamard quotient of two rational series can be realized by a rotating automaton (Theorem 18), and Proposition 7 is crucial in this proof. This proposition applies to $\mathbb{Q}$ and $\mathbb{R}$; it can also be used to prove Theorem 18 in $\mathbb{C}$. For other fields, dedicated proofs should be provided.

The conversion from two-way $\mathbb{Q}$-automata to rotating $\mathbb{Q}$-automata heavily relies on the inversion of a matrix describing the computations in the two-way $\mathbb{Q}$-automaton. This inversion is considered as the quotient between some coefficients of the adjugate matrix and the determinant and we exhibit one-way $\mathbb{Q}$-automata that realize this computation. It is still an open question to find a more combinatorial argument to the equivalence between the two models. It could help in characterizing semirings where two-way and rotating automata are equivalent. It could also lead to more efficient algorithms to convert two-way $\mathbb{Q}$-automata into rotating $\mathbb{Q}$-automata or to compute $\mathbb{Q}$-Hadamard expressions of the series they realize.

Abstract

Assume that Alice has a binary string x and Bob a binary string y, both strings are of length n. Their goal is to output 0, if x and y are at least L-close in Hamming distance, and output 1, if x and y are at least U-far in Hamming distance, where $L < U$ are some integer parameters known to both parties. If the Hamming distance between x and y lies in the interval (L, U), they are allowed to output anything. This problem is called the Gap Hamming Distance. In this paper we study public-coin one-sided error communication complexity of this problem. The error with probability at most $1/2$ is allowed only for pairs at Hamming distance at least U. In this paper we determine this complexity up to factors logarithmic in L. The protocol we construct for the upper bound is simultaneous.

1 Communication complexity of GHD

Given two strings $x = x_1 \dots x_n \in \{0,1\}^n$, $y = y_1 \dots y_n \in \{0,1\}^n$, Hamming distance between x and y is defined as the number of positions, where x and y differ:

$$d(x,y) = |\{i \in \{1,\dots,n\} \mid x_i \neq y_i\}|.$$

Let $L < U \leqslant n$ be integer numbers. In this paper we consider the following communication problem $\mathsf{GHD}_{L,U}$, called the Gap Hamming Distance problem:

▶ **Definition 1.** Let Alice receive an n-bit string x and Bob an n-bit string y such that either $d(x,y) \leqslant L$, or $d(x,y) \geqslant U$. They have to output 0, if the first inequality holds, and 1, if the second inequality holds. If the promise is not fulfilled, they may output anything.

1.1 Prior work

1.1.1 Two-sided error upper bounds

Let $R(\mathsf{GHD}_{L,U})$ denote randomized two-sided error public coin communication complexity of $\mathsf{GHD}_{L,U}$. It is known (see [11, 15]) that $R(\mathsf{GHD}_{L,U})) = O(L^2/(U-L)^2)$ (assuming the constant error probability less than 1/2).

The paper [9] established the upper bound $R(\mathsf{GHD}_{L,U}) = O(L \log L)$ in the case $U = L+1$, that is, there is no gap. This bound is much better than $O(L^2/(U-L)^2)$, which is $O(L^2)$ in this case.

It turns out that the protocols attaining these two upper bounds are *simultaneous*. That is, in these protocols Alice and Bob do not communicate at all, but rather send messages to the third party, Charlie, who then computes the output of the protocol. Charlie doesn't see inputs of Alice and Bob but sees public coins. The corresponding model, called simultaneous message passing (SMP) model, is even more restricted than one-way public-coin communication: every simultaneous protocol can be converted into one-way protocol without increasing communication cost.

1.1.2 One-sided error public coin communication protocols

The one-sided error public coin communication complexity will be denoted by R^0. The superscript 0 means that the protocol is allowed to err only for input pairs which are at least U-far in Hamming distance. Here we assume that the maximal probability of error[2] is 1/2 The superscript 1 will mean the opposite: protocols are allowed to err only for input pairs which are at least L-close in Hamming distance.

Let us first note that for all x, y we have

$$\mathsf{GHD}_{L,U}(x,y) = \neg\mathsf{GHD}_{n-U,n-L}(\neg x, y).$$

(Alice flips all bits of her input string.) Thus $\mathsf{GHD}_{L,U}(x,y)$ reduces to $\mathsf{GHD}_{n-U,n-L}$ and the other way around. This reduction maps 0-instances to 1-instances and vice verse. This observation implies that

$$R^1(\mathsf{GHD}_{L,U}) = R^0(\mathsf{GHD}_{n-U,n-L}).$$

Thus it suffices to study only one of these quantities and we will stick to R^0 (the error is allowed when the distance is at least U) .

The paper [8] noticed that for all $U > L$ it holds that $R^0(\mathsf{GHD}_{L,U}) = O(L \log n)$. Once again, there is a public coin SMP protocol attaining this bound (which is just a simple modification of the standard protocol for EQUALITY).

1.1.3 GHD and the lower bounds in data streams and property testing

Several works used GHD to obtain lower bounds for streaming algorithms and for property testing problems. As was discovered in [14] by Woodruff, there is a reduction from GHD to a number of fundamental data stream problems, including the problem of estimating frequency moments. More specifically, if there is a $\Omega(n)$ lower bound against any r-round two-sided error communication protocol for $\mathsf{GHD}_{n/2-\Theta(\sqrt{n}),\ n/2+\Theta(\sqrt{n})}$, then there is a $\Omega(1/(r\varepsilon^2))$ lower bound on the space complexity of any r-pass streaming algorithm estimating the frequency moments in a data stream within a factor of $(1+\varepsilon)$.

[2] By the standard amplification argument we could have any constant between 0 and 1 instead of 1/2.

In [14] Woodruff proved $\Omega(n)$ lower bound against 1-round protocols (see also [10] for more direct and simple proof). In a subsequent works ([2, 3]) this lower bound was extended to $O(1)$-round protocols. Finally, $\Omega(n)$ lower bound in the most general setting, when there is no restriction on the number of rounds at all, was obtained in [6, 13, 12].

As it turns out, lower bounds on the one-sided error version of GHD are also useful. In [5] Buhrman, Cleve and Wigderson proved that for any constant $c < 1$ it holds that $R^1(\mathsf{GHD}_{0,\,cn}) = \Omega(n)$. Moreover, they showed that $\Omega(n)$ lower bound holds also for a weaker version of $\mathsf{GHD}_{0,\,cn}$ problem, in which Hamming distance between the inputs is either 0 or *exactly* cn (provided that cn is an even integer).

Blais, Brody and Matulef in [1] used this result to obtain lower bounds on testing decision trees and signed majorities with one-sided error.

Further, Brody and Woodruff ([4]) used lower bound on one-sided error GHD from [5] to obtain lower bounds for streaming algorithms with *one-sided approximation*, i.e., for algorithms which either always return an overestimate or always return an underestimate on the objective function. Their results include lower bounds for the problem of over(under)-estimating the number of non-zero rows in a matrix and the Earth Mover Distance between two multisets.

1.2 This work

In this paper we study public-coin one-sided error communication complexity R^0 of $\mathsf{GHD}_{L,U}$. Once again, the error is allowed only for pairs at Hamming distance at least U.

1.2.1 The upper bound

Our main result is a one-sided error public-coin simultaneous protocol for $\mathsf{GHD}_{L,U}$ on n-bit strings with communication complexity $O((L^2/U)\log L)$. It is constructed in the following 4 steps (description of the protocol in this section is a bit informal, and the precise bounds can be found below in the paper). Let us stress that steps 1 and 2 are enough to obtain $O((L^2/U)\log n)$ solution; the purpose of steps 3 and 4 is to replace $O(\log n)$-factor by $O(\log L)$-factor. Importance of eliminating dependency on n in the upper bounds was also acknowledged in previous works ([15, 9]).

Step 1. On this step we construct our main novel protocol, called *the Triangle Inequality Protocol*. This protocol communicates $O((L^2/U)\log n)$ bits (which is a bit more than required, since $\log L$ is replaced by $\log n$) and solves the $\mathsf{GHD}_{L,U}$ problem when the ratio U/L is larger than a certain constant.

The protocol works as follows. It randomly splits x and y in $b = O(L^2/U)$ blocks $x^1, \ldots, x^b$ and $y^1, \ldots, y^b$. The ith bit x_i of x goes in the block x^j where j is chosen at random with uniform probability distribution over $\{1, \ldots, b\}$, and decisions for different i's are independent. Each bit y_i of y goes in the block y^j with the same index as x_i goes in. This partition is made using the shared random source (so that the parties have the same partition). Both parties also read random strings $r^1, \ldots, r^b$ from the shared random source and Alice communicates $d(x^j, r^j)$ to Charlie for all $j = 1, \ldots, b$. Bob does the same with $d(y^j, r^j)$. Thus the communication is $b \log n = O((L^2/U)\log n)$. Charlie outputs 0 if the sum

$$\sum_{j=1}^{b} |d(x^j, r^j) - d(y^j, r^j)|$$

is at most L and 1 otherwise. By the triangle inequality each term in this sum is at most $d(x^j, y^j)$ and thus the sum is at most $d(x, y)$. Therefore this protocol does not err if $d(x, y) \leqslant L$.

On the other hand, if $d(x, y) \geqslant U \geqslant C'L$ for a certain constant C', then for any fixed j the average value of $d(x^j, y^j)$ is at least 2. From the properties of binomial distributions it follows that we have $d(x^j, y^j) \geqslant d(x, y)/10b$ with probability at least $1/3$. The value $d(x^j, r^j) - d(y^j, r^j)$ is distributed as the distance from the origin in a random walk with $d(x^j, y^j)$ steps along a line (each step has length 1 and is directed to the left or to the right with equal probabilities). From the properties of random walks it follows that for every j we have $|d(x^j, r^j) - d(y^j, r^j)| > \sqrt{d(x^j, y^j)}$ with constant positive probability. These two facts imply that with constant probability the sum $\sum_{j=1}^{b} |d(x^j, r^j) - d(y^j, r^j)|$ is $\Omega(b\sqrt{d(x, y)/10b}) = \Omega(\sqrt{bd(x, y)})$. Recall that $b = O(L^2/U)$ and we assume that $d(x, y) \geqslant U$. If the constant hidden in O-notation is large enough then the lower bound $\Omega(\sqrt{bd(x, y)})$ for the sum $\sum_{j=1}^{b} |d(x^j, r^j) - d(y^j, r^j)|$ is larger than L.

Step 2. In [8] it was noticed that for all $L < U$ there is one-sided error public-coin simultaneous protocol for $\mathsf{GHD}_{L,U}$ with communication $O(L \log n)$. This protocol is just a modification of the standard protocol for equality and it never errs for inputs at distance at most L.

Our second protocol runs the Triangle Inequality Protocol if $U > C'L$ and the protocol from [8] otherwise. Notice that in the latter case $L = O(L^2/U)$, and thus we obtain a protocol with communication $O((L^2/U) \log n)$ for all L, U.

Step 3. On this step we use the techniques from [9] to replace the $\log n$ factor by a $\log L$ factor. More specifically, we run the protocol from the second step for the strings u, v of length $O(L^8)$ obtained from the original strings x, y by the following transformation. As in the Triangle Inequality Protocol, we split x, y into $b = O(L^8)$ blocks and then replace each block by the parity of its bits. Obviously, $d(u, v) \leqslant d(x, y)$. We then show that $d(u, v) = d(x, y)$ with constant probability provided $d(x, y) \leqslant L^4$. Therefore this protocol has constant one-sided error probability for all input pairs with $d(x, y) \leqslant L^4$. By construction this protocol communicates $O((L^2/U) \log L)$ bits.

Step 4. Finally, to handle the case $d(x, y) > L^4$, we consider the following protocol. We run the protocol from step 3 and then a simplified version of the Triangle Inequality Protocol. If any of these two protocols output 1, we output 1 and otherwise 0. The simplified version of the Triangle Inequality Protocol works as follows. Alice and Bob read a random n-bit string r from the shared random source. They compute distance from their inputs to r. Observe that due to triangle inequality $|d(x, r) - d(y, r)| \leqslant d(x, y)$. Hence $d(x, y) \leqslant L$ implies $|d(x, r) - d(y, r)| \leqslant L$. On the other hand, if $d(x, y) > L^4$, then due to the properties of random walks with constant positive probability it holds that $|d(x, r) - d(y, r)| > L^2$.

Thus step 4 is reduced to the following communication problem. Alice holds a number $a \in \{0, 1, \ldots, n\}$, Bob holds a number $b \in \{0, 1, \ldots, n\}$ and it is known that either $|a - b| \leqslant L$ or $|a - b| > L^2$. The goal is to find out whether the first or the second inequality is true. We construct a public-coin simultaneous protocol with communication $O(\log L)$ which always outputs 0 when $|a - b| \leqslant L$ and which with some constant positive probability outputs 1 when $|a - b| > L^2$.

There is a simple SMP protocol communicating $O(\log L + \log \log n)$ bits to solve even a gapless (L vs $L + 1$) version of this problem. Let $p_1, \ldots, p_k$ be the first $k = (4L + 2) \cdot \log_2(n + L)$

primes. Parties read a random $p \in \{p_1, \ldots, p_k\}$ from the shared random source. Alice and Bob communicate $a \pmod p$ and $b \pmod p$ to Charlie. He checks, whether there is $i \in [-L, L]$ such that $a + i \pmod p = b \pmod p$. If there is such i, he outputs 0, otherwise 1. A straightforward analysis shows that this protocol has an error at most $1/2$ only in the case when $|a - b| \geqslant L + 1$.

The problem with this protocol is that a and b range from 0 to n. To get rid of $O(\log \log n)$ term we do the following. Instead of taking remainders modulo $p_1, \ldots, p_k$ we just hash our $O(n)$-size universe into $O(L)$-size universe simply by taking remainder modulo $4L + 2$. Of course this may lead to a collision when two number which were far from each other become L-close. We resolve this issue by considering $Z_0 + \ldots + Z_a$ and $Z_0 + \ldots + Z_b$ instead of a and b, where $Z_0, \ldots, Z_n$ are independent symmetric Bernoulli random variables. It can be shown that provided $|a - b| > L^2$, the difference $Z_{a+1} + \ldots + Z_b$ is distributed almost uniformly modulo $4L + 2$. This guaranties that the collision probability is by a constant bounded away from 1.

1.2.2 Lower bounds

As it turns out, a very simple argument proves an almost matching $\Omega(L^2/U)$ lower bound. We include this argument for completeness.

As we mentioned, provided that U is even and $U = (1 - \Omega(1))n$, the paper [5] proves $\Omega(n)$ lower bound on one-sided error communication complexity R^1 of an easier version of $\mathsf{GHD}_{0,U}$, in which the distance between inputs is either 0 or exactly U. However, we need a lower bound in the regime when U is very close to n. We observe that a simple modification of a proof from [5] works as well in such regime when one switches to a harder problem, in which the distance between inputs can be greater than U. Namely, we show that $R^1(\mathsf{GHD}_{0,U}) = \Omega((n - U)^2/n)$ for $\mathsf{GHD}_{0\,U}$ on n-bit strings.

As a corollary we obtain the lower bound $\Omega(L^2/U)$ for one-sided error complexity R^0 of $\mathsf{GHD}_{L,U}$ (the error is allowed when the distance is at least U). As we explained earlier, R^1 of $\mathsf{GHD}_{0,U-L}$ on U-bit strings equals R^0 of $\mathsf{GHD}_{L,U}$ on U-bit strings. As the former is $\Omega((U - (U - L))^2/U)$ we obtain the lower bound $\Omega(L^2/U)$ for the latter. On the other hand, the problem $\mathsf{GHD}_{L,U}$ on U-bit strings reduces to the problem $\mathsf{GHD}_{L,U}$ on n-bit strings (Alice and Bob append $n - U$ zeros to their strings), hence the one-sided complexity R^0 of the latter is also $\Omega(L^2/U)$.

1.2.3 The summary

Let us summarize our results.

▶ **Theorem 2.** *The one-sided error public-coin communication complexity R^0 of $\mathsf{GHD}_{L,U}$ on n-bit strings is at most*

$$O\left(\left(\frac{L^2}{U} + 1\right)\log(L + 2)\right)$$

(The error is allowed only when the distance is at least U.) There is a public-coin simultaneous protocol attaining this bound.

▶ **Theorem 3.** *The one-sided error public-coin communication complexity R^1 of $\mathsf{GHD}_{0,U}$ on n-bit strings is at least*

$$\Omega\left(\frac{(n - U)^2}{n} + 1\right).$$

(The error is allowed only when the distance is 0.)

▶ **Corollary 4.** *The one-sided error public-coin communication complexity R^0 of $\mathsf{GHD}_{L,U}$ on n-bit strings is at least*

$$\Omega\left(\frac{L^2}{U}+1\right).$$

(The error is allowed only when the distance is at least U.)

Thus our results determine the one-sided public-coin communication complexity of $\mathsf{GHD}_{L,U}$ (up to a factor $O(\log L)$) in the case when the parties are allowed to err only for input pairs at distance at least U. If the parties are allowed to err only for input pairs at distance at most L, then the one-sided public-coin communication complexity of $\mathsf{GHD}_{L,U}$ is $(n-U)^2/(n-L)$ up to a factor of $O(\log(n-U))$.

2 Preliminaries

2.1 Communication Complexity

Let $f : \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ be a Boolean function.

▶ **Definition 5.** A deterministic communication protocol is a rooted binary tree, in which each non-leaf vertex is associated either with Alice or with Bob and each leaf is labeled by 0 or 1. Each non-leaf vertex v, associated with Alice, is assigned a function $f_v : \mathcal{X} \to \{0,1\}$ and each non-leaf vertex u, associated with Bob, is assigned a function $g_u : \mathcal{Y} \to \{0,1\}$. For each non-leaf vertex one of its out-going edges is labeled by 0 and other one is labeled by 1.

A computation according to a deterministic protocol runs as follows. Alice is given $x \in \mathcal{X}$, Bob is given $y \in \mathcal{Y}$. They start at the root of tree. If they are in a non-leaf vertex v, associated with Alice, Alice sends $f_v(x)$ to Bob and they move to the son of v by the edge labeled by $f_v(x)$. If they are in a non-leaf vertex, associated with Bob, they act in a similar same way, however this time it is Bob who sends a bit to Alice. When they reach a leaf, they output the bit which labels this leaf.

▶ **Definition 6.** Communication complexity of a deterministic protocol π, denoted by $CC(\pi)$, is defined as the depth of the corresponding binary tree.

Randomized protocols with shared randomness (aka public-coin protocols) can be defined as follows:

▶ **Definition 7.** A public-coin communication protocol is a probability distribution over deterministic protocols. Communication complexity of a public-coin protocol τ, denoted by $CC(\tau)$, is defined as $\max_{\pi} CC(\pi)$, where π is taken over the deterministic protocols from the support of τ (recall that τ is a distribution).

Given a public-coin protocol τ, Alice and Bob choose the deterministic protocol to be executed according to the distribution, defined by τ.

▶ **Definition 8.** We say that a public-coin protocol computes a partial function f with error probability ε, if for every pair of inputs (x,y) in the domain of f with probability at least $1-\varepsilon$ that protocol outputs $f(x,y)$. Randomized communication complexity of f is defined as

$$R_\varepsilon(f) = \min_{\pi} CC(\pi),$$

where minimum is over all protocols that compute f with error probability ε.

A deterministic *simultaneous* protocol τ is a triple $\langle \phi, \psi, \theta \rangle$ where

$$\phi : \mathcal{X} \to \{0,1\}^{c_1}, \qquad \psi : \mathcal{Y} \to \{0,1\}^{c_2},$$

$$\theta : \{0,1\}^{c_1} \times \{0,1\}^{c_2} \to \{0,1\}.$$

The communication cost of τ is $c_1 + c_2$. A public-coin simultaneous protocol π is a probability distribution over deterministic simultaneous protocols. Communication cost of π is the maximal possible communication cost of τ, where τ is a deterministic simultaneous protocol taken from the support of π.

Assume that Alice is given $x \in \mathcal{X}$ and Bob is given $y \in \mathcal{Y}$. The output of a public-coin simultaneous protocol π on (x, y) is a random variable defined as follows. Sample a deterministic simultaneous protocol $\tau = \langle \phi, \psi, \theta \rangle$ according to π. Output $\theta(\phi(x), \psi(y))$.

If for $i \in \{0,1\}$ we require that the protocol never errs on inputs from $f^{-1}(i)$, then the corresponding notion is called "randomized one-sided error communication complexity" and is denoted by $R^i_\varepsilon(f)$.

The Gap Hamming Distance problem is the problem of computing the following partial function:

$$\mathsf{GHD}^n_{L,U}(x,y) = \begin{cases} 0 & d(x,y) \leqslant L, \\ 1 & d(x,y) \geqslant U, \\ \text{undefined} & L < d(x,y) < U, \end{cases} \qquad \text{for } x, y \in \{0,1\}^n.$$

2.2 Hamming Space

▶ **Definition 9.** The function

$$h(x) = x \log_2 \frac{1}{x} + (1-x) \log_2 \frac{1}{1-x}$$

is called the *Shannon function*.

For any $B \subset \{0,1\}^n$ define $\mathsf{diam}(B) = \max\limits_{x,y \in B} d(x,y)$. Let $V_2(n,r)$ denote the size of Hamming ball of radius r, that is $V_2(n,r) = \binom{n}{0} + \ldots + \binom{n}{r}$.

We will use the following well-known facts about the size of Hamming balls.

▶ **Proposition 10** ([7]). *If $r \leqslant \frac{n}{2}$, then $V_2(n,r) \leqslant 2^{h\left(\frac{r}{n}\right)n}$.*

▶ **Proposition 11** ([7]). *If $B \subset \{0,1\}^n$, r is natural, $\mathsf{diam}(B) \leqslant 2r$ and $n \geqslant 2r+1$, then*

$$|B| \leqslant V_2(n,r).$$

Propositions 11, 10 and the fact that $h'(1/2) = 0, h''(1/2) < 0$ easily imply the following

▶ **Lemma 12.** *Assume that $r < n/2$. Then the cardinality of every set $B \subset \{0,1\}^n$ with $\mathsf{diam}(B) \leqslant 2r$ is at most $2^{n(1-c(1-(2r/n))^2)}$ for some absolute positive constant c.*

2.3 Probability Theory

▶ **Definition 13** (Probability distributions). Let $B(n,p)$ denote the binomial distribution with parameters $n \in \mathbb{N}$ and $p \in (0,1)$. For every natural n let S_n denote the one-dimensional random walk with n steps. More specifically, let S_n be equal to

$$S_n = X_1 + \ldots + X_n,$$

where $X_1, \ldots, X_n$ are independent random variables taking values in $\{-1, 1\}$, such that for each i the following holds: $\Pr[X_i = 1] = \Pr[X_i = -1] = \frac{1}{2}$.

3 The upper bound

The protocol for Theorem 2 is a combination of three different protocols. The most important of them solves $\mathsf{GHD}_{L,U}$ with one sided error in the case when U/L exceeds some constant. Its communication length is $O((L^2/U+1)\log n)$. We call that protocol the "Triangle Inequality Protocol", because it uses the triangle inequality for Hamming distance.

3.1 The Triangle Inequality Protocol

The following Lemma is the standard fact of Probability Theory:

▶ **Lemma 14.** *There exists a positive constant $\alpha > 0$ such that for every m it holds that*

$$\Pr[S_m \geqslant \sqrt{m}] \geqslant \alpha,$$

where S_m denotes one-dimensional random walk with m steps, i.e, S_m is equal to the sum of m independent random variables, each taking the values 1 and -1 with probabilities 1/2.

Everywhere below α stands for the constant from Lemma 14.

Let $x, y \in \{0,1\}^n$ denote Alice's and Bob's input strings, respectively. The parties set $b = \lceil CL^2/U + 1 \rceil$, where $C = 360/\alpha^2$. Then they use public coins to sample a function $\chi : \{1,2,\ldots,n\} \to \{1,2,\ldots,b\}$ uniformly at random. They use χ to divide x and y into b blocks

$$x^1,\ldots,x^b, \qquad y^1,\ldots,y^b.$$

The block x^j consists of all bits x_i of x such that $\chi(i) = j$. Similarly, y^j consists of all bits y_i with $\chi(i) = j$. The order in which bits of jth block are arranged is not important, the parties care only that they use the same order.

Then they use public coins to sample b random strings $r^1,\ldots,r^b$ of the same lengths, as $x^1,\ldots,x^b$ and $y^1,\ldots,y^b$. Alice then sends b numbers to Charlie:

$$d(x^1,r^1),\ldots,d(x^b,r^b).$$

In turn, Bob sends

$$d(y^1,r^1),\ldots,d(y^b,r^b).$$

Then Charlie computes the sum

$$T = \sum_{j=1}^{b} \left| d(x^j,r^j) - d(y^j,r^j) \right|.$$

If $T \leqslant L$, Charlie outputs 0. Otherwise he outputs 1.

If $d(x,y) \leqslant L$, then the protocol always outputs 0. Indeed, since Hamming distance satisfies the triangle inequality, we have that

$$T = \sum_{j=1}^{b} \left| d(x^j,r^j) - d(y^j,r^j) \right| \leqslant \sum_{j=1}^{b} d(x^j,y^j) = d(x,y) \leqslant L.$$

Thus this protocol has a one-sided error: it can err only if $d(x,y) \geqslant U$. Now we will estimate the probability of error in the case when $d(x,y) \geqslant U$.

▶ **Lemma 15.** *Assume that $U \geqslant 2b$. Then the protocol for the input pair x, y at distance at least U outputs 1 with some positive constant probability (more specifically, with probability at least $\alpha/6$).*

Proof. Assume that U, L, x, y satisfy the assumption of the lemma. Fix $j = 1, \ldots, b$. First we have to understand what is the distribution of the random variable $|d(x^j, r^j) - d(y^j, r^j)|$. By construction Alice and Bob choose a random function χ that governs the partition of x, y into blocks. For each i such that $x_i \neq y_i$ the probability that x_i, y_i land into the block with number j is $1/b$. Hence the random variable $d(x^j, y^j)$ has binomial distribution $B(d(x, y), 1/b)$ with parameters $d(x, y)$ and $1/b$, i.e., the probability of the event $d(x^j, y^j) = k$ equals

$$\binom{d(x,y)}{k}(1/b)^k(1-1/b)^{d(x,y)-k}.$$

The average value of $d(x^j, y^j)$ is thus equal to $d(x, y)/b$.

Once x^j, y^j are determined, Alice and Bob sample r^j. The value $d(x^j, r^j) - d(y^j, r^j)$ can be represented as the sum of $|x^j| = |y^j|$ terms where each term corresponds to a number i with $\chi(i) = j$. If $x_i = y_i$ then the term is 0. Otherwise it is either -1 or 1 depending on whether the respective bit of r^j is equal to x_i or to y_i. Thus for every fixed partition into blocks the value $|d(x^j, r^j) - d(y^j, r^j)|$ is distributed as the distance from origin in the random walk along the line with $d(x^j, y^j)$ independent steps where each step is 1 with probability $1/2$ and -1 with the same probability.

To finish the proof we will use the following fact about binomial distribution.

▶ **Lemma 16.** *If X is distributed according to the binomial distribution $B(n, p)$ and $pn \geqslant 2$, then*

$$\Pr\left[X > \frac{pn}{10}\right] \geqslant \frac{1}{3}.$$

Proof of Lemma 16. The expectation and variation of X are given by:

$$\mathrm{E}X = pn, \qquad \mathrm{Var}X = p(1-p)n \leqslant pn.$$

Hence by Chebyshev inequality we get

$$\Pr\left[X \leqslant \frac{pn}{10}\right] \leqslant \frac{\mathrm{Var}X}{\left(pn \cdot \left(1 - \frac{1}{10}\right)\right)^2} \leqslant \frac{\frac{100}{81}}{pn} \leqslant \frac{100}{162} \leqslant \frac{2}{3}.$$ ◀

Recall that the random variable $d(x^j, y^j)$ has binomial distribution $B(d(x, y), 1/b)$ and we assume that $d(x, y)/b \geqslant U/b \geqslant 2$. Hence by Lemma 16 with probability at least $1/3$ we have $d(x^j, y^j) \geqslant d(x, y)/10b$.

Fix any partition into blocks such that $d(x^j, y^j) \geqslant d(x, y)/10b$. By Lemma 14 with probability at least α we have

$$|d(x^j, r^j) - d(y^j, r^j)| \geqslant \sqrt{d(x^j, y^j)} \geqslant \sqrt{d(x, y)/10b}.$$

We have proved that for every fixed j with probability at least $\alpha/3$ we have $|d(x^j, r^j) - d(y^j, r^j)| \geqslant \sqrt{d(x, y)/10b}$. A simple averaging argument shows that with probability at least $\alpha/6$ the fraction of j that satisfy this inequality is bigger than $\alpha/6$. Indeed, let the random variable θ denote the fraction of j that satisfy this inequality. Its average is at least $\alpha/3$. On the other hand, we can upperbound its average by the sum

$$\Pr[\theta > \alpha/6] \cdot 1 + \Pr[\theta \leqslant \alpha/6] \cdot (\alpha/6) \leqslant \Pr[\theta > \alpha/6] + \alpha/6.$$

Thus with probability $\alpha/6$ we have

$$\sum_{j=1}^{b} |d(x^j, r^j) - d(y^j, r^j)| > (\alpha/6)b\sqrt{d(x,y)/10b} = (\alpha/6)\sqrt{b \cdot d(x,y)/10}.$$

Recall that $b = \lceil CL^2/U + 1 \rceil$, where $C = 360/\alpha^2$, and $d(x,y) \geqslant U$. So the right hand side of the last displayed inequality is strictly larger than L. ◀

If the ratio U/L is larger than a certain constant then the protocol solves $\mathsf{GHD}_{L,U}$ with constant one-sided error-probability. One can verify that the assumption $U \geqslant 2b$ of Lemma 15 is met for all $U \geqslant 2CL + 4$.

Recall that the communication length of the protocol is $O((L^2/U + 1)\log n)$. Now we need a protocol with the same communication length for L, U such that $U \leqslant 2CL + 3$. Notice that in this case the upper bound $O((L^2/U)\log n)$ for communication boils down to $O(L \log n)$. A protocol with such performance was constructed in [8].

3.2 The protocol of [8]

For the reader's convenience and to stress that the protocol from [8] has one-sided error we give here its full description.

Here $\oplus$ stands for the bit-wise XOR over n-bit vectors and $\langle \cdot, \cdot \rangle : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ denotes the inner product over $\mathbb{F}_2$:

$$\langle a, b \rangle = \sum_{i=1}^{n} a_i b_i \pmod 2.$$

Let $x, y \in \{0,1\}^n$ denote Alice's and Bob's input strings, respectively. They use public coins to sample N vectors

$$R_1, \ldots, R_N \in \{0,1\}^n$$

independently uniformly at random. Alice sends $\langle x, R_1 \rangle, \ldots, \langle x, R_N \rangle$ to Charlie. Bob does the same with y. If there is $f \in \{0,1\}^n$ of Hamming weight at most L such that:

$$\langle x \oplus f, R_1 \rangle = \langle y, R_1 \rangle, \ldots, \langle x \oplus f, R_N \rangle = \langle y, R_N \rangle, \tag{1}$$

then Charlie outputs 0. Otherwise Charlie outputs 1.

Such protocol costs $O(N)$ bits. If $d(x,y) \leqslant L$, then the protocol outputs 0 with probability 1. Indeed, $f = x \oplus y$ (which is of Hamming weight at most L in this case) satisfies (1).

Now assume that $d(x,y) > L$. Then any $f \in \{0,1\}^n$ of Hamming weight at most L satisfies (1) only with probability at most 2^{-N} (because $x + f \neq y$). Hence the error probability of the protocol is at most $V_2(n,L) \cdot 2^{-N}$ in this case. Here $V_2(n,L)$ is the size of Hamming ball of radius L. As $V_2(n,L) \leqslant (n+1)^L$, it is enough to take $N = O(L \log n)$.

3.3 The simplified version of the Triangle Inequality Protocol

Thus for all L, U we have a public-coin simultaneous protocol with communication length $O((L^2/U + 1)\log n)$ to solve $\mathsf{GHD}_{L,U}$ with constant one-sided error probability. To replace $\log n$ factor by $\log L$ factor we will need the following public-coin simultaneous protocol with communication length $O(\log L)$ to solve $\mathsf{GHD}_{L,\,(4L+2+N_0)^4}$ with constant one-sided error probability. Here N_0 is a constant from the following Lemma.

▶ **Lemma 17.** *There is a positive integer N_0 and a positive real c such that the following holds. Assume that m and N are positive integers and $N \geqslant \max\{N_0, m^2\}$. Consider N independent random variables $Z_1, \ldots, Z_N$, where each variable takes the values 0 and 1 with probabilities 1/2. Then for every $i \in \{0, 1, \ldots, m-1\}$ it holds that:*

$$\Pr[Z_1 + \ldots + Z_N = i \pmod m] \geqslant \frac{c}{m}.$$

(The proof of this Lemma will be given in the end of this subsection). Notice that $O((L^2/U + 1)\log L)$ becomes just $O(\log L)$ for $U = (4L + 2 + N_0)^4$.

The protocol. The parties use public coins to sample a vector $r \in \{0,1\}^n$ uniformly at random. Alice and Bob compute the distance from r to their input strings. If $d(x, y) \leqslant L$, then by Triangle Inequality we have $|d(x, r) - d(y, r)| \leqslant d(x, y) \leqslant L$. On the other hand, assume that $d(x, y) \geqslant (4L + 2 + N_0)^4$. From Lemma 14 it follows that in this case with constant positive probability we have $|d(x, r) - d(y, r)| \geqslant \sqrt{d(x, y)} > (4L + 2)^2 + N_0^2$.

Consider the following auxiliary problem. Alice holds a number $a \in \{0, 1, \ldots, n\}$, Bob holds a number $b \in \{0, 1, \ldots n\}$ and it is promised that either $|a - b| \leqslant L$ or $|a - b| > (4L + 2)^2 + N_0^2$. They want to know whether the first or the second inequality is true. As the previous paragraph shows, if there is a public-coin SMP protocol with communication length $O(\log L)$, which always outputs 0 when $|a - b| \leqslant L$ and which with constant positive probability outputs 1 when $|a - b| > (4L + 2)^2 + N_0^2$, then we are done.

Define $m = 4L + 2$. Use public coins to sample $n + 1$ independent random variables

$$Z_0, Z_1, Z_2, \ldots, Z_n,$$

where each variable takes the values 0 and 1 with probabilities 1/2.

Alice sends $\sum_{i=0}^{a} Z_i \pmod m$ to Charlie, Bob sends $\sum_{i=0}^{b} Z_i \pmod m$ to Charlie. This takes only $O(\log m) = O(\log L)$ bits. Let (s, t) be any pair of integers satisfying the following three conditions:

$$s \equiv \sum_{i=0}^{a} Z_i \pmod m \tag{2}$$

$$t \equiv \sum_{i=0}^{b} Z_i \pmod m \tag{3}$$

$$|s - t| = \min\left\{|s' - t'| : s' \equiv \sum_{i=0}^{a} Z_i \pmod m, t' \equiv \sum_{i=0}^{b} Z_i \pmod m\right\}. \tag{4}$$

Obviously, knowing $\sum_{i=0}^{a} Z_i \pmod m$, $\sum_{i=0}^{b} Z_i \pmod m$, Charlie is able to find (s, t) satisfying these tree conditions. He then simply checks whether $|s - t| \leqslant L$. If this is the case, he outputs 0. Otherwise he outputs 1.

Once again, the protocol communicates only $O(\log L)$ bits, as required. Further, it is easy to see that the protocol has one-sided error. Indeed, assume that $|a - b| \leqslant L$. Note that a pair $(\sum_{i=0}^{a} Z_i, \sum_{i=0}^{b} Z_i)$ satisfies (2) and (3) . Hence $|s - t| \leqslant \left|\sum_{i=0}^{a} Z_i - \sum_{i=0}^{b} Z_i\right| \leqslant |a - b| \leqslant L$.

Now, let's consider the case when $|a-b| > (4L+2)^2+N_0^2$. Assume without loss of generality that $a < b$. Let E be the event that there is no $r \in [-L, L]$ such that $Z_{a+1} + \ldots + Z_b \equiv r$

(mod m). Let us verify that E implies that $|s-t| > L$ (which means that Charlie outputs 1). Indeed, observe that

$$t - s \equiv \sum_{i=0}^{b} Z_i - \sum_{i=0}^{a} Z_i \equiv Z_{a+1} + \ldots + Z_b \pmod{m},$$

but if $|s-t| \leqslant L$, this contradicts E.

It only remains to show that E happens with constant positive probability. This follows from Lemma 17. Namely, this lemma implies that $\Pr[E] \geqslant \frac{c(m-2L-1)}{m} = c/2$. Parameters are chosen in such a way that restrictions of Lemma 17 are satisfied:

$$b - a > (4L+2)^2 + N_0^2 \geqslant (\max\{N_0, 4L+2\})^2 \geqslant \max\{N_0, m^2\}.$$

Proof of Lemma 17. Take N_0 to be the first natural satisfying the following condition: there exists $d > 0$ such that for all $N \geqslant N_0$ and for every k between $N/2 - \sqrt{N}$ and $N/2 + \sqrt{N}$ the following holds:

$$\Pr[Z_1 + \ldots + Z_N = k] = \binom{N}{k} 2^{-N} \geqslant \frac{d}{\sqrt{N}}.$$

The existence of such N_0, d is just a standard corollary of the Stirling formula, applied to $\binom{N}{k}$.

Now let us show that for all $m > 0$, $N \geqslant m^2$ and $i \in \{0, 1, \ldots, m-1\}$ the number of k between $N/2 - \sqrt{N}$ and $N/2 + \sqrt{N}$ such that $k \equiv i \pmod{m}$ is at least $\frac{\sqrt{N}}{m}$. The number of such k is equal to the number of $r \in \mathbb{Z}$ satisfying:

$$N/2 - \sqrt{N} \leqslant mr + i \leqslant N/2 + \sqrt{N},$$

This number is at least

$$\left\lfloor \frac{N/2 + \sqrt{N} - i}{m} \right\rfloor - \left\lceil \frac{N/2 - \sqrt{N} - i}{m} \right\rceil + 1 \geqslant \frac{2\sqrt{N}}{m} - 1.$$

Provided $N \geqslant m^2$, the last expression is at least $\frac{\sqrt{N}}{m}$.

Set $c = d$ and observe that for all m, N such that $m > 0$ and $N \geqslant \max\{N_0, m^2\}$ and for every $i \in \{0, 1, \ldots, m-1\}$ it holds that

$$\Pr[Z_1 + \ldots + Z_N \equiv i \pmod{m}] \geqslant \frac{\sqrt{N}}{m} \cdot \frac{d}{\sqrt{N}} = \frac{c}{m}.$$

◀

3.4 The final protocol for Theorem 2

The protocol. *Step 1.* Alice and Bob first run the Simplified Triangle Inequality Protocol from the previous subsection. If that protocol outputs 1 they output 1 and halt. Otherwise they proceed to Step 2.

Step 2. They divide x and y into $w = 2(4L + 2 + N_0)^8$ blocks randomly (as in the construction of the Triangle Inequality Protocol). Let

$$x^1, \ldots, x^w, \qquad y^1, \ldots, y^w$$

denote the resulting blocks. Let u_i be the XOR of all bits from x^i and let v_i be the XOR of all bits from y^i. Alice privately computes $u_1, \dots, u_w$ and sets $u = u_1 \dots u_w$. Bob privately computes $v_1, \dots, v_w$ and sets $v = v_1 \dots v_w$.

Recall that we have a protocol (a combination of the Triangle Inequality Protocol and the protocol of [8]) with communication length $O((L^2/U + 1) \log w) = O((L^2/U + 1) \log L)$ to solve $\mathsf{GHD}_{L,U}$ on w-bit strings with constant positive one-sided error probability.

Alice and Bob run this protocol for input pair (u, v) (and not (x, y)). They output the result of this run.

The communication length of the constructed protocol is $O((L^2/U + 1) \log L)$. We have to show that it has one-sided constant error probability.

If $d(x, y) \leqslant L$ then the run of the Simplified Triangle Inequality Protocol will output 0 with probability 1. Thus they proceed to Step 2. The distance between u and v does not exceed the distance between x and y and hence is at most L. Thus the run of the second protocol also outputs 0 with probability 1.

Assume that $d(x, y) \geqslant U$. If $d(x, y) \geqslant (4L + 2 + N_0)^4$, then the Simplified Triangle Inequality Protocol outputs 1 with positive constant probability, they output 1 and halt.

Assume that $U \leqslant d(x, y) < (4L + 2 + N_0)^4$. We claim that in this case with constant positive probability we have $d(u, v) = d(x, y)$. Indeed, consider any two positions in which x and y differ. Those positions land into the same block with probability $\frac{1}{w}$. By union bound, with probability at least

$$1 - \frac{d(x, y)^2}{w} \geqslant 1 - \frac{(4L + 2 + N_0)^8}{2(4L + 2 + N_0)^8} = 0.5$$

all the positions in which x and y differ land in different blocks. The latter means that for all i the blocks x^i and y^i differ in at most 1 position and hence $d(u, v) = d(x, y)$. Thus with probability at least $1/2$ we have $d(u, v) \geqslant U$ and Alice and Bob output 1 with positive constant probability on the second step.

4 The lower bound

In this section we prove Theorem 3.

Proof of Theorem 3. Let τ be a protocol witnessing $R^1_{\frac{1}{2}}(\mathsf{GHD}_{0,U})$. Then the following hold:

- for each $x \in \{0, 1\}^n$ the protocol τ for input (x, x) outputs 0 with probability at least $\frac{1}{2}$;
- for all $x, y \in \{0, 1\}^n$ with $d(x, y) \geqslant U$ the protocol τ always outputs 1.

By the standard averaging argument due to von Neumann there is a deterministic protocol π such that

- the communication complexity of π is at most $R^1_{\frac{1}{2}}(\mathsf{GHD}_{0,U})$;
- π outputs 0 for at least half of diagonal input pairs (x, x);
- π outputs 1 for all inputs pairs at Hamming distance at least U.

Consider any 0-leaf of π and the corresponding rectangle $R = A \times B \subset \{0, 1\}^n \times \{0, 1\}^n$. The number of diagonal pairs from R is equal to $|A \cap B|$. Diameter of $A \cap B$ must be less than U. Indeed, if there are $x, y \in A \cap B$ such that $d(x, y) \geqslant U$, then π outputs 0 for input pair (x, y).

It turns out that the largest set of diameter $2r < n$ is the Hamming ball of radius r and the diameter of the latter is at most $2^{n(1-c(1-2r/n)^2)}$ for some positive constant c (Lemma 12).

Let $r = \lfloor U/2 \rfloor$. For $U = n$ the lower bound in Theorem 3 is constant and thus the statement is obvious. Therefore we may assume that $U < n$ and hence $r < n/2$. The diameter of $A \cap B$ is at most $2r$ (recall that the diameter of $A \cap B$ is strictly less than U). By Lemma 12 we have

$$|A \cap B| \leqslant 2^{n(1-c(1-2r/n)^2)} \leqslant 2^{n(1-c(1-U/n)^2)}.$$

We have shown that if R is the rectangle corresponding to a 0-leaf of π, then R covers at most $2^{n(1-c(1-U/n)^2)}$ diagonal pairs. As the total number of diagonal pairs covered by 0-leaves of π is at least 2^{n-1}, the number of 0-leaves in π is at least $2^{cn(1-U/n)^2-1}$. Thus we have

$$R^1_{\frac{1}{2}}(\mathsf{GHD}_{0,U}) \geqslant c \cdot \frac{(n-U)^2}{n} - 1. \tag{5}$$

Obviously we also have

$$R^1_{\frac{1}{2}}(\mathsf{GHD}_{0,U}) \geqslant 1. \tag{6}$$

From inequalities (5) and (6) we can easily deduce that

$$R^1_{\frac{1}{2}}(\mathsf{GHD}_{0,U}) \geqslant \Omega\left(\frac{(n-U)^2}{n} + 1\right)$$

(for example, we can add these inequalities with appropriate positive weights). ◀

Abstract

We study the online maximum matching problem in a model in which the edges are associated with a known recourse parameter k. An online algorithm for this problem has to maintain a valid matching while edges of the underlying graph are presented one after the other. At any moment the algorithm can decide to include an edge into the matching or to exclude it, under the restriction that at most k such actions per edge take place, where k is typically a small constant. This problem was introduced and studied in the context of general online packing problems with recourse by Avitabile *et al.* [1], whereas the special case $k = 2$ was studied by Boyar *et al.* [3].

In the first part of this paper, we consider the *edge arrival* model, in which an arriving edge never disappears from the graph. Here, we first show an improved analysis on the performance of the algorithm AMP given in [1], by exploiting the structure of the matching problem. In addition, we extend the result of [3] and show that the greedy algorithm has competitive ratio $3/2$ for every even k and ratio 2 for every odd k. Moreover, we present and analyze an improvement of the greedy algorithm which we call L-Greedy, and we show that for small values of k it outperforms the algorithm of [1]. In terms of lower bounds, we show that no deterministic algorithm better than $1 + 1/(k-1)$ exists, improving upon the lower bound of $1 + 1/k$ shown in [1].

The second part of the paper is devoted to the *edge arrival/departure model*, which is the fully dynamic variant of online matching with recourse. The analysis of L-Greedy and AMP carry through in this model; moreover we show a lower bound of $\frac{k^2-3k+6}{k^2-4k+7}$ for all even $k \geq 4$. For $k \in \{2, 3\}$, the competitive ratio is $3/2$.

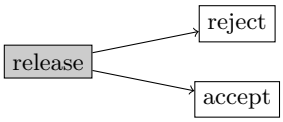
1 Introduction

In the standard framework of online computation, the input to the algorithm is revealed incrementally, i.e., request by request. For each such requested input item, the online algorithm must make a decision that is typically *irrevocable*, in the sense that the algorithm commits, in a permanent manner, to the decision associated with the request. More precisely, the algorithm may not alter any previously made decisions while considering later requests. This rather stringent constraint is meant to capture what informally can be described as "the past cannot be undone"; equally significantly, it is at the heart of adversarial arguments that can be used to argue that the competitive ratio of a given online problem cannot be improved beyond a certain bound.

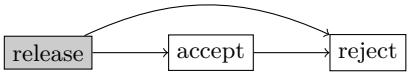
Nevertheless, there are real-life applications in which some (limited) rearrangement of the online solution during the execution of the algorithm may be doable, or even requisite. For instance, online call admission protocols may sporadically reconfigure the virtual paths assigned in the network. For a different example, in online scheduling (or resource allocation) problems, it may be permissible for a job to be transfered to a processor other than the one specified by the original decision associated with the job. Clearly, a trade-off is to be found between the guaranteed competitive ratio and the cost of re-optimizing the current solution. Different approaches to this objective have been considered. One such approach has studied the minimum total re-optimization cost required in order to maintain an optimal solution, see Bernstein *et al.* [2]. Another approach has focused on the best achievable competitive ratio when there is some bound on the allowed re-optimization, which has been first studied by Avitabile *et al.* [1], and is the main model we consider in this paper.

More specifically, we study the *online maximum cardinality matching* problem, in which the goal is to maintain a vertex disjoint edge set of maximum cardinality for a given graph. Two different online models have been studied in the past. In the *vertex arrival model*, vertices arrive in online fashion, revealing, at the same time, the edges incident to previously arrived vertices. This model has mainly been considered for bipartite graphs, with left side vertices arriving online, and right side vertices being initially known (see the survey [16]). In the *edge arrival model* the edges arrive online in arbitrary order, revealing at the same time incident vertices. We emphasize that in this work we consider the maximum cardinality matching problem; some previous work (with or without recourse) has considered the generalized *weighted matching* problem, in which each edge has a weight and the objective is to maximize the weight of matched edges.

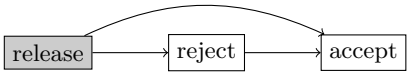
In the standard model, every edge constitutes a request and has to be immediately either accepted in the matching, or rejected. To quantify the impact of recourse, several models have been proposed that relax the irrevocable nature of a decision. In the *late reject* model [3], which is also called the *preemptive model* [5], an edge can be accepted only upon its arrival, but can be later rejected. In the *edge-bounded recourse* model, introduced in [1], the algorithm can switch between accepting and rejecting an edge that has already appeared, but is allowed up to k such modifications per edge. We emphasize that the initial default state of an edge is *rejected*, and therefore rejecting a newly arriving edge does not count as decision modification. However, accepting an edge or rejecting a previously accepted edge does count as a decision modification. For concreteness, we call this problem the *online maximum cardinality matching problem with edge-bounded recourse*. Boyar *et al.* [3] refer to this model for $k = 1$ as the *late accept* model, and for $k = 2$ as the *late accept/reject* model. Clearly, the competitive ratio is monotone in k, and our objective is to quantify this dependency. Figure 1 illustrates the algorithm's actions under the different models.



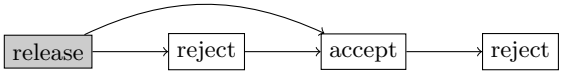
Standard model.



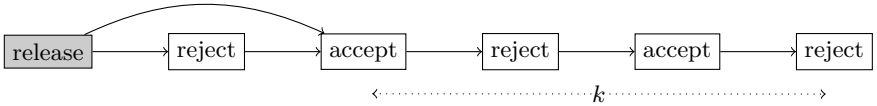
Late reject model, also called free disposal or preemptive model.



Late accept model, also called edge 1-bounded recourse model.



Late accept/reject model, also called edge 2-bounded recourse model.



Edge-bounded recourse model with general parameter k.

Figure 1 Illustration of the actions of an online matching algorithm under the different edge-arrival models with recourse.

In this work we also introduce and study the setting in which edges may undergo both arrivals and departures. In other words, edges may not only arrive (in the form of a request), but may also disappear adversarially (subsequently to their appearance). This setting is motivated by similar models that have been studied in the context of the online Steiner tree problem [9]. We call this problem the online maximum matching problem under the *edge arrival/departure model with edge-bounded recourse*. For this problem, we further distinguish two models concerning the edge departures. In the *full departure* model, the adversary is allowed to delete any edge in the graph, and thus also any edge that may have been provisionally accepted by the online algorithm. We show that this model is quite restrictive, since it yields excessive power to the adversary. We thus also study the *limited departure* model, in which the adversary may delete only edges not currently accepted by the online algorithm.

The limited departure setting can also model some natural applications related to resource allocation. For instance, consider a bipartite graph representing compatibility between tasks and workers, and that we seek to maximize the number of tasks assigned to workers. The compatibility of tasks and worker skills can change over time. Then the limited departure model stipulates that if worker w remains assigned to task t by the online algorithm, then w does not lose his qualification for t, in the sense that the worker has a continual occupation with the said task and maintains the required skills for the task. However, once the online algorithm decides to remove worker w from task t (i.e., the online algorithm provisionally rejects edge (w, t)), then the worker might lose his qualification for the task over time.

An online algorithm ALG for a maximization problem is said to be c-competitive if there is a constant d such that $\mathrm{ALG}(\sigma) \geq \mathrm{OPT}(\sigma)/c - d$, for all request sequences σ. Here $\mathrm{ALG}(\sigma)$ stands for the objective value of the solution produced by ALG on σ, while $\mathrm{OPT}(\sigma)$ stands for the value of the optimal solution. If $d = 0$, the algorithm is called *strictly* c-competitive. Note that some previous work on the matching problem has used the reciprocal ratio. The smallest c for which an online algorithm ALG is c-competitive is called the *competitive ratio* of ALG. The strict competitive ratio is defined similarly. If it so happens that this minimum value does not exist, the competitive ratio is actually defined by the corresponding infimum. In this setting an *upper bound* on the (strict or not) competitive ratio establishes the performance guarantee of an online algorithm, whereas a *lower bound* is a negative result.

Both upper and lower bounds in this work are shown for the strict competitive ratio. This implies that the upper bounds carry over to the more general definition, but this generalization does not necessarily hold for the lower bounds. We emphasize, however, that the known lower bounds for edge-bounded recourse problems in [1, 3] are likewise expressed in terms of the strict competitive ratio. This is due, perhaps, to difficulties in applying techniques that extend the lower bounds to the standard definition of the competitive ratio that are inherent to the recourse setting, and which do not arise in the traditional online framework of irrevocable decisions. Specifically, it is not obvious how to use techniques based on multiple copies of an adversarial instance in order to lower-bound the performance of any online algorithm, although this may be possible for specific online algorithms. For convenience, we will henceforth refer to the strict competitive ratio as simply the "competitive ratio".

Related work

Several online optimization problems have been studied under the recourse setting. The broad objective is to quantify the trade-off between the competitive ratio and a measure on the modifications allowed on the solution. Some representative examples include online problems such as minimum spanning trees and TSP [15], Steiner trees [9, 8], knapsack problems [11, 12], assignment problems in bipartite unweighted graphs [10], and general packing problems [1]. In the remainder of this section we review work related to online maximum matching.

Online matching in the standard model. For online weighted matching in the standard model (without recourse), it is easy to see that no algorithm can achieve a bounded competitive ratio. This holds for both the vertex and the edge arrival models. For unweighted matching, the seminal work of Karp *et al.* [13, 7] gave a randomized online algorithm with competitive ratio $\mathrm{e}/(\mathrm{e}-1)$ in the vertex arrival model together with a matching lower bound on any online algorithm. For the edge arrival model and the randomized competitive ratio, [4] showed a lower bound of $(3+1/\varphi^2)/2$, where φ is the golden ratio, as well as an upper bound of 1.8 for the special case of forests.

It is well known that any inclusion-wise maximal matching has cardinality at least half of the optimal maximum cardinality matching. From this it follows that the greedy online algorithm has competitive ratio at most 2, which in the standard model is optimal among all deterministic online algorithms.

Late reject. In the vertex arrival model, the greedy algorithm achieves trivially the competitive ratio of 2, which is optimal for all deterministic online algorithms. The situation differs in the edge arrival model. Epstein *et al.* [6] showed that for online weighted matching,

the deterministic competitive ratio is exactly $3 + 2\sqrt{2} \approx 5.828$, as the upper bound of [14] matches the lower bound of [18]. The same paper [6] shows that the randomized competitive ratio is between $1 + \log 2 \approx 1.693$ and 5.356. Chiplunkar *et al.* [5] presented a randomized 28/15-competitive algorithm for trees and a 4/3-competitive algorithm for paths.

Edge k-bounded recourse. This model was introduced and studied by Avitabile *et al.* [1] for the edge arrival setting, in the context of a much broader class of online packing problems. They gave an algorithm, which we call AMP, that combines doubling techniques with optimal solutions to offline instances of the problem, which has competitive ratio $1 + O\left(\frac{\log k}{k}\right)$ (see Section 2.1 for an analysis of AMP). On the negative side, they showed that no randomized algorithm can be better than $1 + 1/(9k - 1)$-competitive; we note also that their construction implies a lower bound of $1 + 1/k$ for all deterministic algorithms.

Boyar *et al.* [3] showed that the deterministic competitive ratio is 2 for $k = 1$ and 3/2 for $k = 2$, and these optimal ratios are achieved by the greedy algorithm. Moreover, [3] studied several other problems for a value of the recourse parameter equal to 2, such as independent set, vertex cover and minimum spanning forest.

Minimizing recourse. Bernstein *et al.* [2] studied a different recourse model in which the algorithm has to maintain an optimal matching, while minimizing a recourse measure, namely the number of times edges enter or leave the matching maintained by the algorithm. They considered the setting of a bipartite graph and the vertex arrival model and showed that a simple greedy algorithm achieves optimality using $O(n \log^2 n)$ replacements, where n is the number of nodes in the arriving bipartition, whereas the corresponding lower bound for any replacement strategy is $\Omega(n \log n)$.

The results of Avitabile *et al.* [1] were originally formulated in a similar dual setting. More precisely, [1] asks the question: how big should the edge budget k be such that there is a $1 + \varepsilon$ competitive online algorithm that makes at most k changes per edge? They showed that $k = O(\log(1/\varepsilon)/\varepsilon)$ suffices.

Contribution of this work

In the first part of this work, we study the online matching problem with edge k-bounded recourse under the edge arrival model. For this problem, we provide improvements on both upper and lower bounds. First, we revisit the doubling algorithm of [1] that was originally analyzed in the general context of online packing problems. We give a better analysis, specifically for the problem at hand, that uses concepts and ideas related to the matching problem; we also show that the AMP algorithm has competitive ratio $1 + O(\frac{\log k}{k})$. On the negative side, we show that no deterministic algorithm is better than $1 + 1/(k - 1)$ competitive, improving upon the known bound of $1 + 1/k$ of [1].

At first sight these improvements may seem marginal; however one should take into consideration that k is typically a small parameter, and thus the improvements are by no means negligible. In this spirit, we propose and analyze a variant of the greedy algorithm which we call L-Greedy. This algorithm applies, at any step, augmenting paths as long as their length is at most $2L + 1$. We show that for a suitable choice of L, this algorithm is $(1 + O(1/\sqrt{k}))$-competitive. While this algorithm is thus not superior to AMP for large k (and more specifically, to its improved analysis in the context of the matching problem), for small k (and in particular, for $k \leq 20$) it does achieve an improved competitive ratio. Boyar *et al.* [3] showed that the greedy algorithm is 3/2-competitive for $k = 2$. We extended this result to all even k, while for odd k, the competitive ratio is 2.

In terms of techniques, we analyze both AMP and L-Greedy using amortization arguments in which the profit of the algorithms is expressed in terms of weights appropriately distributed over nodes in the graph. We achieve these improvements by exploiting properties of augmenting paths in matching algorithms.

The second part of the paper is devoted to the *edge arrival/departure model*, which is the fully dynamic variant of the online matching problem. First, we observe that the analysis of L-Greedy and AMP carries through in this model as well. On the negative side, we show a lower bound of $(k^2-3k+6)/(k^2-4k+7)$ for all even $k \geq 4$. For $k \in \{2,3\}$, the competitive ratio is $3/2$. We obtain the lower bounds by modeling the game between the algorithm and the adversary as a game played over *strings* of numbers 0 up to k.

We note that, for the analysis of AMP and of L-Greedy, we assume that k is even. This assumption is borrowed from [1] and is required for the analysis. Of course for odd $k \geq 3$ these algorithms can be run with budget $k-1$, providing a valid upper bound on the competitive ratio. Note that our lower bound in the arrival model holds for all values of k.

Due to space limitations some of the proofs are omitted in this paper.

1.1 Preliminaries

A *matching* in a graph $G = (V, E)$ is a set of edges $M \subseteq E$ with disjoint endpoints. A vertex $v \in V$ is said to be *matched* by M if there is an edge $e \in M$ incident to v, and is *unmatched* otherwise. A key concept in maximum matching algorithms is the notion of an *augmenting alternating path*, or simply *augmenting path*. A path P in G is a sequence of vertices $v_0, v_1, \ldots, v_\ell$ for some length $\ell \geq 2$, such that $(v_i, v_{i+1}) \in E$ for all $i = 0, \ldots, \ell-1$. It is said to be *alternating with respect to* M if every other edge of P belongs to M. Moreover it is said to be *augmenting* if the first and the last vertex is unmatched by M. Applying such a path P to M consists in removing from M the edges in $M \cap P$ and adding the edges in $P \setminus M$. The resulting matching has cardinality $M+1$, and every previously matched vertex remains matched.

We define some concepts that will be useful in the analysis of algorithms throughout the paper. We will associate each edge with a *type* which is an integer in $[0, k]$. An edge is of type i if it has undergone i decision flips by the algorithm. Hence, for an edge of type k, where k is the recourse budget, its decision has been finalized, and cannot change further; we call such an edge *blocked*. The type of a path P is defined by the sequence of the types of its edges, and to make this concept unambiguous, we choose between the two orientations of the path the one that results in the lexicographically minimal such sequence. Note that when the algorithm applies some augmenting path P to its current matching M, then the type of every edge in P is increased by 1. Moreover, the two extreme edges of an augmenting path are of type 0, because the endpoints of P are unmatched. We will call a path *blocked* if it contains a blocked edge.

2 The edge arrival model

2.1 The algorithm AMP

In the more general *online set packing problem* sets arrive online and the goal is to maintain a collection of disjoint sets, maximizing their number. Avitabile *et al.* [1] proposed the *doubling algorithm* which is defined for even k only. It has a parameter $r > 1$ and there is a decision variable for every set which can be changed at most k times. The algorithm works in phases, sequentially numbered by an integer p. Initially $p = 0$, and $\mathrm{ALG}_0 = \emptyset$. Let ℓ be the largest

integer such that the optimal solution has value at least r^ℓ, and let ℓ be $-\infty$ if the optimal solution is empty. Whenever this value increases, the algorithms starts a new phase. We define $\ell(p)$ as the value ℓ during phase p. We have $\ell(p) + i \leq \ell(p + i)$ for every positive integer i. At the beginning of a new phase, all decision variables that have been changed fewer than k times are set as in OPT, resulting in the current solution ALG_p (note that the algorithm crucially depends on k being even in order to produce a feasible solution).

Avitabile *et al.* show that the competitive ratio of the algorithm is at most

$$\min_{r>r_0} \frac{r^k(r-1)}{r^{k-1}(r-1)-r}, \tag{1}$$

where r_0 is the solution to the equation $r^{k-1}(r-1) - r = 0$ in $[1, +\infty)$.

We will show how to obtain an improved analysis of the algorithm in the context of the matching problem. Since we know optimal algorithms for $k = 1, 2$ [3] and for $k = 3$ (see Section 2.4), for the analysis we assume $k \geq 4$. We begin by a restatement of the update phase that will help us exploit the structure of solutions obtained via augmenting paths. More specifically, on every edge arrival the algorithm updates a current optimal solution OPT.

At the beginning of a new phase, the algorithm produces a matching ALG_p obtained from ALG_{p-1} as follows: every edge $e \in \mathrm{ALG}_{p-1} \setminus \mathrm{OPT}$ is removed from the current matching, and every edge $e \in \mathrm{OPT} \setminus \mathrm{ALG}_{p-1}$ which is of type strictly smaller than k is added to the current matching. Note that edges adjacent to e have been removed, hence ALG_p is indeed a matching. Also note that all edges added or removed by the algorithm have their type increased by one.

Since ALG_{p-1} and OPT are matchings, their symmetric difference, excluding type k edges, consists of alternating cycles and alternating paths which can be of even or odd length. This means that the algorithm simply applies at the beginning of every phase all those alternating paths and cycles.

We start the analysis of the competitive ratio by bounding OPT during phase p as

$$r^{\ell(p)} \leq \mathrm{OPT} < r^{\ell(p)+1}, \tag{2}$$

which follows by the definition of phases.

During the phase $p \geq 1$ the competitive ratio is $\mathrm{OPT}/\mathrm{ALG}_p$. The type of an edge increases by 1 at most with each phase. Hence in the beginning of the k first phases the algorithm synchronizes with OPT as there are no blocked edges yet, and as a result during these phases the ratio is 1 at the beginning and does not exceed r by the upper bound in (2).

For the remaining phases we need the following argument.

▶ **Proposition 1.** *For even k and any phase $p \geq k + 1$, AMP maintains a matching ALG_p of size at least $r^{\ell(p)} - r^{\ell(p-k+1)+1}$.*

Proof. We denote by the *type of a vertex v* the maximum type of the edges adjacent to v, and by $n_{i,p}$ the number of vertices of type i in phase p. In addition, we denote by OPT_p the value of OPT at the beginning of phase p. With every new phase the type of a vertex can increase at most by 1. Hence every vertex of type k in phase p had positive type in phase $p - k + 1$. Thus

$$n_{k,p} \leq \sum_{i=1}^{k} n_{i,p-k+1} \leq 2 \cdot \mathrm{OPT}_{p-k+1},$$

where the last inequality uses the fact that the left hand side counts the number of vertices matched by the algorithm. In phase p, the difference between the optimal matching and the matching of the algorithm is at most the number of blocked augmenting paths, and each of them contains at least two type k vertices. Hence

$$\begin{aligned} ALG_p &\geq \mathrm{OPT}_p - \frac{1}{2} \cdot n_{k,p} \\ &\geq \mathrm{OPT}_p - \mathrm{OPT}_{p-k+1} \\ &> r^{\ell(p)} - r^{\ell(p-k+1)+1}. \end{aligned}$$

The last inequality holds since $r^{\ell(p)} \leq \mathrm{OPT}_p < r^{\ell(p)+1}$. ◀

Combining this proposition with the bounds (2) we obtain the following bound.

▶ **Proposition 2.** *The competitive ratio of AMP for $k \geq 4$ is upper bounded by the expression*

$$\min_{r>1} \frac{r^k}{r^{k-1} - r}. \tag{3}$$

In addition we can show that this is a better upper bound.

▶ **Proposition 3.** *For all even $k \geq 4$, Expression* (1) *upper bounds Expression* (3)*.*

The following theorem concludes the asymptotic analysis of the performance of AMP.

▶ **Theorem 1.** *For all even k, AMP has competitive ratio $1 + O(\frac{\log k}{k})$.*

Proof sketch. We first sketch a simple argument based on the Puiseux series expansion [17]: this is a type of power series that allows fractional powers, as opposed to only integer ones (e.g., Taylor series). In the full version we provide a second proof that relies only on standard calculus. Let r denote the optimal choice of the parameter, namely the one that minimizes (3). By analyzing the derivative, it follows that $r = (k-1)^{1/(k-2)}$, hence the competitive ratio is at most $\frac{(k-1)^{\frac{k-1}{k-2}}}{k-2}$, whose Puiseux series expansion at $k = \infty$ is $1 + \frac{\log k + 1}{k} + O(\frac{1}{k^2})$. ◀

2.2 The algorithm Greedy

We consider the algorithm Greedy, which repeatedly applies an arbitrary augmenting path whenever possible. This algorithm achieves an upper bound of 3/2 for $k = 2$ as has been shown in [3]. We show that the same guarantee holds for all even k.In what concerns the lower bound, the idea is to force the algorithm to augment an arbitrarily long path in order to create a configuration with an arbitrarily large number of blocked augmenting paths of lengths 5, which locally have ratio 3/2.

▶ **Proposition 4.** *The competitive ratio of* Greedy *is* 3/2 *for every even k and* 2 *for every odd k.*

2.3 The algorithm L-Greedy

The greedy algorithm has inferior performance because it augments along arbitrarily long augmenting paths, therefore sometimes sacrificing edge budget for only a marginal increase in the matching size. A natural idea towards an improvement would be to apply only short augmenting paths, as they are more budget efficient. For technical reasons, we restrict the choice of augmenting paths even further.

We define the algorithm L-Greedy for some given parameter L, which applies any non-blocked augmenting path of length at most $2L+1$ that is in the symmetric difference between the current matching and some particular optimal matching OPT. The latter is updated after each edge arrival by applying an augmenting path for OPT. Note that L-Greedy may not change its solution even if there is a short augmenting path in the current graph if it contains edges which are not in this particular optimal matching OPT. We will later optimize the parameter L as function of k.

2.3.1 Analysis of L-Greedy

We begin by observing that for $L = 0$ the algorithm collects greedily vertex disjoint edges without any recourse, which is precisely the behavior of Greedy for $k = 1$ and has competitive ratio 2. For $L = 1$ the algorithm L-Greedy applies only augmenting paths of length at most 3. In this case, the same argument as in the proof of Proposition 4 shows that the competitive ratio of L-Greedy is 3/2.

In what follows we analyze the general case $L \geq 2$. To this end, we assign weights to vertices in such a way that the total vertex weight equals the size of the current matching. Therefore, whenever the size of the matching is increased by 1, a total weight of 1 is distributed on the vertices along the augmenting path. Vertices in this path that were already matched receive a weight α, where $\alpha \geq 0$ is some constant that we specify later. Finally, the two vertices on the endpoints of the augmenting path receive the remaining weight, that is $1/2 - \ell\alpha$, where $2\ell + 1$ is the length of the path. It follows, from this weight assignment, that every unmatched vertex has weight 0, that every matched vertex has weight at least $1/2 - L\alpha$, and that every endpoint of a type k edge has weight at least $1/2 - L\alpha + (k-1)\alpha$.

Suppose that the online algorithm reaches a configuration in which it cannot apply any augmenting path, as specified in its statement. We consider the symmetric difference between the matching produced by the algorithm and the optimal matching maintained internally by the algorithm. This symmetric difference consists of alternating paths and/or alternating cycles, and we will upper bound for each such component the ratio between the number of edges in the optimal matching and the total vertex weight, which we call the *local ratio*. In particular, a component in the symmetric difference falls in one of the following cases: Either it is an augmenting path of length $2\ell + 1 \leq 2L + 1$, or an augmenting path of length $2\ell + 1 > 2L + 1$, or an alternating cycle or alternating path of even length.

Case 1: Augmenting path of length $2\ell + 1 \leq 2L + 1$. Such a path contains at least one edge of type k. It follows that $\ell \geq 2$, since an augmenting path of length 1 is a single type 0 edge, and an augmenting path of length 3 has edge types respectively $0, t, 0$ for some odd t (and k is assumed to be even). The path contains 2ℓ matched vertices, and at least 2 of them are adjacent to a type k edge. Hence the total vertex weight is at least $2\ell\left(\frac{1}{2} - L\alpha\right) + 2(k-1)\alpha$, and the local ratio of this component is at most

$$\frac{\ell + 1}{\ell - 2\ell L\alpha + 2(k-1)\alpha}. \tag{4}$$

Case 2: Augmenting path of length $2\ell + 1 > 2L + 1$. Such a path contains 2ℓ matched vertices and therefore the local ratio is at most

$$\frac{\ell + 1}{\ell - 2\ell L\alpha}. \tag{5}$$

Case 3: Alternating cycle or path of even length. Such a component contains 2ℓ matched vertices and therefore the local ratio is at most

$$\frac{\ell}{\ell - 2\ell L\alpha}, \tag{6}$$

which is dominated by (5). We choose α so as to minimize the maximum of the local ratios, as defined by (4) and (5). Then for this choice of α we optimize L; namely we choose the value $L = \lfloor\sqrt{k-1}\rfloor$. Note that for $k = 4$, this leads to the choice $L = 1$, which we analyzed in the beginning of the section. We obtain the following performance guarantee.

▶ **Theorem 2.** *The competitive ratio of* L-Greedy *with* $L = \lfloor\sqrt{k-1}\rfloor$ *is at most*

$$\frac{k(L+2)-2}{(L+1)(k-1)} = 1 + O\left(\frac{1}{\sqrt{k}}\right),$$

for even $k \geq 6$ *and at most* $3/2$ *for* $k = 4$.

One can show that this analysis of L-Greedy is essentially tight.

2.4 Lower bound for deterministic algorithms

Boyar *et al.* [3] show that the deterministic competitive ratio of the problem is 2 for $k = 1$ and $3/2$ for $k = 2$. We complete this picture by showing a lower bound of $1 + \frac{1}{k-1}$ for all $k \geq 3$. Note that the lower bound is tight for $k = 3$, as the algorithm Greedy, which works by assuming that k is only 2, has competitive ratio $3/2$.

▶ **Theorem 3.** *The deterministic competitive ratio of the online matching problem with edge-bounded recourse is at least* $1 + \frac{1}{k-1}$ *for all* $k \geq 3$.

Proof sketch. We consider three cases, namely the cases $k = 3$, k is even and at least 4, and finally k is odd and at least 5. For each case we present an appropriate adversarial argument. Due to space limitations we only present the case $k = 3$. Suppose, by way of contradiction, that for $k = 3$ some algorithm claims a competitive ratio strictly smaller than $(3n+2)/(2n+2)$ for some arbitrary $n \geq 1$. The adversary releases a single edge, creating an augmenting path of length 1. Then the algorithm applies the augmenting path, which the adversary extends by appending one edge on each side, creating an augmenting path of type 0,1,0, as shown in Figure 2(a). Since the current ratio is 2, the algorithm needs to apply this path, which the adversary again extends by appending an edge on each side, creating an augmenting path of type 0,1,2,1,0, as shown in Figure 2(b). Since the current ratio is $3/2$, the algorithm applies this path. In response the adversary appends an edge at each endpoint of the type 3 edge, and at each endpoint of one of the type 1 edges, as shown in Figure 2(c). The resulting graph has a blocked augmenting path of type 0,3,0, and an augmenting path of type 0,1,0, as shown in Figure 2(c). The algorithm needs to apply the latter one as the ratio is currently $5/3 > 3/2$.

At this point, the adversary repeats this construction $n - 1$ times, by identifying the shaded part of Figure 2(c) as the graph of Figure 2(a), and reapplying the above construction. The final graph consists of n blocked augmenting paths of type 0,3,0 and $n + 1$ edges of type 1 that belong both to the optimal and the algorithm's matchings. Figure 2(d) illustrates this final graph for $n = 4$. Hence the competitive ratio is $(3n+1)/(2n+1)$, contradicting the claimed ratio and showing a lower bound of $3/2$. ◀

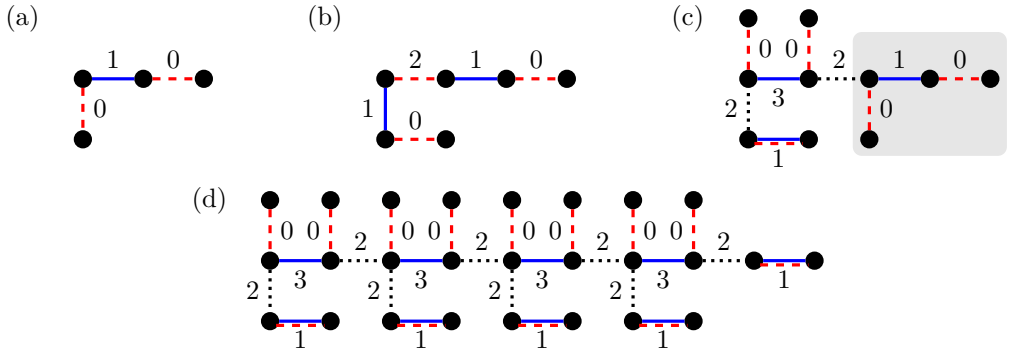


Figure 2 Lower bound construction for the case $k = 3$.

Table 1 Summary of lower bounds (LB) and upper bounds on the competitive ratio for the problem, for all even $4 \leq k \leq 22$. The lower bounds for the arrival/departure model are discussed in Section 3. The analysis of L-Greedy and AMP carry through to the (limited) edge arrival/departure model. For $k \geq 22$, the upper bound of AMP is superior to the upper bound of L-Greedy.

k	LB (arr.)	LB (arr./dep.)	L-Greedy	AMP

2.5 Comparing the algorithms L-Greedy and AMP

We have analyzed two deterministic online algorithms: the algorithm AMP, which has competitive ratio $1+O\left(\log(k)/k\right)$, and the algorithm L-Greedy, which has competitive ratio $1+\Theta(1/\sqrt{k})$. Since the analysis of L-Greedy is tight, it follows that AMP is asymptotically (i.e., for large k) superior to L-Greedy. However, for small values of k, namely $k \leq 20$, we observe that L-Greedy performs better, in comparison to the performance bound we have shown for AMP. These findings are summarized in Table 1 and Figure 3.

3 The edge arrival/departure model

In this section we consider the online matching problem in the setting in which edges may arrive but also *depart* online. In this context one can distinguish two models. In the *limited departure model* an edge cannot be removed from the instance while it is matched by the online algorithm, while in the stronger *full departure model* any edge can be removed.

It turns out that the latter model is quite restrictive. This is because it is possible for the adversary to force an online algorithm to augment some augmenting path and then to remove one of the edges in its matching. Eventually the algorithm can end up with blocked edges (type k), without having the chance to augment its matching. This intuition is formalized in the following lemma.

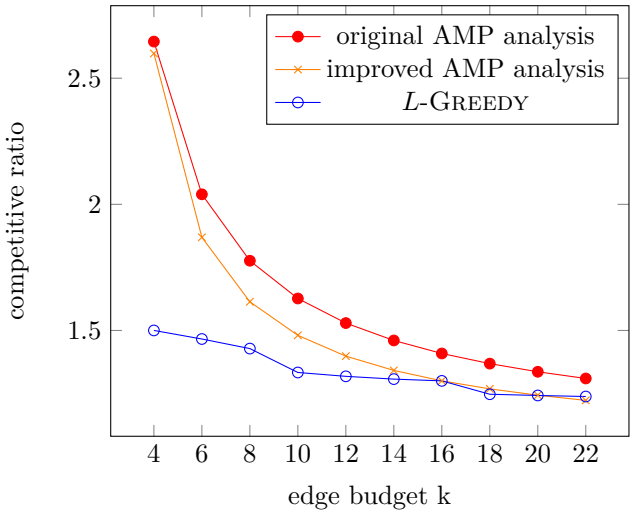

Figure 3 Comparison of the competitive ratios of the algorithm AMP and the algorithm L-Greedy.

▶ **Lemma 4.** *The competitive ratio in the full departure model is* 2.

Since the full departure model is very restrictive for the algorithm, as shown in Lemma 4, we will concentrate on the limited departure model, as defined in the introduction. For this model, we observe that the algorithms L-Greedy and AMP have the same performance guarantee as in the edge arrival model. This is because the analysis of L-Greedy uses weights on vertices which are not affected by edge departures, and the analysis of AMP is based on an upper bound over the number of type k edges, which still holds under edge departures. We thus focus on obtaining stronger lower bounds in this model (also included in Table 1). We begin by observing that the bound of 3/2 of the competitive ratio in the edge arrival model for $k \in \{2, 3\}$ still holds for the limited departure model, where the adversary is stronger. Hence, the smallest interesting value for k in this model is $k = 4$, for which we provide the following specific lower bound. The proof will also provide some intuition about the adversarial argument for general k.

▶ **Theorem 5.** *The competitive ratio in the* limited departure model *is at least* $10/7$ *for* $k = 4$.

Proof. We specify a particular adversary that maintains a graph such that the symmetric difference between the matching produced by the algorithm and the optimal matching consists only of augmenting paths and has no alternating cycles or alternating paths of even length.

The edge types along any path form a string over the integers $\{0, 1, \ldots, k\}$ with alternating parity and starting and ending with 0. We call these strings *alternating*. Thus, rather than a game played between the algorithm and the adversary on a *graph*, we will consider the game played on a *collection of alternating strings*.

Whenever the algorithm applies an augmenting path, this translates into the increment of each integer of the corresponding string, for example $01210 \to 12321$. The adversary responds to this action by three types of actions. First, the adversary may possibly split the string into smaller strings, for example $12321 \to 123, 1$ or $12321 \to 1, 3, 1$. This corresponds to deleting some edges which are currently not matched by the algorithm. Second, the adversary may possibly merge some of the resulting strings by concatenating them on both

sides of a 0, for example $1,1 \to 101$. Finally the adversary may append 0's to the ends of the strings, where needed to make them alternating, for example $101 \to 01010$. The last two actions correspond to the insertion of (type 0) edges by the adversary.

The main idea is as follows. Consider an algorithm that claims a competitive ratio at most $(10-\epsilon)/7$ for some sufficiently small $\epsilon > 0$. We will then show that the adversary can force the algorithm into a final configuration of ratio at least $10/7$, a contradiction.

We describe the current configuration by variables v, w, x, y, z which count the number of the specific strings that are described in Figure 4. In particular, z is the total number of strings 030 and 01410, which we call *bad strings*. The name is motivated by the fact that 01410 has worst local ratio among all blocked strings and is created from 030 strings.

The adversary starts by presenting the string 0, which the algorithm has to augment, resulting in a single string 010. This unique adversarial action has been omitted for simplification from Figure 4. From this moment onwards, we distinguish 3 different phases during the game, decided by the adversary, and depicted in Figure 4. For example, if the algorithm augments the string 01010, then in phase 1 the adversary will replace it with the strings 010 and 01210, while in phases 2 and 3 he will replace it with the string 0121210.

At a high level, the objective in phase 1 is to create a large enough number of bad strings, while phase 2 creates a large enough proportion of bad strings. Last, phase 3 leads the algorithm to a configuration which consists only of blocked strings.

The game starts with phase 1. During this phase the competitive ratio is at least $3/2$, thus forcing the algorithm to continue augmenting strings. After a finite number of steps, the condition $7z+3 > 4/\epsilon$ holds and the game moves to phase 2. During the second phase we have the invariants (1) $7z+3 > 4/\epsilon$ and (2) $2x+y+2w \le z+1$. Invariant (1) holds because the left-hand side will not decrease throughout the phase. Moreover, Invariant (2) follows from the definitions of the involved parameters and the transitions between strings, as defined by the statement of the phase. Together both invariants imply that the competitive ratio is strictly larger than $(10-\epsilon)/7$, forcing the algorithm to augment strings. This is because the competitive ratio can be lower bounded by

$$\frac{3z+3y+4(x+w)}{2z+2y+3(x+w)} \ge \frac{10z+2y+4}{7z+y+3} \ge \frac{10z+4}{7z+3} \ge \frac{10-\epsilon/2}{7},$$

where the first inequality follows from Invariant (2) and the last one from (1).

In phase 2, at some moment eventually the condition $z \ge 8(x+y+v+w)$ will hold since $x+y+v+w$ does not change, but any sequence of $x+y+1$ steps increases z. At that moment, the game starts phase 3. We note that the condition is preserved during phase 3 and that it implies a ratio of at least $10/7$, forcing the algorithm to a configuration consisting only of the blocked strings 01410 and 012343210. This is because $z \ge 8(x+y+v+w)$ implies $z+y+x \ge 2w+8v$, which in turn implies

$$\frac{3(x+y+z)+4w+6v}{2(x+y+z)+3w+5v} \ge \frac{10}{7},$$

where the left hand side lower bounds the competitive ratio in phase 3. ◀

We can generalize the ideas in the proof of Theorem 5 so as to obtain a non-trivial lower bound for general even $k \ge 4$, see Figure 5.

▶ **Theorem 6.** *The competitive ratio in the limited departure model is at least* $\frac{k^2-3k+6}{k^2-4k+7}$*, for all even* $k \ge 4$*.*

Since $\frac{k^2-3k+6}{k^2-4k+7} > 1 + \frac{1}{k-1}$ for all $k \ge 4$, Theorem 6 shows a stronger lower bound for even k than Theorem 3 under the limited departure model.

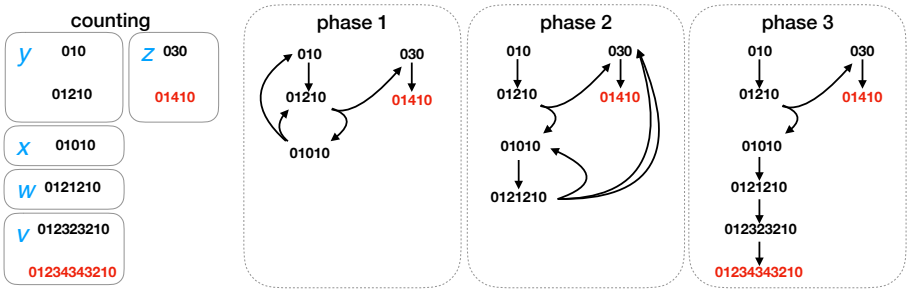

Figure 4 The lower bound construction in the arrival/departure model and $k = 4$.

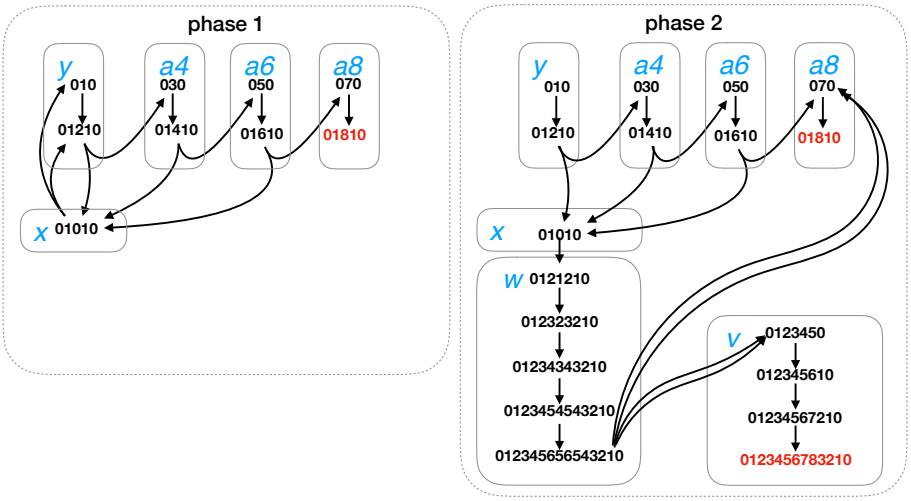

Figure 5 The lower bound construction in the arrival/departure model illustrated for $k = 8$. Blocked strings are depicted in red. The arcs illustrate the adversarial strategy. For example, if the algorithm augments the string 012345656543210, the adversary replaces the resulting string by two strings 070 and two strings 0123450.

Abstract

Focusing and selection are techniques that shrink the proof search space for respectively sequent calculi and resolution. To bring out a link between them, we generalize them both: we introduce a sequent calculus where each *occurrence* of an atom can have a positive or a negative polarity; and a resolution method where each literal, whatever its sign, can be selected in input clauses. We prove the equivalence between cut-free proofs in this sequent calculus and derivations of the empty clause in that resolution method. Such a generalization is not semi-complete in general, which allows us to consider complete instances that correspond to theories of any logical strength. We present three complete instances: first, our framework allows us to show that ordinary focusing corresponds to hyperresolution and semantic resolution; the second instance is deduction modulo theory; and a new setting, not captured by any existing framework, extends deduction modulo theory with rewriting rules having several left-hand sides, which restricts even more the proof search space.

1 Introduction

In addition to clever implementation techniques and data structures, a key point that explains the success of state-of-the-art automated theorem provers is the use of calculi that dramatically reduce proof search space. In the last decades, the independent developments of two families of techniques can be highlighted. First, in the kind of methods based on resolution, proof search space can be shrunk using ordering and selection techniques. The intuition is to restrict the application of the resolution rule to only some literals in a clause. If equality is considered, this leads to the superposition calculus [2] which is the base calculus of the currently most efficient automated provers for first-order classical logic. Second, in sequent calculi, Andreoli [1] introduced a technique called focusing to reduce non-determinism in the application of sequent-calculus rules. It works by first applying all invertible rules (those whose conclusion is logically equivalent to their premises) and second by chaining the application of non-invertible rules. Originally developed for linear logic, focusing has been extended to intuitionistic and classical first-order logic [26]. Focusing is mostly used in fields where sequent calculi, and related inverse and tableaux methods, are the most accurate proving method. For instance, there exists tools for first-order linear logic [12], for intuitionistic logic [27] and for modal logic [28]. Focusing is also the key ingredient in Miller's ProofCert project aiming at building a universal framework for proof certification [15].

Despite their apparent lack of relation, we show in this paper that selection in refinements of the resolution calculus and focusing in sequent calculus are in fact strongly related, so that ordinary focusing in classical first-order logic corresponds actually to hyperresolution, where all negative literals are selected in a clause and are resolved at once. This connection is obtained by relaxing both techniques: concerning resolution, we allow any literal of the input clauses to be selected, whatever its sign; for the focusing part, we allow polarization not only of connectives, but also of all occurrences of literals. The main theorem of this paper, Theorem 3, shows that the sets of clauses whose insatisfiability can be proved by the resolution method with arbitrary input selection are exactly the sequents that have a cut-free proof in the generalized focusing setting.

This generalization allows us to cover a wider spectrum of proof systems. In particular, this permits to consider systems that search for proofs modulo some theory. Indeed, in real world applications, proof obligations are often verified within one or several theories. This explains the interest in and the success of Satisfiability Modulo Theory tools in recent years. Embedding a theory in our framework amounts to giving an axiomatic presentation of it where some literals are selected.

By relaxing the conditions for selecting literals, our framework is not always refutationaly complete. However, this should not be considered as a drawback, but as an essential point to be able to represent efficiently all kinds of theories. Indeed, let us consider a proof search method $\mathbb{P}(\mathcal{T})$ parameterized by a theory $\mathcal{T}$. Ideally, $\mathbb{P}(\mathcal{T})$ should be as efficient as a generic proof search method if it is fed with a formula that is not related to the theory $\mathcal{T}$. In particular, if it tries to refute the true formula $\top$, it should terminate, and with the answer "NO". Let us say that $\mathbb{P}(\mathcal{T})$ is relatively consistent if it is the case. As we pointed out with Dowek [8], we cannot have a generic proof of the completeness of a relatively consistent method $\mathbb{P}(\mathcal{T})$ that would work for all $\mathcal{T}$. Indeed, such a proof would imply the consistency of the theory $\mathcal{T}$, and, according to Gödel, this cannot be performed in $\mathcal{T}$ itself. So either the completeness of the proof system is proved once and for all, but it cannot represent theories that are logically at least as strong as that proof of completeness; or it is not complete in general but it can be proved to be complete for particular theories of some arbitrary logical strength. What is interesting therefore is to give proofs of completeness of $\mathbb{P}(\mathcal{T})$ for particular theories $\mathcal{T}$.

Therefore, we give three instances of our framework, where we can have proofs of completeness. First, as stated above, we link ordinary focusing with hyperresolution, and, in the ground case, with semantic resolution. Second, we show that Deduction Modulo Theory [20] is also a particular instance of this framework, knowing that there exists numerous proof techniques to prove the completeness of Deduction Modulo a particular theory, for instance [24, 21, 18, 7]. Third, we show how completeness in our framework can be reduced to completeness of several instances of Deduction Modulo Theory. To give an intuition about this last part, and to illustrate how much the proof search space can be constrained without losing completeness, let us consider for example the theory defining the powerset:

$$\forall X,\ \forall Y,\ (X \in \mathcal{P}(Y)) \Leftrightarrow (\forall Z,\ (Z \in X) \Rightarrow (Z \in Y))$$

This theory can be put in clausal normal form, using d as a Skolem symbol, and we select (by underlining them) some literals in these clauses[1]:

[1] We use the associative-commutative-idempotent symbol $\curlyvee$ in clauses to distinguish it from the symbol $\vee$ that is used in formulas.

$$\underline{\neg X \in \mathcal{P}(Y)} \curlyvee \underline{\neg Z \in X} \curlyvee Z \in Y \tag{1}$$

$$\underline{X \in \mathcal{P}(Y)} \curlyvee d(X,Y) \in X \tag{2}$$

$$\underline{X \in \mathcal{P}(Y)} \curlyvee \underline{\neg d(X,Y) \in Y} \tag{3}$$

Using focusing in general, and in our framework in particular, the decomposition of connectives is so restricted that, given an axiom, a proof derivation decomposing this axiom would necessarily have certain shapes. Thus, the axiom can be replaced by new inference rules, called synthetic rules, that are used instead of the derivation of those shapes. See end of Section 2, page 6, for more details. In our framework, this would lead to the following three synthetic rules, that can be used in place of the axioms (the explanation how these rules are obtained is given in Section 5.3):

$$(1)\vdash \frac{\Delta, u \in \mathcal{P}(v), t \in u, t \in v \vdash}{\Delta, u \in \mathcal{P}(v), t \in u \vdash} \qquad (2)\vdash \frac{\Delta, \neg u \in \mathcal{P}(v), d(u,v) \in u \vdash}{\Delta, \neg u \in \mathcal{P}(v) \vdash}$$

$$(3)\vdash \frac{}{\Delta, \neg u \in \mathcal{P}(v), d(u,v) \in v \vdash}$$

The only proof of transitivity of the membership in the powerset is then

$$\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{}{a \in \mathcal{P}(b), b \in \mathcal{P}(c), \neg a \in \mathcal{P}(c), d(a,c) \in a, d(a,c) \in b, d(a,c) \in c \vdash}(3)}{a \in \mathcal{P}(b), b \in \mathcal{P}(c), \neg a \in \mathcal{P}(c), d(a,c) \in a, d(a,c) \in b \vdash}(1)}{a \in \mathcal{P}(b), b \in \mathcal{P}(c), \neg a \in \mathcal{P}(c), d(a,c) \in a \vdash}(1)}{a \in \mathcal{P}(b), b \in \mathcal{P}(c), \neg a \in \mathcal{P}(c) \vdash}(2)}{a \in \mathcal{P}(b) \wedge b \in \mathcal{P}(c) \wedge \neg a \in \mathcal{P}(c) \vdash}\wedge\vdash}{\exists A.\ \exists B.\ \exists C.\ A \in \mathcal{P}(B) \wedge B \in \mathcal{P}(C) \wedge \neg A \in \mathcal{P}(C) \vdash}\exists\vdash$$

where the active formulas in a sequent are underwaved, and double lines indicate potentially several applications of an inference rule.

On the resolution side, clauses (1) to (3) lead to the following ground derived rules (see also Section 5.3):

$$(1)\ \frac{u \in \mathcal{P}(v) \curlyvee C \qquad t \in u \curlyvee D}{t \in v \curlyvee C \curlyvee D} \qquad (2)\ \frac{\neg u \in \mathcal{P}(v) \curlyvee C}{d(u,v) \in u \curlyvee C}$$

$$(3)\ \frac{\neg u \in \mathcal{P}(v) \curlyvee C \qquad d(u,v) \in v \curlyvee D}{C \curlyvee D}$$

Once again, there is only one proof of transitivity, i.e. starting from the set of clauses $\{a \in \mathcal{P}(b); b \in \mathcal{P}(c); \neg a \in \mathcal{P}(c)\}$:

$$(3)\ \frac{\neg a \in \mathcal{P}(c) \qquad (1)\ \dfrac{b \in \mathcal{P}(c) \qquad (1)\ \dfrac{a \in \mathcal{P}(b) \qquad (2)\ \dfrac{\neg a \in \mathcal{P}(c)}{d(a,c) \in a}}{d(a,c) \in b}}{d(a,c) \in c}}{\square}$$

and we cannot even infer other clauses than those. We let the reader compare with what happens if we used clauses (1) to (3) in resolution, even using the ordered resolution with selection refinement.

Related work. Chaudhuri et al. [13] show that hyperresolution for Horn clauses can be explained as an instance of a sequent calculus for intuitionistic linear logic with focusing where atoms are given a negative polarity.

Farooque et al. [23] developed a sequent calculus, based on focusing, that is able to simulate DPLL($\mathcal{T}$), the most common calculus used in SMT provers. The main difference with our framework is that in [23], the theory is considered as a black box which is called as an oracle. Here, the theory is considered as a first-class citizen.

Within the ProofCert project, resolution proofs can be checked by a kernel built upon a sequent calculus with focusing [15]. Based on this, the tool `Checkers` [14] is able to verify proofs coming from automated theorem provers based on resolution such as E-prover. Different from here, they translate resolution derivations using cuts to get smaller proofs.

Hermant [25] proves the correspondance between the cut-free fragment of a sequent calculus and a resolution method, in the setting of Deduction Modulo Theory. Since Deduction Modulo Theory is subsumed by our framework, Theorem 3 is a generalization of Hermant's work. Proving it is simpler in our setting because focusing restrains the shape of possible sequent calculus proofs, whereas Hermant had to prove technical lemmas to give proofs a canonical shape.

Notations and conventions. We use standard definitions for terms, predicates, formulas (with connectives $\bot, \top, \neg, \wedge, \vee$ and quantifiers $\forall, \exists$), sequents and substitutions. A literal is an atom or its negation. A clause is a set of literals. We will identify a literal with the unit clause containing it. Unless stated otherwise, letters $P, Q, R, P', P_1, \dots$ denote atoms, $L, K, L', L_1, \dots$ denote literals, $A, B, A', A_1, \dots$ denote formulas, $C, D, C', C_1, \dots$ denote clauses, Γ, Δ denote set of clauses or set of formulas (depending on the context). $A^{\perp}$ denotes the negation normal form of $\neg A$.

2 Focusing with Polarized Occurrences of Atoms

Focusing was introduced by Andreoli [1] to restrict the non-determinism in some sequent calculus for linear logic. It relies on the alternation of two phases: During the asynchronous phase (sequents with $\Uparrow$), all invertible rules are applied on the formulas of the sequent. Recall that a rule is said invertible if its conclusion implies the conjunction of its premises. During the synchronous phase (sequents with $\Downarrow$), a particular formula is selected – the focus is on it – and all possible non-invertible rules are successively applied on it. This idea has been extended to intuitionistic and classical first-order logic [26]. In these, connectives may have invertible and non-invertible versions of their sequent calculus rules. Therefore, one considers in that case two versions of a connective, one called positive when the right introduction rule is non-invertible, and one called negative when it is invertible. Some connectives, i.e. $\exists$ in classical logic, only have a positive version, and dually, others, such as $\forall$ in classical logic, only have a negative version. Given a usual formula, one can decide which version of a connective one wants to use at a particular occurrence, which is called a polarization of the formula.[2] Note that the polarity of a connective does not affect its semantics, it only alters the shape of the sequent calculus proofs. Similarly, one can decide the polarity of each literal. If a literal with negative polarity L is focused on in a branch, then this branch

[2] Let us note that this notion of polarity is a standard denomination when dealing with focusing, and should not be confused with the more usual but unrelated notion defined by the parity of the negation-depth of a position in a formula.

Asynchronous phase:

$$\widehat{\Uparrow}\vdash \frac{}{\Gamma, L, L^\perp \Uparrow \vdash} \qquad \Uparrow\exists\vdash \frac{\Gamma \Uparrow \Delta, A \vdash}{\Gamma \Uparrow \Delta, \exists x.\ A \vdash}\ x \text{ not free in } \Gamma, \Delta$$

$$\Uparrow\vee\vdash \frac{\Gamma \Uparrow \Delta, A \vdash \qquad \Gamma \Uparrow \Delta, B \vdash}{\Gamma \Uparrow \Delta, A \vee^+ B \vdash} \qquad \Uparrow\wedge\vdash \frac{\Gamma \Uparrow \Delta, A, B \vdash}{\Gamma \Uparrow \Delta, A \wedge^+ B \vdash} \qquad \Uparrow\top\vdash \frac{\Gamma \Uparrow \Delta \vdash}{\Gamma \Uparrow \Delta, \top \vdash}$$

Synchronous phase:

$$\widehat{\Downarrow}\vdash \frac{}{\Gamma, L^\perp \Downarrow \underline{L} \vdash} \qquad \Downarrow\forall\vdash \frac{\Gamma \Downarrow \{t/x\}A \vdash}{\Gamma \Downarrow \forall x.\ A \vdash} \qquad \Downarrow\perp\vdash \frac{}{\Gamma \Downarrow \perp \vdash}$$

$$\Downarrow\vee\vdash \frac{\Gamma \Downarrow A \vdash \qquad \Gamma \Downarrow B \vdash}{\Gamma \Downarrow A \vee^- B \vdash} \qquad \Downarrow\wedge_1\vdash \frac{\Gamma \Downarrow A \vdash}{\Gamma \Downarrow A \wedge^- B \vdash} \qquad \Downarrow\wedge_2\vdash \frac{\Gamma \Downarrow B \vdash}{\Gamma \Downarrow A \wedge^- B \vdash}$$

$$\textsf{Focus}\ \frac{\Gamma, A \Downarrow A \vdash}{\Gamma, A \Uparrow \vdash}\ A \text{ negative} \qquad \textsf{Release}\ \frac{\Gamma \Uparrow A \vdash}{\Gamma \Downarrow A \vdash}\ A \text{ positive} \qquad \textsf{Store}\ \frac{\Gamma, A \Uparrow \Delta \vdash}{\Gamma \Uparrow A, \Delta \vdash}\ A \text{ negative or literal}$$

Figure 1 The sequent calculus LKF$^\perp$.

must necessarily be closed, with $L^\perp$ in the same context. (See rule $\widehat{\Downarrow}\vdash$ in Figure 1.) In the ordinary presentation of focusing, this polarity is chosen globally for all occurrences of each atom, and the polarity of $\neg P$ is defined as the inverse of that of P. In our setting, the polarity is attached to the position of the literal in the formula. In particular, if a substitution is applied to the formula, the polarities of the resulting literals do not change. The polarity of a formula is defined as the polarity of its top connective. Besides, note that to switch the polarity of a formula, e.g. to impose a change of phase, one can prefix it by so-called delays: $\delta^- A$ is negative whatever the polarity of A. Delays can be defined for instance by $\delta^- A = \forall x.\ A$ where x is not free in A, so we do not need them in the syntax and the rules.

Liang and Miller [26] introduce the sequent calculus LKF, and prove it to be complete for classical first-order logic. In Figure 1, we present the calculus LKF$^\perp$, which is almost the same with the following differences:

- All formulas are put on the left-hand side of the sequent, instead of the right-hand side. Therefore, one does not try to prove a disjunction of formulas, but one tries to refute a conjunction of formulas. This is the same thanks to the dual nature of classical first-order logic, and this helps to be closer to the resolution derivations. Note that, consequently, the focus is on negative formulas, and invertible rules are applied on positive formulas.
- The polarity of atoms is not chosen globally, but each *occurrence* of a literal can have a positive or a negative polarity. In particular, we can have two literals L and $L^\perp$ which are both negative, or both positive. We denote by $\underline{L}$ the fact that the literal L has a negative polarity. To be able to close branches on which we have two positive opposed literals, we add a rule $\widehat{\Uparrow}\vdash$.

We denote by $\Gamma \Uparrow \Delta \vdash$ (with Γ or Δ, possibly empty, containing polarized formulas) the fact that there exists a proof of the sequent $\Gamma \Uparrow \Delta \vdash$ in LKF$^\perp$, that is, a derivation starting from this sequent and whose branches are all closed (by $\widehat{\Downarrow}\vdash$, $\widehat{\Uparrow}\vdash$ or $\Downarrow\perp\vdash$). Thanks to focusing, such a proof has the following shape :

- Since one starts in an asynchronous ($\Uparrow$) phase, invertible rules are successively applied to the positive formulas of Δ, until one obtains negative formulas or literals that are put on the left of $\Uparrow$ using Store.
- When no formula appears on the right of $\Uparrow$, then either the branch is closed by $\widehat{\Uparrow}\vdash$; or the focus is put on a negative formula using Focus.
- In the latter case, one is now in synchronous ($\Downarrow$) phase where non-invertible rules are

successively applied to the formula upon which the focus is, until either the branch is closed using $\overset{\frown}{\Downarrow}\vdash$ or $\Downarrow\bot\vdash$; or one obtains a positive formula and the synchronous phase ends using Release.

- In the latter case, one starts again in the asynchronous phase.

Focusing therefore strongly constraints the shape of possible proofs, and therefore reduces the proof search space. The $\overset{\frown}{\Downarrow}\vdash$ in particular imposes to close branches immediately when the focus is on a negative literal, and thus rules out many derivations.

Note that proofs can be closed when the polarities of an atom and its negation are both positive (rule $\overset{\frown}{\Uparrow}\vdash$), or when one is positive and the other negative (rule $\overset{\frown}{\Downarrow}\vdash$), but not when they are both negative. Therefore, this restricts how formulas that contains literals with negative polarities can interact one with the others, and this is the main point of $\mathrm{LKF}^{\bot}$ to reduce the proof search space.

Restricting proof search using focusing leads to what are called synthetic rules (see for instance [13, pp.148–150] where they are called derived rules). The idea is to replace some formula A in the context of the sequent by new inference rules. Instead of proving the sequent $A, \Delta \vdash$ in $\mathrm{LKF}^{\bot}$, one proves $\Delta \vdash$ in ($\mathrm{LKF}^{\bot}$+ the synthetic rules obtained from A). Indeed, a proof focusing on A can only have certain shapes, and thus instead of having A in the context, it can be replaced by new rules synthesizing those shapes. For instance, the formula $\underline{P} \vee^{-} (Q \wedge^{+} \underline{R})$ in a context Γ can only lead to the following derivations when the focus is put on it:

$$\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{}{\Gamma \Downarrow P \vdash}\,\overset{\frown}{\Downarrow}\vdash \qquad \dfrac{\dfrac{\dfrac{\Gamma, Q \Uparrow \vdash}{\Gamma \Uparrow Q \vdash}\,\mathsf{Store}}{\Gamma \Downarrow Q \vdash}\,\mathsf{Release}}{\Gamma \Downarrow Q \wedge^{-} \underline{R} \vdash}\,\Downarrow\wedge_1\vdash}{\Gamma \Downarrow P \vee^{-} (Q \wedge^{-} \underline{R}) \vdash}\,\Downarrow\vee\vdash}{\Gamma \Uparrow \vdash}\,\mathsf{Focus}$$

and

$$\dfrac{\dfrac{\dfrac{\dfrac{}{\Gamma \Downarrow P \vdash}\,\overset{\frown}{\Downarrow}\vdash \qquad \dfrac{\dfrac{}{\Gamma \Downarrow \underline{R} \vdash}\,\overset{\frown}{\Downarrow}\vdash}{\Gamma \Downarrow Q \wedge^{-} \underline{R} \vdash}\,\Downarrow\wedge_2\vdash}{\Gamma \Downarrow P \vee^{-} (Q \wedge^{-} \underline{R}) \vdash}\,\Downarrow\vee\vdash}{\Gamma \Uparrow \vdash}\,\mathsf{Focus}$$

.

In the left derivation, $P^{\bot}$ must be in Γ to be able to close the left branch, so Γ is in fact of the form $\underline{P} \vee^{-} (Q \wedge^{+} \underline{R}), \Delta, P^{\bot}$. In the right one, Γ must be of the form $\underline{P} \vee^{-} (Q \wedge^{+} \underline{R}), \Delta, P^{\bot}, R^{\bot}$. Instead of searching for a proof with $\underline{P} \vee^{-} (Q \wedge^{+} \underline{R})$ in the context, the following two synthetic rules can therefore be used:

$$\mathsf{Syn1}\ \dfrac{\Delta, P^{\bot}, Q \Uparrow \vdash}{\Delta, P^{\bot} \Uparrow \vdash} \qquad\qquad \mathsf{Syn2}\ \dfrac{}{\Delta, P^{\bot}, R^{\bot} \Uparrow \vdash}$$

Provability is the same because each application of a synthetic rule can be replaced by applying Focus on $\underline{P} \vee^{-} (Q \wedge^{+} \underline{R})$ and following the derivation leading the synthetic rule, and vice versa. This is used for instance in provers based on the inverse method and focusing [27].

The sequent calculus $\mathrm{LKF}^{\bot}$ is not complete in general. One of the simplest examples of incompleteness is the sequent $\underline{P} \vee^{-} Q, \underline{\neg P} \vee^{-} Q, \neg Q \Uparrow \vdash$ which has no proof although $P \vee Q, \neg P \vee Q, \neg Q$ is not satisfiable.

3 Resolution with Input Selection

Two approaches can be used to reduce the proof search space of the resolution calculus: first, one can restrict on which pairs of clauses the resolution rule can be applied; this leads for instance to the set-of-support strategy [32], in which clauses are split into two sets, called the theory and the set of support; at least one of the clauses involved in a resolution step must be in the set of support. Second, one can restrict which literals in the clauses can be resolved

Resolution $\dfrac{L \curlyvee C \qquad L'^{\perp} \curlyvee D}{\sigma(C \curlyvee D)}$

- $\mathcal{S}(L \curlyvee C) = \emptyset$
- $\mathcal{S}(L'^{\perp} \curlyvee D) = \emptyset$
- σ is the most general unifier of $L =^? L'$

Factoring $\dfrac{L \curlyvee L' \curlyvee C}{\sigma(L \curlyvee C)}$

- $\mathcal{S}(L \curlyvee L' \curlyvee C) = \emptyset$
- σ is the most general unifier of $L =^? L'$

Resolution with Selection $\dfrac{\underline{K_1} \curlyvee \ldots \curlyvee \underline{K_n} \curlyvee C \qquad K_1'^{\perp} \curlyvee D_1 \qquad \ldots \qquad K_n'^{\perp} \curlyvee D_n}{\sigma(C \curlyvee D_1 \curlyvee \ldots \curlyvee D_n)}$

- $\mathcal{S}(\underline{K_1} \curlyvee \ldots \curlyvee \underline{K_n} \curlyvee C) = \{K_1; \ldots; K_n\}$
- $\mathcal{S}(K_i'^{\perp} \curlyvee D_i) = \emptyset$
- σ is the mgu of the simultaneous unification problem $K_1 =^? K_1', \ldots, K_n =^? K_n'$

Figure 2 Resolution with Input Selection.

upon; those literals are said to be selected in the clause. Resolution with free selection is complete for Horn clauses, but incomplete in general. Selecting a subset of the negative literals (if no literal is selected, then any literal of the clause can be used in resolution) is however complete, and combining this with an ordering restriction on clauses with no selected literals leads to Ordered Resolution with Selection, which was introduced by Bachmair and Ganzinger [2] (see also [3]) as a complete refinement of resolution.

Resolution with Input Selection combines these two approaches. It is parameterized by a selection function $\mathcal{S}$ that associate to each input clause a subset of its literals. If the selection function selects at least one literal, only those can be used in Resolution. Otherwise, any of them can be used. Note that for generated clauses, we impose that $\mathcal{S}(C) = \emptyset$. We also allow to have the same input clause several times with different selections. (That is, we actually work with couples composed of a clause and its selected literals.) The inference rules of Resolution with Input Selection are presented in Fig. 2. Literals that are selected in a clause are underlined. We will see that they indeed correspond to the literals that have a negative polarization in $\mathrm{LKF}^{\perp}$. As usual, variables are renamed in the clauses to avoid that premises of the inference rules share variables. We have two flavors of the resolution rule: the usual binary resolution, that is applied on two premises that do not select any literal; and Resolution with Selection that is applied on a clause in which n literals are selected and n clauses is which no literal is selected. Consequently, clauses with a non-empty selection cannot be resolved one with the others. By considering them as the theory part, and the clauses with an empty selection as the set of support, it is easy to see that Resolution with Input Selection is a generalization of the set-of-support strategy. Notwithstanding, note that neither Resolution with Input Selection is a generalization of Ordered Resolution with Selection nor the converse.

▶ **Definition 1** (Resolution derivation)**.** We write $\Gamma \rightsquigarrow C$ if C can be derived from some clauses in Γ using the inference rules Resolution with Selection, Resolution, or Factoring presented in Figure 2. We write $\Gamma \rightsquigarrow^* C$ if

- $C \in \Gamma$ or if
- there exists D such that $\Gamma \rightsquigarrow D$ and $\Gamma, D \rightsquigarrow^* C$.

As usual in resolution methods, the goal is to produce the empty clause $\square$ starting from a set of clauses Γ to show, since all rules are sound, that Γ is unsatisfiable. Here again, the calculus is not complete in general: from the set of clauses $\underline{P} \curlyvee Q, \underline{\neg P} \curlyvee Q, \neg Q$, no inference rule can be applied: to apply Resolution with Selection, we would need a clause where P, or $\neg P$, is not selected, and Resolution needs two clauses without selection.

4 LKF$^\perp$ is a Conservative Extension of Resolution with Input Selection

To link LKF$^\perp$ with Resolution with Input Selection, we need to indicate how clauses are related to polarized formulas.

▶ **Definition 2.** Given a clause $C = \underline{L_1} \curlyvee \cdots \curlyvee \underline{L_n} \curlyvee K_1 \curlyvee \ldots \curlyvee K_m$ whose free variables are $x_1, \ldots, x_l$ and such that $\mathcal{S}(C) = \{L_1; \ldots; L_n\}$, we define the associated formula $\ulcorner C \urcorner = \forall x_1, \ldots, x_l.\ \underline{L_1} \vee^- \cdots \vee^- \underline{L_n} \vee^- \delta^-(K_1 \vee^+ \cdots \vee^+ K_m)$. $\ulcorner C \urcorner$ is said to be in clausal form. By extension, $\ulcorner \Gamma \urcorner$ is the set of the formulas associated to the clauses of the set Γ.

The main theorem of this article relates LKF$^\perp$ with Resolution with Input Selection:

▶ **Theorem 3.** *Let Γ be a set of clauses. We have $\ulcorner \Gamma \urcorner \Uparrow \vdash$ iff $\Gamma \rightsquigarrow^* \square$.*

The proof can be found in the long version of the paper (`https://hal.inria.fr/hal-01670476`). To prove the right-to-left direction, we prove that all inference rules of Resolution with Input Selection are admissible in LKF$^\perp$, in the sense that if $\Gamma \rightsquigarrow C$ then LKF$^\perp$ proofs of $\ulcorner \Gamma \urcorner, \ulcorner C \urcorner \Uparrow \vdash$ can be turned into proofs of $\ulcorner \Gamma \urcorner \Uparrow \vdash$. Note that they are admissible, but they are not derivable. In particular, the size of the proof in LKF$^\perp$ can be much larger than the resolution derivation, as expected in a cut-free sequent calculus. Using cuts would lead to a closer correspondence between resolution derivations and sequent-calculus proofs, as in [15]. However, we chose to stay in the cut-free fragment to prove that, even in the incomplete case, resolution coincides with cut-free proofs, as in [25].

5 Complete Instances

5.1 Ordinary Focusing and Semantic Hyperresolution

As said earlier, in standard LKF, not all occurrences of literals can have an arbitrary polarity. Instead, each atom P is given globally a polarity, and $P^\perp$ has the opposite polarity.

Let us first look at the simple case where atoms are given a positive polarity. We recall the completeness proof of LKF:

▶ **Theorem 4** (Corollary of [26, Theorem 17])**.** *If the literals with a positive polarity are exactly the atoms, LKF$^\perp$ is (sound and) complete.*

If we look at the corresponding resolution calculus, Resolution with Selection for this particular instance becomes:

$$\text{R.w.S.}\ \frac{\neg P_1 \curlyvee \ldots \curlyvee \neg P_n \curlyvee C \qquad P'_1 \curlyvee D_1 \quad \ldots \quad P'_n \curlyvee D_n}{\sigma(C \curlyvee D_1 \curlyvee \ldots \curlyvee D_n)}$$

where C and D_i for all i contain only positive literals, and σ is the most general unifier of $P_1 =^? P'_1, \ldots, P_n =^? P'_n$. Note that the clause $\sigma(C \curlyvee D_1 \curlyvee \ldots \curlyvee D_n)$ contains only positive literals, so no literal would be selected in it even if it was an input clause. Besides, Resolution cannot be applied, since there exists no clause $\neg P \curlyvee C$ with $\mathcal{S}(\neg P \curlyvee C) = \emptyset$.

This corresponding resolution calculus is therefore exactly hyperresolution of [29]: premises of an inference contains all only positive literals, except one clause whose all negative literals are resolved at once. Theorem 3 therefore links ordinary focusing with hyperresolution. Consequently, Theorem 4 implies the completeness of hyperresolution.

Chaudhuri et al. [13, Theorem 16] prove a similar result by establishing a correspondence between hyperresolution derivations and proofs in a focused sequent calculus for intuitionistic

linear logic, but only considering Horn clauses. In their setting, choosing a negative polarity for atoms leads to SLD resolution, which is the reasoning mechanism of Prolog.

Let us now look at the general case, where atoms are given an arbitrary polarity. Let us stick to the ground case. We first recall a refinement of resolution called Semantic hyperresolution [31][11, Sect. 1.3.5.3]. Let I be an arbitrary Herbrand interpretation, i.e. a model whose domain is the set of terms interpreted as themselves. Note that I is not assumed to be a model of the input set of clauses (which is fortunate, since one is trying to show that it is unsatisfiable). Given a clause C, the idea of semantic hyperresolution is to resolve all literals of C that are valid in I at once, with clauses whose literals are all not valid in I. This gives the rule:

$$\mathsf{SHR}\ \frac{K_1 \curlyvee \ldots \curlyvee K_n \curlyvee C \qquad {K_1}^{\perp} \curlyvee D_1 \quad \ldots \quad {K_n}^{\perp} \curlyvee D_n}{C \curlyvee D_1 \curlyvee \ldots \curlyvee D_n}$$

where for all i, $I \models K_i$ (and thus $I \not\models K_i^{\perp}$), $I \not\models C$ and $I \not\models D_i$. Note that $I \not\models C \curlyvee D_1 \curlyvee \ldots \curlyvee D_n$.

Semantic hyperresolution for a Herbrand interpretation I can be seen as an instance of Resolution with Input Selection by using the following polarization of atoms: a literal L has a negative polarity iff $I \models L$. In that case, SHR corresponds exactly to Resolution with Selection, and Resolution cannot be applied since we cannot have clauses $P \curlyvee C$ and $\neg P \curlyvee D$ where both P and $\neg P$ are not valid in I.

This particular instance of polarization is in fact the ordinary version of focusing. Indeed, once a global polarity is assigned to each atom, the set of literals whose polarity is negative defines an Herbrand interpretation, and we saw reciprocally how to design a global polarization from the Herbrand interpretation. Theorem 3 therefore links ordinary focusing in the ground case with semantic hyperresolution. They are both complete, thanks to this theorem:

▶ **Theorem 5** (Corollary of [26, Theorem 17]). *Given a global polarization of atoms, where the polarity of $P^{\perp}$ is the opposite of that of P, $LKF^{\perp}$ is (sound and) complete.*

5.2 Deduction Modulo Theory

Deduction Modulo Theory [20] is a framework that consists in applying the inference rules of an existing proof system modulo some congruence over formulas. This congruence represents the theory, and it is in general defined by means of rewriting rules. To be expressive enough, these rules are defined not only at the term level, but also for formulas. To get simpler presentations of theories, we distinguish between rewrite rules that can be applied at positive and at negative positions by giving them a polarity[3], where by negative position we mean under an odd number of $\neg$. We therefore have positive rules $P \to^{+} A$ and negative rules $P \to^{-} A$ where P is an atom and A an arbitrary formula whose free variables appears in P. Given a rule $P \to^{+} A$, the rewrite relation $B_1 \xrightarrow{+} B_2$ is defined as usual by saying that there exists a position $\mathfrak{p}$ and a substitution σ such that the subformula of B_1 at position $\mathfrak{p}$ is σP and B_2 equals B_1 where the subformula at position $\mathfrak{p}$ is replaced by σA. $\xrightarrow{-}$ is defined similarly. In Polarized Sequent Calculus Modulo theory [17], the inference rules of the sequent calculus are applied modulo such a polarized rewriting system, as in for instance in $\vdash\wedge\ \dfrac{\Gamma \vdash A, \Delta \qquad \Gamma \vdash B, \Delta}{\Gamma \vdash C, \Delta}\ C \xrightarrow{+}{}^{*} A \wedge B$. Note that the implicit semantics of a negative

[3] This polarity must not be confused with the other notions of polarity mentioned in the paper.

$$\frown\vdash \frac{}{\Gamma, L, L^\perp \vdash} \qquad \top\vdash \frac{\Gamma \vdash}{\Gamma, \top \vdash} \qquad \perp\vdash \frac{}{\Gamma, \perp \vdash} \qquad \vee\vdash \frac{\Gamma, A \vdash \qquad \Gamma, B \vdash}{\Gamma, A \vee B \vdash}$$

$$\wedge\vdash \frac{\Gamma, A, B \vdash}{\Gamma, A \wedge B \vdash} \qquad \exists\vdash \frac{\Gamma, A \vdash}{\Gamma, \exists x.\ A \vdash}\ x \text{ not free in } \Gamma \qquad \forall\vdash \frac{\Gamma, \forall x.\ A, \{t/x\}A \vdash}{\Gamma, \forall x.\ A \vdash}$$

$$\uparrow^-\vdash \frac{\Gamma, P, A \vdash}{\Gamma, P \vdash}\ P \xrightarrow{-} A \qquad \uparrow^+\vdash \frac{\Gamma, \neg P, A^\perp \vdash}{\Gamma, \neg P \vdash}\ P \xrightarrow{+} A$$

Figure 3 The sequent calculus PUSC$^\perp$.

rule $P \to^- A$ is therefore $\overline{\forall x}.\ (P \Rightarrow A)$, whereas the semantics of $P \to^+ A$ is $\overline{\forall x}.\ (A \Rightarrow P)$, where $\overline{x}$ are the free variables of P.

With Kirchner [9], we proved the equivalence of Polarized Sequent Calculus Modulo theory to a sequent calculus where polarized rewriting rules are applied only on literals, using explicit rules. This calculus, Polarized Unfolding Sequent Calculus, is almost the calculus PUSC$^\perp$ presented in Figure 3. The only difference is that all formulas are put on the left of the sequent in PUSC$^\perp$. We denote by $\Gamma \vdash_{\mathcal{R}}$ the fact that $\Gamma \vdash$ can be proved in PUSC$^\perp$ using the polarized rewriting system $\mathcal{R}$. Note that the rule for the universal quantifier $\forall\vdash$ as well as the unfolding rules $\uparrow^-\vdash$ and $\uparrow^+\vdash$ contain an implicit contraction rule, as in the sequent calculus G4 of Kleene, in order to ensure that all rules of PUSC$^\perp$ are invertible.

We can translate polarized rewriting rules as formulas with selection, and see PUSC$^\perp$ as an instance of LKF$^\perp$. We first consider how to translate formulas of the right-hand side of polarized rewriting rules. We polarize them by choosing positive connectives for $\vee$ and $\wedge$ and, to unchain the introduction of the universal quantifier, we introduce delays. (Let us recall that a delay δ^+ allows to force a formula to be positive, and it can be encoded using an existantial quantifier.) This gives the translation:

$$|L| = L \quad \text{when } L \text{ is } \top, \perp \text{ or a literal} \qquad |A \wedge B| = |A| \wedge^+ |B|$$
$$|A \vee B| = |A| \vee^+ |B| \qquad |\exists x.\ A| = \exists x.\ |A| \qquad |\forall x.\ A| = \forall x.\ \delta^+|A|$$

▶ **Definition 6.** Given a negative rewriting rule $P \to^- A$ where the free variables of P are $x_1, \ldots, x_n$, its translation as a formula with selection is $[\![P \to^- A]\!] = \forall x_1 \ldots x_n.\ \underline{\neg P} \vee^- \delta^+|A|$.

Given a positive rewriting rule $P \to^+ A$ where the free variables of P are $x_1, \ldots, x_n$, its translation as a formula with selection is $[\![P \to^+ A]\!] = \forall x_1.\ \ldots \forall x_n.\ \underline{P} \vee^- \delta^+|A^\perp|$.

The translation $[\![\mathcal{R}]\!]$ of a polarized rewriting system $\mathcal{R}$ is the multiset of the translation of its rules.

▶ **Definition 7.** Let $N_1, \ldots, N_n$ be a multiset of formulas whose top connective is $\forall$ or $\perp$ or that are literals, and let $P_1, \ldots, P_m$ be a multiset of non-literal formulas whose top connective is neither $\forall$ nor $\perp$, then the translation of the PUSC$^\perp$ sequent $N_1, \ldots, N_n, P_1, \ldots, P_m \vdash$ modulo the rewriting system $\mathcal{R}$ is the LKF$^\perp$ sequent $[\![\mathcal{R}]\!], |N_1|, \ldots, |N_n| \Uparrow |P_1|, \ldots, |P_m| \vdash$.

▶ **Theorem 8.** *With the same assumptions as previous definition,* $N_1, \ldots, N_n, P_1, \ldots, P_m \vdash_{\mathcal{R}}$ *in PUSC*$^\perp$ *iff* $[\![\mathcal{R}]\!], |N_1|, \ldots, |N_n| \Uparrow |P_1|, \ldots, |P_m| \vdash$ *in LKF*$^\perp$.

The proof can be found in the long version of the paper.

Let us now consider the subcase where the rewriting rules are clausal, according to the terminology of [19], e.g. they are of the form $P \to^- C$ or $P \to^+ \neg C$ for some formula C in clausal normal form. In that case, the resolution method based on Deduction Modulo Theory [20] can be refined into what is called Polarized Resolution Modulo theory [19], whose rules are given in Fig. 4. (A refinement of) Polarized Resolution Modulo theory is actually implemented in the automated theorem prover iProverModulo [5].

$$\text{Resolution}\ \frac{P \curlyvee C \qquad \neg Q \curlyvee D}{\sigma(C \curlyvee D)}\ {}^{a} \qquad \text{Factoring}\ \frac{L \curlyvee K \curlyvee C}{\sigma(L \curlyvee C)}\ \sigma = mgu(L,K)$$

$$\text{Ext. Narr.}^{-}\ \frac{P \curlyvee C}{\sigma(D \curlyvee C)}\ {}^{a},\ Q \to^{-} D \qquad \text{Ext. Narr.}^{+}\ \frac{\neg Q \curlyvee D}{\sigma(C \curlyvee D)}\ {}^{a},\ P \to^{+} \neg C$$

[a] $\sigma = mgu(P,Q)$

Figure 4 Inference rules of Polarized Resolution Modulo theory.

By noting that the translation of the rule $Q \to^{-} D$ is $[\![Q \to^{-} D]\!] = \forall x_1.\ \ldots \forall x_n.\ \underline{\neg Q} \vee^{-} \delta^{+}|D|$ whereas $\ulcorner \underline{\neg Q} \curlyvee D \urcorner = \forall x_1.\ \ldots \forall x_n.\ \underline{\neg Q} \vee^{-} \delta^{-}|D|$, we can relate the rule $Q \to^{-} D$ with the clause with selection $\underline{\neg Q} \curlyvee D$, which is called a one-way clause by Dowek [19]. Indeed, the change of phase is always needed in that particular case, so that the delays are in fact useless. Ext. Narr.$^{-}$ can therefore be seen as an instance of the Resolution with Selection rule:

$$\text{Resolution with Selection}\ \frac{\underline{\neg Q} \curlyvee D \qquad P \curlyvee C}{\sigma(D \curlyvee C)}\ \sigma = mgu(P,Q)\ .$$

Similarly, $P \to^{+} \neg C$ is related to $\underline{P} \curlyvee C$.

Consequently, since PUSC$^{\perp}$ corresponds to LKF$^{\perp}$, and Resolution with Input Selection corresponds to Polarized Resolution Modulo theory, Theorem 3 leads to a new and more generic proof of the correspondence between PUSC$^{\perp}$ and Polarized Resolution Modulo theory.

Deduction Modulo Theory is not always complete. This is the case only if the cut rule is admissible in Polarized Sequent Calculus Modulo theory. It holds for some particular theories, e.g. Simple Type Theory [20] and arithmetic [22]. There are more or less powerful techniques that ensures this property [24, 21, 18, 7]. We even proved that any consistent first-order theory can be presented by a rewriting system admitting the cut rule [6]. As presented with Dowek [8] and discussed in the introduction, the fact that completeness is not proved once for all, but needs to be proved for each particular theory, is essential. Indeed, if a theory is presented entirely by rewriting rules, completeness implies the consistency of the theory, since no rule can be applied on the empty set of clauses. Consequently, the proof of the completeness cannot be easier than the proof of consistency of the theory, and, according to Gödel, cannot be proven in the theory itself.

5.3 Beyond Deduction Modulo Theory

We now consider the general case where several literals are selected in a clause, and show how proving completeness in LKF$^{\perp}$ can be reduced to proving completeness of several systems in Deduction Modulo Theory.

▶ **Example 9.** Let us recall the set of clauses from the Introduction:

$$\underline{\neg X \in \mathcal{P}(Y)} \curlyvee \underline{\neg Z \in X} \curlyvee Z \in Y \quad (1) \qquad \underline{X \in \mathcal{P}(Y)} \curlyvee d(X,Y) \in X \quad (2)$$

$$\underline{X \in \mathcal{P}(Y)} \curlyvee \underline{\neg d(X,Y) \in Y} \quad (3)$$

Note that this example is not covered by Ordered Resolution with Selection, at least not if a simplification ordering is used, because we cannot have $X \in \mathcal{P}(Y) \succ \delta(X,Y) \in X$ since with $\theta = \{X \mapsto \mathcal{P}(Z); Y \mapsto Z\}$ their instances are ordered in the wrong direction: $\mathcal{P}(Z) \in \mathcal{P}(Z) \prec \delta(\mathcal{P}(Z), Z) \in \mathcal{P}(Z)$.

The synthetic rules of the example from the Introduction correspond to the derivations when one of the clauses is focused. For instance, if we consider the clause (1), in a context

Γ containing this clause, a proof putting the focus on $\ulcorner(1)\urcorner$ necessarily is of the following shape:

$$\dfrac{\dfrac{\dfrac{}{\Gamma \Downarrow \underline{\neg u \in \mathcal{P}(v)} \vdash}\,\widehat{\Downarrow}\vdash \quad \dfrac{}{\Gamma \Downarrow \underline{\neg t \in u} \vdash}\,\widehat{\Downarrow}\vdash \quad \dfrac{\dfrac{\Gamma, t \in v \Uparrow \vdash}{\Gamma \Uparrow t \in v \vdash}\,\text{Store}}{\Gamma \Downarrow t \in v \vdash}\,\text{Release}}{\Gamma \Downarrow \underline{\neg u \in \mathcal{P}(v)} \vee^- \underline{\neg t \in u} \vee^- t \in v \vdash}\,\Downarrow\vee\vdash}{\Gamma \Downarrow \forall X\ Y\ Z.\ \underline{\neg X \in \mathcal{P}(Y)} \vee^- \underline{\neg Z \in X} \vee^- Z \in Y \vdash}\,\Downarrow\forall\vdash}{\Gamma \Uparrow \vdash}\,\text{Focus}$$

where t, u, v are arbitrary terms, and where, to be able to close the left and middle branches, $u \in \mathcal{P}(v)$ and $t \in u$ must belong to Γ. So Γ is in fact of the form
$\forall X\ Y\ Z.\ \underline{\neg X \in \mathcal{P}(Y)} \vee^+ \underline{\neg Z \in X} \vee^+ Z \in Y, \Delta, u \in \mathcal{P}(v), t \in u$ for some Δ, and the axiom
$\forall X\ Y\ Z.\ \underline{\neg X \in \mathcal{P}(Y)} \vee^+ \underline{\neg Z \in X} \vee^+ Z \in Y$ can be replaced by the synthetic rule:

$$(1)\vdash \dfrac{\Delta, u \in \mathcal{P}(v), t \in u, t \in v \Uparrow \vdash}{\Delta, u \in \mathcal{P}(v), t \in u \Uparrow \vdash}\ .$$

The computation of the other synthetic rules is left as an exercise for the reader.

The resolution rules given in the Introduction corresponds to the ground instances of Resolution with Selection with our three input clauses.

The question that remains is how we can prove the completeness of such a selection. We can in fact consider only subselections.

▶ **Definition 10** (Singleton subselection)**.** Given a selection function $\mathcal{S}$, the selection function $\mathcal{S}_1$ is a singleton subselection of $\mathcal{S}$ if
- $\mathcal{S}_1(C) \subseteq \mathcal{S}(C)$ for all C
- if $\mathcal{S}(C) \neq \emptyset$ then $\text{card}(\mathcal{S}_1(C)) = 1$

▶ **Example 11.** A singleton subselection of Example 9 can be

$$\neg X \in \mathcal{P}(Y) \curlyvee \underline{\neg Z \in X} \curlyvee Z \in Y \qquad \underline{X \in \mathcal{P}(Y)} \curlyvee d(X,Y) \in X \qquad \underline{X \in \mathcal{P}(Y)} \curlyvee \neg d(X,Y) \in Y$$

▶ **Theorem 12.** *Resolution with input selection $\mathcal{S}$ is complete iff for all singleton subselections $\mathcal{S}_1$ of $\mathcal{S}$, Resolution with input selection $\mathcal{S}_1$ is complete.*

The proof can be found in the long version of the paper.

Since singleton subselections can be linked with rewriting systems in Deduction Modulo Theory according to last subsection, we can reduce the problem of completeness in our framework to several problems of completeness in Deduction Modulo Theory.

Conclusion and Further Work

We generalized focusing and resolution with selection, proved that they correspond, and showed how known calculi are instances of this framework, namely ordinary focusing, hyper-resolution and Deduction Modulo Theory. In the long version of the paper, other frameworks, such as Superdeduction [4] or Schroeder-Heister's Definitional reflection [30], are also considered. Furthermore, we presented how to reduce completeness of this framework to several completeness proofs in Deduction Modulo Theory. We can therefore reuse the various techniques for proving completeness in Deduction Modulo Theory [24, 21, 18, 7] in our framework. As Deduction Modulo Theory already gives significant results in industrial applications when the theory is a variant of set theory (more precisely, set theory of the B method) [10], we

can expect our framework to lead to even better outcomes. The notable results presented here raise the following new areas of investigations.

First, we need to study how to apply selection also in the generated clauses. This should allow us to cover the cases of Ordered Resolution with Selection and of Semantic Resolution in the first-order case. Dually, in the sequent calculus part, this would correspond to the possibility to dynamically add selection in formulas of subderivations. This could probably be linked with the work of Deplagne [16] where rewrite rules corresponding to induction hypotheses are dynamically added in the rewriting system of a sequent calculus for Deduction Modulo Theory. Note that we already have one direction, namely from Resolution with Input Selection to $\mathrm{LKF}^{\perp}$, since the proof for this direction (see the long version) does not assume anything on the generated clauses; except, for Factoring, that it selects only instances of literals that were already selected. The converse direction would require a meta-theorem of completeness, since obviously it is not complete for all possible dynamic choices of selection.

Since focusing is defined not only for classical first-order logic but also for linear, intuitionistic, modal logics, the work in this paper could serve as a starting point to study how to get automated proof search methods for these logics with a selection mechanism.

Another worthwhile point is how equality should be handled in our framework. In particular, it would be interesting to see how paramodulation calculi, in particular superposition, can be embedded into a sequent calculus.

Finally, it would be worth investigating whether completeness proofs based on model construction, such as semantic completeness proofs of tableaux (related to sequent calculus), and completeness proof of superposition [2], can be linked in our framework.

Abstract

We develop team semantics for Linear Temporal Logic (LTL) to express hyperproperties, which have recently been identified as a key concept in the verification of information flow properties. Conceptually, we consider an asynchronous and a synchronous variant of team semantics. We study basic properties of this new logic and classify the computational complexity of its satisfiability, path, and model checking problem. Further, we examine how extensions of these basic logics react on adding other atomic operators. Finally, we compare its expressivity to the one of HyperLTL, another recently introduced logic for hyperproperties. Our results show that LTL under team semantics is a viable alternative to HyperLTL, which complements the expressivity of HyperLTL and has partially better algorithmic properties.

1 Introduction

Guaranteeing security and privacy of user information is a key requirement in software development. However, it is also one of the hardest goals to accomplish. One reason for this difficulty is that such requirements typically amount to reasoning about the flow of information and relating different execution traces of the system. In particular, these

[1] Funded by the German Research Foundation DFG, project ME 4279/1-2.
[2] Funded by the German Research Foundation DFG, project "TriCS" (ZI 1516/1-1).

requirements are no longer trace properties, i.e., properties whose satisfaction can be verified by considering each trace in isolation. For example, the property "the system terminates eventually" is satisfied if every trace eventually reaches a final state. Formally, a trace property φ is a set of traces and a system satisfies φ if each of its traces is in φ.

In contrast, the property "the system terminates within a bounded amount of time" is no longer a trace property; consider a system that has a trace t_n for every n, so that t_n only reaches a final state after n steps. This system does not satisfy the bounded termination property, but each individual trace t_n could also stem from a system that does satisfy it. Thus, satisfaction of the property cannot be verified by considering each trace in isolation.

Properties with this characteristic were termed *hyperproperties* by Clarkson and Schneider [6]. Formally, a hyperproperty φ is a set of sets of traces and a system satisfies φ if its set of traces is contained in φ. The conceptual difference to trace properties allows specifying a much richer landscape of properties including information flow and trace properties. Further, one can also express specifications for symmetric access to critical resources in distributed protocols and Hamming distances between code words in coding theory [29]. However, the increase in expressiveness requires novel approaches to specification and verification.

HyperLTL. Trace properties are typically specified in temporal logics, most prominently in Linear Temporal Logic (LTL) [28]. Verification of LTL specifications is routinely employed in industrial settings and marks one of the most successful applications of formal methods to real-life problems. Recently, this work has been extended to hyperproperties: HyperLTL, LTL equipped with trace quantifiers, has been introduced to specify hyperproperties [5]. Accordingly, a model of a HyperLTL formula is a set of traces and the quantifiers range over these traces. This logic is able to express the majority of the information flow properties found in the literature (we refer to Section 3 of [5] for a full list). The satisfiability problem for HyperLTL is undecidable [10] while the model checking problem is decidable, albeit of non-elementary complexity [5, 13]. In view of this, the full logic is too strong. Fortunately most information flow properties found in the literature can be expressed with at most one quantifier alternation and consequently belong to decidable (and tractable) fragments. Further works have studied runtime verification [2, 11], connections to first-order logic [14], provided tool support [13, 10], and presented applications to "software doping" [7] and the verification of web-based workflows [12]. In contrast, there are natural properties, e.g., bounded termination, which are not expressible in HyperLTL (which is an easy consequence of a much stronger non-expressibility result [3]).

Team Semantics. Intriguingly, there exists another modern family of logics, *Dependence Logics* [32, 9], which operate as well on sets of objects instead of objects alone. Informally, these logics extend first-order logic (FO) by atoms expressing, e.g., that "the value of a variable x functionally determines the value of a variable y" or that "the value of a variable x is informationally independent of the value of a variable y". Obviously, such statements only make sense when being evaluated over a set of assignments. In the language of dependence logic, such sets are called *teams* and the semantics is termed *team semantics*.

In 1997, Hodges introduced compositional semantics for Hintikka's Independence-friendly logic [19]. This can be seen as the cornerstone of the mathematical framework of dependence logics. Intuitively, this semantics allows for interpreting a team as a database table. In this approach, variables of the table correspond to attributes and assignments to rows or records. In 2007, Väänänen [32] introduced his modern approach to such logics and adopted team semantics as a core notion, as dependence atoms are meaningless under Tarskian semantics.

After the introduction of dependence logic, a whole family of logics with different atomic statements have been introduced in this framework: *independence logic* [17] and *inclusion logic* [15] being the most prominent. Interest in these logics is rapidly growing and the research community aims to connect their area to a plethora of disciplines, e.g., linguistics [16], biology [16], game [4] and social choice theory [30], philosophy [30], and computer science [16]. We are the first to exhibit connections to formal languages via application of Büchi automata (see Theorem 4.3). Team semantics has also found their way into modal [33] and temporal logic [20], as well as statistics [8].

Recently, Krebs et al. [20] proposed team semantics for Computation Tree Logic (CTL), where a team consists of worlds of the transition system under consideration. They considered synchronous and asynchronous team semantics, which differ in how time evolves in the semantics of the temporal operators. They proved that satisfiability is EXPTIME-complete under both semantics while model checking is PSPACE-complete under synchronous semantics and P-complete under asynchronous semantics.

Our Contribution. The conceptual similarities between HyperLTL and team semantics raise the question how an LTL variant under team semantics relates to HyperLTL. For this reason, we develop team semantics for LTL, analyse the complexity of its satisfiability and model checking problems, and subsequently compare the novel logic to HyperLTL.

When defining the logic, we follow the approach of Krebs et al. [20] for defining team semantics for CTL: we introduce synchronous and asynchronous team semantics for LTL, where teams are now sets of traces. In particular, as a result, we have to consider potentially uncountable teams, while all previous work on model checking problems for logics under team semantics has been restricted to the realm of finite teams.

We prove that the satisfiability problem for team LTL is PSPACE-complete under both semantics, by showing that the problems are equivalent to LTL satisfiability under classical semantics. Generally, we observe that for the basic asynchronous variant all of our investigated problems trivially reduce to and from classical LTL semantics. However, for the synchronous semantics this is not the case for two variants of the model checking problem. As there are uncountably many traces, we have to represent teams, i.e., sets of traces, in a finitary manner. The path checking problem asks to check whether a finite team of ultimately periodic traces satisfies a given formula. As our main result, we establish this problem to be PSPACE-complete for synchronous semantics. In the (general) model checking problem, a team is represented by a finite transition system. Formally, given a transition system and a formula, the model checking problem asks to determine whether the set of traces of the system satisfies the formula. For the synchronous case we give a polynomial space algorithm for the model checking problem for the disjunction-free fragment, while we leave open the complexity of the general problem. Disjunction plays a special role in team semantics, as it splits a team into two. As a result, this operator is commonly called *splitjunction* instead of disjunction. In our setting, the splitjunction requires us to deal with possibly infinitely many splits of uncountable teams, if a splitjunction is under the scope of a G-operator, which raises interesting language-theoretic questions.

Further, we study the effects for complexity that follow when our logics are extended by dependence atoms and the contradictory negation. Finally, we show that LTL under team semantics is able to specify properties which are not expressible in HyperLTL and *vice versa*.

Recall that satisfiability for HyperLTL is undecidable and model checking of non-elementary complexity. Our results show that similar problems for LTL under team semantics have a much simpler complexity while some hyperproperties are still expressible (e.g., input

determinism, see page 11, or bounded termination). This proposes LTL under team semantics to be a significant alternative for the specification and verification of hyperproperties that complements HyperLTL.

2 Preliminaries

The non-negative integers are denoted by $\mathbb{N}$ and the power set of a set S is denoted by 2^S. Throughout the paper, we fix a finite set AP of atomic propositions.

Computational Complexity. We will make use of standard notions in complexity theory. In particular, we will use the complexity classes P and PSPACE. Most reductions used in the paper are $\leq_{\mathrm{m}}^{\mathrm{p}}$-reductions, that is, polynomial time, many-to-one reductions.

Traces. A *trace* over AP is an infinite sequence from $(2^{\mathrm{AP}})^\omega$; a finite trace is a finite sequence from $(2^{\mathrm{AP}})^*$. The length of a finite trace t is denoted by $|t|$. The empty trace is denoted by ε and the concatenation of two finite traces t_0 and t_1 by t_0t_1. Unless stated otherwise, a trace is always assumed to be infinite. A *team* is a (potentially infinite) set of traces.

Given a trace $t = t(0)t(1)t(2)\cdots$ and $i \geq 0$, we define $t[i,\infty) := t(i)t(i+1)t(i+2)\cdots$, which we lift to teams $T \subseteq (2^{\mathrm{AP}})^\omega$ by defining $T[i,\infty) := \{t[i,\infty) \mid t \in T\}$. A trace t is *ultimately periodic*, if it is of the form $t = t_0 \cdot t_1^\omega = t_0t_1t_1t_1\cdots$ for two finite traces t_0 and t_1 with $|t_1| > 0$. As a result, an ultimately periodic trace t is finitely represented by the pair (t_0, t_1); we define $[\![(t_0,t_1)]\!] = t_0t_1^\omega$. Given a set $\mathcal{T}$ of such pairs, we define $[\![\mathcal{T}]\!] = \{[\![(t_0,t_1)]\!] \mid (t_0,t_1) \in \mathcal{T}\}$, which is a team of ultimately periodic traces. We call $\mathcal{T}$ a team encoding of $[\![\mathcal{T}]\!]$.

Linear Temporal Logic. The formulas of Linear Temporal Logic (LTL) [28] are defined via the grammar $\varphi ::= p \mid \neg p \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \mathsf{X}\varphi \mid \mathsf{F}\varphi \mid \mathsf{G}\varphi \mid \varphi\mathsf{U}\varphi \mid \varphi\mathsf{R}\varphi$, where p ranges over the atomic propositions in AP. The length of a formula is defined to be the number of Boolean and temporal connectives occurring in it. The length of an LTL formula is often defined to be the number of syntactically different subformulas, which might be exponentially smaller. Here, we need to distinguish syntactically equal subformulas which becomes clearer after defining the semantics (see also Example 2.1 afterwards on this). As we only consider formulas in negation normal form, we use the full set of temporal operators.

Next, we recall the classical semantics of LTL before we introduce team semantics. For traces $t \in (2^{\mathrm{AP}})^\omega$ we define

$$
\begin{aligned}
t &\models^{\mathrm{c}} p && \text{if } p \in t(0),\\
t &\models^{\mathrm{c}} \neg p && \text{if } p \notin t(0),\\
t &\models^{\mathrm{c}} \psi \wedge \varphi && \text{if } t \models^{\mathrm{c}} \psi \text{ and } t \models^{\mathrm{c}} \varphi,\\
t &\models^{\mathrm{c}} \psi \vee \varphi && \text{if } t \models^{\mathrm{c}} \psi \text{ or } t \models^{\mathrm{c}} \varphi,\\
t &\models^{\mathrm{c}} \mathsf{X}\varphi && \text{if } t[1,\infty) \models^{\mathrm{c}} \varphi,\\
t &\models^{\mathrm{c}} \mathsf{F}\varphi && \text{if } \exists k \geq 0 : t[k,\infty) \models^{\mathrm{c}} \varphi,\\
t &\models^{\mathrm{c}} \mathsf{G}\varphi && \text{if } \forall k \geq 0 : t[k,\infty) \models^{\mathrm{c}} \varphi,\\
t &\models^{\mathrm{c}} \psi\mathsf{U}\varphi && \text{if } \exists k \geq 0 : t[k,\infty) \models^{\mathrm{c}} \varphi \text{ and}\\
& && \quad \forall k' < k : t[k',\infty) \models^{\mathrm{c}} \psi,\\
t &\models^{\mathrm{c}} \psi\mathsf{R}\varphi && \text{if } \forall k \geq 0 : t[k,\infty) \models^{\mathrm{c}} \varphi \text{ or}\\
& && \quad \exists k' < k : t[k',\infty) \models^{\mathrm{c}} \psi.
\end{aligned}
$$

Team Semantics for LTL. Next, we introduce two variants of team semantics for LTL, which differ in their interpretation of the temporal operators: a synchronous semantics ($\models^{\mathrm{s}}$), where time proceeds in lockstep along all traces of the team, and an asynchronous semantics ($\models^{\mathrm{a}}$) in which, on each trace of the team, time proceeds independently. We write $\models^{\star}$ whenever

property	definition	$\models^{a}$	$\models^{s}$
empty team property	$\emptyset \models^{\star} \varphi$	✓	✓
downwards closure	$T \models^{\star} \varphi$ implies $\forall T' \subseteq T$: $T' \models^{\star} \varphi$	✓	✓
union closure	$T \models^{\star} \varphi$, $T' \models^{\star} \varphi$ implies $T \cup T' \models^{\star} \varphi$	✓	×
flatness	$T \models^{\star} \varphi$ if and only if $\forall t \in T$: $\{t\} \models^{\star} \varphi$	✓	×
singleton equivalence	$\{t\} \models^{\star} \varphi$ if and only if $t \models^{c} \varphi$	✓	✓

Figure 1 Structural properties overview.

a definition coincides for both semantics. For teams $T \subseteq (2^{\mathrm{AP}})^{\omega}$ let

$T \models^{\star} p$ if $\forall t \in T : p \in t(0)$,
$T \models^{\star} \neg p$ if $\forall t \in T : p \notin t(0)$,
$T \models^{\star} \psi \wedge \varphi$ if $T \models^{\star} \psi$ and $T \models^{\star} \varphi$,
$T \models^{\star} \psi \vee \varphi$ if $\exists T_1 \cup T_2 = T : T_1 \models^{\star} \psi$ and $T_2 \models^{\star} \varphi$,
$T \models^{\star} \mathsf{X}\varphi$ if $T[1, \infty) \models^{\star} \varphi$.

This concludes the cases where both semantics coincide. Next, we present the remaining cases for the synchronous semantics, which are inherited from the classical semantics of LTL.

$T \models^{s} \mathsf{F}\varphi$ if $\exists k \geq 0 : T[k, \infty) \models^{s} \varphi$,
$T \models^{s} \mathsf{G}\varphi$ if $\forall k \geq 0 : T[k, \infty) \models^{s} \varphi$,
$T \models^{s} \psi \mathsf{U} \varphi$ if $\exists k \geq 0 : T[k, \infty) \models^{s} \varphi$ and $\forall k' < k : T[k', \infty) \models^{s} \psi$, and
$T \models^{s} \psi \mathsf{R} \varphi$ if $\forall k \geq 0 : T[k, \infty) \models^{s} \varphi$ or $\exists k' < k : T[k', \infty) \models^{s} \psi$.

Finally, we present the remaining cases for the asynchronous semantics. Note that, here there is no unique timepoint k, but a timepoint k_t for every trace t, i.e., time evolves asynchronously between different traces.

$T \models^{a} \mathsf{F}\varphi$ if $\exists k_t \geq 0$, for each $t \in T$: $\{t[k_t, \infty) \mid t \in T\} \models^{a} \varphi$
$T \models^{a} \mathsf{G}\varphi$ if $\forall k_t \geq 0$, for each $t \in T$: $\{t[k_t, \infty) \mid t \in T\} \models^{a} \varphi$,
$T \models^{a} \psi \mathsf{U} \varphi$ if $\exists k_t \geq 0$, for each $t \in T$: $\{t[k_t, \infty) \mid t \in T\} \models^{a} \varphi$, and
$\forall k'_t < k_t$, for each $t \in T$: $\{t[k'_t, \infty) \mid t \in T\} \models^{a} \psi$, and
$T \models^{a} \psi \mathsf{R} \varphi$ if $\forall k_t \geq 0$, for each $t \in T$: $\{t[k_t, \infty) \mid t \in T\} \models^{a} \varphi$ or
$\exists k'_t < k_t$, for each $t \in T$: $\{t[k'_t, \infty) \mid t \in T\} \models^{a} \psi$.

We call expressions of the form $\psi \vee \varphi$ *splitjunctions* to emphasise on the team semantics where we split a team into two parts. Similarly, the $\vee$-operator is referred to as a *splitjunction*.

Let us illustrate the difference between synchronous and asynchronous semantics with an example involving the F operator. Similar examples can be constructed for the other temporal operators (but for X) as well.

▶ **Example 2.1.** Let $T = \{\{p\}\emptyset^{\omega}, \emptyset\{p\}\emptyset^{\omega}\}$. We have that $T \models^{a} \mathsf{F}p$, as we can pick $k_t = 0$ if $t = \{p\}\emptyset^{\omega}$, and $k_t = 1$ if $t = \emptyset\{p\}\emptyset^{\omega}$. On the other hand, there is no single k such that $T[k, \infty) \models^{s} p$, as the occurrences of p are at different positions. Consequently $T \not\models^{s} \mathsf{F}p$.

Moreover, consider the formula $\mathsf{F}p \vee \mathsf{F}p$ which is satisfied by T on both semantics. However, $\mathsf{F}p$ is not satisfied by T under synchronous semantics. Accordingly, we need to distinguish the two disjuncts $\mathsf{F}p$ and $\mathsf{F}p$ of $\mathsf{F}p \vee \mathsf{F}p$ to assign them to different teams.

In contrast, synchronous satisfaction implies asynchronous satisfaction, i.e., $T \models^{s} \varphi$ implies $T \models^{a} \varphi$. The simplest way to prove this is by applying downward closure, singleton equivalence, and flatness (see Fig. 1). Example 2.1 shows that the converse does not hold.

Next, we define the most important verification problems for LTL in team semantics setting, namely satisfiability and two variants of the model checking problem: For classical

LTL, one studies the path checking problem and the model checking problem. The difference between these two problems lies in the type of structures one considers. Recall that a model of an LTL formula is a single trace. In the path checking problem, a trace t and a formula φ are given, and one has to decide whether $t \models^{c} \varphi$. This problem has applications to runtime verification and monitoring of reactive systems [23, 26]. In the model checking problem, a Kripke structure $\mathcal{K}$ and a formula φ are given, and one has to decide whether every execution trace t of $\mathcal{K}$ satisfies φ.

The satisfiability problem of LTL under team semantics is defined as follows.

Problem: LTL satisfiability w.r.t. teams (TSAT*) for $\star \in \{\mathrm{a}, \mathrm{s}\}$.
Input: LTL formula φ.
Question: Is there a non-empty team T such that $T \models^{\star} \varphi$?

The non-emptiness condition is necessary, as otherwise every formula is satisfiable due to the empty team property (see Fig. 1).

We consider the generalisation of the path checking problem for LTL (denoted by LTL-PC), which asks for a given ultimately periodic trace t and a given formula φ, whether $t \models^{c} \varphi$ holds. In the team semantics setting, the corresponding question is whether a given finite team comprised of ultimately periodic traces satisfies a given formula. Such a team is given by a team encoding $\mathcal{T}$. To simplify our notation, we will write $\mathcal{T} \models^{\star} \varphi$ instead of $[\![\mathcal{T}]\!] \models^{\star} \varphi$.

Problem: TeamPathChecking (TPC*) for $\star \in \{\mathrm{a}, \mathrm{s}\}$.
Input: LTL formula φ and a finite team encoding $\mathcal{T}$.
Question: $\mathcal{T} \models^{\star} \varphi$?

Consider the generalised model checking problem where one checks whether the team of traces of a Kripke structure satisfies a given formula. This is the natural generalisation of the model checking problem for classical semantics, denoted by LTL-MC, which asks, for a given Kripke structure $\mathcal{K}$ and a given LTL formula φ, whether $t \models^{c} \varphi$ for every trace t of $\mathcal{K}$.

A Kripke structure $\mathcal{K} = (W, R, \eta, w_I)$ consists of a finite set W of worlds, a left-total transition relation $R \subseteq W \times W$, a labeling function $\eta \colon W \to 2^{\mathrm{AP}}$, and an initial world $w_I \in W$. A path π through $\mathcal{K}$ is an infinite sequence $\pi = \pi(0)\pi(1)\pi(2)\cdots \in W^\omega$ such that $\pi(0) = w_I$ and $(\pi(i), \pi(i+1)) \in R$ for every $i \geq 0$. The trace of π is defined as $t(\pi) = \eta(\pi(0))\eta(\pi(1))\eta(\pi(2))\cdots \in (2^{\mathrm{AP}})^\omega$. The Kripke structure $\mathcal{K}$ induces the team $T(\mathcal{K}) = \{t(\pi) \mid \pi \text{ is a path through } \mathcal{K}\}$.

Problem: TeamModelChecking (TMC*) for $\star \in \{\mathrm{a}, \mathrm{s}\}$.
Input: LTL formula φ and a Kripke structure $\mathcal{K}$.
Question: $T(\mathcal{K}) \models^{\star} \varphi$?

3 Basic Properties

We consider several standard properties of team semantics (cf., e.g. [9]) and verify which of these hold for our two semantics for LTL. These properties are later used to analyse the complexity of the satisfiability and model checking problems. To simplify our notation, $\models^{\star}$ denotes $\models^{\mathrm{a}}$ or $\models^{\mathrm{s}}$. See Figure 1 for the definitions of the properties and a summary for which semantics the properties hold. The positive results follow via simple inductive arguments. For the fact that synchronous semantics is not union closed, consider teams $T = \{\{p\}\emptyset^\omega\}$ and $T' = \{\emptyset\{p\}\emptyset^\omega\}$. Then, we have $T \models^{\mathrm{s}} \mathsf{F}p$ and $T' \models^{\mathrm{s}} \mathsf{F}p$ but $T \cup T' \not\models^{\mathrm{s}} \mathsf{F}p$. Note also that flatness is equivalent of being both downward and union closed.

It turns out that, by Figure 1, LTL under asynchronous team semantics is essentially classical LTL with a bit of universal quantification: for a team T and an LTL-formula φ,

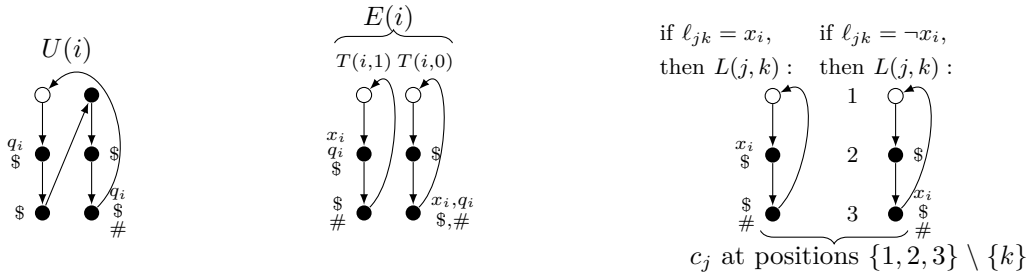

Figure 2 Traces for the reduction defined in the proof of Lemma 4.1.

we have $T \models^{\mathrm{a}} \varphi$ if and only if $\forall t \in T : t \models^{\mathrm{c}} \varphi$. This however does not mean that LTL under asynchronous team semantics is not worth of a study; it only means that asynchronous LTL is essentially classical LTL if we do not introduce additional atomic formulas that describe properties of teams directly. This is a common phenomenon in the team semantics setting. For instance, team semantics of first-order logic has the flatness property, but its extension by so-called *dependence atoms*, is equi-expressive with existential second-order logic [32]. Extensions of LTL under team semantics are discussed in Section 5.

At this point, it should not come as a surprise that, due to the flatness property and singleton equivalence, the complexity of satisfiability, path checking, and model checking for LTL under asynchronous team semantics coincides with those of classical LTL semantics. Firstly, note that an LTL-formula φ is satisfiable under asynchronous or synchronous team semantics if and only if there is a singleton team that satisfies the formula. Secondly, note that to check whether a given team satisfies φ under asynchronous semantics, it is enough to check whether each trace in the team satisfies φ under classical LTL; this can be computed by an AC^0-circuit using oracle gates for LTL-PC. Putting these observations together, we obtain the following results from the identical results for LTL under classical semantics [22, 23, 26, 31].

The circuit complexity class AC^i encompass of polynomial sized circuits of depth $O(\log^i(n))$ and unbounded fan-in; NC^i is similarly defined but with bounded fan-in. A language A is *constant-depth reducible* to a language B, in symbols $A \leq_{\mathrm{cd}} B$, if there exists a logtime-uniform AC^0-circuit family with oracle gates for B that decides membership in A. In this context, *logtime-uniform* means that there exists a deterministic Turing machine that can check the structure of the circuit family $\mathcal{C}$ in time $O(\log |\mathcal{C}|)$. For further information on circuit complexity, we refer the reader to the textbook of Vollmer [35]. Furthermore, logDCFL is the set of languages which are logspace reducible to a deterministic context-free language.

▶ **Proposition 3.1.**
1. $\mathrm{TMC}^{\mathrm{a}}$, $\mathrm{TSAT}^{\mathrm{a}}$, *and* $\mathrm{TSAT}^{\mathrm{s}}$ *are* PSPACE*-complete w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*
2. $\mathrm{TPC}^{\mathrm{a}}$ *is in* $\mathrm{AC}^1(\mathrm{logDCFL})$ *and* NC^1*-hard w.r.t.* $\leq_{\mathrm{cd}}$*-reductions.*

4 Classification of Decision Problems Under Synchronous Semantics

In this section, we examine the computational complexity of path and model checking with respect to the synchronous semantics. Our main result settles the complexity of $\mathrm{TPC}^{\mathrm{s}}$. It turns out that this problem is harder than the asynchronous version.

▶ **Lemma 4.1.** $\mathrm{TPC}^{\mathrm{s}}$ *is* PSPACE*-hard w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

Proof. Determining whether a given quantified Boolean formula (qBf) is valid (QBF-VAL) is a well-known PSPACE-complete problem [25]. The problem stays PSPACE-complete if the matrix (i.e., the propositional part) of the given qBf is in 3CNF. To prove the claim of the lemma, we will show that QBF-VAL $\leq_{\mathrm{m}}^{\mathrm{p}}$ TPC$^{\mathrm{s}}$. Given a quantified Boolean formula φ, we stipulate, w.l.o.g., that φ is of the form $\exists x_1 \forall x_2 \cdots Q x_n \chi$, where $\chi = \bigwedge_{j=1}^{m} \bigvee_{k=1}^{3} \ell_{jk}$, $Q \in \{\exists, \forall\}$, and $x_1, \ldots, x_n$ are exactly the free variables of χ and pairwise distinct.

In the following we define a reduction which is composed of two functions f and g. Given a qBf φ, the function f will define an LTL-formula and g will define a team such that φ is valid if and only if $g(\varphi) \models^{\mathrm{s}} f(\varphi)$. Essentially, the team $g(\varphi)$ will contain three kinds of traces, see Figure 2: (i) traces which are used to mimic universal quantification ($U(i)$ and $E(i)$), (ii) traces that are used to simulate existential quantification ($E(i)$), and (iii) traces used to encode the matrix of φ ($L(j,k)$). Moreover the trace $T(i,1)$ ($T(i,0)$, resp.) is used inside the proof to encode an assignment that maps the variable x_i true (false, resp.). Note that, $U(i), T(i,1), T(i,0), L(j,k)$ are technically singleton sets of traces. For convenience, we identify them with the traces they contain.

Next we inductively define the reduction function f that maps qBf-formulas to LTL-formulas:

$$f(\chi) := \bigvee_{i=1}^{n} \mathsf{F} x_i \vee \bigvee_{i=1}^{m} \mathsf{F} c_i,$$

where χ is the 3CNF-formula $\bigwedge_{j=1}^{m} \bigvee_{k=1}^{3} \ell_{jk}$ with free variables $x_1, \ldots, x_n$,

$$f(\exists x_i \psi) := (\mathsf{F} q_i) \vee f(\psi),$$
$$f(\forall x_i \psi) := \big(\$ \vee (\neg q_i \mathsf{U} q_i) \vee \mathsf{F}[\# \wedge \mathsf{X} f(\psi)]\big) \mathsf{U} \#.$$

The reduction function g that maps qBf-formulas to teams is defined as follows with respect to the traces in Figure 2.

$$g(\chi) := \bigcup_{j=1}^{m} L(j,1) \cup L(j,2) \cup L(j,3),$$

where χ is the 3CNF-formula $\bigwedge_{j=1}^{m} \bigvee_{k=1}^{3} \ell_{jk}$ with free variables $x_1, \ldots, x_n$ and

$$g(\exists x_i \psi) := E(i) \cup g(\psi),$$
$$g(\forall x_i \psi) := U(i) \cup E(i) \cup g(\psi).$$

In Fig. 2, the first position of each trace is marked with a white circle. For instance, the trace of $U(i)$ is then encoded via

$$(\varepsilon, \emptyset\{q_i, \$\}\{\$\}\emptyset\{\$\}\{q_i, \$, \#\}).$$

The reduction function showing QBF-VAL $\leq_{\mathrm{m}}^{\mathrm{p}}$ TPC$^{\mathrm{s}}$ is then $\varphi \mapsto \langle g(\varphi), f(\varphi) \rangle$. Clearly $f(\varphi)$ and $g(\varphi)$ can be computed in linear time with respect to $|\varphi|$.

Intuitively, for the existential quantifier case, the formula $(\mathsf{F} q_i) \vee f(\psi)$ allows to continue in $f(\psi)$ with exactly one of $T(i,1)$ or $T(i,0)$. If $b \in \{0,1\}$ is a truth value then selecting $T(i,b)$ in the team is the same as setting x_i to b. For the case of $f(\forall x_i \psi)$, the formula $(\neg q_i \mathsf{U} q_i) \vee \mathsf{F}[\# \wedge \mathsf{X} f(\psi)]$ with respect to the team $(U(i) \cup E(i))[0, \infty)$ is similar to the existential case choosing x_i to be 1 whereas for $(U(i) \cup E(i))[3, \infty)$ one selects x_i to be 0. The use of the until operator in combination with \$ and # then forces both cases to happen.

Let $\varphi' = Q'x_{n'+1} \cdots Qx_n\chi$, where $Q', Q \in \{\exists, \forall\}$ and let I be an assignment of the variables in $\{x_1, \ldots, x_{n'}\}$ for $n' \leq n$. Then, let

$$g(I, \varphi') := g(\varphi') \cup \bigcup_{x_i \in \mathrm{Dom}(I)} T(i, I(x_i)).$$

We claim $I \models \varphi'$ if and only if $g(I, \varphi') \models^{\mathrm{s}} f(\varphi')$.

Note that when $\varphi' = \varphi$ it follows that $I = \emptyset$ and that $g(I, \varphi') = g(\varphi)$. Accordingly, the lemma follows from the claim of correctness. The claim is proven by induction on the number of quantifier alternations in φ'. The details can be found in the full version [21]. ◀

The matching upper bound follows via a PSPACE algorithm implementing the semantics in straightforward way. The details can be found in the full version [21].

▶ **Theorem 4.2.** $\mathrm{TPC}^{\mathrm{s}}$ *is* PSPACE*-complete w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

The next theorem deals with model checking of the splitjunction-free fragment of LTL under synchronous team semantics.

▶ **Theorem 4.3.** $\mathrm{TMC}^{\mathrm{s}}$ *restricted to splitjunction-free formulas is in* PSPACE.

Proof. Fix $\mathcal{K} = (W, R, \eta, w_I)$ and a splitjunction-free formula φ. We define $S_0 = \{w_I\}$ and $S_{i+1} = \{w' \in W \mid (w, w') \in R \text{ for some } w \in S_i\}$ for all $i \geq 0$. By the pigeonhole principle, this sequence is ultimately periodic with a characteristic (s, p) with $s + p \leq 2^{|W|}$.[3] Next, we define a trace t over $\mathrm{AP} \cup \{\overline{p} \mid p \in \mathrm{AP}\}$ via

$$t(i) = \{p \in \mathrm{AP} \mid p \in \eta(w) \text{ for all } w \in S_i\} \cup \{\overline{p} \mid p \notin \eta(w) \text{ for all } w \in S_i\}$$

that reflects the team semantics of (negated) atomic formulas, which have to hold in every element of the team.

An induction over the construction of φ shows that $T(\mathcal{K}) \models^{\mathrm{s}} \varphi$ if and only if $t \models^{\mathrm{c}} \overline{\varphi}$, where $\overline{\varphi}$ is obtained from φ by replacing each negated atomic proposition $\neg p$ by $\overline{p}$. To conclude the proof, we show that $t \models^{\mathrm{c}} \overline{\varphi}$ can be checked in non-deterministic polynomial space, exploiting the fact that t is ultimately periodic and of the same characteristic as $S_0S_1S_2\cdots$. However, as $s + p$ might be exponential, we cannot just construct a finite representation of t of characteristic (s, p) and then check satisfaction in polynomial space.

Instead, we present an on-the-fly approach which is inspired by similar algorithms in the literature. It is based on two properties:

1. Every S_i can be represented in polynomial space, and from S_i one can compute S_{i+1} in polynomial time.
2. For every LTL formula $\overline{\varphi}$, there is an equivalent non-deterministic Büchi automaton $\mathcal{A}_{\overline{\varphi}}$ of exponential size (see, e.g., [1] for a formal definition of Büchi automata and for the construction of $\mathcal{A}_{\overline{\varphi}}$). States of $\mathcal{A}_{\overline{\varphi}}$ can be represented in polynomial space and given two states, one can check in polynomial time, whether one is a successor of the other.

These properties allow us to construct both t and a run of $\mathcal{A}_{\overline{\varphi}}$ on t on the fly. The details can be found in the full version [21]. ◀

[3] The characteristic of an encoding (t_0, t_1) of an ultimately periodic trace $t_0t_1t_1t_1\cdots$ is the pair $(|t_0|, |t_1|)$. Slightly abusively, we say that $(|t_0|, |t_1|)$ is the characteristic of $t_0t_1t_1t_1\cdots$, although this is not unique.

The complexity of general model checking problem is left open. It is trivially PSPACE-hard, due to Theorem 4.2 and the fact that finite teams of ultimately periodic traces can be represented by Kripke structures. However, the problem is potentially much harder, as one has to deal with infinitely many splits of possibly uncountable teams with non-periodic traces, if a split occurs under the scope of a G-operator. Currently, we are working on interesting language-theoretic problems one encounters when trying to generalise our algorithms for the general path checking problem and for the splitjunction-free model checking problem, e.g., how complex can an LTL-definable split be, if the team to be split is one induced by a Kripke structure.

5 Extensions

In this section we take a brief look into extensions of our logics by dependence atoms and contradictory negation. Contradictory negation combined with team semantics allows for powerful constructions. For instance, the complexity of model checking for propositional logic jumps from NC^1 to PSPACE [27], whereas the complexity of validity and satisfiability jumps all the way to alternating exponential time with polynomially many alternations (ATIME-ALT(exp, pol)) [18].

Formally, we define that $T \models^{\star} \sim\varphi$ if $T \not\models \varphi$. Note that the negation $\sim$ is not equivalent to the negation $\neg$ of atomic propositions defined earlier, i.e., $\sim p$ and $\neg p$ are not equivalent. In the following, problems of the form $\mathrm{TPC}^{\mathrm{a}}(\sim)$, etc., refer to LTL-formulas with negation $\sim$.

Also, we are interested in atoms expressible in first-order (FO) logic over the atomic propositions; the most widely studied ones are dependence, independence, and inclusion atoms [9]. The notion of generalised atoms in the setting of first-order team semantics was introduced by Kuusisto [24]. It turns out that the algorithm for $\mathrm{TPC}^{\mathrm{s}}$ is very robust to such strengthenings of the logic under consideration.

We consider FO-formulas over the signature $(A_p)_{p\in\mathrm{AP}}$, where each A_p is a unary predicate. Furthermore, we interpret a team T as a relational structure $\mathfrak{A}(T)$ over the same signature with universe T such that $t \in T$ is in $A_p^{\mathfrak{A}}$ if and only if $p \in t(0)$. The formulas then express properties of the atomic propositions holding in the initial positions of traces in T. An FO-formula φ *FO-defines* the atomic formula D with $T \models^{\star} D \iff \mathfrak{A}(T) \models \varphi$. In this case, D is also called an *FO-definable generalised atom*.

For instance, the dependence atom $\mathrm{dep}(x; y)$ is FO-definable by $\forall t\forall t'((A_x(t) \leftrightarrow A_x(t')) \to \big(A_y(t) \leftrightarrow A_y(t')\big))$, for $x, y \in \mathrm{AP}$. We call an LTL-formula extended by a generalised atom D an $\mathrm{LTL}(D)$-formula. Similarly, we lift this notion to *sets of generalised atoms* as well as to the corresponding decision problems, i.e., $\mathrm{TPC}^{\mathrm{s}}(D)$ is the path checking problem over synchronous semantics with LTL formulas which may use the generalised atom D.

The result of Theorem 4.2 can be extended to facilitate also the contradictory negation and first-order definable generalised atoms.

▶ **Theorem 5.1.** *Let $\mathcal{D}$ be a finite set of first-order definable generalised atoms. Then $\mathrm{TPC}^{\mathrm{s}}(\mathcal{D})$ and $\mathrm{TPC}^{\mathrm{s}}(\sim)$ are* PSPACE*-complete w.r.t. $\leq^{\mathrm{p}}_{\mathrm{m}}$-reductions.*

The next proposition translates a result from Hannula et al. [18] to our setting. They show completeness for ATIME-ALT(exp, pol) for the satisfiability problem of propositional team logic with negation. This logic coincides with LTL-formulas without temporal operators under team semantics.

▶ **Proposition 5.2** ([18])**.** $\mathrm{TSAT}^{\mathrm{a}}(\sim)$ *and* $\mathrm{TSAT}^{\mathrm{s}}(\sim)$ *for formulas without temporal operators are complete for* ATIME-ALT(exp, pol) *w.r.t. $\leq^{\mathrm{p}}_{\mathrm{m}}$-reductions.*

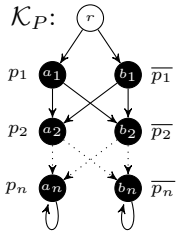

Figure 3 Kripke structure for the proof of Theorem 5.3.

▶ **Theorem 5.3.** $\mathrm{TMC}^{\mathrm{a}}(\sim)$ *and* $\mathrm{TMC}^{\mathrm{s}}(\sim)$ *are hard for* $\mathrm{ATIME\text{-}ALT}(\exp, \mathrm{pol})$ *w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

Proof. We will state a reduction from the satisfiability problem of propositional team logic with negation $\sim$ (short $\mathrm{PL}(\sim)$). The stated hardness then follows from Proposition 5.2.

For $P = \{p_1, \ldots, p_n\}$, consider the traces starting from the root r of the Kripke structure $\mathcal{K}_P$ depicted in Figure 3 using proposition symbols $p_1, \ldots, p_n, \overline{p_1}, \ldots, \overline{p_n}$. Each trace in the model corresponds to a propositional assignment on P. For $\varphi \in \mathrm{PL}(\sim)$, let φ^* denote the $\mathrm{LTL}(\sim)$-formula obtained by simultaneously replacing each (non-negated) variable p_i by $\mathsf{F}p_i$ and each negated variable $\neg p_i$ by $\mathsf{F}\overline{p_i}$. Let P denote the set of variables that occur in φ. Define $\top := (p \vee \neg p)$ and $\bot := p \wedge \neg p$, then $T(\mathcal{K}_P) \models^\star \big(\top \vee ((\sim\bot) \wedge \varphi^*)\big)$ *if and only if* $T' \models^\star \varphi^*$ for some non-empty $T' \subseteq T(\mathcal{K}_P)$. It is easy to check that $T' \models^\star \varphi^*$ *if and only if* the propositional team corresponding to T' satisfies φ and thus the above holds if and only if φ is satisfiable. ◀

In the following, we define the semantics for dependence atoms. For Teams $T \subseteq (2^{\mathrm{AP}})^\omega$ we define $T \models^\star \mathrm{dep}(p_1, \ldots, p_n; q_1, \ldots, q_m)$ if

$$\forall t, t' \in T: \ (t(0) \overset{p_1}{\Leftrightarrow} t'(0), \ldots, t(0) \overset{p_n}{\Leftrightarrow} t'(0)) \text{ implies } (t(0) \overset{q_1}{\Leftrightarrow} t'(0), \ldots, t(0) \overset{q_m}{\Leftrightarrow} t'(0)),$$

where $t(i) \overset{p}{\Leftrightarrow} t(j)$ means the sets $t(i)$ and $t(j)$ agree on proposition p, i.e., both contain p or not. Observe that the formula $\mathrm{dep}(;p)$ merely means that p has to be constant on the team. Often, due to convenience we will write $\mathrm{dep}(p)$ instead of $\mathrm{dep}(;p)$. Note that the hyperproperties 'input determinism' now can be very easily expressed via the formula $\mathrm{dep}(i_1, \ldots, i_n; o_1, \ldots, o_m)$, where i_j are the (public) input variables and o_j are the (public) output variables.

Problems of the form $\mathrm{TSAT}^{\mathrm{a}}(\mathrm{dep})$, etc., refer to LTL-formulas with dependence operator dep. The following proposition follows from the corresponding result for classical LTL using downwards closure and the fact that on singleton teams dependence atoms are trivially fulfilled.

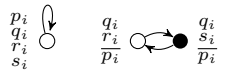
▶ **Proposition 5.4.** $\mathrm{TSAT}^{\mathrm{a}}(\mathrm{dep})$ *and* $\mathrm{TSAT}^{\mathrm{s}}(\mathrm{dep})$ *are* PSPACE*-complete.*

In the following, we will show a lower bound while the matching upper bound still is open.

▶ **Theorem 5.5.** $\mathrm{TPC}^{\mathrm{a}}(\mathrm{dep})$ *is* PSPACE*-hard w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

Proof. As in the proof of Lemma 4.1, we reduce from QBF-VAL.

Consider a given quantified Boolean formula $\exists x_1 \forall x_2 \cdots Q x_n \chi$, where $\chi = \bigwedge_{j=1}^{m} \bigvee_{k=1}^{3} \ell_{jk}$, $Q \in \{\exists, \forall\}$, and $x_1, \ldots, x_n$ are exactly the free variables of χ and pairwise distinct. We will use two traces for each variable x_i (gadget for x_i) as shown in Figure 4.



everywhere $p_j, \overline{p_j}$ for $i \neq j$

Figure 4 Traces in the proof of Theorem 5.5.

Intuitively, the proposition p_i marks that the variable x_i is set true while the proposition $\overline{p}_i$ marks that x_i is set false, q_i encodes that the gadget is used to quantify x_i, and s_i, r_i are auxiliary propositions. Picking the left trace corresponds to setting x_i to true and picking the right trace corresponds to setting x_i to false. In the following, we omit the p_j and $\overline{p_j}$, when $j \neq i$, for readability. Then, the team T is defined as

$$T := \{(\varepsilon, \{p_i, q_i, r_i, s_i\}), (\varepsilon, \{q_i, r_i, \overline{p}_i\}\{q_i, s_i, \overline{p}_i\}) \mid 1 \leq i \leq n\}.$$

Next, we recursively define the LTL(dep)-formula used in the reduction: $f(\chi)$ is obtained from χ by substituting every positive literal x_i by p_i and negated literal $\neg x_i$ by $\overline{p_i}$, $f(\exists x_i \psi) := \big(q_i \wedge \mathrm{dep}(p_i)\big) \vee f(\psi)\big)$, and

$$f(\forall x_i \psi) := \mathsf{G}\Big(\big(\mathrm{dep}(p_i) \wedge q_i \wedge r_i\big) \vee \big(s_i \wedge f(\psi)\big)\Big).$$

In the existential quantification of x_i, the splitjunction requires for the x_i-trace-pair to put $(\varepsilon, \{p_i, q_i, r_i, s_i\})$ into the left or right subteam (of the split). The trace $(\varepsilon, \{q_i, r_i, \overline{p}_i\}\{q_i, s_i, \overline{p}_i\})$ has to go to the opposite subteam as $\mathrm{dep}(p_i)$ requires p_i to be of constant value. (Technically both of the traces could be put to the right subteam, but this logic is downwards closed and, accordingly, this allows to omit this case.) As explained before, we existentially quantify x_i by this split. For universal quantification, the idea is a bit more involved. To verify $T \models^{\star} \mathsf{G}\theta$, where $\mathsf{G}\theta = f(\forall x_i \psi)$ essentially two different teams T' for which $T' \models \theta$ need to be verified.
(1.) $(\varepsilon, \{p_i, q_i, r_i, s_i\}), (\varepsilon, \{q_i, r_i, \overline{p}_i\}\{q_i, s_i, \overline{p}_i\}) \in T'$. In this case, $(\varepsilon, \{p_i, q_i, r_i, s_i\})$ must be put to the right subteam of the split and $(\varepsilon, \{q_i, r_i, \overline{p}_i\}\{q_i, s_i, \overline{p}_i\})$ to the left subteam, setting x_i true.
(2.) $(\varepsilon, \{p_i, q_i, r_i, s_i\}), (\varepsilon, \{q_i, s_i, \overline{p}_i\}\{q_i, r_i, \overline{p}_i\}) \in T'$. In this case, $(\varepsilon, \{p_i, q_i, r_i, s_i\})$ must be put to the left and $(\varepsilon, \{q_i, s_i, \overline{p}_i\}\{q_i, r_i, \overline{p}_i\})$ to the right subteam, implicitly forcing x_i to be false. These observations are utilised to prove that $\langle \exists x_1 \forall x_2 \cdots Q x_n \chi \rangle \in$ QBF-VAL if and only if $\langle f(\exists x_1 \forall x_2 \cdots Q x_n \chi), T \rangle \in \mathrm{TPC}^{\mathrm{a}}(\mathrm{dep})$. The reduction is polynomial time computable in the input size. ◀

The following result from Virtema talks about the validity problem of propositional team logic.

▶ **Proposition 5.6** ([34]). *Validity of propositional logic with dependence atoms is* NEXPTIME*-complete w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

▶ **Theorem 5.7.** $\mathrm{TMC}^{\mathrm{a}}(\mathrm{dep})$ *and* $\mathrm{TMC}^{\mathrm{s}}(\mathrm{dep})$ *are* NEXPTIME*-hard w.r.t.* $\leq^{\mathrm{p}}_{\mathrm{m}}$*-reductions.*

Proof. The proof of this result uses the same construction idea as in the proof of Theorem 5.3, but this time from a different problem, namely, validity of propositional logic with dependence atoms which settles the lower bound by Proposition 5.6. Due to downwards closure the validity of propositional formulas with dependence atoms boils down to model checking the maximal team in the propositional (and not in the trace) setting, which essentially is achieved by $T(\mathcal{K})$, where $\mathcal{K}$ is the Kripke structure from the proof of Theorem 5.3. ◀

6 LTL under Team Semantics vs. HyperLTL

LTL under team semantics expresses hyperproperties [6], that is, sets of teams, or equivalently, sets of sets of traces. Recently, HyperLTL [5] was proposed to express information flow properties, which are naturally hyperproperties. For example, input determinism can be expressed as follows: every pair of traces that coincides on their input variables, also coincides on their output variables (this can be expressed in LTL with team semantics by a dependence atom dep as sketched is Section 5). To formalise such properties, HyperLTL allows to quantify over traces. This results in a powerful formalism with vastly different properties than LTL [14]. After introducing syntax and semantics of HyperLTL, we compare the expressive power of LTL under team semantics and HyperLTL.

The formulas of HyperLTL are given by the grammar

$$\varphi ::= \exists \pi.\varphi \mid \forall \pi.\varphi \mid \psi, \qquad \psi ::= p_\pi \mid \neg\psi \mid \psi \vee \psi \mid \mathsf{X}\psi \mid \psi \mathsf{U} \psi,$$

where p ranges over atomic propositions in AP and where π ranges over a given countable set $\mathcal{V}$ of *trace variables*. The other Boolean connectives and the temporal operators release R, eventually F, and always G are derived as usual, due to closure under negation. A sentence is a closed formula, i.e., one without free trace variables.

The semantics of HyperLTL is defined with respect to trace assignments that are a partial mappings $\Pi\colon \mathcal{V} \to (2^{\mathrm{AP}})^\omega$. The assignment with empty domain is denoted by $\Pi_\emptyset$. Given a trace assignment Π, a trace variable π, and a trace t, denote by $\Pi[\pi \to t]$ the assignment that coincides with Π everywhere but at π, which is mapped to t. Further, $\Pi[i, \infty)$ denotes the assignment mapping every π in Π's domain to $\Pi(\pi)[i, \infty)$. For teams T and trace-assignments Π we define

$$\begin{array}{ll}
(T,\Pi) \models^{\mathrm{h}} p_\pi & \text{if } p \in \Pi(\pi)(0), \\
(T,\Pi) \models^{\mathrm{h}} \neg\psi & \text{if } (T,\Pi) \not\models^{\mathrm{h}} \psi, \\
(T,\Pi) \models^{\mathrm{h}} \psi_1 \vee \psi_2 & \text{if } (T,\Pi) \models^{\mathrm{h}} \psi_1 \text{ or } (T,\Pi) \models^{\mathrm{h}} \psi_2, \\
(T,\Pi) \models^{\mathrm{h}} \mathsf{X}\psi & \text{if } (T,\Pi[1,\infty)) \models^{\mathrm{h}} \psi, \\
(T,\Pi) \models^{\mathrm{h}} \psi_1 \mathsf{U} \psi_2 & \text{if } \exists k \geq 0 : (T,\Pi[k,\infty)) \models^{\mathrm{h}} \psi_2 \text{ and } \forall 0 \leq k' < k : (T,\Pi[k',\infty)) \models^{\mathrm{h}} \psi_1, \\
(T,\Pi) \models^{\mathrm{h}} \exists \pi.\psi & \text{if } \exists t \in T : (T,\Pi[\pi \to t]) \models^{\mathrm{h}} \psi, \text{ and} \\
(T,\Pi) \models^{\mathrm{h}} \forall \pi.\psi & \text{if } \forall t \in T : (T,\Pi[\pi \to t]) \models^{\mathrm{h}} \psi.
\end{array}$$

We say that T satisfies a sentence φ, if $(T, \Pi_\emptyset) \models^{\mathrm{h}} \varphi$, and write $T \models^{\mathrm{h}} \varphi$. The semantics of HyperLTL are synchronous, i.e., the semantics of the until refers to a single k. Accordingly, one could expect that HyperLTL is closer related to LTL under synchronous team semantics than to LTL under asynchronous team semantics. In the following, we refute this intuition.

Formally, a HyperLTL sentence φ and an LTL formula φ' under synchronous (asynchronous) team semantics are equivalent, if for all teams T: $T \models^{\mathrm{h}} \varphi$ if and only if $T \models^{\mathrm{s}} \varphi'$ ($T \models^{\mathrm{a}} \varphi'$). In the following, let $\forall$-HyperLTL denote that set of HyperLTL sentences of the form $\forall \pi.\, \psi$ with quantifier-free ψ, i.e., sentences with a single universal quantifier.

▶ **Theorem 6.1.** 1. *No* LTL*-formula under synchronous or asynchronous team semantics is equivalent to* $\exists \pi.p_\pi$.
2. *No* HyperLTL *sentence is equivalent to* $\mathsf{F}p$ *under synchronous team semantics.*
3. LTL *under asynchronous team semantics is as expressive as* $\forall$-HyperLTL.

Proof.

1. Consider $T = \{\emptyset^\omega, \{p\}\emptyset^\omega\}$. We have $T \models^{\mathrm{h}} \exists \pi.p_\pi$. Assume there is an equivalent LTL formula under team semantics, call it φ. Then, $T \models^{\star} \varphi$ and thus $\{\emptyset^\omega\} \models^{\star} \varphi$ by downwards closure. Hence, by equivalence, $\{\emptyset^\omega\} \models^{\mathrm{h}} \exists \pi.p_\pi$, yielding a contradiction.

2. Bozzelli et al. proved that the property encoded by $\mathsf{F}p$ under synchronous team semantics cannot be expressed in HyperLTL [3].
3. Let φ be an LTL-formula and define $\varphi_h := \forall\pi.\varphi'$, where φ' is obtained from φ by replacing each atomic proposition p by p_π. Then, due to singleton equivalence, $T \models^{\mathrm{a}} \varphi$ if and only if $T \models^{\mathrm{h}} \varphi_h$. For the other implication, let $\varphi = \forall\pi.\psi$ be a HyperLTL sentence with quantifier-free ψ and let ψ' be obtained from ψ by replacing each atomic proposition p_π by p. Then, again due to the singleton equivalence, we have $T \models^{\mathrm{h}} \varphi$ if and only if $T \models^{\mathrm{a}} \psi'$.

◀

Note that these separations are obtained by very simple formulas, and are valid for LTL(dep) formulas, too. In particular, the HyperLTL formulas are all negation-free.

▶ **Corollary 6.2.** HyperLTL *and* LTL *under synchronous team semantics are of incomparable expressiveness and* HyperLTL *is strictly more expressive than* LTL *under asynchronous team semantics.*

7 Conclusion

We introduced synchronous and asynchronous team semantics for linear temporal logic LTL, studied complexity and expressive power of related logics, and compared them to HyperLTL. We concluded that LTL under team semantics is a valuable logic which allows to express relevant hyperproperties and complements the expressiveness of HyperLTL while allowing for computationally simpler decision problems. We conclude with some directions of future work and open problems.

1. We showed that some important properties that cannot be expressed in HyperLTL (such as uniform termination) can be expressed by LTL-formulas in synchronous team semantics. Moreover input determinism can be expressed in LTL(dep). What other important and practical hyperproperties can be expressed in LTL under team semantics? What about in its extensions with dependence, inclusion, and independence atoms, or the contradictory negation.
2. We showed that with respect to expressive power HyperLTL and LTL under synchronous team semantics are incomparable. What about the extensions of LTL under team semantics? For example the HyperLTL formula $\exists\pi.p_\pi$ is expressible in LTL($\sim$). Can we characterise the expressive power of relevant extensions of team LTL as has been done in first-order and modal contexts?
3. We studied the complexity of path-checking, model checking, and satisfiability problems of team LTL and its extensions with dependence atoms and the contradictory negation. Many problems are still open: Can we show matching upper bounds for the hardness results of Section 5? What is the complexity of $\mathrm{TMC}^{\mathrm{s}}$ when splitjunctions are allowed? What happens when LTL is extended with inclusion or independence atoms?
4. Can we give a natural team semantics to CTL^* and compare it to $\mathrm{HyperCTL}^*$ [5]?

Consistency for Counting Quantifiers

Florent R. Madelaine

Barnaby Martin
Department of Computer Science, Durham University, U.K.

Abstract

We apply the algebraic approach for Constraint Satisfaction Problems (CSPs) with counting quantifiers, developed by Bulatov and Hedayaty, for the first time to obtain classifications for computational complexity. We develop the consistency approach for expanding polymorphisms to deduce that, if H has an expanding majority polymorphism, then the corresponding CSP with counting quantifiers is tractable. We elaborate some applications of our result, in particular deriving a complexity classification for partially reflexive graphs endowed with all unary relations. For each such structure, either the corresponding CSP with counting quantifiers is in P, or it is NP-hard.

1 Introduction

The *constraint satisfaction problem*, CSP($\mathcal{B}$), originating in artificial intelligence, is known to admit several equivalent formulations. Two of the best known consider the parameter $\mathcal{B}$ to be a relational structure and may be phrased as the problem of query evaluation of primitive positive (pp) sentences – those involving only $\{\exists, \wedge, =\}$ – on $\mathcal{B}$, and the homomorphism problem to $\mathcal{B}$ (see, e.g., [19]). For finite $\mathcal{B}$, CSP($\mathcal{B}$) is NP-complete in general, and a great deal of effort was expended in classifying its complexity in various different classes. It was conjectured by Feder and Vardi [13] that all such CSP($\mathcal{B}$) are either in P or NP-complete and this was finally proved last year independently by Bulatov [6] and Zhuk [23].

A popular generalisation of the CSP involves considering the query evaluation problem for the logic involving only $\{\forall, \exists, \wedge, =\}$. (This logic admits various names but we will leave it nameless in this work as was the case in the foundational [2].) The resulting *Quantified Constraint Satisfaction Problem*, QCSP($\mathcal{B}$), allows for a broader class, used in artificial intelligence to capture non-monotonic reasoning, whose complexities rise to Pspace-complete.

In this paper, we study counting quantifiers of the form $\exists^{\geq j}$, which allow one to assert the existence of at least j elements such that the ensuing property holds. Thus, on a structure $\mathcal{B}$ with domain of size n, the quantifiers $\exists^{\geq 1}$ and $\exists^{\geq n}$ are precisely $\exists$ and $\forall$, respectively. Counting quantifiers have been fiercely studied in finite model theory (see [12, 22]), where the focus is on supplementing the descriptive power of various logics. Of wider interest is the majority quantifier $\exists^{\geq n/2}$ (on a structure of domain size n), which sits broadly midway between $\exists$ and $\forall$. Majority quantifiers turn up across diverse fields of logic and have various practical applications, e.g. in cognitive appraisal and voting theory [11].

We postulate variants of CSP($\mathcal{B}$) in which the input sentence to be evaluated on $\mathcal{B}$ (of size $|B|$) remains positive conjunctive in its quantifier-free part, but is quantified by various counting quantifiers from some non-empty set.

For $X \subseteq \{1, \ldots, |B|\}$, $X \neq \emptyset$, the X-CSP($\mathcal{B}$), introduced in [21], takes as input a sentence given by a conjunction of atoms quantified by quantifiers of the form $\exists^{\geq j}$ for $j \in X$ (this logic is termed X-pp). It then asks whether this sentence is true on $\mathcal{B}$. In the present paper, we will mostly consider the situation in which all counting quantifiers are present, and we will denote this problem CQCSP($\mathcal{B}$), instead of $\{1, \ldots, |B|\}$-CSP($\mathcal{B}$). The corresponding logic, involving only $\{\exists^{\geq 1}, \ldots, \exists^{\geq |B|}, \wedge, =\}$, we will call cq-pp.

The algebraic method has been very potent in understanding the complexity of CSPs and QCSPs [5, 6, 23, 10]. Recently, an algebraic theory tailored to counting quantifiers has been given [8] (early version was [7]).

A *polymorphism* of a structure $\mathcal{B}$ is a homomorphism from $\mathcal{B}^k$ to $\mathcal{B}$, for some k. Let $\{1\} \subseteq X \subseteq \{1, \ldots, |B|\}$. Call a function $f : B^k \to B$ *expanding on* X if, for all $X_1, \ldots, X_k \subseteq B$ such that $|X_1| = \ldots = |X_k| = j \in X$, we have $|f(X_1, \ldots, X_k)| \geq j$. This condition at $j = 1$ is trivial (it says that f is a function) and at $j = |B|$ asserts surjectivity. If $X = \{1, \ldots, |B|\}$ we simply term f *expanding*.

▶ **Lemma 1** (Theorem 8 [7]; Corollary 14 [8]). *The relations that are cq-pp-definable over $\mathcal{B}$ are exactly those that are preserved by the expanding polymorphisms of $\mathcal{B}$.*

In this paper, we will only make use of the "easy" direction of Lemma 1, that is, any relation that is cq-pp-definable over $\mathcal{B}$ is preserved by the expanding polymorphisms of $\mathcal{B}$.

The *list homomorphism* problem, which we will call List-CSP($\mathcal{B}$), is defined as CSP($\mathcal{B}$), save that one gives lists for each input variable stating which elements of the domain B that variable may be evaluated on. This is equivalent to CSP($\mathcal{B}^*$), where $\mathcal{B}^*$ is $\mathcal{B}$ endowed with additional unary relations for each subset of B. Indeed, this class of CSPs was among the first to be proved in line with the Feder-Vardi dichotomy conjecture [4]. The key class of polymorphisms here is known as *conservative* and the property they have is that $f(x_1, \ldots, x_k) \in \{x_1, \ldots, x_k\}$, for all $x_1, \ldots, x_k$ in the domain. Let us give explicitly the classification for this problem in the special case of graphs. We call a k-ary operation *near-unanimity*, for $k \geq 3$, if it returns the repeated argument when all but at most one of its arguments is the same. Ternary near-unanimity operations are called *majority*. We refer to a graph as *partially reflexive* to indicate that each vertex may or may not have a self-loop.

▶ **Theorem 2** (From Theorem 5.3 [3] and Theorem 2.1 [15]). *Let $\mathcal{H}^*$ be a partially reflexive graph expanded with all possible unary relations. Then either $\mathcal{H}^*$ admits a conservative majority polymorphism and* CSP*($\mathcal{H}^*$) is in* P*; or* CSP*($\mathcal{H}^*$) is* NP*-complete.*

Contribution

It is easy to see, but does not appear to have been noted, that conservative polymorphisms are expanding polymorphisms *in excelsis*. That is, they are the most natural examples of such polymorphisms that one is likely to imagine.

▶ **Lemma 3.** *Let f be a k-ary operation that is conservative. Then f is also expanding.*

Proof. Consider k subsets of the domain A of f, $A_1, \ldots, A_k$, each of size $m \leq |A|$. We need to argue that $|f(A_1, \ldots, A_k)| \geq m$. We proceed by induction on m where the base case $m = 1$ is trivial. Suppose it holds for m but does not hold for $m + 1$. Take $A'_1, \ldots, A'_k$, each of size $m+1 \leq |A|$. There must be $a'_1 \in A'_1, \ldots, a'_k \in A'_k$ so that none of $a'_1, \ldots, a'_k \in f(A'_1, \ldots, A'_k)$, since $|f(A'_1, \ldots, A'_k)| < m + 1$. By inductive hypothesis, $|f(A'_1 \setminus \{a'_1\}, \ldots, A'_k \setminus \{a'_k\})| \geq m$. But $f(a'_1, \ldots, a'_k) \in \{a'_1, \ldots, a'_k\}$ by conservativity, which is a contradiction. ◀

We prove that if a finite structure $\mathcal{B}$ admits an expanding majority polymorphism, then CQCSP($\mathcal{B}$) is in P. In doing so, we answer Question 1 of [21], for the case in the paragraph immediately after it. The algorithm is rather more sophisticated than in the case of CSP or QCSP. We note that a majority that is not expanding can appear as a polymorphism of $\mathcal{B}$ despite that CQCSP($\mathcal{B}$) is NP-hard. We derive as a corollary a complexity classification for CQCSP($\mathcal{H}^*$), where $\mathcal{H}^*$ is a partially reflexive graph endowed with all unary relations. This classification is in line with that of Theorem 2. We further derive a classification for successive approximations to CQCSP($\mathcal{B}$), where $\mathcal{B}$ is a binary first-order expansion of $(\mathbb{Z}; succ)$, whose relations (as digraphs) have bounded-degree. We then make some further observations on the usefulness of expanding majority polymorphisms and relate our work to some recent developments in surjective CSP involving the concept of endo-triviality.

Structure of the paper

This paper is organised as follows. After the preliminaries, Section 3 elaborates the consistency algorithm, and Section 4 gives some applications of this algorithm to complexity classifications. In Section 5, we close with some final remarks about the relationship between List-CSP and CQCSP. Owing to reasons of space, some proofs are deferred to the appendix.

2 Preliminaries

The reader will probably already have picked up that, if $\mathcal{B}$ is a relational structure, then B is its domain and $|B|$ the size of its domain. A *homomorphism*, from a structure $\mathcal{A}$ to a structure $\mathcal{B}$ over the same signature σ, is a function $h : A \to B$ such that, for each relation $R \in \sigma$, if $(x_1, \ldots, x_r) \in R^{\mathcal{A}}$, then $(h(x_1), \ldots, h(x_r)) \in R^{\mathcal{B}}$. A *k-ary polymorphism* of $\mathcal{B}$ is a k-ary operation f on B so that, $(x_1^1, \ldots, x_r^1), \ldots, (x_1^k, \ldots, x_r^k) \in R^{\mathcal{B}}$, then also $(f(x_1^1, \ldots, x_1^k), \ldots, f(x_r^1, \ldots, x_r^k)) \in R^{\mathcal{B}}$.

Given a set B, and an integer $i \geq 0$, we denote its ith power by B^i (B^0 being $\emptyset$). For an integer $c \geq 1$ We write $\binom{B}{c}$ for the following set of subsets of B : $\{S \subseteq B$ such that S has c elements$\}$. A *Skolem (partial) function* g_x for a variable x quantified as $\exists^{\geq c} x$ in the sentence is a partial function to $\binom{B}{c}$, whose arity is the number of variables coming before x in the quantifier prefix of the formula.

The Skolem functions g_i from B^{i-1} to $\binom{B}{c_i}$ $(1 \leq i \leq m)$ *witness that* φ *holds in* $\mathcal{B}$ iff $\forall b_1 \in g_1 \forall b_2 \in g_2(b_1) \ldots \forall b_n \in g_n(b_1, b_2, \ldots, b_{n-1})$ $\mathcal{B} \models \varphi(b_1, b_2, \ldots, b_m)$. If there are such Skolem functions then $\mathcal{B}$ models φ.

For a r-ary relation R in σ and sets $B_1, B_2, \ldots, B_r$, we write that $R(B_1, B_2, \ldots, B_r)$ holds in $\mathcal{B}$ iff for every $1 \leq i \leq r$ and every b_i in B_i, it is the case that $R(b_1, b_2, \ldots, b_r)$ holds in $\mathcal{B}$.

Let us note that counting quantifiers of the same cardinality do not in general commute. In particular, for every choice of $1 < i < n$, there exists a structure $\mathcal{B}$ over the signature of digraph (a single binary predicate E) of size $|B| = n$, such that $\exists^{\geq i} x \exists^{\geq i} y\, E(x, y)$ holds in $\mathcal{B}$ but $\exists^{\geq i} y \exists^{\geq i} x\, E(x, y)$ does not. For more on this, see [21].

3 An algorithm for consistency

In this section we will prove the following main theorem.

▶ **Theorem 4.** *Suppose* $\mathcal{B}$ *has an expanding majority polymorphism. Then CQCSP*($\mathcal{B}$) *is in* P.

Just as in the case of CSP and QCSP, by monotonicity, a sentence does not hold if any subsentence does not. Here, by subsentence we mean the sentence induced by selecting some variables. This means that for any structure, a not necessarily complete but polynomial algorithm consists in selecting some subsentences of bounded size and checking whether they hold : if one subsentence fails to hold, then we may answer no. A slightly cleverer way of doing this consists in propagating a potential solution from subsentences with overlapping variables. This is a basic approach known as enforcing local consistency, which is known to imply global consistency for CSP whenever the constraint language is closed under a majority operation [16, 18]. Our algorithm is a careful adaptation to our context.

The consistency argument will be somewhat more fiddly than for CSP. This is due to the fact that quantifiers do not commute and also that we have counting quantifiers and need to keep track of Skolem functions that witness (un)satisfiability of a sentence with counting quantifiers.

The consistency algorithm for establishing our Theorem 4 that we propose does this for the constraints induced by subsentences obtained by selecting up to 3 variables of the prefix and the atoms involving them in the quantifier-free part (we assume w.l.o.g. that the sentence is in prenex form) and maintaining consistency between the witnesses. These witnesses are sets of suitable size, namely the range of the Skolem functions corresponding to the counting quantifiers.

In the following and unless specified otherwise, subset means subset of the domain B of the structure $\mathcal{B}$. We assume some arbitrary order over B and subsets are ordered accordingly.

3.1 Sentences with three variables

Let us examine first a 3 variable sentence φ of the following form:

$$\exists^{\geq c_1} x_1 \exists^{\geq c_2} x_2 \exists^{\geq c_3} x_3 R_{1,2}(x_1, x_2) \wedge R_{2,3}(x_2, x_3) \wedge R_{1,3}(x_1, x_3).$$

For a subset S of size c_1, and subsets T_i of size c_2, we write $OK_{1,2}(S, T_1, \ldots, T_{c_1})$ whenever $R_{1,2}(s_i, T_i)$ holds for all s_i in S (recall that sets are ordered). We proceed similarly to define the $c_1 + 1$-ary predicate $OK_{1,3}$ between a subset of size c_1 and c_1 subsets of size c_3 and the $c_2 + 1$-ary predicate $OK_{2,3}$ between a subset of size c_2 and c_2 subsets of size c_3. The sentence φ holds whenever there is a subset S of size c_1, subsets T_i of size c_2 with $1 \leq i \leq c_1$, subsets $U_{i,j}$ of size c_3 with $1 \leq j \leq c_2$ such that :

$$OK_{1,2}(S, T_1, \ldots, T_{c_1}) \wedge \bigwedge_{1 \leq i \leq c_1} OK_{2,3}(T_i, U_{i,1}, \ldots, U_{i,c_2}) \wedge \bigwedge_{1 \leq j_1 \leq c_2} \cdots \bigwedge_{1 \leq j_{c_1} \leq c_2} OK_{1,3}(S, U_{1,j_1}, \ldots, U_{c_1,j_{c_1}}).$$

3.2 Data structure

With this small example in mind, the following data structure used by our algorithm should become clearer.

- Each variable $\exists^{\geq c_i} x_i$ is represented by a domain that consists of subsets S of size c_i.
- We maintain a $c_i + 1$-ary predicate $OK_{i,j}$ as in the above example between the domains of any pair of variables x_i, x_j as long as x_j comes after x_i in the prefix of quantification and that x_i and x_j occur both in some atom.

3.3 Binary Predicates Only

Of course, unlike in our small example, the input sentence φ' may well have non binary atoms and the parameter structure $\mathcal{B}'$ corresponding relations of arity 3 or more. We project almost in the usual fashion all atoms/relations involving two variables x_1 and x_2 into a single binary constraint R_{x_1,x_2} (if there are constraints, otherwise there is no binary constraint).

Unlike in the CSP case, *we check that counting requirements induced by the sentence are met.* Formally, for every pair of distinct variables x_1, x_2 quantified as $\exists^{\geq c_1} x_1 \exists^{\geq c_2} x_2$, we consider the binary constraint R_{x_1,x_2} to be the intersection of the binary relations R'_{x_1,x_2} induced by atoms $R'(\bar{y})$ such that both x_1 and x_2 occur in $\bar{y}$ as follows. $R'_{x_1,x_2}(b_1, b_2)$ holds whenever for any variable y distinct from both x_1 and x_2 with quantifier prefix $\exists^{\geq c_y} y$ occurring at position i in $\bar{y}$ (to distinguish the potentially many occurrences of y, we will write y_i for the occurrence of y at position i) there exists a set B_i of size at least c_y such that $R'(\pi(\bar{y}))$ holds where $\pi(x_1) = b_1, \pi(x_2) = b_2$ and $\pi(y_i) = B_i$.

We denote by φ this sentence with binary atoms and by $\psi(\bar{x})$ its subsentence induced naturally by the variables $\bar{x}$. We write $\mathcal{B}$ for the structure with binary relations. Note that these relations are cq-pp interpretations of the relations of $\mathcal{B}'$.

▶ **Proposition 1.** *If $\mathcal{B}'$ has an expanding majority f, then*

(i) *$\mathcal{B}$ has also f as an expanding majority*

(ii) *$\mathcal{B}$ models φ (binary setting) iff $\mathcal{B}'$ models φ' (general setting).*

Proof. Since $\mathcal{B}$ was obtained by cq-pp interpretation from $\mathcal{B}'$, it follows that $\mathcal{B}$ has also a majority polymorphism f (via the easy direction of the Galois connection of Lemma 1).

We now show that a collection of Skolem functions witnesses φ iff it does also for φ'. The right to left implication holds by construction and for any structure $\mathcal{B}'$. We only need to establish the left to right implication in the presence of an expanding majority f.

Let $g_1, g_2, \ldots, g_n$ be a collection of Skolem functions witnessing that $\mathcal{B} \models \varphi$. Let $b_1 \in g_1, b_2 \in g_2(b_1) \ldots b_n \in g_n(b_1, b_2, \ldots, b_{n-1})$. We write $g_i(\bar{b})$ as an abbreviation for $g_i(b_1, b_2, \ldots, b_{i-1})$.

Let $R(x_{i_1}, x_{i_2}, \ldots, x_{i_r})$ be some r-ary atom of φ' with $r \geq 3$. We write c_{i_j} to denote the counting requirement on variable i_j for $1 \leq j \leq r$.

Since $R_{x_{i_1},x_{i_2}}(g_{i_1}(\bar{b}), g_{i_2}(\bar{b}))$ holds in $\mathcal{B}$, by construction there are some set of values $S_{i_3}, S_{i_4}, \ldots, S_{i_r}$ of respective sizes $c_{i_3}, c_{i_4}, \ldots, c_{i_r}$. Similarly, there are some sets of the correct count such that $R(g_{i_1}(\bar{b}), S'_{i_2}, g_{i_3}(\bar{b}), S'_{i_4}, \ldots, S'_{i_r})$ and $R(S''_{i_1}, g_{i_2}(\bar{b}), g_{i_3}(\bar{b}), S''_{i_4}, \ldots, S''_{i_r})$. Applying f, since it is a majority, it means the following holds.

$$R(g_{i_1}(\bar{b}), g_{i_2}(\bar{b}), g_{i_3}(\bar{b}), f(S_{i_4}, S'_{i_4}, S''_{i_4}), \ldots, f(S_{i_r}, S'_{i_r}, S''_{i_r})).$$

Since it is expanding, we may select arbitrarily subsets $\widetilde{S_{i_4}} \subseteq f(S_{i_4}, S'_{i_4}, S''_{i_4}) \ldots \widetilde{S_{i_r}} \subseteq f(S_{i_r}, S'_{i_r}, S''_{i_r})$ of respective sizes $c_{i_4}, \ldots, c_{i_r}$ such that the following holds.

$$R(g_{i_1}(\bar{b}), g_{i_2}(\bar{b}), g_{i_3}(\bar{b}), \widetilde{S_{i_4}}, \ldots, \widetilde{S_{i_r}}).$$

Note that there is nothing special about the position 1, 2 and 3 within the tuple R. The same argument applies to any choice of three positions. Furthermore, there is nothing special in our argument using the fact that we have only three positions that agree with the value of the Skolem functions. So we can bootstrap the same argument to extend progressively the tuple by one position and show eventually that : $R(g_{i_1}(\bar{b}), g_{i_2}(\bar{b}), g_{i_3}(\bar{b}), \ldots, g_{i_r}(\bar{b}))$ holds. ◀

From now on, instead of considering a structure $\mathcal{B}'$, in the light of Proposition 1, we will concentrate on the corresponding binary structure $\mathcal{B}$ (to fulfill this we may need to expand the signature but it will still remain finite).

3.4 The Algorithm: path consistency for counting quantifiers (PCCQ)

Initialisation

- The domain of x_i contains all subsets that are consistent with all unary atoms involving x_i, that is $\{S \in \binom{B}{c_i}$ such that $S \subseteq M^{\mathcal{B}}$ for every unary atom $M(x_i)$ of $\varphi\}$
- For every binary relation $R_{i,j}$, the predicate $OK_{i,j}$ holds between any set S in the domain of x_i and c_i sets $T_1, \ldots, T_{c_i}$ in the domain of x_j whenever $R_{i,j}(s_k, T_k)$ holds for any $1 \leq k \leq c_i$

Maintaining consistency

Do
For all triples of variables $x_{i_1}, x_{i_2}, x_{i_3}$ (in the order of quantification),
For every distinct k, l in $\{i_1, i_2, i_3\}$,
For every S in the domain of x_k,
If there are no OK tuple $OK_{k,l}$ mentioning S (in the first coordinate), then
discard S and all other OK tuples that mention S.
For every $OK_{k,l}$ tuple t
if there are no additional OK tuples witnessing that t participates in a solution to $\varphi(x_{i_1}, x_{i_2}, x_{i_3})$
Remove the $OK_{k,l}$ tuple t.
If there are no more $OK_{k,l}$ tuples then reject.
Loop until no further OK tuples are deleted.

3.5 Properties of the PCCQ algoritm

▶ **Proposition 2.** *PCCQ runs in polynomial time.*

Proof. Let $\sharp v$ denote the number of variables of φ. The data structure needs to store at most $|B|^j \leq 2^{|B|}$ sets of size at most $j \leq |B|$ for each variable associated with a count j. One OK tuple originating from this variable with count j to a variable with count k will relate at most $j+1$ sets, one of size j and the others of size k. There are therefore at most $2^j.(2^k)^j \leq (2^{|B|})^{|B|+1}$ such OK tuples for one binary constraint. There are at most $\sharp v(\sharp v - 1)$ such constraints. The algorithm runs clearly in time polynomial in these quantities, and $(2^{|B|})^{|B|+1}$ is a constant since $|B|$ is fixed. ◀

Let $\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})}$ be a list of some OK tuples, as many as the arity of an expanding polymorphism f. Applying f coordinate wise, as we would for an ordinary tuple, we have $f(\overline{S}) = S'$ and $f(\overline{T_j}) = T'_j$ for any $1 \leq j \leq c_i$. However, the images $S', T'_1, \ldots, T'_{c_i}$ may be too large to feature in an OK tuple. We will say that an OK tuple (with aptly sized sets) $OK_{i,j}(S'', T''_1, \ldots, T''_{c_i})$ belongs to $f(\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})})$, whenever $S'' \subseteq S', T''_j \subseteq T'_j$ for all $1 \leq j \leq c_i$.

We say that a set $\mathcal{R}$ of OK tuples are *preserved* by f if, and only if, for any OK tuples $\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})}$ in $\mathcal{R}$, any OK tuple that belongs to $f(\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})})$, also belongs to $\mathcal{R}$.

▶ **Proposition 3.** *Let f be an expanding polymorphism of $\mathcal{B}$. If the algorithm PCCQ does not reject, the OK tuples that remain when the algorithm stops are preserved by f.*

Proof. Let $OK_{i,j}(S'', T''_1, \ldots, T''_{c_i})$ be an OK tuple in the image $f(\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})})$ under f of remaining OK tuples $\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})}$. We prove that $OK_{i,j}(S'', T''_1, \ldots, T''_{c_i})$ can not be removed by the algorithm as follows.

Initially, the relations are preserved under f, so it is straightforward to verify that OK tuples are also closed under f. So this removal of $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$ must happen after initialisation. We shall assume further that $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$ is the first OK tuple in the image of f of remaining OK tuples that is removed by the algorithm PCCQ.

Assume further that $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$ is removed by the algorithm while checking the sentence with some other variable k. Assume for now that the order of quantification induces the order i, j, k over the indices.

Since the tuples $\overline{OK_{i,j}(S, T_1, \ldots, T_{c_i})}$ are remaining OK tuples, there must be *remaining* tuples $OK_{i,k}$ and $OK_{j,k}$ witnessing that each of them participate in a solution to $\varphi(x_i, x_j, x_k)$.

Taking the image of these witnesses under f provide us with $OK_{i,k}$ and $OK_{i,k}$ witnessing that $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$ participate in a solution to $\varphi(x_i, x_j, x_k)$.

By time minimality of the removal of $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$, these last witnesses may not be remaining tuples but they must remain at the time of removal of $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$. This contradicts the fact that the algorithm could remove $OK_{i,j}(S'', T_1'', \ldots, T_{c_i}'')$.

To conclude the proof, note further that the above argument applies independently of the quantification order of i, j and k. ◀

▶ **Proposition 4.** *If $\mathcal{B}$ has an expanding majority f and the algorithm PCCQ does not reject, then $\mathcal{B}$ models φ.*

Proof. Let $x_1, x_2, \ldots, x_n$ be the variables occurring in φ. For any choice of variables $\overline{x}$ in $\{x_1, x_2, \ldots, x_n\}$, we denote by $\psi(\overline{x})$ the subsentence of φ induced by the variables $\overline{x}$.

We prove by induction on $2 \leq i < n$ that : for any choice of i variables $\overline{x}$, for any additional variable z occurring after the variables $\overline{x}$ in the order of quantification, any Skolem witnesses $\{g_1, g_2, \ldots, g_i\}$ for $\psi(\overline{x})$ can be extended by an i-ary Skolem function g_z for the variable z such that $\{g_1, g_2, \ldots, g_i, g_z\}$ witnesses that $\varphi(\overline{x}, z)$ holds. Moreover, this Skolem function ranges over sets that were not removed by the algorithm from the domain of z.

The base case for $i = 2$ holds : this is precisely the property that is enforced by the consistency algorithm we outlined.

We proceed to show the induction step. Let $x_1, x_2, x_3, \ldots, x_i$ be a choice of $i \geq 3$ variables and z a variable occurring after them. Let $\{g_1, g_2, g_3, \ldots, g_i\}$ be a collection of Skolem functions witnessing that $\psi(x_1, x_2, x_3, \ldots, x_i)$ holds.

We write I_1 for the image of g_1 and for $1 < j \leq i$, we write I_j for $g_j(I_1, \ldots, I_{j-1})$. Let $\alpha : \emptyset \to I_1$, $\beta : I_1 \to I_2$ and $\gamma : I_1 \times I_2 \to I_3$. We pick only such functions that are consistent with the fact that $\{g_1, g_2, g_3, \ldots, g_i\}$ are Skolem functions, namely we insist that for any b_1 in I_1, $\beta(b_1)$ belongs to the image of $g_2(b_1)$ and for any b_1 in I_1, and any b_2 in $g_2(b_1)$, $\gamma(b_1, b_2)$ lies in the image of $g_3(b_1, b_2)$.

We derive naturally three collections of $i - 1$ Skolem functions by essentially fixing the first, second or third coordinate of the i Skolem functions at hand. Each collection witnesses the subsentence obtained by removal of x_1, x_2 or x_3.

- Let the Skolem functions $\{g_2^\alpha, g_3^\alpha, \ldots, g_i^\alpha\}$ be defined as $g_j^\alpha(x_2, \ldots, x_{j-1}) = g_j(\alpha, x_2, \ldots, x_{j-1})$[1]. By construction, they are witnessing that $\psi(x_2, x_3, \ldots, x_i)$ holds. By the induction hypothesis, they can be extended by some $(i-1)$-ary function g_z^α witnessing $\psi(x_2, x_3, \ldots, x_i, z)$.

[1] If g_j is undefined, we let g_j^α be also undefined. Alternatively, we could have defined our Skolem functions precisely where we cared, e.g. for any x_2 in $g_1(\alpha)$, any x_3 in $g(\alpha, x_2)$, etc. But this would only introduce unnecessary notation.

- Similarly, we derive Skolem functions $\{g_1^\beta, g_3^\beta, \ldots, g_i^\beta\}$ witnessing $\psi(x_1, x_3, \ldots, x_i)$ from $\{g_1, g_2, \ldots, g_i\}$ by setting $g_1^\beta = g_1$ and for any $3 \leq j \leq i$, and any b_1 in I_1, we define $g_j^\beta(b_1, x_3, x_4, \ldots, x_{j-1}) := g_j(b_1, \beta(b_1), x_3, \ldots, x_{j-1})$. By the induction hypothesis, they can be extended by some $(i-1)$-ary function g_z^β witnessing $\psi(x_1, x_3, \ldots, x_i, z)$.
- Finally, we derive Skolem functions $\{g_1^\gamma, g_2^\gamma, g_4^\gamma \ldots, g_i^\gamma\}$ witnessing $\psi(x_1, x_2, x_4 \ldots, x_i)$ from $\{g_1, g_2, \ldots, g_i\}$ by setting $g_1^\gamma = g_1$, $g_2^\gamma = g_2$ and for any $4 \leq j \leq i$ any b_1 in I_1 and any b_2 in $g_2(b_1)$ that $g_j^\gamma(b_1, b_2, x_4, \ldots, x_{j-1}) := g_j(b_1, b_2, \gamma(b_1, b_2), x_4, \ldots, x_{j-1})$. By the induction hypothesis, they can be extended by some $(i-1)$-ary function g_z^γ witnessing $\psi(x_1, x_2, x_4, \ldots, x_i, z)$.

We will define the Skolem function g_z piecewise for each choice of the first three variables.

For specific b_1 in I_1 and b_2 in $g_2(b_1)$ and b_3 in $g_3(b_1, b_2)$, we set $\alpha() := b1$, $\beta(b_1) := b_2$, and $\gamma(b_1, b_2) := b_3$. The other values of β and γ are arbitrary but constrained as explained above.

Recall that f is an expanding majority of $\mathcal{B}$.

We define the Skolem function g_z as follows for this choice to the first three variables :

$$g_z(b_1, b_2, b_3, x_4, \ldots, x_i) := f(g_z^\alpha(b_2, b_3, x_4 \ldots, x_i), g_z^\beta(b_1, b_3, x_4 \ldots, x_i), g_z^\gamma(b_1, b_2, x_4 \ldots, x_i)).$$

The fact that f is expanding[2] implies that g_z has a range of correct size.

Note that this definition ensures that indeed g_z ranges over sets that were not filtered out by the algorithm from the domain of z by the (previous) Proposition 3.

The fact that f is a majority will allow us to derive that g_z is indeed an extension of $\{g_1, g_2, g_3, g_4, \ldots, g_i\}$ witnessing $\varphi(x_1, x_2, x_3, x_4 \ldots, x_i, z)$. We need only check this independently for each pair of variables x_j, z, since all atoms are binary. Since, we defined g_z piecewise, we can also check this independently for each piece, induced by the choices of b_1, b_2, b_3. For simplicity, we denote by R an atom that should hold between x_j and z.

- If $j \geq 4$, then applying majority on the variants α, β and γ works naturally, since the value for j is the same for each variant by construction and f is idempotent.
  With full notational details : by assumption $R(g_j^\alpha(b_2, b_3, x_4, \ldots, x_{j-1}), g_z^\alpha(b_2, b_3, x_4 \ldots, x_i))$ holds and $R(g_j^\beta(b_1, b_3, x_4, \ldots, x_{j-1}), g_z^\beta(b_1, b_3, x_4 \ldots, x_i))$ holds and

  $$R(g_j^\gamma(b_1, b_2, x_4, \ldots, x_{j-1}), g_z^\gamma(b_1, b_2, x_4 \ldots, x_i))$$

  holds. By construction of $g_j^\alpha, g_j^\beta, g_j^\gamma$ and the specific choice of values b_1, b_2, b_3, we have

  $$g_j^\alpha(b_2, b_3, x_4, \ldots, x_{j-1}) = g_j^\beta(b_1, b_3, x_4, \ldots, x_{j-1}) =$$
  $$g_j^\gamma(b_1, b_2, x_4, \ldots, x_{j-1}) = g_j(b_1, b_2, b_3, x_4, \ldots, x_{j-1}).$$

  Hence the image of the first coordinate under f is $g_j(b_1, b_2, b_3, x_4, \ldots, x_{j-1})$ since f is idempotent. The second coordinates is precisely the value we defined for g_z. Thus we conclude that $R(g_j(b_1, b_2, b_3, x_4, \ldots, x_{j-1}), g_z(b_1, b_2, b_3, x_4, \ldots, x_i))$ holds as required.
- If $j = 1$. The value for $g_z^\alpha(b_2, b_3, x_4 \ldots, x_i)$ occurs as a set in the domain of the variable z after variable x_1. So the algorithm must have left an OK tuple between x_1 and z that mentions $g_z^\alpha(b_2, b_3, x_4 \ldots, x_i)$. This means that there is a singleton b_1' such that $R(b_1', g_z^\alpha(b_2, b_3, x_4 \ldots, x_i))$ holds. Further, by assumption $R(g_1^\beta, g_z^\beta(b_1, b_3, x_4 \ldots, x_i))$ holds and $R(g_1^\gamma, g_z^\gamma(b_1, b_2, x_4 \ldots, x_i))$ holds. Since $g_1^\beta = g_1^\gamma = b_1$, applying f we obtain b_1 for the first coordinate since f is a majority operation. For the second coordinate we obtain the value we defined for g_z. Thus we conclude that $R(b_1, g_z(b_1, b_2, b_3, x_4, \ldots, x_i))$ holds as required.

- If $j = 2$, then similarly to the previous case, there is some singleton b'_2 in the domain of x_2 such that $R(b'_2, g^\beta_z(b_1, b_3, x_4 \ldots, x_i))$ holds. Further, by assumption $R(g^\alpha_2(b_1), g^\alpha_z(b_2, b_3, x_4 \ldots, x_i))$ holds and $R(g^\gamma_2(b_1), g^\gamma_z(b_1, b_2, x_4 \ldots, x_i))$ holds. Since $g^\alpha_2(b_1) = g^\gamma_2(b_1) = b_2$, applying f we obtain b_2 for the first coordinate since f is a majority operation. For the second coordinate we obtain the value we defined for g_z. Thus we conclude that $R(b_2, g_z(b_1, b_2, b_3, x_4, \ldots, x_i))$ holds as required.
- If $j = 3$, then similarly to the two previous cases, there is some singleton b'_3 in the domain of x_3 such that $R(b'_3, g^\gamma_z(b_1, b_2, x_4 \ldots, x_i))$ holds. Further, by assumption $R(g^\alpha_3(b_2), g^\alpha_z(b_2, b_3, x_4 \ldots, x_i))$ holds and $R(g^\beta_3(b_1), g^\beta_z(b_1, b_2, x_4 \ldots, x_i))$ holds. Since $g^\alpha_3(b_2) = g^\beta_3(b_1) = g_3(b_1, b_2) = b_3$, applying f we obtain b_3 for the first coordinate since f is a majority operation. For the second coordinate we obtain the value we defined for g_z. Thus we conclude that $R(b_3, g_z(b_1, b_2, b_3, x_4, \ldots, x_i))$ holds as required. ◀

We can now wrap-up to complete the proof of our main theorem.

Proof of Theorem 4. By Proposition 1, we reduce the question whether φ' holds on $\mathcal{B}'$ to the question whether φ holds on $\mathcal{B}$. This can be achieved in polynomial time, since we assume we assume a fixed signature, and have therefore bounded arity. We know that $\mathcal{B}$ is also preserved by the same expanding majority, thus we can appeal to Proposition 4, which states that if PCCQ does not reject then the sentence φ holds in $\mathcal{B}$. Since PCCQ runs in polynomial time by Proposition 2, we are done. ◀

Suppose now that X is some strict subset of $\{1, \ldots, |B|\}$. The variant of Lemma 1 that talks of X-pp-definability and polymorphisms that expand at cardinalities in X is not explicit in [8]. However, the easy direction, that X-pp-definability entails preservation by polymorphisms that expand at cardinalities in X, is straightforward to prove.

▶ **Theorem 5.** *Suppose $\mathcal{B}$ has an majority polymorphism that expands at cardinalities $\{c_1, \ldots, c_m\}$. Then $\{c_1, \ldots, c_m\}$-CSP($\mathcal{B}$) is in* P.

3.6 Expanding polymorphisms are necessary

We will now argue that the condition of expansion was necessary in Theorem 4, since there is a structure admitting non-expanding majority whose CQCSP is NP-hard. Let $\mathcal{H}_4$ be the 4-vertex graph built from the irreflexive triangle $\mathcal{K}_3$ on $\{1, 2, 3\}$ by adding a dominating vertex 0 with a self-loop. It is easy to verify that $\mathcal{H}_4$ enjoys the majority polymorphism f that maps any tuple of distinct arguments to 0. This f is clearly not conservative and it even violates the condition of expansion because $|f(\{0, 1\}, \{0, 2\}, \{0, 3\})| = 1$.

▶ **Lemma 6.** *CQCSP($\mathcal{H}_4$) is* NP*-hard.*

Proof. By reduction from 3-COL, a.k.a. CSP($\mathcal{K}_3$). Take an input φ for CSP($\mathcal{K}_3$) and build an input ψ for CQCSP($\mathcal{H}_4$) by changing all $\exists$ quantifiers to $\exists^{\geq 2}$.

($\mathcal{K}_3 \models \varphi$ implies $\mathcal{H}_4 \models \psi$.) Evaluate each variables v in ψ according to its evaluation φ but additionally with the second possibility 0.

($\mathcal{H}_4 \models \psi$ implies $\mathcal{K}_3 \models \varphi$.) Evaluate each variable v in φ according to one of the possibilities for v in ψ that is not equal to 0. ◀

4 Applications of our result

We will now see that conservative majority polymorphisms demarcate tractability in diverse places.

▶ **Corollary 7.** *Let $\mathcal{H}^*$ be a partially reflexive graph $\mathcal{H}$ endowed with all unary relations. Either $\mathcal{H}^*$ admits an expanding majority and CQCSP($\mathcal{H}^*$) is in* P*, or CQCSP($\mathcal{H}^*$) is* NP*-hard.*

Proof. We know all polymorphisms of $\mathcal{H}^*$ are conservative since it has all unary relations. From Theorem 2 we further know that either $\mathcal{H}^*$ admits a conservative majority polymorphism or CSP($\mathcal{H}^*$) is NP-hard. The result follows from Lemma 3 and Theorem 4. ◀

The following is a strengthening of Theorem 7.16 of [21] in the case of paths.[3]

▶ **Corollary 8.** *Let $\mathcal{P}$ be an irreflexive (undirected) path. Then CQCSP($\mathcal{P}$) is in* P*.*

Proof. Suppose $\mathcal{P}$ is over vertices $\{1, \ldots, n\}$ so that $(i, i+1) \in E^{\mathcal{P}}$. Then $\mathcal{P}$ admits the conservative majority polymorphism m communicated to us by Tomás Feder: $m(x, y, z)$ is defined to be the median of x, y, z, if they all have the same parity; otherwise it is the smaller of the pair with repeated parity. The result follows from Lemma 3 and Theorem 4. ◀

Sadly we cannot use conservative majorities for irreflexive trees, since it is well-known that the tree $\mathcal{T}_{10}$, built from three paths on four vertices by identifying one end of each of these three paths as a single vertex, does not admit a conservative majority. This has been known, based on complexity-theoretic assumptions, since [14, 4] but we have checked also using the polymorphism program of Miklós Maróti[4].

We will now see how to apply our result to infinite-domain (CQ)CSPs. The (d-)*modular median* operation of [1] is defined on $\mathbb{Z}$ as follows. $f(x, y, z) = median(x, y, z)$, if $x \equiv y \equiv z \bmod d$. If two among $\{x, y, z\}$ are equivalent mod d, then $f(x, y, z)$ is the minimum of these two; otherwise $f(x, y, z) = x$. Note that these modular median operations are conservative majorities.

▶ **Corollary 9.** *Let $\mathcal{B}$ be a finite-signature binary first-order expansion of $(\mathbb{Z}; succ)$ whose relations, viewed as digraphs, have bounded degree. Either $\mathcal{B}$ admits a modular median polymorphism, and, for each j, $\{1, \ldots, j\}$-CSP($\mathcal{B}$) is in* P*, or CSP($\mathcal{B}$) is* NP*-hard.*

Proof. By Proposition 6 in [1],[5] we know that if $\mathcal{B}$ omits all modular median operations, then CSP($\mathcal{B}$) is NP-hard. Thus, we are left with the question of tractability. Let e be maximal so that $(x, x+e)$ appears in some relation of $\mathcal{B}$. Let ϕ be an input for CQCSP($\mathcal{B}$) involving n variables. Now, we can see that ϕ is true on $\mathcal{B}$ just in case it is true on the substructure $\mathcal{B}'$of $\mathcal{B}$ induced by the interval $[0, ne]$. $\mathcal{B}'$ admits the same conservative majority that $\mathcal{B}$ does and the result follows from Propositions 4 when we consider from the proof of Proposition 2 that the size of subsets in the OK tuples is bounded by j. This is because the number of OK tuples per binary constraint is bound by $(j(ne)^j)^{j+1}$ (which takes the place of the term $(2^{|B|})^{|B|+1}$ in the calculation for complexity in Proposition 2). ◀

To consider CQCSP over an infinite-domain structure, albeit with a finite signature, one must consider how to encode i in $\exists^{\geq i}$. The most natural encoding here is binary. We leave as an open question whether CQCSP($\mathcal{B}$) is in P, whenever $\mathcal{B}$ is a finite-signature binary first-order expansion of $(\mathbb{Z}; succ)$ whose relations, viewed as digraphs, have bounded degree,

[3] Theorem 7.16 of [21] deals with $\{1, 2\}$-CSP on trees, but its very long proof does not become much simpler if one restricts to paths.

[4] See: `http://www.math.u-szeged.hu~maroti/applets/GraphPoly.html`

[5] Proposition 6 lacks a counterpart in the journal version of [1] For a proof, see Proposition 35 in v2 of the arxiv version.

which admits a modular median polymorphism. Note that this question remains open even if we choose the unary encoding for i.

4.1 Endo-triviality

The concept of endo-triviality has recently been introduced in the context of surjective CSPs [20]. We note here that endo-triviality is strong enough to deduce results also for CQCSPs. An *endomorphism* of a digraph $\mathcal{H}$ is a homomorphism from $\mathcal{H}$ to itself. Call $\mathcal{H}$ a *core* if all of its endomorphisms of $\mathcal{H}$ are automorphisms (the importance of cores is discussed, e.g., in [17]). Call $\mathcal{H}$ *endo-trivial* if all of its endomorphisms either have range of size 1 or are automorphisms.

The *retraction* problem $\mathrm{Ret}(\mathcal{H})$ takes as input a graph $\mathcal{G}$ containing $\mathcal{H}$ as an induced substructure and asks whether there is a homomorphism from $\mathcal{G}$ to $\mathcal{H}$ that is the identity on $\mathcal{H}$ (such an endomorphism of $\mathcal{G}$ is termed a *retraction to* $\mathcal{H}$)

The proofs of the following are deferred to the appendix.

▶ **Lemma 10.** *Let $\mathcal{H}$ be a graph that is endo-trivial. The there is a polynomial-time reduction from Ret($\mathcal{H}$) to CQCSP($\mathcal{H}$).*

▶ **Corollary 11.** *Let $\mathcal{C}$ be a reflexive directed cycle. If $\mathcal{C}$ is of length 2 then CQCSP($\mathcal{C}$) is in* L*, otherwise CQCSP($\mathcal{C}$) is* NP*-hard.*

5 Final remarks

Near-unanimity polymorphisms. Note that Theorem 4 relativises to any subset of counts $X \subset \{1, 2 \ldots, |B|\}$ for the problem X-CSP($\mathcal{B}$) with the weaker hypothesis that requires that $\mathcal{B}$ has a majority f that is expanding on X. Note that, if $1 \notin X$, one has to move to partial polymorphisms. Indeed, we do not need f to be a majority, only that it satisfies the identities of a majority where we replace uniformly the variables by set variables of the same size from X.

We can also generalise the algorithm and the proof principle to a larger class of structures.

▶ **Theorem 12.** *If $\mathcal{B}$ has an expanding near unanimity polymorphism. Then CQCSP($\mathcal{B}$) is in* P*.*

CQCSP and List-CSP. We have seen that conservative operations are expanding, but what is the actual relationship between CQCSP and List-CSP? Does ability to quantify set cardinalities with $\exists^{\geq j}$ relate to talking about subsets of size j? For this latter question, it seems the answer is no. Designate $\{1, 2\}$-List-CSP the restriction of List-CSP in which only subsets of size 1 and 2 are available. Recall the tree $\mathcal{T}_{10}$, built from three paths on four vertices by identifying one end of each of these three paths as a single vertex. List-CSP($\mathcal{T}_{10}$) is known to be NP-complete since [14]. NP-completeness for $\{1, 2\}$-List-CSP($\mathcal{T}_{10}$) follows from [4]. On the other hand, $\{1, 2\}$-CSP($\mathcal{T}_{10}$) is in P, as proved in Theorem 7.16 of [21]. However, we are still missing an exemplar $\mathcal{B}$ so that one of CQCSP($\mathcal{B}$) and List-CSP($\mathcal{B}$) is tractable and the other is not.

CQCSP and Retraction. In Lemma 10, we show a sufficient condition for which Ret($\mathcal{B}$) is polynomially reducible to CQCSP($\mathcal{B}$). It should be possible to reconstruct the argument from [20] in order to prove that, if $\mathcal{H}$ is a reflexive tournament, then either $\mathcal{H}$ has a conservative majority polymorphism (the median) and CQCSP($\mathcal{B}$) is in P; or Ret($\mathcal{H}$) can be polynomially

reduced to CQCSP($\mathcal{H}$) and both are NP-hard. Note that a classification for QCSP on reflexive tournaments is not yet known. However, what we would like is much stronger : is it the case that for all finite $\mathcal{B}$, Ret($\mathcal{H}$) can be polynomially reduced to CQCSP($\mathcal{H}$)? That is, are all constants cq-pp-definable up to isomorphism?

Core-ness and finite categoricity. Closely related to the previous question is whether all non-isomorphic finite structures can be distinguished by cq-pp. Let us explore this question through the Weisfeiler-Lehman (WL) method, as discussed in [9] (where logics with counting also play a central role). The *degree sequence* of a graph is a non-increasing list of positive integers that list the degrees of its vertices. This can be thought of as a 0-dimensional WL descriptor. Obviously, if two graphs are isomorphic, then they have the same degree sequence, but the converse is not necessarily true. Cq-pp can not specify vertex degree but it can specify a lower bound for it. Firstly, then, two graphs on vertex sets of distinct sizes can be distinguished by some $\exists^{\geq a_1} x\,(x = x)$. For two graphs with vertex sets the same size, if their two degree sequences differ, with the first being lexicographically the larger, then counting down from the top until the first difference, one will find necessarily some a_1, a_2 so that $\exists^{\geq a_1} x_1 \exists^{\geq a_2} x_2\, E(x_1, x_2)$ is true on the first graph but false on the second. We do this by setting $a_1 - 1$ to be the number of vertices before the degree sequence differs and a_2 to be the degree at which the degree sequences diverge.

The 1-dimensional WL descriptor is defined inductively by expanding each integer associated with a vertex from the 0-dimensional WL descriptor into a tree of depth one whose leaves list, in descending order, the degrees of that vertex's neighbours. These leaves are now associated with that corresponding neighbour. The process is then iterated, and would go on for ever, save that we stop it when a fixed-point is reached in terms of the subtrees added being endlessly the same. Now suppose two graphs each give rise to a forest built in this fashion and let k be the height at which these forests first differ (else they are indistinguishable by 1-dimensional WL) and let the first graph be lexicographically the smaller (apply closeness to the root as higher in the lexicography). We can follow the previous reasoning, and the path through the forests on which the graphs differ, to find some $\exists^{\geq a_1} x_1 \exists^{\geq a_2} x_2 \ldots \exists^{\geq a_k} x_k \exists^{\geq a_{k+1}} x_{k+1}\, E(x_1, x_2) \wedge \ldots \wedge E(x_k, x_{k+1})$ that is true on the first graph but not the second.

The 1-dimensional WL descriptor does not capture isomorphism, and unfortunately, we do not see an implementation of the more general r-dimensional WL descriptor in cq-pp, since this can measure isomorphism type of an induced subgraph of size r.

Abstract

In this paper, we introduce the concept of b-branchings in digraphs, which is a generalization of branchings serving as a counterpart of b-matchings. Here b is a positive integer vector on the vertex set of a digraph, and a b-branching is defined as a common independent set of two matroids defined by b: an arc set is a b-branching if it has at most $b(v)$ arcs sharing the terminal vertex v, and it is an independent set of a certain sparsity matroid defined by b. We demonstrate that b-branchings yield an appropriate generalization of branchings by extending several classical results on branchings. We first present a multi-phase greedy algorithm for finding a maximum-weight b-branching. We then prove a packing theorem extending Edmonds' disjoint branchings theorem, and provide a strongly polynomial algorithm for finding optimal disjoint b-branchings. As a consequence of the packing theorem, we prove the integer decomposition property of the b-branching polytope. Finally, we deal with a further generalization in which a matroid constraint is imposed on the $b(v)$ arcs sharing the terminal vertex v.

1 Introduction

Since the pioneering work of Edmonds [12, 14], the importance of *matroid intersection* has been well appreciated. A special case of matroid intersection is *branchings* (or *arborescences*) in digraphs. Branchings have several good properties which do not hold for general matroid intersection. The objective of this paper is to propose a class of the matroid intersection problem which generalizes branchings and inherits those good properties of branchings.

One of the good properties of branchings is that a maximum-weight branching can be found by a simple combinatorial algorithm [4, 6, 11, 23]. This algorithm is much simpler than general weighted matroid intersection algorithms, and is referred to as a "multi-phase greedy algorithm" in the textbook by Kleinberg and Tardos [35].

Another good property is the elegant theorem for packing disjoint branchings [13]. In terms of matroid intersection, this theorem says that, if there exist k disjoint bases in each of the two matroids, then there exist k disjoint common bases. This packing theorem leads to a proof that the branching polytope has the *integer decomposition property* (defined in Section 2).

In this paper, we propose *b-branchings*, a class of matroid intersection generalizing branchings, while maintaining the above two good properties. This offers a new direction of fundamental extensions of the classical theorems on branchings.

Let $D = (V, A)$ be a digraph and let $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V. For $v \in V$ and $F \subseteq A$, let $\delta^-_F(v)$ denote the set of arcs in F entering v, and let $d^-_F(v) = |\delta^-_F(v)|$. One matroid $\mathbf{M}_{\mathrm{in}}$ on A has its independent set family $\mathcal{I}_{\mathrm{in}}$ defined by

$$\mathcal{I}_{\mathrm{in}} = \{F \subseteq A \colon d^-_F(v) \leq b(v) \text{ for each } v \in V\}. \tag{1}$$

That is, $\mathbf{M}_{\mathrm{in}}$ is the direct sum of a uniform matroid on $\delta^-_A(v)$ of rank $b(v)$ for every $v \in V$. Hence, each vertex can have indegree at most $b(v)$, which can be more than one. Indeed, this is the reason why we refer to it as a b-branching, as a counterpart of a b-matching.

In order to make b-branchings a satisfying generalization of branchings, the other matroid should be defined appropriately. Our answer is a *sparsity matroid* determined by D and b, which is defined as follows. For $F \subseteq A$ and $X \subseteq V$, let $F[X]$ denote the set of arcs in F induced by X. Also, denote $\sum_{v \in X} b(v)$ by $b(X)$. Now define a matroid $\mathbf{M}_{\mathrm{sp}}$ on A with independent set family $\mathcal{I}_{\mathrm{sp}}$ by

$$\mathcal{I}_{\mathrm{sp}} = \{F \subseteq A \colon |F[X]| \leq b(X) - 1 \ (\emptyset \neq X \subseteq V)\}. \tag{2}$$

It is known that $\mathbf{M}_{\mathrm{sp}}$ is a matroid [20, Theorem 13.5.1], referred to as a *count matroid* or a *sparsity matroid*.

Now we refer to an arc set $F \subseteq A$ as a *b-branching* if $F \in \mathcal{I}_{\mathrm{in}} \cap \mathcal{I}_{\mathrm{sp}}$. It is clear that a branching is a special case of a b-branching where $b(v) = 1$ for each $v \in V$. We demonstrate that b-branchings yield a reasonable generalization of branching by proving that the two fundamental results on branchings can be extended. That is, we present a multi-phase greedy algorithm for finding a maximum-weight b-branching, and a theorem for packing disjoint b-branchings.

Our multi-phase greedy algorithm is an extension of the weighted branching algorithm [4, 6, 11, 23], and it has the following features. First, its running time is $\mathrm{O}(|V||A|)$, which is as fast as a simple implementation of the weighted branching algorithm [4, 6, 11, 23], and faster than the current best general weighted matroid intersection algorithm. Second, our algorithm also finds an optimal dual solution, which is integer if the arc weights are integer. Thus, the algorithm constructively proves the total dual integrality of the associated linear system. Finally, the algorithm leads to a characterization of the existence of a b-branching with prescribed indegree, which is a generalization of that for an arborescence [4, 11, 23].

This characterization theorem is extended to a theorem on packing disjoint b-branchings. Let k be a positive integer, and $b_1, \ldots, b_k$ be nonnegative integer vectors on V such that $b_i(v) \leq b(v)$ for each $v \in V$ and $b_i \neq b$ $(i = 1, \ldots, k)$. Note that, when there exists a b-branching B_i satisfying $d^-_{B_i}(v) = b_i(v)$ for each $v \in V$ $(i = 1, \ldots, k)$, these assumptions about b_i follow from the definition (1) and (2) of b-branchings. We provide a necessary and sufficient

condition for D to contain k disjoint b-branchings $B_1, \ldots, B_k$ satisfying $d^-_{B_i}(v) = b_i(v)$ for every $v \in V$ and $i = 1, \ldots, k$, which extends Edmonds' disjoint branching theorem [13]. We then show such disjoint b-branchings $B_1, \ldots, B_k$ can be found in strongly polynomial time by at most $|A|$ times of submodular function minimization [28, 37, 46]. We further prove that, when the arc-weight vector $w \in \mathbb{R}^A_+$ is given, disjoint b-branchings $B_1, \ldots, B_k$ that minimize $w(B_1) + \cdots + w(B_k)$ can be found in strongly polynomial time by optimization over a submodular flow polyhedron [16, 21, 29, 30]. By utilizing our disjoint b-branchings theorem, we also prove the integer decomposition property of the b-branching polytope.

We further deal with a generalized class of *matroid-restricted b-branchings*. This is a special case of matroid intersection in which $\mathbf{M}_{\mathrm{in}}$ is the direct sum of an arbitrary matroid on $\delta^-_A(v)$ of rank $b(v)$ for all $v \in V$. Note that, in the class of b-branchings, the matroid $\mathbf{M}_{\mathrm{in}}$ is the direct sum of a uniform matroid on $\delta^-_A(v)$ of rank $b(v)$. We show that our multi-phase greedy algorithm can be extended to this generalized class.

Let us conclude this section with describing related work. The weighted matroid intersection problem is a common generalization of various combinatorial optimization problems such as bipartite matchings, packing spanning trees, and branchings (or arborescences) in a digraph. The problem has also been applied to various engineering problems, e.g., in electric circuit theory [43, 44], rigidity theory [44], and network coding [8, 25]. Since 1970s, quite a few algorithms have been proposed for matroid intersection problems, e.g., [5, 18, 27, 37, 39, 40] (See [26] for further references). However, all known algorithms are not greedy, but based on augmentation; repeatedly incrementing a current solution by exchanging some elements.

The matroids in branchings are a partition matroid and a graphic matroid, which are interconnected by a given digraph. Such interconnection makes branchings more interesting. As mentioned before, branchings have properties that matroid intersection of an arbitrary pair of a partition matroid and a graphic matroid does not have. In particular, extending the packing theorem of branchings [13] is indeed a recent active topic. Kamiyama, Katoh, and Takizawa [33] presented a fundamental extension based on reachability in digraphs, which is followed by a further extension based on convexity in digraphs due to Fujishige [22]. Durand de Gevigney, Nguyen, and Szigeti [9] proved a theorem for packing arborescences with matroid constraints. Király [34] generalized the result of [9] in the same direction of [33]. A matroid-restricted packing of arborescences [3, 19] is another generalization concerning a matroid constraint. We remark that our packing and matroid restriction for b-branchings differ from the above matroidal extensions of packing of arborescences.

The organization of this paper is as follows. In Section 2, we review the literature of branchings and matroid intersection, including algorithmic, polyhedral, and packing results. In Section 3, we present a multi-phase greedy algorithm for finding a maximum-weight b-branching. Section 4 is devoted to proving a theorem on packing disjoint b-branchings. In Section 5, we extend the multi-phase greedy algorithm to matroid-restricted b-branchings. In Section 6, we conclude this paper with a couple of remarks.

2 Preliminaries

In this section, we review fundamental results on branchings and related theory of matroid intersection and polyhedral combinatorics. For more details, refer to [32, 36, 47].

In a digraph $D = (V, A)$, an arc subset $B \subseteq A$ is a *branching* if, in the subgraph (V, B), the indegree of every vertex is at most one and there does not exist a cycle in the undirected sense. In terms of matroid intersection, a branching is a common independent set of a

partition matroid and a graphic matroid, i.e., intersection of

$$\{F \subseteq A\colon d^-_F(v) \leq 1 \text{ for each } v \in V\}, \tag{3}$$
$$\{F \subseteq A\colon |F[X]| \leq |X| - 1 \ (\emptyset \neq X \subseteq V)\}. \tag{4}$$

Recall that a branching is a special case of a b-branching where $b(v) = 1$ for each $v \in V$. Indeed, by putting $b(v) = 1$ for each $v \in V$ in (1) and (2), we obtain (3) and (4), respectively.

As stated in Section 1, a maximum-weight branching can be found by a multi-phase greedy algorithm [4, 6, 11, 23], which appears in standard textbooks such as [35, 36, 47]. To the best of our knowledge, we have no other nontrivial special case of matroid intersection which can be solved greedily. For example, intersection of two partition matroids is equivalent to bipartite matching. This seems the simplest nontrivial example of matroid intersection, but we do not know a greedy algorithm for finding a maximum bipartite matching.

Another important result on branchings is the disjoint branchings theorem by Edmonds [13], described as follows. For a positive integer k, the set of integers $\{1, \ldots, k\}$ is denoted by $[k]$. For $F \subseteq A$ and $X \subseteq V$, let $\delta^-_F(X) \subseteq A$ denote the set of arcs in F from $V \setminus X$ to X, and let $d^-_F(X) = |\delta^-_F(X)|$.

▶ **Theorem 1** (Edmonds [13]). *Let $D = (V, A)$ be a digraph and k be a positive integer, and $U_1, \ldots, U_k$ be subsets of V. Then, there exist disjoint branchings $B_1, \ldots, B_k$ such that $U_i = \{v \in V\colon d^-_{B_i}(v) = 1\}$ for each $i \in [k]$ if and only if*

$$d^-_A(X) \geq |\{i \in [k]\colon X \subseteq U_i\}| \quad (\emptyset \neq X \subseteq V).$$

From Theorem 1, we obtain a theorem on covering a digraph by branchings [17, 41].

▶ **Theorem 2** ([17, 41]). *Let $D = (V, A)$ be a digraph and let k be a nonnegative integer. Then, the arc set A can be covered by k branchings if and only if*

$$d^-_A(v) \leq k \quad (v \in V),$$
$$|A[X]| \leq k(|X| - 1) \quad (\emptyset \neq X \subseteq V).$$

Theorem 2 leads to the *integer decomposition property* of the branching polytope. The *branching polytope* is a convex hull of the characteristic vectors of all branchings. It follows from the total dual integrality of matroid intersection [12] that the branching polytope is determined by the following linear system:

$$x(\delta^-(v)) \leq 1 \qquad (v \in V), \tag{5}$$
$$x(A[X]) \leq |X| - 1 \quad (\emptyset \neq X \subseteq V), \tag{6}$$
$$x(a) \geq 0 \qquad (a \in A). \tag{7}$$

▶ **Theorem 3** (see [47]). *The linear system (5)–(7) is totally dual integral.*

▶ **Corollary 4** (see [47]). *The linear system (5)–(7) determines the branching polytope.*

For a polytope P and a positive integer k, define $kP = \{x\colon \exists x' \in P, x = kx'\}$. A polytope P has the *integer decomposition property* if, for each positive integer k, any integer vector $x \in kP$ can be represented as the sum of k integer vectors in P. The integer decomposition property of the branching polytope is a direct consequence of Theorem 2 and Corollary 4.

▶ **Corollary 5** ([1]). *The branching polytope has the integer decomposition property.*

We remark that the integer decomposition property does not hold for an arbitrary matroid intersection polytope. Schrijver [47] presents an example of matroid intersection defined on the edge set of K_4 without integer decomposition property. Indeed, finding a class of polyhedra with integer decomposition property is a classical topic in combinatorics. Typical examples of polyhedra with integer decomposition property include polymatroids [1, 24], the branching polytope [1], and intersection of two strongly base orderable matroids [7, 42]. While there is some recent progress [2], the integer decomposition property of polyhedra is far from being well understood. In Section 4, we will prove that the b-branching polytope is a new example of polytopes with integer decomposition property.

3 Multi-phase greedy algorithm

3.1 Algorithm description

In this subsection, we present a multi-phase greedy algorithm for finding a maximum-weight b-branching by extending the one for branchings [4, 6, 11, 23]. Let $D = (V, A)$ be a digraph and $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V. Recall that an arc set $F \subseteq A$ is a b-branching if $F \in \mathcal{I}_{\mathrm{in}} \cap \mathcal{I}_{\mathrm{sp}}$, where $\mathcal{I}_{\mathrm{in}}$ and $\mathcal{I}_{\mathrm{sp}}$ are defined by (1) and (2), respectively.

We first show a key property of $\mathbf{M}_{\mathrm{in}}$ and $\mathbf{M}_{\mathrm{sp}}$, which plays an important role in our algorithm. Its proof can be found in the full version [31].

▶ **Lemma 6.** *An independent set F in $\mathbf{M}_{\mathrm{in}}$ is not independent in $\mathbf{M}_{\mathrm{sp}}$ if and only if (V, F) has a strong component X such that*

$$|F[X]| = b(X). \tag{8}$$

Moreover, for every strong component X in (V, F) satisfying (8), $F[X]$ is a circuit of $\mathbf{M}_{\mathrm{sp}}$.

Lemma 6 enables us to design the following multi-phase greedy algorithm for finding a maximum-weight b-branching:

- Find a maximum-weight independent set F in $\mathbf{M}_{\mathrm{in}}$.
- If (V, F) has a strong component X satisfying (8), then contract X, reset b and the weights of the remaining arcs appropriately, and recurse.

At the end of the algorithm, we expand every contracted component X in the following manner. Suppose that the solution F has an arc a' entering the vertex v_X created when contracting X. Denote the terminal vertex of a' before contracting X by $v' \in X$. In expanding X, we add $b(X) - 1$ arcs to F, consisting of $b(v)$ heaviest arcs among $\delta^-_A(v) \cap A[X]$ for each $v \in X \setminus \{v'\}$ and $b(v') - 1$ heaviest arcs among $\delta^-_A(v') \cap A[X]$. If F has no arc entering v_X, then we add $b(X) - 1$ arcs to F, consisting of $b(v)$ heaviest arcs among $\delta^-_A(v) \cap A[X]$ for each $v \in X$ except for the arc of minimum weight among those $b(X)$ arcs.

A formal description of the algorithm is as follows. We denote an arc $a \in A$ with initial vertex u and terminal vertex v by (u, v). We assume that the arc weights are nonnegative, which are represented by a vector $w \in \mathbb{R}^A_+$. For $F \subseteq A$, we denote $w(F) = \sum_{a \in F} w(a)$.

The complexity of Algorithm bB is analyzed as follows. It is clear that there are at most $|V|$ iterations. It is also straightforward to see that the i-th iteration requires $O(|A^{(i)}|)$ time: Steps 2, 3, and 4 respectively require $O(|A^{(i)}|)$ time. Thus, the total time complexity of the algorithms is $O(|V||A|)$.

3.2 Optimality of the algorithm and totally dual integral system

In this subsection, we prove that the output of Algorithm bB is a maximum-weight b-branching by the following primal-dual argument. We first present a linear program describing

Algorithm 1 ALGORITHM bB.

Input. A digraph $D = (V, A)$, and vectors $b \in \mathbb{Z}^V_{++}$ and $w \in \mathbb{R}^A_+$.
Output. A b-branching $F \subseteq A$ maximizing $w(F)$.
Step 1. Set $i := 0$, $D^{(0)} := D$, $b^{(0)} := b$, and $w^{(0)} := w$.
Step 2. Define a matroid $\mathbf{M}^{(i)}_{\mathrm{in}} = (A^{(i)}, \mathcal{I}^{(i)}_{\mathrm{in}})$ accordingly to $D^{(i)}$ and $b^{(i)}$ by (1). Then, find $F^{(i)} \in \mathcal{I}^{(i)}_{\mathrm{in}}$ maximizing $w^{(i)}(F^{(i)})$.
Step 3. If $(V^{(i)}, F^{(i)})$ has a strong component X such that

$$|F^{(i)}[X]| = b^{(i)}(X), \tag{9}$$

then go to Step 4. Otherwise, let $F := F^{(i)}$ and go to Step 5.
Step 4. Denote by $\mathcal{X} \subseteq 2^{V^{(i)}}$ the family of strong components X in $(V^{(i)}, F^{(i)})$ satisfying (9). Execute the following updates to construct $D^{(i+1)} = (V^{(i+1)}, A^{(i+1)})$, $b^{(i+1)} \in \mathbb{Z}^{V^{(i+1)}}_{++}$, and $w^{(i+1)} \in \mathbb{R}^{A^{(i+1)}}_+$.

- For each $X \in \mathcal{X}$, execute the following updates. First, contract X to obtain a new vertex v_X. Then, for every arc $a = (z, y) \in A^{(i)}$ with $z \in V^{(i)} \setminus X$ and $y \in X$,

$$\begin{aligned} z' &:= \begin{cases} v_{X'} & (z \in X' \text{ for some } X' \in \mathcal{X}), \\ z & (\text{otherwise}), \end{cases} \\ a' &:= (z', v_X), \\ \Psi(a') &:= a, \\ w^{(i+1)}(a') &:= w^{(i)}(a) - w^{(i)}(\alpha(a, F^{(i)})) + w^{(i)}(a_X), \end{aligned}$$

  where $\alpha(a, F^{(i)})$ is an arc in $\delta^-_{F^{(i)}}(y)$ minimizing $w^{(i)}$, and a_X is an arc in $F^{(i)}[X]$ minimizing $w^{(i)}$.[4]
- Define $b^{(i+1)} \in \mathbb{Z}^{V^{(i+1)}}_{++}$ by

$$b^{(i+1)}(v) := \begin{cases} 1 & (v = v_X \text{ for some } X \in \mathcal{X}), \\ b^{(i)}(v) & (\text{otherwise}). \end{cases}$$

Let $i := i + 1$ and go back to Step 2.
Step 5. If $i = 0$, then return F.
Step 6. For every strong component X in $(V^{(i-1)}, F^{(i-1)})$ such that (9) holds, apply the following update:

$$F := \begin{cases} ((F \setminus \{a'\}) \cup \{\Psi(a')\}) \cup (F^{(i-1)}[X] \setminus \{\alpha(\Psi(a'), F^{(i-1)})\}) & (\exists a' = (z, v_X) \in F), \\ F \cup (F^{(i-1)}[X] \setminus \{a_X\}) & (\text{otherwise}). \end{cases}$$

Let $i := i - 1$ and go back to Step 5.

the maximum-weight b-branching problem. It is a special case of the linear program for weighted matroid intersection, and hence we already know that the linear system is endowed with total dual integrality. Here we show an algorithmic proof for the total dual integrality. That is, we show that, when w is an integer vector, integral optimal primal and dual solutions can be computed via ALGORITHM bB.

Consider the following linear program, in variable $x \in \mathbb{R}^A$, associated with the maximum-weight b-branching problem:

$$\text{maximize} \quad \sum_{a \in A} w(a)x(a) \tag{10}$$

$$\text{subject to} \quad x(\delta_A^-(v)) \leq b(v) \quad (v \in V), \tag{11}$$

$$x(A[X]) \leq b(X) - 1 \quad (\emptyset \neq X \subseteq V), \tag{12}$$

$$0 \leq x(a) \leq 1 \quad (a \in A). \tag{13}$$

The constraints (11)–(13) are indeed a special case of a linear system describing the common independent sets in two matroids, which is totally dual integral (see [47]).

▶ **Theorem 7.** *The linear system* (11)–(13) *is totally dual integral. In particular, the linear system* (11)–(13) *determines the b-branching polytope.*

The dual problem of (10)–(13), in variable $p \in \mathbb{R}^{2^V}$ and $q \in \mathbb{R}^A$, is described as follows.

$$\text{minimize} \quad \sum_{v \in V} b(v)p(v) + \sum_{X\colon \emptyset \neq X \subseteq V} (b(X) - 1)p(X) + \sum_{a \in A} q(a) \tag{14}$$

$$\text{subject to} \quad p(v) + \sum_{X\colon a \in A[X]} p(X) + q(a) \geq w(a) \quad (a = uv \in A), \tag{15}$$

$$p(X) \geq 0 \quad (X \subseteq V), \tag{16}$$

$$q(a) \geq 0 \quad (a \in A). \tag{17}$$

Note that the dual variable $p(X)$ corresponds to the primal constraint (11) if $|X| = 1$, and to (12) if $|X| \geq 2$. The primal constraint (12) for X with $|X| = 1$ does not have a corresponding dual variable, since it is redundant in the linear problem (10)–(13).

An optimal solution (p^*, q^*) is computed via Algorithm bB in the following manner. At the beginning of Algorithm bB, set $w^\circ = w$, $p(X) = 0$ for each $X \subseteq V$, and $q(a) = 0$ for each $a \in A$. In Step 4 of Algorithm bB, for each strong component $X \in \mathcal{X}$, define $p^*(X) \in \mathbb{R}$ by

$$p^*(X) = \min\{\min\{w^\circ(\alpha^\circ(a)) - w^\circ(a)\colon a \in \delta^-_{A^{(i)}}(X)\}, \min\{w^\circ(a')\colon a' \in F^{(i)}[X]\}\},$$

where $\alpha^\circ(a)$ is the $b(y)$-th optimal arc with respect to w° among the arcs sharing the terminal vertex $y \in V$ with a in the original digraph D. Then for each arc $a \in A$ such that $a \in A^{(i)}[X]$ or a is deleted in the contraction of X' with $v_{X'}$ included in X, set $w^\circ(a) := w^\circ(a) - p^*(X)$. After the termination of Algorithm bB, let the value $p^*(v)$ be equal to the $b(v)$-th maximum value among $\{w^\circ(a)\colon a \in \delta_A^-(v)\}$ for each vertex $v \in V$. Finally, let $q^*(a) = \max\{w(a) - p^*(v) - \sum_{X\colon a \in A[X]} p^*(X), 0\}$. Observe that $w^\circ(a) \geq 0$ holds for $a \in F$, and $w^\circ(a) \leq 0$ for $a \notin F$.

We can prove the optimality of F and (p^*, q^*) in the following way. We first show that F is a b-branching. It is straightforward to see that $F \in \mathcal{I}_{\text{in}}$. Then, it follows from Lemma 6 that $F \in \mathcal{I}_{\text{sp}}$ as well, since a strong component X satisfying (8) is always contracted in the algorithm and hence never exists in the output F. Next, the feasibility of (p^*, q^*) for (15)–(17) is obvious. Finally, we prove that the characteristic vector χ_F of the output F and (p^*, q^*) satisfy the complementary slackness condition as follows:

- Suppose $\chi_F(\delta_A^-(v)) < b(v)$ for $v \in V$. If v is not contained in a contracted vertex set, then, by Step 2 of Algorithm bB, $\delta_A^-(v)$ contains less than $b(v)$ arcs with positive weight, and hence $p^*(v) = 0$. If v is contained in a contracted vertex set $X \subseteq V^{(i)}$, it follows that v is the terminal vertex of $a_X \in F^{(i)}[X]$ and $p^*(X) = w^\circ(a_X)$. Then $w^\circ(a_X)$ is the $b(v)$-th maximum value among $\{w^\circ(a) \colon a \in \delta_A^-(v)\}$ and becomes zero after contracting X, which implies that $p^*(v) = 0$.
- If $\chi_F(A[X]) < b(X) - 1$ for $X \subseteq V$ with $|X| \geq 2$, it follows that X is not contracted in the algorithm, and thus $p^*(X)$ is never changed from zero.
- If $\chi_F(a) > 0$ for $a \in A$, then it follows that $w^\circ(a) = w(a) - p^*(v) - \sum_{X \colon a \in A[X]} p^*(X) \geq 0$, and thus $q^*(a) = w(a) - p^*(v) - \sum_{X \colon a \in A[X]} p^*(X)$, implying the equality in (15).
- If $\chi_F(a) < 1$ for $a \in A$, then it follows that $w^\circ(a) = w(a) - p^*(v) - \sum_{X \colon a \in A[X]} p^*(X) \leq 0$ and thus $q^*(a) = 0$.

Therefore, F and (p^*, q^*) are optimal solutions for the linear programs (10)–(13) and (14)–(17), respectively. Moreover, (p^*, q^*) is integer if w is integer, which implies that (11)–(13) is totally dual integral.

3.3 Existence of a b-branching with prescribed indegree

Our algorithm leads to the following theorem characterizing the existence of b-branching with prescribed indegree, which is an extension of that for arborescences [4, 11, 23].

▶ **Theorem 8.** *Let $D = (V, A)$ be a digraph and $b \in \mathbb{Z}_{++}^V$ be a positive integer vector on V. Let $b' \in \mathbb{Z}_+^V$ be a nonnegative integer vector such that $b'(v) \leq b(v)$ for every $v \in V$ and $b' \neq b$. Then, D has a b-branching B such that $d_B^-(v) = b'(v)$ for each $v \in V$ if and only if*

$$d_A^-(v) \geq b'(v) \quad (v \in V), \tag{18}$$

$$d_A^-(X) \geq 1 \quad (\emptyset \neq X \subsetneq V,\ b'(X) = b(X) \neq 0). \tag{19}$$

Let $r \in V$ be a specified vertex. A characterization of the existence of an r-arborescence [4, 11, 23] is obtained as a special case of Theorem 8, by putting $b(v) = 1$ for every $v \in V$, $b'(v) = 1$ for every $v \in V \setminus \{r\}$, and $b'(r) = 0$.

Theorem 8 can be proved in two ways. The necessity of (18) and (19) is clear. One way to derive the sufficiency of (18) and (19) is Algorithm bB. Apply Algorithm bB to the case where $b = b'$ and $w(a) = 1$ for each $a \in A$. Then, (18) and (19) certify that $F^{(i)}$ found in Step 2 of Algorithm bB is always a base of $\mathbf{M}_{\mathrm{in}}^{(i)}$. It thus follows that the output F of Algorithm bB is a b-branching with $d_F^- = b'$. An alternative proof for the sufficiency of (18) and (19) is implied by the proof for Theorem 10 in Section 4, which extends Theorem 8 to a characterization of the existence of disjoint b-branchings with prescribed indegree.

4 Packing disjoint b-branchings

In this section, we present a theorem on packing disjoint b-branchings $B_1, \ldots, B_k$ with prescribed indegree, which extends Theorem 1, as well as Theorem 8. We then show that such disjoint b-branchings can be found in strongly polynomial time. We further show that disjoint b-branchings $B_1, \ldots, B_k$ minimizing the weight $w(B_1) + \cdots + w(B_k)$ can be found in strongly polynomial time. Finally, as a consequence of our packing theorem, we prove the integer decomposition property of the b-branching polytope.

4.1 Characterizing theorem for disjoint b-branchings

Let $D = (V, A)$ be a digraph, $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V, and k be a positive integer. For $i \in [k]$, let $b_i \in \mathbb{Z}^V_+$ be a nonnegative integer vector such that $b_i(v) \leq b(v)$ for every $v \in V$ and $b_i \neq b$. We present a theorem for chracterizing whether D contains disjoint b-branchings $B_1, \ldots, B_k$ such that $d^-_{B_i} = b_i$ for each $i \in [k]$.

We begin with introducing a function which plays a key role in the sequel. Define a function $g : 2^V \to \mathbb{Z}_+$ by

$$g(X) = |\{i \in [k] \colon b_i(X) = b(X) \neq 0\}| \quad (X \subseteq V). \tag{20}$$

The following lemma is straightforward to observe. Its proof is described in the full version [31].

▶ **Lemma 9.** *The function g is supermodular.*

Our characterization theorem is described as follows.

▶ **Theorem 10.** *Let $D = (V, A)$ be a digraph, $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V, and k be a positive integer. For $i \in [k]$, let $b_i \in \mathbb{Z}^V_+$ be a nonnegative integer vector such that $b_i(v) \leq b(v)$ for every $v \in V$ and $b_i \neq b$. Then, D has disjoint b-branchings $B_1, \ldots, B_k$ such that $d^-_{B_i} = b_i$ for each $i \in [k]$ if and only if the following two conditions are satisfied:*

$$d^-_A(v) \geq \sum_{i=1}^{k} b_i(v) \quad (v \in V), \tag{21}$$

$$d^-_A(X) \geq g(X) \qquad (X \subseteq V). \tag{22}$$

We remark that Szegő's generalization of Theorem 1 for packing arc sets which cover some intersecting families [48] (see also [19, Theorem 10.3.2]) looks similar to Theorem 10, but it does not directly implies Theorem 10. In Theorem 10, every arc set should cover $\delta^-_A(v)$ multiple times (i.e., $\delta^-_A(v)$ should be covered $b_i(v)$ times by B_i), and this coverage is not immediately rephrased in the form of [48].

Below is a proof for Theorem 10, which extends the proof for Theorem 1 by Lovász [38].

Proof of Theorem 10. Necessity is clear. We prove sufficiency by induction on $\sum_{i=1}^{k} b_i(V)$. The case $\sum_{i=1}^{k} b_i(V) = 0$ is trivial; $B_i = \emptyset$ for each $i \in [k]$.

Without loss of generality, suppose $b_1(V) > 0$. Define a partition $\{V_0, V_1, V_2\}$ of V by $V_0 = \{v \in V \colon b_1(v) = 0\}$, $V_1 = \{v \in V \colon 0 < b_1(v) < b(v)\}$, and $V_2 = \{v \in V \colon b_1(v) = b(v)\}$. Then, it holds that

$$V_0 \cup V_1 \neq \emptyset, \tag{23}$$

$$V_0 \neq V, \tag{24}$$

which follow from $b_1 \neq b$ and $b_1(V) > 0$, respectively.

For $X \subseteq V$, define $g(X) = |\{i \in [k] \colon b_i(X) = b(X) \neq 0\}|$. Let $W \subseteq V$ be an inclusionwise minimal vertex subset satisfying

$$W \cap (V_0 \cup V_1) \neq \emptyset, \tag{25}$$

$$W \setminus V_0 \neq \emptyset, \tag{26}$$

$$d^-_A(W) = g(W). \tag{27}$$

Such W always exists, since $W = V$ satisfies (25)–(27): (25) follows from (23); (26) from (24); and (27) from $b_i \neq b$ ($i \in [k]$) and hence $g(V) = 0$. Let $W_j = W \cap V_j$ ($j = 0, 1, 2$).

▶ **Claim 1.** *There exists an arc $(u, v) \in A$ such that $u \in W_0 \cup W_1$ and $v \in W_1 \cup W_2$.*

Proof. First, suppose that $W_2 \neq \emptyset$. Then, it holds that $g(W_2) > g(W)$, since every $i \in [k]$ contributing to $g(W)$ also contributes to $g(W_2)$, and $i = 1$ does not contribute to $g(W)$ but to $g(W_2)$. Hence we obtain that

$$d_A^-(W_2) \geq g(W_2) > g(W) = d_A^-(W). \tag{28}$$

Now (28) implies that there exists an arc $(u, v) \in A$ such that $u \in W_0 \cup W_1$ and $v \in W_2$.

Next, suppose that $W_2 = \emptyset$. By (26), we have that $W_1 \neq \emptyset$. Then, it holds that

$$\begin{aligned}
\sum_{v \in W_1} d_A^-(v) &\geq \sum_{i=1}^{k} b_i(W_1) \quad (\because (21)) \\
&> \sum_{i=2}^{k} b_i(W_1) \quad (\because b_1(W_1) > 0) \\
&\geq |\{i \in [k] \colon b_i(W) = b(W) \neq 0\}| \quad (\because b_1(W) \neq b(W)) \\
&= g(W) = d_A^-(W),
\end{aligned}$$

implying that there exists an arc $(u, v) \in A$ such that $u \in W = W_0 \cup W_1$ and $v \in W_1$. ◀

Let $a = (u, v) \in A$ be an arc in Claim 1. We then show that resetting

$$A := A \setminus \{a\}, \tag{29}$$
$$b_1(v) := b_1(v) - 1 \tag{30}$$

maintains (21) and (22). (This resetting amounts to augmenting B_1 by adding a.)

It is straightforward to see that the resetting (29) and (30) maintain (21). To prove that it also maintain (22), suppose to the contrary that $X \subseteq V$ violates (22) after the resetting.

This violation implies that $d_A^-(X) = g(X)$ before the resetting, and $d_A^-(X)$ has decreased by one while $g(X)$ has remained unchanged by the resetting. It then follows that

$$u \in V \setminus X \quad \text{and} \quad v \in X. \tag{31}$$

It also follows that $i = 1$ does not contribute to $g(X)$, and hence before the resetting, it holds that

$$X \cap (V_0 \cup V_1) \neq \emptyset. \tag{32}$$

By (31), we have that $u \in W \setminus X$ and $v \in X \cap W$, and hence $\emptyset \neq X \cap W \subsetneqq W$. Here we show that $X \cap W$ satisfies (25)–(27), which contradicts the minimality of W.

Before the resetting, it holds that

$$\begin{aligned}
d_A^-(X \cap W) &\leq d_A^-(X) + d_A^-(W) - d_A^-(X \cup W) && (33) \\
&\leq g(X) + g(W) - g(X \cup W) && (34) \\
&\leq g(X \cap W). && (35)
\end{aligned}$$

Indeed, (33) follows from submodularity of d_A^-. The inequality (34) follows from $d_A^-(X) = g(X)$, $d_A^-(W) = g(W)$, and $d_A^-(X \cup W) \geq g(X \cup W)$. Finally, (35) follows from Lemma 9.

Since $d_A^-(X \cap W) \geq g(X \cap W)$ by (22), all inequalities (33)–(35) hold with equality, and hence $d_A^-(X \cap W) = g(X \cap W)$ holds before the resetting.

Equality in (35) implies that $(X \cap W) \cap (V_0 \cup V_1) \neq \emptyset$. Indeed, we have that $W \cap (V_0 \cup V_1) \neq \emptyset$ because $u \in W \cap (V_0 \cup V_1)$, and hence $i = 1$ does not contribute to $g(W)$. Combined with (32), $i = 1$ contributes to none of $g(X)$, $g(W)$, and $g(X \cup W)$. Thus, by the equality in (35), $i = 1$ does not contribute to $g(X \cap W)$ as well, and hence $(X \cap W) \cap (V_0 \cup V_1) \neq \emptyset$ must hold.

We also have $(X \cap W) \setminus V_0 \neq \emptyset$, because $v \in (X \cap W) \setminus V_0$. Therefore, $X \cap W$ satisfies (25)–(27), contradicting the minimality of W. Thus, we have finished proving that resetting of (29) and (30) maintains (22).

Now we can apply induction to obtain disjoint b-branchings $B_1, \ldots, B_k$ in the digraph $(V, A \setminus \{a\})$ such that $d^-_{B_1} = b_1 - \chi_v$ and $d^-_{B_i} = b_i$ for $i = 2, \ldots, k$, where $\chi_v \in \mathbb{Z}^V$ is a vector defined by $\chi_v(v) = 1$ and $\chi_v(u) = 0$ for e very $u \in V \setminus \{v\}$. We complete the proof by showing that $B_1 \cup \{a\}$ is a b-branching.

In resetting, we always have $u \in W_0 \cup W_1$, which implies that the construction of B_1 begins with a vertex r with $b_1(r) < b(r)$ and the component in (V, B_1) containing a includes r. Thus, no $X \subseteq V$ comes to satisfy $|B_1[X]| = b(X)$. ◀

4.2 Algorithm for finding disjoint b-branchings

Let us discuss the algorithmic aspect of Theorem 10. First, we can determine whether (21) and (22) hold in strongly polynomial time. Condition (21) is clear. For (22), we have that $d^-_A(X)$ is submodular and $g(X)$ is supermodular (Lemma 9), and hence $d^-_A(X) - g(X)$ is submodular. Thus, we can determine whether there exists X with $d^-_A(X) - g(X) < 0$ by submodular function minimization, in strongly polynomial time [28, 37, 46].

Finding b-branchings $B_1, \ldots, B_k$ can also be done in strongly polynomial time. By the proof for Theorem 10, it suffices to find an arc $a \in A$ such that resetting

$$A := A \setminus \{a\}, \quad b_1(v) := b_1(v) - 1 \tag{36}$$

maintains (22). This can be done by determining whether there exists X with $d^-_A(X) - g(X) < 0$ after resetting (36) for each $a \in A$, i.e., at most $|A|$ times of submodular function minimization [28, 37, 46].

▶ **Theorem 11.** *Conditions* (21) *and* (22) *can be checked in strongly polynomial time. Moreover, if* (21) *and* (22) *hold, then disjoint b-branchings* $B_1, \ldots, B_k$ *such that* $d^-_{B_i} = b_i$ *for each* $i \in [k]$ *can be found in strongly polynomial time.*

Further, if a weight vector $w \in \mathbb{R}^A_+$ is given, we can find disjoint b-branchings $B_1, \ldots, B_k$ minimizing $w(B_1) + \cdots + w(B_k)$ in strongly polynomial time. Indeed, conditions (21) and (22) derive a totally dual integral system which determines a *submodular flow polyhedron*. A set family $\mathcal{C} \subseteq 2^V$ is called a *crossing family* if, for each $X, Y \in \mathcal{C}$ with $X \cup Y \neq V$ and $X \cap Y \neq \emptyset$, it holds that $X \cup Y, X \cap Y \in \mathcal{C}$. A function $f : \mathcal{C} \to \mathbb{R}$ defined on a crossing family $\mathcal{C} \subseteq V$ is called *crossing submodular* if, for each $X, Y \in \mathcal{C}$ with $X \cup Y \neq V$ and $X \cap Y \neq \emptyset$, it holds that $f(X) + f(Y) \geq f(X \cup Y) + f(X \cap Y)$. A function f is *crossing supermodular* if $-f$ is crossing submodular. A *submodular flow polyhedron* is a polyhedron described as

$$\begin{aligned} &x(\delta^-_A(X)) - x(\delta^+_A(X)) \leq f(X) && (X \in \mathcal{C}), \\ &l(a) \leq x(a) \leq u(a) && (a \in A) \end{aligned}$$

by some digraph (V, A), crossing submodular function f on a crossing family $\mathcal{C} \subseteq 2^V$, and vectors $l, u \in \mathbb{R}^A$, where $\delta^+_A(X)$ denotes the set of arcs in A from X to $V \setminus X$.

▶ **Lemma 12** ([45]). *For a digraph $D = (V, A)$, let $f\colon 2^V \to \mathbb{R}$ be a crossing supermodular function on $\mathcal{C} \subseteq 2^V$ and $u \in \mathbb{R}^A$. Then, a polyhedron determined by*

$$x(\delta_A^-(X)) \geq f(X) \quad (X \in \mathcal{C}),$$
$$0 \leq x(a) \leq u(a) \quad (a \in A)$$

is a submodular flow polyhedron.

By Lemma 12, the linear inequality system (21) and (22) determines a submodular flow polyhedron. Indeed, we can define a crossing supermodular function $f\colon 2^V \to \mathbb{R}$ by

$$f(X) = \begin{cases} \sum_{i=1}^{k} b_i(v) & (X = \{v\} \text{ for some } v \in V), \\ g(X) & (\text{otherwise}). \end{cases}$$

Since a submodular flow polyherdron is totally dual integral [15], an arc set $B \subseteq A$ with (21) and (22) minimizing $w(B)$ can be found by optimization over a submodular flow polyhedron, which can be done in strongly polynomial time [16, 21, 29, 30]. After that, we can partition B into b-branchings $B_1, \ldots, B_k$ with $d^-_{B_i} = b_i$ $(i \in [k])$ in the same manner as above.

▶ **Theorem 13.** *If (21) and (22) hold, disjoint b-branchings $B_1, \ldots, B_k$ such that $d^-_{B_i} = b_i$ for each $i \in [k]$ minimizing $w(B_1) + \cdots + w(B_k)$ can be found in strongly polynomial time.*

4.3 Integer decomposition property of the b-branching polytope

In this subsection we show another consequence of Theorem 10: the integer decomposition property of the b-branching polytope. First, Theorem 10 leads to the following min-max relation on covering by b-branchings. This is an extension of Theorem 2, the theorem on covering by branchings [17, 41]. Its proof appears in the full version [31].

▶ **Corollary 14.** *Let $D = (V, A)$ be a digraph, $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V, and k be a positive integer. Then, the arc set A can be covered by k b-branchings if and only if*

$$d_A^-(v) \leq k \cdot b(v) \quad (v \in V), \tag{37}$$
$$|A[X]| \leq k(b(X) - 1) \quad (\emptyset \neq X \subseteq V). \tag{38}$$

The integer decomposition property of the b-branching polytope is a direct consequence of Corollary 14. Its proof is described in the full version [31].

▶ **Corollary 15.** *The b-branching polytope has the integer decomposition property.*

5 Matroid-restricted b-branchings

Our multi-phase greedy algorithm (Algorithm bB) can be extended to a more generalized problem of finding a maximum-weight *matroid-restricted b-branching*. Let $D = (V, A)$ be a digraph and $b \in \mathbb{Z}^V_{++}$ be a positive integer vector on V. For each vertex $v \in V$, a matroid $\mathbf{M}_v = (\delta^-(v), \mathcal{I}_v)$ with rank $b(v)$ is attached. We denote the direct sum of $\mathbf{M}_v$ for every $v \in V$ by $\mathbf{M}_V = (A, \mathcal{I}_V)$. Now an arc set $F \subseteq A$ is an *$\mathbf{M}_V$-restricted b-branching* if $F \in \mathcal{I}_V \cap \mathcal{I}_{\mathrm{sp}}$. Note that a b-branching is a special case where $\mathbf{M}_v$ is a uniform matroid for each $v \in V$.

A maximum-weight $\mathbf{M}_V$-restricted b-branching can be found by a slight extension of Algorithm bB. The extended algorithm is described in the full version [31].

6 Concluding remarks

In this paper, we have proposed b-branchings, a generalization of branchings. In a b-branching, a vertex v can have indegree at most $b(v)$, and thus b-branchings serve as a counterpart of b-matchings for matchings.

It is somewhat surprising that, to the best of our knowledge, such a fundamental generalization of branchings has never appeared in the literature. The reason might be that, in order to obtain a reasonable generalization, it is far from being trivial how the other matroid (graphic matroid) in branchings is generalized. We have succeeded in obtaining a generalization inheriting the multi-phase greedy algorithm [4, 6, 11, 23] and the packing theorem [13] for branchings by setting a sparsity matroid defined by (2) as the other matroid.

An important property of the two matroids is Lemma 6, which says that an independent set of one matroid is decomposed into an independent set and some circuits in the other matroid. This plays an important role in the design of a multi-phase greedy algorithm: find an optimal independent F set in one matroid; contract the circuits in F with respect to the other matroid; and the optimal common independent set can be found recursively. We remark that the definitions (1) and (2) are essential to attain this property. For example, the property fails if the vector b is not identical in (1) and (2). It also fails if the sparsity matroid is defined by $|F[X]| \leq b(X) - k$ for $k \neq 1$.

Another remark is on the similarity of our algorithm and the blossom algorithm for non-bipartite matchings [10], where a factor-critical component can be contracted and expanded. In our b-branching algorithm, for each strong component $X \in \mathcal{X}$ and each $v^* \in X$, there exists an arc set $F_X \subseteq A[X]$ such that $d^-_{F_X}(v^*) = b(v^*) - 1$ and $d^-_{F_X}(v) = b(v)$ for each $v \in X \setminus \{v^*\}$. In the blossom algorithm for nonbipatite matchings, for each factor-critical component X and each vertex $v^* \in X$, there exists a matching exactly covering $X \setminus \{v^*\}$.

We finally remark that the problem of finding a maximum-weight b-branching is a special case of a modest generalization of the framework of the $\mathcal{U}$-feasible t-matching problem in bipartite graphs [49]. In [49], it is proved that the $\mathcal{U}$-feasible t-matching problem in bipartite graphs is efficiently tractable under certain assumptions on the family of excluded structures $\mathcal{U}$. The b-branching problem can be regarded as a new problem which falls in this tractable class of the (generalized) $\mathcal{U}$-feasible t-matching problem.

Abstract

The pairing heap is a classical heap data structure introduced in 1986 by Fredman, Sedgewick, Sleator, and Tarjan. It is remarkable both for its simplicity and for its excellent performance in practice. The "magic" of pairing heaps lies in the restructuring that happens after the deletion of the smallest item. The resulting collection of trees is consolidated in two rounds: a left-to-right pairing round, followed by a right-to-left accumulation round. Fredman et al. showed, via an elegant correspondence to splay trees, that in a pairing heap of size n all heap operations take $O(\log n)$ amortized time. They also proposed an arguably more natural variant, where both pairing and accumulation are performed in a combined left-to-right round (called the forward variant of pairing heaps). The analogy to splaying breaks down in this case, and the analysis of the forward variant was left open.

In this paper we show that inserting an item and deleting the minimum in a forward-variant pairing heap both take amortized time $O(\log n \cdot 4^{\sqrt{\log n}})$. This is the first improvement over the $O(\sqrt{n})$ bound showed by Fredman et al. three decades ago. Our analysis relies on a new potential function that tracks parent-child rank-differences in the heap.

1 Introduction

A heap is an abstract data structure that stores a set of keys, supporting the usual operations of creating an empty heap, inserting a key, finding and deleting the smallest key, decreasing a key, and merging ("melding") two heaps. Heaps are ubiquitous in computer science, used,

[1] Research supported by The Israeli Centers of Research Excellence (I-CORE) program (Center No. 4/11), Israel Science Foundation grant no. 1841-14.
[2] Work done while at Tel Aviv University. Research supported by The Israeli Centers of Research Excellence (I-CORE) program (Center No. 4/11).
[3] Research supported by BSF grant no. 2012338 and by The Israeli Centers of Research Excellence (I-CORE) program (Center No. 4/11).

for instance, in Dijkstra's shortest path algorithm and in the Jarník-Prim minimum spanning tree algorithm (see e.g., [5]). Heaps are typically implemented as trees (binary or multiary), where each node stores a key, and no key may be smaller than its parent-key.

The pairing heap, introduced by Fredman, Sedgewick, Sleator, and Tarjan [9], is a popular heap implementation that supports all operations in $O(\log n)$ amortized time. It is intended to be a simpler, *self-adjusting* alternative to the Fibonacci heap [10], and has been observed to have excellent performance in practice [27, 23, 20, 22]. Despite significant research, the exact complexity of pairing heap operations is still not fully understood [9, 8, 14, 24, 6, 17, 18].

Self-adjusting data structures. Many of the fundamental heap- and tree- data structures in the literature are designed with a certain "good structure" in mind, which guarantees their efficiency. Binary search trees, for instance, need to be (more or less) balanced in order to support operations in $O(\log n)$ time. In the case of heaps, a reasonable goal is to keep node-degrees low, as it is costly to delete a node with many children. Maintaining a tree structure in such a favorable state at all times requires considerable book-keeping. Indeed, data structures of this flavor (AVL-trees [1], red-black trees [2, 11], Binomial heaps [29], Fibonacci heaps [10], etc.) store structural parameters in the nodes of the tree, and enforce strict rules on how the tree may evolve.

By contrast, pairing heaps and other *self-adjusting* data structures store no additional information besides the keys and the pointers that represent the tree itself. Instead, they perform local re-adjustments after each operation, seemingly ignoring global structure. Due to their simplicity and low memory footprint, self-adjusting data structures are appealing in practice. Moreover, self-adjustment allows data structures to *adapt* to various usage patterns. This has led, in the case of search trees, to a rich theory of instance-specific bounds (see e.g., [26, 15]). The price to pay for the simplicity and power of self-adjusting data structures is the complexity of their analysis. With no rigid structure, self-adjusting data structures are typically analysed via potential functions that measure, informally speaking, how far the data structure is from an ideal state.

The standard analysis of pairing heaps [9] borrows the potential function developed for splay trees by Sleator and Tarjan [26]. This technique is not directly applicable to other variants of pairing heaps. There is a large design space of self-adjusting heaps similar to pairing heaps, yet, we currently lack the tools to analyse their behavior (apart from isolated cases). We find it a worthy task to develop tools to remedy this situation.

Description of pairing heaps. A pairing heap is built as a single tree with nodes of arbitrary degree. Each node is identified with a key, with the usual min-heap condition: every (non-root) key is larger than its parent key.

The heap operations are implemented using the unit-cost *linking* primitive: given two nodes x and y (with their respective subtrees), `link`(x, y) compares x and y and lets the greater of the two become the leftmost child of the smaller.

The `delete-min` operation works as follows. We first delete (and return) the root r of the heap (i.e., the minimum), whose children are $x_1, \ldots, x_k$. We then perform a left-to-right pairing round, calling `link`(x_{2i-1}, x_{2i}) for all $i = 1, \ldots, \lfloor k/2 \rfloor$. The resulting roots are denoted $y_1, \ldots, y_{\lceil k/2 \rceil}$. (Observe that if k is odd, the last root is not linked.) Finally, we perform a right-to-left accumulate round, calling `link`(p_i, y_{i-1}) for all $i = \lceil k/2 \rceil, \ldots, 2$, where p_i is the minimum among $y_i, \ldots, y_{\lceil k/2 \rceil}$. We illustrate this process in Figure 1.

The other operations are straightforward. In `decrease-key`, we cut out the node whose key is decreased (together with its subtree) and link it with the root. In `insert`, we link the new node with the root. In `meld`, we link the two roots.

Fredman et al. [9] showed that the amortized time of all operations is $O(\log n)$. They also conjectured that, similarly to Fibonacci heaps, the amortized time of `decrease-key` is in fact constant. This conjecture was disproved by Fredman [8], who showed that in certain sequences, `decrease-key` requires $\Omega(\log \log n)$ time. In fact, the result of Fredman holds for a more general family of heap algorithms. Iacono and Özkan [17, 16] gave a similar lower bound for a different generalization[4] of pairing heaps. Assuming $O(\log n)$ time for `decrease-key`, Iacono [14] showed that `insert` takes constant amortized time. Pettie [24] proved that both `decrease-key` and `insert` take $O(4^{\sqrt{\log \log n}})$ time. Improving these trade-offs remains a challenging open problem.

Pairing heap variants. We refer to the pairing heap data structure described above as the *standard* pairing heap. Fredman et al. [9] also proposed a number of variants that differ in the way the heap is consolidated during a `delete-min` operation.

We describe first the *forward variant*, which is the main subject of this paper (in the original pairing heap paper this is called the *front-to-back variant*). The pairing round in the forward variant is identical to the standard variant, resulting in roots $y_1, \ldots, y_t$, where $t = \lceil k/2 \rceil$, and k is the number of children of the deleted root. In the forward variant, however, we perform the second round also from left to right: for all $i = 1, \ldots, t-1$, we call `link`(p_i, y_{i+1}), where p_i is the minimum among $y_1, \ldots, y_i$. Occasionally we refer to p_i as the current *left-to-right minimum*. See Figure 1 for an illustration. What may seem like a minor change causes the data structure to behave differently. Currently, the forward variant appears to be much more difficult to analyse than the standard variant.

The implementation of the forward variant is arguably simpler. The two passes can be performed together in a single pass, using only the standard *leftmost child* and *right sibling* pointers. In fact, it is possible to implement the two rounds in one pass also in the standard variant. To achieve this, we need to perform both the pairing and accumulation rounds *from right to left*. As shown by Fredman et al. [9], this can be done with a slightly more complicated link structure, and the original analysis goes through essentially unchanged. Regardless of the low-level details, it remains the case that of the two most natural pairing heap variants one is significantly better understood than the other.

Yet another variant described by Fredman et al. [8] is the *multipass* pairing heap. Here, instead of an accumulation round, repeated pairing rounds are executed, until a single root remains. For multipass pairing heaps, the bound of $O\big(\log n \cdot \log \log n / \log \log \log n\big)$ was shown [9] on the cost of a `delete-min`.[5]

Fredman et al. [9] also describe what we could call the *arbitrary pairing and linking* variant. Here, before performing the initial pairing round, the roots may be arbitrarily reordered. After the pairing round, arbitrary pairs of roots (not necessarily neighbors) are linked, until there is a single root left. For this general case (that subsumes all previous variants) Fredman et al. [9] show a tight[6] $\Theta(\sqrt{n})$ amortized bound for `delete-min`. Even in the special case of the forward variant, the $O(\sqrt{n})$ upper bound has never been improved.

Our main result is the following.

[4] Both results are rather subtle, for instance, it is not clear whether `decrease-key` remains costly in an implementation where we cut an affected node only if its decreased key is smaller than that of its parent.

[5] A recently claimed improvement by Pettie [25] would reduce this to an almost, but not quite, logarithmic bound. The result of Pettie has, in some sense, inspired our results.

[6] It is not clear how efficient this strategy is if we only allow `link` operations between neighboring siblings.

▶ **Theorem 1.** *In the forward variant of pairing heaps, the amortized costs of* `delete-min` *and* `insert` *are* $O(\log n \cdot 4^{\sqrt{\log n}})$*, where* n *is the number of items in the heap when the operation is performed.*

The result holds for sequences of `insert` and `delete-min` operations arbitrarily intermixed, starting from an empty heap. Note that an `insert` operation performs a single `link`, its worst-case cost is therefore constant.

The quantity in the running time is asymptotically smaller than n^ε, for all $\varepsilon > 0$. We remark that the $4^{\sqrt{\log n}}$ term grows much faster than the $\log n$ term, as for arbitrary constants $c, d > 1$ it holds that $c^{\sqrt{\log n}} = \omega(\log^d n)$.

Besides the concrete result (heaps with proven logarithmic cost are known, afterall), the contribution of our paper is in the development of a new, fairly general potential function, that may have further applications.

There has been significant further work in designing heap data structures, with the goal of finding a simpler alternative to Fibonacci heaps, matching, or almost matching their theoretical guarantees (e.g., [27, 19, 7, 12, 13, 4]). These heaps are typically more complicated than pairing heaps. Moreover, they are not self-adjusting, i.e., they store extra information at the nodes, are thus out of the scope of this paper.

Splaying and sorting. There is a standard representation of multi-way rooted trees as binary trees ([21, § 2.3.2], [9]), by renaming the *leftmost child* and *right sibling* pointers as *left child* and *right child*. (See Figure 1.) In this binary tree representation, the restructuring performed when we delete the minimum from a pairing heap closely resembles the restructuring performed by an access to an item in a splay tree. The correspondence is sufficiently close that the proof of logarithmic access cost in splay trees [26] also goes through for the pairing heap. (We note that this correspondence is far from trivial: one has to relabel some nodes and swap their left and right children in the analysis to make it work; we refer to the original pairing heap paper [9] for details.)

In case of the forward variant, the analogy with splay trees breaks down, with no apparent way to fix it. The reason is that the accumulation round of the forward variant may reverse the ordering of large groups of consecutive neighbors. In splay-view, this has the effect of turning long portions of the search path upside-down, something known to be notoriously hard to analyse, see [28, 3].

There is a close link between heaps and sorting. The ancestor-descendant relationship in a heap captures everything we know about the order of the keys at a certain time. A sequence of `delete-min`s in a pairing heap (or in any other heap, for that matter), can be seen as transitioning from the current partial order towards the total order, i.e., sorting. (More precisely, we have here a special kind of selection-sort, in which only candidate minima are ever compared.) It would then be natural for the potential function to capture some measure of "sortedness" of the heap, for example, the entropy of the partial order or some other quantity related to the number of linear extensions. In general, as observed by Pettie [24], this is far from being the case for the splay potential.

The potential function in the classical analysis of splay trees is equal to the sum of the logarithms of subtree-sizes of all nodes in the tree. A subtree in the splay-view corresponds, in the heap-view, to the set of subtrees of a node and all of its right siblings (Figure 1). It is far from intuitive why such a quantity would be useful in analysing pairing heaps. In particular, this potential function does not distinguish between left and right children in the splay-view, even though, in the heap-view, they play different roles: one is a provably larger key, and the other is (so far) incomparable. It may seem that, implicitly, the splay

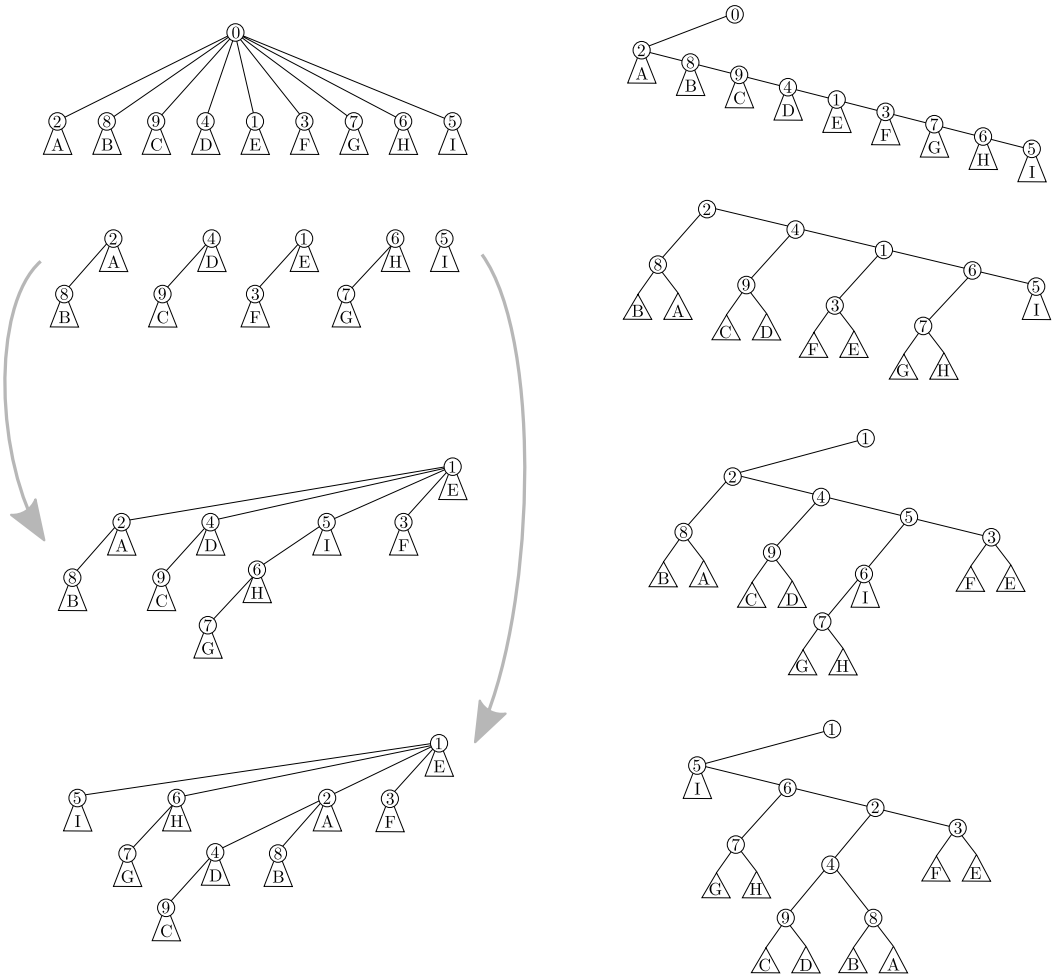

Figure 1 Pairing heap `delete-min` operation. Left: heap-view, right: binary tree-view (splay-view). From top to bottom: (i) initial heap, (ii) deleting the root and a left-to-right pairing round, (iii) standard variant, resulting heap after right-to-left accumulation round, (iv) forward-variant, resulting heap after left-to-right accumulation round. Circled numbers are keys, letters indicate arbitrary subtrees. Observe that the forward variant (iv) reverses the ordering of the siblings with keys 2,6,5.

potential assumes that the left-to-right ordering of siblings (in heap-view) is, to some extent, correlated with the sorted order. We argue that such an assumption is reasonable for the standard variant of pairing heaps, but not for the forward variant (since the accumulation round of the forward variant frequently reverses blocks of consecutive siblings).

As a simple example, consider either the standard or the forward variant, and look at a group of consecutive siblings $x_1, x_2, \ldots, x_k, y$ (arbitrarily shuffled), of which y is the smallest. Suppose, for simplicity, that these nodes interact with each other *only in pairing rounds*, i.e., the minimum of the accumulation round always comes from "outside the group", and does not change within the group. Assume also that, in each pairing round following a deletion of the parent of the group, y gains one node from the group as its new leftmost child.

If x_i and x_j both become children of y, and x_i is to the left of x_j, then x_i became the child of y in a later round than x_j, having "survived" more rounds (winning the links it took part in) at the same level as y. This fact is an indication that x_i may be smaller than x_j.

When y is eventually deleted, the standard variant will preserve the order of its children, whereas the forward variant will reverse it (assuming again, that there is no minimum-change within the group during the accumulation round).

There are limits to this intuition, and it is easy to construct examples that break it. Nonetheless, this interpretation suggests that we analyse the forward variant by somehow directly using the order-information, instead of trying to infer it from the tree structure. This motivates our potential function in § 2.

The intuition described earlier also hints at why the standard variant of pairing heaps may in fact be faster than the forward variant. If the left-to-right ordering of siblings is indeed the increasing order, then a right-to-left accumulate round is vastly more efficient then a left-to-right round. (The former immediately achieves the sorted order, whereas the latter merely finds the minimum.) On the other hand, in this case, the left-to-right round also reverses the order of siblings, making it optimal for the subsequent round. This intuition is consistent with our experiments that show the forward-variant to be somewhat slower[7] than the standard variant. However, the possibility that the forward-variant also has logarithmic cost has not been ruled out.

It remains an interesting open question to determine the exact complexity of the forward variant, and to characterize the types of instances on which it may outperform the standard variant. We also leave open the question whether `decrease-key` may take $o(\log n)$ time in this variant, noting that the lower bound of Fredman [8] applies to this case, whereas the upper bound of Pettie [24] does not.

More importantly, one can hope that new techniques for the analysis of pairing heaps will find their way to the analysis of splay trees and other dynamic search tree algorithms. Splaying and its variants pose some of the most intriguing and central open questions of the field, such as the dynamic optimality conjecture [26, 15].

2 Analysis of the forward variant of pairing heaps

Before proving our main result, as a warm-up, we look at the *arbitrary pairing and linking* variant of pairing heaps. First we introduce some terminology.

We define the *rank* of a node x as the number of nodes in the heap with a smaller key,[8] e.g., the rank of the root is 0. (For simplicity, we assume that the keys are unique.) We denote the rank of x by $r(x)$. The *rank-difference* $rd(x)$ of a node x is defined as $rd(x) = r(x) - r(p(x))$, where $p(x)$ is the parent node of x. It is clear that $rd(x)$ is positive for all non-root nodes x. For the root r, we define $rd(r) = 0$.

2.1 Arbitrary pairing and linking

We show that starting with an arbitrary initial heap of size n, the cost of n `delete-min`s using arbitrary pairing and linking is $O(n\sqrt{n})$. This was already known, as a corollary of Fredman et al.'s result in the original pairing heap paper [9]. Our proof is different (and arguably simpler), and is intended to illustrate the use of rank-differences in the analysis.

Consider a heap of size n. Let Φ denote the sum of rank-differences over all nodes of the heap. Observe that the ranks take all values $0, \ldots, n-1$, and the rank-difference of a node is not more than its rank. It follows that $0 \leq \Phi \leq n(n-1)/2$.

[7] Experiments also suggest that multipass is somewhat slower than the standard variant [27].
[8] Contrary to many other *rank*s in the data structures literature, we use the word in its "original" meaning.

For the purpose of the analysis, we slightly change the implementation of `delete-min`. Rather than deleting the root first, we first do the pairing and accumulation rounds on the children of the root, until the root has only one child. Only then, we actually delete the root. This modified algorithm is equivalent to the original.

In this implementation, all `link` operations take place between children of the root. Consider a `link` between nodes x and y, whose rank-differences are a and b, respectively. Suppose $x < y$, and consequently $a < b$. After the operation, y becomes the leftmost child of x. The new rank-difference of y is $b - a$. Observe that the rank-differences of nodes other than y remain unchanged, therefore the potential Φ decreases by a.

▶ **Theorem 2.** *The cost of n* `delete-min` *operations from an arbitrary initial heap of size n, using arbitrary pairing and linking, is $O(n\sqrt{n})$.*

Proof. Consider a `delete-min` in which the root has k children. In the pairing round we perform $\lfloor k/2 \rfloor$ `link` operations. By the earlier observation, the potential Φ goes down by $a_1 + \cdots + a_{\lfloor k/2 \rfloor}$, where a_i is the rank-difference of the "winner" (i.e., smaller node) in the i-th `link`. The values a_i are distinct (since all respective nodes have different ranks, and the same parent), and $a_i > 0$ for all i. Thus, the entire pairing round reduces Φ by at least $1 + 2 + \cdots + \lfloor k/2 \rfloor \geq (k^2 - 1)/8 \geq (k-1)^2/8$. The remaining operations can only further decrease the potential.

Let k_i be the number of children of the root before the i-th `delete-min` operation. (This is also our estimate for the cost of the operation.) The total reduction in potential due to this operation is at least $\sum_{i=1}^{n} (k_i - 1)^2/8$. On the other hand, the total reduction in potential over all n operations is not more than $n^2/2$. It follows that $\sum_i (k_i - 1)^2 \leq 4n^2$. Under this condition, setting $k_1 = \cdots = k_n = 2\sqrt{n} + 1$ maximizes the total real cost $\sum_i k_i$. ◀

In its current form, the potential function is not well suited for analysing operations other than `delete-min`; a single `insert`, for example, may increase Φ by a linear term. We sketch a new analysis for sequences of `insert` and `delete-min` operations that foretells the technique used in § 2.2.

Define the potential of a node x, denoted by $\phi(x)$, to be $rd(x)$, if $rd(x) \leq \sqrt{n} - 1$, and $\sqrt{n} - 1 + rd(x)/\sqrt{n}$ otherwise. Call nodes of the first kind *light*, and nodes of the second kind *heavy*. The potential function Φ is now defined as the sum of $\phi(x)$ over all nodes x. Observe that for a heap of size n, the total potential is $\Phi < 2n\sqrt{n}$.

Consider the pairing round in a `delete-min` operation. Since there are less than $\sqrt{n}$ light nodes among the children of the root, all but $\sqrt{n}$ of the link operations are between heavy nodes. It is easy to verify that a `link` between two heavy nodes reduces the potential by at least 1. The amortized $O(\sqrt{n})$ cost of `delete-min` follows.

Next we bound the amortized cost of an `insert` operation, considering the increase in potential that it may cause.

First, we have to add the potential of the newly inserted key, which is at most $2\sqrt{n}$. (In case the newly inserted key is the new minimum, it does not contribute to the potential.)

The second, more subtle effect of `insert` is that it may cause a change in the rank-differences of other nodes. A given node y is affected by a newly inserted node x if the rank of x falls between the rank of y and that of its parent $p(y)$. If the affected node y is a light node (before the `insert`), then its rank $r(y)$ (before the `insert`) can be larger than $r(x)$ by at most $\sqrt{n} - 2$ (otherwise, the rank-difference of y would have been too large). There can be at most $\sqrt{n} - 1$ such nodes, and the potential of each may go up by 1. Otherwise, if y is a heavy node, then $\phi(y)$ may go up only by $1/\sqrt{n}$. Overall, the potential Φ increases by at most $2\sqrt{n}$. The amortized $O(\sqrt{n})$ cost of `insert` follows.

The reader may observe that we ignored the change in potential due to the change in the value of n. We can deal with this technicality by keeping n unchanged, as long as it does not get *too far* away from the true number of elements. When that happens, n can be updated by a standard doubling-halving strategy, without affecting the claimed amortized costs. We discuss this issue in more detail in the context of our main result.

2.2 The main result

▶ **Theorem 1.** *In the forward variant of pairing heaps, the amortized costs of* `delete-min` *and* `insert` *are* $O(\log n \cdot 4^{\sqrt{\log n}})$*, where* n *is the number of items in the heap when the operation is performed.*

To prove Theorem 1, we replace the simple potential function used in § 2.1 by one with a more fine-grained scaling. Again, first we present the tools necessary to analyse the heap in a *sorting mode*, i.e., we compute the cost of n `delete-min` operations on an arbitrary initial heap of size n, then we make the necessary changes to analyse both `insert` and `delete-min`.

In the following, for the purpose of analysis, we assume that n is an upper bound on the number of nodes in the heap, not greater than four times the true value. (Except for the beginning, when the heap is empty, and we set n to a small constant value, say $n = 4$.) At the end, we describe how we update n, if, after a certain number of operations, the true value reaches n, or falls far below n.

Let $q = q(n)$ be the *scaling factor* for n, an integer that we optimize later; assume for now that $1 < q < n$. The *category* of a (non-root) node x, denoted $c(x)$ is defined as $c(x) = \lfloor \log_q rd(x) \rfloor$. Observe that $c = c(x)$ is the unique integer for which $q^c \leq rd(x) < q^{c+1}$. For all nodes x we have $0 \leq c(x) < t$, where $t = t(n) = \lfloor \log_q (n-1) \rfloor + 1$, and $t \geq 2$.

For all non-root nodes x, we define the *node potential* of x as

$$\phi(x) = \frac{rd(x) - q^c}{q^c - q^{c-1}} + c \cdot q, \text{ where } c = c(x).$$

For the root r, we let $\phi(r) = 0$. The total node potential is $\Phi_N = \sum \phi(x)$, where the sum ranges over all nodes x. Some observations about the node potential are in order.

▶ **Lemma 3.** *With the previous definitions, we have:*

(i) *If* $rd(y) = rd(x) + 1$*, and* $rd(x) \geq 1$*, then* $\phi(y) = \phi(x) + 1/(q^c - q^{c-1})$*, where* $c = c(x)$*.*

(ii) *For every node* x*, it holds that* $0 \leq \phi(x) \leq t \cdot q$*, and therefore* $\Phi_N \leq n \cdot t \cdot q$*.*

(iii) *If two nodes of the same category are linked, then* Φ_N *decreases by at least 1.*

Proof.

(i) Suppose $c(y) = c(x) = c$. Then, $\phi(y) - \phi(x) = (rd(y) - rd(x))/(q^c - q^{c-1}) = 1/(q^c - q^{c-1})$. Otherwise, suppose $c(y) = c(x) + 1$. Let $c = c(x)$. Then, $rd(y) = q^{c+1}$, and $rd(x) = q^{c+1} - 1$. Thus, $\phi(y) - \phi(x) = (c+1) \cdot q - (q^{c+1} - 1 - q^c)/(q^c - q^{c-1}) - c \cdot q = 1/(q^c - q^{c-1})$.

(ii) From (i) it follows that $\phi(x)$ is maximal if $rd(x) = n - 1$. Then, $c(x) = t - 1$, and $\phi(x) \leq (q^t - q^{t-1})/(q^{t-1} - q^{t-2}) + (t-1) \cdot q = t \cdot q$.

(iii) Let us define the function $f(\cdot)$ that maps $rd(x)$ to $\phi(x)$ for all x. It is easy to verify that $f(\cdot)$ is strictly increasing for $rd(x) \geq 1$.
Suppose that $x < y$, and $c(x) = c(y) = c$. Then, $q^c \leq rd(x) < rd(y) < q^{c+1}$. Only the potential of y changes after the link operation, from $f(rd(y))$ to $f(rd(y) - rd(x))$.
We want to show $f(rd(y)) - f(rd(y) - rd(x)) \geq 1$. This quantity is minimized if $rd(x) = q^c$. By (i), $f(rd(y) - q^c) \leq f(rd(y)) - q^c/(q^c - q^{c-1}) \leq f(rd(y)) - 1$. The result follows. ◀

Suppose that $x_1, \ldots, x_k$ are children of the same node in the heap, indexed in left-to-right order. A subset $\{x_i, x_{i+1}, \ldots, x_j\}$ of these nodes, for $1 \leq i < j \leq k$, is referred to as a *contiguous group* of siblings. Within the heap, we consider certain contiguous groups of siblings to be *in a box*; this is only for the purpose of the analysis, with no effect on the implementation.

We define a second kind of potential to capture the current state of the boxes. Throughout the lifetime of the heap we maintain a number of invariants about the boxes, as follows.

(A) The size of a box (i.e., the number of nodes in a box) is of the form $2^b - 1$, for some $2 \leq b \leq t$.

(B) Boxes are pairwise disjoint.

(C) A box of size $2^b - 1$ can only contain nodes of category $b - 2$ or smaller.

The *box potential*, denoted Φ_B is a sum over all boxes of $(b - t - 1)/t$, where $2^b - 1$ is the size of the box. In particular, the largest possible box of size $2^t - 1$ contributes $-1/t$ to the box potential, and the smallest possible box of size 3 contributes $(1/t - 1)$. Observe that $-n < \Phi_B \leq 0$. At the beginning of the operations there are no boxes, therefore $\Phi_B = 0$.

The *total potential* Φ combines the node potential and the box potential, as $\Phi = \Phi_N + \Phi_B$.

We are ready to analyse the individual operations and their effect on the potential.

Delete-min only. Again, assume that the `delete-min` operation performs the pairing and accumulation rounds first, and deleting the root afterwards. We need to account for the change of node and box potential in all steps.

Consider an operation `link`(x, y), and assume w.l.o.g. that $x < y$, and therefore x becomes the parent of y. We say that the link is a *good link* if one of the following holds:

(1) before the link x and y were of the same category,

(2) the link occurs in the accumulation round, is not of type (1), and y is the left-to-right minimum before the link (being replaced by x in this role).

At a high level, our strategy is to show that for every $t \cdot 2^t$ link operations, one good link occurs. A good link of the type specified in case (1) decreases the node potential by at least 1. Therefore, by Lemma 3(ii), there are at most $n \cdot t \cdot q$ such links. (In our current setting no action increases the node potential.) A good link of the type specified in case (2) can occur at most $t - 1$ times during a `delete-min`. To see that there are no more than $t - 1$ type-(2) good links in a `delete-min`, observe that such an event necessarily leads to a decrease in category of the current left-to-right minimum, and the number of possible categories is t.

The link operations that we charge to a single good link may be scattered through multiple `delete-min` operations. The purpose of the boxes is to keep track of link operations that we have not yet accounted for.

Let k denote the number of children of the deleted root, i.e., the real cost of the operation, up to a constant factor, and let us look in turn at the pairing round, accumulation round, and the deletion of the root.

Pairing round. Consider the links involving nodes from a box of size $2^b - 1$. If at least one of these is a good link of type (1), we simply remove the box. The result is an increase in box potential by $(t - b + 1)/t$ due to the deletion of the box, and a decrease in node potential by at least 1 due to the good link. This amounts to a decrease in total potential of $(b - 1)/t \geq 1/t$. Observe that if the box size before the operation is $2^2 - 1 = 3$ (i.e., minimal), then the link operation within the box is *always* a good link. This is because, by invariant (C), all nodes in the box are of category 0.

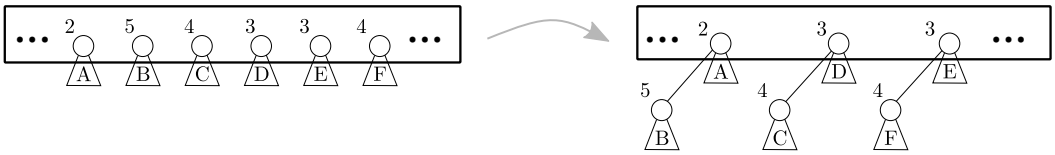

Figure 2 The evolution of a box. Numbers indicate categories of nodes. The losers of the comparisons drop out of the box.

Suppose that we process a box of size $2^b - 1$ for $b > 2$, and no good link occurs within the box. Then, the box continues to exist around the winners of the link operations where both nodes were in the same box, i.e., the *losers* of the link operations, and possibly the nodes "on the margin" leave the box. Observe that the size of the box goes from $2^b - 1$ to $2^{b-1} - 1$. Due to the decrease of the box size, we have a decrease in box potential by $1/t$, and consequently a decrease by $1/t$ in total potential. (See Figure 2 for illustration.)

Now suppose we execute $T = 2^t - 1$ consecutive non-good link operations without encountering a box. Then, we form a box around the $2^t - 1$ winners of these links. Due to the newly created box of maximum size, the total potential decreases by $1/t$.

Consider a sequence of T consecutive links. Then, either (i) one of the links is good, or (ii) we create a new box containing the T winners, or (iii) we encounter an existing box. In the latter case, we process the box until its end. Thus, in all cases, for at most $2T - 1$ consecutive link operations, we achieve a saving in potential of at least $1/t$. This yields (for the entire pairing round) a decrease in potential of at least

$$\left\lfloor \frac{\lfloor k/2 \rfloor}{2 \cdot 2^t - 3} \right\rfloor \cdot \frac{1}{t} \geq \frac{k}{4 \cdot t \cdot 2^t} - \frac{2}{t}.$$

We need to argue that in the cases described above, the box invariants are maintained. Condition (A) clearly holds in every case. When we create a new box, we only use nodes that are not in a box, therefore condition (B) holds. We never add new nodes to an existing box, thus (B) continues to hold. We next discuss the validity of invariant (C), which is the crucial ingredient of the proof.

When a new box of size $2^t - 1$ is created, we claim that there cannot be any node of category $t - 1$ within the box. This is because, if any node in the box was of category $t - 1$, its "winning" of the linking would have happened against another node of category $t - 1$, a type-(1) good link that contradicts our condition for creating the box.

Similarly, when shrinking an existing box from size $2^b - 1$ to $2^{b-1} - 1$, if invariant (C) was true before the operation (i.e., there were only nodes of category $0, \ldots, b - 2$ in the box), then the nodes in the box after the operation can only be of category $0, \ldots, b - 3$. A node of category $b - 2$ could only have "won" against another node of category $b - 2$, a type-(1) good link that contradicts our condition for maintaining the box. This establishes the invariants.

Accumulation round. By Lemma 3(i), the node potential can only further decrease. We need to argue that the box-structure is not destroyed by this round.

Recall that we start with the leftmost node (the current minimum), and keep linking against the nodes from left to right. As long as there is no type-(2) good link, the nodes that we encounter left-to-right become the children of the current minimum in right-to-left order. The box invariants are clearly not affected by this reversal of order, the box, together with its parent node simply moves further down the tree. (Categories of nodes in the box can only decrease.)

If there is a change in the minimum, i.e., a type-(2) event, while we are processing the nodes in a box, then we delete the box. By deleting the box, we may increase the box potential by $1 - 1/t < 1$. This is the only kind of potential-change we need to consider in this round, yielding an increase in total potential of at most $t - 1$ (since there are at most $t - 1$ type-(2) events).

Deleting the root. The actual deletion of the root leaves the node potential unchanged, since at that time the root has only one child, its successor, which has rank-difference 1, and consequently, node potential 0. The box potential is unaffected, since the root cannot be in a box.

To summarize, if the actual cost of `delete-min` is k, then, collecting the terms from the different rounds, the decrease in potential is at least $k/(4t \cdot 2^t) - 2/t - (t-1) \geq k/(4t \cdot 2^t) - t$.

Denoting the actual costs of the n `delete-min` oparations by $k_1, \ldots, k_n$, for the total potential decrease $\Delta\Phi$ we have:

$$\Delta\Phi \geq \left(\frac{1}{4t \cdot 2^t} \sum_{i=1}^{n} k_i \right) - n \cdot t.$$

From Lemma 3(i) it follows that $\Phi \leq n \cdot t \cdot q$, for an arbitrary heap. For the empty heap, we have $\Phi = 0$. Thus, $\Delta\Phi \leq n \cdot t \cdot q$. It follows that the total cost is $\sum k_i \leq (n \cdot t \cdot q + n \cdot t) \cdot (4t \cdot 2^t)$.

Let us now choose the scaling factor used in the analysis. Recall that $t = \lfloor \log_q (n-1) \rfloor$. Fixing $t = \lfloor \sqrt{\log n} \rfloor$, we have $q = O(n^{1/\sqrt{\log n}}) = O(2^{\sqrt{\log n}})$. Thus, we obtain that the amortized cost of `delete-min` is $O(\log n \cdot 4^{\sqrt{\log n}})$.

Insert and Delete-min. Next, we consider sequences of `insert` and `delete-min` operations, arbitrarily intermixed. The amortised cost of an operation is defined as the true cost *plus* the increase in potential due to the operation.

The analysis of `delete-min` is the same as before, yielding a decrease in total potential due to a `delete-min` of at least $k/(4t \cdot 2^t) - t$, where k is the actual cost of the operation.

The true cost of `insert` is $O(1)$, but we also need to consider the increase in potential. The box potential is not affected by `insert`, as we do not create any new boxes and neither the root, nor the newly inserted node are in a box.

When a key x is inserted, its first contribution is its own node potential $\phi(x)$, in case it becomes the child of the root. (If x is smaller than the root, then, after the linking, both x and the old root have node potential zero.) By Lemma 3(ii), the resulting increase in the node potential is at most $t \cdot q$.

As in § 2.1, we need to deal with the fact that an `insert` operation may change the ranks of existing nodes, possibly increasing their rank-difference. We could proceed with an argument similar to the one in § 2.1, estimating the change in potential for nodes in each category. The argument gets complicated, however, because the increase in rank-difference may also cause an increase in category, invalidating the box invariants.[9]

To avoid the issue of updating ranks during an `insert` operation, we redefine *rank* to take into account not just the items currently in the heap, but also the items that will be inserted into the heap in the future. (Since we use ranks only in the analysis, we can assume that future operations are known to us.) In this way, an `insert` operation has no effect on

[9] We observe that our problem of maintaining the ranks under insertions is reminiscent of the well-studied *ordered list maintenance* problem, for which efficient (although quite involved) solutions exist. Luckily, we can get away with a simpler solution.

ranks, rank-differences, or categories of existing items, since the rank of the newly inserted item has already been taken into consideration. Therefore, there is no further change in potential that we need to consider.

There remains the issue, that we cannot afford to look *too far* into the future, as we want the value n to be, at all times, close to the current size of the heap. Therefore, we split the operations into epochs, and keep the value of n fixed throughout an epoch. If the heap is empty, e.g., in the beginning, we let $n = 4$.

An epoch ends when the true size of the heap increases to n (after an `insert`), or decreases to $\lfloor n/4 \rfloor$ (after a `delete-min`), or if, within the epoch, n distinct keys have already been encountered (including those that were in the heap at the beginning of the epoch). In all three cases, we reset n to be twice the true size of the heap, remove all boxes, and start a new epoch. (We stress that epochs and boxes are used only in the analysis, with no effect on the actual operation of the data structure.) As mentioned, the ranks of the items are computed with respect to *all items* encountered during an epoch, they are therefore, fixed within the epoch. Clearly, all ranks and rank-differences are still upper bounded by n.

We make four observations, all of which are easy to verify based on the preceding discussion: (1) The true size of the heap is between $\lfloor n/4 \rfloor$ and n. (2) Within a finished epoch there must have been at least $\lceil n/4 \rceil$ operations. (3) The increase in node potential due to the resetting of n is not more than $n \cdot t \cdot q$. (4) Since the boxes are disjoint, there are less than n boxes that we are removing, increasing the total potential by at most n.

We distribute the increase in potential of at most $n \cdot t \cdot q + n$ among the $\lceil n/4 \rceil$ operations in the finished epoch, obtaining that the *increase* in potential during an `insert` is at most $5 \cdot t \cdot q + 4$, and the increase in potential during a `delete-min` is at most $t - k/(4t \cdot 2^t) + 4 \cdot t \cdot q + 4$. Scaling the potential by $t \cdot 2^t$, we obtain that the amortized cost of both `insert` and `delete-min` is $O(t^2 \cdot q \cdot 2^t)$.

Again, choosing $t = \lfloor \sqrt{\log n} \rfloor$, we obtain $q = O(n^{1/\sqrt{\log n}}) = O(2^{\sqrt{\log n}})$, and the amortized costs of $O(\log n \cdot 4^{\sqrt{\log n}})$ follow.

Meld. A `meld` operation is similar to an `insert`, in that only one node changes its rank-difference, and thereby its node potential (the root with the larger key). Furthermore, `meld` also leaves the box potential unaffected, so its analysis goes through similarly to the analysis of `insert`, yielding the same amortized cost for `meld` as for `insert` and `delete-min`. Observe, however, that if we also include `meld` operations in a sequence of operations, then the value n that appears in the cost no longer denotes just the size of the affected heap, it is instead, the number of items in *all heaps* that we are currently working with.

Other variants. The presented analysis is fairly general. It is not difficult to adapt it to the *standard* and *multipass* variants of pairing heaps, yielding similar upper bounds. For the standard variant the analysis is essentially the same as for the forward variant. For multipass, the analysis becomes simpler, since boxes need to be maintained only during individual `delete-min` operations. However, for these variants, stronger upper bounds are already known, as discussed in § 1.

Recall that during a `link` operation, the larger of the two items is linked as the leftmost child of the smaller. The reader may observe that the different behaviors of the standard and forward variants depend on this particular way of implementing `link`. If we were to link by making the larger item the *rightmost* child of the smaller, then the situation would reverse, with the forward variant being easy, and the standard variant hard to analyse.

We may modify the implementation of `link`, such as to link *arbitrarily* as the leftmost or rightmost child (i.e., deciding independently for every `link` operation whether to link at the left or at the right). Our analysis also extends to this more general class of pairing heap algorithms (that use the modified `link` implementation) with minimal changes. The only difficulty that arises in the new setting is that during the accumulation round, an existing box may split into two, one part going to the left, the other to the right side of the current minimum. To account for this loss, we need to start with a larger initial box (4^t instead of 2^t). The resulting bounds are still of the form $2^{O(\sqrt{\log n})}$.

Improving (significantly) the bounds presented in the paper and extending the analysis to other operations should be possible but will likely require new ideas.

Simultaneous Multiparty Communication Protocols for Composed Functions

Abstract

The Number On the Forehead (NOF) model is a multiparty communication game between k players that collaboratively want to evaluate a given function $F : \mathcal{X}_1 \times \cdots \times \mathcal{X}_k \to \mathcal{Y}$ on some input $(x_1, \ldots, x_k)$ by broadcasting bits according to a predetermined protocol. The input is distributed in such a way that each player i sees all of it except x_i (as if x_i is written on the forehead of player i). In the Simultaneous Message Passing (SMP) model, the players have the extra condition that they cannot speak to each other, but instead send information to a referee. The referee does not know the players' inputs, and cannot give any information back. At the end, the referee must be able to recover $F(x_1, \ldots, x_k)$ from what she obtained from the players.

A central open question in the simultaneous NOF model, called the $\log n$ *barrier*, is to find a function which is hard to compute when the number of players is polylog(n) or more (where the x_i's have size poly(n)). This has an important application in circuit complexity, as it could help to separate ACC^0 from other complexity classes [22, 3]. One of the candidates for breaking the $\log n$ barrier belongs to the family of *composed functions*. The input to these functions in the k-party NOF model is represented by a $k \times (t \cdot n)$ boolean matrix M, whose row i is the number x_i on the forehead of player i and t is a block-width parameter. A symmetric composed function acting on M is specified by two symmetric n- and kt-variate functions f and g (respectively), that output $f \circ g(M) = f(g(B_1), \ldots, g(B_n))$ where B_j is the j-th block of width t of M. As the majority function $\textsc{Maj}$ is conjectured to be outside of ACC^0, Babai *et. al.* [5, 3] suggested to study the composed function $\textsc{Maj} \circ \textsc{Maj}_t$, with t large enough, for breaking the $\log n$ barrier (where $\textsc{Maj}_t$ outputs 1 if at least $kt/2$ bits of the input block are set to 1).

So far, it was only known that block-width $t = 1$ is not enough for $\textsc{Maj} \circ \textsc{Maj}_t$ to break the $\log n$ barrier in the simultaneous NOF model [3] (Chattopadhyay and Saks [17] found an efficient protocol for $t \leq$ polyloglog(n), but it requires randomness to be simultaneous). In this paper, we extend this result to any constant block-width $t > 1$ by giving a *deterministic simultaneous* protocol of cost $2^{\mathcal{O}(2^t)} \log^{2^{t+1}}(n)$ for *any* symmetric composed function $f \circ g$ (which includes $\textsc{Maj} \circ \textsc{Maj}_t$) when there are more than $2^{\Omega(2^t)} \log n$ players.

1 Introduction

1.1 Number On the Forehead and Simultaneous models

The *Number On the Forehead* (NOF) model is a multiparty communication model introduced by Chandra, Furst and Lipton [15] that generalizes the two player communication game of Yao [36]. In this model, k players are given k inputs $x_1 \in \mathcal{X}_1, \ldots, x_k \in \mathcal{X}_k$ on which they want to compute some function $F : \mathcal{X}_1 \times \cdots \times \mathcal{X}_k \to \mathcal{Y}$. Each player i sees all of the input $(x_1, \ldots, x_k)$, except x_i. The situation is as if input x_i is written on the forehead of player i.

In order to collaboratively evaluate $F(x_1, \ldots, x_k)$, the players communicate by *broadcasting* bits according to a predetermined *protocol*. This protocol specifies whose turn it is to speak, and which bit is to be sent given the information exchanged so far and the input seen by the speaking player. It also determines when communication stops. At the end, all the players must be able to recover $F(x_1, \ldots, x_k)$ from the input they see and the transcript of the exchange. The cost of the protocol on input $(x_1, \ldots, x_k)$ is the number of exchanged bits, and the total cost is the worst case cost on all inputs. The k-party deterministic communication complexity of F, denoted $\mathsf{D}_k(F)$, is the cost of the most efficient protocol computing F.

In most of the settings, the x_i's are poly n-bits long (for some parameter n) and $\mathcal{Y} = \{0, 1\}$. In this case, the naive protocol is to broadcast first the entire input x_1 (this can be done by player 2), and then player 1 computes $F(x_1, \ldots, x_k)$ and sends the result to the other players. This protocol has cost $m + 1$ (where $m = \text{poly}(n)$ is the number of bits required for sending x_1), which proves $\mathsf{D}_k(F) = \mathcal{O}(\text{poly}\, n)$. Consequently, a protocol will be said to be *efficient* if it has cost $\mathcal{O}(\text{polylog}\, n)$ (i.e. we seek for exponential speed-up over the naive protocol).

Among the many variants of the previous framework (randomized, quantum, etc.), we will be interested in the *simultaneous* (or *Simultaneous Message Passing - SMP*) model [36, 25, 5, 28] in which the players cannot speak to each other but instead send information to a referee. The referee does not know the players' inputs, and cannot give any information back. At the end, the referee must be able to recover $F(x_1, \ldots, x_k)$ from what she obtained from the players. The simultaneous deterministic communication complexity is denoted $\mathsf{D}^{||}_k(F)$, and it always satisfies $\mathsf{D}_k(F) \leq \mathsf{D}^{||}_k(F)$. It has often been easier to reason first in this weaker model for proving lower bounds [3, 28, 10, 7]. It is also more suitable and fruitful for studying certain functions, such as Equality in the two party setting [36, 2, 24, 4, 14, 19, 13]. We will show in the next section that the simultaneous deterministic communication model is also closely connected to lower bound results in the complexity class ACC^0.

1.2 The log n barrier problem and ACC^0 lower bounds

The NOF model has proved to be of value in the study of many areas of computer science, such as branching programs [15], Ramsey theory [15], circuit complexity [22, 12], quasirandom graphs [18], proof complexity [9], etc. One of the most interesting connections, pointed out by Håstad and Goldmann [22] and refined in [3], is a way to derive lower bounds for the complexity class[1] ACC^0 from lower bounds in the *simultaneous* NOF model. More precisely, according to a result from Yao, Beigel and Tarui [37, 12], any function $f \in \mathsf{ACC}^0$ can be expressed as a depth-2 circuit whose top gate is a symmetric gate of fan-in $2^{\log^c n}$, and each bottom gate is an And gate of fan-in $\log^d n$ (for some constants c, d). Consequently, for

[1] ACC_0 refers to the functions computable by constant-depth poly-size circuits with unbounded fan-in And, OR, Not and Mod_m gates (where Mod_m outputs 0 iff the sum of its inputs is divisible by m).

any partition of the input of f between $k = \log^d n - 1$ players in the *simultaneous* NOF model, there exists a partition of the AND gates between the players such that each of them sees all the input bits she needs to evaluate the gates she received. The players can then send to the referee the number of gates that evaluate to 1, which enables the referee to compute f. The total cost of this protocol is $\mathcal{O}\left(k \log\left(2^{\log^c n}\right)\right) = \mathcal{O}\left(\log^{c+d} n\right)$. Conversely, any super-polylogarithmic lower bound in the *simultaneous* NOF model for a function f and a partition of its input between polylog(n) players would imply $f \notin \mathsf{ACC}^0$.

Separating ACC^0 from other complexity classes is a central question in complexity theory. It is conjectured that ACC^0 does not contain the majority function MAJ, but the only result known so far is $\mathsf{NEXP} \not\subset \mathsf{ACC}^0$ [35]. The aforementioned connection with communication complexity has motivated the search for a function which is hard to compute for $k \geq \log n$ players in the simultaneous NOF model. This problem is called the $\log n$ *barrier*.

Obtaining lower bounds in the NOF model is a challenging task, as the current methods become very weak when $k \geq \log n$. The only general lower bound technique known so far is the discrepancy method and its variants [6, 18, 30, 31]. One of the early application of it was an $\Omega(n/4^k)$ lower bound on the randomized complexity of the *Generalized Inner Product* (GIP) function [6]. A long series of generalizations and improvements of the discrepancy method subsequently led to an $\Omega\left(\frac{\sqrt{n}}{k2^k}\right)$ (resp. $\Omega(n/4^k)$) lower bound on the randomized (resp. deterministic) complexity of the *Disjointness* (DISJ) function [34, 11, 16, 23, 8, 33, 32, 29]. It might seem like other lower bound arguments could prove that GIP and DISJ remain hard for $k \geq \log n$ players. However, surprising non-simultaneous [21, 1] and simultaneous [3, 1] protocols proved that the aforementioned lower bounds are nearly optimal, and that these two functions cannot break the $\log n$ barrier. Very recently, Podolskii and Sherstov [27] showed that the randomized complexity of GIP and DISJ is exactly $\Theta\left(\frac{\log n}{\lceil 1+k/\log n \rceil} + 1\right)$ when $k \geq \log n$, and built a function having complexity $\Omega(\log n)$ independently of k. Although these last results do not break the $\log n$ barrier, they are the first superconstant lower bounds proved for explicit functions when $k \geq \log n$.

1.3 Composed Functions

An input $x_1, \ldots, x_k \in \{0,1\}^n$ to k players in the NOF model can be visualized as a $k \times n$ boolean matrix M where row i is the number x_i on the forehead of player i. The protocols known so far for GIP and DISJ strongly rely on the particular way these functions act on matrix M. They both consist in applying the $g = \text{AND}$ function on each of the n columns of M, followed by the $f = \text{MOD}_2$ (for GIP) or $f = \text{NOR}$ (for DISJ) function on the n resulting bits. Since GIP and DISJ do not break the $\log n$ barrier, a natural move has been to try other f and g functions, and to increase the number t of columns on which each g function applies. These are called the *composed functions*, formally defined below and depicted in Figure 1.

▶ **Definition 1** (Boolean input version)**.** Fix a block-width parameter $t \geq 1$, and consider functions $f : \{0,1\}^n \to \{0,1\}$ and $\vec{g} = (g_1, \ldots, g_n)$ where $g_j : (\{0,1\}^t)^k \to \{0,1\}$. Given $x_1, \ldots, x_k \in \{0,1\}^{t \cdot n}$, the *composed function* $f \circ \vec{g}$ for k players outputs $f \circ \vec{g}(x_1, \ldots, x_k) = f(g_1(B_1), \ldots, g_n(B_n))$ where $B_j \in (\{0,1\}^t)^k$ is the j^{th} block of width t in the matrix representation M of the input. When $g = g_1 = \cdots = g_n$, we denote $f \circ \vec{g}$ by $f \circ g$.

Both $\text{GIP} = \text{MOD}_2 \circ \text{AND}$ and $\text{DISJ} = \text{NOR} \circ \text{AND}$ are composed functions for $t = 1$, with the additional property that MOD_2, NOR and AND are *symmetric* functions (i.e. invariant under any permutation of their input). Since the majority function MAJ is conjectured to be outside of ACC^0, Babai *et. al.* [5, 3] suggested to look at $\text{MAJ} \circ \text{MAJ}_t$ and $\text{MAJ} \circ \text{THR}_t^s$ for

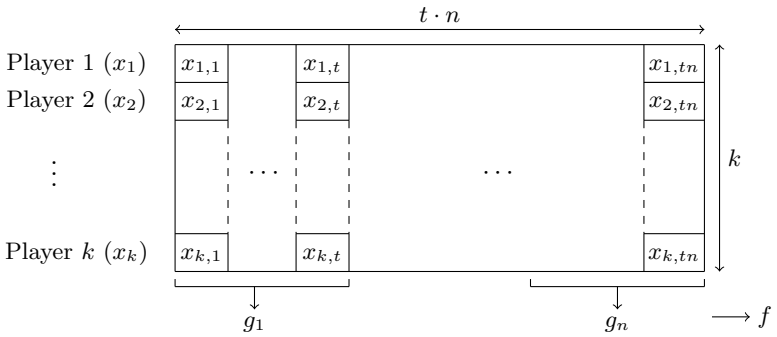

Figure 1 Matrix structure of a composed function $f \circ \vec{g}$ of block-width t.

breaking the $\log n$ barrier (where $\textsc{Maj}_t$ outputs 1 if at least $kt/2$ bits of the input block are set to 1, and $\textsc{Thr}_t^s(r_1, \ldots, r_k) = 1$ if $r_1 + \cdots + r_k \geq s$ for $r_1, \ldots, r_k$ seen as t-bits numbers).

Another way to look at composed functions of block-width t is to interpret each sub-row $r \in \{0,1\}^t$ of each block as a number in $\mathbb{Z}_d$, where $d = 2^t$. This representation of the input as a $k \times n$ matrix M over some set $\mathbb{Z}_d$ is sometimes more convenient to use. Below, we reformulate Definition 1 using this point of view.

▶ **Definition 2** (Integer input version)**.** Fix an integer $d \geq 2$ and consider functions $f : \{0,1\}^n \to \{0,1\}$ and $\vec{g} = (g_1, \ldots, g_n)$ where $g_j : \mathbb{Z}_d^k \to \{0,1\}$. Given $x_1, \ldots, x_k \in \mathbb{Z}_d^n$, the *composed function* $f \circ \vec{g}$ for k players outputs $f \circ \vec{g}(x_1, \ldots, x_k) = f(g_1(C_1), \ldots, g_n(C_n))$ where $C_j \in \mathbb{Z}_d^k$ is the j^{th} column in the matrix representation M of the input. When $g = g_1 = \cdots = g_n$, we denote $f \circ \vec{g}$ by $f \circ g$.

The set of all composed functions $f \circ \vec{g}$ (resp. $f \circ g$) over $\mathbb{Z}_d$ is denoted $\mathsf{ANY} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$ (resp. $\mathsf{ANY} \circ \mathsf{ANY}_{\mathbb{Z}_d}$). Similarly, $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ is the set of $f \circ g$ for symmetric f and symmetric g functions, $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$ is the set of $f \circ \vec{g}$ for symmetric f and any $\vec{g}$, etc. If $d = 2$ (which corresponds to block-width $t = 1$), we will drop the subscript and write $\mathsf{ANY} \circ \overrightarrow{\mathsf{ANY}}$, $\mathsf{SYM} \circ \mathsf{SYM}$, etc. We have for instance $\textsc{Gip}, \textsc{Disj} \in \mathsf{SYM} \circ \mathsf{SYM}$ and $\textsc{Maj} \circ \textsc{Maj}_t, \textsc{Maj} \circ \textsc{Thr}_t^s \in \mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_{2^t}}$.

The first efficient protocol for composed functions with polylog(n) or more players was given by Grolmusz [21]. It is a *non-simultaneous* protocol of cost $\mathcal{O}\left(\log^2 n\right)$ for any composed function in $\mathsf{SYM} \circ \textsc{And}$ (the inner function is fixed to be $\textsc{And}$) when $k \geq \log n$. The study of composed functions with symmetric outer function f was subsequently continued, as it captures many other interesting cases in communication complexity. Babai *et. al.* [5] proposed first $\textsc{Maj} \circ \textsc{Maj}_1$ as a candidate to break the $\log n$ barrier. However, in a subsequent work [3], they found a *simultaneous* protocol that applies to $\mathsf{SYM} \circ \mathsf{COMP}^c$ (where COMP^c holds for *c-compressible symmetric* functions[2], a subset of SYM that contains $\textsc{Maj}$ and $\textsc{And}$). It has cost $\mathcal{O}\left(\log^{2+c} n\right)$ when $k > 1 + \log n$. Later, Ada *et. al.* [1] generalized this result to $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}$, with a *simultaneous* protocol of cost $\mathcal{O}\left(\log^3 n\right)$ for $k > 1 + 2\log n$ players. The only protocol known so far for block-width $t > 1$ has been discovered by Chattopadhyay and Saks [17]. It has cost $\mathcal{O}\left(d \log n \log(dn)\right)$ for $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$ when $k > 1 + d\log(3n)$ (which is

[2] A class $\mathcal{G}$ (parameterized by k) of symmetric functions $g : \{0,1\}^k \to \{0,1\}$ is c-compressible if for any function $g \in \mathcal{G}$, set $S \subsetneq \{1, \ldots, k\}$ and input $(x_i)_{i \in S} \in \{0,1\}^{|S|}$ there is a message m_S of size $\mathcal{O}(1) + c\log(k - |S|)$ such that $g(x_1, \ldots, x_k)$ can be computed for all $(x_i)_{i \in \{1,\ldots,k\} \setminus S} \in \{0,1\}^{k-|S|}$ from knowledge of m_S and $(x_i)_{i \in \{1,\ldots,k\} \setminus S}$ only. The $\textsc{Maj}_1$ and $\textsc{Thr}_1^s$ functions are 1-compressible [3].

Table 1 Deterministic protocols for different families of composed functions. The top three results apply only to block-width 1 (i.e. $d = 2$), whereas the last two results work for any d. Note that the protocol of [17] can be made simultaneous using shared randomness between the players.

	Supported functions	Complexity of the protocol	Simultaneous	Number of players required
Grolmusz [21]	$\mathsf{SYM} \circ \textsc{And}$	$\mathcal{O}\left(\log^2 n\right)$	No	$k \geq \log n$
Babai *et. al.* [3]	$\mathsf{SYM} \circ \mathsf{COMP}^c$	$\mathcal{O}\left(\log^{2+c} n\right)$	Yes	$k > 1 + \log n$
Ada *et. al.* [1]	$\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}$	$\mathcal{O}\left(\log^3 n\right)$	Yes	$k > 1 + 2\log n$
C. and Saks [17]	$\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$	$\mathcal{O}\left(d \log n \log(dn)\right)$	No	$k > 1 + d\log(3n)$
This work	$\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$	$2^{\mathcal{O}(d)} \log^{4d}(n)$	Yes	$k \geq 4^{2d} \log n$

efficient for $d \leq \text{polylog}\, n$). However, it is *not simultaneous* in the deterministic setting (the authors showed how to make it simultaneous using shared randomness between the players). Thus, none of these previous results prevents from breaking the $\log n$ barrier in the SMP model with composed functions of block-width as small as $t = 2$. The goal of this paper is to rule out this possibility for all symmetric composed functions of constant block-width $t > 1$.

1.4 Summary of Results and Comparison to Previous Protocols

Below, we describe our main results, and summarize in Table 1 the complexity of all the known protocols for composed functions. Then, we review the main ideas used in the previous literature, and we explain how we differ from them.

Our results. In this paper, we describe the first *deterministic simultaneous* protocol for symmetric composed functions of block-width $t > 1$. Our result is divided into two parts. We first give (Section 3.1) a protocol of cost $\mathcal{O}\left(k(k+d)^{d-1} \log n\right)$ for $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ when the number of players is $k \geq 4^{d-1} \log n$. In a second time (Section 3.2), we build upon this result to give a simultaneous protocol of cost $2^{\mathcal{O}(d)} \log^{2 \cdot 2^{\lceil \log d \rceil}}(n)$ for $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ when $k \geq 4^{2d} \log n$. Unlike the first protocol, this last result also works with different inner functions $g_1, \ldots, g_n$ and it is efficient even if k is super-polylogarithmic.

Adjacent vertices of the $\{0,1\}^n$ hypercube. For block-width $t = 1$ and an input matrix $M \in \{0,1\}^{k \times n}$, denote n_c the number of times column $c \in \{0,1\}^k$ occurs in M. Grolsmusz [21] noticed that if $c_1, \ldots, c_m$ is a sequence of adjacent vertices of the $\{0,1\}^k$ hypercube (i.e. c_{l+1} differs from c_l by exactly one coordinate) then $n_{c_1} = \left(\sum_{l=1}^{m-1} (-1)^{l+1} (n_{c_l} + n_{c_{l+1}})\right) + (-1)^{m+1} n_{c_m}$. Moreover, if position i is the coordinate at which c_l and c_{l+1} differ, then the quantity $n_{c_l} + n_{c_{l+1}}$ is known by player i. This leads to a straightforward simultaneous protocol of cost $\mathcal{O}(k \log n)$ for computing n_{c_1}, provided that n_{c_m} is known by the referee. In his initial work, Grolsmusz [21] gave a non-simultaneous way to find some initial n_{c_m}. Ada *et. al.* [1] noticed later that this step can be made simultaneous using the protocol of Babai *et. al.* [3], and that the idea of Grolsmusz (initially designed for $\mathsf{SYM} \circ \textsc{And}$) easily adapts to $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}$. Unfortunately, this "hypercube view" does not generalize to block-width $t > 1$: for each i and $c \in (\{0,1\}^t)^k$, the number of vertices that differ from c only at position i is now $2^t - 1 > 1$. It is easy to see that writing a similar telescoping sum as above, in which each term would be known by a player, is no longer possible.

Counting up to symmetry. Given a $k \times n$ matrix M over $\mathbb{Z}_d$, for all $0 \leq e_1 + \cdots + e_{d-1} \leq k$

denote $y_{e_1,\ldots,e_{d-1}}$ the number of columns of M with exactly e_s occurrences of each $s \in \mathbb{Z}_d \backslash \{0\}$ (we do not put e_0 since it is always equal to $k - (e_1 + \cdots + e_{d-1})$). These numbers provide less information than the n_c's defined above, but they still unable us to compute $f \circ g(M)$ for all $f \circ g \in \mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$. If M is distributed between k players in the NOF model (player i does not see row i), a naive *simultaneous* protocol is to have each player i send the number of columns $a^i_{e_1,\ldots,e_{d-1}}$ which contain, *from her point of view*, exactly e_s occurrences of each element $s \in \{1, \ldots, d-1\}$ (for all $e_1 + \cdots + e_{d-1} \leq k-1$). Babai *et. al.* [3] analyzed this protocol in the case $d = 2$, and showed that it gives the referee enough information to recover the $y_{e_1,\ldots,e_{d-1}}$'s, provided that $k > 1 + \log n$. In Section 3.1, we extend this analysis to any $d > 2$. The core of the proof, as in [3], is to define a specific equation (using the $a^i_{e_1,\ldots,e_{d-1}}$'s) whose only integral solution is the $y_{e_1,\ldots,e_{d-1}}$'s.

The shifted basis technique. The only protocol [17] known prior to this work for block-width $t > 1$ is based on the following observation: given polynomial representations of the inner functions g_j (over variables $x_{1,j}, \ldots, x_{k,j}$), each term involving strictly less than k variables can be evaluated on input matrix M by at least one player (in fact, by all the players that have one of the missing variables on their foreheads). The key idea of [17] is to get rid of the remaining terms by expressing the g_j in a s-shifted basis where all terms of degree k will evaluate to 0 on M (shifting for instance monomial $x_{1,j} \cdots x_{k,j}$ by $s = (s_1, \ldots, s_k)$ means to replace it with $(x_{1,j} - s_1) \cdots (x_{k,j} - s_k)$). To this end, it would suffice to find some s that shares at least one coordinate in common with each column of M. Provided that k is large enough, [17] showed that a randomly picked s has this property with high probability. This gives rise to a simultaneous protocol for $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$ *if* the players have access to a shared random string. In the deterministic setting (no shared randomness), it is not known how to make this protocol simultaneous.

Different inner functions, and reducing the number of players. The communication complexity is expected to decrease as k grows up (since the overlap of information among the players increases). However, this fact is not reflected in the cost of our first protocol (Section 3.1). This issue is closely related to that of having different inner functions $g_1, \ldots, g_n$. Indeed, the problem of computing $f \circ g \in \mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ with k players on a matrix $M \in \mathbb{Z}_d^{k \times n}$ can be changed into computing $f \circ (\widetilde{g_1}, \ldots, \widetilde{g_n}) \in \mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ with the first $\ell < k$ players on the submatrix $\widetilde{M} \in \mathbb{Z}_d^{\ell \times n}$ (first ℓ rows of M), where $\widetilde{g_j} : \mathbb{Z}_d^\ell \to \{0,1\}$ is defined as $\widetilde{g_j}(u) = g(u \cdot v_j)$ and v_j is the values occurring from row $\ell + 1$ to k in the j-th column of M (note that the new $\widetilde{g_j}$ functions are still symmetric, but unknown to the referee). Our first protocol cannot handle different inner functions, but this issue will be solved in Section 3.2 where we describe a protocol for $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ based on a new use of the *polynomial representations* (different than [17]). We will show that each inner function $\widetilde{g_j}$ can be represented into a (small) basis of symmetric functions $\{m_a\}_a$ (Section 2), which will allow us to split the problem of computing $f \circ (\widetilde{g_1}, \ldots, \widetilde{g_n})$ on $\widetilde{M}$ into computing each $f \circ m_a \in \mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ on a well-chosen matrix $\widetilde{M_a}$. This last step can be done with the initial protocol of Section 3.1.

2 Polynomial Representations for Symmetric Functions

Throughout this paper, $\mathbb{Z}_d$ will denote the set of integers $\{0, \ldots, d-1\}$ and $\mathbb{F}_p$ is the finite field with p elements. Furthermore, a function $f : \mathcal{X}^m \to \mathcal{Y}$ is said to be *m-symmetric* (or *symmetric*) if it is invariant under any permutation of the input variables (i.e. for any input $(x_1, \ldots, x_m)$ and permutation $\sigma \in S_m$, we have $f(x_1, \ldots, x_m) = f(x_{\sigma(1)}, \ldots, x_{\sigma(m)})$).

The protocol designed in Section 3.2 for composed functions $f \circ \vec{g}$ requires a concise polynomial representation of the inner functions $g_1, \ldots, g_n : (\{0,1\}^t)^k \to \{0,1\}$. Informally,

we look for a field K and polynomials $G_j \in K[X]$ with variables $X = (x_{u,v})_{1\leq u\leq k, 1\leq v\leq t}$, such that:

- **(a)** for all $x \in (\{0,1\}^t)^k$, $g_j(x) = G_j(x)$
- **(b)** the order of K is at least $n+1$ (so that the set $\{0,\dots,n\}$ of values taken by $\sum_j g_j(x^{(j)})$ for $x^{(1)},\dots,x^{(n)} \in (\{0,1\}^t)^k$ can be embedded into K)
- **(c)** the G_j polynomials can be represented in a basis of size $\mathcal{O}(\operatorname{poly} k)$ when t is constant
- **(d)** the values of the coefficients of the G_j polynomials in this basis are less than n^c, for some absolute constant c independent of k and t.

The first step towards this end is to look at the usual $\mathbb{R}$-*multilinear representation* (also called *Fourier expansion* [26]) of a function $g : (\{0,1\}^t)^k \to \{0,1\}$. For each $a = (a_{u,v})_{1\leq u\leq k, 1\leq v\leq t} \in (\{0,1\}^t)^k$ we define the *indicator polynomial* $1_{\{a\}}(x)$ to be $1_{\{a\}}(x) = \prod_{1\leq u\leq k, 1\leq v\leq t}(1 - a_{u,v} + (2a_{u,v}-1)x_{u,v})$. It is easy to see that it takes value 1 when $x = a$ and value 0 when $x \in (\{0,1\}^t)^k \setminus \{a\}$. Consequently, we have $g(x) = \sum_{a\in(\{0,1\}^t)^k} g(a)1_{\{a\}}(x)$ for all $x \in (\{0,1\}^t)^k$. If we let x^a be the monomial $\prod_{(u,v):a_{u,v}=1} x_{u,v}$, then there exist real coefficients $\widehat{g}(a)$ such that it can be rewritten as the following multilinear polynomial

$$g(x) = \sum_{a\in(\{0,1\}^t)^k} \widehat{g}(a)x^a \tag{1}$$

Moreover, the $\widehat{g}(a)$ coefficients are given by the Möbius inversion formula

$$\widehat{g}(a) = \sum_{a'\subseteq a} (-1)^{|a|-|a'|} g(a') \tag{2}$$

where $|a|$ is the number of 1 in $a \in (\{0,1\}^t)^k$, and $a' \subseteq a$ means $a'_{u,v} = 0$ whenever $a_{u,v} = 0$.

Polynomial (1) is called the $\mathbb{R}$-*multilinear representation* of function g. It satisfies requirements (a) and (b) above, but not requirement (c). Indeed, these polynomials are expressed in the basis of monomials $\{x^a\}_{a\in(\{0,1\}^t)^k}$ which has size $2^{t\cdot k}$.

In order to reduce the size of the basis, we restrict ourselves to the k-symmetric functions $g : (\{0,1\}^t)^k \to \{0,1\}$ (as will be the case in Section 3.2). This condition leads to the following equalities between coefficients.

▶ **Lemma 3.** *For any $a = (a_1,\dots,a_k) \in (\{0,1\}^t)^k$ and any permutation $\sigma \in S_k$, if $g : (\{0,1\}^t)^k \to \{0,1\}$ is a k-symmetric function then the coefficients $\widehat{g}(a)$ and $\widehat{g}(\sigma(a))$ in the $\mathbb{R}$-multilinear representation of g are equal (where $\sigma(a) = (a_{\sigma(1)},\dots,a_{\sigma(k)})$).*

Proof. The proof is direct from Equation (2). ◀

This lemma motivates the definition of the following polynomials, that will be used to obtain a basis for the k-symmetric functions over $(\{0,1\}^t)^k$.

▶ **Definition 4.** Given $a \in (\{0,1\}^t)^k$, the *monomial k-symmetric polynomial* $m_a(x)$ over variables $(x_{u,v})_{1\leq u\leq k, 1\leq v\leq t}$ is defined to be the sum of all the *distinct* monomials $x^{\sigma(a)}$ where $\sigma \in S_k$ ranges over all the permutations.

▶ **Example 5.** If $(t,k) = (2,3)$ and $a = ((1,1),(0,1),(0,1))$ then $m_a(x) = x_{1,1}x_{1,2}x_{2,2}x_{3,2} + x_{1,2}x_{2,1}x_{2,2}x_{3,2} + x_{1,2}x_{2,2}x_{3,1}x_{3,2}$.

According to Lemma 3, any k-symmetric function $g : (\{0,1\}^t)^k \to \{0,1\}$ can be expressed as a linear combination of monomial k-symmetric polynomials. From this observation, we can derive a basis for the k-symmetric functions by taking all the *distinct* monomial k-symmetric polynomials. We specify a subset of elements $a \in (\{0,1\}^t)^k$ that corresponds to this basis.

▶ **Definition 6.** We define a tuple $a = (a_1, \ldots, a_k) \in (\{0,1\}^t)^k$ to be *sorted*, if $|a_u| \leq |a_{u'}|$ for all $1 \leq u \leq u' \leq k$, and $a_u \leq_{lex} a_{u'}$ whenever $|a_u| = |a_{u'}|$ (where $|a_u|$ is the Hamming weight of a_u, and $\leq_{lex}$ is the lexicographic order over $\{0,1\}^t$). The set of all the sorted tuples over $(\{0,1\}^t)^k$ is denoted $\mathcal{S}(t,k)$.

▶ **Lemma 7.** *The set $\{m_a(x) : a \in \mathcal{S}(t,k)\}$ is a basis for the k-symmetric functions $g : (\{0,1\}^t)^k \to \{0,1\}$. Moreover, it has size $\binom{k+2^t-1}{2^t-1}$.*

Proof. It is straightforward to see that all the possible monomial k-symmetric polynomials belong to $\{m_a(x) : a \in \mathcal{S}(t,k)\}$, and that no two elements in this set have a monomial in common. Thus, it is a basis for the k-symmetric functions.

Consider the total order $\prec$ over $\{0,1\}^t$ defined as $a_u \prec a_{u'}$ if and only if $|a_u| \leq |a_{u'}|$, or $|a_u| = |a_{u'}|$ and $a_u \leq_{lex} a_{u'}$. Each $a \in \mathcal{S}(t,k)$ can be seen as a (distinct) non-decreasing sequence of length k from the totally ordered set $(\{0,1\}^t, \prec)$ of size 2^t. The total number of such sequences is known to be $\binom{k+2^t-1}{2^t-1}$. ◀

Finally, given a parameter n, we want the coefficients of the k-symmetric functions in the chosen basis to be less than n^c for some constant c independent of k and t (requirement (d)). To this end, it suffices to reformulate the previous results over a field $\mathbb{F}_p$, for some prime $p \in (n, 2n)$. We obtain the following polynomial representation for k-symmetric functions:

▶ **Proposition 8.** *Any k-symmetric function $g : (\{0,1\}^t)^k \to \{0,1\}$ can be written as*

$$g(x) = \sum_{a \in \mathcal{S}(t,k)} c_a(g) \cdot m_a(x) \mod p$$

where $p \in (n, 2n)$ is prime, $c_a(g) \in \mathbb{F}_p$ and m_a is the monomial k-symmetric polynomial corresponding to the sorted tuple a. Moreover, $\mathcal{S}(t,k)$ has size $\binom{k+2^t-1}{2^t-1}$.

3 Simultaneous Protocol for $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$

We now describe in detail our simultaneous protocol for symmetric composed functions. The result is divided into two parts. We first give in Section 3.1 a protocol of cost $\mathcal{O}\left(k(k+d)^{d-1} \log n\right)$ for $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ when $k \geq 4^{d-1} \log n$. This is a generalization of the idea of [3], which was based on solving a particular equation. We build upon this result in Section 3.2 to give an efficient protocol of cost $\mathcal{O}\left(\log^{4d}(n)\right)$ for $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ when $k \geq 4^{2d} \log n$ and d is constant. This last result uses the protocol of Theorem 9 as a subroutine, and the polynomial representations described in Section 2.

3.1 The Equation Solving part

We extend the protocol for $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_2}$ from [3] to any $d > 1$. It applies to all functions in $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ as long as $k \geq 4^{d-1} \log n$, but it is not efficient if d is nonconstant or if the number k of players is super-polylogarithmic (we will remove this last condition in the next section). For convenience in the proof, we state the result over $\mathbb{Z}_{d+1}$ instead of $\mathbb{Z}_d$:

▶ **Theorem 9.** *Let M be a $k \times n$ matrix over $\mathbb{Z}_{d+1}$, where $n \geq 2$ and $d \geq 1$. For $0 \leq e_1 + \cdots + e_d \leq k$, denote $y_{e_1,\ldots,e_d}$ the number of columns of M with exactly e_s occurrences of each $s \in \mathbb{Z}_{d+1} \backslash \{0\}$. For each $i = 1, \ldots, k$, let player i see all of M except row i. If $k \geq 4^d \log n$ then there exists a deterministic simultaneous NOF protocol of cost $k\binom{k+d}{d}\lceil \log n \rceil$, at the end of which the referee knows all the $y_{e_1,\ldots,e_d}$'s.*

Proof. The communication part of the protocol is pretty simple: each player i sends to the referee the number of columns $a^i_{e_1,\dots,e_d}$ which contain, *from her point of view* (i.e. without taking row i into account), exactly e_s occurrences of each element $s \in \{1,\dots,d\}$ (for all $e_1+\cdots+e_d \leq k-1$).

The referee computes then $b_{e_1,\dots,e_d} = \sum_{i=1}^{k} a^i_{e_1,\dots,e_d}$ (for all $e_1+\cdots+e_d \leq k-1$). The important thing to note is that these numbers must verify the following equalities:

$$\begin{cases} (k-(e_1+\cdots+e_d))y_{e_1,\dots,e_d} + \sum_{s=1}^{d}(e_s+1)y_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_d} = b_{e_1,\dots,e_d} \\ 0 \leq e_1+\cdots+e_d \leq k-1 \end{cases} \tag{3}$$

To see why it is true, consider a column C of M that contributes to a given $b_{e_1,\dots,e_d}$. Either C contains exactly e_s occurrences of each element $s \in \{1,\dots,d\}$, or there is one $s' \in \{1,\dots,d\}$ that occurs $e_{s'}+1$ times in C (the other s having exactly e_s occurrences in C). In the first case, C contributes to $y_{e_1,\dots,e_d}$ and to the quantity $a_i(e_1,\dots,e_d)$ of each player i having a 0 entry of C on her forehead (there are $k-(e_1+\cdots+e_d)$ such players). In the second case, C contributes to $y_{e_1,\dots,e_{s'-1},e_{s'}+1,e_{s'+1},\dots,e_d}$ and to the quantity $a_i(e_1,\dots,e_d)$ of each player i having a s' entry of C on her forehead (there are $e_{s'}+1$ such players). Thus, the total contribution for $b_{e_1,\dots,e_d}$ is $(k-(e_1+\cdots+e_d))y_{e_1,\dots,e_d}+\sum_{s'=1}^{d}(e_{s'}+1)y_{e_1,\dots,e_{s'-1},e_{s'}+1,e_{s'+1},\dots,e_d}$.

Equalities (3) can be seen as a system of equations whose unknowns are the $y_{e_1,\dots,e_d}$'s. Since the referee is not computationally restricted she can enumerate all the integral solutions, but she does not know which one corresponds to matrix M. The key lemma is to show that Equations (3), under mild constraints

$$y_{e_1,\dots,e_d} \geq 0,\ 0 \leq e_1+\cdots+e_d \leq k \quad \textit{and} \quad \sum_{e_1+\cdots+e_d \leq k} y_{e_1,\dots,e_d} \leq n \tag{4}$$

have at most one integral solution when $k \geq 4^d \log n$. We prove it by induction on d (the base case $d=1$ corresponds to the work of [3], the induction step is more involved and is given in Appendix A). Consequently, the referee is able to know unambiguously the correct $y_{e_1,\dots,e_d}$'s that correspond to M. This protocol is clearly simultaneous since the players do not need to talk to each other. Each of the k players sends $\binom{k+d}{d}$ numbers $a_i(e_1,\dots,e_d) \leq n$. Thus the total communication cost is at most $k\binom{k+d}{d}\lceil \log n \rceil$. ◀

▶ **Corollary 10.** *Let $n \geq 2$, $d \geq 2$ and suppose $k \geq 4^{d-1}\log n$. There is a deterministic simultaneous NOF protocol of cost $k\binom{k+d-1}{d-1}\lceil \log n \rceil$, at the end of which the referee can compute* all *composed functions $f \circ g \in \mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$ of her choice.*

This result can also be adapted to the case of $k < 4^d \log n$ players by splitting the initial matrix into sufficiently many parts. Previously, Ada *et. al.* [1] also generalized their work to any number k of players, by giving a protocol of cost $\mathcal{O}\left(n/2^k \cdot \log n + k \log n\right)$ for $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}$. However, it was not simultaneous and it did not apply to $t > 1$.

▶ **Proposition 11.** *Let M be a $k \times n$ matrix over $\mathbb{Z}_{d+1}$, where $n \geq 2$ and $d \geq 1$. For $0 \leq e_1+\cdots+e_d \leq k$, denote $y_{e_1,\dots,e_d}$ the number of columns of M with exactly e_s occurrences of each $s \in \mathbb{Z}_{d+1}\backslash\{0\}$. For each $i = 1,\dots,k$, let player i see all of M except row i. If $4^d \leq k < 4^d \log n$ then there exists a deterministic simultaneous NOF protocol of cost at most $\mathcal{O}\left(\frac{n}{2^{k/4^d}} \cdot (k+d)^{d+2}\right)$, at the end of which the referee knows all the $y_{e_1,\dots,e_d}$'s.*

Proof. We split M into $\left\lceil \frac{n}{\lfloor 2^{k/4^d} \rfloor} \right\rceil$ matrices, each of size $k \times \left\lfloor 2^{k/4^d} \right\rfloor$ (except one matrix that can have less columns). These matrices have few enough columns to apply (separately) the

protocol of Theorem 9 on them. The $y_{e_1,\dots,e_d}$'s for the original matrix M are computed by recombining all the obtained results. The total cost is $\mathcal{O}\left(\frac{n}{2^{k/4^d}} \cdot k\binom{k+d}{d} \log\left(2^{k/4^d}\right)\right)$. ◀

3.2 The Polynomial Representation part

Using the polynomial representation of Proposition 8, we give a protocol that improves upon Corollary 10 in two ways: it is still efficient when k is super-polylogarithmic, and the inner functions $g_1, \dots, g_n$ can be different (i.e. it applies to $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ instead of $\mathsf{SYM} \circ \mathsf{SYM}_{\mathbb{Z}_d}$).

▶ **Theorem 12.** *Let $n \geq 2$, $d \geq 2$ and suppose $k \geq 4^{2^{\lceil \log d \rceil}} \log n$. For any composed function $f \circ \vec{g} \in \mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ there exists a deterministic simultaneous NOF protocol that computes it with cost $4^{2^{\lceil \log d \rceil + 2}} \log^{2 \cdot 2^{\lceil \log d \rceil}}(n)$.*

Proof. Let $\vec{g} = (g_1, \dots, g_n)$. In order to use the polynomial representation of Section 2, we change the range of the g_j functions as $g_j : (\{0,1\}^t)^k \to \{0,1\}$, where $t = \lceil \log d \rceil$. This requires to encode each number $x \in \mathbb{Z}_d$ as an element $\bar{x} \in \{0,1\}^t$. If d is not a power of two then some $y \in \{0,1\}^t$ will not correspond to any $x \in \mathbb{Z}_d$. We extend each g_j as the zero function on inputs that contain such numbers (note that the functions are still k-symmetric).

The input is now a $k \times (t \cdot n)$ boolean matrix M. Each function g_j acts on the j^{th} block of M, which will be denoted $B_j \in (\{0,1\}^t)^k$. Let $\ell = 4^{2^t} \log n$, so that only the first ℓ players are going to speak. For each block B_j, if we let $v_j \in (\{0,1\}^t)^{(k-\ell)}$ be the sub-block occurring from row $\ell+1$ to k, then $g_j : (\{0,1\}^t)^k \to \{0,1\}$ induces a new function $\widetilde{g_j} : (\{0,1\}^t)^\ell \to \{0,1\}$ such that $\widetilde{g_j}(u) = g_j(u \cdot v_j)$. Moreover, $\widetilde{g_j}$ is still a symmetric function. Thus, our task reduces to find an efficient simultaneous protocol for $f \circ (\widetilde{g_1}, \dots, \widetilde{g_n})$ with $\ell = 4^{2^t} \log n$ players. We denote $\widetilde{M}$ the $\ell \times (t \cdot n)$ submatrix of M on which we now work, and $\widetilde{B_j} \in (\{0,1\}^t)^\ell$ is the sub-block of B_j corresponding to $\widetilde{M}$.

We cannot apply directly the protocol of Theorem 9, since it only works for equal inner functions $\widetilde{g_1} = \dots = \widetilde{g_n}$. Instead, we use first Proposition 8 on the $\widetilde{g_j}$ functions: for each $j \in \{1, \dots, n\}$ there exist coefficients $(c_a(\widetilde{g_j}))_{a \in \mathcal{S}(t,\ell)}$ over $\mathbb{F}_p$ such that $\widetilde{g_j}(x) = \sum_{a \in \mathcal{S}(t,\ell)} c_a(\widetilde{g_j}) \cdot m_a(x) \mod p$ where $p \in (n, 2n)$, m_a is the monomial k-symmetric polynomial corresponding to the sorted tuple a and $|\mathcal{S}(t,\ell)| = \binom{\ell + 2^t - 1}{2^t - 1}$. The coefficients $c_a(\widetilde{g_j})$ are known by the first ℓ players, but not by the referee (since they depend on rows $\ell+1$ to k of M).

For each $a \in \mathcal{S}(t,\ell)$, the players build a new matrix $\widetilde{M_a}$ of size $\ell \times (c_a(\widetilde{g_1}) + \dots + c_a(\widetilde{g_n}))$ where block $\widetilde{B_j}$ from $\widetilde{M}$ is copied $c_a(\widetilde{g_j}) \in [0, 2n)$ times. Note that $\widetilde{M_a}$ has at most $2n^2$ blocks, and there are enough players $\ell = 4^{2^t} \log n$ for applying (the boolean input version of) the simultaneous protocol of Theorem 9. It allows the referee to know the number of blocks of $\widetilde{M_a}$ which are equal – up to row permutation – to any $\widetilde{B} \in (\{0,1\}^t)^\ell$. This information is sufficient to compute $\sum_{j=1}^n c_a(\widetilde{g_j}) \cdot m_a(\widetilde{B_j})$ since the m_a functions are k-symmetric.

Finally, the referee sums these quantities modulo p over all a. It gives her $\sum_{a \in \mathcal{S}(t,\ell)} \sum_{j=1}^n c_a(\widetilde{g_j}) \cdot m_a(\widetilde{B_j}) \mod p = \sum_{j=1}^n \widetilde{g_j}(\widetilde{B_j}) \mod p$. Since $\sum_{j=1}^n \widetilde{g_j}(\widetilde{B_j}) \leq n$ and $p > n$, it equals $\sum_{j=1}^n \widetilde{g_j}(\widetilde{B_j}) = \sum_{j=1}^n g_j(B_j)$. Knowing this, the referee can compute $f \circ (g_1, \dots, g_n)(M)$ since f is symmetric.

Regarding the cost of the protocol, we applied $|\mathcal{S}(t,\ell)| = \binom{\ell + 2^t - 1}{2^t - 1}$ times the protocol of Theorem 9, with ℓ players and inputs of size at most $2n^2$. Thus the total cost is at most $\binom{\ell+2^t-1}{2^t-1} \cdot \ell \binom{\ell+2^t-1}{2^t-1} \lceil \log 2n^2 \rceil \leq \ell(\ell + 2^t)^{2^{t+1}-2} \log n$. Since $\ell = 4^{2^t} \log n$ and $t = \lceil \log d \rceil$, this is less than $4^{2^t + (2^t+1)(2^{t+1}-2)} \log^{2^{t+1}}(n) \leq 4^{2^{\lceil \log d \rceil + 2}} \log^{2 \cdot 2^{\lceil \log d \rceil}}(n)$. ◀

4 Conclusion and Open Problems

One of the main open problems in communication complexity remains to find a function which is hard to compute for $k \geq \log n$ players in the simultaneous Number On the Forehead model. We discarded this possibility for the composed functions in $\mathsf{SYM} \circ \overrightarrow{\mathsf{SYM}}_{\mathbb{Z}_d}$ (for constant d) by giving the first efficient *deterministic simultaneous* protocol for composed functions of block-width $t > 1$. In the non-simultaneous setting, the best result so far applies to $\mathsf{SYM} \circ \overrightarrow{\mathsf{ANY}}_{\mathbb{Z}_d}$ and $d = \mathcal{O}(\text{polylog}\, n)$ [17]. Extending these protocols to larger d, bigger families of composed functions or to the simultaneous setting (for [17]) would give a better insight on composed functions. Indeed, it is conjectured that the $\log n$ barrier can be broken by such functions for large d, two of the candidates being $\textsc{Maj} \circ \textsc{Maj}_t$ and $\textsc{Maj} \circ \textsc{Thr}_t^s$.

Note that both the Equation Solving and the Polynomial Representation parts of our protocol are bottleneck for handling non-constant d in our result. It could be interesting to restrict to smaller families than symmetric functions (or to choose specific inner or outer functions, such as threshold functions), or to find other relevant equations that could be solved by the referee with fewer information than in our protocol.

Apart from composed functions, there are a few other candidates for breaking the $\log n$ barrier. Some of them are matrix related problems, such as deciding the top-left entry of the multiplication of k matrices in $\mathbb{F}_2^{n \times n}$ (an $\Omega(n/2^k)$ lower bound has been obtained by Raz [30]). More recently, Gowers and Viola [20] studied the interleaved group products, where each player receives a tuple $(x_{i,1}, \ldots, x_{i,n})$ in $G = SL(2, q)$, with the promise that $\prod_{i=1}^{n} x_{1,i} \cdots x_{k,i} = g$ *or* h. Finding which is the case has cost $\Omega(n \log |G|)$ when $k = 2$, and it is conjectured to remain hard for larger k.

A Lemma for the Equation Solving part

In this section, we prove the following lemma:

▶ **Lemma 13.** *Let $n \geq 2$, $d \geq 1$ and $k \geq 4^d \log n$. Let $(b_{e_1,\dots,e_d})_{0 \leq e_1+\cdots+e_d \leq k-1}$ be integers. Consider the following system of equations:*

$$\begin{cases} (k - (e_1 + \cdots + e_d))y_{e_1,\dots,e_d} + \sum_{s=1}^{d} (e_s + 1) y_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_d} = b_{e_1,\dots,e_d} \\ 0 \leq e_1 + \cdots + e_d \leq k - 1 \end{cases} \tag{5}$$

Assume further that

$$y_{e_1,\dots,e_d} \geq 0, \ 0 \leq e_1 + \cdots + e_d \leq k \quad \text{and} \quad \sum_{e_1+\cdots+e_d \leq k} y_{e_1,\dots,e_d} \leq n \tag{6}$$

Then, under constraints (6), the system of equations (5) has at most one integral solution.

We will show a stronger result:

▶ **Lemma 14.** *Let $n \geq 2$, $d \geq 1$ and $k > 4^d \log n - d$. Let $(b_{e_1,\dots,e_d})_{0 \leq e_1+\cdots+e_d \leq k-1}$ be integers. Consider the following system of equations:*

$$\begin{cases} (k - (e_1 + \cdots + e_d))z_{e_1,\dots,e_d} + \sum_{s=1}^{d} (e_s + 1) z_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_d} = 0 \\ 0 \leq e_1 + \cdots + e_d \leq k - 1 \end{cases} \tag{7}$$

Assume further that

$$\sum_{e_1+\cdots+e_d \leq k} |z_{e_1,\dots,e_d}| \leq 2n \tag{8}$$

Then, under constraints (8), the system of equations (7) cannot have a non-zero integral solution.

Proof that Lemma 14 implies Lemma 13. Assume by contradiction that Equations (5) under Constraints (6) have two different integral solutions $y = (y_{e_1,\dots,e_d})_{0 \leq e_1+\cdots+e_d \leq k}$ and $y' = (y'_{e_1,\dots,e_d})_{0 \leq e_1+\cdots+e_d \leq k}$ for $k \geq 4^d \log n$. Define $z_{e_1,\dots,e_d} = y_{e_1,\dots,e_d} - y'_{e_1,\dots,e_d}$. It is easy

to see that it must verify (7), and since $y \neq y'$ there is at least one $z_{e_1,\dots,e_d} \neq 0$. Finally, since $z_{e_1,\dots,e_d} = |y_{e_1,\dots,e_d} - y'_{e_1,\dots,e_d}| \leq y_{e_1,\dots,e_d} + y'_{e_1,\dots,e_d}$, we have

$$\sum_{e_1+\dots+e_d\leq k} |z_{e_1,\dots,e_d}| \leq \sum_{e_1+\dots+e_d\leq k} (y_{e_1,\dots,e_d} + y'_{e_1,\dots,e_d}) \leq 2n$$

◀

Proof of Lemma 14. We prove the result by induction on d. The base case has already been established in [3], we recall it for completeness.

Base case (d = 1). We denote $(z_i)_{0\leq i\leq k}$ the variables. Equations (7) under Constraints (8) become

$$\begin{cases} (k-i)z_i + (i+1)z_{i+1} = 0, \ i = 0, 1, \dots, k-1 \\ \sum_{i=0}^{k} |z_i| \leq 2n \end{cases}$$

Thus, $z_1 = -kz_0 = -\binom{k}{1}z_0$, $z_2 = -\frac{k-1}{2}z_1 = \binom{k}{2}z_0$, and more generally $z_i = (-1)^i\binom{k}{i}z_0$. Consequently, if $(z_i)_{0\leq i\leq k}$ is a nonzero integral solution, then $z_0 \neq 0$ and $|z_i| = \binom{k}{i}|z_0| \geq \binom{k}{i}$ for all i. We obtain a contradiction: $2n \geq \sum_{i=0}^{k}|z_i| \geq \sum_{i=0}^{k}\binom{k}{i} = 2^k > 2^{4\log n-1} > 2n$. Thus, Lemma 14 is true for $d = 1$.

Induction step. Assuming that Lemma 14 is true for $d-1$, we prove that it is also the case for $d \geq 2$. Suppose by contradiction that Equations (7) under Constraints (8) have a non-zero integral solution $z = (z_{e_1,\dots,e_d})_{0\leq e_1+\dots+e_d\leq k}$ for $k > 4^d \log n - d$. As in the proof of the base case, we want to show $\sum_{e_1+\dots+e_d\leq k}|z_{e_1,\dots,e_d}| > 2n$, which would be a contradiction.

To this end, we are going to focus for each $0 \leq i \leq k$ on the largest element of $\{|z_{e_1,\dots,e_d}| : e_1 + \dots + e_d = i\}$. We define

$$Z_i = \max_{e_1+\dots+e_d=i} |z_{e_1,\dots,e_d}| \quad \text{and} \quad k^+ = \min\{i : Z_i \neq 0\}$$

Since z is a nonzero solution, k^+ is well defined. We conduct the proof as follows:

(a) Using the induction hypothesis, we show that the first nonzero Z_i must occur for $i = k^+ \leq 4^{d-1}\log n - (d-1)$.

(b) The sequence $(Z_i)_i$ verifies $\frac{k-i}{i+d}Z_i \leq Z_{i+1}$.

(c) Using the two previous results, we prove $\sum_{i=0}^{k} Z_i > 2n$.

The contradiction comes then from $\sum_{i=0}^{k} Z_i \leq \sum_{e_1+\dots+e_d\leq k}|z_{e_1,\dots,e_d}| \leq 2n$

Proof of (a). Assume $k^+ > 0$ (otherwise the result is trivial). According to Equations (7), and knowing that $z_{e_1,\dots,e_d} = 0$ whenever $e_1 + \dots + e_d < k^+$, we have

$$\sum_{s=1}^{d}(e_s+1)z_{e_1,\dots,e_s-1,e_s+1,e_{s+1},\dots,e_d} = 0$$

for all $e_1 + \dots + e_d = k^+ - 1$. If we set apart the last term $z_{e_1,\dots,e_{d-1},e_d+1}$, we obtain

$$(k^+ - (e_1 + \dots + e_{d-1}))z_{e_1,\dots,e_{d-1},e_d+1} + \sum_{s=1}^{d-1}(e_s+1)z_{e_1,\dots,e_s-1,e_s+1,e_{s+1},\dots,e_d} = 0$$

Let $z'_{e_1,\dots,e_{d-1}} = z_{e_1,\dots,e_{d-1},k^+-(e_1+\cdots+e_{d-1})}$ for all $0 \leq e_1+\cdots+e_{d-1} \leq k^+$. We can change the variables in the previous equation as follows

$$\begin{cases} (k^+ - (e_1+\cdots+e_{d-1}))z'_{e_1,\dots,e_{d-1}} + \sum_{s=1}^{d-1}(e_s+1)z'_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_{d-1}} = 0 \\ 0 \leq e_1+\cdots+e_{d-1} \leq k^+ - 1 \end{cases}$$

This is equivalent to Equations (7) at rank $d-1$. Moreover, $\sum_{e_1+\cdots+e_{d-1}\leq k^+} |z'_{e_1,\dots,e_{d-1}}| \leq 2n$, and there exists $e_1+\cdots+e_d = k^+$ such that $z_{e_1,\dots,e_d} \neq 0$ (by definition of k^+), i.e. $z'_{e_1,\dots,e_{d-1}} \neq 0$. Consequently, it corresponds to a nonzero integral solution to Equations (7) under Constraints (8) at rank $d-1$ with parameter k^+. According to our induction hypothesis it implies $k^+ \leq 4^{d-1}\log n - (d-1)$.

Proof of (b). Setting apart $z_{e_1,\dots,e_d}$ in Equations (7), and using the triangle inequality, we obtain

$$(k-(e_1+\cdots+e_d))|z_{e_1,\dots,e_d}| \leq \sum_{s=1}^{d}(e_s+1)|z_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_d}|$$

for all $e_1+\cdots+e_d \leq k$. In particular, if we choose $e_1+\cdots+e_d$ such that $Z_{e_1+\cdots+e_d} = |z_{e_1,\dots,e_d}|$ then

$$\begin{aligned}(k-(e_1+\cdots+e_d))Z_{e_1+\cdots+e_d} &\leq \sum_{s=1}^{d}(e_s+1)|z_{e_1,\dots,e_{s-1},e_s+1,e_{s+1},\dots,e_d}| \\ &\leq \sum_{s=1}^{d}(e_s+1)Z_{e_1+\cdots+e_d+1} \\ &\leq (e_1+\cdots+e_d+d)Z_{e_1+\cdots+e_d+1}\end{aligned}$$

Thus $(k-i)Z_i \leq (i+d)Z_{i+1}$, where $i = e_1+\cdots+e_d$.

Proof of (c). Using (b), first note for $i > k^+$ that

$$\begin{aligned}Z_i &\geq \frac{k-(i-1)}{(i-1)+d}\cdot\frac{k-(i-2)}{(i-2)+d}\cdots\frac{k-k^+}{k^++d}\cdot Z_{k^+} \\ &= \frac{(k-k^+)!}{(k-i)!}\cdot\frac{(k^++d-1)!}{(i+d-1)!}\cdot Z_{k^+} \\ &= \frac{(k+d-1)!}{(k-i)!(i+d-1)!}\cdot\frac{(k-k^+)!(k^++d-1)!}{(k+d-1)!}\cdot Z_{k^+} \\ &= \binom{k+d-1}{i+d-1}\binom{k+d-1}{k^++d-1}^{-1}\cdot Z_{k^+} \\ &\geq \binom{k+d-1}{i+d-1}\binom{k+d-1}{k^++d-1}^{-1} \qquad \text{since } Z_{k^+}\geq 1\end{aligned}$$

According to (a) and our initial hypothesis on k, we have $k^++d-1 \leq 4^{d-1}\log n \leq (k+d-1)/4$. Thus $\sum_{i=k^+}^{k}\binom{k+d-1}{i+d-1} \geq \frac{1}{2}\cdot\sum_{i=0}^{k+d-1}\binom{k+d-1}{i} = 2^{k+d-2}$ and $\binom{k+d-1}{k^++d-1}^{-1} \geq 2^{-(k+d-1)H(1/4)}$ (using the well-known bound $\binom{m}{\alpha m} \leq 2^{mH(\alpha)}$ where $H(\alpha) = -\log(\alpha^\alpha(1-\alpha)^{1-\alpha})$). Consequently, since $d \geq 2$ and $n \geq 2$, we obtain $\sum_{i=k^+}^{k} Z_i \geq 2^{(1-H(1/4))(k+d-1)-1}$ $\geq 2^{(1-H(1/4))4^d\log n - 1} > 2n$. ◀

Sliding Windows over Context-Free Languages

Abstract

We study the space complexity of sliding window streaming algorithms that check membership of the window content in a fixed context-free language. For regular languages, this complexity is either constant, logarithmic or linear [4]. We prove that every context-free language whose sliding window space complexity is $\log_2(n) - \omega(1)$ must be regular and has constant space complexity. Moreover, for every $c \in \mathbb{N}$, $c \geq 1$ we construct a (nondeterministic) context-free language whose sliding window space complexity is $\mathcal{O}(n^{1/c}) \setminus o(n^{1/c})$. Finally, we give an example of a deterministic one-counter language whose sliding window space complexity is $\Theta((\log n)^2)$.

1 Introduction

In many streaming applications, data items are outdated after a certain time and the sliding window model is a simple way to model this: *Sliding window algorithms* process an input sequence $a_1 a_2 \cdots a_m$ from left to right and have at time t only direct access to the current symbol a_t. Moreover, at each time instant t the algorithm is required to compute a value that depends on the last n symbols. The value n is called the *window size* and the last n symbols form the *active window* at time t. A general goal in the area of sliding window algorithms is to avoid the explicit storage of the window content (which requires $\Omega(n)$ bits), and, instead, to work in considerably smaller space, e.g., polylogarithmic space in the window size n. An introduction into the sliding window model can be found in [1, Chapter 8].

In our recent papers [3, 4] we initiated the study of sliding window algorithms for regular languages. In general, a sliding window algorithm for a language $L \subseteq \Sigma^*$ decides, at every time instant, whether the word in the active window belongs to L. In [4] we proved that for every regular language L the optimal space bound for a sliding window algorithm for L is either constant, logarithmic or linear in the window size. In [3] we also gave several characterizations for the three space classes: A regular language has a sliding window algorithm with space bound $\mathcal{O}(\log n)$ (resp., $\mathcal{O}(1)$) if and only if it belongs to the Boolean closure of regular left ideals and regular length languages (resp., the Boolean closure of suffix-testable languages and regular length languages); see [3] for the formal definition of these language classes.

In this paper we investigate to which extent the results from [3, 4] can be generalized to context-free languages. Our first main result (Theorem 2) states that if L is a context-free language that has a sliding window algorithm with space bound $\log_2(n) - \omega(1)$ (recall that $f(n) \in \omega(1)$ iff $\forall c > 0\, \exists m\, \forall n \geq m : f(n) \geq c$) then L must be regular. By the results from [3, 4] this implies that L has a constant space sliding window algorithm and is a Boolean combination of suffix-testable languages and regular length languages. Our proof uses a variant of the classical pumping lemma. The crucial observation is that taking a reversed Greibach normal form grammar for G, we can ensure that pumping in a word of length n does not affect a suffix of length $o(n)$.

Theorem 2 shows that, analogously to regular languages, there is a gap between $\mathcal{O}(1)$ and $\mathcal{O}(\log n)$ in the space complexity spectrum for context-free languages. This leads to the question whether there is also a gap between $\mathcal{O}(\log n)$ and $\mathcal{O}(n)$ (as it is the case for regular languages). We answer this question negatively. For this we construct from a linear bounded automaton (LBA) a context-free language, whose sliding window space complexity is related to the time complexity of the LBA in a certain way. The precise technical statement can be found in Theorem 9. From this result we obtain for every $c \in \mathbb{N}$ a context-free language, whose optimal sliding window algorithm uses space $\mathcal{O}(n^{1/c})$ (Theorem 10).

The context-free languages from the proof of Theorem 9 are non-deterministic. They are obtained by taking the complement of all accepting computations of an LBA on an input from a^* (as usual, a computation is encoded by a sequence of configuration words). These complements are context-free since one can guess errors, but they are not deterministic context-free. This leads to the question whether there exist deterministic context-free languages for which the optimal sliding window algorithm has space complexity $o(n) \setminus \mathcal{O}(\log n)$. We answer this question positively by constructing a deterministic one-counter language whose optimal sliding window algorithm uses space $\mathcal{O}((\log n)^2)$ (Theorem 15).

The results from Theorem 10 and 15 are also shown for a more general sliding window model, which is known as the variable-size model in the literature. In the sliding window model discussed so far, the window size is fixed and for every window size there exists a streaming algorithm. In contrast, in the variable-size model, there is a single streaming algorithm and the window can grow and shrink. In other words, the arrival of new symbols and expiration of old symbols can happen independently. A formal definition can be found in Section 2. The space complexity of a variable-size streaming algorithm is measured with respect to the maximal window size seen in the past. In [4] it was shown that analogously to the fixed-size model, the space complexity of a regular language with respect to the variable-size model is either constant, logarithmic, or linear. Moreover, a regular language has space complexity $\mathcal{O}(\log n)$ in the variable-size model if and only if it has space complexity $\mathcal{O}(\log n)$ in the fixed-size model (on the other hand only trivial languages have constant space complexity in the variable-size model). Corollary 13 states that there exists a deterministic one-counter language whose optimal variable-size sliding window algorithm uses space $\Theta((\log n)^2)$.

Finally, we prove that our results for deterministic one-counter languages can be also shown for the reversals of the latter (i.e., for languages that can be accepted by a deterministic one-counter automaton that works from right to left). This is not obvious, since the reversal of a deterministic context-free language is in general not deterministic context-free. Moreover, the arguments for our space trichotomy result for regular languages [3, 4] mainly use a DFA for the reverse language, hence one might think that these arguments extend to reversals of deterministic context-free languages.

2 Preliminaries

For a function $f : \mathbb{N} \to \mathbb{N}$, we use the standard Landau notations $\mathcal{O}(f)$, $\Omega(f)$, $o(f)$ and $\Theta(f)$.

We assume that the reader is familiar with the basic notions of formal languages, in particular regular languages, see e.g. [7] for more details. Let Σ be a finite alphabet of symbols. With ε we denote the empty word. For a word $w = a_1 \cdots a_m \in \Sigma^*$ of length $|w| = m$ we define $w[i] = a_i$ and $w[i : j] = a_i \cdots a_j$ if $i \leq j$ and $w[i : j] = \varepsilon$ if $i > j$. We define $w[i :] = w[i : m]$ and $w[: j] = [1 : j]$. Let $\Sigma^n = \{w \in \Sigma^* : |w| = n\}$, $\Sigma^{\leq n} = \{w \in \Sigma^* : |w| \leq n\}$, and $\Sigma^{\geq n} = \{w \in \Sigma^* : |w| \geq n\}$. A word $v \in \Sigma^*$ is a *prefix* (resp., *suffix*) of the word w if there exists a word $u \in \Sigma^*$ such that $w = vu$ (resp., $w = uv$). With $\mathrm{prefix}(w)$ we denote the set of all prefixes of w. For a word $w = a_1 a_2 \cdots a_m$ let $\mathrm{rev}(w) = a_m \cdots a_2 a_1$ denotes the word w read from right to left.

2.1 Automata and streaming algorithms

We use standard definitions from automata theory. A *deterministic automaton* is a tuple $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$, where Q is a possibly infinite set of states, Σ is an alphabet, $q_0 \in Q$ is the initial states, $\delta \colon Q \times \Sigma \to Q$ is the transition relation, and F is the set of final states. The transition function δ is extended to a function $\delta \colon Q \times \Sigma^* \to Q$ in the usual way and we set $\mathcal{A}(x) = \delta(q_0, x)$ for all $x \in \Sigma^*$. The language accepted from a state $q \in Q$ is denoted by $L(\mathcal{A}, q) = \{x \in \Sigma^* \mid \delta(q, x) \in F\}$ and the language accepted by $\mathcal{A}$ is defined by $L(\mathcal{A}) = L(\mathcal{A}, q_0)$. If Q is finite, then A is a *deterministic finite automaton* (DFA).

A data stream is a finite sequence of data values. We make the assumption that these data values are from a finite set Σ. Thus, a data stream is a finite word $w = a_1 a_2 \cdots a_m \in \Sigma^*$. A streaming algorithm reads the symbols of a data stream from left to right. At time instant t the algorithm has only access to the symbol a_t and the internal storage, which is encoded by a bit string. The goal of the streaming algorithm is to compute a certain function $f \colon \Sigma^* \to A$ into some domain A, which means that at time instant t the streaming algorithm outputs the value $f(a_1 a_2 \cdots a_t)$. In this paper, we only consider the Boolean case $A = \{0, 1\}$; in other words, the streaming algorithm tests membership in a fixed language. Thus, a *streaming algorithm* over Σ can be seen as a deterministic (possibly infinite) automaton $\mathcal{A} = (S, \Sigma, s_0, \delta, F)$. Furthermore, we abstract away from the actual computation and only analyze the space requirement, which in particular means that we encode the states of $\mathcal{A}$ by bit strings. We describe this encoding by an injective function $\mathrm{enc} \colon S \to \{0, 1\}^*$. The *space function* $\mathrm{space}(\mathcal{A}, \cdot) \colon \Sigma^* \to \mathbb{N}$ specifies the space used by $\mathcal{A}$ on a certain input: For $w \in \Sigma^*$ let $\mathrm{space}(\mathcal{A}, w) = \max\{|\mathrm{enc}(\mathcal{A}(u))| : u \in \mathrm{prefix}(w)\}$. We also say that $\mathcal{A}$ is a *streaming algorithm for* the accepted language $L(\mathcal{A})$.

2.2 Sliding window streaming models

In the above streaming model, the output value of the streaming algorithm at time t depends on the whole past $a_1 a_2 \cdots a_t$ of the data stream. However, in many practical applications one is only interested in the relevant part of the past. Two formalizations of "relevant past" can be found in the literature:

- Only the suffix of $a_1 a_2 \cdots a_t$ of length n is relevant. Here, n is a fixed constant. This streaming model is called the *fixed-size sliding window model*.
- The relevant suffix of $a_1 a_2 \cdots a_t$ is determined by an adversary. In this model, at every time instant the adversary can either remove the first symbol from the active window (expiration of a data value), or add a new symbol at the right end (arrival of a new data value). This streaming model is also called the *variable-size sliding window model*.

In the following we formally define these two models.

Fixed-size sliding windows. Given a word $w \in \Sigma^*$ of length m and a window size $n \geq 0$, we define $\mathrm{last}_n(w) \in \Sigma^n$ by

$$\mathrm{last}_n(w) = \begin{cases} w[m-n+1:] & \text{if } n \leq m, \\ a^{n-m}w, & \text{if } n > m, \end{cases}$$

which is called the *active window*. Here $a \in \Sigma$ is an arbitrary, but fixed, symbol, which fills the initial window. For a language L and $n \geq 0$ let $L_n = \{w \in \Sigma^* : \mathrm{last}_n(w) \in L\}$. A sequence $\mathcal{A} = (\mathcal{A}_n)_{n\geq 0}$ is a *fixed-size sliding window algorithm* for a language $L \subseteq \Sigma^*$ if for each n the $\mathcal{A}_n$ is a streaming algorithm for L_n. Its *space complexity* is the function $f_{\mathcal{A}} \colon \mathbb{N} \to \mathbb{N} \cup \{\infty\}$ where $f_{\mathcal{A}}(n)$ is the maximum encoding length of a state in $\mathcal{A}_n$.

Note that for every language L and every n the language L_n is regular, which ensures that $\mathcal{A}_n$ can be chosen to be a DFA and hence $f_{\mathcal{A}}(n) < \infty$ for all $n \geq 0$. The trivial fixed-size sliding window algorithm for L is the sequence $\mathcal{B} = (\mathcal{B}_n)_{n\geq 0}$, where $\mathcal{B}_n$ is the DFA with state set Σ^n and transitions $au \xrightarrow{b} ub$ for $a, b \in \Sigma$, $u \in \Sigma^{n-1}$. States of $\mathcal{B}_n$ can be encoded with $\mathcal{O}(\log|\Sigma| \cdot n)$ bits. Let $\mathcal{A}_n$ be the minimal DFA for L_n and encode each state of $\mathcal{A}_n$ with at most $\lfloor \log_2(a_n) \rfloor$ bits, where a_n is the number of states of $\mathcal{A}_n$. Then $\mathcal{A} = (\mathcal{A}_n)_{n\geq 0}$ is an *optimal fixed-size sliding window algorithm* $\mathcal{A}$ for L. Finally, we define $F_L(n) = f_{\mathcal{A}}(n) = \lfloor \log_2(a_n) \rfloor$. Thus, F_L is the space complexity of an optimal fixed-size sliding window algorithm for L. Notice that F_L is not necessarily monotonic. For instance, for $L = \{au \colon u \in \{a,b\}^*, |u| \text{ odd}\}$ we have $F_L(2n) \in \Theta(n)$ and $F_L(2n+1) \in \mathcal{O}(1)$. The above trivial algorithm $\mathcal{B}$ yields $F_L(n) \in \mathcal{O}(n)$ for every language L.

Note that the fixed-size sliding window is a *non-uniform* model: for every window size we have a separate streaming algorithm and these algorithms do not have to follow a common pattern. Working with a non-uniform model makes lower bounds stronger. In contrast, the variable-size sliding window model that we discuss next is a uniform model in the sense that there is a single streaming algorithm that works for every window size.

Variable-size sliding windows. For an alphabet Σ we define the extended alphabet $\overline{\Sigma} = \Sigma \cup \{\downarrow\}$. In the variable-size model the *active window* $\mathrm{wnd}(u) \in \Sigma^*$ for a stream $u \in \overline{\Sigma}^*$ is defined by

- $\mathrm{wnd}(\varepsilon) = \varepsilon$
- $\mathrm{wnd}(ua) = \mathrm{wnd}(u)a$ for $a \in \Sigma$
- $\mathrm{wnd}(u\downarrow) = \varepsilon$ if $\mathrm{wnd}(u) = \varepsilon$
- $\mathrm{wnd}(u\downarrow) = v$ if $\mathrm{wnd}(u) = av$ for $a \in \Sigma$

A *variable-size sliding window algorithm* for a language $L \subseteq \Sigma^*$ is a streaming algorithm $\mathcal{A}$ for $\{w \in \overline{\Sigma}^* : \mathrm{wnd}(w) \in L\}$. Following [3], we define its *space complexity* as the function $v_{\mathcal{A}} \colon \mathbb{N} \to \mathbb{N} \cup \{\infty\}$ mapping each window size n to the maximum number of bits used by $\mathcal{A}$ on inputs producing an active window of size at most n. Formally, it is the monotonic function $v_{\mathcal{A}}(n) = \max\{\mathrm{space}(\mathcal{A}, u) : u \in \overline{\Sigma}^*, |\mathrm{wnd}(v)| \leq n \text{ for all } v \in \mathrm{prefix}(u)\}$. By taking the minimal (possibly infinite) deterministic automaton for $\{w \in \overline{\Sigma}^* : \mathrm{wnd}(w) \in L\}$ and encoding states appropriately one can prove that there exists an optimal space bound:

▶ **Lemma 1** ([3]). *For every language $L \subseteq \Sigma^*$ there exists a variable-size sliding window algorithm $\mathcal{A}$ for L such that $v_{\mathcal{A}}(n) \leq v_{\mathcal{B}}(n)$ for every variable-size sliding window algorithm $\mathcal{B}$ for L and every n.*

We define $V_L(n) = v_{\mathcal{A}}(n)$, where $\mathcal{A}$ is a *space optimal variable-size sliding window algorithm* for L from Lemma 1. Since any algorithm in the variable-size model yields an algorithm in the fixed-size model, we have $F_L(n) \leq V_L(n)$.

3 Sliding windows over context-free languages: below logspace

The goal of this section is to prove the following result:

▶ **Theorem 2.** *If L is a context-free language with $F_L(n) \in \log_2(n) - \omega(1)$, then L is regular and $F_L(n) \in \mathcal{O}(1)$.*

We start with some definitions. A language $L \subseteq \Sigma^*$ is *k-suffix testable* if it is a finite Boolean combination of languages of the form $\Sigma^* w$ where $w \in \Sigma^{\leq k}$. An equivalent condition is: for all $x, y, z \in \Sigma^*$ with $|z| = k$ we have $xz \in L$ if and only if $yz \in L$. We call L *suffix testable* if it is k-suffix testable for some k. Note that every suffix testable language is regular. Let $f\colon \mathbb{N} \to \mathbb{N}$ be a function. A language $L \subseteq \Sigma^*$ is *f-suffix definable* if for all $n \in \mathbb{N}$ and words $u, v, w \in \Sigma^*$ such that $|uw| = |vw| = n$ and $|w| = f(n)$ we have $uw \in L$ if and only if $vw \in L$. Similarly, one defines prefix testable and f-prefix definable languages. A *length language* is a language $L \subseteq \Sigma^*$ such that for every $n \geq 0$, either $\Sigma^n \subseteq L$ or $L \cap \Sigma^n = \emptyset$. We prove Theorem 2 in two steps:

▶ **Theorem 3.** *Every language $L \subseteq \Sigma^*$ is $(2^{F_L(n)+1} - 1)$-suffix definable.*

▶ **Theorem 4.** *If a context-free language L is f-suffix definable for a function $f(n) \in o(n)$, then L is a finite Boolean combination of suffix testable languages and regular length languages.*

Combining Theorem 3 and 4 yields Theorem 2: If a context-free language L satisfies $F_L(n) \in \log_2(n) - \omega(1)$ then L is f-suffix definable for a function $f(n) \in o(n)$ by Theorem 3. Theorem 4 implies that L is a finite Boolean combination of suffix testable languages and regular length languages. Hence L is regular and $F_L(n) \in \mathcal{O}(1)$. The rest of this section is devoted to the proofs of Theorem 3 and 4.

3.1 Proof of Theorem 3

For two languages L_1 and L_2 we define their distance $d(L_1, L_2)$ as follows: If $L_1 = L_2$, then we set $d(L_1, L_2) = 0$, and otherwise $d(L_1, L_2) = \sup\{|u| : u \in L_1 \triangle L_2\} + 1$ where $L_1 \triangle L_2 = (L_1 \setminus L_2) \cup (L_2 \setminus L_1)$ denotes the symmetric difference of L_1 and L_2. Notice that $d(L_1, L_2) < \infty$ if and only if $L_1 \triangle L_2$ is finite. If $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$ is a DFA, we define the distance between two states $p, q \in Q$ by $d(p, q) = d(L(\mathcal{A}, p), L(\mathcal{A}, q))$. We will use a result from [5, Lemma 1] stating that $d(p, q) < \infty$ implies that $d(p, q) \leq |Q|$.

▶ **Lemma 5.** *Let $L \subseteq \Sigma^*$ be regular and $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$ be its minimal DFA. We have:*
- **(i)** *$d(p, q) \leq k$ if and only if $\delta(p, z) = \delta(q, z)$ for all $p, q \in Q$ and $z \in \Sigma^k$.*
- **(ii)** *L is k-suffix testable if and only if $d(p, q) \leq k$ for all $p, q \in Q$.*
- **(iii)** *If there exists $k \geq 0$ such that L is k-suffix testable, then L is $|Q|$-suffix testable.*

Proof. The proof of (i) is an easy induction: If $k = 0$, the statement is $d(p, q) = 0$ iff $p = q$, which is true because $\mathcal{A}$ is minimal. For the induction step, we have $d(p, q) \leq k + 1$ iff $d(\delta(p, a), \delta(q, a)) \leq k$ for all $a \in \Sigma$ iff $\delta(p, z) = \delta(q, z)$ for all $z \in \Sigma^{k+1}$.

For (ii), assume that L is k-suffix testable and consider two states $p = \mathcal{A}(x)$ and $q = \mathcal{A}(y)$. If $z \in L(\mathcal{A}, p) \triangle L(\mathcal{A}, q)$, then $|z| < k$ because $xz \in L$ iff $yz \notin L$ and L is k-suffix testable. Now assume that $d(p, q) \leq k$ for all $p, q \in Q$ and consider $x, y \in \Sigma^*$, $z \in \Sigma^k$. Since

$d(\mathcal{A}(x), \mathcal{A}(y)) \leq k$, (i) implies $\mathcal{A}(xz) = \mathcal{A}(yz)$, and in particular $xz \in L$ iff $yz \in L$. Therefore, L is k-suffix testable.

Point (iii) follows from (ii) and the above mentioned result from [5, Lemma 1]. ◀

Proof of Theorem 3. Let $n \geq 0$ and $L_n = \{w \in \Sigma^* : \text{last}_n(w) \in L\}$. Let $\mathcal{A}_n$ be the minimal DFA for L_n, which has at most $f(n) := 2^{F_L(n)+1} - 1$ states. Since $\text{last}_n(xy) = y$ for all $x \in \Sigma^*$ and $y \in \Sigma^n$, the language L_n is n-suffix testable. Therefore L_n is $f(n)$-suffix testable by Lemma 5(iii). This implies that L is f-suffix definable because for all words $u, v, w \in \Sigma^*$ such that $|uw| = |vw| = n$ and $|w| = f(n)$ we have $uw \in L$ iff $uw \in L_n$ iff $vw \in L_n$ iff $vw \in L$. ◀

3.2 Proof of Theorem 4

We prove the variant of Theorem 4 that talks about prefix-definability. This makes no difference, since the reversal of a context-free languages is again context-free. Also note that the requirement $f(n) \in o(n)$ in Theorem 4 cannot be relaxed: For every $k \geq 1$, the language $\{xay : x, y \in \{a, b\}^*, |x| = k|ay|\}$ is context-free and $\lceil n/(k+1) \rceil$-suffix definable but not even regular.

First, we show that in the proof of Theorem 4 we can restrict ourselves to functions f with the following property: A monotonic function $f\colon \mathbb{N} \to \mathbb{N}$ has the *increasing plateau property* if for every $k \geq 1$ there exists an n_0 such that for all $n \geq n_0$ we have: $f(n+k) - f(n) \leq 1$. Clearly, if f has the increasing plateau property then $f \in o(n)$.

▶ **Lemma 6.** *Let $f\colon \mathbb{N} \to \mathbb{R}_{\geq 0}$. If $f(n) \in o(n)$ then there exists a monotonic function $g\colon \mathbb{N} \to \mathbb{N}$ with the increasing plateau property and such that $f(n) \leq g(n)$ for all $n \in \mathbb{N}$.*

Proof. For a linear function $g : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ of the form $g(x) = \alpha \cdot x + \beta$ we call α the *slope* of g. We will first define a sequence of natural numbers $n_1 < n_2 < n_3 \cdots$ such that f is bounded by a continuous piecewise linear function $h : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ that has slope $1/i$ on the interval $[n_i, n_{i+1}]$ and slope 0 on the interval $[0, n_1]$. Then we show that $g : \mathbb{N} \to \mathbb{N}$ with $g(n) = \lceil h(n) \rceil$ has the properties from the lemma.

First, for every $i \geq 1$ we define $n_i \in \mathbb{N}$ and a linear function $h_i : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ of slope $1/i$ such that: (i) $n_{i+1} > n_i$, (ii) for all natural numbers $n \geq n_i$ we have $f(n) \leq h_i(n)$, and (iii) $h_i(n_{i+1}) = h_{i+1}(n_{i+1})$.

Let $n_1 \geq 0$ be the smallest natural number such that $f(n) \leq n$ for $n \geq n_1$ and $f(n) \leq n_1$ for $n < n_1$. Clearly such an n_1 exists, as $f(n) \in o(n)$. Define h_1 by $h_1(x) = x$ for all $x \in \mathbb{R}_{\geq 0}$. Hence, we have $f(n) \leq h_1(n)$ for all $n \geq n_1$.

For the induction step, assume that n_i and the linear function $h_i : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ (of slope $1/i$) are defined such that $f(n) \leq h_i(n)$ for all $n \geq n_i$. Define the linear function $u_{i+1}(x) = h_i(n_i) + (x - n_i)/(i+1)$, which has a slope $1/(i+1)$ and $u_{i+1}(n_i) = h_i(n_i)$. Then there is a smallest natural n_{i+1} such that $n_{i+1} > n_i$ and $u_{i+1}(n) \geq f(n)$ for each $n \geq n_{i+1}$. This holds because $f(n) \in o(n)$, and hence for any constants $\alpha > 0, \beta \in \mathbb{R}$ we have $f(n) \leq \alpha \cdot n + \beta$ for large enough n. Take this n_{i+1} and define the function h_{i+1} by $h_{i+1}(x) = h_i(n_{i+1}) + (x - n_{i+1})/(i+1)$. It has slope $1/(i+1)$ and satisfies $h_{i+1}(n_{i+1}) = h_i(n_{i+1})$. Finally, for all $n \geq n_{i+1}$ we have

$$\begin{aligned} h_{i+1}(n) &= h_i(n_{i+1}) + (n - n_{i+1})/(i+1) \\ &= h_i(n_i) + (n_{i+1} - n_i)/i + (n - n_{i+1})/(i+1) \\ &\geq h_i(n_i) + (n_{i+1} - n_i)/(i+1) + (n - n_{i+1})/(i+1) \\ &= h_i(n_i) + (n - n_i)/(i+1) = u_{i+1}(n) \geq f(n). \end{aligned}$$

Hence, n_{i+1} and h_{i+1} have all the desired properties.

We now define the function $h : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$:

$$h(x) = \begin{cases} n_1 & \text{if } x \in [0, n_1] \\ h_i(x) & \text{if } x \in [n_i, n_{i+1}] \text{ for some } i \geq 1. \end{cases}$$

Since $h_i(n_{i+1}) = h_{i+1}(n_{i+1})$ and $h_1(n_1) = n_1$, h is uniquely defined. Finally, let $g(n) = \lceil h(n) \rceil$ for all $n \in \mathbb{N}$.

Since $f(n) \leq h_i(n)$ for all $n \geq n_i$ and $f(n) \leq f(n_1) \leq n_1$ for all $n \leq n_1$, we have $f(n) \leq h(n) \leq g(n)$ for all $n \in \mathbb{N}$. Moreover, h is clearly monotonic, which implies that g is monotonic, too. It remains to show that g has the increasing plateau property.

Let $k \geq 1$ and $n \geq n_k$. Since h is continuous and piecewise linear with slopes $\leq 1/k$ on $[n_k, \infty)$, we have $h(n+k) - h(n) \leq (n+k-n)/k = 1$. This implies $g(n+k) - g(n) \leq 1$. ◀

▶ **Lemma 7.** *Let L be a context-free language and $f : \mathbb{N} \to \mathbb{N} \setminus \{0\}$ be monotonic with $f(n) \in o(n)$. There are constants n_0 and $c > 0$ (only depending on L and f) such that the following hold for every $n \geq n_0$:*

- *$n \geq f(n) + c$ and*
- *for all words u, v with $uv \in L$, $|uv| = n$, $|u| = f(n)$, and $|v| = n - f(n)$, there exist words v', v'' with $|v'| = |v| - c$, $|v''| = |v| + c$, and $uv', uv'' \in L$.*

Proof. Consider the following variant of the pumping lemma for context-free languages (see also [7, Chapter 6.1]), which simultaneously considers all languages defined by various nonterminals of the grammar; it can be shown in the same way as the standard variant:

Given a context-free grammar G with set of nonterminals N and productions P, let L_A denote the language generated by the grammar G_A with productions P and the start nonterminal A. Then there exists a natural number c_1 depending only on G and not on A, such that if $w \in L_A$ and $|w| \geq c_1$, then w can be written as $w = w_1 w_2 w_3 w_4 w_5$ with: $w_1 w_2^k w_3 w_4^k w_5 \in L_A$ for every $k \geq 0$, $|w_2 w_3 w_4| \leq c_1$ and $|w_2 w_4| > 0$. In particular, the word $w_1 w_2^{1+c_1!/|w_2 w_4|} w_3 w_4^{1+c_1!/|w_2 w_4|} w_5$ of length $|w| + c_1!$ belongs to L_A.

Let G be a grammar for L in Greibach normal form, i.e., all productions are of the form $A \to aA_1 \cdots A_k$ for $k \geq 0$, nonterminals $A, A_1, \ldots, A_k$ and a terminal a (such a grammar exists for every context-free language); see also [7, Chapter 4.6]. Let r be the maximal length of the productions' right-hand sides in G, let N be the set of nonterminals, and let c_1 be the constant from the above pumping lemma for G. We can assume that $r \geq 2$, otherwise L is finite and the lemma holds. Define $c = c_1!$ and choose an n_0 such that for all $n \geq n_0$ the following three inequalities hold:

$$\frac{n}{f(n)} > 1 + (r-1) r^{2|N| \cdot (r c_1 |N| + 1)!} \tag{1}$$

$$\frac{n}{f(n)} > 1 + c_1 (r-1) \tag{2}$$

$$n > f(n) + c$$

As the right-hand sides are constant and $f(n) \in o(n)$, such an n_0 exists. Hence, for all $n \geq n_0$ the following two inequalities hold ((1) is equivalent to (3) and (2) is equivalent to (4)):

$$\log_r \left(\frac{n - f(n)}{f(n)(r-1)} \right) > 2|N|(r c_1 |N| + 1)! \tag{3}$$

$$\frac{n - f(n)}{f(n)(r-1)} > c_1 \tag{4}$$

Consider a string uv of length $n \geq n_0$ generated by G, where $|u| = f(n)$. Fix a leftmost derivation of uv and consider the first moment, at which the current sentential form has u as a prefix. This happens after $|u| = f(n)$ derivation steps since G is in Greibach normal form. Apart from the prefix u, the rest of the sentential form has length at most $1 + f(n)(r-2) \leq f(n)(r-1)$ and it derives the word v of length $n - f(n)$. So one of the nonterminals in the sentential form, say A, generates a word x with

$$|x| \geq \frac{n - f(n)}{f(n)(r-1)} \overset{(4)}{>} c_1 \ . \tag{5}$$

The further analysis splits into several cases depending on the claim we want to prove.

We first show the second claim of the lemma, that there exists v'' such that $|v''| = |v| + c$ and $uv'' \in L(G)$. Since $|x| \geq c_1$, we can apply the pumping lemma and replace in the derivation of uv the word x by a word of length $|x| + c_1! = |x| + c$. The resulting derivation yields a word uv'' with $|v''| = |v| + c$, as claimed.

So let us now prove that there is v' such that $uv' \in L(G)$, where $|v'| = |v| - c$. Again, consider the nonterminal A that generates a string x satisfying (5). Since the length of each right-hand side is at most r, there is a path Π in the derivation tree of length at least

$$\log_r \left(\frac{n - f(n)}{f(n)(r-1)} \right) > 2|N| \cdot (rc_1|N| + 1)! \ ,$$

where the estimation follows from (3). We are going to color some nodes on the path Π black or grey: if a node v on Π has a child that does not belong to Π and derives a string of length at least c_1, then we color v black. Then, as long as there are two uncolored nodes v, v' on Π (v above v') such that (i) v and v' are labelled with the same nonterminal, (ii) the path from v to v' has length at most $|N|$, and (iii) does not contain a black node, then we color v black and v' grey.

There can be at most $|N|$ consecutive nodes on the path that are not colored and there are at least as many black nodes as grey nodes. Thus, the number of black nodes is at least

$$\left\lfloor \frac{1}{2} \left\lfloor \frac{2|N| \cdot (rc_1|N| + 1)!}{|N|} \right\rfloor \right\rfloor = (rc_1|N| + 1)!$$

For each black node we can shorten the derivation such that the derived word is shorter by at least 1 and at most $rc_1|N|$ without affecting other colored nodes:

- For the first type of black nodes this follows directly from the pumping lemma. Note that we can apply the pumping lemma to a subtree that is disjoint from Π.
- For the second kind of black nodes, let v and v' be the corresponding nodes colored black and grey, respectively. We can delete the subtree rooted in v and replace it with the one rooted in v'. The length of the path is $\leq |N|$, the arity of the rules $\leq r$ and each deleted nonterminal derived a string of length $\leq c_1$ (otherwise it would be black).

So for some $m \in \{1, 2, \ldots, rc_1|N|\}$ there are $\frac{(rc_1|N|+1)!}{rc_1|N|} > (rc_1|N|)!$ different possibilities to shorten the derived word by m letters. We choose $(rc_1|N|)!/m$ of them so that the word is shortened by $(rc_1|N|)!$ letters. Thus we showed that there exists v' such that $uv' \in L(G)$ and $|uv'| = n - (rc_1|N|)!$. As $c = c_1!$ divides $(rc_1|N|)!$, by applying $((rc_1|N|)!/c - 1)$ times the already proved second claim of the lemma we can first obtain a word $uz \in L(G)$ such that $|uz| = n + (rc_1|N|)! - c$ and then use the argument above to obtain a word $uv' \in L(G)$ such that $|uv'| = |uz| - (rc_1|N|)! = |uv| - c$. Here, we use monotonicity of f, which ensures that the prefix u is not touched when using the above argument for the longer word uz. ◀

▶ **Lemma 8.** *Let L be a context-free language that is f-prefix definable for a function $f(n) \in o(n)$. Then there exists a constant α such that for every word u of length α and all words v, w with $|v| = |w|$ we have $uv \in L$ if and only if $uw \in L$.*

Proof. By Lemma 6 there exists a monotonic function $g(n) \in o(n)$ having the increasing plateau property and such that $f(n) \leq g(n)$ for all $n \geq 0$. Hence, L is still g-prefix definable. Moreover, let $f' \in o(n)$ be defined by $f'(n) = g(n) + 1$ for all n. Take the constants n_0 and c from Lemma 7 for L and f' (instead of f). Choose m such that (i) $m \geq n_0 + c$ and (ii) $g(n) - g(n-c) \leq 1$ for all $n \geq m$, which is possible by the increasing plateau property. We take $\alpha = g(m)$. Heading for a contradiction, let us take words u, v, w such that $|u| = \alpha$, $|v| = |w|$, $uv \in L$ and $uw \notin L$. We can assume that $|v| = |w|$ is minimal with these properties. Let $n = |uv| = |uw|$ in the following. We now distinguish two cases.

Case 1. $n \leq m$, which implies $g(n) \leq g(m) = |u|$. Hence, uv and uw have the same prefix of length $g(n)$. Since L is g-prefix definable, we have $uv \in L$ iff $uw \in L$, which is a contradiction.

Case 2. $n > m$, and thus $n > n_0 + c$ and $g(n) \geq g(m) = |u|$. Since $n - g(m) \geq n - g(n) = n - f'(n) + 1 > c > 0$, we can write $v = v_1 a v_2$ and $w = w_1 b w_2$ such that $a, b \in \Sigma$ and $|uv_1| = |uw_1| = g(n)$. Thus, $|uv_1 a| = |uw_1 b| = f'(n)$. By Lemma 7 there exists a word v_2' with $|v_2'| = |v_2| - c$ and $uv_1 a v_2' \in L$. Take any word w_2' of length $|w_2'| = |w_2| - c$. By the length-minimality of v and w we must have $uw_1 b w_2' \in L$ (note that $c > 0$). Note that $|uw_1 b w_2'| = |uw| - c = n - c > n_0$. Therefore, we can apply Lemma 7 to the word $uw_1 b w_2'$. Note that $g(n) - g(n-c) \leq 1$ since $n \geq m$. Thus, $f'(n-c) = g(n-c) + 1 \geq g(n)$ and the prefix of $uw_1 b w_2'$ of length $f'(n-c)$ starts with uw_1. We can conclude with Lemma 7 that there is a word w_2'' such that $uw_1 w_2'' \in L$ and $|uw_1 w_2''| = n$. But since $|uw_1| = g(n)$ and $|uw_1 w_2''| = n$, the g-prefix definability of L implies that $uw_1 y \in L$ for all words y of length $n - g(n)$. In particular, we get $uw_1 b w_2 = uw \in L$, which is a contradiction. ◀

We can now prove (the prefix version of) Theorem 4:

Proof of Theorem 4. Let L be a f-prefix definable context-free language with $f(n) \in o(n)$. Let α be the constant from Lemma 8. For every word u of length α let $L_u = \{w \colon uw \in L\}$. Each of these finitely many languages is context-free and by Lemma 8 it is a length language. It is a direct consequence of Parikh's theorem [8] (or the fact that every unary context-free language is regular) that a context-free length language is regular. Hence, every L_u (for $|u| = \alpha$) is a regular length language. We can now decompose L as follows:

$$L = (L \cap \Sigma^{<\alpha}) \cup \bigcup_{u \in \Sigma^\alpha} uL_u = (L \cap \Sigma^{<\alpha}) \cup \bigcup_{u \in \Sigma^\alpha} (u\Sigma^* \cap \Sigma^\alpha L_u).$$

Since L_u is a regular length language, also $\Sigma^\alpha L_u$ is a regular length language. Moreover, $u\Sigma^*$ is prefix testable. Finally, every finite language (and hence $L \cap \Sigma^{<\alpha}$) is a finite Boolean combination of prefix testable languages. This shows the theorem. ◀

4 Sliding windows over context-free languages: above logspace

In this section, we show that the trichotomy result for regular languages [4] does not carry over the context-free languages. More precisely, we show that for every natural number $c \geq 1$ there exists a one-counter language L_c such that $F_{L_c}(n) \in \mathcal{O}(n^{1/c}) \setminus o(n^{1/c})$ and $V_{L_c}(n) \in \Theta(n^{1/c})$. Recall that a one-counter language is a language that can be accepted by a nondeterministic pushdown automaton with a singleton pushdown alphabet (a so called

one-counter automaton). Also recall that a linear bounded automaton (LBA for short) is a Turing machine that only uses the space that is occupied by the input word; see also [7, Chapter 9.3]. We first show the following technical result:

▶ **Theorem 9.** *Let $t(k)$ be a monotonically increasing function and M be an LBA which halts on input a^k after exactly $t(k)$ steps. Let $f(n)$ be the function with*[1]

$$f(n) = \begin{cases} k & \text{if } n = k(t(k)+3) \text{ for some } k \\ 0 & \text{else} \end{cases}$$

and let $g(n) = \max\{f(m) \colon m \leq n\}$. There is a one-counter language L such that $F_L(n) \in \Theta(f(n))$ and $V_L(n) \in \Theta(g(n))$.

Proof. Let Γ be the tape alphabet of M and Q the set of states of M. A configuration of M is encoded by a word from $\Gamma^*(Q \times \Gamma)\Gamma^*$ over the alphabet $\Delta := \Gamma \cup (Q \times \Gamma)$. A computation of M on an input a^k ($k \geq 1$) is a sequence of configurations $c_0 \vdash_M \cdots \vdash_M c_{t(k)}$ where $|c_i| = k$ for all $1 \leq i \leq t(k)$, $c_0 = (q_0, a)a^{k-1}$ is the start configuration on input a^k, every c_{i+1} is obtained from c_i by applying a transition of M for $0 \leq i \leq t(k)-1$, and $c_{t(k)}$ is an accepting computation. Let $\Delta' = \{x' \mid x \in \Delta\}$ be a disjoint copy of Δ and define w' for a word $w \in \Delta^*$ by applying the homomorphism $x \mapsto x'$ ($x \in \Delta$) to w. Finally, let K be the set of all words

$$c_0 \operatorname{rev}(c_1)' \, c_2 \operatorname{rev}(c_3)' \cdots c_{t(k)} \, s \operatorname{rev}(s) \text{ or} \tag{6}$$

$$c_0 \operatorname{rev}(c_1)' \, c_2 \operatorname{rev}(c_3)' \cdots \operatorname{rev}(c_{t(k)})' \, s \operatorname{rev}(s) \tag{7}$$

such that $k \geq 1$, $c_0 \vdash_M \cdots \vdash_M c_{t(k)}$ is a computation on input a^k, $s \in \{0,1\}^*$ is an arbitrary word of length k (0 and 1 are arbitrary symbols not in $\Delta \cup \Delta'$), and $t(k)$ even (resp., odd) in case (6) (resp., (7)). Notice that the words in (6) and (7) have length $k(t(k)+3)$. We can assume that M never goes back to the initial state q_0. This ensures that every word has at most one non-empty suffix that is a prefix of a word from K.

For the language L from the theorem, we take the complement of K. It is not hard to see that L can be recognized by a nondeterministic one-counter automaton by guessing an error in the input word w. Possible errors are the following, where we call a block of w a maximal factor from $\Delta^+ \cup (\Delta')^+ \cup \{0,1\}^+$ in w, m is the number of blocks of w and u_i denotes the i-th block of w for $1 \leq i \leq m$:

1. $m < 2$,
2. u_1 is not an initial configuration, i.e., of the form $(q_0, a)a^{k-1}$ for some $k \geq 1$,
3. for some odd $i < m$, u_i is not a configuration,
4. for some even $i < m$, u_i is not of the form c' for a configuration c,
5. u_{m-1} is not an accepting confiuration,
6. there exists $1 \leq i < m-1$ with $|u_i| \neq |u_{i+1}|$,
7. $|u_m| \neq 2|u_{m-1}|$,
8. there exists $1 \leq i < m-1$ odd such that $u_i \vdash_M \operatorname{rev}(u)$ does not hold for $u' = u_{i+1}$,
9. there exists $1 \leq i < m-1$ even such that $\operatorname{rev}(u) \vdash_M u_{i+1}$ does not hold for $u' = u_i$,
10. u_m is not a palindrome over the alphabet $\{0,1\}^*$.

The conditions in points 1–5 are regular. Points 6–10 can be checked with a single counter.

The upper bound in the theorem has to be shown for the variable-size model. Since $F_K(n) = F_L(n)$ and $V_K(n) = V_L(n)$, it is enough to show the bounds for the language K. Let us first present a variable-size streaming algorithm with space complexity $\mathcal{O}(g(n))$. Assume that w is the active window. The algorithm stores the following data n, i, t, k, ℓ, s:

[1] Since $t(k)$ is monotonically increasing, the number k in the first case is unique.

- $n = |w|$ is the length of the active window.
- i is the smallest position x such that $w[x:]$ is a prefix of a word from K. If this prefix is empty, then $i = n + 1$.
- t is the number of blocks in $w[i:]$ minus 1 (where i is from the previous point); this tells us the number of computation steps that M has executed.
- k is the largest number y such that $w[i:]$ starts with $(q_0, a)a^{y-1}$; hence, k tells us the input length.
- In case $1 \leq t \leq t(k)$, ℓ is the length of the last block of $w[i:]$ (if $t = 0$ or $t = t(k) + 1$ we store some dummy value in ℓ).
- In case $t = t(k) + 1$, s is the maximal suffix of $w[i:]$ from $\{0,1\}^*$. If the length of this suffix exceeds k then s stores only its prefix of length k.

It is easy to see that these variables can be updated. The main observation is that in case $1 \leq t \leq t(k)$ and $\ell < k$ then the algorithm internally simulates M for t steps on input a^k. In this way, the algorithm can check whether the arriving symbol is the right one, namely the (possibly primed) $(\ell+1)$-th symbol of the configuration reached after t steps on input a^k. In this case, the algorithm sets $\ell := \ell + 1$, otherwise the algorithm sets $i := n + 1$. If t is set to $t(k) + 1$ then the algorithm starts to accumulate the window suffix $s \in \{0,1\}^*$ up to length k. If s has length k then the next k arriving symbols are compared in reversed order with s. If a match is obtained, the algorithm accepts if $i = 1$ at the same time.

Let us now compute the space complexity of the algorithm. The numbers n, i, t, k and ℓ need $\mathcal{O}(\log n)$ bits. Recall that s has maximal length k. But we only store symbols in s if $n \geq k(t(k) + 1) \geq \lfloor k/3 \rfloor (t(\lfloor k/3 \rfloor) + 3)$, since the window must already contain a complete computation on input a^k before s becomes non-empty. We get $\lfloor k/3 \rfloor = f(\lfloor k/3 \rfloor (t(\lfloor k/3 \rfloor) + 3)) \leq g(n)$, i.e., $k \leq 3g(n) + 3$. Finally, since $g(n)$ is the maximal value k such that $k(t(k) + 3) \leq n$ and $t(k) \in 2^{\mathcal{O}(k)}$, we get $g(n) \in \Omega(\log n)$. This shows that the algorithm works in space $\mathcal{O}(g(n))$.

To show that $F_K(n) \in \mathcal{O}(f(n))$ we can argue similarly. Of course, in the fixed-size model, we do not have to store the window size n. If the window size n is not of the form $k(t(k)+3)$ for some k then the algorithm always rejects and no space at all is needed. Otherwise, since $t(k)$ is monotonically increasing, there is a unique k with $n = k(t(k) + 3)$.

Finally, we show that $F_K(n) \geq f(n)$ for all n, which implies that $V_K(n) \geq g(n)$ for all n since $V_K(n) \geq F_K(n)$ and $V_K(n)$ is monotonic. It suffices to consider a window size $n = k(t(k) + 3)$ for some k, as otherwise $f(n) = 0$. Hence, $f(n) = k$. Moreover, consider an accepting computation $c_0 \vdash_M c_1 \vdash_M \cdots \vdash_M c_{t(k)}$ where $|c_0| = \cdots = |c_{t(k)}| = k$. Let us assume that k is even; the case that k is odd is analogous. Now consider the 2^k many distinct words $w(s) := 0^k\, c_0\, \mathrm{rev}(c_1)'\, c_2\, \mathrm{rev}(c_3)' \cdots c_{t(k)}\, s$ for $s \in \{0,1\}^k$. The length of these words is $n = k(t(k) + 3)$, which is the window size.

Consider now the minimal DFA $\mathcal{A}_n$ for the language K_n, and let r be the number of states of $\mathcal{A}_n$ (hence, $F_K(n) = \lfloor \log_2 r \rfloor$). We claim that $\mathcal{A}_n(w(s)) \neq \mathcal{A}_n(w(u))$ for all $s, u \in \{0,1\}^k$ with $s \neq u$. To see this, assume that $\mathcal{A}_n(w(s)) = \mathcal{A}_n(w(u))$ for $s, u \in \{0,1\}^k$ with $s \neq u$. Hence, $\mathcal{A}_n(w(s)\,\mathrm{rev}(s)) = \mathcal{A}_n(w(u)\,\mathrm{rev}(s))$. On the other hand, the above definition of $w(s)$ and $w(u)$ implies $w(s)\,\mathrm{rev}(s) \in K$ and $w(u)\,\mathrm{rev}(s) \notin K$, which yields a contradiction. We get $r \geq 2^k$, and thus $F_K(n) \geq k = f(n)$. ◀

Theorem 9 yields a quite dense spectrum of space complexity functions for context-free languages. We only prove the existence of context-free languages with sliding-window space complexity $n^{1/c}$ for $c \in \mathbb{N}$, $c \geq 1$:

▶ **Theorem 10.** *For every $c \in \mathbb{N}$, $c \geq 1$, there exists a one-counter language L_c such that $F_{L_c}(n) \in \mathcal{O}(n^{1/c}) \setminus o(n^{1/c})$ and $V_{L_c}(n) \in \Theta(n^{1/c})$.*

Proof. One can easily construct a deterministic LBA M that on input a^k terminates after exactly k^{c-1} steps. For instance, an LBA that terminates after exactly k^2 steps makes k phases, where in each phase the read-write head moves from the left input end to the right end or vice versa and thereby replaces the first a that is seen on the tape by a b-symbol. This construction can be iterated to obtain the above LBA M for an arbitrary k. The mapping $f(n)$ from Theorem 9 then satisfies $f(k(t(k)+3)) = f(k(k^{c-1}+3)) = f(k^c+3k) = k$ and $f(n) = 0$ if n is not of the form $k^c + 3k$ for some k. This implies $f(n) \in \mathcal{O}(n^{1/c}) \setminus o(n^{1/c})$ and $g(n) \in \Theta(n^{1/c})$ for the mapping $g(n)$ from Theorem 9. Hence, by Theorem 9 there is a one-counter language L_c with the properties stated in the theorem. ◀

To fully exploit Theorem 9 one would have to analyze the spectrum of time complexity functions of linear bounded automata. We are not aware of specific results in this direction.

5 Sliding windows over deterministic one-counter languages

The context-free language L_c from Theorem 10 is not deterministic context-free and it is open whether the same result can be obtained for deterministic context-free languages. In this section we exhibit a deterministic one-turn one-counter language with space complexity $\Theta((\log n)^2)$ in the variable-size (resp., fixed-size) model. A *t-turn pushdown automaton* has the property that in any accepting run there are at most t alternations between push and pop operations [6].

We start with the variable-size model. A maximal factor β in a word $w \in \{a,b\}^*$ of the form $\beta = ab^i$ is called a *block* of length $i+1$ in w (this notion is not related to the blocks used in the proof of Theorem 9). Define the language

$$L = \{ab^k av : k \geq 0,\, v \in \{a,b\}^{\leq k}\} \cup ab^*, \tag{8}$$

which is recognized by a deterministic one-turn one-counter automaton. Put differently, L contains those words $w \in \{a,b\}^*$ which begin with a block of length $\geq |w|/2$.

▶ **Lemma 11.** *We have $V_L(n) \in \mathcal{O}((\log n)^2)$.*

Proof. Any word $w \in \{a,b\}^*$ can be uniquely factorized as $w = b^s\beta_m\beta_{m-1}\cdots\beta_2\beta_1$ where $s, m \geq 0$ and each β_i is a block. A block β_i is *relevant* if it is at least as long as the remaining suffix, i.e. $|\beta_i| \geq \sum_{j=1}^{i-1} |\beta_j|$. For an active window $w \in \{a,b\}^*$ our variable-size algorithm maintains the window size and for each relevant block β_i its starting position and its length. If the first symbol in the window expires, every relevant block stays relevant (and the starting position is decremented) with the possible exception of a relevant block with starting position 1, which is removed. If an a arrives, we create a new relevant block of length 1. If a b arrives, we prolong the rightmost relevant block (which is also rightmost among all blocks) by 1. Furthermore, using this information we can determine whether $w \in L$: This is the case if and only if the leftmost relevant block starts at the first position and its length is at least $n/2$ where n is the current window size.

To show that the space complexity of the algorithm is $\mathcal{O}((\log n)^2)$, it suffices to show that each word $w \in \{a,b\}^n$ has $\mathcal{O}(\log n)$ relevant blocks. Let $\gamma_k, \gamma_{k-1}, \ldots, \gamma_2, \gamma_1$ be the sequence of relevant blocks in w. Then we know that $|\gamma_i| \geq \sum_{j=1}^{i-1} |\gamma_j|$ for all $1 \leq i \leq k$. Inductively, we show that $|\gamma_i| \geq 2^{i-2}|\gamma_1|$ for all $2 \leq i \leq k$. This is immediate for $i = 2$ and for the induction step, observe that $|\gamma_i| \geq |\gamma_1| + \sum_{j=2}^{i-1} |\gamma_j| \geq |\gamma_1| + |\gamma_1| \sum_{j=2}^{i-1} 2^{j-2} = 2^{i-2}|\gamma_1|$ for all $i \geq 3$. This proves $k = \mathcal{O}(\log n)$, which concludes the proof. ◀

▶ **Lemma 12.** *We have* $V_L(n) \in \Omega((\log n)^2)$.

Proof. For each $k \geq 0$ we define *arrangements* of length 3^k: The word a is the only arrangement of length $3^0 = 1$. An arrangement of length 3^{k+1} is any word of the form $ub^{3^k}v$ where $u, v \in \{a, b\}^{3^k}$, u begins with a and has at most one other a-symbol and v is any arrangement of length 3^k. Notice that an arrangement $ub^{3^k}v$ contains one or two blocks in the factor ub^{3^k}, one of which is relevant. If $\alpha_1 \neq \alpha_2$ are distinct arrangements of length 3^k, consider the maximal common suffix α_3 of α_1 and α_2 which is again an arrangement. Consider the suffixes of α_1, α_2 of length $3|\alpha_3|$. By the construction, these suffixes are also arrangements. Hence, their "middle parts" consist solely of b's, so they have the common suffix $b^{|\alpha_3|}\alpha_3$. Since α_1 and α_2 differ, there exists a number $\ell \geq |\alpha_3|$ such that α_1 has the suffix $ab^\ell\alpha_3$ and α_2 has the suffix $b^{\ell+1}\alpha_3$, or vice versa.

Now consider a variable-size sliding window algorithm for L. We claim that the algorithm can distinguish any two distinct arrangements $\alpha_1 \neq \alpha_2$ of length 3^k. Consider two instances of the algorithm, where the active windows are α_1 and α_2, respectively. By performing a suitable number of $\downarrow$-operations the two windows contain the words $ab^\ell\alpha_3$ and $b^{\ell+1}\alpha_3$, respectively. Since $|\alpha_3| \leq \ell$, we have $ab^\ell\alpha_3 \in L$ and $b^{\ell+1}\alpha_3 \notin L$.

It is easy to see that the number n_k of arrangements of length 3^k is exactly $\prod_{i=0}^{k-1} 3^i$: to construct an arrangement of length 3^k, note that among its first 3^{k-1} letters the first one is a and there is at most one further a. So, there are 3^{k-1} choices for the prefix of length 3^{k-1}. The next 3^{k-1} letters are fixed, and then one of n_{k-1} many arrangements of length 3^{k-1} follows. Thus $n_k = 3^{k-1}n_{k-1}$ and $n_0 = 1$, which yields the claim. Note that $\log_3(n_k) = \sum_{i=0}^{k-1} i = \Theta(k^2)$. Therefore, the algorithm needs $\Omega((\log n)^2)$ bits of space. ◀

▶ **Corollary 13.** *There exists a deterministic one-turn one-counter language* L *such that* $V_L(n) = \Theta((\log n)^2)$.

The language L from (8) is an example of a language where the space complexity in the fixed-size model is strictly below the space complexity in the variable-size model:

▶ **Lemma 14.** *We have* $F_L(n) \in \mathcal{O}(\log n)$.

Proof. Let $n \geq 0$ be the window size. For the active window we store (i) the starting position of the leftmost block of length at least $n/2$ (if such a block does not exist we set a special flag) and (ii) the length of the unique suffix from ab^* (again, a flag is set if the window content is in b^*). This information can be stored with $\mathcal{O}(\log n)$ bits and it can be updated at each step. Moreover, the active window belongs to L if the leftmost block of length at least $n/2$ starts at position 1. ◀

We now prove the variant of Corollary 13 for the fixed-size model: For the language L from (8) let $K = Lc^*$, which is a deterministic one-turn one-counter language.

▶ **Theorem 15.** *We have* $F_K(n) = \Theta((\log n)^2)$.

Proof. Let n be the window size. Consider the maximal suffix of the active window which has the form vc^i where $v \in \{a, b\}^*$. Using $\mathcal{O}(\log n)$ bits we maintain the starting position of that suffix and the length $|v|$. Furthermore, we maintain the same data structure as in the proof of Lemma 11 for the word $v \in \{a, b\}^*$. The algorithm accepts iff v begins at the first position, the leftmost relevant block also starts at the first position and has length at least $|v|/2$. In total, the space complexity is bounded by $\mathcal{O}((\log n)^2)$.

The proof for the lower bound is similar to the proof of Lemma 12. Let k be maximal such that $3^k \leq n$. Then the number of bits required to encode an arrangement of length 3^k is $\Omega((\log n)^2)$. The rest of the proof follows the proof of Lemma 12; we only have to replace every $\downarrow$-operation by the insertion of a c-symbol. ◀

For the language L from (8) let $L' = \{\#^j \mathrm{rev}(u)v\$^i : u \in L,\, i \geq 0,\, v \in \{a,b\}^i,\, j \geq 1\}$. Its reversal $\mathrm{rev}(L') = \{\$^i v \mid i \geq 0,\, v \in \{a,b\}^i\}\, L\, \#^+$ is accepted by a deterministic one-counter three-turn automaton.

▶ **Theorem 16.** *We have* $V_{L'}(n) = \mathcal{O}((\log n)^2)$ *and* $F_{L'}(n) \notin o((\log n)^2)$.

Proof. We first exhibit a variable-size sliding window algorithm for L'. Of course, we maintain the window size n. For the active window consider its longest suffix of the form $\#^j w\$^i$ where $w \in \{a,b\}^*$ and $i,j \geq 0$. Using $\mathcal{O}(\log n)$ bits we can maintain the numbers i, j, the length $|w|$, and the maximal number k such that b^k is a suffix of w.

Furthermore, if $j \geq 1$ we maintain for each relevant block in $\mathrm{rev}(w)$ its starting position and its length, which requires $\mathcal{O}((\log n)^2)$ bits (see the proof of Lemma 11). Let us argue why this information can be maintained. Let n, i, j, k and w have the meaning from the previous paragraph. If j is set from 0 to 1, then w is empty and $\mathrm{rev}(w)$ contains no blocks. If $j \geq 1$ we can prolong w as long as the active window does not end with \$-symbols ($i = 0$). In this case, every time an a-symbol arrives, a new block in $\mathrm{rev}(w)$ is formed, which has length $k+1$. If it is not relevant, then it is immediately discarded. Also notice that when w is prolonged by a or b, all relevant blocks in $\mathrm{rev}(w)$ stay relevant. A $\downarrow$-operation only affects w if $j \in \{0,1\}$ and $n = j + |w| + i$. In this case j is set to zero, and we no longer have to store the relevant blocks of w.

It remains to show the lower bound. Let the window size n be of the form $2 \cdot 3^k$. Again we show that any fixed-size sliding window algorithm for L' must distinguish any two distinct arrangements. Let $\alpha_1 \neq \alpha_2$ be two arrangements of length 3^k. As shown in the proof of Lemma 12, there exists a number $0 \leq \ell < 3^k$ and an arrangement α_3 of length at most ℓ such that α_1 and α_2 have the suffixes $ab^\ell\alpha_3 \in L$ and $b^{\ell+1}\alpha_3 \notin L$, respectively (or vice versa). Without loss of generality, $\alpha_1 = v_1 ab^\ell \alpha_3$ and $\alpha_2 = v_2 b^{\ell+1}\alpha_3$ for some $v_1, v_2 \in \{a,b\}^*$. Both words v_1 and v_2 have length $r := 3^k - (\ell + 1 + |\alpha_3|)$. We have

$$\mathrm{last}_n(\#^{3^k}\mathrm{rev}(\alpha_1)\$^r) = \#^{3^k-r}\mathrm{rev}(ab^\ell\alpha_3)\,\mathrm{rev}(v_1)\$^r \in L' \quad \text{and}$$
$$\mathrm{last}_n(\#^{3^k}\mathrm{rev}(\alpha_2)\$^r) = \#^{3^k-r}\mathrm{rev}(b^{\ell+1}\alpha_3)\,\mathrm{rev}(v_2)\$^r \notin L'.$$

This shows that the algorithm must distinguish the words $\#^{3^k}\mathrm{rev}(\alpha_1)$ and $\#^{3^k}\mathrm{rev}(\alpha_2)$. Note that adding a \$ at the right end of the word removes the right-most symbol (a or b) in the factor which has to belong to $\mathrm{rev}(L)$ in order to have a word from L'. The rest of the proof follows the arguments from the proof of Lemma 12. ◀

6 Open problems

Our results lead to several open problems; in particular for deterministic context-free languages: Are there deterministic context-free languages where the optimal space bound (for the variable-size or the fixed-size model) is in $o(n) \cap \omega((\log n)^2)$?

An interesting subclass of the deterministic context-free languages are the visibly pushdown languages [2, 9], which are also known as input-driven languages. Visibly pushdown languages have better algorithmic properties than general deterministic context-free languages [2, 9]. Our deterministic context-free languages from Section 5 are not visibly pushdown languages. This leads to the question, whether our space trichotomy result for regular languages [4] extends to visibly pushdown languages (or at least visibly one-counter languages).

Abstract

We study the average size of the minimal directed acyclic graph (DAG) with respect to so-called leaf-centric binary tree sources as studied by Zhang, Yang, and Kieffer. A leaf-centric binary tree source induces for every $n \geq 2$ a probability distribution on all binary trees with n leaves. We generalize a result shown by Flajolet, Gourdon, Martinez and Devroye according to which the average size of the minimal DAG of a binary tree that is produced by the binary search tree model is $\Theta(n/\log n)$.

1 Introduction

One of the most important and widely used compression methods for trees is to represent a tree by its minimal *directed acyclic graph*, shortly referred to as minimal DAG. The minimal DAG of a tree t is obtained by keeping for each subtree s of t only one isomorphic copy of s to which all edges leading to roots of s-copies are redirected. DAGs found applications in numerous areas of computer science; let us mention compiler construction [1, Chapter 6.1 and 8.5], unification [14], XML compression and querying [5, 9], and symbolic model-checking (binary decision diagrams) [4]. Recently, in information theory the average size of the minimal DAG with respect to a probability distribution turned out to be the key in order to obtain tree compressors whose average redundancy converges to zero [10, 16].

In this paper, we consider the problem of deriving asymptotic estimates for the average size of the minimal DAG of a randomly chosen binary tree of size n. So far, this problem has been analyzed mainly for two particular distributions: In [8], Flajolet, Sipala and Steyaert proved that the average size of the minimal DAG with respect to the uniform distribution on all binary trees of size n is asymptotically equal to $c \cdot n/\sqrt{\ln n}$, where c is the constant $2\sqrt{\ln(4/\pi)}$. This result was extended to unranked and node-labelled trees in [3] (with a different constant c). An alternative proof to the result of Flajolet et al. was presented in [15] by Ralaivaosaona and Wagner. For the so-called binary search tree model, Flajolet, Gourdon and Martinez [7] and Devroye [6] proved that the average size of the minimal DAG becomes $\Theta(n/\log n)$. In the binary search tree model, a binary search tree of size n is built by inserting the keys $1, \ldots, n$ according to a uniformly chosen random permutation on $1, \ldots, n$.

A general concept to produce probability distributions on the set of binary trees of size n was introduced by Zhang, Yang, and Kieffer in [16] (see also [11]), where the authors extend the classical notion of an information source on finite sequences to so-called *structured binary tree sources*, or binary tree sources for short. This yields a general framework for studying the average size of a minimal DAG. Let $\mathcal{T}$ denote the set of all binary trees[1] and let $\mathcal{T}_n$ denote the set of binary trees with n leaves. A binary tree source is a tuple $(\mathcal{T}, (\mathcal{T}_n)_{n\in\mathbb{N}}, P)$, in which P is a mapping from the set of binary trees to the unit intervall $[0,1]$, such that $\sum_{t\in\mathcal{T}_n} P(t) = 1$ for every $n \geq 1$. This is a very general definition that was further restricted by Zhang et al. in order to yield interesting results. More precisely, they considered so-called *leaf-centric binary tree sources*, which are induced by a mapping $\sigma : (\mathbb{N}\setminus\{0\}) \times (\mathbb{N}\setminus\{0\}) \to [0,1]$ that satisfies $\sum_{i=1}^{n-1} \sigma(i, n-i) = 1$ for every $n \geq 2$. In other words, σ restricted to $S_n := \{(i, n-i) \colon 1 \leq i \leq n-1\}$ is a probability mass function for every $n \geq 2$. To randomly produce a tree with n leaves, one starts with a single root node labelled with n and randomly chooses a pair $(i, n-i)$ according to the distribution σ on S_n. Then, a left (resp., right) child labelled with i (resp.-, $n-i$) is attached to the root, and the process is repeated with these two nodes. The process stops at nodes with label 1. This yields a function P_σ that restricts to a probability mass function on every set $\mathcal{T}_n$ for $n \geq 2$.

The binary search tree model is the leaf-centric binary tree source where σ corresponds to the uniform distribution on S_n for every $n \geq 2$. Moreover, also the uniform distribution on all trees with n leaves can be obtained from a leaf-centric binary tree source by choosing σ suitably, see Section 4. Another well-known leaf-centric binary tree source is the *digitial search tree model* [13], where the distribution on S_n is a binomial distribution.

Let $\mathcal{D}_t$ denote the minimal DAG of a binary tree t and let $|\mathcal{D}_t|$ denote the number of nodes of $\mathcal{D}_t$. The average size of the minimal DAG with respect to a leaf-centric binary tree source $(\mathcal{T}, (\mathcal{T}_n)_{n\in\mathbb{N}}, P_\sigma)$ is the mapping

$$\mathcal{D}_\sigma(n) := \sum_{t\in\mathcal{T}_n} P_\sigma(t)|\mathcal{D}_t|. \tag{1}$$

In this work, we generalize the results of [6, 7] on the average size of the minimal DAG with respect to the binary search tree model in several ways. For this, we consider three classes of leaf-centric binary tree sources, which are defined by the following three properties of the corresponding σ-mappings:

- **(i)** There exists an integer $N \geq 2$ and a monotonically decreasing function $\psi : \mathbb{R} \to (0,1]$ such that $\psi(n) \geq \frac{2}{n-1}$ and $\sigma^*(i, n-i) \leq \psi(n)$ for every $n \geq N$ and $1 \leq i \leq n-1$. Here, σ^* is defined by $\sigma^*(i,i) = \sigma(i,i)$ and $\sigma^*(i,j) = \sigma(i,j) + \sigma(j,i)$ for $i \neq j$.
- **(ii)** There exists an integer $N \geq 2$ and a constant $0 < \rho < 1$, such that $\sigma(i, n-i) \leq \rho$ for every $n \geq N$ and $1 \leq i \leq n-1$.
- **(iii)** There is a monotonically decreasing function $\phi : \mathbb{N} \to (0,1]$ and a constant $c \geq 3$ such that for every $n \geq 2$,

$$\sum_{\frac{n}{c} \leq i \leq n-\frac{n}{c}} \sigma(i, n-i) \geq \phi(n).$$

Property (iii) generalizes the concept of *balanced* binary tree sources from [10, 11]: When randomly constructing a binary tree with respect to a leaf-centric source of type (iii), the probability that the current weight is roughly equally splitted among the two children is

[1] We consider binary trees, where every non-leaf node has a left and a right child, but the whole framework can be easily extended to binary trees, where a node may have only a left or right child.

lower bounded by a function. Therefore, for slowly decreasing functions ϕ, balanced trees are preferred by this model. The binary search tree model satisfies all three conditions (i), (ii) and (iii). As our main results, we obtain for each of these three types of leaf-centric binary tree sources asymptotic bounds for the average size of the minimal DAG:

(a) For leaf-centric sources of type (i), the average size of the minimal DAG is upper bounded by $\mathcal{O}\left(\psi\left(\frac{1}{2}\log_4(n)\right)n\right)$, which is in $o(n)$ if $\psi(x) \in o(1)$.

(b) Using a simple entropy argument based on a result from [11], we show that for every leaf-centric binary tree source of type (ii), the average size of the minimal DAG is lower bounded by $\Omega(n/\log n)$.

(c) For leaf-centric binary tree sources of type (iii), the average size of the minimal DAG is upper bounded by $\mathcal{O}\left(\frac{n}{\phi(n)\log n}\right)$, which is in $o(n)$ if $\phi(n) \in \omega(1/\log n)$.

Both (a) and (c) imply the upper bound $\mathcal{O}(n/\log n)$ for the binary search tree model [7], whereas (b) yields an information-theoretic proof of the lower bound $\Omega(n/\log n)$ from [6].

The upper bounds (a) and (c) can be applied to the problem of universal tree compression [10, 16]. It is shown in [16] that a suitable binary encoding of the DAG yields a tree encoding whose average-case redundancy converges to zero assuming the trees are produced by a leaf-centric tree source for which the average DAG size is $o(n)$. See [16] for precise definitions.

2 Preliminaries

We use the classical Landau notations $\mathcal{O}$, o, Ω and ω. Quite often, we write sums of the form $\sum_{q_0 \le k \le q_1} a_k$ for rational numbers q_0, q_1. With this, we mean the sum $\sum_{k=\lceil q_0 \rceil}^{\lfloor q_1 \rfloor} a_k$. In the following, $\log x$ will always denote the binary logarithm $\log_2 x$ of a positive real number x. With $[0,1]$ we denote the unit interval of reals, and $(0,1] = [0,1] \setminus \{0\}$.

2.1 Trees and DAGs

We define binary trees as terms over the two symbols a (for leaves) and f (for binary nodes). The set $\mathcal{T}$ of *binary trees* is the smallest set of terms in f and a such that (i) $a \in \mathcal{T}$, and (ii) if $t_1, t_2 \in \mathcal{T}$, then $f(t_1, t_2) \in \mathcal{T}$. Thus, if we consider elements in $\mathcal{T}$ as graphs in the usual way, a binary tree is an ordered, rooted tree such that each node has either exactly two or no children. With $\mathcal{T}_n$ we denote the set of binary trees which have exactly n leaves. The *size* of a binary tree t is the number of leaves of t and denoted with $|t|$. A *fringe subtree* of a binary tree t is a subtree which consists of a node of t and all its descendants. For a node v of a binary tree $t \in \mathcal{T}$, let $t[v]$ denote the fringe subtree of t which is rooted at v. The *leaf-size* of a node v of t is the size of the subtree $t[v]$. For a binary tree $t \in \mathcal{T}$ and an integer $k \ge 1$, let $N(t,k)$ denote the number of nodes of t of leaf-size greater than k.

For a binary tree $t \in \mathcal{T}$, let $\mathcal{D}_t$ denote its minimal *directed acyclic graph*, often shortly referred to as its minimal DAG. It is obtained by merging nodes u and v if $t[u]$ and $t[v]$ are isomorphic. The size $|\mathcal{D}_t|$ of $\mathcal{D}_t$ is the number of different pairwise non-isomorphic fringe subtrees of t. An example of a binary tree and its minimal DAG can be found in Figure 1.

2.2 Leaf-centric binary tree sources

In this paper we are interested in the average size of minimal DAGs. For this, we need for every $n \ge 1$ a probability distribution on $\mathcal{T}_n$. We restrict here to so-called leaf-centric binary tree sources that were studied in [11, 16]. Let Σ denote the set of all functions

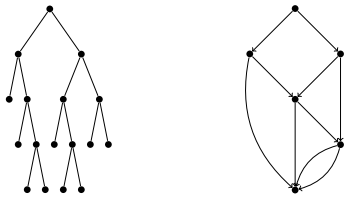

Figure 1 A binary tree (left) and its minimal DAG (right).

$\sigma : (\mathbb{N} \setminus \{0\}) \times (\mathbb{N} \setminus \{0\}) \to [0,1]$ which satisfy

$$\sum_{i=1}^{n-1} \sigma(i, n-i) = 1$$

for every integer $n \geq 2$. We define $P_\sigma : \mathcal{T} \to [0,1]$ inductively by $P_\sigma(a) = 1$ and $P_\sigma(f(u,v)) = \sigma(|u|,|v|) \cdot P_\sigma(u) \cdot P_\sigma(v)$. For every $n \geq 1$, P_σ restricts to a probability mass function on $\mathcal{T}_n$. The tuple $(\mathcal{T}, (\mathcal{T}_n)_{n\in\mathbb{N}}, P_\sigma)$ is called a *leaf-centric binary tree source*.

For an element $\sigma \in \Sigma$ define the mapping $\sigma^* : (\mathbb{N} \setminus \{0\}) \times (\mathbb{N} \setminus \{0\}) \to [0,1]$ by

$$\sigma^*(i,j) = \begin{cases} \sigma(i,j) + \sigma(j,i) & \text{if } i \neq j \\ \sigma(i,j) & \text{if } i = j. \end{cases}$$

Note that $\sigma^*(i,j) \leq 1$ for all i,j and that $\sum_{k=1}^{\lfloor n/2 \rfloor} \sigma^*(k, n-k) = 1$.

3 Average size of the minimal DAG

Consider $\sigma \in \Sigma$. The *average size of the minimal DAG* with respect to the leaf-centric binary tree source $(\mathcal{T}, (\mathcal{T}_n)_{n\in\mathbb{N}}, P_\sigma)$ is the function $\mathcal{D}_\sigma : \mathbb{N} \to \mathbb{R}$ defined by equation (1). In the following, we present three natural classes of leaf-centric binary tree sources and investigate the average size of the minimal DAG with respect to these leaf-centric binary tree sources. In particular, we present conditions on $\sigma \in \Sigma$ that imply $\mathcal{D}_\sigma(n) \in o(n)$. In order to estimate $\mathcal{D}_\sigma$, we use the so-called cut-point argument that was applied in several papers [6, 15].

For a mapping $\sigma \in \Sigma$ and integers $b \geq 1$ and $n \geq 1$, let $E_{\sigma,b}(n)$ denote the expected value of $N(t,b)$ with respect to the probability mass function P_σ on the set of binary trees $\mathcal{T}_n$:

$$E_{\sigma,b}(n) = \sum_{t \in \mathcal{T}_n} P_\sigma(t) \cdot N(t,b).$$

Clearly, $E_{\sigma,b}(n) = 0$ if $n \leq b$. The following lemma constitutes the crucial argument we need in order to estimate the average size of a minimal DAG.

▶ **Lemma 1.** *Let $\sigma \in \Sigma$ and let $n \geq b \geq 1$. Then $\mathcal{D}_\sigma(n) \leq E_{\sigma,b}(n) + 4^b/3$.*

Proof. Let $t \in \mathcal{T}_n$. The size of the minimal DAG $\mathcal{D}_t$ of t is upper bounded by

(i) the number $N(t,b)$ of nodes of t of leaf-size greater than b plus

(ii) the number of binary trees with at most b leaves.

Recall that the number of binary trees with k leaves is the $(k-1)^{\text{th}}$ Catalan number C_{k-1}, which is bounded by 4^{k-1}. Hence, the number in (ii) is upper bounded by $\sum_{k=1}^{b} 4^{k-1} \leq 4^b/3$. This proves the lemma. ◀

The integer $b \geq 1$ from Lemma 1 is called the cutpoint. In order to apply Lemma 1 to estimate $\mathcal{D}_\sigma$, we first have to obtain estimates for $E_{\sigma,b}(n)$. This will be done inductively: Let $t = f(u,v) \in \mathcal{T}_n$ and let $b < n$. The number of nodes of t of leaf-size greater than b is composed of the number of nodes of the left subtree u of leaf-size greater than b plus the number of nodes of the right subtree v of leaf-size greater than b plus one (for the root), i.e., $N(t,b) = N(u,b) + N(v,b) + 1$. This observation easily yields the following recurrence relation for the expected value $E_{\sigma,b}(n)$:

$$E_{\sigma,b}(n) \;=\; 1 + \sum_{k=b+1}^{n-1} (\sigma(k, n-k) + \sigma(n-k, k)) \cdot E_{\sigma,b}(k).$$

With our definition of σ^*, this is equivalent to

$$E_{\sigma,b}(n) = \; 1 + \sum_{k=b+1}^{n-1} \sigma^*(k, n-k) \cdot E_{\sigma,b}(k) \tag{2}$$

if $b+1 > \frac{n}{2}$ and

$$E_{\sigma,b}(n) = 1 + \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)(E_{\sigma,b}(k) + E_{\sigma,b}(n-k)) \; + \sum_{k=n-b}^{n-1} \sigma^*(k, n-k) E_{\sigma,b}(k) \tag{3}$$

if $b+1 \leq \frac{n}{2}$.

3.1 Average size of the minimal DAG for bounded σ-functions

First, we consider leaf-centric binary tree sources $(\mathcal{T}, (\mathcal{T}_n)_{n\in\mathbb{N}}, P_\sigma)$, where the function values of σ (or σ^*) are upper bounded by a function. We will prove an upper as well as a lower bound on the average DAG size.

3.1.1 Upper bound on the average DAG size

▶ **Definition 2** (the class Σ_*^ψ)**.** For a monotonically decreasing function $\psi : \mathbb{R} \to (0,1]$ such that $\psi(x) \geq 2/(x-1)$ for all large enough $x > 1$, let $\Sigma_*^\psi \subseteq \Sigma$ denote the set of mappings $\sigma \in \Sigma$ such that $\sigma^*(k, n-k) \leq \psi(n)$ for all large enough $n \geq 2$ and all $1 \leq k \leq n-1$.

The restriction $\psi(x) \geq 2/(x-1)$ is quite natural, at least for odd $x \in \mathbb{N}$, because $\sum_{k=1}^{n-1} \sigma^*(k, n-k) = 2$ if n is odd.

As our first main theorem, we prove an upper bound on $\mathcal{D}_\sigma(n)$ for every $\sigma \in \Sigma_*^\psi$:

▶ **Theorem 3.** *For every $\sigma \in \Sigma_*^\psi$, we have $\mathcal{D}_\sigma(n) \in \mathcal{O}\left(\psi\left(\frac{1}{2}\log_4(n)\right) \cdot n\right)$.*

Note that Theorem 3 only makes a nontrivial statement if ψ converges to zero: if ψ is lower bounded by a nonzero constant then we only obtain the trivial bound $\mathcal{D}_\sigma(n) \in \mathcal{O}(n)$. Moreover, the bound $\mathcal{D}_\sigma(n) \in \mathcal{O}\left(\psi\left(\frac{1}{2}\log_4(n)\right) \cdot n\right)$ also holds if we require that $\sigma(k, n-k) \leq \psi(n)$ for all large enough n and $1 \leq k \leq n-1$, since the latter implies that $\sigma^*(k, n-k) \leq 2\psi(n)$.

Let us fix a monotonically decreasing function $\psi : \mathbb{R} \to (0,1]$ such that $\psi(n) \geq 2/(n-1)$ for all large enough n. Moreover, let $\sigma \in \Sigma_*^\psi$. We can choose a constant N_σ such that $\psi(n) \geq 2/(n-1)$ and $\sigma^*(k, n-k) \leq \psi(n)$ for all $n \geq N_\sigma$ and all $1 \leq k \leq n-1$. In order to prove Theorem 3, we use the cut-point argument from Lemma 1. Thus, we start with an upper bound for $E_{\sigma,b}(n)$. A similar statement for the special case of the binary search tree model was shown by Knuth [12, p. 121].

▶ **Lemma 4.** *For all n, b with $n \geq b+1 > N_\sigma$ we have $E_{\sigma,b}(n) \leq 4n\psi(b) - 2$.*

In the proof of Lemma 4, we make use of the following lemma from linear optimization:

▶ **Lemma 5.** *Let $a_0 \leq a_1 \leq \cdots \leq a_{n-1}$ be a finite sequence of monotonically increasing positive real numbers and let $0 \leq c, \omega \leq 1$ and $l := \lfloor \omega/c \rfloor$. Moreover, let $x_0, \ldots, x_{n-1}$ denote real numbers satisfying $0 \leq x_i \leq c$ for every $0 \leq i \leq n-1$ and $\sum_{k=0}^{n-1} x_k = \omega$. Then*

$$\sum_{i=0}^{n-1} a_i x_i \leq c \sum_{i=n-l}^{n-1} a_i + (\omega - lc) a_{n-l-1}. \tag{4}$$

Proof. Since $0 \leq a_0 \leq a_1 \leq \cdots \leq a_{n-1}$ and $0 \leq x_i \leq c$, the sum $\sum_{i=0}^{n-1} a_i x_i$ is maximized if we choose the maximal weight c for the l largest values $a_{n-l} \leq \cdots \leq a_{n-1}$ (i.e., $x_{n-l} = \cdots = x_{n-1} = c$), and put the remaining weight $\omega - lc$ (note that $\omega/c - 1 \leq l \leq \omega/c$, which implies $0 \leq \omega - lc \leq c$) on the $(l-1)$-th largest value a_{n-l-1} (i.e., $x_{n-l-1} = \omega - l \cdot c$). The remaining $x_1, \ldots, x_{n-l-2}$ are set to zero. Then $\sum_{i=0}^{n-1} a_i x_i$ becomes the right-hand side of (4). ◀

Proof of Lemma 4. We prove the statement inductively in $n \geq b+1 > N_\sigma$. For the base case, let $n = b+1$. We have $E_{\sigma,b}(b+1) = 1 \leq 4(b+1)\psi(b) - 2$, as $\psi(b) \geq \frac{2}{b-1}$ by assumption.

For the induction step take an $n > b+1 > N_\sigma$ such that $E_{\sigma,b}(k) \leq 4k\psi(b) - 2$ for every $b < k \leq n-1$. By assumption, we have $n - 1 \geq n - \frac{1}{\psi(n)} > \frac{n}{2}$, as $n > N_\sigma$. We distinguish three subcases:

Case 1: $\frac{n}{2} < b+1 < n - \frac{1}{\psi(n)}$. By equation (2) and the induction hypothesis, we have

$$E_{\sigma,b}(n) \leq 1 + \sum_{k=b+1}^{n-1} \sigma^*(k, n-k) \left(4k\psi(b) - 2\right). \tag{5}$$

Note that $\frac{n}{2} < b+1$ implies that $\sum_{k=b+1}^{n-1} \sigma^*(k, n-k) \leq 1$. Without loss of generality, we can assume that $\sum_{k=b+1}^{n-1} \sigma^*(k, n-k) = 1$: since $4k\psi(b) - 2 > 0$ for every k with $b+1 \leq k \leq n-1$, this makes the right-hand side in (5) only larger. Let $l := \left\lfloor \frac{1}{\psi(n)} \right\rfloor$ and $\delta := \frac{1}{\psi(n)} - l$. Applying Lemma 5 (with $a_k = 4k\psi(b) - 2$, $x_k = \sigma^*(k, n-k)$, $c = \psi(n)$ and $\omega = 1$), we get

$$E_{\sigma,b}(n) \leq 1 + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2) + (1 - l\psi(n)) \left(4(n-l-1)\psi(b) - 2\right). \tag{6}$$

By simplifying the right hand side and using $0 \leq \delta < 1$ and $\psi(n) \leq \psi(b)$, we get

$$\begin{aligned} E_{\sigma,b}(n) &\leq 4n\psi(b) - 1 - 4l\psi(b) - 4\psi(b) + 2l^2\psi(n)\psi(b) + 2l\psi(n)\psi(b) \\ &= 4n\psi(b) - 1 - \frac{2\psi(b)}{\psi(n)} - 2\psi(b) - 2\delta\psi(n)\psi(b) + 2\delta^2\psi(n)\psi(b) \\ &\leq 4n\psi(b) - 1 - \frac{2\psi(b)}{\psi(n)} - 2\psi(b) \leq 4n\psi(b) - 2. \end{aligned}$$

Case 2: $b+1 \geq n - \frac{1}{\psi(n)}$. By equation (2) and by the induction hypothesis, we get

$$E_{\sigma,b}(n) \leq 1 + \sum_{k=b+1}^{n-1} \sigma^*(k, n-k) \left(4k\psi(b) - 2\right).$$

Again, let $l := \left\lfloor \frac{1}{\psi(n)} \right\rfloor$ and $\delta := \frac{1}{\psi(n)} - l$. Since $b+1 \geq n - \frac{1}{\psi(n)}$ by assumption and $b+1 \in \mathbb{N}$ we have $b+1 \geq n-l$. Moreover, $n - \frac{1}{\psi(n)} > \frac{n}{2}$ implies $n - l > \frac{n}{2}$. Since $n-l$ is an integer, we get $n-l-1 \geq \frac{n-1}{2}$. This implies

$$4(n-l-1)\psi(b) - 2 \geq 2(n-1)\psi(b) - 2 \geq 2(n-1)\psi(n) - 2 \geq 2(n-1)\frac{2}{n-1} - 2 > 0$$

and hence also $4k\psi(b) - 2 > 0$ for all $n-l-1 \leq k \leq n-1$. As $\sigma \in \Sigma_*^\psi$, we have $\sigma^*(k, n-k) \leq \psi(n)$ for every $1 \leq k \leq n-1$. We get

$$E_{\sigma,b}(n) \leq 1 + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2)\,.$$

Moreover, we have $1 - \psi(n)l \geq 0$ and $4(n-l-1)\psi(b) - 2 \geq 0$ and thus

$$E_{\sigma,b}(n) \leq 1 + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2) + (1 - \psi(n)l)\,(4(n-l-1)\psi(b) - 2)\,.$$

This is equation (6) from Case 1. The statement follows now as in Case 1.

Case 3: $b+1 \leq \frac{n}{2}$. By equation (3) and the induction hypothesis, we have

$$\begin{aligned} E_{\sigma,b}(n) &= 1 + \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)\,(E_{\sigma,b}(k) + E_{\sigma,b}(n-k)) + \sum_{k=n-b}^{n-1} \sigma^*(k, n-k) E_{\sigma,b}(k) \\ &\leq 1 + (4n\psi(b) - 4) \sum_{k=b+1}^{n-b-1} \sigma(k, n-k) + \sum_{k=n-b}^{n-1} \sigma^*(k, n-k)\,(4k\psi(b) - 2)\,. \end{aligned}$$

We set $\alpha := \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)$. Hence, we have $\sum_{k=n-b}^{n-1} \sigma^*(k, n-k) = 1 - \alpha$. Set $l := \lfloor \frac{1-\alpha}{\psi(n)} \rfloor$. Note that $l \leq \frac{1}{\psi(n)} \leq \frac{n-1}{2}$ and that $4k\psi(b) - 2 \geq 0$ for all $n - b \leq k \leq n-1$ since $n - b > \frac{n}{2}$ and $\psi(b) \geq \psi(n) > \frac{2}{n}$. We distinguish two subcases:

Case 3.1: $b > l$ and thus, $n - b < n - l$. Applying Lemma 5 (with $a_k = 4k\psi(b) - 2$ and $x_k = \sigma^*(k, n-k)$ for $n - b \leq k \leq n-1$ and $c = \psi(n)$, $\omega = 1 - \alpha$) yields

$$\begin{aligned} E_{\sigma,b}(n) \leq\ & 1 + (4n\psi(b) - 4)\,\alpha + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2) \\ & + (1 - \alpha - l\psi(n))\,(4(n-l-1)\psi(b) - 2)\,. \end{aligned} \tag{7}$$

Simplifying the right-hand side yields

$$E_{\sigma,b}(n) \leq 4n\psi(b) - 2\alpha - 1 + 2l\psi(n)\psi(b) + 2l^2\psi(n)\psi(b) - 4(1-\alpha)\psi(b) - 4(1-\alpha)l\psi(b).$$

Setting $\delta := \frac{(1-\alpha)}{\psi(n)} - l$, we get

$$E_{\sigma,b}(n) \leq 4n\psi(b) - 2\alpha - 1 - 2(1-\alpha)\psi(b) - \frac{2\psi(b)(1-\alpha)^2}{\psi(n)} - 2\delta\psi(n)\psi(b) + 2\delta^2\psi(n)\psi(b).$$

As $0 \leq \delta < 1$ and $\psi(n) \leq \psi(b)$, we have

$$\begin{aligned} E_{\sigma,b}(n) &\leq 4n\psi(b) - 2\alpha - 1 - 2(1-\alpha)\psi(b) - \frac{2\psi(b)(1-\alpha)^2}{\psi(n)} \\ &\leq 4n\psi(b) - 2\alpha - 1 - 2(1-\alpha)\psi(b) - 2(1-\alpha)^2. \end{aligned}$$

With $-2\alpha - 2(1-\alpha)^2 \leq -1$ for every value $0 \leq \alpha \leq 1$, the statement follows.

Case 3.2: $b \leq l$ and thus $n - b \geq n - l$. Since $n - l - 1 \geq n - \frac{n-1}{2} - 1 = \frac{n-1}{2}$ and $\psi(b) \geq \psi(n) \geq \frac{2}{n-1}$ we have $4(n-l-1)\psi(b) - 2 \geq 0$. Thus, we also have $4k\psi(b) - 2 \geq 0$ for every $n - l \leq k \leq n - 1$. Moreover, as $\sigma^*(k, n-k) \leq \psi(n)$, we get

$$E_{\sigma,b}(n) \leq 1 + (4n\psi(b) - 4)\,\alpha + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2)\,.$$

Furthermore, as $1 - \alpha - l\psi(n) \geq 0$, we obtain

$$\begin{aligned} E_{\sigma,b}(n) \;\leq\; & 1 + (4n\psi(b) - 4)\,\alpha + \psi(n) \sum_{k=n-l}^{n-1} (4k\psi(b) - 2) \\ & + (1 - \alpha - l\psi(n))\,(4(n-l-1)\psi(b) - 2)\,. \end{aligned}$$

This is equation (7) from Case 3.1, and we can conclude as in Case 3.1. This finishes the proof of Lemma 4. ◀

With Lemma 4, we are able to prove Theorem 3 using the cut-point argument from Lemma 1:

Proof of Theorem 3. Let $\sigma \in \Sigma_*^\psi$, $n > 4^{2N_\sigma}$ and $N_\sigma \leq b < n$. By Lemma 1 and 4 we have $\mathcal{D}_\sigma(n) \leq E_{\sigma,b}(n) + 4^b/3 \leq 4n \cdot \psi(b) + 4^b/3$. Choose $b := \lceil \log_4(n)/2 \rceil$. As $n > 4^{2N_\sigma}$, this accords with $b \geq N_\sigma$. We obtain $\mathcal{D}_\sigma(n) \leq 4n \cdot \psi\left(\log_4(n)/2\right) + \Theta(\sqrt{n})$. Since $n \cdot \psi\left(\log_4(n)/2\right) \geq \frac{2n}{\log_4(n)/2-1}$ grows faster than $\Theta(\sqrt{n})$, this finishes the proof. ◀

In the following examples, we consider the results of Theorem 3 with respect to some concrete functions ψ:

▶ **Example 6.** Let $\sigma_{\mathrm{bst}}(k, n-k) = \frac{1}{n-1}$ for every integer $1 \leq k \leq n-1$ and $n \geq 2$. The leaf-centric binary tree source $(\mathcal{T}, (\mathcal{T}_n)_{n\geq 1}, P_{\sigma_{\mathrm{bst}}})$ corresponds to the well-known binary search tree model. Let $\psi(x) = \frac{2}{x-1}$ for every $x > 1$. We find $\sigma_{\mathrm{bst}} \in \Sigma_*^\psi$. With Theorem 3, we have $\mathcal{D}_{\sigma_{\mathrm{bst}}} \in \mathcal{O}(n/\log n)$, which accords with the results of [6]. ◀

▶ **Example 7.** There are plenty of other ways to choose ψ in Theorem 3. For example $\psi(x) \in \Theta(1/x^\alpha)$ with $0 \leq \alpha \leq 1$ yields $\mathcal{D}_\sigma(n) \in \mathcal{O}(n/\log(n)^\alpha)$ for every $\sigma \in \Sigma_*^\psi$. For $\psi(x) \in \Theta(1/\log x)$ we get $\mathcal{D}_\sigma(n) \in \mathcal{O}(n/\log\log n)$ for every $\sigma \in \Sigma_*^\psi$. ◀

3.1.2 Lower bound on the average DAG size

In this section we prove a lower bound for $\mathcal{D}_\sigma(n)$.

▶ **Definition 8** (the class Σ^ρ)**.** For a constant ρ with $0 < \rho < 1$ let Σ^ρ denote the set of mappings $\sigma \in \Sigma$ such that $\sigma(k, n-k) \leq \rho$ for all large enough n and all $1 \leq k \leq n-1$.

By Theorem 3, we only know $\mathcal{D}_\sigma(n) \in \mathcal{O}(n)$ for $\sigma \in \Sigma^\rho$. In the following theorem, we present a lower bound for $\mathcal{D}_\sigma(n)$ with respect to a mapping $\sigma \in \Sigma^\rho$:

▶ **Theorem 9.** *If $\sigma \in \Sigma^\rho$, then $\mathcal{D}_\sigma(n) \in \Omega(n/\log n)$.*

Let us fix a mapping $\sigma \in \Sigma^\rho$, where $0 < \rho < 1$, and let $N_\sigma \geq 2$ such that $\sigma(k, n-k) \leq \rho$ for all $n \geq N_\sigma$ and all $1 \leq k \leq n-1$. In order to prove Theorem 9, we make use of an information-theoretic argument. We need the following notations: For a mapping $\sigma \in \Sigma$, let X_σ^n denote the random variable taking values in $\mathcal{T}_n$ according to the probability mass function P_σ on $\mathcal{T}_n$. Moreover, let $H(X_\sigma^n)$ denote the Shannon entropy of X_σ^n, i.e.,

$$H(X_\sigma^n) = \sum_{t \in \mathcal{T}_n} P_\sigma(t) \cdot \log(1/P_\sigma(t)).$$

▶ **Lemma 10.** *If $\sigma \in \Sigma^\rho$, then $H(X_\sigma^n) \geq \log\left(\frac{1}{\rho}\right)\left(\frac{n}{4N_\sigma - 4}\right)$ for every $n \geq N_\sigma$.*

In order to prove Lemma 10, we need a lower bound for $E_{\sigma,b}(n)$:

▶ **Lemma 11.** *For a mapping $\sigma \in \Sigma$ and integers $n > b \geq 1$, we have $E_{\sigma,b}(n) \geq \frac{n}{4b}$.*

Proof. We prove the statement inductively in $n \geq b+1$: For the base case, let $n = b+1$. A binary tree $t \in \mathcal{T}_{b+1}$ has exactly one node of leaf-size greater than b, which is the root of t. Thus, $E_{\sigma,b}(b+1) = 1 \geq \frac{b+1}{4b}$ for every integer $b \geq 1$. For the induction hypothesis, take an integer $n > b+1$ such that $E_{\sigma,b}(k) \geq \frac{k}{4b}$ for every integer $b+1 \leq k \leq n-1$.

In the induction step, we distinguish two cases:

Case 1: $\frac{n}{2} < b+1 \leq n-1$. We thus have $\frac{n}{4b} \leq 1$. By equation (2), we have

$$E_{\sigma,b}(n) = 1 + \sum_{k=b+1}^{n-1} \sigma^*(k, n-k) E_{\sigma,b}(k) \geq 1 \geq \frac{n}{4b}.$$

Case 2: $b+1 \leq \frac{n}{2}$. Let $\alpha := \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)$. From equation (3) and the induction hypothesis we get

$$\begin{aligned}
E_{\sigma,b}(n) &= 1 + \sum_{k=b+1}^{n-b-1} \sigma(k,n-k)(E_{\sigma,b}(k) + E_{\sigma,b}(n-k)) + \sum_{k=n-b}^{n-1} \sigma^*(k,n-k) E_{\sigma,b}(k) \\
&\geq 1 + \sum_{k=b+1}^{n-b-1} \sigma(k,n-k)\frac{n}{4b} + \sum_{k=n-b}^{n-1} \sigma^*(k,n-k)\frac{k}{4b} \\
&\geq 1 + \frac{n}{4b}\sum_{k=b+1}^{n-b-1} \sigma(k,n-k) + \frac{n-b}{4b}\sum_{k=n-b}^{n-1} \sigma^*(k,n-k) \\
&= 1 + \alpha\frac{n}{4b} + (1-\alpha)\left(\frac{n-b}{4b}\right) = \frac{n}{4b} + \frac{3}{4} + \frac{\alpha}{4}.
\end{aligned}$$

As $0 \leq \alpha \leq 1$, the statement follows. ◀

Proof of Lemma 10. Lemma 10 follows from identity (4) in [11]: Define

$$h_k(\sigma) := \sum_{\substack{i,j \geq 1 \\ i+j=k}} \sigma(i,j) \log\left(\frac{1}{\sigma(i,j)}\right),$$

that is, $h_k(\sigma)$ is the Shannon entropy of the random variable taking values in $\{(i, k-i) \colon 1 \leq i \leq k-1\}$ according to the probility mass function σ. As $\sigma(i,j) \leq \rho$ for $i+j \geq N_\sigma$, we find

$$h_k(\sigma) \geq \log\left(\frac{1}{\rho}\right) \sum_{\substack{i,j \geq 1 \\ i+j=k}} \sigma(i,j) = \log\left(\frac{1}{\rho}\right)$$

for every $k \geq N_\sigma$. Identity (4) in [11] states that $H(X_\sigma^n) = \sum_{j=2}^n \left(E_{\sigma,j-1}(n) - E_{\sigma,j}(n)\right) h_j(\sigma)$. With $n \geq N_\sigma$, we obtain

$$\begin{aligned}
H(X_\sigma^n) &\geq \sum_{j=N_\sigma}^{n} \left(E_{\sigma,j-1}(n) - E_{\sigma,j}(n)\right) h_j(\sigma) \geq \log\left(\frac{1}{\rho}\right) \sum_{j=N_\sigma}^{n} \left(E_{\sigma,j-1}(n) - E_{\sigma,j}(n)\right) \\
&= \log\left(\frac{1}{\rho}\right)\left(E_{\sigma,N_\sigma-1}(n) - E_{\sigma,n}(n)\right) = \log\left(\frac{1}{\rho}\right) E_{\sigma,N_\sigma-1}(n).
\end{aligned}$$

By Lemma 11, we have $H(X_\sigma^n) \geq \log\left(\frac{1}{\rho}\right)\left(\frac{n}{4N_\sigma - 4}\right)$. This proves the statement. ◀

With Lemma 10, we are able to prove Theorem 9:

Proof of Theorem 9. We first show that a binary tree $t \in \mathcal{T}_n$ can be encoded with at most $2m\lceil\log(2n-1)\rceil$ bits, where $m = |\mathcal{D}_t| \leq 2n-1$ (note that t has exactly $2n-1$ nodes). It suffices to encode $\mathcal{D}_t$. W.l.o.g. assume that the nodes of $\mathcal{D}_t$ are the numbers $1,\dots,m$, where m is the unique leaf node of $\mathcal{D}_t$. For $1 \leq k \leq m-1$ let l_k (resp., r_k) be the left (resp., right) child of node k. We encode each number $1,\dots,m$ by a bit string of length exactly $\lceil\log(2n-1)\rceil$. The DAG $\mathcal{D}_t$ can be uniquely encoded by the bit string $l_1r_1l_2r_2\cdots l_{m-1}r_{m-1}$, which has length $2(m-1)\lceil\log(2n-1)\rceil$.

Let $\sigma \in \Sigma^\rho$. By Lemma 10, we know that $H(X_\sigma^n) \geq \log\left(\frac{1}{\rho}\right)\left(\frac{n}{4N_\sigma-4}\right)$ for every $n \geq N_\sigma$. Shannon's coding theorem implies

$$H(X_\sigma^n) \leq 2\lceil\log(2n-1)\rceil \sum_{t\in\mathcal{T}_n} P_\sigma(t)|\mathcal{D}_t| = 2\lceil\log(2n-1)\rceil\mathcal{D}_\sigma(n).$$

We get $\log(1/\rho)\left(\frac{n}{4N_\sigma-4}\right) \leq 2\lceil\log(2n-1)\rceil\mathcal{D}_\sigma(n)$ for all $n \geq 2$, which concludes the proof. ◀

3.2 Average size of the minimal DAG for weakly balanced tree sources

In this subsection, we present so-called *weakly balanced* binary tree sources, which represent a generalization of balanced binary tree sources introduced in [11] and further analysed in [10]. Let us fix a constant $c \geq 3$ for the rest of this subsection.

▶ **Definition 12** (the class Σ_ϕ)**.** For a monotonically decreasing function $\phi : \mathbb{N} \to (0,1]$ let $\Sigma_\phi \subseteq \Sigma$ denote the set of mappings σ such that for every $n \geq 2$,

$$\sum_{\frac{n}{c}\leq k\leq n-\frac{n}{c}} \sigma(k,n-k) \geq \phi(n).$$

We call a binary tree source $(\mathcal{T},(\mathcal{T}_n)_{n\geq 1},P_\sigma)$ with $\sigma \in \Sigma_\phi$ *weakly balanced*. We obtain the following upper bound for $\mathcal{D}_\sigma$ with respect to a weakly balanced tree source:

▶ **Theorem 13.** *For every $\sigma \in \Sigma_\phi$, we have $\mathcal{D}_\sigma(n) \in \mathcal{O}\left(\frac{n}{\phi(n)\log n}\right)$.*

Theorem 13 can be used to reprove the upper bound $\mathcal{D}_{\sigma_{\text{bst}}}(n) \in \mathcal{O}(n/\log n)$ for the binary search tree model from Example 6 (note that $\sum_{n/4\leq k\leq 3n/4}\frac{1}{n-1} > \frac{1}{2}$). More generally, if $\phi(n) \in \omega(1/\log n)$, then Theorem 13 yields $\mathcal{D}_\sigma(n) \in o(n)$ for every $\sigma \in \Sigma_\phi$.

Analogously to Theorem 3, we show Theorem 13 using the cut-point argument from Lemma 1. The strategy in the proof of the following lemma is similar to Lemma 4.

▶ **Lemma 14.** *For every $\sigma \in \Sigma_\phi$ and all $b \geq 1$, $n \geq b+1$ we have $E_{\sigma,b}(n) \leq \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)}$.*

Proof. We prove the statement inductively in $n \geq b+1$. For the base case, note that a binary tree $t \in \mathcal{T}_{b+1}$ has exactly one node of leaf-size $> b$, which is the root of t. Thus,

$$E_{\sigma,b}(b+1) = 1 \leq \frac{c(b+1)}{\phi(b+1)b} - \frac{1}{\phi(b+1)}.$$

Let us now deal with the induction step. Take an integer $n > b+1$ such that $E_{\sigma,b}(k) \leq \frac{ck}{\phi(k)b} - \frac{1}{\phi(k)}$ for every integer $b+1 \leq k \leq n-1$. We distinguish six cases:

Case 1: $c \geq n$ and thus $c > b$. We have $\frac{n}{c} \leq 1$ and $n-1 \leq n-\frac{n}{c}$. Case 1 splits into two subcases:

Case 1.1: $\frac{n}{2} < b+1 \leq n-1$. By equation (2), the induction hypothesis, and the fact that ϕ is monotonically decreasing, we get

$$\begin{aligned} E_{\sigma,b}(n) &= 1 + \sum_{k=b+1}^{n-1} \sigma^*(k,n-k)\left(\frac{ck}{\phi(k)b} - \frac{1}{\phi(k)}\right) \\ &\leq 1 + \left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right) \sum_{k=b+1}^{n-1} \sigma^*(k,n-k). \end{aligned}$$

As $b+1 > \frac{n}{2}$ and $\sigma \in \Sigma$, we have $\sum_{k=b+1}^{n-1} \sigma^*(k,n-k) \leq 1$ and thus

$$E_{\sigma,b}(n) \leq \frac{cn}{\phi(n)b} - \frac{c}{\phi(n)b} - \frac{1}{\phi(n)} + 1 \leq \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)}.$$

Case 1.2: $b+1 \leq \frac{n}{2}$. Equation (3), the induction hypothesis, and the fact that ϕ is monotonically decreasing yield

$$\begin{aligned} E_{\sigma,b}(n) &= 1 + \sum_{k=b+1}^{n-b-1} \sigma(k,n-k)\left(E_{\sigma,b}(k) + E_{\sigma,b}(n-k)\right) + \sum_{k=n-b}^{n-1} \sigma^*(k,n-k)E_{\sigma,b}(k) \\ &\leq 1 + \sum_{k=b+1}^{n-b-1} \sigma(k,n-k)\left(\frac{cn}{\phi(n)b} - \frac{2}{\phi(n)}\right) \\ &\quad + \sum_{k=n-b}^{n-1} \sigma^*(k,n-k)\left(\frac{ck}{\phi(k)b} - \frac{1}{\phi(k)}\right) \\ &\leq 1 + \left(\frac{cn}{\phi(n)b} - \frac{2}{\phi(n)}\right) \sum_{k=b+1}^{n-b-1} \sigma(k,n-k) \\ &\quad + \left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right) \sum_{k=n-b}^{n-1} \sigma^*(k,n-k). \end{aligned}$$

We set $\alpha := \sum_{k=b+1}^{n-b-1} \sigma(k,n-k)$ and get

$$\begin{aligned} E_{\sigma,b}(n) &\leq 1 + \left(\frac{cn}{\phi(n)b} - \frac{2}{\phi(n)}\right)\alpha + \left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right)(1-\alpha) \\ &= \frac{cn}{\phi(n)b} - \frac{c}{\phi(n)b} + 1 - \frac{1}{\phi(n)} + \alpha\left(\frac{c}{\phi(n)b} - \frac{1}{\phi(n)}\right). \end{aligned}$$

As $c > b$ by assumption, the last term is monotonically increasing in α. With $\alpha \leq 1$, we have

$$E_{\sigma,b}(n) \leq \frac{cn}{\phi(n)b} - \frac{2}{\phi(n)} + 1 \leq \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)}.$$

Case 2: $n > c$. We have $\frac{n}{c} > 1$ and $n - \frac{n}{c} < n-1$. Case 2 splits into four subcases:

Case 2.1: $n - \frac{n}{c} < b+1 \leq n-1$. This case is very similar to Case 1.1 and left to the reader; see also the long version [2].

Case 2.2: $\frac{n}{2} < b+1 \leq n - \frac{n}{c}$. Equation (2), the induction hypothesis and the monotonicity of ϕ yield

$$\begin{aligned} E_{\sigma,b}(n) &= 1 + \sum_{b+1 \leq k \leq n-\frac{n}{c}} \sigma^*(k,n-k)E_{\sigma,b}(k) + \sum_{n-\frac{n}{c} < k \leq n-1} \sigma^*(k,n-k)E_{\sigma,b}(k) \\ &\leq 1 + \left(\frac{(c-1)n}{\phi(n)b} - \frac{1}{\phi(n)}\right) \sum_{b+1 \leq k \leq n-\frac{n}{c}} \sigma^*(k,n-k) \\ &\quad + \left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right) \sum_{n-\frac{n}{c} < k \leq n-1} \sigma^*(k,n-k). \end{aligned}$$

We set $\alpha := \sum_{n-\frac{n}{c}<k\leq n-1} \sigma^*(k, n-k)$. Since $b+1 > \frac{n}{2}$ we have $\sum_{b+1\leq k\leq n-\frac{n}{c}} \sigma^*(k, n-k) \leq 1-\alpha$ and get

$$\begin{aligned} E_{\sigma,b}(n) &\leq 1 + (1-\alpha)\left(\frac{(c-1)n}{\phi(n)b} - \frac{1}{\phi(n)}\right) + \alpha\left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right) \\ &= \frac{cn}{\phi(n)b} - \frac{n}{\phi(n)b} - \frac{1}{\phi(n)} + 1 + \alpha\frac{(n-c)}{\phi(n)b}. \end{aligned}$$

As $n > c$ by assumption, the last term is monotonically increasing in α. With $\alpha \leq 1-\phi(n)$ as $\sigma \in \Sigma_\phi$, we find

$$E_{\sigma,b}(n) \leq \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)} + 1 - \frac{c}{\phi(n)b} + \frac{c}{b} - \frac{n}{b} \leq \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)}.$$

Case 2.3: $\frac{n}{c} \leq b+1 \leq \frac{n}{2}$. Equation (3), the induction hypothesis, and the monotonicity of ϕ yield

$$\begin{aligned} E_{\sigma,b}(n) &= 1 + \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)(E_{\sigma,b}(k) + E_{\sigma,b}(n-k)) \\ &\quad + \sum_{n-b\leq k\leq n-\frac{n}{c}} \sigma^*(k, n-k)E_{\sigma,b}(k) + \sum_{n-\frac{n}{c}<k\leq n-1} \sigma^*(k, n-k)E_{\sigma,b}(k) \\ &\leq 1 + \left(\frac{cn}{\phi(n)b} - \frac{2}{\phi(n)}\right)\sum_{k=b+1}^{n-b-1} \sigma(k, n-k) \\ &\quad + \left(\frac{(c-1)n}{\phi(n)b} - \frac{1}{\phi(n)}\right)\sum_{n-b\leq k\leq n-\frac{n}{c}} \sigma^*(k, n-k) \\ &\quad + \left(\frac{c(n-1)}{\phi(n)b} - \frac{1}{\phi(n)}\right)\sum_{n-\frac{n}{c}<k\leq n-1} \sigma^*(k, n-k). \end{aligned}$$

With $\alpha := \sum_{k=b+1}^{n-b-1} \sigma(k, n-k)$ and $\beta := \sum_{n-\frac{n}{c}<k\leq n-1} \sigma^*(k, n-k)$ one can simplify this to

$$E_{\sigma,b}(n) = \frac{cn}{\phi(n)b} - \frac{n}{\phi(n)b} - \frac{1}{\phi(n)} + 1 + \alpha\left(\frac{n}{\phi(n)b} - \frac{1}{\phi(n)}\right) + \beta\left(\frac{n-c}{\phi(n)b}\right). \tag{8}$$

As $b < n$ and $c < n$ by assumption, the term in the last line is monotonically increasing in α and β. Using this fact, as well as $0 \leq \beta \leq 1-\phi(n)$ (as $\sigma \in \Sigma_\phi$), $0 \leq \alpha \leq 1$ and $\alpha+\beta \leq 1$, one can show that

$$\alpha\left(\frac{n}{\phi(n)b} - \frac{1}{\phi(n)}\right) + \beta\left(\frac{n-c}{\phi(n)b}\right) \leq \frac{n}{\phi(n)b} - 1$$

(see the long version [2] for details). Plugging this into (8) yields

$$E_{\sigma,b}(n) \leq \frac{cn}{\phi(n)b} - \frac{n}{\phi(n)b} - \frac{1}{\phi(n)} + 1 + \frac{n}{\phi(n)b} - 1 = \frac{cn}{\phi(n)b} - \frac{1}{\phi(n)}.$$

Case 2.4: $b+1 < \frac{n}{c}$. This case is very similar to Case 1.2 and left to the reader; see also the long version [2].

◀

Proof of Theorem 13. Let $n \geq 2$ and let $1 \leq b < n$. By Lemma 1 and 14, we have

$$\mathcal{D}_\sigma(n) \leq E_{\sigma,b}(n) + \frac{4^b}{3} \leq \frac{cn}{\phi(n)b} + \frac{4^b}{3}.$$

Choosing $b := \lceil \frac{1}{2}\log_4(n) \rceil$, the statement follows. ◀

In the following corollary we identify a constant $\nu \in (0,1]$ with the function mapping every $n \in \mathbb{N}$ to ν. The corollary follows immediately from Theorem 13 and 9.

▶ **Corollary 15.** *For all* $0 < \nu, \rho < 1$ *and all* $\sigma \in \Sigma_\nu \cap \Sigma^\rho$ *we have* $\mathcal{D}_\sigma(n) \in \Theta(n/\log n)$.

▶ **Example 16.** In this example, we investigate the binomial random tree model, which was studied in [11] for the case $p = 1/2$, and which is a slight variant of the digital search tree model, see [13]. Let $0 < p < 1$ and define $\sigma_p \in \Sigma$ by

$$\sigma_p(k, n-k) = p^{k-1}(1-p)^{n-k-1}\binom{n-2}{k-1}$$

for every integer $n \geq 2$ and $1 \leq k \leq n-1$. We use the abbreviation $\pi(i) = \sigma_p(i, n-i)$ in the following. By the binomial theorem, we have $\sum_{k=1}^{n-1} \pi(k) = 1$. In the following, we will prove that $\mathcal{D}_{\sigma_p}(n) \in \mathcal{O}(n/\log n)$. We distinguish two cases.

Case 1: $0 < p \leq \frac{1}{2}$. Let $\nu := 1 - \frac{4-4p}{4+p}$. We find $\nu > 0$ for $0 < p \leq \frac{1}{2}$. We claim that with $c := \frac{6}{p}$, we have $\sigma_p \in \Sigma_\nu$. Then Theorem 13 yields $\mathcal{D}_{\sigma_p}(n) \in \mathcal{O}(n/\log n)$.
In order to prove $\sigma_p \in \Sigma_\nu$, we show

$$\sum_{\frac{np}{6} \leq i \leq n - \frac{np}{6}} \sigma_p(i, n-i) = \sum_{\frac{np}{6} \leq i \leq n - \frac{np}{6}} \pi(i) \geq 1 - \frac{4-4p}{4+p}.$$

Without loss of generality, let $n \geq 3$. Let X_p^n denote the random variable taking values in the set $\{1, \ldots, n-1\}$ according to the probability mass function π. Thus, $X_p^n = 1 + Y_p^n$, where Y_p^n is binomially distributed with parameters $n-2$ and p. For the expected value and variance of X_p^n we obtain $\mathsf{E}[X_p^n] = p(n-2)+1$ and $\mathsf{Var}[X_p^n] = p(1-p)(n-2)$. Let $\kappa := p(n-2)/2$ so that $\mathsf{E}[X_p^n] = 2\kappa + 1$ and $\mathsf{Var}[X_p^n] = 2\kappa(1-p)$. By Chebyshev's inequality, we have ($\mathsf{Prob}(A)$ denotes the probability of the event A)

$$\begin{aligned}\mathsf{Prob}\left(|X_p^n - \mathsf{E}[X_p^n]| < \kappa + 1\right) &\geq 1 - \frac{\mathsf{Var}[X_p^n]}{(\kappa+1)^2} = 1 - \frac{2\kappa(1-p)}{\kappa^2 + 2\kappa + 1} \geq 1 - \frac{2(1-p)}{\kappa+2} \\ &= 1 - \frac{4(1-p)}{p(n-2)+4} \geq 1 - \frac{4(1-p)}{p+4}\end{aligned}$$

where the last inequality holds due to $n \geq 3$. Moreover, with $\mathsf{E}[X_p^n] = 2\kappa + 1$, we have

$$\mathsf{Prob}\left(|X_p^n - \mathsf{E}[X_p^n]| < \kappa + 1\right) = \sum_{\kappa < i < 3\kappa + 2} \pi(i).$$

As $n \geq 3$ and $0 < p \leq \frac{1}{2}$, we have $\kappa \geq \frac{pn}{6}$ and $3\kappa + 2 \leq n - \frac{pn}{6}$. Thus, we have

$$\sum_{\frac{pn}{6} \leq i \leq n - \frac{pn}{6}} \pi(i) \geq \sum_{\kappa < i < 3\kappa+2} \pi(i) = \mathsf{Prob}\left(|X_p^n - \mathsf{E}[X_p^n]| < \kappa + 1\right) \geq 1 - \frac{4(1-p)}{p+4}.$$

This finishes the proof of Case 1.

Case 2: $\frac{1}{2} < p < 1$. Define a mapping $\vartheta : \mathcal{T} \to \mathcal{T}$ inductively by $\vartheta(a) = a$ and $\vartheta(f(u,v)) = f(\vartheta(v), \vartheta(u))$. Intuitively, ϑ exchanges the right child node and the left child node of every node of a binary tree t. It is easy to see that $\vartheta : \mathcal{T}_n \to \mathcal{T}_n$ is a bijection for every $n \geq 1$ and that ϑ^2 is the identity mapping. Moreover, t and $\vartheta(t)$ have the same number of different pairwise non-isomorphic subtrees and thus, $|\mathcal{D}_t| = |\mathcal{D}_{\vartheta(t)}|$. We show inductively in $n \geq 1$, that $P_{\sigma_p}(\vartheta(t)) = P_{\sigma_{1-p}}(t)$ for a binary tree $t \in \mathcal{T}_n$: For the base case, let $t = a$. We find $P_{\sigma_p}(\vartheta(a)) = 1 = P_{\sigma_{1-p}}(a)$.

For the induction step, let $t = f(u, v) \in \mathcal{T}_n$. We have

$$\begin{aligned} P_{\sigma_p}(\vartheta(t)) &= P_{\sigma_p}(f(\vartheta(v), \vartheta(u))) &&= \sigma_p(|\vartheta(v)|, |\vartheta(u)|) P_{\sigma_p}(\vartheta(v)) P_{\sigma_p}(\vartheta(u)) \\ &&&= \sigma_p(|v|, |u|) P_{\sigma_{1-p}}(u) P_{\sigma_{1-p}}(v), \end{aligned}$$

where the last equality holds by the induction hypothesis. Moreover, with $|u| = n - |v|$ and by definition of σ_p, we find that $\sigma_p(|v|, |u|) = \sigma_{1-p}(|u|, |v|)$. Thus, we have

$$\sigma_p(|v|, |u|) P_{\sigma_{1-p}}(u) P_{\sigma_{1-p}}(v) = \sigma_{1-p}(|u|, |v|) P_{\sigma_{1-p}}(u) P_{\sigma_{1-p}}(v) = P_{\sigma_{1-p}}(t).$$

This finishes the induction. Altogether, and as $\vartheta : \mathcal{T}_n \to \mathcal{T}_n$ is a bijection, we get

$$\mathcal{D}_{\sigma_p}(n) = \sum_{t \in \mathcal{T}_n} P_{\sigma_p}(t) |\mathcal{D}_t| = \sum_{t \in \mathcal{T}_n} P_{\sigma_p}(\vartheta(t)) |\mathcal{D}_{\vartheta(t)}| = \sum_{t \in \mathcal{T}_n} P_{\sigma_{1-p}}(t) |\mathcal{D}_t| = \mathcal{D}_{\sigma_{1-p}}(n).$$

Since $\frac{1}{2} < p < 1$, we have $0 < 1 - p < \frac{1}{2}$. Thus, the result for Case 2 follows from Case 1.

4 Open Problems

Perhaps the most natural probability distribution on the set of binary trees with n leaves is the uniform distribution with $P_\sigma(t) = 1/C_{n-1}$ for every $t \in \mathcal{T}_n$, where C_n denotes the n^{th} Catalan number. The corresponding leaf-centric binary tree source is induced by the mapping $\sigma_{\text{eq}} \in \Sigma$ with $\sigma_{\text{eq}}(k, n-k) = C_{k-1} C_{n-k-1} / C_{n-1}$. In [8], it was shown that $\mathcal{D}_{\sigma_{\text{eq}}}(n) \in \Theta(n/\sqrt{\log n})$. Unfortunately, our main results Theorem 3 and Theorem 13 only yield the trivial bound $\mathcal{D}_{\sigma_{\text{eq}}} \in \mathcal{O}(n)$: An easy computation shows that $\sigma_{\text{eq}} \in \Sigma^\rho$ with $\rho = 1/4$ and $\sigma_{\text{eq}} \in \Sigma_\phi$ with $\phi(n) \in \Theta(1/\sqrt{n})$. An interesting open problem would be to find a nontrivial subset $\Sigma' \subseteq \Sigma$ that contains σ_{eq} and such that $\mathcal{D}_\sigma(n) \in \mathcal{O}(n/\sqrt{\log n})$ for all $\sigma \in \Sigma'$.

Another type of binary tree sources are so-called *depth-centric binary tree sources*, which yield probability distributions on the set of binary trees of a fixed depth; see for example [10, 16]. Depth-centric binary tree sources resemble leaf-centric binary tree sources in many ways. An interesting problem would be to estimate the average size of the minimal DAG with respect to certain classes of depth-centric binary tree sources.

Abstract

Satisfiability of Boolean circuits is NP-complete in general but becomes polynomial time when restricted for example either to monotone gates or linear gates. We go outside Boolean realm and consider circuits built of any fixed set of gates on an arbitrary large finite domain. From the complexity point of view this is connected with solving equations over finite algebras. This in turn is one of the oldest and well-known mathematical problems which for centuries was the driving force of research in algebra. Let us only mention Galois theory, Gaussian elimination or Diophantine Equations. The last problem has been shown to be undecidable, however in finite realms such problems are obviously decidable in nondeterministic polynomial time.

A project of characterizing finite algebras $\mathbf{A}$ with polynomial time algorithms deciding satisfiability of circuits over $\mathbf{A}$ has been undertaken in [12]. Unfortunately that paper leaves a gap for nilpotent but not supernilpotent algebras. In this paper we discuss possible attacks on filling this gap.

1 Introduction

Solving equations (or systems of equations) over an algebra $\mathbf{A}$ is one of the oldest and well-known mathematical problems which for centuries was the driving force of research in algebra. Let us only mention Galois theory, Gaussian elimination or Diophantine Equations. In fact, for $\mathbf{A}$ being the ring of integers this is the famous 10th Hilbert Problem on Diophantine Equations, which has been shown to be undecidable [17]. In finite realms such problems are obviously decidable in nondeterministic polynomial time.

The decision version of solving systems of equations is strictly connected with Constraint Satisfaction Problem for relational structures. A bisimulation between these two problems has been presented in [15] and [5]. Due to this bisimulation and the recent dichotomy results for CSP [2, 20] one can translate the beautiful splitting conditions into the language of satisfiability of systems of equations. Unfortunately such a bisimulation between satisfiability of a single equation (denoted by PolSat) and CSP is not known. Therefore the search for a characterization of finite algebras with tractable PolSat seems to be challenging. There were isolated results for particular algebraic structures like groups [7, 10, 9], rings [8] or lattices [19]. However, already a study of PolSat for groups has shown [11] that for the alternating group $\mathbf{A}_4$ the problem has a polynomial time solution in the pure group language, while it is NP-complete after endowing $\mathbf{A}_4$ with binary commutator operation (which is obviously definable by group multiplication). Here the polynomial time complexity is a result of artificial inflation of the size of input – indeed the terms used in proving NP-completeness are exponentially longer in pure group language than in the language allowing group commutator. This unwanted phenomena should be eliminated when one wants to get a characterization of abstract algebras with polynomial time procedures for satisfiability of single equations. This project has been taken over in [12] where a measure of the size of input is based on circuits representing terms/polynomials. This eliminates the mentioned exponential inflation of the size of terms by replacing all terms by circuits that computes them. For a detailed discussion of this we refer to [12]. Here we only recall definitions (in this new setting) of two problems based on PolSat and its dual.

- Csat($\mathbf{A}$)
  given a circuit over the algebra $\mathbf{A}$ with two output gates $\mathbf{g}_1, \mathbf{g}_2$ is there a valuation of input gates $\overline{x} = (x_1, \ldots, x_n)$ that gives the same output on both $\mathbf{g}_1$ and $\mathbf{g}_2$, i.e. $\mathbf{g}_1(\overline{x}) = \mathbf{g}_2(\overline{x})$ for some $\overline{x} \in A^n$.
- Ceqv($\mathbf{A}$)
  given a circuit over the algebra $\mathbf{A}$ is it true that for all inputs $\overline{x}$ we have the same values on given two output gates $\mathbf{g}_1, \mathbf{g}_2$, i.e. $\mathbf{g}_1(\overline{x}) = \mathbf{g}_2(\overline{x})$.

This new approach proved itself to be very useful as the mentioned results for groups, rings and lattices have been extended in [12] to much more general setting. Actually the main result of [12] shows that both nilpotent groups and distributive lattices (isolated in [7] and [19] as those with Ptime algorithm for PolSat) form a paradigm for algebras with Csat solvable in polynomial time. Unfortunately nilpotent groups hide an extremely interesting phenomena, namely every finite nilpotent group is a direct product of groups of prime power order. In universal algebraic terms this means that nilpotent groups are supernilpotent. In fact, one of the the results contained in [12] (independently also shown in [14]) generalizes polynomial time algorithms from nilpotent groups to supernilpotent algebras. On the other hand, the results of [12] leave a gap: solvable algebras considered in [12] that are not nilpotent have NP-complete Csat and co-NP-complete Ceqv, while the complexity of Csat and Ceqv for nilpotent but not supernilpotent algebras is not known. Unfortunately to fill this gap the

PTIME algorithms presented in [1, 12, 14] are useless – they do not work in general nilpotent setting. They rely on the fact that if an equation has a solution then it must have one among relatively small set S of tuples (although there may exist some other solutions outside the set S). More precisely: if $\mathbf{A}$ is a supernilpotent algebra (or a distributive lattice) then there is a constant d so that for each natural number n there is $S_n \subseteq A^n$ such that

- $|S_n|$ is $O(n^d)$,
- for two n-ary polynomials $\mathbf{s}$ and $\mathbf{t}$ the equation $\mathbf{s}(\overline{x}) = \mathbf{t}(\overline{x})$ has a solution $\overline{x} \in A^n$ iff it has a solution in S_n.

Also showing that two n-ary polynomials over an algebra determine the same n-ary function is reduced to checking this on a relatively small set S_n.

In this paper we show two things:

1. For nilpotent but not supernilpotent finite algebras one cannot expect polynomial time algorithms for CSAT or CEQV based on small search spaces S_n described above, (unless $\mathsf{P} = \mathsf{NP}$).
2. On the other hand there are finite nilpotent but not supernilpotent algebras with tractable CSAT and CEQV problems.

The examples mentioned in the second item are expanded abelian groups $(\mathbb{Z}_{pq}; +, f)$ where p, q are different primes, $+$ is the addition modulo pq and $f(x)$ is a unary function that returns x modulo p. Algorithms solving CEQV and CSAT for those algebras in polynomial time are described in sections 4 and 5, respectively. Those algorithms are based on a precise analysis of some kind of normal form of polynomials. The existence of such nice normal form is shown in section 3.

The evidence for the first item is provided by algebras with the very same clone of all polynomials as $(\mathbb{Z}_{pq}; +, f)$ but given by a different and infinite set of precisely chosen basic operations. In fact we show in section 6 that such algebras have co-NP-complete CEQV problem and NP-complete CSAT.

The reader should be warned here that leaving the safe realm, in which only finitely many basic operations are allowed, results in several fundamental problems. To start with, note that presenting an equation $\mathbf{s}(\overline{x}) = \mathbf{t}(\overline{x})$ we need to identify the basic operations that occur in $\mathbf{s}$ or $\mathbf{t}$. In fact, even the decidability of such redefined CSAT is not clear. One way to overcome this is to have an algebra $\mathbf{A} = (A; \mathbf{f}_0, \mathbf{f}_1, \ldots)$ encoded by a Turing machine $TM_{\mathbf{A}}$ which given the (k-ary) operation $\mathbf{f}_m$ and $a_1, \ldots, a_k \in A$ returns $TM_{\mathbf{A}}(m, a_1, \ldots, a_k) = \mathbf{f}_m(a_1, \ldots, a_k)$. Such approach puts extended CSAT($\mathbf{A}$) into NP whenever $TM_{\mathbf{A}}$ works in polynomial time. But it can be applied only to algebras with recursively enumerable set of fundamental operations.

The other way is to present an instance $\mathbf{s}(\overline{x}) = \mathbf{t}(\overline{x})$ of the problem together with the descriptions of all fundamental operations that occur in $\mathbf{s}$ or $\mathbf{t}$. Again such description may be done twofold:

- (CSAT$_{\mathrm{T}}$) by presenting the tables of the occurring basic operations, or
- (CSAT$_{\mathrm{TM}}$) by (polynomial time) algorithms $TM_{\mathbf{f}}$ computing the values $\mathbf{f}(a_1, \ldots, a_k)$.

It may seem that presenting operations by tables is more natural, as in many cases the complexity of such extended CSAT$_{\mathrm{T}}$ coincides with the complexity of its original (finite) version CSAT whenever the clone of an algebra is finitely generated (cf. Theorems 4.2, 5.2 and 6.2). On the other hand presenting the tables can again be treated as an artificial inflation of the input size. Indeed, Theorems 6.1 and 6.2 provide examples of nilpotent algebras with polynomial time CSAT$_{\mathrm{T}}$ and NP-complete CSAT$_{\mathrm{TM}}$. In fact item (1) above relies on such examples.

2 Background material

We use standard notation of universal algebra and computational complexity theory which can be found for example in [4], [18]. In particular, by an *algebra* we mean a pair $\mathbf{A} = (A; F)$, where A is a nonempty set and F is a family of finitary operations on A. Together with basic operations of $\mathbf{A}$, i.e. the operations from the set F, we often consider the derived operations – terms and polynomials of $\mathbf{A}$. By a polynomial of $\mathbf{A}$ we mean its term with some variables substituted by constants from A. We often refer to the syntactical side of the set F of operations as the type of $\mathbf{A}$. If $F = \{f_1, \ldots, f_s\}$ we simply write $(A; f_1, \ldots, f_s)$ rather than $(A; F)$ and say that $\mathbf{A}$ is of finite type. We restrict ourselves to finite algebras, i.e. algebras with finite universe A but we do allow infinite sets F of basic operations. The set of all terms (or polynomials) of $\mathbf{A}$ is to be denoted by $\mathrm{Clo}\,\mathbf{A}$ (or $\mathrm{Pol}\,\mathbf{A}$). Two algebras $\mathbf{A}$ and $\mathbf{B}$ are said to be *polynomially equivalent* if they have the same universes and $\mathrm{Pol}\,\mathbf{A} = \mathrm{Pol}\,\mathbf{B}$.

This paper is also restricted to algebras that belong to congruence modular varieties, i.e. to algebras $\mathbf{A}$ that together with all subalgebras $\mathbf{D}$ of the powers $\mathbf{A}^n$ having modular lattices $\mathsf{Con}\,\mathbf{D}$ of their congruences. Congruence modular varieties include most known and well-studied algebras such as groups, rings, modules (and their generalizations like quasigroups, loops, near-rings, nonassociative rings, Lie algebras), lattices (and their extensions like Boolean algebras, Heyting algebras or other algebras connected with multi-valued logics including MV-algebras).

One reason of our restriction to algebras from congruence modular varieties is that the paper [12] deals with such algebras. The other one is that in congruence modular setting there is a pretty well working notion of commutator of congruences that nicely generalizes commutator of normal subgroups (in group theory) and multiplication of ideals (in ring theory). A deep study of this commutator is described in [6]. Here we only recall a couple of definitions needed later. For congruences $\alpha, \beta, \gamma \in \mathsf{Con}\,\mathbf{A}$ we say that α *centralizes* β *modulo* γ (and denote this by $C(\alpha, \beta; \gamma)$) if for every $n \geqslant 1$, every $(n+1)$-ary term $\mathbf{t}$ of $\mathbf{A}$, every $(a, b) \in \alpha$, and every $(c_1, d_1), \ldots, (c_n, d_n) \in \beta$ we have

$$\mathbf{t}(a, \overline{c}) \overset{\gamma}{\equiv} \mathbf{t}(a, \overline{d}) \quad \text{iff} \quad \mathbf{t}(b, \overline{c}) \overset{\gamma}{\equiv} \mathbf{t}(b, \overline{d}).$$

Now the *commutator* $[\alpha, \beta]$ of the congruences $\alpha, \beta \in \mathsf{Con}\,\mathbf{A}$ is the smallest congruence $\gamma \in \mathsf{Con}\,\mathbf{A}$ for which $C(\alpha, \beta; \gamma)$. With the help of the commutator one can define solvable, nilpotent and Abelian congruences. In this paper we are interested only in the two last concepts. To define nilpotency we first iterate the commutator by putting $\theta^{(0)} = \theta$ and $\theta^{(i+1)} = [\theta, \theta^{(i)}]$, whenever $\theta \in \mathsf{Con}\,\mathbf{A}$. Now we say that θ is *k-nilpotent* if θ^k is the identity relation 0_A on $\mathbf{A}$ and the algebra $\mathbf{A}$ is *nilpotent* if the largest congruence 1_A of $\mathbf{A}$ is k-nilpotent for some positive integer k. As in group theory, $\mathbf{A}$ is called *Abelian* if 1_A is 1-nilpotent. Abelian algebras from congruence modular varieties have been shown in [6] to have particularly nice structure. In fact they are *affine*, i.e. polynomially equivalent to unitary modules (over a ring with unit).

We will also need the following strengthening of the nilpotency. First, for a bunch of congruences $\alpha_1, \ldots, \alpha_k, \beta, \gamma \in \mathsf{Con}\,\mathbf{A}$ we say that $\alpha_1, \ldots, \alpha_k$ centralize β modulo γ, and write $C(\alpha_1, \ldots, \alpha_k, \beta; \gamma)$, if for all polynomials $\mathbf{p} \in \mathrm{Pol}\,\mathbf{A}$ and all tuples $\overline{a}_1 \overset{\alpha_1}{\equiv} \overline{b}_1, \ldots, \overline{a}_k \overset{\alpha_k}{\equiv} \overline{b}_k$ and $\overline{u} \overset{\beta}{\equiv} \overline{v}$ such that

$$\mathbf{p}(\overline{x}_1, \ldots, \overline{x}_k, \overline{u}) \overset{\gamma}{\equiv} \mathbf{p}(\overline{x}_1, \ldots, \overline{x}_k, \overline{v})$$

for all possible choices of $(\overline{x}_1, \ldots, \overline{x}_k)$ in $\{\overline{a}_1, \overline{b}_1\} \times \ldots \times \{\overline{a}_k, \overline{b}_k\}$ but $(\overline{b}_1, \ldots . \overline{b}_k)$, we also have

$$\mathbf{p}(\overline{b}_1, \ldots, \overline{b}_k, \overline{u}) \overset{\gamma}{\equiv} \mathbf{p}(\overline{b}_1, \ldots, \overline{b}_k, \overline{v}).$$

This notion was introduced by A. Bulatov [3] and further developed by E. Aichinger and N. Mudrinski [1]. In particular they have shown that for all $\alpha_1, \dots, \alpha_k \in \mathsf{Con}\,\mathbf{A}$ there is the smallest congruence γ with $C(\alpha_1, \dots, \alpha_k; \gamma)$ called the k-ary commutator and denoted by $[\alpha_1, \dots, \alpha_k]$. Such generalized commutator behaves especially well in algebras from congruence modular varieties. In particular this commutator is monotone, join-distributive and we have $[\alpha_1, [\alpha_2, \dots, \alpha_k]] \leqslant [\alpha_1, \dots, \alpha_k]$. Thus every k-supernilpotent algebra, i.e. algebra satisfying $[\underbrace{1, \dots, 1}_{k+1 \text{ times}}] = 0$, is k-nilpotent. The following properties, that can be easily inferred from the deep work of R. Freese and R. McKenzie [6] and K. Kearnes [13], have been summarized in [1].

▶ **Theorem 2.1.** *For a finite algebra* $\mathbf{A}$ *from a congruence modular variety the following conditions are equivalent:*

1. $\mathbf{A}$ *is* k*-supernilpotent,*
2. $\mathbf{A}$ *is* k*-nilpotent, decomposes into a direct product of algebras of prime power order and the clone* $\operatorname{Clo}\mathbf{A}$ *is generated by finitely many operations,*
3. $\mathbf{A}$ *is* k*-nilpotent and all commutator polynomials have rank at most* k*.*

Commutator polynomials mentioned in condition (3) of Theorem 2.1 are the paradigms for the failure of supernilpotency and are easily seen to be useful in coding a k-ary conjunction. We say that $\mathbf{t}(x_1, \dots, x_{k-1}, z) \in \operatorname{Pol}_k\mathbf{A}$ is a commutator polynomial of rank k if

- $\mathbf{t}(a_1, \dots, a_{k-1}, b) = b$ whenever $b \in \{a_1, \dots, a_{k-1}\} \subseteq A$,
- $\mathbf{t}(a_1, \dots, a_{k-1}, b) \neq b$ for some $a_1, \dots, a_{k-1}, b \in A$.

As we have mentioned in the Introduction this paper is intended to give a better understanding of the problems Csat and Ceqv for nilpotent but not supernilpotent algebras. Like in the groups, in nilpotent setting the inputs $\mathbf{g}_1(\overline{x}) = \mathbf{g}_2(\overline{x})$ of Csat or Ceqv can be restricted to the ones in which one of the polynomials is constant, i.e. of the form $\mathbf{g}(\overline{x}) = c$. Indeed, with the help of Corollary 7.4 in [6] it suffices to choose any $c \in A$ and put $\mathbf{g}(\overline{x}) = \mathbf{m}(\mathbf{g}_1(\overline{x}), \mathbf{g}_2(\overline{x}), c)$, where $\mathbf{m}(x, y, z)$ is a Mal'cev term for $\mathbf{A}$, i.e. a term satisfying $\mathbf{m}(x, x, y) = y = \mathbf{m}(y, x, x)$ for all $x, y \in A$.

3 The structure of 2-nilpotent algebras

To fill the nilpotent versus supernilpotent gap mentioned in the Introduction we need to understand the structure of nilpotent algebras. Since all algebras considered in this paper are 2-nilpotent we will use the description of their structure presented in Chapter VII of [6]. It reduces to an action of one abelian algebra over the other abelian one. Thus, after fixing the set F of operations we need two affine algebras:

- an upper one, say $\mathbf{U}$, which is polynomially equivalent to a module $(U; \oplus)$ over a ring $\mathbf{R}_U$, and
- a lower one, say $\mathbf{L}$, which is polynomially equivalent to a module $(L; +)$ over a ring $\mathbf{R}_L$,

and for each basic operation $f \in F$, say k-ary, we need a function $\widehat{f} : U^k \longrightarrow L$. This allows us to construct an algebra $\mathbf{L} \otimes^F \mathbf{U}$ of type F on the set $L \times U$ by putting

$$f^{\mathbf{L}\otimes^F\mathbf{U}}((l_1, u_1), \dots, (l_k, u_k)) = (f^{\mathbf{L}}(l_1, \dots, l_k) + \widehat{f}(u_1, \dots, u_k), f^{\mathbf{U}}(u_1, \dots, u_k)). \tag{1}$$

The usefulness of this construction is described in Corollary 7.2 in [6], where every 2-nilpotent algebra of type F is shown to be of the form $\mathbf{L} \otimes^F \mathbf{U}$ for some triple $\mathbf{U}, \mathbf{L}, \left\{\widehat{f} : f \in F\right\}$. The rest of this section is devoted to presenting a nice normal form of arbitrary polynomial $\mathbf{p}$ of $\mathbf{A}$ that will be useful to construct polynomial time algorithms for Ceqv($\mathbf{A}$) and Csat($\mathbf{A}$).

To start with, note that the equation (1) remains valid for f being not just a basic operation but an arbitrary polynomial of $\mathbf{A}$, where $\widehat{f}$ is appropriately chosen. Moreover having in mind that both $\mathbf{L}$ and $\mathbf{U}$ are affine we know that $f^{\mathbf{L}}(l_1,\dots,l_k)$ and $f^{\mathbf{U}}(u_1,\dots,u_k)$ are affine combinations $\sum_{i=1}^{k}\lambda_i l_i + l_0$ and $\bigoplus_{i=1}^{k}\alpha_i u_i \oplus u_0$. Thus for a polynomial $\mathbf{p}$ we have

$$\mathbf{p}^{\mathbf{L}\otimes^F\mathbf{U}}((l_1,u_1),\dots,(l_k,u_k)) = \left(\sum_{i=1}^{k}\lambda_i l_i + \widehat{\mathbf{p}}(u_1,\dots,u_k), \bigoplus_{i=1}^{k}\alpha_i u_i + u_0\right),$$

where l_0 is absorbed by $\widehat{\mathbf{p}}$. Moreover, $\widehat{\mathbf{p}}(u_1,\dots,u_k)$ can be presented as a sum of elements of the form

$$\mu\cdot\widehat{g}\left(\bigoplus_{i=1}^{k}\beta_i^{(1)}u_i\oplus u_0^{(1)},\dots,\bigoplus_{i=1}^{k}\beta_i^{(s)}u_i\oplus u_0^{(s)}\right),$$

with $\widehat{g}$ ranging over basic operations (and its occurrences) used to build $\mathbf{p}$.

The normal form, we have just started to build, has particularly nice shape in the cases where the $\widehat{g}$'s can be presented as affine combinations of unary $\widehat{f}$'s. One of such case is presented in the following Lemma.

▶ **Lemma 3.1.** *Let* $\mathbf{U}$ *and* $\mathbf{L}$ *be algebras polynomially equivalent to 1-dimentional vector spaces over prime fields of different characteristics. Moreover let* $f: U\longrightarrow L$ *be such that* $f(0_{\mathbf{U}})=0_{\mathbf{L}}$ *and* $\sum_{u\in U}f(u)\neq 0_{\mathbf{L}}$*. Then, every function* $g\colon U^k\longrightarrow L$ *can be expressed by*

$$g(x_1,\dots,x_k) = \sum_{(\overline{\beta},u)\in F_U^k\times U}\mu_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^{k}\beta_i x_i\oplus u\right). \tag{2}$$

Proof. Let $h^k_{a_1,\dots,a_k,a}\colon U^k\longrightarrow L$ be constantly $0_{\mathbf{L}}$ except $h^k_{a_1,\dots,a_k,a}(a_1,\dots,a_k)=a$. Observe that for every function $g\colon U^k\longrightarrow L$ we have

$$g(x_1,\dots,x_k) = \sum_{(a_1,\dots,a_k)\in U^k} h^k_{a_1,\dots,a_k,g(a_1,\dots,a_k)}(x_1,\dots,x_k).$$

Moreover we can express one spike function by any other one by putting

$$h^k_{a_1,\dots,a_k,a}(x_1,\dots,x_k) = a\cdot b^{-1}\cdot h^k_{b_1,\dots,b_k,b}(x_1-a_1+b_1,\dots,x_k-a_k+b_k).$$

In the above we use 1-dimensionality so that the universes of $\mathbf{L}$ and $\mathbf{F}_L$ coincide, so that the vectors $a,b\in L$ can be also treated as scalars from $\mathbf{F}_L$.

The last two displays yield that to finish the proof of the Lemma it suffices to represent, for each k, one spike function in the form described in (2). The rest of the proof shows how this can be done in the presence of a unary function f described in the Lemma, which is to be called $(\mathbf{U},\mathbf{L})$-normal in the rest of the paper. Our construction of such spike functions is based on counting partitions (into special sums) of elements in vector spaces over finite fields.

Being left with representing one spike function of arbitrary large arity by an expression of the form (2) we start with letting p and q to be characteristics of the fields $\mathbf{F}_U$ and $\mathbf{F}_L$, respectively. Moreover let $f\colon U\longrightarrow L$ be $(\mathbf{U},\mathbf{L})$-normal . Put

$$t_s(x_1,\dots,x_s) = \sum_{\emptyset\neq I\subseteq\{1,\dots,s\}}(-1)^{|I|}f\left(\bigoplus_{i\in I}x_i\right)$$

and note that $t_s(x_1,\dots,x_s)=0_{\mathbf{L}}$ whenever $0_{\mathbf{U}}\in\{x_1,\dots,x_s\}$. We fix an enumeration of the set $U=\{0_{\mathbf{U}},u_1,\dots,u_{p-1}\}$ and define

$$w_k(x_1,\dots,x_k)=t_{k(p-1)}(x_1-u_1,\dots,x_k-u_1,x_1-u_2,\dots,x_k-u_2,\dots,x_1-u_{p-1},\dots,x_k-u_{p-1}).$$

Observe that $w_k(\overline{x})=0_{\mathbf{L}}$ whenever at least one of the x_i's is non-zero. To prove that w_k is a spike function it remains to show $w_k(0_{\mathbf{U}},\dots,0_{\mathbf{U}})\neq 0_{\mathbf{L}}$. Our first claim is

$$w_k(0_{\mathbf{U}},\dots,0_{\mathbf{U}}) \quad = \quad t_{p-1}(u_1,\dots,u_{p-1}). \tag{3}$$

Since t_s is fully symetric, we have

$$w_k(0_{\mathbf{U}},\dots,0_{\mathbf{U}})=t_{k(p-1)}(\overbrace{u_1,\dots,u_1}^{k\text{ times}},\overbrace{u_2,\dots,u_2}^{k\text{ times}},\dots,\overbrace{u_{p-1},\dots,u_{p-1}}^{k\text{ times}}).$$

Without loss of generality we may assume that $k=q^a$, as for any other k' to get a k'-ary spike we choose the smallest power $q^a\geqslant k'$ and replace q^a-k' arguments with $0_{\mathbf{U}}$. From the definition of $t_{k(p-1)}$ we get

$$\begin{aligned}&t_{k(p-1)}(u_1,\dots,u_1,u_2,\dots,u_2,\dots,u_{p-1},\dots,u_{p-1})=\\&=\sum_{k=1}^{(p-1)\cdot q^a}(-1)^k\sum_{\substack{k_1+\dots+k_{p-1}=k\\k_i\leqslant q^a}}\binom{q^a}{k_1}\cdot\ldots\cdot\binom{q^a}{k_{p-1}}f\left(\bigoplus_{i=1}^{k_1}u_1\oplus\ldots\oplus\bigoplus_{i=1}^{k_{p-1}}u_{p-1}\right).\end{aligned}$$

Observe that $\binom{q^a}{k_i}$ is divisible by q whenever $k_i\notin\{0,q^a\}$. Thus the only summands that do not vanish are those with $k_i\in\{0,q^a\}$ for all i so that $\binom{q^a}{k_1}\cdot\ldots\cdot\binom{q^a}{k_{p-1}}=1$. Thus, by changing notation, we have

$$\begin{aligned}&t_{k(p-1)}(u_1,\dots,u_1,u_2,\dots,u_2,\dots,u_{p-1},\dots,u_{p-1})=\\&=\sum_{k'=1}^{p-1}(-1)^{k'\cdot q^a}\sum_{\substack{k'_1+\dots+k'_{p-1}=k'\\k'_i\in\{0,1\}}}f\left(\bigoplus_{i=1}^{k'_1\cdot q^a}u_1\oplus\ldots\oplus\bigoplus_{i=1}^{k'_{p-1}\cdot q^a}u_{p-1}\right)=\\&=\sum_{k'=1}^{p-1}(-1)^{k'\cdot q^a}\sum_{\substack{S\subseteq\{1,\dots,p-1\}\\|S|=k'}}f\left(\bigoplus_{i\in S}u_i\right),\end{aligned}$$

where the last equality follows from the fact that the multisets

$$\left\{\left\{\bigoplus_{i=1}^{k'_1\cdot q^a}u_1\oplus\ldots\oplus\bigoplus_{i=1}^{k'_{p-1}\cdot q^a}u_{p-1}\colon k'_1+\ldots+k'_{p-1}=k',k'_i\in\{0,1\}\right\}\right\}$$

and

$$\left\{\left\{\bigoplus_{i\in S}u_i\colon S\subseteq\{1,\dots,p-1\},|S|=k'\right\}\right\}.$$

are equal. To complete the proof of (3) observe that $(-1)^{k'\cdot q^a}=(-1)^{k'}$. This is obvious for q being odd, while otherwise it follows from the fact that $x=-x$.

We will conclude our proof by showing that

$$w_k(0_{\mathbf{U}},\dots,0_{\mathbf{U}})\neq 0_{\mathbf{L}}. \tag{4}$$

From the definition of t_s we know that

$$t_{p-1}(u_1,\dots,u_{p-1}) = \sum_{k=1}^{p-1}(-1)^k \sum_{\substack{S\subseteq\{1,\dots,p-1\}\\ |S|=k}} f\left(\bigoplus_{i\in S} u_i\right).$$

Now, if $\ell^k_{u_i}$ denotes a number of partition of the element u_i into a sum of k non-zero pairwise different elements from U then by appropriately grouping the $f\left(\bigoplus_{i\in S} u_i\right)$'s and noting that $\mathbf{f}(0_\mathbf{U}) = 0_\mathbf{L}$ we can replace the last sum by

$$\sum_{k=1}^{p-1}(-1)^k \sum_{i=1}^{p-1} \ell^k_{u_i} f(u_i)$$

The numbers $\ell^k_{u_i}$ were calculated in [16] to be $\ell^k = \ell^k_{u_i} = \frac{1}{p}\left(\binom{p-1}{k} + (-1)^{k+1}\right)$ independently of $u_i \neq 0_\mathbf{U}$. This gives that

$$t_{p-1}(u_1,\dots,u_{p-1}) = \sum_{k=1}^{p-1}(-1)^k \ell^k \sum_{i=1}^{p-1} f(u_i) = \left(\sum_{k=1}^{p-1}(-1)^k \ell^k\right)\left(\sum_{i=1}^{p-1} f(u_i)\right).$$

Using the explicit formulas for the ℓ^k's we get

$$\begin{aligned}
\sum_{k=1}^{p-1}(-1)^k \ell^k &= \frac{1}{p}\sum_{k=1}^{p-1}(-1)^k\left[\binom{p-1}{k} + (-1)^{k+1}\right]\\
&= \frac{1}{p}\sum_{k=1}^{p-1}\left[(-1)^k\binom{p-1}{k} + (-1)^{2k+1}\right]\\
&= \frac{1}{p}\left[\sum_{k=1}^{p-1}(-1)^k\binom{p-1}{k} + \sum_{k=1}^{p-1}(-1)\right]\\
&= \frac{1}{p}\left[-1-(p-1)\right] = -1
\end{aligned}$$

This gives us that

$$w_k(0_\mathbf{U},\dots,0_\mathbf{U}) = t_{p-1}(u_1,\dots,u_{p-1}) = -\sum_{i=1}^{p-1} f(u_i)$$

is not equal to $0_\mathbf{L}$ as f is $(\mathbf{U},\mathbf{L})$-normal . Thus the claim (4) holds, proving that w_k is a spike function, as required. ◀

Lemma 3.1 yields that, in its setting, every polynomial $\mathbf{p}$ of $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ can be represented as

$$\mathbf{p}((l_1,u_1),\dots,(l_k,u_k)) = \left(\sum_{i=1}^{k}\lambda_i l_i + \sum_{\substack{\overline{\beta}\in R_U^k\\ u\in U}} \mu_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^{k}\beta_i u_i \oplus u\right), \bigoplus_{i=1}^{k}\alpha_i u_i \oplus u_0\right) \quad (5)$$

where f is a $(\mathbf{U},\mathbf{L})$-normal function. Representations of the above form are to be called f-normal. The size of such normal form is essentially the number of non-zero coefficients among the λ_i's, $\mu_{\overline{\beta},u}$'s and α_i's.

Most of our arguments in this paper refer to f-normal forms where the modules hidden in $\mathbf{U}$ and $\mathbf{L}$ are actually 1-dimensional vector spaces over prime fields of different characteristics. However f-normal forms could be useful in more general settings as shown in the following Lemma as well as in Lemma 4.1.

▶ **Lemma 3.2.** *Let* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *be a finite 2-nilpotent algebra. Then for each* $f\colon U \longrightarrow L$ *there exists a polynomial time procedure that returns* f*-normal form for a polynomial* $\mathbf{g}$ *of* $\mathbf{A}$ *presented together with* f*-normal forms of all the basic operations occurring in* $\mathbf{g}$*.*

Proof. To prove the lemma we start with two polynomials $\mathbf{h}_1, \mathbf{h}_2$ of $\mathbf{A}$ presented in their f-normal forms to carefully compute f-normal form of the superposition

$$\mathbf{g}(x_1, \dots, x_{k_1+k_2-1}) = \mathbf{h}_2(\mathbf{h}_1(x_1, \dots, x_{k_1}), x_{k_1+1}, \dots, x_{k_1+k_2-1})$$

in a polynomial time. Let

$$\mathbf{h}_j((l_1, u_1), \dots, (l_{k_j}, u_{k_j})) = \left(\sum_{i=1}^{k_j} \lambda_i^{(j)} l_i + \sum_{(\overline{\beta}, u) \in \Gamma_j} \mu^{(j)}_{\overline{\beta}, c} \cdot f\left(\bigoplus_{i=1}^{k_j} \beta_i u_i \oplus u \right), \bigoplus_{i=1}^{k_j} \alpha_i^{(j)} u_i \oplus u_0^{(j)} \right)$$

for appropriate $\Gamma_j \subseteq \mathbf{R}_U^{k_j} \times U$.
Now the second and the first coordinates of $\mathbf{g}((l_1, u_1), \dots, (l_{k_1+k_2-1}, u_{k_1+k_2-1}))$ are easily seen to be

$$\bigoplus_{i=1}^{k_1} \alpha_1^{(2)} \alpha_i^{(1)} u_i \oplus \bigoplus_{i=2}^{k_2} \alpha_i^{(2)} u_{i+k_1-1} \oplus \alpha_1^{(2)} u_0^{(1)} \oplus u_0^{(2)},$$

and

$$\sum_{i=1}^{k_1} \lambda_1^{(2)} \lambda_i^{(1)} l_i + \sum_{i=2}^{k_2} \lambda_i^{(2)} l_{i+k_1-1} + \lambda_1^{(2)} \cdot \sum_{(\overline{\beta}, u) \in \Gamma_1} \mu^{(1)}_{\overline{\beta}, u} \cdot f\left(\bigoplus_{i=1}^{k_1} \beta_i u_i \oplus u \right) + g'(\overline{u}),$$

where $g'(u_1, \dots, u_{k_1+k_2-1})$ is obtained from $\sum_{(\overline{\beta}, u) \in \Gamma_2} \mu^{(2)}_{\overline{\beta}, u} \cdot f\left(\beta_1 u_1 \oplus \bigoplus_{i=2}^{k_2} \beta_i u_{k_1+i-1} \oplus u \right)$ by substituting every occurrence of u_1 by $\bigoplus_{i=1}^{k_1} \alpha_i^{(1)} u_i \oplus u_0^{(1)}$.

It should be obvious that both these coordinates give f-normal form of $\mathbf{g}$ and that they can be computed in a polynomial time in size of f-normal forms of $\mathbf{h}_1$ and $\mathbf{h}_2$. Actually a careful inspection of our argument allows us to bound the number of non-zero summands so that the f-normal forms of more complicated superpositions of polynomials of $\mathbf{A}$ can be also computed efficiently. ◀

Combining Lemmas 3.1 and 3.2 we get

▶ **Corollary 3.3.** *Let* $\mathbf{L}$ *and* $\mathbf{U}$ *be algebras polynomially equivalent to one dimensional vectors spaces over prime fields of different characteristics and* $f\colon U \longrightarrow L$ *be* $(\mathbf{U}, \mathbf{L})$*-normal . Then every polynomial operation of* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *has* f*-normal forms and, if the type* F *of* $\mathbf{A}$ *is finite then one of these* f*-normal forms can be computed in polynomial time.*

4 Equivalence

The last paragraph of Section 2 shows that in the nilpotent setting in CEQV it suffices to consider equivalence of two polynomials one of which is constant.

▶ **Lemma 4.1.** *Let* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *with* $\mathbf{L}$ *and* $\mathbf{U}$ *being polynomially equivalent to one-dimensional vector spaces over finite fields of different characteristics. Then there exists a polynomial time algorithm which for polynomials* $\mathbf{p}$ *of* $\mathbf{A}$ *given in some* f*-normal form decides if* $\mathbf{p}$ *is a constant function.*

Proof. Let

$$\mathbf{p}((l_1,u_1),\dots,(l_k,u_k)) = \left(\mathbf{p}^{\mathbf{L}}(l_1,\dots,l_k) + \sum_{\substack{\overline{\beta}\in\mathbf{F}_U^k\\ u\in U}} \mu_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^k \beta_i u_i \oplus u\right), \mathbf{p}^{\mathbf{U}}(u_1,\dots,u_k)\right)$$

be an f-normal form of $\mathbf{p}$. Obviously such polynomial $\mathbf{p}$ is constant iff both coordinates of the right-hand side above are constant. This can be efficiently checked for $\mathbf{p}^{\mathbf{U}}(u_1,\dots,u_k)$ as it is simply a polynomial of a vector space. Since both summands of the first coordinate on the right-hand side depend on disjoint sets of variables (the l_i's and the u_i's) to keep their sum constant we need to keep both summands constant. Again, checking that for $\mathbf{p}^{\mathbf{L}}$ (in a vector space) is fast so that we are left with the expression of the form

$$\widehat{\mathbf{p}}(u_1,\dots,u_k) = \sum_{\substack{(\overline{\beta},u)\in\mathbf{F}_U^k\times U\\ \overline{\beta}\neq\overline{0}}} \mu_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^k \beta_i u_i \oplus u\right). \tag{6}$$

This in turn can be done with the help of the following claim.

($\star$) $\widehat{\mathbf{p}}$ is constant iff for each $\overline{\beta}\in\mathbf{F}_U^k\setminus\{\overline{0}\}$ the function $S_{\overline{\beta}}(x) = \sum_{(\kappa,u)\in F_U^*\times U}\mu_{\kappa\cdot\overline{\beta},u}\cdot f(\kappa x\oplus u)$ is constant on U.

Indeed, having ($\star$) we argue as follows. If for a particular $\overline{\beta}$ all the $\mu_{\kappa\cdot\overline{\beta},u}$'s are zero then $S_{\overline{\beta}}(x)=0$ for all $x\in U$. For any other $\overline{\beta}$ we simply check if $S_{\overline{\beta}}$ is constant by computing all of the $|U|$ values for the x's. This is fast as we have at most $|U|^2$ summands. Finally, the number of the $\overline{\beta}$'s of the second kind is linear in the number of non-zero coefficients $\mu_{\overline{\beta},u}$. This in turn is bounded by the length of the expression (6) which is the part of the input.

Thus we are left with the proof of ($\star$). To see the 'only if' direction for $\overline{\beta}\in\mathbf{F}_{\mathbf{U}}^k\setminus\{\overline{0}\}$ and $a\in U$ define $\mathbf{O}_{a,\overline{\beta}} = \{\overline{u}\in U^k : \bigoplus_{i=1}^k\beta_i u_i = a\}$. Observe that the size of the solution set $\mathbf{O}_{a,\overline{\beta}}$ of a nontrivial linear equation is always $|U|^{k-1}$ independently of the choice of $(a,\overline{\beta})$. Now, since $\widehat{\mathbf{p}}$ is constant, for each $\overline{\beta}\in F_U^k\setminus\{0\}^k$ and $a,b\in L$ we have

$$\begin{aligned}
0 &= \sum_{\overline{u}\in\mathbf{O}_{a,\overline{\beta}}}\widehat{\mathbf{p}}(\overline{u}) - \sum_{\overline{u}\in\mathbf{O}_{b,\overline{\beta}}}\widehat{\mathbf{p}}(\overline{u})\\
&= \sum_{\overline{u}\in\mathbf{O}_{a,\overline{\beta}}}\sum_{\substack{(\overline{\gamma},u)\in\mathbf{F}_U^k\times U\\ \overline{\gamma}\neq\overline{0}}}\mu_{\overline{\gamma},u}\cdot f\left(\bigoplus_{i=1}^k\gamma_i u_i\oplus u\right) - \sum_{\overline{u}\in\mathbf{O}_{b,\overline{\beta}}}\sum_{\substack{(\overline{\gamma},u)\in\mathbf{F}_U^k\times U\\ \overline{\gamma}\neq\overline{0}}}\mu_{\overline{\gamma},u}\cdot f\left(\bigoplus_{i=1}^k\gamma_i u_i\oplus u\right)\\
&= \sum_{\substack{(\overline{\gamma},u)\in\mathbf{F}_U^k\times U\\ \overline{\gamma}\neq\overline{0}}}\mu_{\overline{\gamma},u}\cdot\left(\sum_{\overline{u}\in\mathbf{O}_{a,\overline{\beta}}} f\left(\bigoplus_{i=1}^k\gamma_i u_i\oplus u\right) - \sum_{\overline{u}\in\mathbf{O}_{b,\overline{\beta}}} f\left(\bigoplus_{i=1}^k\gamma_i u_i\oplus u\right)\right)\\
&= \sum_{\substack{(\overline{\gamma},u)\in\mathbf{F}_U^k\times U\\ \overline{\gamma}\neq\overline{0}}}\mu_{\overline{\gamma},u}\cdot\left(t(a,\overline{\beta},\overline{\gamma},u) - t(b,\overline{\beta},\overline{\gamma},u)\right),
\end{aligned}$$

where $t(x,\overline{\beta},\overline{\gamma},u) = \sum_{\overline{u}\in\mathbf{O}_{x,\overline{\beta}}} f\left(\bigoplus_{i=1}^k\gamma_i u_i\oplus u\right)$. Now, if the vectors $\overline{\beta},\overline{\gamma}\in\mathbf{F}_U^k$ are linearly dependent, i.e. $\overline{\gamma}=\kappa\cdot\overline{\beta}$ we have $t(x,\overline{\beta},\overline{\gamma},u) = |U|^{k-1}\cdot f(\kappa\cdot x\oplus u)$. Otherwise, if $\overline{\beta}$ and $\overline{\gamma}$ are linearly independent then $t(x,\overline{\beta},\overline{\gamma},u) = |U|^{k-2}\sum_{d\in U} f(d)$, as the system of the following

two equations

$$\begin{cases} \bigoplus_{i=1}^{k} \beta_i u_i = x \\ \bigoplus_{i=1}^{k} \gamma_i u_i \oplus u = d \end{cases}$$

has exactly $|U|^{k-2}$ solutions. Summing up in the big display above the summands with $\overline{\gamma}$'s that are linearly independent with $\overline{\beta}$ diminishes so that this display reduces to

$$\begin{aligned} 0 &= \sum_{\substack{(\overline{\gamma},u)\in \mathbf{F}_U^k \times U \\ \overline{\gamma}\neq\overline{0}}} \mu_{\overline{\gamma},u} \cdot \big(t(a,\overline{\beta},\overline{\gamma},u) - t(b,\overline{\beta},\overline{\gamma},u)\big) \\ &= |U|^{k-1} \cdot \left(\sum_{(\kappa,u)\in \mathbf{F}_U^* \times U} \mu_{\kappa\cdot\overline{\beta},u} f(\kappa\cdot a \oplus u) - \sum_{(\kappa,u)\in \mathbf{F}_U^* \times U} \mu_{\kappa\cdot\overline{\beta},u} f(\kappa\cdot b \oplus u) \right). \end{aligned}$$

Since $|U|$ and $|L|$ are coprime, the difference in the parenthesis is zero which shows the 'only if' direction of $(\star)$.

To prove the 'if' direction observe that $R = \{(\overline{\beta},\kappa\overline{\beta})\colon \overline{\beta}\in F_U^k \setminus \{\overline{0}\}, \kappa\in \mathbf{F}_U^*\}$ is an equivalence relation. Let $\overline{\beta}^{(1)},\overline{\beta}^{(2)},\dots,\overline{\beta}^{(m)}$ be the transversal of R. Then for $\overline{x}\in U^k$ we have

$$\begin{aligned} \widehat{\mathbf{p}}(x_1,\dots,x_k) &= \sum_{\substack{(\overline{\gamma},u)\in F_{\mathbf{U}}^k \times U \\ \overline{\gamma}\neq\overline{0}}} \mu_{\overline{\gamma},u} \cdot f\left(\bigoplus_{i=1}^{k} \gamma_i \cdot x_i \oplus u\right) \\ &= \sum_{j\in\{1,\dots,m\}} \sum_{(\kappa,u)\in F_{\mathbf{U}}^* \times U} \mu_{\kappa\cdot\overline{\beta}^{(j)},u} \cdot f\left(\kappa\cdot\bigoplus_{i=1}^{k} \beta_i^{(j)} x_i \oplus u\right) \\ &= \sum_{j\in\{1,\dots,m\}} S_{\overline{\beta}^{(j)}}\left(\bigoplus_{i=1}^{k} \beta_i^{(j)} x_i\right). \end{aligned}$$

Now our assumption that all the $S_{\overline{\beta}^{(j)}}$ are constant shows that $\widehat{\mathbf{p}}$ is constant, as well. ◀

Corollary 3.3 together with Lemma 4.1 immediately give the following theorem.

▶ **Theorem 4.2.** *Let* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *with* $\mathbf{L}$ *and* $\mathbf{U}$ *being polynomially equivalent to* 1*-dimensional vector spaces over prime fields of different characteristics. Then* $\textsc{Ceqv}(\mathbf{A})$ *is in P.*

5 Satisfiability

Again, in nilpotent realm the last paragraph of Section 2 allows us to fix one side of the equations considered in Csat to be a constant polynomial.

▶ **Lemma 5.1.** *Let* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *with* $\mathbf{L}$ *and* $\mathbf{U}$ *being polynomially equivalent to one-dimensional vector spaces over finite fields of different characteristics. Then there exists a polynomial time algorithm which for a constant* $c\in A$ *and polynomials* $\mathbf{p}$ *of* $\mathbf{A}$ *given in some* f*-normal form decides if the equation* $\mathbf{p}(\overline{x}) = c$ *has a solution.*

Proof. Since our polynomial is given in f-normal form we start with the following equation

$$\left(p^{\mathbf{L}}(l_1,\dots,l_k) + \sum_{(\overline{\beta},u)\in \mathbf{F}_U^k \times U} \mu_{\overline{\beta},u} \cdot f\left(\bigoplus_{i=1}^{k} \beta_i \cdot u_i \oplus u\right), p^{\mathbf{U}}(u_1,\dots,u_k) \right) = (c_L, c_U). \quad (7)$$

We start with observing that since $\mathbf{L}$ and $\mathbf{U}$ are polynomially equivalent to one-dimensional vector spaces the range of $p^{\mathbf{L}}$ (and $p^{\mathbf{U}}$) is either one element or the entire L (or U). Now, if $p^{\mathbf{L}}$ is not constant then it suffices to check whether $p^{\mathbf{U}}(u_1,\dots,u_k) = c_U$ has a solution in U, as the solution in first coordinate always exists. Thus we assume that $p^{\mathbf{L}}$ is constant and put $d = c_L - p^{\mathbf{L}}(0_{\mathbf{L}},\dots,0_{\mathbf{L}})$. Moreover we may assume that $p^{\mathbf{U}}$ is not constant or equal to c_U, as otherwise our equation has no solution.

We want to reduce our equation in $\mathbf{A}$ to an equivalent equation of the form

$$\sum_{(\overline{\beta},u)\in\mathbf{F}_U^k\times U} \nu_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^{k}\beta_i\cdot u_i\oplus u\right) \;=\; d \tag{8}$$

in $\mathbf{L}$, but with the u_i's taking values in U. Now, if $p^{\mathbf{U}}$ is constant (and therefore equal to c_U) then we are done with $\nu_{\overline{\beta},u} = \mu_{\overline{\beta},u}$ for all $\overline{\beta}$'s and u's. Otherwise $p^{\mathbf{U}}(u_1,\dots,u_k) = c_U$ reduces to something of the form $u_j = \bigoplus_{i\neq j}\delta_i u_i \oplus c_U$. This allows us to replace all occurrences of the u_j by the sum $\bigoplus_{i\neq j}\delta_i u_i\oplus c_U$ and after recalculating the coefficients $\mu_{\overline{\beta},u}$ we get the desired $\nu_{\overline{\beta},u}$'s as required in (8).

Denote the left-hand side of (8) by $p'(u_1,\dots,u_k)$ and note that since the set L carries the multiplication inherited from the field $\mathbf{F}_L$ the equation $p'(u_1,\dots,u_k) = d$ has a solution iff

$$\prod_{d'\in L-\{d\}} (p'(u_1,\dots,u_k) - d') = 0_{\mathbf{L}}$$

is not an identity. Note however that the product above is not directly expressible as a polynomial of $\mathbf{A}$. Nevertheless distributing over the factors we can replace the product by the sum

$$\sum_{(\overline{\beta}^{(1)},u^{(1)})}\sum_{(\overline{\beta}^{(2)},u^{(2)})}\cdots\sum_{(\overline{\beta}^{(m)},u^{(m)})} \nu_{\mathcal{I}}\cdot f\left(\bigoplus_{i=1}^{k}\beta_i^{(1)}u_i\oplus u^{(1)}\right)\cdot\ldots\cdot f\left(\bigoplus_{i=1}^{k}\beta_i^{(m)}u_i\oplus u^{(m)}\right),$$

where $\mathcal{I} = \left(\overline{\beta}^{(1)},u^{(1)},\dots,\overline{\beta}^{(m)},u^{(m)}\right)$ and $m = |U|-1$. Lemma 3.1 supplies us with a representation of the product $f(x_1)\cdot\ldots\cdot f(x_m)$ sending U^m into L by an expression of the right-hand side of (2). This leads to the representation of the form

$$\prod_{d'\in L-\{d\}} (p'(u_1,\dots,u_k) - d') = \sum_{(\overline{\beta},u)\in\mathbf{F}_U^n\times U} \mu'_{\overline{\beta},u}\cdot f\left(\bigoplus_{i=1}^{k}\beta_i\cdot u_i\oplus u\right)$$

which, with the help of Lemma 4.1, can be efficiently checked not to be constantly $0_{\mathbf{L}}$. This in turn is equivalent for the starting equation to have a solution. ◀

Corollary 3.3 and Lemma 5.1 yield the following result.

▶ **Theorem 5.2.** *Let* $\mathbf{A} = \mathbf{L}\otimes^F\mathbf{U}$ *with* $\mathbf{L}$ *and* $\mathbf{U}$ *being polynomially equivalent to one dimensional vectors spaces over prime fields of different characteristics. Then* $\textsc{Csat}(\mathbf{A})$ *is in P.*

6 Algebras with infinitely many operations

The reasons we consider infinite languages in this paper are twofold. One motivation comes from the fact that a desire for a simple extension of our polynomial time algorithms from supernilpotent algebras to nilpotent ones is hopeless. Indeed, as it has been already mentioned

in the Introduction, those algorithms are based on a reduction to a small search space. Its size and shape is bounded as a result of the bound for the essential arity of commutator terms (they serve as multi-ary internal conjunctions replacing lack of an external one). At first glance the existence of polynomial time algorithms for nilpotent but not supernilpotent algebras is not so obvious as they do have commutator terms of arbitrary large arity so that one can try to interpret NP-complete problems like in solvable but nonnilpotent case. However all known commutator terms have exponential size with respect to the number of variables whenever they are produced from finitely many operations. In fact the circuits representing those known commutator polynomials are also of exponential size. However, allowing infinitely many operations, we do have the possibility to express arbitrary large conjunctions by short polynomials. This phenomena is presented in the next Theorem.

▶ **Theorem 6.1.** *For two different prime numbers p, q there exists a 2-nilpotent algebra $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ with $\mathbf{U}$ and $\mathbf{L}$ being polynomially equivalent to one dimensional vector spaces over the fields $GF(p)$ and $GF(q)$ respectively, such that $\textsc{Ceqv}_{\textsc{tm}}(\mathbf{A})$ is co-NP-complete and $\textsc{Csat}_{\textsc{tm}}(\mathbf{A})$ is NP-complete.*

Proof. We start with choosing $a \in U - \{0\}$ and $b \in L - \{0\}$ to define the following family of functions:

$$f_k((l_1^1, u_1^1), (l_2^1, u_2^1), (l_3^1, u_3^1), \ldots, (l_1^k, u_1^k), (l_2^k, u_2^k), (l_3^k, u_3^k)) = (\widehat{f_k}(u_1^1, u_2^1, u_3^1, \ldots, u_1^k, u_2^k, u_3^k), 0),$$

where

$$\widehat{f_k}(u_1^1, u_2^1, u_3^1, \ldots, u_1^k, u_2^k, u_3^k) = \begin{cases} b, & \text{if } a \in \{u_1^i, u_2^i, u_3^i\} \text{ for each } i, \\ 0, & \text{otherwise.} \end{cases}$$

Obviously the values of the f_k's can be computed by a single Turing machine in $O(k)$ time.

Now we define $\mathbf{A}$ to be $(L \times U; +_{\mathbf{A}}, \{f_k\}_{k=1}^{\infty})$, where $(L; +)$ and $(U; \oplus)$ are the groups of order q and p, respectively, and $(l_1, u_1) +_{\mathbf{A}} (l_2, u_2) = (l_1 + l_2, u_1 \oplus u_2)$.

To see that $\textsc{Csat}_{\textsc{tm}}(\mathbf{A})$ is NP-complete observe that a 3-CNF formula

$$(\ell_1^1 \vee \ell_2^1 \vee \ell_3^1) \wedge \cdots \wedge (\ell_1^k \vee \ell_2^k \vee \ell_3^k) \tag{9}$$

is satisfiable if and only if the following equation has a solution in $\mathbf{A}$

$$f_k(z_1^1, z_2^1, z_3^1, \ldots, z_1^k, z_2^k, z_3^k) = (b, 0),$$

where $z_i^j = x_i^j$ if ℓ_i^j is a positive literal and $z_i^j = (0, a) - x_i^j$ otherwise.

Similarly a formula (9) is not satisfiable iff the following equation holds in $\mathbf{A}$.

$$f_k(z_1^1, z_2^1, z_3^1, \ldots, z_1^k, z_2^k, z_3^k) = (0, 0).$$

This shows co-NP-completeness of $\textsc{Ceqv}_{\textsc{tm}}(\mathbf{A})$. ◀

Note here that the examples with co-NP-complete $\textsc{Ceqv}_{\textsc{tm}}$ and NP-complete $\textsc{Csat}_{\textsc{tm}}$ do exist even for $p = q$. Actually they are provided (but without detailed description of the input size) in [14]. However, if $p = q$ the resulting algebras must have infinitely many basic operations (as otherwise they would be supernilpotent), while for $p \neq q$ the algebras have finitely generated clone of operations but are presented with infinitely many basic operations only to (artificially) compress the size of the input.

Note also that in fact Theorem 6.1 actually establishes much more than just hardness of $\textsc{Csat}_{\textsc{tm}}$ and $\textsc{Ceqv}_{\textsc{tm}}$. Indeed, these examples show that (unless P = NP) for nilpotent but

not supernilpotent finite algebras one cannot expect polynomial time algorithms for CSAT or CEQV based on small search spaces S_n described in the Introduction. This is because the existence of such search spaces do not depend on the finiteness of the language.

Representing functions by Turing machines gives us a way to compress the input. However one can consider this as a drawback. That is because in this approach we can no longer treat basic operations occurring in the input as parameters in the way we do it for the finite set of operations. This probably denies the intuition behind what should an algorithm parameterized by an algebra mean. That is why $\mathrm{CEQV}_{\mathrm{T}}(\mathbf{A})$ and $\mathrm{CSAT}_{\mathrm{T}}(\mathbf{A})$, as described in the Introduction, appear to be more natural candidates for transferring these problems to the realm with possibly infinitely many basic operations. In contrast to Theorem 6.1 we have the following.

▶ **Theorem 6.2.** *Let* $\mathbf{A} = \mathbf{L} \otimes^F \mathbf{U}$ *with* $\mathbf{L}$ *and* $\mathbf{U}$ *being polynomially equivalent to one dimensional vector spaces over prime fields of different characteristics. Then* $\mathrm{CEQV}_{\mathrm{T}}(\mathbf{A})$ *and* $\mathrm{CSAT}_{\mathrm{T}}(\mathbf{A})$ *are in P.*

Proof. First note that from Corollary 3.3 every polynomial over $\mathbf{A}$ can be represented in some f-normal form. In view of Lemmas 3.2, 4.1 and 5.1 it suffices to show that obtaining f-normal forms of basic operations can be done in time polynomial in size of their tables.

To represent the basic operation g in the form of the right-hand side of (5) we need to compute all the λ_i's, $\mu_{\overline{\beta},u}$'s, α_i's and u_0 from the table of g. For $x \in L \times U$ we will use $\Pi_L(x)$ and $\Pi_U(x)$ to denote the first and second coordinate of x.

Now, to compute the α_i's and u_0 it suffices to solve the following system of $k+1$ linear equations

$$\bigoplus_{i=1}^{k} \alpha_i u_i \oplus u_0 = \Pi_U(g((0,u_1),\dots,(0,u_k)))\,,$$

where $(u_1,\dots,u_k)$ ranges over the set $\{(0,\dots,0),(1,0,\dots,0),(0,1,0,\dots,0)\dots,(0,\dots,0,1)\} \subseteq U^k$ and $\Pi_U(g((0,u_1),\dots,(0,u_k)))$ can be read from the table of g. Similarly, the λ_i's are the solutions of the following system of k linear equations

$$\sum_{i=1}^{k} \lambda_i l_i + \Pi_L(g((0,0),\dots,(0,0))) = \Pi_L(g((l_1,0),\dots,(l_k,0)))\,,$$

where again $(l_1,\dots,l_k)$ ranges over the set $\{(1,0,\dots,0),(0,1,0,\dots,0)\dots,(0,\dots,0,1)\} \subseteq L^k$. Finally, the $\mu_{\overline{\beta},u}$'s can be recovered from the following system of linear equations

$$\sum_{(\overline{\beta},u)\in \mathbf{F}_U^k \times U} \mu_{\overline{\beta},u} \cdot f\left(\bigoplus_{i=1}^{k} \beta_i u_i \oplus u\right) = \Pi_L(g((0,u_1),\dots,(0,u_k)))\,.$$

This time the system consists of $|U|^k$ equations (one for each $(u_1,\dots,u_k) \in U^k$) but this number is linear in the size of the table of g, as g is k-ary. ◀

Abstract

We show how to prove theorems in additive number theory using a decision procedure based on finite automata. Among other things, we obtain the following analogue of Lagrange's theorem: every natural number > 686 is the sum of at most 4 natural numbers whose canonical base-2 representation is a *binary square*, that is, a string of the form xx for some block of bits x. Here the number 4 is optimal. While we cannot embed this theorem itself in a decidable theory, we show that *stronger* lemmas that imply the theorem can be embedded in decidable theories, and show how automated methods can be used to search for these stronger lemmas.

1 Introduction

Additive number theory is the study of the additive properties of integers [12]. In particular, an *additive basis of order* h is a subset $S \subseteq \mathbb{N}$ such that every natural number is the sum of h members, not necessarily distinct, of S. The principal problem of additive number theory is to determine whether a given subset S is an additive basis of order h for some h, and if so, to determine the smallest value of h. There has been much research in the area, and deep techniques, such as the Hardy-Littlewood circle method, have been developed to solve these kinds of problems [20].

One of the earliest results in additive number theory is Lagrange's famous theorem [10] that every natural number is the sum of four squares [5, 11]. In the terminology of

[1] This material is based upon work supported by the National Science Foundation under Grant No. 1527395.

the previous paragraph, this means that $S = \{0^2, 1^2, 2^2, 3^2, \ldots\}$ forms an additive basis of order 4. The celebrated problem of Waring (1770) (see, e.g., [4, 19, 21]) is to determine the corresponding least order $g(k)$ for k'th powers. Since it is easy to see that numbers of the form $4^a(8k + 7)$ cannot be expressed as the sum of three squares, it follows that $g(2) = 4$. It is known that $g(3) = 9$ and $g(4) = 19$.

In a variation on this concept we say that $S \subseteq \mathbb{N}$ is an *asymptotic additive basis of order* h if every *sufficiently large* natural number is the sum of h members, not necessarily distinct, of S. The classical function $G(k)$ is defined to be the least asymptotic basis order for k'th powers. From above we have $G(2) = 4$. It is known that $G(14) = 16$, and $4 \leq G(3) \leq 7$. Despite much work, the exact value of $G(3)$ is currently unknown.

Recently there has been interest in doing additive number theory on sets of natural numbers whose base-k representations have certain properties. For example, Banks [1] proved that every natural number is the sum of at most 49 natural numbers whose decimal representation is a palindrome. This was improved by Cilleruelo, Luca, and Baxter [2] to 3 summands for every base $b \geq 5$. The remaining cases $b = 2, 3, 4$ were recently resolved [17].

In this paper we consider a variation on Lagrange's theorem. Instead of the ordinary notion of the square of an integer, we consider "squares" in the sense of formal language theory [8]. That is, we consider x, the canonical binary (base-2) representation of an integer N, and call N a *binary square* if $N = 0$, or if $x = yy$ for some nonempty string y that starts with a 1. Thus, for example, $N = 221$ is a binary square, since 221 in base 2 is $11011101 = (1101)(1101)$. The first few binary squares are

$$0, 3, 10, 15, 36, 45, 54, 63, 136, 153, 170, 187, 204, 221, 238, 255, \ldots;$$

they form sequence A020330 in the *On-Line Encyclopedia of Integer Sequences* (OEIS) [18]. Clearly a number $N > 0$ is a binary square if and only if it is of the form $a(2^n + 1)$ for $n \geq 1$ and $2^{n-1} \leq a < 2^n$. This is a very natural sequence to study, since the binary squares have density $\Theta(N^{1/2})$ in the natural numbers, just like the ordinary squares. (There exist sets of density $\Theta(N^{1/2})$ that do not form an asymptotic basis of finite order, so density considerations alone do *not* imply our result.)

In this paper we prove the following result.

▶ **Theorem 1.** *The binary squares form an asymptotic basis of order* 4. *More precisely, every natural number* $N > 686$ *is the sum of* 4 *binary squares. There are* 56 *exceptions, given below:*

$$1, 2, 4, 5, 7, 8, 11, 14, 17, 22, 27, 29, 32, 34, 37, 41, 44, 47, 53, 62, 95, 104, 107, 113, 116, 122, 125,$$
$$131, 134, 140, 143, 148, 155, 158, 160, 167, 407, 424, 441, 458, 475, 492, 509, 526, 552, 560,$$
$$569, 587, 599, 608, 613, 620, 638, 653, 671, 686.$$ ◀

The novelty in our approach is that we obtain this theorem in additive number theory *using very little number theory at all*. Instead, we use an approach based on formal language theory, reducing the proof of the theorem to a decidable language emptiness problem. Previously we obtained similar results for palindromes [15, 16, 17].

1.1 Search for appropriate lemmas and proving the theorem

The technique we use for encoding Theorem 1 as a problem dealing with automata is to ask, for all sufficiently large integers N, whether there exist four binary squares with representation $x_i x_i$, $1 \leq i \leq 4$, such that the sum of the numbers they represent is N. Since the language of

binary squares is not regular, we use an encoding where we represent only one copy of each x_i and reuse it to represent the number. However, it turns out that we cannot represent the desired theorem directly as an emptiness/universality problem of finite automata. The reason is that when representing only one copy of the x_i, we can do "school addition" (aligning them and adding the numbers, columnwise, with a carry) only if the words x_i are roughly of the same *length*. More precisely, we require the lengths of the squares employed to either be bounded by a constant, or differ from each other and from the number N only by a bounded length.

For fixed constants k_i, $1 \leq i \leq 4$, we observe that the set of all binary representations of N for which there exist four words x_i, $1 \leq i \leq 4$, of lengths $L - k_i$, such that the binary representation of N is of length $2L$ and the sum of the numbers represented by $x_i x_i$, $1 \leq i \leq 4$ is N, is a regular language. Thus we can prove, using known decision algorithms for automata, lemmas that assert that all numbers of a particular form can be represented by a sum of four binary squares, where the binary squares are of various lengths $L - k_1$, $L - k_2$, $L - k_3$, and $L - k_4$, for a finite set of tuples $\langle k_1, k_2, k_3, k_4 \rangle$ (see Lemma 5 for such a lemma).

Proving such a lemma for a particular set of combinations of lengths implies the theorem, of course, but the lemma itself is stronger. The truth of such stronger lemmas is decidable, while we don't have a way to directly decide the theorem itself!

Thus we need a *search* for an appropriate lemma for a particular combination of length differences that is valid. Given that checking these lemmas for any set of combinations is decidable, we can do the search for these lemmas automatically. We tried various combinations and succeeded in proving one lemma, namely Lemma 5, that implies our theorem.

The above technique can be generalized to some extent – evidently, we could also consider the analogous results for other powers such as cubes, and bases $b \geq 2$, but we do not do that in this paper.

1.2 Notation

We are concerned with the binary representation of numbers, so let us introduce some notation. If N is a natural number, then by $(N)_2$ we mean the string giving the canonical base-2 representation of N, having no leading zeroes. For example, $(43)_2 = 101011$. The canonical representation of 0 is ϵ, the empty string.

If $2^{n-1} \leq N < 2^n$ for $n \geq 1$, we say that N is an *n-bit integer* in base 2. Note that the first bit of the binary representation of an n-bit integer is always nonzero. The *length* of an integer N satisfying $2^{n-1} \leq N < 2^n$ is defined to be n; alternatively, the length of N is $1 + \lfloor \log_2 N \rfloor$. For $n \geq 1$ we define $C_n = \{a \cdot (2^n + 1) \ : \ 2^{n-1} \leq a < 2^n\}$, the set of all $2n$-bit binary squares.

2 A classical approach

In this section we describe how one can apply classical number-theoretic and combinatorial tools to this problem to obtain some results weaker than Theorem 1. The idea is to show that the numbers that are the sum of two binary squares form a set of positive lower asymptotic density. (In contrast, our approach via automata, which we discuss in later sections, provides more precise results.)

For sets $S, T \subseteq \mathbb{N}$ we define the sumset $S + T = \{s + t \ : \ s \in S, \ t \in T\}$. The cardinality of a finite set S is denoted by $|S|$. Given a set $S \subseteq \mathbb{N}$, the *lower asymptotic density* of S is defined to be

$$d(S) = \liminf_{n \to \infty} \frac{|\{x \in S \ : \ 1 \leq x \leq n\}|}{n}.$$

We first prove

▶ **Lemma 2.** *For $n \geq 1$ we have $|C_n + C_{n+1}| = 2^{2n-1}$.*

Proof. Since $|C_n| = 2^{n-1}$ and $|C_{n+1}| = 2^n$, this lemma is equivalent to the claim that each member of the sumset $C_n + C_{n+1}$ has a *unique* representation as the sum of one element of C_n and one element of C_{n+1}.

We argue by contradiction. Suppose the representation is not unique, and there exist integers a, a' with $2^{n-1} \leq a, a' < 2^n - 1$ and integers b, b' with $2^n \leq b, b' < 2^{n+1}$ such that $(a, a') \neq (b, b')$ but

$$a \cdot (2^n + 1) + b \cdot (2^{n+1} + 1) = a' \cdot (2^n + 1) + b' \cdot (2^{n+1} + 1). \tag{1}$$

Computing Eq. (1) modulo 2^n+1, we see that $-b \equiv -b' \pmod{2^n+1}$. Since $2^n \leq b, b' < 2^{n+1}$ we see the congruence in fact implies that $b = b'$. But then $a = a'$, a contradiction. ◀

▶ **Theorem 3.** *The numbers that are the sum of two binary squares form a set of lower asymptotic density $\geq 1/40$.*

Proof. Let S_2 be the set of numbers that are the sum of two binary squares. Clearly $C_n + C_{n+1} \subseteq S_2$.

There are 2^{2n-1} elements in the sumset $C_n + C_{n+1}$, whose largest element is $(2^n - 1)2^n + (2^{n+1} - 1)2^{n+1} = 5 \cdot 2^{2n} - 3 \cdot 2^n$. Given an integer $m \geq 14$, choose $n \geq 1$ such that $5 \cdot 2^{2n} - 3 \cdot 2^n \leq m < 5 \cdot 2^{2n+2} - 3 \cdot 2^{n+1}$. Then

$$\frac{|\{x \in S_2 \ : \ 1 \leq x \leq m\}|}{m} \geq \frac{2^{2n-1}}{5 \cdot 2^{2n+2}} = \frac{1}{40}.$$

◀

▶ **Corollary 4.** *The binary squares form an asymptotic basis of finite order.*

Proof. This is a direct consequence of a result of Nathanson [13, Theorem 11.6, p. 366], which says that if a subset S of $\mathbb{N}$ has $0 \in S$, $\gcd(S) = 1$, and has positive lower asymptotic density, then it is an asymptotic basis of finite order. It is now easy to check that the hypotheses are fulfilled for $S = S_2$. ◀

▶ Remark. It would be interesting to determine the exact lower asymptotic density of the set S_2. Numerical computation suggests that perhaps $d(S_2) \doteq .14$.

3 The automaton approach: the main lemma

Now we turn to a completely different approach to the theorem for binary squares, as sketched in Section 1, using automata theory. This allows us to obtain the upper bound 4 for the number of binary squares, a stronger result than obtained using the classical approach.

Our main lemma is

▶ **Lemma 5.**

(a) *Every length-n integer, n odd, $n \geq 13$, is the sum of binary squares as follows: either*

- *one of length $n-1$ and one of length $n-3$, or*
- *two of length $n-1$ and one of length $n-3$, or*
- *one of length $n-1$ and two of length $n-3$, or*
- *one each of lengths $n-1$, $n-3$, and $n-5$, or*
- *two of length $n-1$ and two of length $n-3$, or*
- *two of length $n-1$, one of length $n-3$, and one of length $n-5$.*

(b) *Every length-n integer, n even, $n \geq 18$, is the sum of binary squares as follows: either*
- *two of length $n-2$ and two of length $n-4$, or*
- *three of length $n-2$ and one of length $n-4$, or*
- *one each of lengths n, $n-4$, and $n-6$, or*
- *two of length $n-2$, one of length $n-4$, and one of length $n-6$.*

Lemma 5 almost immediately proves Theorem 1:

Proof. If $N < 2^{17} = 131072$, the result can be proved by a completely straightforward computation using dynamic programming: to form the sumset $S \oplus T$, given finite sets of natural numbers S and T, we use a bit vector corresponding to the elements of S, and then take its XOR shifted by each element of T. When we do this, we find that there are
- 256 binary squares $< 2^{17}$;
- 19542 numbers $< 2^{17}$ that are the sum of two binary squares;
- 95422 numbers $< 2^{17}$ that are the sum of three binary squares;
- 131016 numbers $< 2^{17}$ that are the sum of four binary squares.

Otherwise $N \geq 2^{17}$, so $(N)_2$ is a binary string of length $n \geq 18$. If n is odd, the result follows from Lemma 5 (a). If n is even, the result follows from Lemma 5 (b). ◀

It now remains to prove Lemma 5. We do this in the next section.

4 Proof of Lemma 5

In this section we prove Lemma 5 in detail.

Proof. The basic idea is to use nondeterministic finite automata (NFAs). These are finite-state machines where each input corresponds to multiple computational paths; an input is accepted iff *some* computational path leads to a final state. We assume the reader is familiar with the basics of this theory; if not, please consult, e.g., [8]. For us, an NFA is a quintuple $(Q, \Sigma, \delta, q_0, F)$, where Q is the set of states, Σ is the input alphabet, δ is the transition function, q_0 is the initial state, and F is the set of final states.

We construct an NFA that, on input an integer N written in binary, "guesses" a representation as a sum of binary squares, and then verifies that the sum is indeed N. Everything is done using a reversed representation, with least significant digits processed first. There are some complications, however.

First, with an NFA we cannot verify that a guessed string is indeed a binary square, as the language $\{xx \ : \ x \in 1\{0,1\}^*\}$ is not a regular language. So instead we only guess the "first half" of a binary square. Now, however, we are forced to choose a slightly unusual representation for N, in order to be able to compare the sum of our guessed powers with the input N. If N were represented in its ordinary base-2 representation, this would be impossible with an NFA, since once we process the guessed "first half" and compare it to the input, we would no longer have the "second half" (identical to the first) to compare to the rest of the input.

To get around this problem, we represent integers N in a kind of "folded representation" over the input alphabet $\Sigma_2 \cup (\Sigma_2 \times \Sigma_2)$, where $\Sigma_k = \{0, 1, \ldots, k-1\}$. The idea is to present our NFA with two bits of the input string at once, so that we can add both halves of our guessed powers at the same time, verifying that we are producing N as we go. Note that we use slightly different representations for the two parts of Lemma 5. The precise representations are detailed in their respective subsections.

We can now prove Lemma 5 by phrasing it as a language inclusion problem. For each of the two parts of the lemma, we can build an NFA A that only accepts such folded strings if

they repesent numbers that are the sum of any of the combination of squares as described in the lemma. We also create an NFA, B, that accepts all valid folded representations that are sufficiently long. We then check the assertion that the language recognized by B is a subset of that recognized by A.

4.1 Odd-length inputs

Again, to flag certain positions of the input tape, we use an extended alphabet. Define

$$\Gamma = \{1_f\} \cup \bigcup_{\alpha\in\{a,b,c,d,e\}} \{[0,0]_\alpha, [0,1]_\alpha, [1,0]_\alpha, [1,1]_\alpha\}.$$

Let N be an integer, and let $n = 2i+1$ be the length of its binary representation. We write $(N)_2 = a_{2i}a_{2i-1}\cdots a_1a_0$ and fold this to produce the input string

$$[a_i, a_0]_a[a_{i+1}, a_1]_a \cdots [a_{2i-5}, a_{i-5}]_a[a_{2i-4}, a_{i-4}]_b[a_{2i-3}, a_{i-3}]_c[a_{2i-2}, a_{i-2}]_d[a_{2i-1}, a_{i-1}]_e a_{2i_f}.$$

Let A_{odd} be the NFA that recognizes those odd-length integers, represented in this folded format, that are the sum of binary squares meeting any of the 6 conditions listed in Lemma 5 (a). We construct A_{odd} as the union of several automata $A(t_{n-1}, t_{n-3}, m_a)$ and $B(t_{n-1}, t_{n-3}, t_{n-5}, m_b)$. The parameters t_p represent the number of summands of length p we are guessing. The parameters m_a and m_b are the carries that we are guessing will be produced by the first half of the summed binary squares. A-type machines try summands of lengths $n-1$ and $n-3$ only, while B-type machines include at least one $(n-5)$-length summand. We note that for the purpose of summing, guessing t binary squares is equivalent to guessing a *single* square over the larger alphabet Σ_{t+1}.

We now consider the construction of a single automaton

$$A(t_{n-1}, t_{n-3}, m) = (Q \cup \{q_{\text{acc}}, q_0, s_1\}, \Gamma, \delta, q_0, \{q_{\text{acc}}\}).$$

The elements of Q have 4 non-negative parameters and are of the form $q(x_1, x_2, c_1, c_2)$. Because the t_{n-3} summand is not aligned with the input, we use our states to "remember" our guesses. When we make a guess at the higher end of the t_{n-3} summand, it must be used as the guess for its lower end on the *next step*. We remember this guess by storing it as the x_2 parameter. The parameter $x_1 \le t_{n-3}$ is the last digit of the guessed summand of length $n-3$. We use c_1 to track the higher carry, and c_2 to track the lower carry. We must have $c_1, c_2 < t_{n-1} + t_{n-3}$.

We now discuss the transition function, δ of our NFA. In this section, we say that the sum of natural numbers, μ_1 and μ_2, "produces" an output bit of $\theta \in \Sigma_2$ with a "carry" of γ if $\mu_1 + \mu_2 \equiv \theta \pmod 2$ and $\gamma = \left\lfloor \frac{\mu_1+\mu_2}{2} \right\rfloor$.

We allow a transition from q_0 to $q(x_1, x_2, c_1, c_2)$ on the letter $[j,k]_a$ iff there exists $0 \le r \le t_{n-1}$ such that $x_2 + r + m$ produces an output of j with a carry of c_1 and $x_1 + r$ produces an output of k with a carry of c_2.

We allow a transition from $q(x_1, x_2, c_1, c_2)$ to $q(x_1', x_2', c_1', c_2')$ on the letters $[j,k]_a$ and $[j,k]_b$ iff there exists $0 \le r \le t_{n-1}$ such that $x_2' + r + c_1$ produces an output of j with a carry of c_1' and $x_2 + r + c_2$ produces an output of k with a carry of c_2'. Elements of Q have identical transitions on inputs with subscripts a and b. The reason we have the letters with subscript b is for B-machines, which guess a summand of length $n-5$.

There is only one letter of the input with the subscript c, and it corresponds to the last higher guess of the summand of length $n-3$. We allow a transition from $q(x_1, x_2, c_1, c_2)$ to $q(x_1', t_{n-3}, c_1', c_2')$ on the letter $[j,k]_c$ iff there exists $0 \le r \le t_{n-1}$ such that $t_{n-3} + r + c_1$

produces an output of j with a carry of c_1' and $x_2 + r + c_2$ produces an output of k with a carry of c_2'.

There is only one letter of the input with the subscript d, and it corresponds to the second-last lower guess of the summand of length $n-3$. We allow a transition from $q(x_1, t_{n-3}, c_1, c_2)$ to $q(x_1', 0, c_1', c_2')$ on the letter $[j,k]_d$ iff there exists $0 \leq r \leq t_{n-1}$ such that $r + c_1$ produces an output of j with a carry of c_1' and $t_{n-3} + r + c_2$ produces an output of k with a carry of c_2'.

There is only one letter of the input with the subscript e, and it corresponds to the last lower guess of the summand of length $n-3$. We allow a transition from $q(x_1, 0, c_1, c_2)$ to s_1 on the letter $[j,k]_e$ iff $t_{n-1} + c_1$ produces an output of j with a carry of 1 and $x_1 + t_{n-1} + c_2$ produces an output of k with a carry of m.

Finally, we add a transition from s_1 to q_{acc} on the letter 1_f.

We now consider the construction of a single automaton

$$B(t_{n-1}, t_{n-3}, t_{n-5}, m) = (P \cup Q \cup \{q_{\text{acc}}, q_0, s_1\}, \Gamma, \delta, q_0, \{q_{\text{acc}}\}).$$

The elements of P have 6 non-negative parameters and are of the form $q(x_1, x_2, y_1, y_3, c_1, c_2)$. The parameter $x_1 \leq t_{n-3}$ is the last digit of the guessed summand of length $n-3$ and $x_2 \leq t_{n-3}$ is the previous higher guess of the length-$n-3$ summand. The parameter $y_1 \leq t_{n-5}$ is the last digit of the guessed summand of length $n-5$ and $y_3 \leq t_{n-5}$ is the previous higher guess of the length-$n-5$ summand. We use c_1 to track the higher carry, and c_2 to track the lower carry. We must have $c_1, c_2 < t_{n-1} + t_{n-3} + t_{n-5}$. The elements of Q have 8 non-negative parameters and are of the form

$$q(x_1, x_2, y_1, y_2, y_3, y_4, c_1, c_2).$$

The parameter $x_1 \leq t_{n-3}$ is the last digit of the guessed summand of length $n-3$ and $x_2 \leq t_{n-3}$ is the previous higher guess of the length-$n-3$ summand. The parameters $y_1, y_2 \leq t_{n-5}$ are the last digit and the second-last digit of the guessed summand of length $n-5$ respectively. The parameter $y_3, y_4 \leq t_{n-5}$ are the two most recent higher guess of the length-$n-5$ summand, with y_4 being the most recent one. We use c_1 to track the higher carry, and c_2 to track the lower carry. We must have $c_1, c_2 < t_{n-1} + t_{n-3} + t_{n-5}$.

We now discuss the transition function, δ of our NFA. We allow a transition from q_0 to $p(x_1, x_2, y_1, y_3, c_1, c_2)$ on the letter $[j,k]_a$ iff there exists $0 \leq r \leq t_{n-1}$ such that $x_2 + y_3 + r + m$ produces an output of j with a carry of c_1 and $x_1 + y_1 + r$ produces an output of k with a carry of c_2.

We use a transition from $p(x_1, x_2, y_1, y_3, c_1, c_2)$ to $q(x_1, x_2', y_1, y_2', y_3, y_4', c_1', c_2')$ on the letter $[j,k]_a$ iff there exists $0 \leq r \leq t_{n-1}$ such that $x_2' + y_4' + r + c_1$ produces an output of j with a carry of c_1 and $x_2 + y_2' + r + c_2$ produces an output of k with a carry of c_2.

We use a transition from $q(x_1, x_2, y_1, y_2, y_3, y_4, c_1, c_2)$ to $q(x_1, x_2', y_1, y_2, y_4, y_4', c_1', c_2')$ on the letter $[j,k]_a$ iff there exists $0 \leq r \leq t_{n-1}$ such that $x_2' + y_4' + r + c_1$ produces an output of j with a carry of c_1 and $x_2 + y_3 + r + c_2$ produces an output of k with a carry of c_2.

We use a transition from $q(x_1, x_2, y_1, y_2, y_3, t_{n-5}, c_1, c_2)$ to $q(x_1, x_2', y_1, y_2, t_{n-5}, t_{n-5}, c_1', c_2')$ on the letter $[j,k]_b$ iff there exists $0 \leq r \leq t_{n-1}$ such that $x_2' + r + c_1$ produces an output of j with a carry of c_1 and $x_2 + y_3 + r + c_2$ produces an output of k with a carry of c_2.

We use a transition from $q(x_1, x_2, y_1, y_2, t_{n-5}, t_{n-5}, c_1, c_2)$ to $q(x_1, t_{n-3}, y_1, y_2, t_{n-5}, t_{n-5}, c_1', c_2')$ on the letter $[j,k]_c$ iff there exists $0 \leq r \leq t_{n-1}$ such that $t_{n-3} + r + c_1$ produces an output of j with a carry of c_1 and $x_2 + y_3 + r + c_2$ produces an output of k with a carry of c_2.

We use a transition from $q(x_1, t_{n-3}, y_1, y_2, t_{n-5}, t_{n-5}, c_1, c_2)$ to $q(x_1, t_{n-3}, y_1, y_2, t_{n-5}, t_{n-5}, c_1', c_2')$ on the letter $[j,k]_d$ iff there exists $0 \leq r \leq t_{n-1}$ such that $r + c_1$ produces an

output of j with a carry of c_1 and $t_{n-3} + y_1 + r + c_2$ produces an output of k with a carry of c_2.

We use a transition from $q(x_1, t_{n-3}, y_1, y_2, t_{n-5}, t_{n-5}, c_1, c_2)$ to s_1 on the letter $[j,k]_e$ iff $t_{n-1} + c_1$ produces an output of j with a carry of 1 and $x_1 + y_2 + t_{n-1} + c_2$ produces an output of k with a carry of m.

Finally, we add a transition from s_1 to q_{acc} on the letter 1_f.

We now turn to verification of the inclusion assertion. We used the Automata Library toolchain of the `ULTIMATE` program analysis framework [7, 6] to establish our results. The `ULTIMATE` code proving our result can be found in the file `OddSquareConjecture.ats` at `https://cs.uwaterloo.ca/~shallit/papers.html`. Since the constructed machines get very large, we wrote a C++ program generating these machines, which can be found in the file `OddSquares.cpp` at the same location.

The final machine, A_{odd}, has 2258 states. The syntax checker, B, has 8 states. We then asserted that the language recognized by B is a subset of that recognized by A. ULTIMATE verified this assertion in under a minute. Since this test succeeded, the proof of Lemma 5 (a) is complete.

4.2 Even-length inputs

In order to flag certain positions of the input tape, we use an extended alphabet. Define

$$\Gamma = \left(\bigcup_{\alpha \in \{a,b,c,d,e\}} \{[0,0]_\alpha, [0,1]_\alpha, [1,0]_\alpha, [1,1]_\alpha\} \right) \cup \left(\bigcup_{\beta \in \{f,g,h,i\}} \{0_\beta, 1_\beta\} \right).$$

Let N be an integer, and let $n = 2i + 4$ be the length of its binary representation. We write $(N)_2 = a_{2i+3}a_{2i+2} \cdots a_1 a_0$ and fold this to produce the input string

$$[a_i, a_0]_a[a_{i+1}, a_1]_b[a_{i+2}, a_2]_c[a_{i+3}, a_3]_c \cdots \\ \cdots [a_{2i-3}, a_{i-3}]_c[a_{2i-2}, a_{i-2}]_d[a_{2i-1}, a_{i-1}]_e a_{2i_f} a_{2i+1_g} a_{2i+2_h} a_{2i+3_i}.$$

Let A_{even} be the NFA that recognizes the even-length integers, represented in this folded format, iff the integer is the sum of binary squares meeting any of the 4 conditions listed in Lemma 5 (b). We construct A_{even} as the union of several automata $A(t_n, t_{n-2}, t_{n-4}, t_{n-6}, m)$. The parameters t_p represent the number of summands of length p we are guessing. The parameter m is the carry that we are guessing will be produced by the first half of the summed binary squares. Again, guessing t binary squares is equivalent to guessing a *single* square over the larger alphabet Σ_{t+1}.

We now consider the construction of a single automaton

$$A(t_n, t_{n-2}, t_{n-4}, t_{n-6}, m) = (Q \cup \{q_{\text{acc}}\}, \Gamma, \delta, q_0, \{q_{\text{acc}}\}).$$

The elements of Q have 8 non-negative parameters and are of the form $q(x_1, x_2, x_3, y_1, z_1, z_2, c_1, c_2)$. The parameter x_1 is the second digit of the guessed summand of length n. The parameters x_2 and x_3 represent the previous 2 lower guesses of the length-n summand; these must be the next 2 higher guesses of this summand. The parameter y_1 represents the previous lower guess of the length-$(n-2)$ summand. We set z_1 as the last digit of the guessed summand of length $n-6$, while z_2 is the previous higher guess of this summand. Finally, c_1 tracks the lower carry, while c_2 tracks the higher carry. For any p, we must have $x_p \le t_n$, $y_p \le t_{n-2}$, $z_p \le t_{n-6}$, and $c_p < t_n + t_{n-2} + t_{n-4} + t_{n-6}$. The initial state, q_0, is $q(0,0,0,0,0,0,0,0)$.

We now discuss the transition function, δ of our NFA. Note that in our representation of even-length integers, the first letter of the input must have the subscript a, and it is the only letter to do so. We only allow the initial state to have outgoing transitions on such letters.

We allow a transition from q_0 to $q(x_1, 0, x_3, y_1, z_1, z_2, c_1, c_2)$ on the letter $[j, k]_a$ iff there exists $0 \leq r \leq t_{n-4}$ such that $x_1 + t_{n-2} + r + z_2 + m$ produces an output of j with a carry of c_2 and $x_3 + y_1 + r + z_1$ produces an output of k with a carry of c_1.

The second letter of the input must have the subscript b, and it is the only letter to do so. We allow a transition from $q(x_1, 0, x_3, y_1, z_1, z_2, c_1, c_2)$ to $q(x_1, x_3, x'_3, y'_1, z_1, z'_2, c'_1, c'_2)$ on the letter $[j, k]_b$ iff there exists $0 \leq r \leq t_{n-4}$ such that $t_n + y_1 + r + z'_2 + c_2$ produces an output of j with a carry of c'_2 and $x'_3 + y'_1 + r + z_2 + c_1$ produces an output of k with a carry of c'_1.

We allow a transition from $q(x_1, x_2, x_3, y_1, z_1, z_2, c_1, c_2)$ to $q(x_1, x_3, x'_3, y'_1, z_1, z'_2, c'_1, c'_2)$ on the letter $[j, k]_c$ iff there exists $0 \leq r \leq t_{n-4}$ such that $x_2 + y_1 + r + z'_2 + c_2$ produces an output of j with a carry of c'_2 and $x'_3 + y'_1 + r + z_2 + c_1$ produces an output of k with a carry of c'_1.

The letter of the input with the subscript d corresponds to the last guess of the lower half of the summand of length $n - 6$, and it is the only letter to do so. We allow a transition from $q(x_1, x_2, x_3, y_1, z_1, t_{n-6}, c_1, c_2)$ to $q(x_1, x_3, x'_3, y'_1, z_1, 0, c'_1, c'_2)$ on the letter $[j, k]_d$ iff there exists $0 \leq r \leq t_{n-4}$ such that $x_2 + y_1 + r + c_2$ produces an output of j with a carry of c'_2 and $x'_3 + y'_1 + r + t_{n-6} + c_1$ produces an output of k with a carry of c'_1.

The letter of the input with the subscript e corresponds to the last guess of both halves of the summand of length $n - 4$, and it is the only letter to do so. We allow a transition from $q(x_1, x_2, x_3, y_1, z_1, 0, c_1, c_2)$ to $q(x_1, x_3, x'_3, y'_1, 0, 0, 0, c'_2)$ on the letter $[j, k]_e$ iff $x_2 + y_1 + t_{n-4} + c_2$ produces an output of j with a carry of c'_2 and $x'_3 + y'_1 + t_{n-4} + z_1 + c_1$ produces an output of k with a carry of m.

We allow a transition from $q(x_1, x_2, x_3, y_1, 0, 0, 0, c_2)$ to $q(x_1, x_3, 0, 0, 0, 0, 0, c'_2)$ on the letter j_f iff $x_2 + y_1 + c_2$ produces an output of j with a carry of c'_2.

We allow a transition from $q(x_1, x_2, 0, 0, 0, 0, c_2)$ to $q(x_1, 0, 0, 0, 0, 0, 0, c'_2)$ on the letter j_g iff $x_2 + t_{n-2} + c_2$ produces an output of j with a carry of c'_2.

We allow a transition from $q(x_1, 0, 0, 0, 0, 0, c_2)$ to $q(0, 0, 0, 0, 0, 0, 0, c'_2)$ on the letter j_h iff $x_1 + c_2$ produces an output of j with a carry of c'_2.

We allow a transition from $q(0, 0, 0, 0, 0, 0, 0, c_2)$ to q_{acc} on the letter 1_i iff $t_n + c_2$ produces an output of 1 with a carry of 0.

The final machine, A_{even} is constructed as the union of 15 automata:

- $A(0, 2, 2, 0, m)$, varying m from 0 to 3
- $A(0, 3, 1, 0, m)$, varying m from 0 to 3
- $A(1, 0, 1, 1, m)$, varying m from 0 to 2
- $A(0, 2, 1, 1, m)$, varying m from 0 to 3

We now turn to verification of the inclusion assertion. The `ULTIMATE` code proving our result can be found in the file `EvenSquareConjecture.ats` at `https://cs.uwaterloo.ca/~shallit/papers.html`. Since the constructed machines get very large, we wrote a C++ program generating these machines, which can be found in the file `EvenSquares.cpp` at the same location.

The final machine, A_{even}, has 1343 states. The syntax checker, B, has 12 states. We then asserted that the language recognized by B is a subset of that recognized by A. ULTIMATE verified this assertion in under a minute. Since this test succeeded, the proof of Lemma 5 (b) is complete. ◀

▶ **Corollary 6.** *Given an integer $N > 686$, we can find an expression for N as the sum of four binary squares in time linear in* $\log N$.

Proof. For $N < 131072$, we do this with a simple brute-force search via dynamic programming, as explained previously. Otherwise we construct the appropriate automaton A (depending on whether the binary representation of N has either even or odd length). Now carry out the usual direct product construction for intersection of languages on A and B, where B is the automaton accepting the folded binary representation of N. The resulting automaton has at most $c \log N$ states and transitions. Now use the usual depth-first search of the transition graph to find a path from the initial state to a final state. The labels of this path gives the desired representation. ◀

4.3 Ensuring correctness

As in every machine-based proof, we want some assurance that our calculations were correct.

We tested our machine by calculating those integers of length 8 that can be expressed as the sum of up to 3 binary squares of length 4, and up to 4 binary squares of length 6. We then used the `ULTIMATE` framework to test that those length-8 integers are accepted by our machine, but all others are rejected. The code running this test can be found as `Minus2Minus4SquareConjecture - Test 1` at `https://cs.uwaterloo.ca/ shallit/papers.html`.

We also tested the machine by calculating those integers of length 10 that can be expressed as the sum of up to to 2 binary squares of length 6, and up to 4 binary squares of length 8. We then built the analogous machine and confirmed that these length-10 integers are accepted, but all others are rejected. We then repeated this test for those integers of length 10 that can be expressed as the sum of up to to 3 binary squares of length 6, and up to 3 binary squares of length 8. The code running these tests can be found as `Minus2Minus4SquareConjecture - Test 2` and `Minus2Minus4SquareConjecture - Test 3` at `https://cs.uwaterloo.ca/~shallit/papers.html`.

5 Optimality

In this section we show that the "4" in Theorem 1 is optimal.

▶ **Theorem 7.** *For $n \geq 1$, n odd, $n \neq 9$, the number 2^n is not the sum of three or fewer (positive) binary squares.*

Proof. Let $m \geq 0$ and $n = 2m + 1$ be odd. The cases $m = 0, 1, 2, 3$ are easy to verify by hand, so assume $m \geq 4$.

In what follows we distinguish between "mod" used in the ordinary notion of congruence (where $x \equiv a \pmod b$ means that b divides $x - a$), and the use of "mod" as a function, where $x = a \bmod b$ means both that $x \equiv a \pmod b$ and that $0 \leq a < b$.

Clearly $N := 2^n$ is not a binary square.

Suppose N is the sum of two positive binary squares. The largest binary square $< N$ is clearly $2^{2m} - 1$. Hence the sum of two binary squares is either larger than N, or no larger than $2(2^{2m} - 1) = 2^{2m+1} - 2 < N$, a contradiction.

The remaining case is that 2^{2m+1} is the sum of three binary squares, say $N = A + B + C$ with

$$A = a(2^e + 1) \geq B = b(2^f + 1) \geq C = c(2^g + 1)$$

with $e \geq f \geq g$ and $2^{e-1} \leq a < 2^e$, $2^{f-1} \leq b < 2^f$, and $2^{g-1} \leq c < 2^g$. Clearly $1 \leq e, f, g \leq m$.

We first observe that $e = m$. For otherwise, $e \leq m-1$ and the inequality $e \geq f \geq g$ implies

$$N = A + B + C \leq 3(2^{m-1} - 1)2^{m-1} < 3 \cdot 2^{2m-2} < N,$$

a contradiction.

Similarly, we observe that $f = m$. For otherwise

$$N = A + B + C \leq (2^m - 1)2^m + 2(2^{m-1} - 1)2^{m-1} < 3 \cdot 2^{2m-1} < N,$$

a contradiction.

Thus, setting $d = a + b$, we see that $N = d(2^m + 1) + c(2^g + 1)$ where $2^m \leq d \leq 2^{m+1} - 2$. Suppose $d = 2^{m+1} - 2$. Then $N = d(2^m + 1) + c(2^g + 1)$ implies that $C = c(2^g + 1) = 2$. But $C = 2$ is not a binary square. So in fact $2^m \leq d \leq 2^{m+1} - 3$.

Next we argue that $g > m/2$. For otherwise $g \leq m/2$ and we have

$$N = d(2^m+1)+c(2^g+1) \leq (2^{m+1}-3)(2^m+1)+(2^{m/2}-1)(2^{m/2}+1) = 2^{2m+1}-4 = N-4,$$

a contradiction.

Next we argue that $g < m$. For otherwise $g = m$ and then $N = 2^{2m+1} = A + B + C = (a + b + c)(2^m + 1)$. But then 2^{2m+1} is divisible by the odd number $2^m + 1$, a contradiction.

Now consider the equation $N = d(2^m + 1) + c(2^g + 1)$ and take it modulo $2^m + 1$. We have $2^{2m+1} - 2 = 2(2^m - 1)(2^m + 1) \equiv 0 \pmod{2^m + 1}$, and so $N = 2^{2m+1} \equiv 2 \pmod{2^m + 1}$.

Thus we get

$$c(2^g + 1) \equiv 2 \pmod{2^m + 1}. \tag{2}$$

It suffices to show that the congruence (2) has no solutions in the possible range for c, except when $m = 4$ and $g = 3$. In order to see this, we need a technical lemma.

▶ **Lemma 8.** *Suppose $m, g \geq 1$ are integers with $m/2 < g < m$. Suppose c is an integer with $2^{g-1} \leq c < 2^g$. Using Euclidean division, find the unique expression of c as $t \cdot 2^{m-g} + u$ for $0 \leq u < 2^{m-g}$. Then*

$$c(2^g + 1) \bmod (2^m + 1) = t(2^{m-g} - 1) + u(2^g + 1).$$

Proof. We have

$$\begin{aligned} c(2^g + 1) &= (t \cdot 2^{m-g} + u)(2^g + 1) \\ &= t \cdot 2^m + t \cdot 2^{m-g} + u(2^g + 1) \\ &= t(2^m + 1) + t(2^{m-g} - 1) + u(2^g + 1) \\ &\equiv t(2^{m-g} - 1) + u(2^g + 1) \pmod{2^m + 1}. \end{aligned}$$

This last congruence alone does not prove what we want; we also have to show that

$$0 \leq t(2^{m-g} - 1) + u(2^g + 1) < 2^m + 1$$

so that the residues don't "wrap around" when computed modulo $2^m + 1$. However, $t = \lfloor c/2^{m-g} \rfloor = 2^{2g-m} - 1$, and so

$$\begin{aligned} t(2^{m-g} - 1) + u(2^g + 1) &\leq (2^{2g-m} - 1)(2^{m-g} - 1) + (2^{m-g} - 1)(2^g + 1) \\ &= 2^m - 2^{2g-m} < 2^m + 1, \end{aligned}$$

as desired. ◀

Now from the Lemma we see that the expression $c(2^g + 1) \bmod (2^m + 1)$ achieves its smallest value when $c = 2^{g-1}$ (for then $t = 2^{2g-m-1}$ and $u = 0$), and this smallest value is $2^{2g-m-1}(2^{m-g} - 1) > 2$, except when $m = 4$, $g = 3$. ◀

▶ Remark. When $m = 4$ and $g = 3$, letting $c = 28$ and $d = 4$ we get the solution $512 = 2^9 = 28 \cdot (2^4 + 1) + 4 \cdot (2^3 + 1)$. This corresponds to two distinct expressions of 2^9 as the sum of three binary squares: $512 = 255 + 221 + 36$ and $512 = 238 + 238 + 36$.

6 Other results

Our technique can be used to obtain other results in additive number theory. For example, recently Crocker [3] and Platt & Trudgian [14] studied the integers representable as the sum of two ordinary squares and two powers of 2. The analogue of this theorem is the following:

▶ **Lemma 9.**

(a) *Every length-n integer, n odd, $n \geq 7$, is the sum of at most two powers of 2 and either:*
- *at most two binary squares of length $n - 1$, or*
- *at most one binary square of length $n - 1$ and one of length $n - 3$.*

(b) *Every length-n integer, n even, $n \geq 10$, is the sum of at most two powers of 2 and either:*
- *at most one binary square of length n and one of length $n - 4$, or*
- *at most one binary square of length $n - 2$ and one of length $n - 4$.*

Proof. We use a similar proof strategy as before. The `ULTIMATE` code proving our result can be found in the files `OddSquarePowerConjecture.ats` and `EvenSquarePowerConjecture.ats` at `https://cs.uwaterloo.ca/~shallit/papers.html`; there one can also find the generators can be found as `OddSquarePower.cpp` and `EvenSquarePower.cpp`.

The final machines for the odd-length and even-length cases have 806 and 2175 states respectively. The language inclusion assertions all hold. This concludes the proof. ◀

We thus have the following theorem:

▶ **Theorem 10.** *Every natural number N is the sum of at most two binary squares and at most two powers of 2.*

Proof. For $N < 512$, the result can be easily verified. Otherwise, we use Lemma 9 (a) if N is an odd-length binary number and Lemma 9 (b) if it is even. ◀

We also consider the notion of *generalized binary squares*. A number N is called a generalized binary square if one can concatenate 0 or more leading zeroes to its binary representation to produce a binary square. As an example, 9 is a generalized binary square, since 9 in base 2 is 1001, which can be written as $001001 = (001)(001)$. The first few generalized binary squares are

$$0, 3, 5, 9, 10, 15, 17, 18, 27, 33, 34, 36, 45, 51, 54, 63, \ldots;$$

they form sequence A175468 in the OEIS [18].

In what follows, when we refer to the length of a generalized binary square, we mean the length including the leading zeroes. Thus, 9 is a generalized binary square of length 6 (and not 4).

▶ **Lemma 11.**

(a) *Every length-n integer, $n \geq 7$, n odd, is the sum of 3 generalized binary squares, of lengths $n + 1$, $n - 1$, and $n - 3$.*

(b) *Every length-n integer, $n \geq 8$, n even, is the sum of 3 generalized binary squares, of lengths n, $n-2$, and $n-4$.*

Proof. We use a very similar proof strategy as in the proof of Lemma 5. We drop the requirement that the most significant digit of our guessed squares be 1, thus allowing for generalized binary squares. Note that the square of length $n+1$ in part (a) must start with a 0.

The `ULTIMATE` code proving our result can be found in the files `OddGenSquareConjecture.ats` and `EvenGenSquareConjecture.ats` at `https://cs.uwaterloo.ca/~shallit/papers.html`; there one can also find the generators `OddGeneralizedSquares.cpp` and `EvenGeneralizedSquares.cpp`. The final machines for the odd-length and even-length cases have 132 and 263 states respectively. ◀

We thus have the following theorem:

▶ **Theorem 12.** *Every natural number $N > 7$ is the sum of 3 generalized binary squares.*

Proof. For $7 < N < 64$ the result can be easily verified. Otherwise, we use Lemma b (a) is an odd-length binary number and Lemma b (b) if it is even. ◀

7 Further work

Numerical evidence suggests the following two conjectures:

▶ **Conjecture 13.** Let α_3 denote the lower asymptotic density of the set S_3 of natural numbers that are the sum of three binary squares. Then $\alpha_3 < 0.9$.

We could also focus on sums of *positive* binary squares. (For the analogous problem dealing with ordinary squares, see, e.g., [5, Chapter 6].) It seems likely that our method could be used to prove the following result.

▶ **Conjecture 14.** Every natural number > 1772 is the sum of exactly four positive binary squares. There are 112 exceptions, given below:

$$0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 13, 14, 15, 16, 17, 18, 20, 21, 22, 23, 25, 27, 28, 29, 30, 32, 34, 35,$$
$$37, 39, 41, 42, 44, 46, 47, 49, 51, 53, 56, 58, 62, 65, 67, 74, 83, 88, 95, 100, 104, 107, 109, 113, 116,$$
$$122, 125, 131, 134, 140, 143, 148, 149, 155, 158, 160, 161, 167, 170, 173, 175, 182, 184, 368, 385,$$
$$402, 407, 419, 424, 436, 441, 458, 475, 492, 509, 526, 543, 552, 560, 569, 587, 599, 608, 613,$$
$$620, 625, 638, 647, 653, 671, 686, 698, 713, 1508, 1541, 1574, 1607, 1640, 1673, 1706, 1739, 1772.$$

Other interesting things to investigate include estimating the number of distinct representations of N as a sum of four binary squares, both in the case where order matters, and where order does not matter. These are sequences A290335 and A298731 in the OEIS, respectively.

In recent work [9] it was proved, using a combinatorial and number-theoretic approach, that the binary k'th powers form an asymptotic basis of finite order for the multiples of $\gcd(k, 2^k - 1)$. However, the constant obtained thereby is rather large.

Abstract

We study property testing in the distributed model and extend its setting from testing with one-sided error to testing with two-sided error. In particular, we develop a two-sided error property tester for general graphs with round complexity $\mathcal{O}(\log(n)/(\epsilon\Phi^2))$ in the CONGEST model, which accepts graphs with conductance Φ and rejects graphs that are ϵ-far from having conductance at least $\Phi^2/1000$ with constant probability. Our main insight is that one can start $\text{poly}(n)$ random walks from a few random vertices without violating the congestion and unite the results to obtain a consistent answer from all vertices. For connected graphs, this is even possible when the number of vertices is unknown. We also obtain a matching $\Omega(\log n)$ lower bound for the LOCAL and CONGEST models by an indistinguishability argument. Although the power of vertex labels that arises from two-sided error might seem to be much stronger than in the sequential query model, we can show that this is not the case.

1 Introduction

Property testing algorithms derive approximate decisions by probing a sublinear part of the input only. A tester for a graph property $\mathcal{P}$ is a randomized algorithm that, with high constant probability, accepts graphs that have the property $\mathcal{P}$ and rejects graphs that are ϵ-far from having the property $\mathcal{P}$, that is, at least an ϵ-fraction of the edges have to be modified to make the graph have the property $\mathcal{P}$. Two-sided error testers may err on all graphs, while one-sided error testers have to present a witness when rejecting a graph. See [12, 13, 14] for introductions and surveys.

Testing graph properties in the classic, sequential computing model has been studied quite extensively. Property testing in the distributed CONGEST model was first studied by Brakerski and Patt-Shamir [1] and later more thoroughly by Censor-Hillel et al. [2]. In this model, each vertex of the graph is equipped with a processor that has a unique identifier of size $\mathcal{O}(\log n)$ (alternatively, one may define the model such that vertices pick their identifier randomly) and it knows only its neighboring vertices. The vertices of the graph communicate with each other in synchronized rounds such that in each round only communication of length $\mathcal{O}(\log n)$ is allowed on every edge. Finally, every vertex casts a vote and a decision rule is applied on all votes to derive the answer of the tester. The complexity measure is the amount of rounds required to test the property. Edge congestion and round complexity strictly limit the amount of information on the whole graph that a single vertex can gather. In [2], it is shown that many one-sided error testers for dense graphs carry over from the sequential to the distributed setting. Furthermore, tight logarithmic bounds for testing bipartiteness and cycle-freeness in bounded degree graphs are proved. In [8, 11], subgraph-freeness is studied for subgraphs on at most five vertices, trees and cliques.

1.1 Our Results

We extend the study of distributed property testing to testers with two-sided error. In particular, we present a two-sided error distributed testing algorithm in the CONGEST model for conductance.

▶ **Theorem 1.** *Testing whether a graph $G = (V, E)$ has conductance at least Φ or is ϵ-far from having conductance at least $\Phi^2/1000$ with two-sided error has complexity $\mathcal{O}(\log(|V| + |E|)/(\epsilon\Phi^2))$ in the CONGEST model.*

In contrast to previous one-sided error testers, our tester can be implemented such that all vertices accept or all vertices reject (see also the discussion of decision rules in Section 5). Furthermore, we prove that the size of the input graph is not required to be known a priori to perform the test if it is connected. On the other hand, there exists no tester for disconnected graphs if no prior knowledge of the graph is assumed at all. Since communication between two connected components is not allowed, we cannot distinguish a graph G with high conductance from a graph G' that is composed of two isolated copies of G.

In the setting of property testing, we aim for an efficient method to check whether the input has the desired property or is at least close to it. For example, we might run the tester for conductance once in a while on a peer-to-peer network to check whether the topology has changed significantly such that efficient communication is no longer possible. Therefore, we think of Φ as a parameter with no or only weak dependence on n.

We complement this result by showing that any distributed tester with this gap requires $\Omega(\log(n + m))$ rounds of communication regardless of the final decision rule.

▶ **Theorem 2.** *Let ϵ, $d > 0$ be constants, and let Φ, c be constants that depend on d. Testing whether a d-regular graph $G = (V, E)$ has conductance at least Φ or is ϵ-far from having conductance at least $c\Phi^2$ requires $\Omega(\log(|V| + |E|))$ rounds of communication in the LOCAL and CONGEST models.*

1.2 Related Work

In the classic, sequential setting of property testing, the problem of testing conductance in bounded degree graphs was first studied in [6, 15]. Kale and Seshadhri [16] and Nachmias and Shapira [22] give $\tilde{\mathcal{O}}(\Phi^{-2}\sqrt{n})$-query two-sided error testers that accept graphs that have

conductance at least Φ and reject graphs that are ϵ-far from having conductance at least $\Omega(\Phi^2)$. An algorithm for testing the cluster structure of graphs has been given in [5]. Testing conductance in unbounded degree graphs in the stronger rotation map model with query complexity roughly $\tilde{\mathcal{O}}(\Phi^{-2}\sqrt{m})$ was studied in [17], and testing conductance properties restricted to small sets has been studied in [18]. However, the optimal query complexity for testing conductance in general graphs of unbounded degree is still open.

In the CONGEST model, random walks have been analyzed by Censor-Hillel et al. [2] to design a tester for bipartiteness. The idea there is to perform a constant number of random walks from every vertex and to test if two such walks intersect in a cycle of odd length. It is crucial to bound the number of random walks that traverse an edge in one step. In contrast, we can perform polynomially many random walks from a constant number of vertices in the graph and we can afford that all walks traverse the same edge simultaneously.

Distributed random walks have also been studied in [7] and [21]. In particular, [21] show that one can approximate the mixing time τ_v of a vertex v in $\mathcal{O}(\tau_v \log n)$ rounds by running $\text{poly}(n)$ random walks v and comparing their endpoint distribution to the stationary distribution. The graph's mixing time $\tau = \max_v \tau_v$ relates to the conductance by $c_1\Phi^2/\log n \leq 1/\tau \leq c_2\Phi$. A straightforward approach based on [21] leads to an $\mathcal{O}(n \log^2(n)/\Phi^2)$ round algorithm for *approximating* Φ with a multiplicative gap of $\Theta(\Phi/\log n)$. In comparison, our *tester's* gap does not depend on n and its complexity is only logarithmic in n. One reason is that if the graph is *far from* having conductance $\Omega(\Phi^2)$, there exist many vertices with large mixing times compared to the case that the graph has conductance Φ (see the proof of Theorem 1 for details). This is not necessarily the case if the graph is not ϵ-far from having conductance $\Omega(\Phi^2)$.

1.3 Overview

The classic tester [16] for bounded degree graphs exploits that random walks converge rapidly to the uniform distribution in graphs with high conductance and they mix slowly for at least a small fraction of start vertices in graphs that are ϵ-far from having high conductance. This boils down to approximating the collision probability of random walks for a few start vertices. However, in general graphs the stationary distribution is not uniform, and collisions at vertices with high degree are more important than at vertices with low degree.

In the distributed model, one has to take care of edge congestion, too. Simulating $\omega(1)$ random walks while keeping them distinguishable is very costly. A key observation is that for approximating the discrepancy, it is sufficient to maintain only some statistics of the random walks, which reduces the congestion significantly: one has to transfer only the number of random walks that pass through an edge for each of a constant number of start vertices.

For the lower bound, we construct two distributions on graphs of high and low conductance respectively such that the vertices' neighborhoods of radius $\Omega(\log n)$ are isomorphic. The idea is that within only $\mathcal{O}(\log n)$ rounds, all vertices receive the same information up to isomorphism and therefore cannot distinguish between the two distributions. However, since the tester is allowed to have two-sided error and it only needs to distinguish graphs that have the property from graphs that are far, it is plausible that it can glean information about the two distributions from the vertex labels of the subgraphs it has seen. For example, certain sets of labeled subgraphs might be present in (many of) the graphs with high conductance that are absent in (many of) the graphs with low conductance. Lower bounds for sequential testers usually argue that with high probability, one can assume that all probes are independent. Since the local views of the vertices in the distributed model always have a large overlap, we base our argument on a reduction and a random labeling argument instead.

2 Preliminaries

Let $G = (V, E)$ be a graph and let $S, T \subseteq V, S \cap T = \emptyset$ be sets of vertices. We denote $|V|$ and $|E|$ by n and m respectively for the graph G at hand. Let $d(v)$ be the degree of vertex $v \in V$. We write $\bar{S}$ for the set $V \backslash S$. The set of vertices in $\bar{S}$ that are adjacent to some $u \in S$ is denoted by $\Gamma(S)$. The *volume* of S is the sum of degrees of vertices in S, that is, $\mathrm{vol}(S) := \sum_{v \in S} d(v)$. The cut between S and T is denoted by $E(S, T) = E \cap (S \times T)$. For a set $S \subseteq V$ such that $\mathrm{vol}(S) \leq \mathrm{vol}(\bar{S})$, the conductance of S is $\mathrm{cond}(S) = |E(S, \bar{S})|/\mathrm{vol}(S)$. The conductance of G is defined as $\Phi(G) = \min_{S \subset V, \mathrm{vol}(S) \leq \mathrm{vol}(\bar{S})} \mathrm{cond}(S)$.

2.1 Distributed Computing

In the distributed computational model, a computation network $G = (V, E)$ with a processor associated to each vertex $v \in V$ is given. Each processor v has access to numbered communication channels to its neighbors in G. Additionally, it may have some specific input $I(v)$. The computation operates in synchronized rounds that are divided into three phases. In each round, each processor may do some local computation first, then it may send a message to each of its neighbors, and finally it receives the messages sent from its neighbors.

▶ **Definition 3** (Distributed Computational Model, DCM). *Let $G = (V, E)$ be a graph and $p_G = (p_v)_{v \in V}$ with $p_v : [d(v)] \to \Gamma(v)$ be a bijective function, that is, an adjacency list representation of G. Let $I : V \to \{0, 1\}^*$ be a mapping from the set of vertices to bit strings. An instance of the distributed computational model on G, p_G and I, $\mathrm{DCM}(G, p_G, I)$, is defined as follows. Each vertex $v \in V$ is a processor that has communication access to its neighbors $p_v(1), \ldots, p_v(d(v))$ by ports numbered $1, \ldots, d(v)$. The model operates in synchronized rounds, where each round r consists of three phases: (i) Each vertex performs local computation, (ii) each vertex v sends a message to its neighbor $p_v(i)$, denoted $s_r(v, i)$, for all $i \in d(v)$, (iii) each vertex u receives a message from its neighbor $p_u(j)$, for all $j \in d(u)$. The distributed computational model DCM is the set of all instances $\mathrm{DCM}(G, p_G, I)$.*

The LOCAL model is the subset of the DCM such that for each vertex $v \in V$, the input $I(v)$ is only n and a numerical vertex identifier from $[n^c]$ for some universal constant c. The CONGEST model is the subset of the LOCAL model such that the size of each message $s_r(v, i)$ is restricted to $c \log n$ bits.

A distributed network decision algorithm $\mathrm{DNDA}(\mathcal{A}, O)$ is an algorithm $\mathcal{A}$ that is deployed to the vertices of a DCM to decide a property of an instance of the model. In particular, the output of $\mathcal{A}$ is a single bit, and the final decision is obtained by applying a function $O(\cdot)$ to the union of all vertices' answers.

▶ **Definition 4** (Distributed Network Decision Algorithm). *Let $\mathcal{A}$ be an algorithm that takes a bit string as input and outputs a single bit, and let $O : \{0, 1\}^* \to \{0, 1\}$ be a function. When the distributed network decision algorithm $\mathrm{DNDA}(\mathcal{A}, O)$ is run on an instance $\mathrm{DCM}(G, p_G, I)$, a copy of $\mathcal{A}$ is deployed to every vertex v with input $I(v)$ and run in parallel as described in Definition 3. We refer to the copy of $\mathcal{A}$ deployed to v by $\mathcal{A}_v$. When every vertex v_i has terminated its computation with output bit b_{v_i}, the decision of $\mathrm{DNDA}(\mathcal{A}, O)$ is $O(b_{v_1} b_{v_2} \cdots b_{v_n})$.*

2.2 Distributed property testing

A distributed property testing algorithm is a distributed algorithm as defined in Definition 4 that accepts graphs that have a property, and rejects graphs that are ϵ-far from the property. We say that a graph G with n vertices and m edges is ϵ-far from a property $\mathcal{P}$ if at least ϵm

edges of G have to be modified to make the new graph have the property $\mathcal{P}$. A one-sided error distributed ϵ-tester accepts all graphs with property $\mathcal{P}$, whereas it rejects, with probability at least $2/3$, all graphs that are ϵ-far from the property. In this paper, we give a two-sided (error) property tester that is also allowed to err, with probability at most $1/3$, when the graph has the property.

▶ **Definition 5** (Two-sided tester). *A two-sided (error) distributed ϵ-tester for a property $\mathcal{P}$ is a* DNDA$(\mathcal{A}, O)$*, where $O(b_{v_1} b_{v_2} \cdots b_{v_n}) = 1$ iff $b_{v_i} = 1$ for all $v_i \in V$ such that the following conditions hold: (i) if G has the property $\mathcal{P}$, then, with probability at least $2/3$, $b_{v_i} = 1$ for all $v_i \in V$, (ii) if G is ϵ-far from $\mathcal{P}$, then, with probability at least $2/3$, there exists a $v_i \in V$ such that $b_{v_i} = 0$.*

The guarantees given by our tester are actually a bit stronger in the sense that the tester can be modified such that either $b_v = 0$ or $b_v = 1$ for all $v \in V$ simultaneously.

3 Testing Using Random Walks

In this section we will present the distributed algorithm for testing whether a graph has conductance at least Φ or is ϵ-far from having conductance at least $\Phi^2/1000$. The core idea of the algorithm is to perform random walks from a small set of vertices and test whether these walks converge to the stationary distribution rapidly, which is the case for graphs with high conductance. It is based on the ideas of Kale and Seshadhri [16] and Goldreich and Ron[15].

Before we describe the algorithm, we give a few useful definitions and lemmas. A *lazy random walk* on a graph $G = (V, E)$ on n vertices is a random walk on the graph, where at each vertex v the walk chooses to stay at v with probability $1/2$ and chooses a neighbor u with probability $1/(2d(v))$. The walk matrix $W = [w_{uv}]_{u,v\in[n]}$ is defined by $w_{uv} := 1/2$ if $u = v$, $w_{uv} := 1/(2d(v))$ if $u \neq v, (u, v) \in E$ and $w_{uv} := 0$ otherwise. Notice that for irregular graphs, W is not symmetric. To analyze these random walks, one can draw on the *normalized walk matrix*, which is a symmetric matrix similar to W. The normalized walk matrix N of G is $D^{-1/2} W D^{1/2}$, where D is the diagonal matrix with $D(u, u) := d(u)$.

Since N is a real symmetric matrix, it has real eigenvalues. Let $1 = \mu_1, \ldots, \mu_n \geq 0$ be its eigenvalues, and let $\{\vec{f_i}\}_{i\in[n]}$ be its orthonormal eigenbasis. We have $\vec{f_1} = \sqrt{\vec{\pi}}$, where $\vec{\pi}$ is the random walk's *stationary distribution*. In particular, it is well known that $\vec{\pi}_v = d(v)/(2m)$. For more details on spectral graph theory, refer to [4].

It is well known that graphs with high conductance have small diameter.

▶ **Lemma 6** ([3, cf. Theorem 2]). *Let $G = (V, E)$ be a graph with conductance Φ. The diameter of G is at most $(3/\Phi)\ln(m)$.*

Sinclair [24] proved that there is a tight connection between the conductance and the mixing time of random walks. In particular, the L_2 distance of any starting distribution $\vec{\pi'}$ to $\vec{\pi}$ after $\Phi^{-2} \log n$ steps is $\mathcal{O}(1/n)$.

▶ **Lemma 7** ([24, cf. Theorem 2.5]). *Let $G = (V, E)$ be a graph with conductance Φ. For any starting distribution $\vec{\pi'}$, it holds that $\|W^\ell \vec{\pi'} - \vec{\pi}\|_2 \leq \left(1 - \Phi^2/2\right)^\ell$.*

3.1 Algorithm

We discuss the algorithm from a global point of view instead of describing an algorithm $\mathcal{A}$ for a single vertex to provide a better explanation of the interactions between vertices.

Lemma 6 implies that if the graph has high conductance, then it has diameter $\mathcal{O}(\log n/\Phi)$, which we want to use as an assumption in the algorithm later. To test the diameter, we perform a BFS of depth $\mathcal{O}(\log n/\Phi)$ of the graph starting from an arbitrary vertex. Initially, every vertex chooses itself as root of the BFS and announces itself as root to all its neighbors. To break the symmetry between the vertices, a vertex accepts every vertex with a lower identifier than its current root as new root and forwards its messages. If the diameter is $\mathcal{O}(\log n/\Phi)$, a unique root has been chosen after $\mathcal{O}(\log n/\Phi)$ rounds and every vertex knows its parent and its children in the BFS tree. Otherwise, at least one of the remaining candidates will reject. Algorithm 3 gives a formal description of the BFS.

From now on, assume that the diameter is $\mathcal{O}(\log n/\Phi)$. Using the previously computed BFS tree, we can compute the number of edges in the graph by summing up vertex degrees from the leaves to the root and transmitting this number to all vertices afterwards. Algorithm 4 describes the procedure in detail.

The key technical lemma from [16] for bounded degree graphs states that if a graph is ϵ-far from having conductance $\Omega(\Phi^2)$, then there exists a $\Omega(\epsilon)$-fraction of *weak* vertices such that random walks starting from these vertices converge only slowly to the stationary distribution. Therefore, a sample $S \subset V$ of size $\mathcal{O}(1)$ will likely contain a weak vertex (technically, we sample each vertex v independently into S with probability $\Theta(d(v)/\epsilon m)$. By Markov's inequality, we may reject if S is much larger than its expected size.). We extend this lemma to unbounded degree graphs. Then, we perform $N = n^{100}$ random walks of length $\ell = 40/\Phi^2 \cdot \log n = \mathcal{O}(\log n/\Phi^2)$ starting from each of the vertices in S to approximate the rate of convergence.

The crucial point here is that in each round of the algorithm, we do not send the full trace of every random walk. Instead, for every origin $v \in S$, every vertex $u \in V$ only transmits the total number of random walks that are leaving it through an edge (u, w) to its neighbor $w \in \Gamma(u)$. Since the size of S is constant, we require $\mathcal{O}(\log n)$ bits per edge to communicate this. On the other hand, this information is sufficient because we are only interested in the distribution of endpoints of the lazy random walks for every $v \in S$. Algorithm 2 gives a formal description of this procedure. Finally, the estimated distribution of endpoints is used to approximate the distance to the stationary distribution for each $v \in S$. The whole algorithm is summarized in Algorithm 1.

First, we show that either the estimates $\widehat{W}^\ell_{v,u}$ of Algorithm 2 are good or the algorithm rejects in line 14 because G has low conductance.

▶ **Lemma 8.** *Consider Algorithm 2. For every $v, u \in V$, it holds with probability at least $1 - m^{-10}$ that (i) $|\widehat{W}^\ell_{v,u} - W^\ell(v,u)| \leq m^{-20}$ and, conditioned on the previous, (ii) if $\widehat{W}^\ell_{v,u} < m^{-2}$ then G has conductance less than Φ.*

Proof. We have $E[\widehat{W}^\ell_{v,u}] = W^\ell(v,u)$. By Hoeffding's inequality, it holds that

$$\Pr[|\widehat{W}^\ell_{v,u} - E[\widehat{W}^\ell_{v,u}]| \geq m^{-10}] \leq 2\exp\left(-\frac{N}{3m^{40}}\right) \leq m^{-10}\,. \tag{1}$$

Condition on $|\widehat{W}^\ell_{v,u} - E[\widehat{W}^\ell_{v,u}]| < m^{-20}$, which happens with probability at least $1 - 1/m^{10}$. If $\widehat{W}^\ell_{v,u} < m^{-2}$, then

$$W^\ell(v,u) = E[\widehat{W}^\ell_{v,u}] < \widehat{W}^\ell_{v,u} + m^{-20} = m^{-2} + m^{-10} < 2m^{-2}\,.$$

Let $\pi' = \mathbb{1}_v$. We bound $\|W^\ell \vec{\boldsymbol{\pi}'} - \vec{\boldsymbol{\pi}}\|_2$ from below.

$$\|W^\ell \vec{\boldsymbol{\pi}'} - \vec{\boldsymbol{\pi}}\|_2 \geq |W^\ell(v,u) - d(u)/2m| \geq -(2m^{-2} - 1/(2m)) \geq 1/(4m)\,.$$

By the contrapositive of Lemma 7, G has conductance less than Φ. ◀

Algorithm 1 Conductance tester.

procedure TestConductance($G = (V, E)$, n, Φ)
  BFS(G, $6/\Phi \ln n$) ▷ construct BFS of depth $6/\Phi \log n$, Algorithm 3
  if BFS visited less than n vertices **then reject**
  $m \leftarrow$ AggregateSum(G, $12/\Phi \ln n$, f) ▷ $f(v) := d(v)/2$, Algorithm 4
  let *every vertex* $v \in V$ **do**
    with probability $\min\{1, 10^4 d(v)/2\epsilon m\}$, mark v
  $S \leftarrow$ marked v, $r \leftarrow$ root of BFS tree
  if $|S| > 10^5/\epsilon$ **then reject**
  RandomWalk(G, S, $40/\Phi^2 \cdot \log n$, n^{100}) ▷ compute local $s_{v,u}$, Algorithm 2
  for all $v \in S$ **do** $s_v \leftarrow$ AggregateSum(G, $12/\Phi \ln n$, f) ▷ $f(u) := s_{v,u}$, Alg. 4
  let *every vertex* $v \in V$ **do**
    if $s_v \leq m^{-15}$ for all $v \in S$ **then accept**
    else reject

Algorithm 2 Perform random walks.

procedure RandomWalk(G,S,ℓ,N)
  let *every vertex* $v \in S$ **do**
    sample $u_1, \cdots, u_N$ independently according to $W\vec{e_v}$
    for all $w \in \Gamma(v)$ **do** send $(v, v, |\{i \mid w = u_i\}|)$ to w
  for ℓ rounds, **let** *every vertex* x **do**
    receive $(u_1, x'_1, k_1), (u_2, x'_2, k_2), \ldots$
    for all $v \in S$ **do**
      sample $u_1, \cdots, u_{n_v}$ independently according to $W\vec{e_x}$, where $n_v = \sum_{u_i = v} k_i$
      for all $w \in \Gamma(v)$ **do** send $(v, x, |\{i \mid w = u_i\}|)$ to w
  let *every vertex* $u \in V$ **do**
    receive $(u_1, x'_1, k_1), (u_2, x'_2, k_2), \ldots$
    for all $v \in S$ **do**
      $\widehat{W}^{\ell}_{v,u} \leftarrow \sum_{v_i = v} n_i/N$
      if $\widehat{W}^{\ell}_{v,u} \leq 2m^{-2}$ **then reject**
      $s_{v,u} \leftarrow (\widehat{W}^{\ell}_{v,u} - \frac{d(v)}{2m})^2$

Algorithm 3 Construct BFS tree.

procedure BFS(G, D)
  let *every vertex* v **do**
    $T_v \leftarrow (v, \cdot)$ ▷ set root to itself, parent to empty
    $minid \leftarrow v$
    send (v, v) to every neighbor $u \in \Gamma(v)$
  for D rounds, **let** *every vertex* w **do**
    $R_v \leftarrow \{(v', u') \text{ received} \mid u' \in \Gamma(w)\}$
    $(v, u) \leftarrow \arg\min_{(v', u') \in R_v} v'$
    if $T_w = (\cdot)$ or $v' < minid$ **then**
      $T_w \leftarrow (v, u)$ ▷ set root to v, parent to u
      send (v, w) to all neighbors $\neq u$

Algorithm 4 Aggregate sum of vertex values and propagate it to all vertices.

Require: $\forall v : v$ has local information $f(v)$
Ensure: $\forall v : v$ has information $\sum_{u \in V} f(u)$
1: **procedure** AggregateSum(G, D, $f : V \to \mathbb{R}$)
2: **for** D rounds, **let** *every vertex* v **do**
3: **if** v received partial sums s_u from all its children u in BFS tree **then**
4: $s_v \leftarrow f(v) + \sum_u s_u$
5: send s_v to parent in BFS tree
6: **let** *vertex root* r *of BFS tree* **do**
7: send total sum $s = \sum_v f(v)$ to all children
8: **for** D rounds, **let** *every vertex* v **do**
9: **if** v received total sum s from its parent **then**
10: send s_v to all children in BFS tree
11: **return** s_v ▷ consider s_v to be the output of the algorithm

Furthermore, Lemma 8 implies that the estimates s_v in Algorithm 1 (see line 10) are also good if Algorithm 2 has not rejected before.

▶ **Lemma 9.** *Consider Algorithm 1. With probability at least* $1 - m^{-8}$ *it holds for every* $v \in S$ *in line 10 that* $\left| \|W^\ell(v, \cdot) - \vec{\boldsymbol{\pi}}\|_2^2 - s_v \right| \leq 3m^{-19}$.

Proof. Let $v \in S$. We have the following equality for the discrepancy of the distribution of the random walks' endpoints that start at v and the stationary distribution:

$$\|W^\ell(v, \cdot) - \vec{\boldsymbol{\pi}}\|_2^2 = \sum_{u \in V} \left(W^\ell(v, u) - \frac{d(u)}{2m} \right)^2 . \tag{2}$$

By Lemma 8, we know that for every $u \in V$ we have $|\widehat{W}^\ell_{u,v} - W^\ell(v, u)| \leq m^{-20}$with probability $1 - 1/m^9$. Then, by the triangle inequality, $|(W^\ell(v, u) - \frac{d(u)}{2m})^2 - s_{v,u}| \leq 3m^{-20}$. Combining this with Eq. (2), a union bound over all $u \in V$ implies that with probability at least $1 - n \cdot m^{-10} \geq 1 - m^{-9}$, we have that $\left| \|W^\ell(v, \cdot) - \vec{\boldsymbol{\pi}}\|_2^2 - \sum_{u \in V} s_{v,u} \right| \leq 3m^{-19}$. A union bound over all $v \in S$ gives that with probability at least $1 - |S|/m^{-9} \geq 1 - m^{-8}$, $\left| \|W^\ell(v, \cdot) - \vec{\boldsymbol{\pi}}\|_2^2 - \sum_{u \in V} s_{v,u} \right| \leq 3m^{-19}$ for every $v \in S$. ◀

3.2 Completeness and Soundness

The proof of completeness is a straightforward application of the results from the previous section.

▶ **Lemma 10** (Completeness). *Let* $G(V, E)$ *be a graph with conductance at least* Φ. *Then, with probability at least* $2/3$, *each vertex in* G *returns* ***accept*** *when it runs Algorithm 1.*

Proof. The probability that the algorithm rejects in Line 8 of Algorithm 1 is at most $1/10$, and we assume, for the remainder of the proof, that this event did not occur. If G has conductance at least Φ, then from Lemma 7 we know that $\|W^\ell(\cdot, v) - \vec{\boldsymbol{\pi}}\|_2^2 \leq \left(1 - \Phi^2/2\right)^{2\ell} \leq \exp(-\Phi^2 \ell/2) \leq m^{-20}$ for every vertex v. Lemma 9 implies that with probability at least $9/10$, it holds that $\left| \|W^\ell(\cdot, v) - \vec{\boldsymbol{\pi}}\|_2^2 - s_v \right| \leq 3m^{-19}$. Conditioning on this event, every vertex accepts in line 12 of Algorithm 1. ◀

To complete the analysis of the tester, we show that whenever the graph is ϵ-far from having conductance $\Omega(\Phi^2)$, the tester rejects with probability at least $2/3$. To this end, we

actually show that if the volume of weak vertices is small, then the graph can be converted to another graph G' by modifying at most ϵm edges such that the conductance is $\Omega(\Phi^2)$. The idea of the analysis is due to Kale and Seshadhri [16], who analyzed a classic property tester for testing expansion in graphs with vertex degrees bounded by a constant. We deviate from their analysis where it becomes necessary to take care of arbitrary vertex degrees.

Let a vertex $v \in V$ be called *weak* if $\|W^\ell(v,\cdot) - \vec{\boldsymbol{\pi}}\|_2 > 6m^{-15}$. The following lemma states that if there exists a set of vertices S with small conductance, then there exists a set of weak vertices T whose volume is at least a constant fraction of the volume of S.

▶ **Lemma 11.** *Let $S \subset V$ be such that $\mathrm{vol}(S) \leq \mathrm{vol}(\bar{S})$ and $\mathrm{cond}(S) \leq \delta$. Then, for any $\ell \in \mathbb{N}$ and any $0 < \theta \leq 1/10$, there exists a set $T \subseteq S$ such that $\mathrm{vol}(T) \geq \theta \mathrm{vol}(S)$ and for every $v \in T$, it holds that $\|W^\ell(v,\cdot) - \vec{\boldsymbol{\pi}}\|_2^2 > \frac{1}{80m^7}(1-4\delta)^{2\ell}$.*

The proof can be found in the arXiv version [10]. We can use Lemma 11 to separate weak vertices from the remaining graph.

▶ **Lemma 12.** *Let $G = (V,E)$ be a graph. If the volume of weak vertices in G is at most $(1/100)\epsilon m$, then there is a partition of V into $P \cup \bar{P}$ such that $\mathrm{vol}(P) \leq \epsilon m/10$ and $\Phi(G[\bar{P}]) \geq \Phi^2/256$.*

Proof. We partition the graph recursively into two sets $(P, \bar{P})$. At the beginning, $P_0 = \emptyset$ and $\bar{P}_0 = V$. As long as there is a cut $(C_i, \bar{C}_i)$ in $\bar{P}_{i-1}$ in step i with $\mathrm{vol}(C_i) \leq \mathrm{vol}(\bar{C}_i)$ and $E(C_i,\bar{C}_i)/\mathrm{vol}(C_i) \leq \Phi^2/256$, we set $P_i = P_{i-1} \cup C_i$ and $\bar{P}_i = V \setminus P_i$. We continue this until we don't find such a cut or the condition $\mathrm{vol}(P_{i+1}) \leq \mathrm{vol}(\bar{P}_{i+1})$ would be violated. The number of edges going across the cut $(P,\bar{P})$ is at most $\sum_i |E(C_i,\bar{C}_i)|$. Therefore, $|E(P,\bar{P})| \leq \frac{\Phi^2}{256}\sum_i \mathrm{vol}(C_i) \leq \frac{\Phi^2}{256}\mathrm{vol}(P)$.

Now, assume that $\mathrm{vol}(P) > (1/10)\epsilon m$. Lemma 11 implies that there exists $P' \subseteq P$ such that $\mathrm{vol}(P') \geq \frac{1}{10}\mathrm{vol}(P) > \epsilon m/100$ (where $\theta = 1/10$) and for all $v \in P'$ we have $\|W^\ell(v,\cdot) - \vec{\boldsymbol{\pi}}\|_2 > \frac{1}{80m^7}(1-4\Phi^2/256)^{2\ell} > \frac{1}{80m^{10}}$. This means that P' contains only weak vertices and has volume at least $\epsilon m/100$, which contradicts our assumption that the volume of weak vertices in G is at most $\epsilon m/100$. Therefore, $\mathrm{vol}(P) \leq \epsilon m/10$ when the partitioning terminates. Hence $\Phi(G[\bar{P}]) \geq \Phi^2/256$. ◀

Finally, the following lemma states that few edge modifications in a graph with separated weak vertices are sufficient to make it a graph with high conductance.

▶ **Lemma 13** ([18, Lemma 9])**.** *Let $G = (V,E)$ be a graph. If there exists a set $P \subseteq V$ such that $\mathrm{vol}(P) \leq \epsilon m/10$ and the subgraph $G[V \setminus P]$ is a Φ'-expander, then there exists an algorithm that modifies at most ϵm edges to get a $\Phi'/3$-expander $G' = (V,E')$.*

Combining the results on the separation of weak vertices and patching the graph (Lemmas 11 to 13) and approximating the endpoint distribution (Lemmas 8 and 9), we prove the soundness of the algorithm.

▶ **Lemma 14** (Soundness)**.** *Let $G(V,E)$ be a graph. If G is ϵ-far from having conductance at least $\Phi^2/768$, then, with probability at least $2/3$, each vertex in G returns **reject** when it runs Algorithm 1.*

Proof. First we note that if the volume of weak vertices is less than $\epsilon m/100$, then by Lemmas 12 and 13, the graph is ϵ-close to having conductance at least $\Phi^2/768$. Therefore, the volume of weak vertices is at least $\epsilon m/100$. Each vertex v is contained in S with probability $\Theta(d(v)/\epsilon m)$. Hence, the expected number of weak vertices that are present in

the sample S is at least 100. Therefore, with probability at least 9/10, at least one weak vertex is sampled in S.

If $W^\ell(v,u) < m^{-2}$ for some $v \in S, u \in V$, then with probability at least 9/10, $\widehat{W}^\ell_{v,u} < 2m^{-2}$ by Lemma 8. In this case, the algorithm will reject in line 14 of Algorithm 2. If $W^\ell(v,u) \geq m^{-2}$ for all $v \in S, u \in V$, then with probability at least 9/10, it holds that $\left|\|W^\ell(v,\cdot) - \vec{\boldsymbol{\pi}}\|_2 - s_v\right| \leq 3m^{-19}$ for every $v \in S$ by Lemma 9. Since at least one vertex $v \in S$ is weak, that is, $\|W^\ell(v,\cdot) - \vec{\boldsymbol{\pi}}\|_2 > 6m^{-15}$, the algorithm rejects in line 13 of Algorithm 1. ◀

3.3 Unknown Size of the Graph

We describe how to get rid of the assumption that the size n of the graph G is known to the tester if G is connected. Note that without any prior knowledge of G, no distributed tester can distinguish between a graph with conductance Φ and two distinct copies of it (the latter is ϵ-far from being a graph with conductance Φ^c for $\epsilon < \Phi^c/2$, $c \geq 1$).

First, we describe a slightly simpler version of the final algorithm. In the setting of the simpler algorithm, we mark a single vertex that will initiate the test and will also give the final answer of the tester. We call this vertex the maintainer (of the graph). The algorithm can be easily adapted to the CONGEST model.

Let $v \in V$ be a fixed vertex. The algorithm either makes n available at all vertices and runs Algorithm 1 afterwards or v rejects because G does not have conductance Φ. If G has conductance Φ, the algorithm never rejects.

We start with an initial set $S = \{v\}$ that is grown in two phases. In the first phase, we extend S to $S \cup \Gamma(S)$ as long as $\mathrm{cond}(S) \geq \Phi$. In particular, v starts a BFS and in every round, the vertices in the last level report their degree and the number of neighbors outside of S to their parents. Similar to Algorithm 1, these are aggregated and sent to v along the edges of the BFS tree. If $\mathrm{cond}(S) < \Phi$ for the first time, the algorithm proceeds to the second phase. It continues the BFS for $-\log(\mathrm{vol}(S))/\log(1-\Phi)$ rounds and stops. If any vertex in the graph notices a neighbor that is not in S after these rounds, then $S \neq V$ and the algorithm rejects. Otherwise, we have obtained the value of $n = |S|$ that can be sent to all vertices, and we continue by executing Algorithm 1.

▶ **Lemma 15.** *Let $G = (V, E)$ be a graph and $\Phi \in [0,1]$. There is an algorithm that computes n if G has conductance at least Φ. Otherwise, it either computes n or rejects. The round complexity is $\mathcal{O}(\log m/\log(1-\Phi))$.*

Proof. It is easy to see that if the algorithm explores the whole graph, it computes n correctly, and else it rejects. Without loss of generality, let G have conductance Φ. Let S_i be the set S after i rounds and let $\bar{S}_i = V \setminus S_i$. We denote the last round of the first (second) phase by k (ℓ).

In the first phase, we have that $\mathrm{vol}(S_i) \geq (1+\Phi) \cdot \mathrm{vol}(S_{i-1})$ for every round i and by induction, $k \leq \log \mathrm{vol}(S_k)/\log(1+\Phi) \leq \log m/\log(1+\Phi)$. We also have that $\mathrm{vol}(S_k) \geq m/2 \geq \mathrm{vol}(\bar{S}_k)$ because G has conductance Φ. In the second phase, we have that $\mathrm{vol}(\bar{S}_i) \leq (1-\Phi) \cdot \mathrm{vol}(\bar{S}_{i-1})$ for every round i. By induction, $\ell - k \geq -\log m/\log(1-\Phi) \geq \log \mathrm{vol}(\bar{S}_k)^{-1}/\log(1-\Phi)$ implies that that $\mathrm{vol}(\bar{S}_\ell) = 0$. Therefore, the algorithm has explored the whole graph. Clearly, $\ell \in \mathcal{O}(\log m/\log(1-\Phi))$. ◀

To transform the algorithm into a tester in the CONGEST model, we start with each vertex being a maintainer initially. In every round every vertex chooses the vertex with the smallest id it has ever received a message from to be the maintainer and it forwards only this vertex' messages (the latter maintains the congestion bound). At the end of the algorithm, if

G has conductance Φ, then there is only one maintainer (the vertex with the smallest id) and the algorithm continues by executing Algorithm 1. Otherwise, there might be multiple vertices that are still maintainers. However, none of these vertices has explored the whole graph, so all of them send a broadcast message to reject.

4 Lower Bound

In this section, we prove a lower bound of $\Omega(\log(n+m))$ on the round complexity for testing the conductance of a graph in the LOCAL model regardless of how the final decision of the tester is derived from the single votes of the vertices.

For any $v \in V$, the k-disc of v, denoted by $\mathrm{disc}_k(G,v)$, is defined as the subgraph that is induced by the vertices that are at distance at most k to v without the edges between vertices at distance exactly k, and it is rooted at v. We refer to the isomorphism type of $\mathrm{disc}_k(G,v)$, that is, the set of all rooted graphs isomorphic to $\mathrm{disc}_k(G,v)$, by $\mathrm{disc}^*_k(G,v)$. Let $\mathrm{girth}(G)$ denote the length of the shortest cycle in G. We need the following two lemmas to obtain the distribution over graphs to prove the lower bound.

▶ **Lemma 16** ([20]; cf. [23, Section 16.8.3]). *For every $n' \in \mathbb{N}$ and every $d' \in \mathbb{N}$ there exists a d-regular graph G of size n such that G has conductance $\Phi(G) = 1/\sqrt{2d}$ and girth $2\log n/\log d$, and $n \geq n'$, $d \geq d'$.*

The second lemma states that we can sparsify an arbitrary cut $E(V_1,V_2)$ in a d-regular graph with girth $3k$ without changing $\mathrm{disc}^*_k(G,v)$ for any $v \in V$. In particular, it states that we can remove two edges in the cut and add them somewhere else, or the cut has size $\mathrm{poly}(d^k)$ only. It is obtained as a special case by observing that we can assume $L = 1$ and $\lambda = 0$ in [9, Lemma 8].

▶ **Lemma 17** ([9, Lemma 8]). *Let $G = (V,E)$ be a d-regular graph with $\mathrm{girth}(G) \geq 3k$ for $k \geq 2$ and let $V_1 \dot\cup V_2 = V$ be a partitioning of V. Then either there exists a graph $H = (V,F)$ such that (i) $\mathrm{girth}(H) \geq 3k$, (ii) $|F \cap (V_1 \times V_2)| \leq |E \cap (V_1 \times V_2)| - 2$, and (iii) $\mathrm{disc}^*_k(H,w) = \mathrm{disc}^*_k(G,w) \forall w \in V$ (that is, H is d-regular), or $E(V_1,V_2) \leq 6d^{3k}$.*

To prove the lower bound, we use an auxiliary model we call the ISO-LOCAL model. In this model, the input $I(\cdot)$ is empty but an additional oracle provides every vertex v with the ability to construct $\mathrm{disc}^*_r(G,v)$ in round r if it knows $\mathrm{disc}^*_{r-1}(G,u_i)$ of its neighbors $u_1,\dots,u_{d(v)}$. It should be noted that the ISO-LOCAL model is not a DCM due to the additional oracle.

▶ **Definition 18** (ISO-LOCAL model). *Let $\mathrm{DCM}(G,p_G,I)$ be a DCM instance such that $I(\cdot)$ maps the whole domain to the empty string. In addition to sending and receiving messages, in every round r every vertex v is provided access to a function $e_{r,v} : (\mathbb{N} \cup \{\star\})^r \times (\mathbb{N} \cup \{\star\})^r \to \{0,1\}$ during the local computation phase. The value of $e_{r,v}((i_1,\dots,i_{r'}),(j_1,\dots,j_{r''}))$ is 1 iff $p'_v(i_1,\dots,i_{r'}) = p'_v(j_1,\dots,j_{r''})$, where*

$$p'_v(i_1,\dots,i_r) := \begin{cases} v & \text{if } i_r = \star \\ p_{p'_v(\star,i_1,\dots,i_{r-1})}(i_r) & \text{otherwise.} \end{cases}$$

The instance $\mathrm{DCM}(G,p_G,I)$ equipped with such an oracle is called ISO-LOCAL.

In other words, $p'_v(\cdot)$ takes a path of length at most r that starts at v and that is defined by a sequence of port numbers as input. Then, it maps the path to its endpoint in V. Finally, $e_{r,v}(\cdot)$ tells whether two such paths end at the same vertex.

The ISO-LOCAL model is a graph where the nodes are not labeled by any strings. To argue the lower bound, we need to prove the existence of graphs that have same local neighborhoods such that one is a good expander and the other is far from having good conductance. Now it is possible that the algorithm can glean information about the different graphs based on the vertex labels even if the local neighborhoods are identical. Without ISO-LOCAL, we would need to argue that a randomized algorithm cannot deduce information from the vertex labels in the LOCAL model directly. This would be easy if for every good expander G we use, there is a bad expander H with exactly the same set of (labeled) k-discs. However, this is not the case as it would imply that G and H are isomorphic. The ISO-LOCAL model formalizes the intuition that, still, isomorphic k-discs should be sufficient to establish the lower bound even for randomized algorithms.

It is a basic observation that a distributed algorithm can only depend on information that has reached it until the moment it performs the computation in question.

▶ **Lemma 19** (folklore; cf. [19, Section 2]). *Let* $\mathrm{DNDA}(\mathcal{A}, O)$ *be a DNDA. After* r *rounds, the state of* $\mathcal{A}_v$ *may depend only on* $d(v)$, $I(v)$, *the state of* $\mathcal{A}_u$ *at time* $r - \mathrm{dist}(v, u)$ *for vertices* u *with* $\mathrm{dist}(v, u) < r$ *and the random coins of* $\mathcal{A}$.

4.1 Proof of the Lower Bound

Let $G = (V, E)$ be an expander graph obtained from applying Lemma 16 and let $k = \Theta(\log n)$. Observe that if a graph is d-regular and it has girth $3k$, then all its k-discs are pairwise isomorphic. In particular, all k-discs are full d-ary trees of depth k.

We will prove that a distributed algorithm $\mathrm{DNDA}(\mathcal{A}, O)$ with round complexity r in the ISO-LOCAL model decides based on the set of views $\mathrm{disc}^*_r(G, v)$ that the different instances of $\mathcal{A}$ have (see Lemma 20). Using Lemma 17, it will be easy to come up with a graph H that is a bad expander but whose k-discs are isomorphic to the ones of G. This implies a lower bound of $k = \Theta(\log n)$ for testing conductance in the ISO-LOCAL model (see Proposition 21). Finally, we prove that a lower bound on the round complexity of a tester in the ISO-LOCAL model implies the same bound in the LOCAL model. Actually, we prove the contrapositive: a tester in the LOCAL model implies a tester in the ISO-LOCAL model (see Proposition 22).

▶ **Lemma 20.** *Let* $\mathrm{DNDA}(\mathcal{A}, O)$ *be a deterministic DNDA in the ISO-LOCAL model. The output of* $\mathcal{A}_v$ *depends only on* $\mathrm{disc}^*_r(G, v)$ *and the port numbering* $(p_v)_{v \in V}$.

Proof. Instead of analyzing $\mathrm{DNDA}(\mathcal{A}, O)$, we analyze a canonical algorithm $\mathrm{DNDA}(\mathcal{B}, O)$ that simulates $\mathrm{DNDA}(\mathcal{A}, O)$ depending only on $\mathrm{disc}^*_r(G, v)$. Employing $\mathcal{B}$, we prove the following statement by induction: After the local computation phase of round r, the state of $\mathcal{A}_v$ depends only on $\mathrm{disc}^*_r(G, v)$.

The first local computation phase of $\mathcal{A}_v$ can only depend on the port numbering and $I(v)$ (the empty string). Therefore, $\mathcal{B}_v$ can simulate the execution of the first round of $\mathcal{A}_v$.

Let the current round be $r > 1$. Algorithm $\mathcal{B}_v$ maintains a rooted graph H_v that resembles $\mathrm{disc}^*_r(G, v)$. The adjacency lists of H_v are ordered according to $(p_v)_{v \in V}$. Let $H_v(r)$ be the value of H_v after the computation phase of round r. In the send phase, vertex v sends $H_v(r)$ to each of its neighbors. In the receive phase, vertex v receives graphs $H_{u_1}(r), \ldots, H_{u_{d(v)}}(r)$ from its neighbors $u_1, \ldots, u_{d(v)}$. In the subsequent computation phase of round $r + 1$, vertex v extends $H_v(r) = \mathrm{disc}^*_r(G, v)$ to $\mathrm{disc}^*_{r+1}(G, v) = H_v(r + 1)$ by querying $e_{r,v}$ on all pairs of vertices of $V(H_v(r)) \cup V(H_{u_1}(r)) \cup \ldots \cup V(H_{u_{d(v)}}(r))$ to identity vertices and patching the different views together.

Note that $H_v(r + 1)$ also provides the isomorphism type of $\mathrm{disc}^*_{r-\mathrm{dist}(v,u)}(G, u)$ for every vertex u at distance at most r from v. Since the adjacency lists of H_v are ordered according

to the port numbering, it is also possible to reconstruct $e_{r-\mathrm{dist}(v,u),u}(\cdot)$. By the induction hypothesis, $\mathcal{B}_v$ can now simulate round $r - \mathrm{dist}(v,u)$ of $\mathcal{A}_u$ for every such u. By Lemma 19, this is enough to simulate the local computation phase of round r of $\mathcal{A}_u$. ◀

We show that there is no tester for conductance in the ISO-LOCAL model.

▶ **Proposition 21.** *Let $G = (V, E)$ be d-regular graph on n vertices, and let $\Phi = 1/\sqrt{2d}$ be a constant. Any algorithm for testing if G has conductance at least Φ or is ϵ-far from having conductance at least $c\Phi^2$ (for constants c and ϵ) in the ISO-LOCAL model that succeeds with probability $2/3$ requires $\Omega(\log n)$ rounds of communication.*

Proof. Let $G = (V, E)$ be a d-regular graph provided by Lemma 16 and choose $k = \frac{1}{3}\log_d\left(\frac{c\Phi^2-\epsilon}{6}dn\right)$. Without loss of generality assume that n is even, and let $S \subset V$ be a set of size $n/2$. Apply Lemma 17 (with $V_1 = S$ and $V_2 = V \setminus S$) repeatedly to G until $|E(S, V \setminus S)| \leq 6d^{3k}$ holds. Let $H = (V, E')$ be the resulting graph. We have that $|E'(S, V \setminus S)| \leq (c\Phi^2 - \epsilon)dn$, and $\mathrm{vol}(S) = nd/2$. Therefore, H is ϵ-far from having conductance $c\Phi^2$. Let $\mathcal{D}_G$ ($\mathcal{D}_H$) be the uniform distribution over all ISO-LOCAL models $\mathrm{DCM}(G, p_G, I)$ ($\mathrm{DCM}(H, p_H, I)$) such that p_G (p_H) ranges over all possible mappings, that is, port numberings.

We use Yao's principle to prove the lower bound. Let $\mathrm{DNDA}(\mathcal{A}, O)$ be a tester for conductance that has round complexity smaller than k in the ISO-LOCAL model. Since G is d-regular and $\mathrm{girth}(G) \geq 3k$, $\mathrm{disc}^*_k(G, v)$ is a full d-ary tree of depth k for every $v \in V$. For any pair $u, v \in V$, we have that $\mathrm{disc}^*_k(G, u)$ is equal to $\mathrm{disc}^*_k(H, v)$ by Lemma 17. Since the port numberings of two vertices are independent of each other, $(p_v)_{v\in V}$ is a valid port numbering for $G \in \mathcal{D}_G$ iff it is valid for $H \in \mathcal{D}_H$. By Lemma 20, $\mathrm{DNDA}(\mathcal{A}, O)$ cannot distinguish between G and H. ◀

To complete the proof of the lower bound, we show that each vertex in the graph in the ISO-LOCAL model can choose an id randomly.

▶ **Proposition 22.** *Let $\mathrm{DNDA}(\mathcal{A}, O)$ be a randomized tester in the LOCAL model that succeeds with probability p. Then, there is a randomized tester $\mathrm{DNDA}(\mathcal{B}, O)$ in the ISO-LOCAL model that succeeds with probability at least $p - o(1)$, and has the same round complexity.*

Proof. We make a simple modification to $\mathcal{A}$ to obtain $\mathcal{B}$: In the first local computation phase, $\mathcal{B}_v$ draws a random number id_v uniformly from $\{1, \ldots, n^3\}$ and feeds it into $\mathcal{A}_v$ as $I(v)$. Then, $\mathcal{A}_v$ is executed as normal. For $u, v \in V$, the probability that id_u and id_v are equal is $1/n^3$. Applying a union bound, with probability $1 - o(1)$, it holds that $id_u \neq id_v$ for every $u, v \in V$. We then run algorithm $\mathcal{A}$ on this new instance and output the result. ◀

5 Open Problems

In the case of one-sided distributed testers, it is natural to define the decision rule $O(\cdot)$ of a distributed tester such that all vertices have to accept or at least one vertex has to reject. This is because in the case of rejection, the tester is required to observe a witness. However, for two-sided testers no such requirement exists. Requiring that all vertices either accept or reject simultaneously seems to be quite strong. For example, if all should vertices accept or at least one vertex should reject, one may overcome the lack of communication between connected components and test, e. g., whether a graph has more than two connected components with two-sided error. On the other hand, it might not always be possible to obtain a lower bound that is independent of the decision rule as in Theorem 2. To this end, it would be interesting to compare the power of different rules.

Abstract

The *graph similarity* problem, also known as approximate graph isomorphism or graph matching problem, has been extensively studied in the machine learning community, but has not received much attention in the algorithms community: Given two graphs G, H of the same order n with adjacency matrices A_G, A_H, a well-studied measure of similarity is the *Frobenius distance*

$$\operatorname{dist}(G,H) := \min_{\pi} \|A_G^{\pi} - A_H\|_F,$$

where π ranges over all permutations of the vertex set of G, where A_G^{π} denotes the matrix obtained from A_G by permuting rows and columns according to π, and where $\|M\|_F$ is the Frobenius norm of a matrix M. The (weighted) graph similarity problem, denoted by GSim (WSim), is the problem of computing this distance for two graphs of same order. This problem is closely related to the notoriously hard *quadratic assignment problem* (QAP), which is known to be NP-hard even for severely restricted cases.

It is known that GSim (WSim) is NP-hard; we strengthen this hardness result by showing that the problem remains NP-hard even for the class of trees. Identifying the boundary of tractability for WSim is best done in the framework of linear algebra. We show that WSim is NP-hard as long as one of the matrices has unbounded rank or negative eigenvalues: hence, the realm of tractability is restricted to positive semi-definite matrices of bounded rank. Our main result is a polynomial time algorithm for the special case where the associated (weighted) adjacency graph for *one of the matrices* has a bounded number of twin equivalence classes. The key parameter underlying our algorithm is the clustering number of a graph; this parameter arises in context of the spectral graph drawing machinery.

1 Introduction

Graph isomorphism has been a central open problem in algorithmics for the last 50 years. The question of whether graph isomorphism is in polynomial time is still wide open, but at least we know that it is in quasi-polynomial time [4]. On the practical side, the problem is largely viewed as solved; there are excellent tools [9, 15, 21, 22] that efficiently decide isomorphism on all but very contrived graphs [25]. However, for many applications, notably in machine learning, we only need to know whether two graphs are "approximately isomorphic", or more generally, how "similar" they are. The resulting *graph similarity* problem has been extensively studied in the machine learning literature under the name *graph matching* (e.g. [1, 10, 14, 29, 30]), and also in the context of the schema matching problem in database systems (e.g. [23]). Given the practical significance of the problem, surprisingly few theoretical results are known. Before we discuss these known and our new results, let us state the problem formally.

Graph Similarity. It is not obvious how to define the distance between two graphs, but the distance measure that we study here seems to be the most straightforward one, and it certainly is the one that has been studied most. For two n-vertex graphs G and H with adjacency matrices A_G and A_H, we define the *Frobenius distance* between G and H to be

$$\operatorname{dist}(G,H) := \min_{\pi} \|A_G^{\pi} - A_H\|_F. \tag{1}$$

Here π ranges over all permutations of the vertex set of G, A_G^{π} denotes the matrix obtained from A_G by permuting rows and columns according to π, and the norm $\|M\|_F := \sqrt{\sum_{i,j} M_{ij}^2}$ is the *Frobenius norm* of a matrix $M = (M_{ij})$. Note that $\operatorname{dist}(G,H)^2$ counts the number of edge mismatches in an optimal alignment of the two graphs. The *graph similarity problem*, denoted by GSim, is the problem of computing $\operatorname{dist}(G,H)$ for graphs G, H of the same order, or, depending on the context, the decision version of this problem (decide whether $\operatorname{dist}(G,H) \le d$ for a given d). We can easily extend the definitions to weighted graphs and denote the *weighted graph similarity problem* by WSim. In practice, this is often the more relevant problem. Instead of the adjacency matrices of graphs, we may also use the Laplacian matrices of the graphs to define distances. Recall that the *Laplacian matrix* of a graph G is the matrix $L_G := D_G - A_G$, where D_G is the diagonal matrix in which the entry $(D_G)_{ii}$ is the degree of the ith vertex, or in the weighted case, the sum of the weights of the incident edges. Let $\operatorname{dist}_L(G,H) := \min_{\pi} \|L_G^{\pi} - L_H\|_F$ be the corresponding distance measure. Intuitively, in the definition of $\operatorname{dist}_L(G,H)$ we prefer permutations that map vertices of similar degrees onto one another. Technically, $\operatorname{dist}_L(G,H)$ is interesting, because the Laplacian matrices are positive semidefinite (if the weights are nonnegative). Both the (weighted) similarity problem and its version for the Laplacian matrices are special cases of the problem MSim of computing $\min_P \|A - PBP^{-1}\|_F$ for given symmetric matrices $A, B \in \mathbb{R}^{n\times n}$. In the Laplacian case, these matrices are positive semidefinite.[1]

The QAP. The graph similarity problem is closely related to *quadratic assignment problem* (QAP) [6]: given two $(n \times n)$-matrices A, B, the goal is to find a permutation $\pi \in S_n$ that minimizes $\sum_{i,j} A_{ij} B_{\pi(i)\pi(j)}$. The usual interpretation is that we have n *facilities* that we

[1] Note that the notion of similarity that we use here has nothing to do with the standard notion of "matrix similarity" from linear algebra.

want to assign to n *locations*. The entry A_{ij} is the *flow* from the ith to the jth facility, and the entry B_{ij} is the *distance* from the ith to the jth location. The goal is to find an assignment of facilities to locations that minimizes the total cost, where the cost for each pair of facilities is defined as the flow times the distance between their locations. The QAP has a large number of real-world applications, as for instance hospital planning [11], typewriter keyboard design [27], ranking of archeological data [18], and scheduling parallel production lines [13]. On the theoretical side, the QAP contains well-known optimization problems as special cases, as for instance the Travelling Salesman Problem, the feedback arc set problem, the maximum clique problem, and all kinds of problems centered around graph partitioning, graph embedding, and graph packing.

In the maximization version MAX-QAP of QAP, the objective is to maximize the quantity $\sum_{i,j} A_{ij}B_{\pi(i)\pi(j)}$ (see [19, 24]). Both QAP and MAX-QAP are notoriously hard combinatorial optimization problems, in terms of practical solvability [28] as well as in terms of theoretical hardness results even for very restricted special cases [5, 8, 7]. It is easy to see that MSIM is equivalent to MAX-QAP, because in reductions between QAP and MSIM the sign of one of the two matrices is flipped. Most of the known results for GSIM and its variants are derived from results for (MAX)QAP.

Previous Work. It seems to be folklore knowledge that GSIM is NP-complete. For example, this can be seen by a reduction from the Hamiltonian path problem: take G to be the n-vertex input graph and H a path of length n; then $\mathrm{dist}(G,H) \leq \sqrt{|E(G)|-n}$ if and only if G has a Hamiltonian path. By the same argument, we can actually reduce the subgraph isomorphism problem to GSIM. Arvind, Köbler, Kuhnert, and Vasudev [3] study several versions of what they call *approximate graph isomorphism*; their problem MIN-PGI is the same as our GSIM. They prove various hardness of approximation results. Based on an earlier QAP-approximation algorithm due to Arora, Frieze, and Kaplan [2], they also obtain a quasi-polynomial time approximation algorithm for the related problem MAX-PGI. Further hardness results were obtained by Makarychev, Manokaran, and Sviridenko [19] and O'Donnell, Wright, Wu, and Zhou [26], who prove an average case hardness result for a variant of GSIM problem that they call *robust graph isomorphism*. Keldenich [16] studied the similarity problem for a wide range matrix norms (instead of the Frobenius norm) and proved hardness for essentially all of them.

Our (hardness) results. So where does all this leave us? Well, GSIM is obviously an extremely hard optimization problem. We start our investigations by adding to the body of known hardness results: we prove that GSIM remains NP-hard even if both input graphs are trees (Theorem 8). Note that in strong contrast to this, the subgraph isomorphism problem becomes easy if both input graphs are trees [20]. The reduction from Hamiltonian path sketched above shows that GSIM is also hard if one input graph is a path. We prove that GSIM is tractable in the very restricted case that one of the input graphs is a path and the other one is a tree (Theorem 9).

As WSIM and MSIM are essentially linear algebraic problems, it makes sense to look for algebraic tractability criteria. We explore bounded rank (of the adjacency matrices) as a tractability criteria for WSIM and MSIM. Indeed, the NP-hardness reductions for GSIM involve graphs which have adjacency matrices of high rank (e.g. paths, cycles). We show that the problem GSIM (and WSIM) remains NP-hard as long as one of the matrices has unbounded rank or negative eigenvalues. (Theorems 10, 11 and 12). Consequently, the realm of tractability for WSIM (and MSIM) is restricted to the class of positive semi-definite (PSD) matrices of bounded rank.

Block Partition Structure. We feel that for a problem as hard as QAP or MSIM, identifying any somewhat natural tractable special case is worthwhile. Since the spectral structure of PSD matrices of bounded rank is quite limited, we consider combinatorial restrictions: in particular, restricting the block structure of these matrices is a natural line of investigation.

Given a weighted graph G, we call two vertices *twins* if they have identical (weighted) adjacency to every vertex of G. The *twin-equivalence partition* of $V(G)$, corresponding to this equivalence relation, induces a block structure on the adjacency matrix A_G. Indeed, if $S_1 \dot\cup \ldots \dot\cup S_p = V(G)$ are the twin-equivalence classes, the submatrix $A_G[S_i, S_j]$ is a constant matrix. Hence, the rows and columns of the matrix A_G can be simultaneously rearranged to yield a $p \times p$ block matrix. The number of twin-equivalence classes will be an important parameter of our interest: we denote this parameter by $\tau(G)$.

Our (algorithmic) results. Our main result is a polynomial time algorithm for MSIM if both input matrices are positive semidefinite and have bounded-rank, and where *one of the input matrices* has a bounded number of twin-equivalence classes. Formally, we prove the following theorem. Here, the $\widetilde{\mathcal{O}}$ notation hides factors polynomial in the input representation.

▶ **Theorem 1.** *The problem* MSIM *can be solved in* $\widetilde{\mathcal{O}}(n^{kp^2})$ *time where*
- **(i)** *the input matrices are* $n \times n$ *PSD matrices of rank at most* k*, and*
- **(ii)** *one of the input matrices has at most* p *twin-equivalence classes.*

For the proof of Theorem 1, we can re-write the (squared) objective function as $\|AP - PB\|_F^2$, where P ranges over all permutation matrices. This is a convex function, and it would be feasible to minimize it over a convex domain. The real difficulty of the problem lies in the fact that we are optimizing over the complicated discrete space of permutation matrices. Our approach relies on a linearization of the solution space, and the key insight (Lemma 19) is that the optimal solution is essentially determined by polynomially many hyperplanes. To prove this, we exploit the convexity of the objective function in a peculiar way.

2 Preliminaries

We denote the set $\{1, \ldots, n\}$ by $[n]$. Unless specified otherwise, we will always assume that the vertex set of an n-vertex graph G is $[n]$. We denote the degree of a vertex v by $d_G(v)$.

Twins. Given a $n \times n$ symmetric matrix A with real entries, let G_A denote the associated weighted adjacency graph. Two vertices are called *twins* if they have identical (weighted) adjacency to every vertex in the graph. Hence, two vertices labeled $i, j \in [n]$ are twins if and only if $A_{il} = A_{jl}$ for all $l \in [n]$. This is an equivalence relation; call the resulting partition of the vertex set as the *twin-equivalence partition*. The number of twin-equivalence classes will be an important parameter of our interest: we denote this parameter by $\tau(G)$. In these definitions, we use the matrix A and its adjacency graph A_G interchangeably. This allows us to define $\tau(A)$ for a matrix A to be $\tau(G_A)$, for the associated weighted adjacency graph G_A. The connection with block structure of the matrix is straighforward: observe that we can simultaneously rearrange the rows and columns of A to obtain a $\tau(A) \times \tau(A)$ block matrix W. If $S_1 \dot\cup \ldots \dot\cup S_p = [n]$ be the twin-equivalence partition, the block W_{lm} (where $l, m \in [\tau(A)]$) is the adjacency matrix for the induced subgraph $G_A[S_l, S_m]$. Moreover, the definition of twin-equivalence partition implies that this subgraph is a weighted complete bipartite graph.

Matrices. Given an $m \times n$ matrix M, the i^{th} row (column) of M is denoted by M^i (M_i). The multiset $\{M^1, \ldots, M^m\}$ is denoted by rows(M). Given $S \subseteq [m]$, the sum $\sum_{i \in S} M^i$ is denoted by M^S. We denote the $n \times n$ identity matrix by I_n. A real symmetric $n \times n$ matrix M is called *positive semi-definite* (PSD), denoted by $M \succeq 0$, if the scalar $z^T M z$ is non-negative for every $z \in \mathbb{R}^n$. The following conditions are well-known to be equivalent.

- **(i)** $M \succeq 0$
- **(ii)** Every eigenvalue of M is non-negative.
- **(iii)** $M = W^T W$ for some $n \times n$ matrix W. In other words, there exist n vectors $w_1, \ldots, w_n \in \mathbb{R}^n$ such that $M_{ij} = w_i^T w_j$.

Given two vectors $x, y \in \mathbb{R}^n$, their dot product $\langle x, y \rangle$ is defined to be $x^T y$. Given $M \succeq 0$, the inner product of x, y w.r.t. M, denoted by $\langle x, y \rangle_M$, is defined to be $x^T M y$. The usual dot product corresponds to the case $M = I$, the identity matrix. Every $n \times n$ symmetric matrix M has a spectral decomposition $M = U \Sigma U^T$, where the rows of U form an eigenbasis. If M has rank k, we can truncate the zero eigenvalues in Σ to obtain a truncated spectral decomposition. Now, Σ is a $k \times k$ diagonal matrix with the eigenvalues $\lambda_1, \ldots, \lambda_k \in \mathbb{R}$ on the diagonal. The matrix U is a $n \times k$ matrix with the corresponding eigenvectors $v_1, \ldots, v_k$ as the columns $U_1, \ldots, U_k$. We will always work with truncated spectral decompositions henceforth.

Frobenius Norm. The trace of a matrix M, denoted by $\mathrm{Tr}(M)$, is defined to be $\sum_{i \in [n]} M_{ii}$. The *trace inner product* of two matrices A and B, denoted by $\mathrm{Tr}(A, B)$, is the scalar $\mathrm{Tr}(A^T B)$. The *Frobenius norm* $\|M\|_F$ of a matrix M is defined to be $\sum_{i,j \in [n]} {M_{ij}}^2$. It is easy to check that $\|M\|_F^2 = \mathrm{Tr}(M, M)$. Given two n-vertex graphs G and H and a permutation $\pi \in S_n$, a *π-mismatch* between G and H is a pair $\{i, j\}$ such that $\{i, j\} \in E(G)$ and $\{i^\pi, j^\pi\} \notin E(H)$ (or vice-versa). In other words, $\pi : V(G) \to V(H)$ does not preserve adjacency for the pair $\{i, j\}$. The following claim will be useful as a combinatorial interpretation of the Frobenius norm. Let Δ denote the number of π-mismatches between G and H.

▶ **Claim 2.** $\|A_G^\pi - A_H\|_F^2 = 2\Delta$.

Proof. The only non-zero terms in the expansion of summation $\|A_G^\pi - A_H\|_F^2$ correspond to π-mismatches. Since every mismatch $\{i, j\}$ contributes 1 and is counted twice in the summation, the claim follows. ◀

Clustering Number. Spectral Graph Drawing is a well-established technique for visualizing graphs via their spectral properties (see e.g. [17]). We introduce the details necessary for our results. Let A be a $n \times n$ matrix of rank k. Let G be the corresponding adjacency graph, with the vertex set $[n]$. Given a spectral decomposition $A = U \Lambda U^T$, Σ is a $k \times k$ matrix and U is a $n \times k$ matrix. Since the spectral decomposition of a matrix is not unique, the following claim will be useful.

▶ **Claim 3.** *Given two spectral decompositions $A = U \Lambda U^T$ and $A = U' \Lambda {U'}^T$, the number of distinct elements in the multi-set* rows(U) *is equal to the number of distinct elements in the multi-set* rows(U').

Therefore, the number of *distinct* elements in the multi-set rows(U) is invariant of our choice of spectral decomposition $A = U \Lambda U^T$. This allows us to define the *clustering number* of a graph G, denoted by $\mathrm{cn}(G)$, as the number of *distinct* elements in the multi-set rows(U), for

some spectral decomposition $A = U\Lambda U^T$. The clustering number of a matrix A, denoted by $\mathrm{cn}(A)$, is defined to be the clustering number of the corresponding adjacency graph.

Let $A = U\Lambda U^T$ be a PSD matrix. The following theorem relates the clustering number $\mathrm{cn}(A)$ to the number of twin-equivalence partitions $\tau(A)$.

▶ **Theorem 4.** *Let A be a PSD matrix. The number of twin-equivalence classes $\tau(A)$ is equal to p if and only if A has p distinct elements in the set* $\mathrm{rows}(U)$ *for a spectral decomposition $A = U\Lambda U^T$.*

Hyperplanes and Convex Functions. A *hyperplane* H in the Euclidean space $\mathbb{R}^k$ is a $(k-1)$-dimensional affine subspace. The usual representation of a hyperplane is a linear equation $\langle c, x\rangle = \alpha$ for some $c \in \mathbb{R}^k, \alpha \in \mathbb{R}$. The convex sets $\{x \mid \langle c, x\rangle > \alpha\}$ and $\{x \mid \langle c, x\rangle < \alpha\}$ are called the open *half-spaces* corresponding to H, denoted by H^+, H^- respectively.

Two sets (S, T) are *weakly linearly separated* if there exists a hyperplane H such that $S \subseteq H^+ \cup H$ and $T \subseteq H^- \cup H$. In this case, we call them weakly linearly separated along H. A family of sets $S_1, \ldots, S_p$ is *weakly linearly separated* if for every $l, m \in [p]$, the sets S_l, S_m are weakly linearly separated. Let Π be a partition of a set S into p sets $S_1, \ldots, S_p$. The partition Π is said to be *mutually linearly separated* if the family of sets $S_1, \ldots, S_p$ is weakly linearly separated.

Recall that a subset $S \subseteq \mathbb{R}^k$ is called *convex* if for every $x, y \in S$, $\alpha x + (1-\alpha)y \in S$, $\alpha \in [0, 1]$. A function $f : \mathbb{R}^k \to \mathbb{R}$ is called *convex* on a convex set S if for every $x, y \in S$, $f(\alpha x + (1-\alpha)y) \leq \alpha f(x) + (1-\alpha)f(y)$. The following theorem about linearization of convex differentiable functions is well-known and is stated without proof. The gradient of a function $f : \mathbb{R}^k \to \mathbb{R}$, denoted by ∇f, is the vector-valued function $[\frac{\partial f}{\partial x_1} \ldots \frac{\partial f}{\partial x_k}]$. Given $X^* \in \mathbb{R}^k$, let μ^* denote the vector $\nabla f(X^*)$.

▶ **Theorem 5** (Convex function linearization)**.** *Let $f : \mathbb{R}^k \to \mathbb{R}$ be a convex function. For all $X \in \mathbb{R}^k$, $f(X) - f(X^*) \geq \langle \mu^*, X - X^*\rangle$.*

Finally, we state an important fact about the convexity of quadratic functions. Given a PSD matrix $M \in \mathbb{R}^{k\times k}$, the quadratic function $Q_M : \mathbb{R}^k \to \mathbb{R}$ is defined as $Q_M(x) = \langle x, x\rangle_M$.

▶ **Lemma 6** (Convexity of PSD)**.** *Q_M is convex on $\mathbb{R}^k$.*

3 Hardness Results

In this section, we show several new hardness results for problems GSim, WSim and MSim. As we will observe, these problems turn out to be algorithmically intractable, even for severely restricted cases. We begin by recalling the following observation.

▶ **Theorem 7** (Folklore)**.** GSim *is NP-hard for the class of simple undirected graphs.*

In fact, the problem turns out to be NP-hard even for very restricted graph classes. The following theorem is the main hardness result of this section.

▶ **Theorem 8.** GSim *is NP-hard for the class of trees.*

Proof. The proof is by a reduction from the following NP-hard variant of the Three-Partition problem [12], which is defined as follows. The input consists of integers A and $a_1, \ldots, a_{3m}$ in unary representation, with $\sum_{i=1}^{3m} a_i = mA$ and with $A/4 < a_i < A/2$ for $1 \leq i \leq 3m$. The question is to decide whether $a_1, \ldots, a_{3m}$ can be partitioned into m triples so that the elements in each triple sum up to precisely A.

We first show that the restriction of GSim to forests is NP-hard. Given an instance of Three-Partition, we compute an instance of GSim on the following two forests F_1 and F_2. Forest F_1 is the disjoint union of $3m$ paths with $a_1, \ldots, a_{3m}$ vertices, respectively. Forest F_2 is the disjoint union of m paths that each consists of A vertices. We claim that the Three-Partition instance has answer YES, if and only if there exists a permutation π such that there are at most $2m$ mismatches. If the desired partition exists, then for each triple we we can pack the three corresponding paths in F_1 into one of the paths in F_2 with two mismatches per triple. Conversely, if there exists a permutation π with at most $2m$ mismatches, then these $2m$ mismatches cut the paths in F_2 into $3m$ subpaths (we consider isolated vertices as paths of length 0). As each of these $3m$ subpaths must be matched with a path in F_1, we easily deduce from this a solution for the Three-Partition instance.

To show that GSim is NP-hard for the class of trees, we modify the above forests F_1 and F_2 into trees T_1 and T_2. Formally, we add a new vertex v_1 to $V(F_1)$ and then connect one end-point of every path in F_1 to v_1 by an edge; note that the degree of vertex v_1 in the resulting tree is $3m$. Analogously, we add a new vertex v_2 to $V(F_2)$, connect it to all paths, and thus produce a tree in which vertex v_2 has degree m. For technical reasons, we furthermore attach $8m$ newly created leaves to every single vertex in $V(F_1)$ and $V(F_2)$. k The resulting trees are denoted T_1 and T_2, respectively.

We claim that the considered Three-Partition instance has answer YES, if and only if there exists $\pi : V(T_1) \to V(T_2)$ with at most $4m$ mismatches. If the desired partition exists, the natural bijection maps every original forest edge in T_1 to an original forest edge in T_2, except for some $2m$ out of the $3m$ edges that are incident to v_1 in T_1; this yields a total number of $2m + 2m = 4m$ mismatches. Conversely, suppose that there exists a permutation π with at most $4m$ mismatches. Then π must map v_1 in T_1 to v_2 in T_2, since otherwise we pay a penalty of more than $4m$ mismatches alone for the edges incident to the vertex mapped into v_2. As the number of mismatches for edges incident to v_1 and v_2 amounts to $2m$, there remain at most $2m$ further mismatches for the remaining edges. Similarly as in our above argument for the forests, these at most $2m$ mismatches yield a solution for the Three-Partition instance. ◀

On the other hand, if we restrict one of the input instances to be a path, the problem can be solved in polynomial time. The following theorem provides a positive example of tractability of GSim.

▶ **Theorem 9.** *An input instance (G, H) of* GSim*, where G is a path and H is a tree, can be solved in polynomial time.*

The above results exhibit the hardness of GSim, and consequently, the hardness of the more general problems WSim and MSim. Since the graphs (for instance cycles and paths) involved in the hardness reductions have adjacency matrices of high rank, it is natural to ask whether MSim would become tractable for matrices of low rank. Our following theorem shows that MSim is NP-hard even for matrices of rank at most 2. The underlying reason for hardness is the well-known problem QAP, which shares the optimization domain S_n.

▶ **Theorem 10.** MSim *is NP-hard for symmetric matrices of rank at most* 2*.*

The key to the above reduction is the fact that one of the matrices has non-negative eigenvalues while the other matrix has non-positive eigenvalues. We show that the MSim is NP-hard even for positive semi-definite matrices. The main idea is to reformulate the hardness reduction in Theorem 7 in terms of Laplacian matrices.

▶ **Theorem 11.** MSim *is NP-hard for positive semi-definite matrices.*

In fact, we show that the problem remains NP-hard, even if one of the matrices is of rank 1. The proof follows by modifying the matrices in the proof of Theorem 10 so that they are positive semi-definite.

▶ **Theorem 12.** MSim *is NP-hard for positive semi-definite matrices, even if one of the matrices has rank* 1*.*

Therefore, the realm of tractability for MSim is restricted to positive definite matrices of bounded rank.

4 The QVP Problem

We proceed towards the proof of Theorem 1, our main algorithmic result about MSim. In order to prove this theorem, we need to define an intermediate problem, called the Quadratic-Vector-Partition (QVP). In this section, we study several aspects of this problem. First, we state this problem, and show an efficient reduction from MSim to QVP (Sections 4.1 and 4.2). The definition of the problem QVP is slightly technical; the ensuing reduction, from MSim to QVP, will justify the introduction of this intermediate problem. In Sections 4.3 and 4.4, we will establish strong conditions on the optimal solutions for a QVP instance. Later on, in Section 5, these conditions will allow us to design efficient algorithms for QVP, which will finish the proof of Theorem 1.

4.1 QVP, definition

Let p and k be fixed positive integers. The *input instance* to QVP is a tuple (W, K, Λ, Δ), where

- W is a set of n vectors $\{w_1, \ldots, w_n\} \subseteq \mathbb{R}^k$,
- K is a $p \times p$ PSD matrix,
- Λ is a $k \times k$ *diagonal* matrix with non-negative entries, and,
- Δ is (the unary encoding of) a p-tuple $(n_1, \ldots, n_p)$ such that $n_1 + \cdots + n_p = n$.

Some additional notation is required, before we proceed further. An ordered partition $T_1 \dot\cup \cdots \dot\cup T_p$ of $[n]$ is said to have *type* Δ if the cardinalities $|T_l| = n_l$, for all $l \in [p]$. Let $\mathcal{P}_\Delta$ denote the set of all (ordered) partitions of $[n]$ of type Δ. Let T be a subset of $[n]$. Denote the subset of W indexed by the set T as $W[T] = \{w_j \mid j \in T\}$. The centroid of the subset $W[T]$ is denoted by $\widehat{w_T}$. In other words, $\widehat{w_T} = \frac{1}{|T|} \sum_{i \in T} w_i$.

We continue with the definition of QVP. Given a partition $P = (T_1, \ldots, T_p) \in \mathcal{P}_\Delta$, the QVP objective function $F(P)$ is defined as

$$F(P) = \sum_{l,m \in [p]} K_{lm} \langle \widehat{w}_{T_l}, \widehat{w}_{T_m} \rangle_\Lambda .$$

The optimization problem QVP is to compute a partition $P^* \in \mathcal{P}_\Delta$ which is a maximizer of the objective function $F(P)$ over the domain $\mathcal{P}_\Delta$.

4.2 MSim reduces to QVP

Let k and p be fixed positive integers. Let (A, B) be an MSIM instance, as defined in Theorem 1: the PSD matrices A and B are of rank at most k, and moreover, $\tau(B) = p$. The following lemma describes a reduction from MSIM to QVP. Here, the $\widetilde{\mathcal{O}}$ notation hides factors polynomial in the size of the input representation.

▶ **Lemma 13.** *There exists an $\widetilde{\mathcal{O}}(n^3)$ running time algorithm which can transform the* MSIM *instance (A, B) into a* QVP*-instance (W, K, Λ, Δ), with the following property. Given an optimal solution for this* QVP*-instance, we can compute an optimal solution for the* MSIM *instance, in $\mathcal{O}(n)$ running time.*

Proof. Fix two spectral decompositions $A = U\Lambda U^T$ and $B = V\Gamma V^T$ of A and B respectively. Since $\tau(B) = p$, the multiset rows(V) has exactly p distinct vectors (by Theorem 4). Let these p distinct vectors be denoted by $\{\tilde{V}^1, \ldots, \tilde{V}^p\}$. Let $n_1, \ldots, n_p$ be the multiplicity of the elements $\tilde{V}^1, \ldots, \tilde{V}^p$ in the multiset rows(V). Clearly, $n_1 + \cdots + n_p = n$. Let $\tilde{P} = S_1 \cup \cdots \cup S_p$ be the partition of the set $[n]$ such that $S_l = \{i \,|\, V^i = \tilde{V}^l\}$, for $l \in [p]$. In other words, the partition $\tilde{P}$ encodes the equivalence relation $V^i = V^j$, where $i, j \in [n]$.

Let us describe the polynomial time transformation of the MSIM instance (A, B) into the QVP instance (W, K, Λ, Δ). Define W as the multiset rows(U). In other words, we can denote $W = \{w_1, \ldots, w_n\}$ where $w_i = U^i$. Define K to be the $p \times p$ matrix defined as $K_{lm} = |S_l| \cdot |S_m| \cdot \langle \tilde{V}^l, \tilde{V}^m \rangle_\Gamma$, for $l, m \in [p]$. Since we can write $K_{lm} = \langle |S_l| \cdot \tilde{V}^l, |S_m| \cdot \tilde{V}^m \rangle_\Gamma$, we can show that K is positive semi-definite. We set Λ to be the $k \times k$ diagonal matrix in the spectral decomposition $A = U\Lambda U^T$. Finally, we set Δ to be $(n_1, \ldots, n_p)$: these numbers were defined in the previous paragraph. The computation of this QVP instance can be performed in $\widetilde{\mathcal{O}}(n^3)$ time, which is the time taken to compute the spectral decompositions for A and B.

It remains to show that an optimal solution for this QVP instance yields an optimal solution for the MSIM instance in $\mathcal{O}(n)$ time. Observe that $\|A^\pi - B\|_F^2 = \mathrm{Tr}(A^\pi - B, A^\pi - B) = \mathrm{Tr}(A^\pi, A^\pi) + \mathrm{Tr}(B, B) - 2\,\mathrm{Tr}(A^\pi, B)$. Since $\mathrm{Tr}(A^\pi, A^\pi) = \|A^\pi\|_F^2 = \|A\|_F^2 = \mathrm{Tr}(A, A)$, we have $\|A^\pi - B\|_F^2 = \mathrm{Tr}(A, A) + \mathrm{Tr}(B, B) - 2\,\mathrm{Tr}(A^\pi, B)$. This derivation implies that we can equivalently maximize $\mathrm{Tr}(A^\pi, B)$ over $\pi \in S_n$. Observe that $\mathrm{Tr}(A^\pi, B)$ can be rewritten as

$$\begin{aligned}
\mathrm{Tr}(A^\pi, B) &= \sum_{i,j \in [n]} a_{i^\pi j^\pi}\, b_{ij} \\
&= \sum_{i,j \in [n]} \langle U^{i^\pi}, U^{j^\pi} \rangle_\Lambda \cdot \langle V^i, V^j \rangle_\Gamma \\
&= \sum_{l,m \in [p]} \left(\sum_{i \in S_l,\, j \in S_m} \langle U^{i^\pi}, U^{j^\pi} \rangle_\Lambda \cdot \langle V^i, V^j \rangle_\Gamma \right)
\end{aligned}$$

which can be further re-written as

$$\begin{aligned}
\mathrm{Tr}(A^\pi, B) &= \sum_{l,m \in [p]} \left(\sum_{i \in S_l,\, j \in S_m} \langle U^{i^\pi}, U^{j^\pi} \rangle_\Lambda \right) \cdot \langle \tilde{V}^l, \tilde{V}^m \rangle_\Gamma \\
&= \sum_{l,m \in [p]} \left\langle \sum_{i \in S_l} U^{i^\pi}, \sum_{j \in S_m} U^{j^\pi} \right\rangle_\Lambda \cdot \langle \tilde{V}^l, \tilde{V}^m \rangle_\Gamma \\
&= \sum_{l,m \in [p]} |S_l| \cdot |S_m| \cdot \left\langle \widehat{w}_{S_l^\pi}, \widehat{w}_{S_m^\pi} \right\rangle_\Lambda \cdot \langle \tilde{V}^l, \tilde{V}^m \rangle_\Gamma
\end{aligned}$$

Define the partition P_π of $[n]$ to be $P_\pi = (S_1^\pi, \ldots, S_p^\pi)$. Observe that P_π is of type Δ, and therefore, $P_\pi \in \mathcal{P}_\Delta$. Using the definition of the matrix K, we can thus rewrite

$$\begin{aligned}\mathrm{Tr}(A^\pi, B) &= \sum_{l,m\in[p]} |S_l| \cdot |S_m| \cdot \left\langle \widehat{w}_{S_l^\pi}, \widehat{w}_{S_m^\pi} \right\rangle_\Lambda \cdot \langle \tilde{V}^l, \tilde{V}^m \rangle_\Gamma \\ &= \sum_{l,m\in[p]} \left\langle \widehat{w}_{S_l^\pi}, \widehat{w}_{S_m^\pi} \right\rangle_\Lambda \cdot K_{lm} \\ &= F(P_\pi),\end{aligned}$$

which allows us to state the following equality.

$$\|A^\pi - B\|_F^2 = \mathrm{Tr}(A, A) + \mathrm{Tr}(B, B) - 2F(P_\pi). \tag{2}$$

We continue with the proof of the lemma. Let P^* be an optimal solution for our QVP instance. In other words, the partition $P^* = (T_1^*, \ldots, T_p^*)$ is a maximizer of $F(P)$ over the set $\mathcal{P}_\Delta$. Let π^* be a permutation which maps the sets S_l to T_l^*, for all $l \in [p]$. We claim that π^* is an optimal solution for the MSim instance. To see this, suppose π^* is not optimal. Instead, let π' be an optimal solution for the MSim instance, and hence, $\|A^{\pi^*} - B\|_F^2 > \|A^{\pi'} - B\|_F^2$. Define a related partition $P_{\pi'} = (S_1^{\pi'}, \ldots, S_p^{\pi'})$: clearly, $\pi' \in \mathcal{P}_\Delta$. Since Equation 2 implies that

$$\begin{aligned}\|A^{\pi^*} - B\|_F^2 &= \mathrm{Tr}(A, A) + \mathrm{Tr}(B, B) - 2F(P^*), \\ \|A^{\pi'} - B\|_F^2 &= \mathrm{Tr}(A, A) + \mathrm{Tr}(B, B) - 2F(P_{\pi'}),\end{aligned}$$

we use $\|A^{\pi^*} - B\|_F^2 > \|A^{\pi'} - B\|_F^2$ to obtain that $F(P^*) < F(P_{\pi'})$. This contradicts the maximality of P^*. Hence, π^* must be an optimal solution for the QVP instance.

Given such an optimal solution P^* for the QVP instance, the computation of the optimal solution π^* for the MSim instance is a straightforward $\widetilde{\mathcal{O}}(n)$ procedure: we define π^* by choosing arbitrary bijections between the sets S_l and T_l^*, for all $l \in [p]$. This finishes the proof of our lemma. ◀

4.3 Linearization of Convex Functions

We take a small detour towards the properties of convex functions. These properties will be useful for studying the optimal solutions to the QVP problem. In general, we show that the linearization of a convex function can be useful in understanding its optima over a finite domain. In this context, we prove the following lemma about convex functions, which is interesting in its own right.

▶ **Lemma 14.** *Let Ω be a finite subset of $\mathbb{R}^k \times \mathbb{R}^\ell$. Let $G : \mathbb{R}^k \to \mathbb{R}$, $H : \mathbb{R}^\ell \to \mathbb{R}$ such that H is convex, and let $F : \mathbb{R}^k \times \mathbb{R}^\ell \to \mathbb{R}$ be defined as $F(X, Y) = G(X) + H(Y)$. Let $(X^*, Y^*) \in \arg\max_{(X,Y)\in\Omega} F(X, Y)$.*

Then there exist a $\mu^* \in \mathbb{R}^\ell$ such that:

- **(i)** *$(X^*, Y^*) \in \arg\max_{(X,Y)\in\Omega} L(X, Y)$ where $L(X, Y) = G(X) + \langle \mu^*, Y \rangle$;*
- **(ii)** *$\arg\max_{(X,Y)\in\Omega} L(X, Y) \subseteq \arg\max_{(X,Y)\in\Omega} F(X, Y)$.*

Proof. Let $(X^*, Y^*) \in \arg\max_{S\in\Omega} F(S)$. Since H is convex, we can use Theorem 5 to linearize H around $Y^* \in \mathbb{R}^\ell$. Hence, there exists a $\mu^* \in \mathbb{R}^\ell$ such that $H(Y) - H(Y^*) \geq \langle \mu^*, Y - Y^* \rangle$, or equivalently,

$$H(Y) - \langle \mu^*, Y \rangle \geq H(Y^*) - \langle \mu^*, Y^* \rangle, \tag{3}$$

for all $Y \in \mathbb{R}^\ell$. Hence with $L(X,Y) = G(X) + \langle \mu^*, Y \rangle$, for all $(X,Y) \in \Omega$ we have

$$L(X^*,Y^*) = F(X^*,Y^*) - H(Y^*) + \langle \mu^*, Y^* \rangle \geq F(X,Y) - H(Y) + \langle \mu^*, Y \rangle = L(X,Y),$$

where the inequality holds by (3) and because (X^*,Y^*) maximizes F. Hence (X^*,Y^*) maximizes L as well, which proves (i).

For (ii), consider $(X^{**},Y^{**}) \in \arg\max_{(X,Y)\in\Omega} L(X,Y)$. To prove that $(X^{**},Y^{**}) \in \arg\max_{(X,Y)\in\Omega} F(X,Y)$, it suffices to prove that $F(X^{**},Y^{**}) \geq F(X^*,Y^*)$. By (i), we have $L(X^*,Y^*) = L(X^{**},Y^{**})$. Thus

$$\begin{aligned} F(X^{**},Y^{**}) = L(X^{**},Y^{**}) + H(Y^{**}) - \langle \mu^*, Y^{**} \rangle &\geq L(X^*,Y^*) + H(Y^*) - \langle \mu^*, Y^* \rangle \\ &= F(X^*,Y^*), \end{aligned}$$

where the inequality holds by (3) with $(X,Y) := (X^{**},Y^{**})$ and as (X^{**},Y^{**}) maximizes L. ◀

In other words, for every (X^*,Y^*) which maximizes F over Ω, there exists a partially "linearized" function L such that (X^*,Y^*) maximizes L over Ω. Moreover, every maximizer of L over Ω is a maximizer of F over Ω. This additional condition is necessary so that this "linearization" does not create spurious optimal solutions.

▶ **Corollary 15.** *Let Ω be a finite subset of $\mathbb{R}^{kp}$. For all $i \in [k]$, let $G_i : \mathbb{R}^k \to \mathbb{R}$ be a convex function. Let $F : \mathbb{R}^{kp} \to \mathbb{R}$ be defined as $F(X_1,\ldots,X_k) := G_1(X_1) + \ldots + G_k(X_k)$. Let $X^* = (X_1^*,\ldots,X_k^*) \in \arg\max_{X\in\Omega} F(X)$.*

Then there are $\mu_1^*,\ldots,\mu_k^* \in \mathbb{R}^p$ such that:

(i) *$X^* \in \arg\max_{X\in\Omega} L(X)$ where $L(X_1,\ldots,X_k) = \sum_{i=1}^k \langle \mu_i^*, X_i \rangle$;*

(ii) *$\arg\max_{X\in\Omega} L(X) \subseteq \arg\max_{\in\Omega} F(X)$.*

Proof. Inductively apply the lemma to the functions

$$F^i((X_1,\ldots,X_{i-1},X_{i+1},\ldots,X_k),X_i) = \underbrace{\left(\sum_{j=1}^{i-1}\langle \mu_j^*, X_j\rangle + \sum_{j=i+1}^{k} G_j(X_j)\right)}_{=:G^i(X_1,\ldots,X_{i-1},X_{i+1},\ldots,X_k)} + \underbrace{G_i(X_i)}_{=:H^i(X_i)}. \quad ◀$$

4.4 Optimal Solution Structure for QVP

Let us express the QVP objective function

$$F(P) = \sum_{l,m\in[p]} K_{lm} \langle \widehat{w}_{T_l}, \widehat{w}_{T_m} \rangle_\Lambda$$

as a restriction of a convex function to a finite domain. Using the results above for linearization of convex functions, we show that the optimal solutions for a QVP instance must satisfy certain structural constraints, specified by Lemma 19.

Formally, given a QVP instance (W,K,Λ,Δ), and a partition $P = (T_1,\ldots,T_p) \in \mathcal{P}_\Delta$, we define k vectors $X_1,\ldots,X_k$ as follows. For $q \in [k]$, let X_q be the vector of length p corresponding to the q^{th} coordinates of vectors $\widehat{w}_{T_1},\ldots,\widehat{w}_{T_p}$. Clearly, the vectors $X_1,\ldots,X_k$ are a function of the partition P. Recall that Λ is a diagonal matrix with k non-negative entries, say $\lambda_1,\ldots,\lambda_k$.

▶ **Claim 16.** $F(P) = \sum_{q=1}^{k} \lambda_q \langle X_q, X_q \rangle_K$.

Observe that the function $G : \mathbb{R}^p \mapsto \mathbb{R}$ defined by $G(Y) = \langle Y, Y \rangle_K$ is a convex function (by Lemma 6). Define a function $\tilde{F}(Y_1, \ldots, Y_p) = \lambda_1 G(Y_1) + \cdots + \lambda_k G(Y_k)$, where the vectors $Y_1, \ldots, Y_k \in \mathbb{R}^p$. This function is convex as well: it is a linear combination of convex functions, with positive co-efficients. Observe that $F(P) = \tilde{F}(X_1, \ldots, X_p)$. Therefore, the problem of maximizing F over $\mathcal{P}_\Delta$ is, essentially, a problem of maximizing a convex function $\tilde{F}(Y_1, \ldots, Y_k)$ over a finite discrete domain.

Using Corollary 15, we claim that a maximizer $P^* = (T_1^*, \ldots, T_p^*)$ of the objective function $F(P)$ over the domain $\mathcal{P}_\Delta$ must be a maximizer for some *linear* objective function $L_1(P)$ over the domain $\mathcal{P}_\Delta$.

▶ **Claim 17.** *There exist vectors $\mu_1^*, \ldots, \mu_k^* \in \mathbb{R}^p$ such that P^* is a maximizer of the function $L_1(P) = \sum_{q=1}^{k} \lambda_q \langle \mu_q^*, X_q \rangle_K$ over $\mathcal{P}_\Delta$. Moreover, every maximizer of $L_1(P)$ is a maximizer of $F(P)$.*

We can further reformulate the optimality conditions of Claim 17 as follows.

▶ **Claim 18.** *There exist vectors $\mu_1, \ldots, \mu_p \in \mathbb{R}^k$ such that P^* is a maximizer of the function $L_2(P) = \sum_{m=1}^{p} \langle \mu_m, \widehat{w}_{T_m} \rangle$ over $\mathcal{P}_\Delta$. Moreover, every maximizer of $L_2(P)$ is a maximizer of $L_1(P)$, and consequently, a maximizer of $F(P)$.*

The above claim leads to a strong geometrical restriction on the partition $W[T_1^*], \ldots, W[T_p^*]$ of W, induced by the optimal partition $P^* \in \mathcal{P}_\Delta$.

▶ **Lemma 19.** *Let $P^* = (T_1^*, \ldots, T_p^*)$ be an optimal solution for a* QVP *instance (W, K, Λ, Δ). The partition $(W[T_1^*], \ldots, W[T_p^*])$ of the set W is (weakly) mutually linearly separated.*

Proof. By Claim 18, there exist vectors $\mu_1, \ldots, \mu_p \in \mathbb{R}^k$ such that P^* is a maximizer of $L_2(P)$. Suppose there exist q, r such that $W[T_q^*]$ and $W[T_r^*]$ are not (weakly) linearly separated. We claim that this leads to a contradiction.

Let n_q and n_r be the cardinalities of the sets T_q^* and T_r^*. We use the notation W^T to denote the sum of the vectors in the set $W[T]$, for a subset $T \subseteq [n]$. Let us isolate the two terms $\langle \mu_q, \widehat{w}_{T_q^*} \rangle + \langle \mu_r, \widehat{w}_{T_r^*} \rangle$ and rewrite them as $\langle \frac{\mu_q}{n_q}, W^{T_q^*} \rangle + \langle \frac{\mu_r}{n_r}, W^{T_r^*} \rangle$. Let us denote $\frac{1}{n_q}\mu_q$ by μ'_q, and $\frac{1}{n_r}\mu_r$ by μ'_r. Therefore, the terms can be re-written as $\langle \mu'_q, W^{T_q^*} \rangle + \langle \mu'_r, W^{T_r^*} \rangle$.

Rewriting further, we can express the above terms as $\langle (\mu'_q - \mu'_r), W^{T_q^*} \rangle + \langle \mu'_r, (W^{T_q^*} + W^{T_r^*}) \rangle$. Recall that the sets $W[T_q^*]$ and $W[T_r^*]$ are not weakly linearly separated. Let us partition the set $W[T_q^*] \cup W[T_r^*]$ into two sets $W[T'_q]$ and $W[T'_r]$ such that (a) $|T'_q| = n_q$, $|T'_r| = n_r$ and (b) the sets $W[T'_q]$ and $W[T'_r]$ are weakly linearly separated along the direction $(\mu'_q - \mu'_r)$. Indeed, we can sort all elements w in $W[T_q^*] \cup W[T_r^*]$ in a descending order, according to their (signed) projection $\langle (\mu'_q - \mu'_r), w \rangle$ along $(\mu'_q - \mu'_r)$. Pick the top n_q elements in this ordering to obtain the set T'_q and collect the remaining n_r elements to form the set T'_r. Note that the sets T'_q and T'_r are weakly linearly separated along the direction $(\mu'_q - \mu'_r)$, and hence, the pair $(T_q^*, T_r^*) \neq (T'_q, T'_r)$.

Clearly, $\langle (\mu'_q - \mu'_r), W^{T'_q} \rangle > \langle (\mu'_q - \mu'_r), W^{T_q^*} \rangle$ by our construction. Moreover, $\langle \mu'_r, (W^{T'_q} + W^{T'_r}) \rangle = \langle \mu'_r, (W^{T_q^*} + W^{T_r^*}) \rangle$, because $T'_q \cup T'_r = T_q^* \cup T_r^*$. Hence, $\langle \mu'_q, W^{T'_q} \rangle + \langle \mu'_r, W^{T'_r} \rangle > \langle \mu'_q, W^{T_q^*} \rangle + \langle \mu'_r, W^{T_r^*} \rangle$, which implies that $\langle \mu_q, \widehat{w}_{T'_q} \rangle + \langle \mu_r, \widehat{w}_{T'_r} \rangle > \langle \mu_q, \widehat{w}_{T_q^*} \rangle + \langle \mu_r, \widehat{w}_{T_r^*} \rangle$. This contradicts the maximality of P^* for the function $L_2(P)$ over the domain $\mathcal{P}_\Delta$. ◀

5 Proof of Theorem 1

In this section, we prove the following algorithmic result about QVP.

▶ **Theorem 20.** *Given a* QVP *instance* (W, K, Λ, Δ)*, we can compute an optimal solution for this instance in* $\widetilde{\mathcal{O}}(n^{kp^2})$ *time.*

In this section, we will prove Theorem 20 in a restricted setting: we assume that the set W is in General Position (G.P.). The proof for the general case is not very different: using a technical tool to handle degeneracies in W, we can reduce the general case to this restricted case. We defer the proof of Theorem 20 (i.e., the general case) to the full version of the paper, and continue with the proof for this restricted setting.

Observe that the proof of Theorem 1 follows immediately from the above theorem.

Proof of Theorem 1. Let (A, B) be an MSim instance, as defined in the statement of Theorem 1. Using the reduction in Lemma 13, we can compute a QVP instance (W, K, Λ, Δ) in $\widetilde{\mathcal{O}}(n^3)$ with the following property: an optimal solution to this QVP instance can be used to compute an optimal solution for the MSim instance (A, B), in $\mathcal{O}(n)$ time. Using Theorem 20, we can compute an optimal solution for the QVP instance (W, K, Λ, Δ) in $\widetilde{\mathcal{O}}(n^{kp^2})$ time. Therefore, we can compute an optimal solution for the MSim instance in overall $\widetilde{\mathcal{O}}(n^{kp^2})$ time. ◀

5.1 Algorithm for QVP, restricted version

We proceed with the proof of Theorem 20, under the G.P. assumption. In other words, given a QVP instance (W, K, Λ, Δ), the input set W is in General Position. Recall that a set S of n points $w_1, \ldots, w_n \in \mathbb{R}^k$ is said to be in *general position* (G.P.), if there is no subset $S' \subseteq S$ with $|S'| > k$ that lies on a common hyperplane. Moreover, we can associate a unique hyperplane H_S with every k-element subset S of W. Let $\mathcal{H}$ be the set of $\binom{n}{k}$ hyperplanes, defined by each k-element subset of W. Under the G.P. assumption, we can further strengthen Lemma 19, as follows.

▶ **Lemma 21.** *Let* $P^* = (T_1, \ldots, T_p)$ *be an optimal solution for a* QVP *instance* (W, K, Λ, Δ)*. For every pair of sets* $W[T_i]$ *and* $W[T_j]$*, where* $i < j$*, there exists a hyperplane* H_{ij} *in the set* $\mathcal{H}$ *such that* $W[T_i]$ *and* $W[T_j]$ *are weakly linearly separated along* H_{ij}*.*

The proof of this lemma follows immediately from the following claim.

▶ **Claim 22.** *Let* W *be a set of* n *points* $\{w_1, \ldots, w_n\} \subset \mathbb{R}^k$ *in general position, where* $n > k$*. Suppose* W_1, W_2 *are two disjoint subsets of* W *which are weakly linearly separated by a hyperplane* H*. Then, there exists another hyperplane* $\tilde{H}$ *with the following properties: (a)* $\tilde{H}$ *passes through exactly* k *points of* W*, and (b)* $\tilde{H}$ *also weakly linearly separates* W_1, W_2*.*

Enumerative Algorithm. We proceed with an informal description of the algorithm. The overall strategy of our algorithm follows from Lemma 19 and Lemma 21. We will enumerate a particular subset $\mathcal{P}$ of $\mathcal{P}_\Delta$ defined as follows. The set $\mathcal{P}$ is the set of all weakly linearly separated partitions $P = (T_1, \ldots, T_p)$ of W with the following property (stated in Lemma 21). For every pair of sets $W[T_i]$ and $W[T_j]$, where $i < j$, there exists a hyperplane H_{ij} in $\mathcal{H}$ such that $W[T_i]$ and $W[T_j]$ are weakly linearly separated along H_{ij}. Clearly, we can maximize the objective function $F(P)$ *over the set* $\mathcal{P}$, instead of the original domain $\mathcal{P}_\Delta$:

by Lemma 21, an optimal solution must lie in the set $\mathcal{P}$. Therefore, it suffices to prove the following lemma.

▶ **Lemma 23** (Enumeration, under G.P. assumption). *Given a* QVP *instance* (W, K, Λ, Δ)*, assume that the set* W *is in General Position. Then, we can enumerate the set* $\mathcal{P}$ *in* $\widetilde{\mathcal{O}}(n^{kp^2})$ *time.*

Proof. From Lemma 21, we can deduce that a partition $P = (T_1, \ldots, T_p) \in \mathcal{P}$ can be associated with a sequence of $\binom{p}{2}$ separating hyperplanes $H_{ij} \in \mathcal{H}$, $i < j$, $i, j \in [p]$. In particular, the hyperplane H_{ij} weakly linearly separates $W[T_i]$ and $W[T_j]$.

Therefore, we enumerate the set $\mathcal{P}$ as follows. We branch over every choice of $|\mathcal{H}|^{\binom{p}{2}} \leq n^{\frac{kp^2}{2}}$ sequences of hyperplanes. We can define p convex regions $R_1, \ldots, R_p$ using these hyperplanes; the region R_i is supposed to contain the set $W[T_i]$, $i \in [p]$.

We assign the elements of W to these p disjoint convex regions $R_1, \ldots, R_p$. It is possible that an element w_j might lie on one or more of the hyperplanes H_{ij}. For such an 'ambigious' point, we brute-force try all possible p assignments of regions R_i. Since every hyperplane in $\mathcal{H}$ contains exactly k points of W, there can be at most $\binom{p}{2} \cdot k$ such ambigious points: this leads to an additional branching factor of at most $p^{\binom{p}{2} \cdot k}$. For each such branch, we obtain a partition $(W_1, \ldots, W_p)$ of W. If the type of this partition is not equal to Δ, we reject it; otherwise we add it to the list $\mathcal{P}$. The overall branching is bounded by $n^{\frac{kp^2}{2}} \cdot p^{\binom{p}{2} \cdot k}$ which is bounded by $n^{\frac{kp^2}{2}} \cdot n^{\frac{kp^2}{2}} \leq n^{kp^2}$. The overall running time is bounded by $\widetilde{\mathcal{O}}(n^{kp^2})$.

Clearly, every partition P in $\mathcal{P}$ can be discovered along some branch of our computation: we branch over all hyperplane sequences and further, over all assignments of 'ambigious' points. Moreover, every partition enumerated above belongs to $\mathcal{P}$, by our construction. Our overall branching factor of $\widetilde{\mathcal{O}}(n^{kp^2})$ is also an upper bound on the cardinality of $\mathcal{P}$. This finishes the proof of the lemma. ◀

Since we can enumerate the set $\mathcal{P}$ in $\widetilde{\mathcal{O}}(n^{kp^2})$ time, the optimal solution can be computed in a similar time as well. We summarize the above discussion as the following theorem.

▶ **Theorem 24** (QVP algorithm, G.P. assumption). QVP *can be solved in* $\widetilde{\mathcal{O}}(n^{kp^2})$ *running time.*

6 Conclusion

Through our results, we were able to gain insight into the tractibility of the problems GSim and MSim. However, there are a few open threads which remain elusive. The regime of bounded rank k and unbounded parameter $\tau(G)$ is still not fully understood for MSim, in the case of positive semi-definite matrices. It is not clear whether the problem is P-time or NP-hard in this case. Indeed, an $n^{O(k)}$ algorithm for MSim, in the case of positive semi-definite matrices, remains a possibility. From the perspective of parameterized complexity, we can ask if MSim is W[1]-hard, where the parameter of interest is the rank k. Finally, the approximability for the problems MSim deserves further examination, especially for the case of bounded rank.

Abstract

We study the problems of finding a shortest synchronizing word and its length for a given prefix code. This is done in two different settings: when the code is defined by an arbitrary decoder recognizing its star and when the code is defined by its literal decoder (whose size is polynomially equivalent to the total length of all words in the code). For the first case for every $\varepsilon > 0$ we prove $n^{1-\varepsilon}$-inapproximability for recognizable binary maximal prefix codes, $\Theta(\log n)$-inapproximability for finite binary maximal prefix codes and $n^{\frac{1}{2}-\varepsilon}$-inapproximability for finite binary prefix codes. By c-inapproximability here we mean the non-existence of a c-approximation polynomial time algorithm under the assumption P $\neq$ NP, and by n the number of states of the decoder in the input. For the second case, we propose approximation and exact algorithms and conjecture that for finite maximal prefix codes the problem can be solved in polynomial time. We also study the related problems of finding a shortest mortal and a shortest avoiding word.

1 Introduction

Prefix codes are a simple and powerful class of variable-length codes that are widely used in information compression and transmission. A famous example of prefix codes is Huffman's codes [15]. In general, variable length codes are not resistant to errors, since one deletion, insertion or change of a symbol can desynchronize the decoder causing incorrect decoding of all the remaining part of the message. However, in a large class of codes called synchronizing codes resynchronization of the decoder is possible in such situations. It is known that almost all maximal finite prefix codes are synchronizing [12]. Synchronization of finite prefix codes has been investigated a lot [5, 7, 8, 10, 21, 22], see also the book [6] and references therein. For efficiency reasons, it is important to use as short words resynchronizing the decoder as

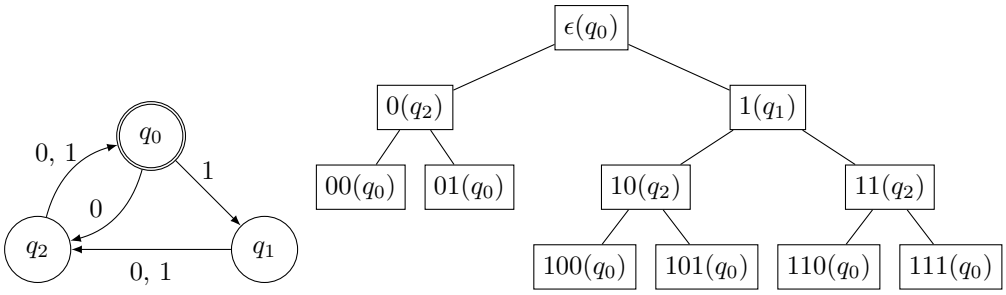

Figure 1 The Wielandt automaton on three states and the tree of the code $0\{0,1\} \cup 1\{0,1\}^2$.

possible to decrease synchronization time. However, despite the interest in synchronizing prefix codes, the computational complexity of finding short synchronizing words for them has not been studied so far. In this paper, we provide a systematic investigation of this topic.

Each recognizable (by a finite automaton) maximal prefix code can be represented by an automaton decoding the star of this code. For a finite code, this automaton can be exponentially smaller than the representation of the code by listing all its words (consider, for example, the code of all words of some fixed length). This can, of course, happen even if the code is synchronizing. An important example here is the code $0\{0,1\}^{n-1} \cup 1\{0,1\}^n$. The minimized decoder of this code is a famous Wielandt automaton with $n+1$ states (see ex. [1]), while the literal automaton contains $2^{n-1} + 2^n$ states, see Figure 1 for the case $n = 3$. In different applications, the first or the second way of representing the code can be useful. In some cases large codes having a short description may be represented by a minimized decoder, while in other applications the code can be described by simply providing the list of all codewords. The number of states of the literal decoder is equal to the number of different prefixes of the codewords, and thus the representations of a prefix code by listing all its codewords and by providing its literal automaton are polynomially equivalent. We study the complexity of problems for both arbitrary and literal decoders of finite prefix codes.

In this paper we study the existence of approximation algorithms for the problem Short Sync Word of finding a shortest synchronizing words in several classes of deterministic automata decoding prefix codes. In Section 2 we describe main definitions and survey existing results in the computational complexity of Short Sync Word. In Section 3 we provide a strong inapproximability result for this problem in the class of strongly connected automata. Section 4 is devoted to the same problem in acyclic automata, which are then used in Section 5 to show logarithmic inapproximability of Short Sync Word in the class of Huffman decoders. In Section 6 we provide a much stronger inapproximability result for partial Huffman decoders. In Section 7 we provide several algorithms for literal Huffman decoders and conjecture that Short Sync Word can be solved in polynomial time in this class. Finally, in Section 8 we apply the developed techniques to the problems of finding shortest mortal and avoiding words.

2 Main Definitions and Related Results

A *partial deterministic finite automaton* (which we simply call a *partial automaton* in this paper) is a triple $A = (Q, \Sigma, \delta)$, where Q is a set of states, Σ is a finite alphabet and $\delta : Q \times \Sigma \to Q$ is a (possibly incomplete) transition function. The function delta can be canonically extended to a function $\delta : Q \times \Sigma^* \to Q$ by defining $\delta(q, wx) = \delta(\delta(q, w), x)$ for

$x \in \Sigma$, $w \in \Sigma^*$. If δ is a complete function, the automaton is called *complete* (in this case we call it just an *automaton*). An automaton is called *strongly connected* if for every ordered pair q, q' of states there is a word mapping q to q'.

A state in a partial automaton is called *sink* if each letter either maps the state to itself or is undefined. A *simple cycle* in a partial automaton $A = (Q, \Sigma, \delta)$ is a sequence $q_1, \dots, q_k$ of its states such that all the states in the sequence are different and there exist letters $x_1, \dots, x_k \in \Sigma$ such that $\delta(q_i, x_i) = q_{i+1}$ for $1 \leq i \leq k-1$ and $\delta(q_k, x_k) = q_1$. A simple cycle is a *self-loop* if it consists of only one state. We call a partial automaton *weakly acyclic* if all its cycles are self-loops, and *strongly acyclic* if moreover all its states with self-loops are sink states. Some properties of these automata have been studied in [19].

There is a strong relation between partial automata and prefix codes [6]. A set X of words is called a *prefix code* if no word in X is a prefix of another word. The class of recognizable (by an automaton) prefix codes can be described as follows. Take a strongly connected partial automaton A and pick a state r in it. Then the set of all *first return words* of r (that is, words mapping r to itself such that each non-empty prefix does not map r to itself) is a recognizable prefix code. Moreover, each recognizable prefix code can be obtained this way. A prefix code is called *maximal* if it is not a subset of another prefix code. The class of maximal recognizable prefix codes corresponds to the class of complete automata. If a state r can be picked in an automaton in such a way that the set of all first return words is a finite prefix code, we call the automaton a *partial Huffman decoder*. If such automaton is complete (and thus the finite prefix code is maximal), we call it simply a *Huffman decoder*.

Let A be a partial automaton. A word w is called *synchronizing* for A if there exists a state q such that w maps each state of A either to q or the mapping of w is undefined for this state, and there is at least one state such that the mapping of w is defined for it. That is, a word is called synchronizing if it maps the whole set of states of the automaton to a set of size exactly one. An automaton having a synchronizing word is called *synchronizing*. A recognizable prefix code is *synchronizing* if a trim (partial) automaton recognizing the star of this code is synchronizing [6] (an automaton is called *trim* if there exists a state such that each state is accessible from this state, and there exists a state such that each state is coaccessible from this state). It can be checked in polynomial time that a strongly connected partial automaton is synchronizing (Proposition 3.6.5 of [6]).

Synchronizing automata have applications in different domains, such as synchronizing codes, symbolic dynamics, manufacturing and testing of reactive systems. They are also the subject of the Černý conjecture, one of the main open problems in automata theory. It stays that every n-state synchronizing automaton has a synchronizing word of length at most $(n-1)^2$, while the best known upper bounds are cubic [17, 24]. See [26] for a survey on this topic. The upper bound on the length of a shortest synchronizing word has been improved in particular for Huffman decoders [2] and further for literal Huffman decoders [5].

We consider the following computational problem.

> Short Sync Word
> *Input*: A synchronizing partial automaton A;
> *Output*: The length of a shortest synchronizing word for A.

Now we shortly survey existing results and techniques in the computational complexity and approximability of finding shortest synchronizing words for deterministic automata. To the best of our knowledge, there are no such results for partial automata. See [23] for an introduction to NP-completeness and [25] for an introduction to inapproximability and gap-preserving reductions.

There exist several techniques of proving that Short Sync Word is hard for different classes of automata. The very first and the most widely used idea is the one of Eppstein [11]. Here, the automaton in the reduction is composed of a set of "pipes", and transitions define the way the active states are changed inside the pipes to reach the state where synchronization takes place. This idea (sometimes extended a lot) allows to prove NP-completeness of Short Sync Word in the classes of strongly acyclic [11], ternary Eulerian [16], binary Eulerian [27], binary cyclic [16] automata. This idea is also used in the proofs of [3] for inapproximability within arbitrary constant factor for binary automata, and for $n^{1-\varepsilon}$-inapproximability for n-state binary automata [13] (the last proof uses the theory of Probabilistically Checkable Proofs). In fact, the proof in [13] holds true for binary automata with linear (in the number of states of the automaton) length of a shortest synchronizing word and a sink state.

Another idea is to construct a reduction from the Set Cover problem. It can be used to show logarithmic inapproximability of the Short Sync Word in weakly acyclic [14] and binary automata [4]. Finally, a reduction from Shortest Common Supersequence provides inapproximability of this problem within a constant factor [14].

In the class of monotonic automata Short Sync Word is solvable in polynomial time: because of the structure of these automata this problem reduces to a problem of finding a shortest words synchronizing a pair of states [20]. For general n-state automata, a $\lceil \frac{n-1}{k-1} \rceil$-approximation polynomial time algorithm exists for every k [14].

3 The Construction of Gawrychowski and Straszak

In this section we briefly recall the construction of a gadget invented by Gawrychowski and Straszak [13] to show $n^{1-\varepsilon}$-inapproximability of the Short Sync Word problem in the general class of automata. Below we will use this construction several times.

Suppose that we have a constraint satisfiablity problem (CSP) with N variables and M constraints such that each constraint is satisfied by at most K assignments (see [13] for the definitions and missing details). Following the results in [13], we can assume that $N, K \leq M^{\varepsilon}$, and also that either the CSP is satisfiable, or at most $\frac{1}{M^{1-\varepsilon}}$ fraction of all constraints can be satisfied by an assignment. It is possible to construct the following ternary automaton A_ϕ in polynomial time. For each constraint C the automaton A_ϕ contains a corresponding binary (over $\{0,1\}$) gadget T_C which is a compressed tree (that is, an acyclic digraph) of height N and the number of states at most N^2K having different leaves corresponding to satisfying and non-satisfying assignments. The automaton A_ϕ also contains a sink state s such that all the leaves corresponding to satisfying assignments are mapped to s, and all other leaves are mapped to the roots of the corresponding trees. The third letter is defined to map all the states of each gadget to its root and to map s to itself. For every $\varepsilon > 0$ it is possible to construct such an automaton with at most $MN^2K \leq M^{1+3\varepsilon}$ states in polynomial time. Moreover, for a satisfiable CSP we get an automaton with a shortest synchronizing word of length at most $N + 1 = O(M^{\varepsilon})$, and for a non-satisfiable CSP the length of a shortest synchronizing word is at least $NM^{1-\varepsilon} \geq M^{1-\varepsilon}$. Since ε can be chosen arbitrary small, this provides a gap-preserving reduction with a gap of $M^{1-\varepsilon}$.

The described construction can be modified to get the same inapproximability in the class of strongly connected automata.

▶ **Theorem 1.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of $n^{1-\varepsilon}$ for every $\varepsilon > 0$ for n-state binary strongly connected automata unless $P = NP$.*

Proof. Consider the automaton A_ϕ described above. Add a new letter c that cyclically permutes the roots of all gadgets, maps s to the root of one of the gadgets and acts as a self-loop for all the remaining states. Observe that thus constructed automaton A is strongly connected and has the property that every non-satisfying assignment satisfies at most the fraction of $\frac{1}{M^{1-\varepsilon}}$ of all constraints. Thus, the gap between the length of a shortest synchronizing word for a satisfying and non-satisfying assignment is still $\Theta(M^{1-\varepsilon})$.

It remains to make the automaton binary. This can be done by using Lemma 3 of [4]. This way we get a binary automaton with $\Theta(M^{1+3\varepsilon})$ states and a gap between $\Theta(M^{\varepsilon})$ and $\Theta(M^{1-\varepsilon})$ in the length of a shortest synchronizing word. By choosing appropriate small enough ε, we get a reduction with gap $n^{1-\varepsilon}$ for binary strongly connected n-state automata, which proves the statement. ◀

4 Acyclic Automata

In this section we investigate the simply-defined classes of weakly acyclic and strongly acyclic automata. The results for strongly acyclic automata are used in Section 5 to obtain inapproximability for Huffman decoders. Even though the automata in the classes of weakly and strongly acyclic automata are very restricted and have a very simple structure, the inapproximability bounds for them are quite strong. Thus we believe that these classes are of independent interest.

We will need the following problem.

> Set Cover
> *Input*: A set X of p elements and a family C of m subsets of X;
> *Output*: A subfamily of C of minimum size covering X.

A family C' of subsets of X is said to *cover* X if X is a subset of the union of the sets in C'. For every $\gamma > 0$, the Set Cover problem with $|C| \leq |X|^{1+\gamma}$ cannot be approximated in polynomial time within a factor of $c' \log p$ for some $c' > 0$ unless P = NP [4].

▶ **Theorem 2.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of $c \log n$ for some $c > 0$ for n-state strongly acyclic automata over an alphabet of size $n^{1+\gamma}$ for every $\gamma > 0$ unless $P = NP$.*

Proof. We reduce the Set Cover problem. Provided X and C, we construct the automaton $A = (Q, \Sigma, \delta)$ as follows. To each set c_k in C we assign a letter $k \in \Sigma$. To each element x_j in X we assign a "pipe" of states $q_1^{(j)}, \ldots, q_p^{(j)}$ in Q. Additionally, we construct a state f in Q.

For $1 \leq i \leq p-1$ and all k and j we define $\delta(q_i^{(j)}, k) = f$ if c_k contains x_j, and $\delta(q_i^{(j)}, k) = q_{i+1}^{(j)}$ otherwise. We also define $\delta(q_p^{(j)}, k) = f$ for all j and k.

We claim that the length of a shortest synchronizing word for A is equal to the minimum size of a set cover in C. Let C' be a set cover of minimum size. Then a concatenation of the letters corresponding to the elements of C' is a synchronizing word of corresponding length.

In the other direction, consider a shortest synchronizing word w for A. No letter appears in w at least twice. If the length of w is less than p, then by construction of A the subset of elements in C corresponding to the letters in w form a set cover. Otherwise we can take an arbitrary subfamily of C of size p which is a set cover (such subfamily trivially exists if C covers X).

The resulting automaton has $p^2 + 1$ states and m letters. Thus we get a reduction with gap $c' \log p \geq c'' \log \sqrt{|Q|} = \frac{1}{2} c'' \log |Q|$ for some $c'' > 0$. Because of the mentioned result of Berlinkov, we can also assume that $m < p^{1+\gamma}$ for arbitrary small $\gamma > 0$. ◀

Now we are going to extend this result to the case of binary weakly acyclic automata.

▶ **Corollary 3.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of* $c \log n$ *for some* $c > 0$ *for* n*-state binary weakly acyclic automata unless* $P = NP$*.*

Proof. We extend the construction from the proof of Theorem 2 by using Lemma 3 of [4]. If we start with a strongly acyclic automaton with p states and k letters, this results in a binary weakly acyclic automaton with $4pk$ states. Moreover, the length of a shortest word of the new automaton is between $\ell(\log k + 1)$ and $(\ell + 1)(\log k + 1)$, where ℓ is the length of a shortest word of the original automaton. Since we can assume $p < k < p^{1+\gamma}$ for arbitrary small $\gamma > 0$, we have $\log n = \Theta(\log p)$, where n is the number of states of the new automaton. Thus we get a gap of $\Theta(\log p) = \Theta(\log n)$. ◀

For ternary strongly acyclic automata it is possible to get $(2 - \varepsilon)$-inapproximability.

▶ **Theorem 4.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of* $2 - \varepsilon$ *for every* $\varepsilon > 0$ *for* n*-state strongly acyclic automata over an alphabet of size three unless* $P = NP$*.*

5 Huffman Decoders

We start with a statement relating strongly acyclic automata to Huffman decoders.

▶ **Lemma 5.** *Let* A *be a synchronizing strongly acyclic automaton over an alphabet of size* k*. Let* ℓ *be the length of a shortest synchronizing word for* A*. Then there exists a Huffman decoder* A_H *over an alphabet of size* $k + 2$ *with the same length of a shortest synchronizing word, and* A_H *can be constructed in polynomial time.*

Proof. Provided a strongly acyclic automaton $A = (Q, \Sigma, \delta)$ we construct a Huffman decoder $A_H = (Q_H, \Sigma_H, \delta_H)$.

Since A is a synchronizing strongly acyclic automaton, it has a unique sink state f. We define the alphabet Σ_H as the union of Σ with two additional letters b_1, b_2. The set of states Q_H is the union of Q with some auxiliary states defined as follows. Consider the set S of states in A having no incoming transitions. Construct a full binary tree with the root f having S as the set of its leaves (if $|S|$ is not a power of two, some subtrees of the tree can be merged). Define b_1 to map each state of this tree to the left child, and b_2 to the right child. Transfer the action of δ to δ_H for all states in Q and all letters in Σ. For all the internal states of the tree define all the letters of Σ to map these states to f. Finally, for all the states in Q define the action of b_1, b_2 in the same way as some fixed letter in Σ.

Observe that any word w over alphabet Σ synchronizing A also synchronizes A_H. In the other direction, any synchronizing word for A_H has to synchronize Q, which means that each state in Q has to be mapped to f first, so the length of a shortest synchronizing word for A_H is at least the length of a shortest synchronizing word for A. ◀

Now we use Lemma 5 to get preliminary inapproximability results for Huffman decoders.

▶ **Corollary 6.**

(i) *The* Short Sync Word *problem is NP-complete for Huffman decoders over an alphabet of size* 4*.*

(ii) *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of* $2 - \varepsilon$ *for every* $\varepsilon > 0$ *for Huffman decoders over an alphabet of size* 5 *unless* $P = NP$*.*

(iii) *For every $\gamma > 0$, the* Short Sync Word *problem cannot be approximated in polynomial time within a factor of $c \log n$ for some $c > 0$ for Huffman decoders over an alphabet of size $n^{1+\gamma}$ unless $P = NP$.*

Proof.

(i) The automaton in the Eppstein's proof of NP-completeness of Short Sync Word [11] is strongly acyclic. Then the reduction described in Lemma 5 can be applied.

(ii) A direct consequence of Theorem 4 and Lemma 5.

(iii) A direct consequence of Theorem 2 and Lemma 5. ◀

Now we show how to get a better inapproximability result for binary Huffman decoders using the composition of synchronizing prefix codes. We present a more general result for the composition of synchronizing codes which is of its own interest. This result shows how to change the size of the alphabet of a synchronizing complete code in such a way that the approximate length of a shortest synchronizing pair for it is preserved.

A set X of words over an alphabet Σ is a *code* if no word can be represented as a concatenation of elements in X in two different ways. In particular, every prefix code is a code. A pair (ℓ_X, r_X) of words in X^* is called *absorbing* if $\ell_X\Sigma^* \cap \Sigma^* r_X \subseteq X^*$. The *length* of a pair is the total length of two word. A code X over an alphabet Σ is called *complete* if every word $w \in \Sigma^*$ is a factor of some word in X^*, that is, if for every word $w \in \Sigma^*$ there exist words $v_1, v_2 \in \Sigma^*$, $u \in X^*$ such that $v_1 w v_2 = u$. In particular, every maximal (by inclusion) code is complete. A complete code having an absorbing pair is called *synchronizing*. We refer to [6] for a survey on the theory of codes.

Let Y be a code over Σ_Y and Z be a code over Σ_Z. Suppose that there exists a bijection $\beta : \Sigma_Y \to Z$. The *composition* $Y \circ_\beta Z$ is then defined as the code $X = \{\beta(y) \mid y \in Y\}$ over the alphabet Σ_Z [6]. Here $\beta(y)$ is defined as $\beta(y_1)\beta(y_2)\dots\beta(y_k)$ for $y = y_1 y_2 \dots y_k$, $y_i \in \Sigma_Y$. Sometimes β is omitted in the notation of composition.

▶ **Theorem 7.** *Let Y and Z be two synchronizing complete codes, such that Z is finite and m and M are the lengths of a shortest and a longest codeword in Z. Suppose that the composition $Y \circ Z$ is defined. Then the code $X = Y \circ Z$ is synchronizing, and the length of a shortest absorbing pair for X is between $m\ell$ and $2M\ell + 2c$, where ℓ is the length of a shortest absorbing pair for Y and c is the length of a shortest absorbing pair for Z.*

Proof. Let $Y \subseteq \Sigma_Y^*$, $X, Z \subseteq \Sigma_Z^*$, and $\beta : \Sigma_Y \to Z$ be such that $X = Y \circ_\beta Z$. First, assume that Y and Z are synchronizing, and let (ℓ_Y, r_Y), (ℓ_Z, r_Z) be shortest absorbing pairs for Y and Z. Then $\ell_Y\Sigma_Y^* \cap \Sigma_Y^* r_Y \subseteq Y^*$ and $\ell_Z\Sigma_Z^* \cap \Sigma_Z^* r_Z \subseteq Z^*$. We will show that $p_1 = (\beta(\ell_Y)\ell_Z r_Z \beta(r_Y), \beta(\ell_Y)\ell_Z r_Z \beta(r_Y))$ is an absorbing pair for X. Consider the set $\beta(\ell_Y)\ell_Z r_Z \beta(r_Y)\Sigma_Z^* \cap \Sigma_Z^*\beta(\ell_Y)\ell_Z r_Z \beta(r_Y)$. It is a subset of the set $\beta(\ell_Y)(\ell_Z\Sigma_Z^* \cap \Sigma_Z^* r_Z)\beta(r_Y) \subseteq \beta(\ell_Y)Z^*\beta(r_Y) = \beta(\ell_Y\Sigma_Y^* r_Y) \subseteq \beta(Y^*) = X^*$. Thus, p_1 is an absorbing pair for X. Moreover, the length of this pair is between $2m(|\ell_Y| + |r_Y|) + 2(|\ell_Z| + |r_Z|)$ and $2M(|\ell_Y| + |r_Y|) + 2(|\ell_Z| + |r_Z|)$.

Conversely, assume that (ℓ_X, r_X) is a shortest absorbing pair for X, hence $\ell_X\Sigma_Z^* \cap \Sigma_Z^* r_X \subseteq X^*$. Then by the definition of composition $X^* \subseteq Z^*$ and $\ell_X, r_X \in Z^*$; thus, (ℓ_X, r_X) is also absorbing for Z. Next, let $\ell_Y = \beta^{-1}(\ell_X)$, $r_Y = \beta^{-1}(r_X)$, $\ell_Y, r_Y \in Y^*$. Then $\beta(\ell_Y\Sigma_Y^* \cap \Sigma_Y^* r_Y) = \ell_X Z^* \cap Z^* r_X \subseteq \ell_X\Sigma_Z^* \cap \Sigma_Z^* r_X \subseteq X^* = \beta(Y^*)$. Since the mapping β is injective, $\ell_Y B^* \cap B^* r_Y \subseteq Y^*$. Consequently Y is synchronizing, and (ℓ_Y, r_Y) is an absorbing pair for it of length between $\frac{1}{M}(|\ell_X| + |r_X|)$ and $\frac{1}{m}(|\ell_X| + |r_X|)$.

Summarizing, we get that the length of a shortest absorbing pair for X is between $m(|\ell_Y| + |r_Y|)$ and $2M(|\ell_Y| + |r_Y|) + 2(|\ell_Z| + |r_Z|)$. ◀

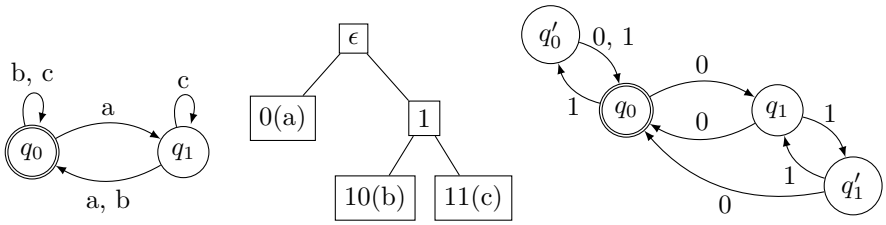

Figure 2 An automaton recognizing some infinite maximal prefix code, the tree of a finite maximal prefix code and an automaton recognizing their composition.

In the case of maximal prefix codes the first element of the absorbing pair can be taken as an empty word. For recognizable maximal prefix codes Y and Z, where Z is finite, a Huffman decoder recognizing the star of $X = Y \circ Z$ can be constructed as follows. Let H_Y be a Huffman decoder for Y. Consider the full tree T_Z for Z, where each edge is marked by the corresponding letter. For each state q in H_Y we substitute the transitions going from this state with a copy of T_Z as follows. The root of T_Z coincides with q, and the inner vertices are new states of the resulting automaton. Suppose that v is a leaf of T_Z, and the path from the root to v is marked by a word w. Let a be the letter of the alphabet of H_Y which is mapped to the word w in the composition. Then the image of q under the mapping defined by a is merged with v. In such a way we get a Huffman decoder with $\Theta(n_Y n_Z)$ states, where n_Y, n_Z is the number of states in H_Y and T_Z. By the definition of composition, this decoder has the same alphabet as Z. See Figure 2 for an example.

▶ **Corollary 8.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of $c \log n$ for some $c > 0$ for binary n-states Huffman decoders unless $P = NP$.*

Proof. We start with claim (iii) in Corollary 6 and use Theorem 7 to reduce the size of the alphabet. Thus, we reduce Short Sync Word for Huffman decoders over an alphabet of size $n^{1+\gamma}$ to Short Sync Word for binary Huffman decoders.

Assume that the size of the alphabet $k = n^{1+\gamma}$ is a power of two (if no, duplicate some letter the required number of times). We take the code $0\{0,1\}^{\log k - 1} \cup 1\{0,1\}^{\log k}$ as Z. This is a code where some words are of length $\log k$ and the other words are of length $\log k + 1$ (after minimization the star of this code is recognized by a Wielandt automaton with $\log k + 1$ states discussed in the introduction). This code has a synchronizing word of length $\Theta((\log k)^2)$ [1]. The number of vertices in the tree of this code is $\Theta(n)$.

Let ℓ be the length of a shortest synchronizing word for the original automaton. By Theorem 7, the length of a shortest synchronizing word for the result of the composition is between $\ell \log k$ and $2(\log k + 1)\ell + \Theta((\log k)^2) = \Theta((\ell + \log k) \log k)$.

For the Set Cover problem the inapproximability result holds even if we assume that the size of the optimal solution is of size at least $d \log |X|$ for some $d > 0$. Indeed, if d is a constant we can check all the subsets of C of size at most $d \log |X|$ in polynomial time. Thus, we can assume that $\ell \geq \log k$ implying $(\ell + \log k) \log k = \Theta(\ell \log k)$. Hence after the composition the length of a shortest synchronizing word is changed by at most constant multiplicative factor, and we we get a gap-reserving reduction with gap $\Theta(\log n)$. The resulting automaton is of size $\Theta(n^{2+\gamma})$, and the $(2 + \gamma)$ dependence is hidden in the constant c in the statement of this corollary. ◀

6 Partial Huffman Decoders

In this section we investigate automata recognizing the star of a non-maximal finite prefix code. Such codes have some noticeable properties which do not hold for maximal finite prefix codes. For example, there exist non-trivial non-maximal finite prefix codes with finite synchronization delay, which provides guarantees on the synchronization time [9]. This allows to read a stream of correctly transmitted compressed data from arbitrary position, which can be useful for audio and video decompression.

First we show that the known upper bounds and approximability for Short Sync Word hold true for strongly connected partial automata. Because of Proposition 3.6.5 of [6], Algorithm 1 of [26] works without any changes for strongly connected partial automata. The analysis of its approximation ratio is the same as in [14]. Thus we get the following.

▶ **Theorem 9.** *There exists a polynomial time algorithm (Algorithm 1 of [26]) finding a synchronizing word of length at most* $\frac{n^3-n}{6}$ *for a* n*-state strongly connected partial automaton. Moreover, this algorithm provides a* $O(n)$*-approximation for the* Short Sync Word *problem.*

Now we provide a lower bound on the approximability of the Short Sync Word problem for partial Huffman decoders by extending the idea used to prove inapproximability for Huffman decoders in the previous sections. First we prove the result for alphabet of size 5 and then use a composition with a maximal finite prefix code to get the same result for the binary case.

▶ **Theorem 10.** *The* Short Sync Word *problem cannot be approximated within a factor of* $n^{\frac{1}{2}-\varepsilon}$ *for every* $\varepsilon > 0$ *for* n*-state partial Huffman decoders over an alphabet of size* 5 *unless* $P = NP$*.*

Proof. First we prove inapproximability for the class of partial strongly acyclic automata, that is, automata having no simple cycles but loops in the sink state. We start with the CSP problem described in Section 3 with all the restriction defined there. Having an instance of this problem with N variables and M constraints such that each constraint is satisfied by at most K assignments, we construct an automaton A^b_ϕ over the alphabet $\{0, 1\}$. For each constraint j, we construct M identical compressed trees $T^1_j, \dots, T^M_j$ corresponding to this constraint (also described in Section 3). Then for $1 \le i \le M-1$ we merge the leaves of T^i_j corresponding to non-satisfying assignments with the root of T^{i+1}_j, and delete all the leaves corresponding to satisfying assignments (leaving all the transition leading to deleted states undefined). For each T^M_j, we again delete all the leaves corresponding to satisfying assignments and merge all the leaves corresponding to non-satisfying assignments with a new state s. This state is a self-loop, that is, $0, 1$ map s to itself. Now we define an additional letter a and M new states $r_1, \dots, r_M$. We define a to map r_j to the root of T^1_j. Finally, we add $N+1$ new states $c_0, \dots, c_N$ such that a maps c_0 to c_1, and $0, 1$ map c_i to c_{i+1} for $1 \le i \le N-1$, and map c_N to s. All other transitions are left undefined.

If a is applied first, the set S of states to be synchronized is c_1 together with the roots of T^1_j for all j. Observe that a cannot be applied anymore, since it would result in mapping all the active states of the automaton to void. If a letter other than a is applied first, a superset of S must be synchronized then.

If there exists a satisfying assignment $x_1, \dots, x_N$ then the word $ax_1 \dots x_N$ is synchronizing, since it maps all the states but c_0 to void. Otherwise, to synchronize the automaton we need to pass through M compressed trees, since each tree can map only at most M^ε states to void (since for every non-satisfiable CSP the maximum number of satisfiable constraints is

M^ε in the construction, see Section 3). Thus we get a gap of $M^{1-\varepsilon} = n^{\frac{1}{2}-\varepsilon}$ for the class of n-state strongly acyclic partial automata.

Now we are going to transfer this result to the case of partial Huffman decoders. We extend the idea of Lemma 5. All we need is to define transitions leading from s to the states having no incoming transitions (which are $r_1, \ldots, r_M$ together with c_0). The only difference is that now we have to make sure that a cannot be applied too early resulting in mapping all the states of the compressed trees to void leaving the state s active.

To do that, we introduce two new letters b_1, b_2 and perform branching as described in Lemma 5. Thus we get $M+1$ leaves of the constructed full binary tree. To each leave we attach a chain of states of length MN ending in the root of T_j^1 (or in c_0). This means that we introduce MN new states and define the letters b_1, b_2 to map a state in each chain to the next state in the same chain. This guarantees that if the letter a appears twice in a word of length at most MN, this word maps all the states of the automaton to void. Finally, the action of b_1, b_2 on the compressed trees and the states $c_0, \ldots, c_N$ repeats, for example, the action of the letter 0.

The number of states of the automaton in the construction is $O(M^{2+3\varepsilon})$ The gap is then $M^{1-2\varepsilon}$. By choosing small enough ε we thus get a gap of $n^{\frac{1}{2}-\varepsilon}$ as required. ◀

The next lemma shows that under some restrictions it is possible to reduce the alphabet of a non-maximal prefix code in a way that approximate length of a shortest synchronizing word is preserved. A word is called *non-mortal* for a prefix code X if it is a factor of some word in X^*.

▶ **Lemma 11.** *Let Y, Z be synchronizing prefix codes such that Z is finite and maximal. Let m and M be the lengths of a shortest and a longest codeword in Z. Suppose that $Y \circ_\beta Z$ is defined for some β. If there exists a synchronizing word w_Z for Z such that $\beta^{-1}(w)$ is a non-mortal word for Y, then the composition $X = Y \circ_\beta Z$ is synchronizing. Moreover, then the length of a shortest synchronizing word for X is between $m\ell$ and $M\ell + |w_Z|$, where ℓ is the length of a shortest synchronizing word for Y.*

Proof. Let $Y \subseteq \Sigma_Y^*$, $X, Z \subseteq \Sigma_Z^*$, and $\beta : \Sigma_Y \to Z$ be such that $X = Y \circ_\beta Z$. Let w_Y be a synchronizing word for Y. Then $w_Z\beta(w_Y)$ is a synchronizing word for X of length at most $M\ell + |w_Z|$. In the other direction, let w_X be a synchronizing word for X. Then $\beta^{-1}(w_X)$ is a synchronizing word for Y. Thus, $|w_X| \geq m\ell$. ◀

▶ **Corollary 12.** *The* Short Sync Word *problem cannot be approximated in polynomial time within a factor of $n^{\frac{1}{2}-\varepsilon}$ for every $\varepsilon > 0$ for binary n-state partial Huffman decoders unless $P = NP$.*

Proof. We use the composition of the automaton constructed in the proof of Theorem 10 with the prefix code $\{aaa, aab, ab, ba, bb\}$ having a synchronizing word $baab$. The word $baab$ is a concatenation of two different codewords, so their pre-images can be taken to be a and 0, resulting in a non-mortal word $a0$ for A, so we can use Lemma 11. ◀

7 Literal Huffman Decoders

In this section we deal with literal Huffman decoders. Given a finite maximal prefix code X over an alphabet Σ, the literal automaton recognizing X^* is an automaton $A = (Q, \Sigma, \delta)$ defined as follows. The states of A correspond to all proper prefixes of the words in X, and the transition function is defined as

$$\delta(q,x) = \begin{cases} qx & \text{if } qx \notin X, \\ \epsilon & \text{if } qx \in X \end{cases}$$

We will need the following useful lemma. The *rank* of a word $w \in \Sigma^*$ with respect to an automaton $A = (Q, \Sigma, \delta)$ is the size of the image of Q under the mapping defined by w.

▶ **Lemma 13** ([5, Lemma 16]). *For every n-state literal Huffman decoder over an alphabet of size k there exists a word of length $\lceil \log_k n \rceil$ and rank at most $\lceil \log_k n \rceil$.*

Note that if a n-state literal Huffman decoder has a synchronizing word of length at most $O(\log n)$, this word can be found in polynomial time by examining all words of length up to $O(\log n)$. Thus, in further algorithms we will assume that the length of a shortest synchronizing word is greater than this value. Lemma 13 stays that a word of rank at most $\lceil \log_k n \rceil$ can also be found in polynomial time.

▶ **Theorem 14.** *There exists a $O(\log n)$-approximation polynomial time algorithm for the* Short Sync Word *problem for literal Huffman decoders.*

Proof. Let $A = (Q, \Sigma, \delta)$ be a literal Huffman decoder, and $|\Sigma| = k$. Let w be a word of rank at most $\lceil \log_k n \rceil$ found as described above. Let Q' be the image of Q under the mapping defined by w, i.e. $Q' = \delta(Q, w)$. Define by v the word subsequently merging pairs of states in Q' with shortest possible words. Note than a shortest word synchronizing A has to synchronize every pair of states, in particular, one that requires a longest word. Thus the length of v is at most $\lceil \log_k n \rceil$ times greater than the length of a shortest word synchronizing A. Then the word wv is a $O(\log n)$-approximation for the Short Sync Word problem. ◀

▶ **Theorem 15.** *For every $\varepsilon > 0$, there exists a $(1+\varepsilon)$-approximation $O(n^{\log n})$-time algorithm for the problem* Short Sync Word *for n-state literal Huffman decoders.*

Proof. Let $A = (Q, \Sigma, \delta)$ be a literal Huffman decoder, and $|\Sigma| = k$. First we check all words of length at most $\frac{1}{\varepsilon}\lceil \log_k n \rceil$, whether they are synchronizing. The number of these words is polynomial, and the check can be performed in polynomial time. If a synchronizing word is found then we have an exact solution. Otherwise, a shortest synchronizing word must be longer than that and we proceed to the second stage.

Let w be a word of rank at most $\lceil \log_k n \rceil$ found as before. Now we construct the power automaton $A^{\leq \lceil \log_k n \rceil}$ restricted to all the subsets of size at most $\lceil \log_k n \rceil$. Using it, we find a shortest word synchronizing the subset $\delta(Q, w)$; let this word be v. We return wv.

Let w' be a shortest synchronizing word for $|A|$. Clearly, $|w'| \geq |v|$ and $\varepsilon|w'| > \lceil \log_k n \rceil$. Thus $|wv| \leq (1+\varepsilon)|w'|$, so wv is a $(1+\varepsilon)$-approximation as required. ◀

In view of the presented results we propose the following conjecture.

▶ **Conjecture 16.** *There exists an exact polynomial time algorithm for the* Short Sync Word *problem for literal Huffman decoders.*

Finally, we remark that it is possible to define the notion of the literal automaton of a non-maximal finite prefix code in the same way. In this case we leave undefined the transitions for a state w and a letter a such that w is a proper prefix of a codeword, but wa is neither a proper prefix of a codeword nor a codeword itself. However, the statement of Lemma 13 is false for partial automata. Indeed, consider a two-word prefix code $\{(0^n1^n)^n, (1^n0^n)^n\}$. Its literal automaton has $2n^2 - 1$ states, and a shortest synchronizing word for it is 0^{n+1} of length $n+1$. Every word of length at most n which is defined for at least one state is of the form 0^*1^* or 1^*0^* and thus has rank at least $n-1$.

8 Mortal and Avoiding Words

A word w is called *mortal* for a partial automaton A if its mapping is undefined for all the states of A. The techniques described in this paper can be easily adapted to get the same inapproximability for the Short Mortal Word problem defined as follows.

> Short Mortal Word
> *Input*: A partial automaton A with at least one undefined transition;
> *Output*: The length of a shortest mortal word for A.

This problem is connected for instance to the famous Restivo's conjecture [18].

▶ **Theorem 17.** *Unless $P = NP$, the* Short Mortal Word *problem cannot be approximated in polynomial time within a factor of*

(i) $n^{1-\varepsilon}$ *for every $\varepsilon > 0$ for n-state binary strongly connected partial automata;*

(ii) $c \log n$ *for some $c > 0$ for n-state binary partial Huffman decoders.*

Proof. It can be seen that in Theorem 1 and Corollary 8 we construct an automaton with a state s such that each state has to visit s before synchronization. Introduce a new state s' having all the transitions the same as s, and for s set the only defined transition (for an arbitrary letter) to map to s'. Thus we get an automaton such that every mortal word has to map each state to s before mapping it to nowhere. Thus we preserve all the estimations on the length of a shortest mortal word, which proves both statements. ◀

Moreover, it is easy to get a $O(\log n)$-approximation polynomial time algorithm for Short Mortal Word for literal Huffman decoders following the idea of Theorem 14. Indeed, it follows from Lemma 13 that either there exists a mortal word of length at most $\lceil \log_k n \rceil$, or there exists a word w of rank at most $\lceil \log_k n \rceil$. In the latter case we can find a word which is a concatenation of w and a shortest word mapping all this states to nowhere one by one. By the arguments similar to the proof of Theorem 14 we then get the following.

▶ **Proposition 18.** *There exists a $O(\log n)$-approximation polynomial time algorithm for the* Short Mortal Word *problem for n-state literal Huffman decoders. This algorithm always finds a mortal word of length $O(n \log n)$.*

Another connected and important problem is to find a shortest avoiding word. Given an automaton $A = (Q, \Sigma, \delta)$, a word w is called *avoiding* for a state $q \in Q$ if q is not contained in the image of Q, that is, $q \notin \delta(Q, w)$. Avoiding words play an important role in the recent improvement on the upper bound on the length of a shortest synchronizing word [24]. They are in some sense dual to synchronizing words.

> Short Avoiding word
> *Input*: An automaton A and its state q admitting a word avoiding q;
> *Output*: The length of a shortest word avoiding q in A.

If q is not the root of a literal Huffman decoder A (that is, not the state corresponding to the empty prefix), then a shortest avoiding word consists of just one letter. So avoiding is non-trivial only for the root state.

▶ **Proposition 19.** *For every $\varepsilon > 0$, there exists a $(1 + \varepsilon)$-approximation $O(n^{\log n})$-time algorithm for the problem* Short Sync Word *for n-state literal Huffman decoders.*

Proof. We use the same algorithm as in the proof of Theorem 15. The only difference is that we check whether the words are avoiding instead of synchronizing. ◀

9 Concluding Remarks

For prefix codes, a synchronizing word is usually required to map all the states to the root [6]. One can see that this property holds for all the constructions of the paper. Moreover, in all the constructions the length of a shortest synchronizing word is linear in the number of states of the automaton. Thus, if we restrict to this case, we still get the same inapproximability results. Also, it should be noted that all the inapproximability results are proved by providing a gap-preserving reduction, thus proving NP-hardness of approximating the Short Sync Word problem within a given factor.

Abstract

We study the ability of efficient quantum verifiers to decide properties of exponentially large subsets given either a classical or quantum witness. We develop a general framework that can be used to prove that QCMA machines, with only classical witnesses, cannot verify certain properties of subsets given implicitly via an oracle. We use this framework to prove an oracle separation between QCMA and QMA using an "in-place" permutation oracle, making the first progress on this question since Aaronson and Kuperberg in 2007 [3]. We also use the framework to prove a particularly simple standard oracle separation between QCMA and AM.

1 Introduction

How much computational power does an efficient quantum verifier gain when given a polynomial sized quantum state to support the validity of a mathematical claim? In particular, is there a problem that can be solved in this model, that cannot be solved if the verifier were instead given a classical bitstring? This question, the so-called QMA vs. QCMA problem, is fundamental in quantum complexity theory. To complexity theorists, the question can be motivated simply by trying to understand the power of quantum nondeterminism, where both QMA and QCMA can be seen as "quantum analogues" of NP. More physically, QMA is characterized by the k-local Hamiltonian problem, in which we must decide if the ground state energy of a local Hamiltonian is above or below a specified threshold [16, 5]. In this setting, the QMA vs. QCMA question asks whether there exists a purely *classical* description of the ground state that allows us to make this decision. For instance, if the ground state of any local Hamiltonian can be prepared by an efficient quantum circuit, then QMA = QCMA, as the classical witness for the k-local Hamiltonian problem would be the

classical description of this quantum circuit. It was this intuition that caused Aharonov and Naveh to conjecture that these classes are equal, in the paper that first defined QCMA [5].

It was recently established [12] that the witness to a QMA machine may always be replaced by a subset state, where a subset state on n qubits has the form $|S\rangle = 1/\sqrt{|S|}\sum_{i\in S}|i\rangle$ for some subset $S \subset [2^n]$. However, it seems difficult to create a classical witness on n bits that captures the information in a subset state $|S\rangle$. Therefore, problems involving subsets seem like ripe ground for understanding the QMA vs. QCMA problem. We investigate the following question: under what circumstances is it possible for a quantum machine to verify properties of a subset? This question is not answered by [12]; they study general properties of languages that are in QMA and QCMA, while we attempt to prove specific languages of interest (that are related to subsets) are either in or not in QMA or QCMA.

In the hopes of further exploring these questions, we exhibit a general framework that can be used to obtain oracle separations against QCMA for subset-based problems. We use this framework to prove the existence of an "in-place" permutation oracle $\boldsymbol{\mathcal{P}}$ (a unitary that permutes standard basis states within a single register) [10, 2] for which $\mathsf{QMA}^{\boldsymbol{\mathcal{P}}} \not\subseteq \mathsf{QCMA}^{\boldsymbol{\mathcal{P}}}$, making the first progress on this problem since Aaronson and Kuperberg in 2007 [3], who attained a "quantum oracle" separation (i.e., a separation relative to an *arbitrary* black-box unitary transformation acting on a polynomial number of qubits). In this problem, for the case of QMA, the in-place permutation oracle allows us to verify that the given witness is indeed the correct subset state. On the other hand, our framework allows us to prove the language is not in QCMA. Our framework is quite general, and we are also able to use it to establish a particularly simple example of a (conventional) oracle $\boldsymbol{\mathcal{O}}$ so that $\mathsf{AM}^{\boldsymbol{\mathcal{O}}} \not\subseteq \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.[1]

1.1 Subset-Verifying Oracle Problems

We consider two oracle problems related to verifying properties of subsets. In *Subset Size Checking*, we are given a black box function $f : [N^2] \to \{0, 1\}$, that marks elements with either a 0 or 1. We are promised that the number of marked items is either N or $0.99N$, and we would like to decide which is the case. We want to verify the size of the subset marked by f.

In the other oracle problem, *Preimage Checking*, we are given a black box permutation on N^2 elements. We are promised that the preimage of the first N elements under the permutation is either mostly even or mostly odd, and we would like to decide which is the case. In this problem, we want to verify this parity property of a subset of the preimage of the function.

Subset Size Checking is in AM [11], and we give a procedure that proves *Preimage Checking* is in QMA when the permutation is given as an in-place quantum oracle. An in-place permutation unitary $\mathcal{P}_\sigma$ acts as $\mathcal{P}_\sigma|i\rangle = |\sigma(i)\rangle$ for a permutation σ. For *Preimage Checking*, we are interested in the set $S_{\mathrm{pre}}(\sigma) = \{i : \sigma(i) \in [N]\}$. Given the subset state $|S_{\mathrm{pre}}(\sigma)\rangle$, it is easy to verify that the correct state was sent, because $\mathcal{P}_\sigma|S_{\mathrm{pre}}(\sigma)\rangle = |[N]\rangle$, which is easy to verify using a measurement in the Hadamard basis.

However, we do not expect subset-based oracle languages like *Subset Size Checking* and *Preimage Checking* to be in QCMA because the classical witness does not have enough information to identify the relevant subset. We make this intuition more precise by providing a general recipe for proving that subset-verifying oracle languages are not in QCMA. We

[1] Note there was previously an example of an oracle separating AM from PP [20]. Since QMA $\subseteq$ PP [18], this is formally a stronger result. Nonetheless, our oracle is substantially different, and uses completely different ideas.

apply this procedure to show that both *Preimage Checking* (with a randomized in-place oracle - see Section 3 for more details) and *Subset Size Checking* are not in QCMA. The procedure involves familiar tools, like the adversary bound [6] (although adapted to our in-place oracle when necessary), as well as a new tool, the *Fixing Procedure*, which finds subsets with nice structure within a large arbitrary set. We now sketch the recipe:

1. We show that for every QCMA machine, there are more valid oracles than possible classical witnesses, so by a counting argument, there must be one classical witness w^* that corresponds to a large number of potential oracles. We then restrict ourselves to considering oracles that correspond to w^*.
2. Because we are considering subset-verifying problems, if we have a collection of black box functions that corresponds to w^*, we immediately have some set of subsets that corresponds to w^*. At this point, we know nothing about this set of subsets except its size, thanks to the counting argument. We next show (using the *Fixing Procedure*) that if we have a set of subsets of a certain size, we can always find a subset of the original set that has nice structure.
3. We apply the adversary bound to the subset with nice structure to show that the number of quantum queries needed to distinguish between YES and NO cases is exponential.
4. We finally put these pieces together in a standard diagonalization argument.

1.2 Technical Contributions

Our adversary bound for in-place permutation oracles provides a query lower-bounding technique for unitary oracles when access is *not* given to the inverse of the oracle. (While Belovs [9] created an adversary bound for arbitrary unitaries, his results assume access to an inverse.) While we typically assume quantum oracles include access to an inverse or are self-inverting, in open quantum systems it is natural to not have an inverse.

When proving that *Preimage Checking* is not in QCMA, we use an oracle that is not unitary. The oracle is a completely-positive trace-preserving (CPTP) map that at each application applies one unitary chosen uniformly at random from among a set of unitaries. Standard lower bounding techniques fail for such an oracle. The closest result is from Regev and Schiff [19] who give a lower bound on solving Grover's problem with an oracle that produces errors. Regev and Schiff deal with the non-unitarity of the map by modeling the state of the system using pure states. This strategy does not work in our case. Instead, we use the fact that every non-unitary CPTP map can be implemented as a unitary on a larger system. In our case, we simulate our random oracle using a unitary black box oracle acting on subsystem B, followed by a fixed unitary that entangles subsystems A and B. The entangling operation can not be efficiently implemented, but as we are bounding query complexity, this is acceptable. This technique may be of use for similar problems; for example, we do not know the query complexity of solving Grover's problem with an oracle that produces a depolarizing error with each application. A depolarizing map is similar to our CPTP map in that both maps can be thought of as applying a unitary at random from among a set of unitaries, and so perhaps this approach will stimulate new approaches for the Grover problem.

1.3 Impact and Directions for Future Research

While Aaronson and Kuperberg have previously proved an oracle separation between QMA and QCMA [3], their oracle seems to be especially quantum, as it is defined by a Haar random quantum state. Our in-place oracle has more of a classical feel, in that it encodes

a classical permutation function. However, it is still not a standard quantum oracle, as it is not self-inverting. Is there a standard (i.e. not in-place) oracle language that separates QMA and QCMA? Although we can only prove a separation when our in-place oracle also has randomness, we believe our techniques could be adapted to prove a similar result but without oracle randomness. While we give a recipe for showing certain subset-based problems are not in QCMA, we believe some of these problems are also not in QMA; for example, is it possible to prove *Subset Size Checking* is not in QMA?

Our contributions to techniques for lower bounding query complexity for non-standard oracles raise several questions. Is there a general adversary bound [14, 17] for in-place permutation oracles? There are examples of problems for which in-place permutation oracles require exponentially fewer queries that standard permutation oracles e.g., [7]. We conjecture that there are also examples of problems for which standard permutation oracles require exponentially fewer queries than in-place oracles. In fact, we do not believe it is possible to obtain a Grover-type speed-up with an in-place oracle; we believe the problem of determining the inverse of an element of an in-place permutation oracle requires N queries for a permutation on N elements. However, in order to prove these results, we suspect one needs a more powerful tool, like a general adversary bound for in-place oracles.

1.4 Organization

The rest of the paper is organized as follows, in Section 2, we introduce notation that will be used throughout the rest of the paper, and define QMA and QCMA. In Section 3, we define and discuss standard, in-place, and randomized in-place quantum permutations, as well as state an adversary lower bound for in-place permutation unitaries. In Section 4, we describe the *Preimage Checking* Problem and prove it is in QMA. In Section 5, we lay out the general recipe for proving subset-based languages are not in QCMA. In Section 6, we apply this procedure to the *Subset Size Checking* problem, and use it to prove an oracle separation between AM and QCMA. Finally, in Section 7, we apply the procedure to *Preimage Checking* and show this problem is not in QCMA.

2 Definitions and Notation

We use the notation $[M] = \{1, 2, \ldots, M\}$. σ will refer to a permutation. Unless otherwise specified, the sets we use, generally denoted S, will be a set of positive integers. Also, we will use bold type-face to denote a set of sets. For instance, $\mathbf{S}$ will refer to a set of sets of positive integers. To make our notation clearer, we will refer to such a set of sets as a *set family*. Likewise, we denote $\boldsymbol{\sigma}$ to be a set of permutations acting on the same set of elements.

For S a set of positive integers, a subset state $|S\rangle$ is $|S\rangle = \frac{1}{\sqrt{|S|}} \sum_{i \in S} |i\rangle$.

Throughout, we use $N = 2^n$. All logarithms are in base 2. We use $\boldsymbol{\sigma}^n$ to be the set of permutations acting on N^2 elements. That is, if $\sigma \in \boldsymbol{\sigma}^n$, $\sigma : [N^2] \to [N^2]$. For positive integers $i > j$, let $\mathbf{C}(i, j)$ be the set family containing j elements of $[i]$: $\mathbf{C}(i, j) = \{S \subset [i] : |S| = j\}$.

We use calligraphic font $\mathcal{P}, \mathcal{U}$ to denote unitary operations. We use elaborated calligraphic font $\mathscr{P}$, $\mathscr{U}$ to denote CPTP maps. For a unitary CPTP map $\mathscr{U}$ acting on a density matrix ρ, we have $\mathscr{U}(\rho) = \mathcal{U}\rho\mathcal{U}^\dagger$, where $(\cdot)^\dagger$ denotes conjugate transpose. We will use $\mathcal{O}$ to denote a unitary oracle, and $\mathscr{O}$ to denote a CPTP map oracle.

We include the following standard definition for completeness (e.g., see also [1, 3]).

▶ **Definition 1.** QMA is the set of promise problems $A = (A_{Yes}, A_{No})$ so that there exists an efficient quantum verifier V_A and a polynomial $p(\cdot)$:

1. *Completeness*: For all $x \in A_{Yes}$ there exists a $p(|x|)$-qubit pure quantum state $|\psi\rangle$ so that $\Pr[V_A(x, |\psi\rangle) = 1] \geq 2/3$
2. *Soundness*: For all $x \in A_{No}$ and any pure quantum state $|\psi\rangle$, $\Pr[V_A(x, |\psi\rangle) = 1] \leq 1/3$.

QCMA is the same class, with the witness $|\psi\rangle$ replaced by a polynomial length classical bitstring.

3 Permutation Maps

3.1 Permutations as Oracles: In-Place Permutation vs. Standard Permutation

Black box permutation unitaries have been considered previously, most notably in the collision and element distinctness problems [2, 4]. However, the unitaries considered in these works were standard oracles. A standard oracle implements the permutation $\sigma \in \boldsymbol{\sigma}^n$ as $\mathcal{P}_\sigma^{\text{stand}}|i\rangle|b\rangle = |i\rangle|b \oplus \sigma(i)\rangle$ for $i, b \in [N^2]$, where $|i\rangle$ for $i \in [N^2]$ are standard basis states and $\oplus$ denotes bitwise XOR. Note that $(\mathcal{P}_\sigma^{\text{stand}})^2 = \mathbb{I}_{N^4}$; that is, acting with the unitary twice produces the $N^4 \times N^4$ identity operation.

We consider in-place permutation unitaries, which implement the permutation $\sigma \in \boldsymbol{\sigma}^n$ as $\mathcal{P}_\sigma|i\rangle = |\sigma(i)\rangle$. In general $(\mathcal{P}_\sigma)^2 \neq \mathbb{I}_{N^2}$. Crucially, given black box access to $\mathcal{P}_\sigma$, *we do not give black box access to its inverse.* In fact, in Section 3.2, we show that given only $\mathcal{P}_\sigma$, it is hard to invert its action. Non-self-inverting permutation unitaries have been considered previously, in [10, 2].

We believe standard and in-place permutation unitaries are of incomparable computational power. That is, given one type that implements σ, you can not efficiently simulate the other type implementing the permutation σ. For example, if we have the state $\sum_{y \in S} |y\rangle|\sigma(y)\rangle$ (normalization omitted), we can create the state $\sum_{y \in S} |y\rangle|0\rangle$ with a single query to $\mathcal{P}_\sigma^{\text{stand}}$. However, if we only have access to the in-place permutation $\mathcal{P}_\sigma$ and not to $\mathcal{P}_{(\sigma)^{-1}} = (\mathcal{P}_\sigma)^{-1}$, it seems difficult to create this state.

On the other hand, suppose we want to prepare the state $\sum_{y \in [N]} |\sigma(y)\rangle$ (normalization omitted). We can create this state in one query to the in-place permutation oracle $\mathcal{P}_\sigma$ by applying the oracle to the uniform superposition $\sum_{y \in [N]} |y\rangle$. In the standard model, this problem is called "index erasure," and requires an exponential number of queries in n to $\mathcal{P}_\sigma^{\text{stand}}$ [7].

3.2 An Adversary Bound for In-Place Permutation Oracles

In Appendix A, we prove a non-weighted adversary bound for in-place permutations oracles that is identical to what Ambainis proves in Theorem 6 in [6] for standard permutation oracles.

▶ **Lemma 2.** *Let $\boldsymbol{\sigma} \subset [V] \to [V]$ be a subset of permutations acting on the elements $[V]$. Let $f : \boldsymbol{\sigma} \to \{0, 1\}$ be a function of permutations. Let $\boldsymbol{\sigma}_X \subset \boldsymbol{\sigma}$ be a set of permutations such that if $\sigma \in \boldsymbol{\sigma}_X$, then $f(\sigma) = 1$. Let $\boldsymbol{\sigma}_Y \subset \boldsymbol{\sigma}$ be a permutation family such that if $\sigma \in \boldsymbol{\sigma}_Y$ then $f(\sigma) = 0$. Let $R \subset \boldsymbol{\sigma}_X \times \boldsymbol{\sigma}_Y$ be such that*

- *For every $\sigma_x \in \boldsymbol{\sigma}_X$, there exists at least m different $\sigma_y \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$.*
- *For every $\sigma_y \in \boldsymbol{\sigma}_Y$, there exists at least m' different $\sigma_x \in \boldsymbol{\sigma}_X$ such that $(\sigma_x, \sigma_y) \in R$.*

- *Let $l_{x,i}$ be the number of $\sigma_y \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$ and $\sigma_x(i) \neq \sigma_y(i)$. Let $l_{y,i}$ be the number of $\sigma_x \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$ and $\sigma_x(i) \neq \sigma_y(i)$. Then let $l_{max} = \max_{(\sigma_x,\sigma_y)\in R,i} l_{x,i} l_{y,i}$.*

Then given an in-place permutation oracle $\mathcal{P}_\sigma$ for $\sigma \in \boldsymbol{\sigma}$ that acts as $\mathcal{P}_\sigma|i\rangle = |\sigma(i)\rangle$, any quantum algorithm that correctly evaluates $f(\sigma)$ with probability $1-\epsilon$ for every element of $\boldsymbol{\sigma}_X$ and $\boldsymbol{\sigma}_Y$ must use $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right)\sqrt{\frac{mm'}{l_{max}}}$ queries to the oracle.

As a corollary of Lemma 2, (using exactly the same technique as Theorem 7 in [6]), we have that the query complexity of inverting an in-place permutation oracle on V elements is $\Omega(V^{1/2})$.

3.3 Permutations with Randomness

Additionally, we consider in-place permutation oracles with internal randomness that are CPTP (completely-positive trace-preserving) maps, rather than unitaries. Oracles with internal randomness were shown to cause a complete loss of quantum speed-up in [19], while in [13], such oracles were shown to give an infinite quantum speed-up.

We consider oracles that apply an in-place permutation at random from among a family of possible permutations. Let $\boldsymbol{\sigma} \subseteq \boldsymbol{\sigma}^n$ be a set of $|\boldsymbol{\sigma}|$ permutations. Then the CPTP map $\mathscr{P}_{\boldsymbol{\sigma}}$ acts as follows:

$$\mathscr{P}_{\boldsymbol{\sigma}}(\rho) = \frac{1}{|\boldsymbol{\sigma}|}\sum_{\sigma\in\boldsymbol{\sigma}} \mathcal{P}_\sigma \rho \mathcal{P}_\sigma^\dagger. \tag{1}$$

4 Pre-Image Checking

In this section, we define a property of oracle families which we call *randomized-preimage-correct*, and construct a decision language based on such oracles that is in QMA. Essentially, the problem is to decide whether the preimage of the first N elements of a permutation is mostly even or odd.

Given a permutation $\sigma \in \boldsymbol{\sigma}^n$, we associate a preimage subset $S_{\text{pre}}(\sigma)$ to that permutation ("pre" is for "preimage"), where $S_{\text{pre}}(\sigma) = \{j : \sigma(j) \in [N]\}$. That is, $S_{\text{pre}}(\sigma)$ is the subset of elements in $[N^2]$ whose image under σ is in $[N]$. Additionally, to each subset $S \subseteq [N^2]$ with $|S| = N$, we associate a set of permutations $\boldsymbol{\sigma}_{\text{pre}}(S)$, where $\boldsymbol{\sigma}_{\text{pre}}(S) = \{\sigma : \sigma \in \boldsymbol{\sigma}^n, S_{\text{pre}}(\sigma) = S\}$. Let

$$\begin{aligned} \boldsymbol{S}^n_{\text{even}} &= \{S : S \subset [N^2], |S| = N, |S \cap \mathbb{Z}_{\text{even}}| = 2/3N\} \\ \boldsymbol{S}^n_{\text{odd}} &= \{S : S \subset [N^2], |S| = N, |S \cap \mathbb{Z}_{\text{odd}}| = 2/3N\}. \end{aligned} \tag{2}$$

▶ **Definition 3** (randomized-preimage-correct oracles)**.** Let $\boldsymbol{\mathcal{O}}$ be a countably infinite set of quantum operators (CPTP maps): $\boldsymbol{\mathcal{O}} = \{\mathscr{O}_1, \mathscr{O}_2, \dots\}$, where each $\mathscr{O}_n$ implements an operation on $(2n)$-qubits. We say that $\boldsymbol{\mathcal{O}}$ is randomized-preimage-correct if for every n, $\mathscr{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{pre}(S)}$, with $S \in \boldsymbol{S}^n_{\text{even}} \cup \boldsymbol{S}^n_{\text{odd}}$.

▶ **Theorem 4.** *For any randomized-preimage-correct $\boldsymbol{\mathcal{O}}$, the unary language $L_{\boldsymbol{\mathcal{O}}}$, which contains those unary strings 1^n such that $\mathscr{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{\text{pre}}(S)}$ with $S \in \boldsymbol{S}^n_{even}$, is in $\mathsf{QMA}^{\boldsymbol{\mathcal{O}}}$.*

Proof. We first prove completeness. We assume $1^n \in L_{\boldsymbol{\mathcal{O}}}$, so $\mathscr{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{\text{pre}}(S)}$ for some $S \in \boldsymbol{S}^n_{\text{even}}$. We consider using as a witness the subset state $|S\rangle$ on $2n$ qubits. We analyze the following verifier: with probability $1/2$, do either

Test (i) Apply $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ to $|S\rangle$, and measure whether the resultant state is $|[N]\rangle$. This measurement can be done by applying $H^{\otimes n}$ to the first n qubits, and then measuring all qubits in the standard basis. If the outcome is 0, output 1; otherwise, output 0.

Test (ii) Measure $|S\rangle$ in the standard basis. Let i^* be the resulting standard basis state. If i^* is odd, output 0. Otherwise, apply $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ to $|i^*\rangle$ and measure the resultant standard basis state. If the resultant state is not in $[N]$, output 0; otherwise, output 1.

If Test (i) is implemented, the verifier always outputs 1 because all the permutations that might be applied by $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ transform $|S\rangle$ into $|[N]\rangle$. If Test (ii) is implemented, the verifier outputs 1 with probability 2/3. Averaging over both Tests, the verifier outputs 1 with probability 5/6.

Now we show soundness. Let $1^n \notin L_{\boldsymbol{\mathcal{O}}}$, so $\mathscr{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ for some $S \in \mathbf{S}^n_{\mathrm{odd}}$. Without loss of generality, let the witness be the $2n$-qubit state $|\psi(S)\rangle = \sum_{i=1}^{N^2} \beta_i |i\rangle$. If $p_{(i)}$ (resp. $p_{(ii)}$) is the probability the verifier outputs 1 after performing Test (i) (resp. Test (ii)), then we have

$$p_{(i)} = \frac{1}{N}\left|\sum_{i\in S}\beta_i\right|^2, \qquad p_{(ii)} = \sum_{i\in\mathbb{Z}_{\mathrm{even}}\cap S}|\beta_i|^2. \tag{3}$$

regardless of which permutation the map $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ applies.

Using Cauchy-Schwarz and the triangle inequality, we have $1 \geq \left(\sqrt{3p_{(i)}} + (\sqrt{2}-1)p_{(ii)}\right)/\sqrt{2}$. Thus the total probability that the verifier outputs 1 is

$$\frac{1}{2}\left(p_{(i)} + p_{(ii)}\right) \leq \frac{1}{2}\left(\frac{2}{3}\left(1 - \frac{\sqrt{2}-1}{\sqrt{2}}p_{(ii)}\right)^2 + p_{(ii)}\right). \tag{4}$$

The derivative of the right hand side is positive for $0 \leq p_{(ii)} \leq 1$, so to maximize the right hand side we take $p_{(ii)} = 1$. Doing this, we find the probability that the verifier outputs 1 is at most 2/3. ◀

We will show that the Preimage Checking problem is not in QCMA in Section 7.

Our proof that the Preimage Checking problem is in QMA works equally well for an in-place oracle without randomness. We use the randomness in our oracle in the proof that randomized-preimage-correct languages can not be decided by QCMA. We believe the separation holds even without randomness in the oracle.

5 Strategy for Proving Subset-Based Oracle Languages are not in QCMA

In this section, we describe a general strategy for showing that certain oracle languages are not in QCMA. In particular, we consider the case when the oracles are related to sets of integers:

▶ **Definition 5** (Subset-Based Oracle). Let $\boldsymbol{\mathcal{O}} = \{\mathscr{O}_1, \mathscr{O}_2, \dots\}$ be an oracle such that each $\mathscr{O}_n$ implements a $p_1(n)$-qubit CPTP map from some set of maps $\boldsymbol{\mathcal{O}}^n$. Then we say $\boldsymbol{\mathcal{O}}$ is a subset-based oracle if there exists a set of bijective functions $\{g^1, g^2, \dots\}$ with $g^n : \boldsymbol{\mathcal{O}}^n \to \mathbf{S}^n$ where $\mathbf{S}^n$ is the union of disjoint subset families $\mathbf{S}^n_X$ and $\mathbf{S}^n_Y$.

We also use the following definition:

▶ **Definition 6.** Given a subset family $\mathbf{S}$ containing subsets of positive integers, and $\beta \in \mathbb{R}$ such that $\beta > 0$, we say $\mathbf{S}$ is β-distributed if:

(1) There exists a (possibly empty) set S_{fixed} such that $S_{fixed} \subset S$ for all $S \in \mathbf{S}$.

(2) For every element $i \in \left(\bigcup_{S\in\mathbf{S}} S\right) \setminus S_{fixed}$, i appears in at most a $2^{-\beta}$-fraction of $S \in \mathbf{S}$.

We call S_{fixed} the "fixed subset" of $\mathbf{S}$.

We use the following Recipe for proving a subset-based oracle language is not in QCMA:

▶ **Recipe 1.**

Set-up. *Fix some enumeration over all poly(n)-size quantum verifiers $M_1, M_2, ...$, which we can do because the number of such machines is countably infinite (by the Solovay-Kitaev theorem [15]). Some of these verifiers may try to decide a language by trivially "hardwiring" its outputs; for example, by returning 1 independent of the input. We start by fixing a unary language L such that no machine M_i hardwires the language. We can always do this because there are more languages than poly(n)-sized machines. Then our goal is to associate a subset-based oracle $\boldsymbol{\mathcal{O}} = \{\mathscr{O}_1, \mathscr{O}_2, \dots\}$ with L, such that $1^n \in L$ if and only if $g^n(\mathscr{O}_n) \in \mathbf{S}_X^n$, and to show that even with access to $\boldsymbol{\mathcal{O}}$, no M_i can efficiently decide L for all n.*

Consider the QCMA *machine M_i, and suppose it is given access to a subset-based oracle $\boldsymbol{\mathcal{O}}$, as well as a witness of $p_{M_i}(n)$ bits for each input 1^n. Then for each $\mathscr{O}_n \in \boldsymbol{\mathcal{O}}$ there is some subset of integers $S \in \mathbf{S}^n$ such that $g^n(\mathscr{O}_n) = S$. Since g^n is bijective, S uniquely defines $\mathscr{O}_n$, so the optimal witness that causes M_i to accept $\mathscr{O}_n$ can be thought of as a function of S. Let $w_i(S)$ be the witness that gives the highest probability of success in convincing M_i that $S \in \mathbf{S}_X^n$. Then we denote $\mathbf{S}_{i,wit}(w) = \{S : S \in \mathbf{S}_X^n, w = w_i(S)\}$.*

Using the pigeonhole principle, there exists some string $w_{i,n}$ of $p_{M_i}(n)$ bits such that

$$|\mathbf{S}_{i,wit}(w_{i,n})| \geq \frac{1}{2^{p_{M_i}(n)}} |\mathbf{S}_X^n| . \tag{5}$$

That is, there exists a witness such that a large number of subsets correspond to that witness.

1. *Prove that for $n \geq n_i^*$, there is a subset family $\mathbf{S}_X \subseteq \mathbf{S}_{i,wit}(w_{i,n})$ that is α-distributed with fixed subset S_{fixed}. Let $\mathbf{S}_Y = \{S : S \in \mathbf{S}_Y^n, S_{fixed} \subset S\}$. Show the cardinality of $\mathbf{S}_Y$ is large.*
2. *Create a relation $\mathbf{R} \subseteq \{\mathscr{O} : \mathscr{O} \in \boldsymbol{\mathcal{O}}^n, g(\mathscr{O}) \in \mathbf{S}_X\} \times \{\mathscr{O} : \mathscr{O} \in \boldsymbol{\mathcal{O}}^n, g(\mathscr{O}) \in \mathbf{S}_Y\}$ and use $\mathbf{R}$ to apply an adversary bound to prove a lower bound of $\Omega(N^{\alpha/2}) = \Omega(2^{n\alpha/2})$ on the number of queries M_i requires to distinguish some oracle $\mathscr{O}_{x,n,i} \in \boldsymbol{\mathcal{O}}^n$ such that $g^n(\mathscr{O}_{x,n,i}) \in \mathbf{S}_X^n$ from an oracle $\mathscr{O}_{y,n,i} \in \boldsymbol{\mathcal{O}}^n$ such that $g^n(\mathscr{O}_{y,n,i}) \in \mathbf{S}_Y^n$.*
3. *Apply a standard Baker-Gill-Solovay diagonalization argument [8] to complete the proof. That is, for each M_i, choose a unique $n_i \geq n_i^*$, and if $1^{n_i} \in L$, set $\mathscr{O}_{n_i} = \mathscr{O}_{x,n_i,i}$ and if $1^{n_i} \notin L$, set $\mathscr{O}_{n_i} = \mathscr{O}_{y,n_i,i}$. Then no* QCMA *machine can efficiently decide the language.*

6 Subset Size Checking

In this section, we create a subset-based oracle language $L_{\boldsymbol{\mathcal{O}}}$, such that $L_{\boldsymbol{\mathcal{O}}} \in \mathsf{AM}^{\boldsymbol{\mathcal{O}}}$, but $L_{\boldsymbol{\mathcal{O}}} \notin \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$. We use the strategy of Section 5 to prove $L_{\boldsymbol{\mathcal{O}}} \notin \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.

Let f_S be a function that marks a subset $S \subset [N^2]$. That is $f_S : \{0,1\}^{2n} \to \{0,1\}$, such that $f_S(i) = 1$ if $i \in S$ and 0 otherwise. Let $\mathcal{F}_S$ be the unitary such that $\mathcal{F}_S|i\rangle = (-1)^{f_S(i)}|i\rangle$.

▶ **Definition 7.** Let $\boldsymbol{\mathcal{O}}$ be a countably infinite set of unitaries (resp. boolean functions): $\boldsymbol{\mathcal{O}} = \{\mathcal{O}_1, \mathcal{O}_2, ...\}$, where $\mathcal{O}_n$ implements a $2n$-qubit (resp. bit) unitary (function). We say $\boldsymbol{\mathcal{O}}$ is subset-gapped if for every n, $\mathcal{O}_n = \mathcal{F}_S$ (resp. $\mathcal{O}_n = f_S$) for $|S| = N$ or $|S| = 0.99N$.

Clearly $\boldsymbol{\mathcal{O}}$ is a subset-based oracle (see Definition 5), with $g^n(\mathcal{O}_n) = g^n(\mathcal{F}_S) = S$.

Then the following two lemmas give the desired oracle separation between AM and QCMA:

▶ **Lemma 8.** *For any subset-gapped $\boldsymbol{\mathcal{O}}$, the language $L_{\boldsymbol{\mathcal{O}}}$ that contains those strings 1^n such that $\mathcal{O}_n = f_S$ with $|S| = N$, is in $AM^{\boldsymbol{\mathcal{O}}}$.*

Lemma 8 is proven by Goldwasser and Sipser in [11].

▶ **Lemma 9.** *For any subset-gapped $\boldsymbol{\mathcal{O}}$, the language $L_{\boldsymbol{\mathcal{O}}}$ that contains those strings 1^n such that $\mathcal{O}_n = \mathcal{F}_S$ with $|S| = N$, is not in $\mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.*

To prove this lemma, we follow Recipe 1. We address step 2 of the recipe in Lemma 10:

▶ **Lemma 10.** *Let $0 < \alpha < 1/2$ be a constant and $p(\cdot)$ be a polynomial function. Then there exists a positive integer $n^*(p, \alpha)$, such that for every positive integer $n > n^*(p, \alpha)$, and every subset family $\mathbf{S} \subseteq \mathbf{C}(N^2, N)$ such that $|\mathbf{S}| \geq |\mathbf{C}(N^2, N)|2^{-p(n)}$, there exists a subset family $\mathbf{S}_X \subseteq \mathbf{S}$ such that $\mathbf{S}_X$ is α-distributed with $|S_{fixed}| < .5N$.*

(Since $|S_{\text{fixed}}| < .5N$, this implies $|\{S : S \in \mathbf{S}_Y^n, S_{\text{fixed}} \subset S\}|$ is large, as desired.)

Proof Sketch. (Full proof in Appendix B.) We prove the existence of $\mathbf{S}_X$ by construction. Let $\mathbf{S}$ be any subset of $\mathbf{C}(N^2, N)$ with $|\mathbf{S}| \geq |\mathbf{C}(N^2, N)|2^{-p(n)}$. We construct $\mathbf{S}_X$ using the Fixing Procedure:

Fixing Procedure

1. Set $\mathbf{S}_X = \mathbf{S}$, and set $S_{\text{fixed}} = \emptyset$.
2. **a.** Let $\nu(i)$ be the number of subsets $S \in \mathbf{S}_X$ such that $i \in S$.
   b. If there exists some element i for which $|\mathbf{S}_X| > \nu(i) \geq |\mathbf{S}_X|N^{-\alpha}$, set $\mathbf{S}' \leftarrow \{S : S \in \mathbf{S}_X \text{ and } i \in S\}$, set $S_{\text{fixed}} \leftarrow S_{\text{fixed}} \cup i$, and return to step 2(a). Otherwise exit the Fixing Procedure.

By construction, the Fixing Procedure returns a set that is α-distributed (see Definition 6), so we only need to ensure that not too many elements are fixed. We obtain a lower bound on the final size of $\mathbf{S}_X$ because each time an element is fixed, the size of the set decreases by at most $N^{-\alpha}$. On the other hand, because $\mathbf{S}_X$ is contained in $\mathbf{C}(N^2, N)$, if a certain number of items are fixed, we have an upper bound on the size of $\mathbf{S}_X$ using the structure of $\mathbf{C}(N^2, N)$ and a combinatorial argument. We show that if more than $.5N$ items are fixed, these upper and lower bounds contradict each other, proving that less than $.5N$ items must be fixed before the Fixing Procedure terminates.

We address Step 3 of Recipe 1 with the following Lemma:

▶ **Lemma 11.** *Suppose $\mathbf{S}_X \subset \mathbf{C}(N^2, N)$ is the α-distributed subset created using the Fixing Procedure of Lemma 10, with fixed subset S_{fixed}. Let $\mathbf{S}_Y = \{S : S \in \mathbf{C}(N^2, 0.99N), S_{fixed} \subset S\}$. Then we can construct an adversary bound to prove that for every quantum algorithm G, there exists $S_x \in \mathbf{S}_X$, and $S_y \in \mathbf{S}_Y$, (that depend on G) such that, given oracle access to $\mathcal{F}_{S_x}$ or $\mathcal{F}_{S_y}$, G can not distinguish them with probability $\epsilon > .5$ without using $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right) N^{\alpha/2}$ queries.*

Proof Sketch. (Full proof in Appendix B.) We use Theorem 6 from [6]. This result is identical to our Lemma 2, except with standard oracles rather than permutation oracles.

We let $\mathbf{R} = \mathbf{S}_X \times \mathbf{S}_Y$. To apply Theorem 6, we need to show that for elements i such that $i \in S_x$ but $i \notin S_y$ for $(S_x, S_y) \in \mathbf{R}$ that either (1) S_x is not connected to many other

sets S_y where $i \notin S_y$ or (2) S_y is not connected to many other sets S_x where $i \in S_x$. We use the α-distributed property of $\mathbf{S}_X$ to show that property (2) holds. We show a similar result for the case $i \notin S_x$ but $i \in S_y$ for $(S_x, S_y) \in \mathbf{R}$.

7 Oracle Separation of QMA and QCMA

In this section, we prove an oracle separation between QMA and QCMA. In particular, we show:

▶ **Theorem 12.** *There exists a randomized-preimage-correct oracle $\boldsymbol{\mathcal{O}}$, and a language $L_{\boldsymbol{\mathcal{O}}}$ which contains those unary strings 1^n where $\mathscr{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S)}$ with $S \in \boldsymbol{S}^n_{even}$ such that $L_{\boldsymbol{\mathcal{O}}} \notin \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.*

Combined with Theorem 4, this gives the desired separation between QMA and QCMA.

Really, we would like to prove a different result, one that involves preimage-correct oracles:

▶ **Definition 13** (preimage-correct oracles)**.** Let $\boldsymbol{\mathcal{O}}$ be a countably infinite set of unitaries: $\boldsymbol{\mathcal{O}} = \{\mathcal{O}_1, \mathcal{O}_2, \dots\}$, where each $\mathcal{O}_n$ implements an $(2n)$-qubit unitary. We say that $\boldsymbol{\mathcal{O}}$ is preimage-correct if for every n, $\mathcal{O}_n = \mathcal{P}_\sigma$, for some σ such that $S_{\mathrm{pre}}(\sigma) \in \mathbf{S}^n_{\mathrm{even}} \cup \mathbf{S}^n_{\mathrm{odd}}$.

The definition of preimage-correct oracles is very similar to that of randomized-preimage-correct oracles in Definition 3, except there is no randomness in preimage-correct oracles – they are unitaries. In fact, we believe:

▶ **Conjecture 1.** *There exists a preimage-correct oracle $\boldsymbol{\mathcal{O}}$, and a language $L_{\boldsymbol{\mathcal{O}}}$ which contains those unary strings 1^n where $\mathscr{O}_n = P_\sigma$ with $S_{pre}(\sigma) \in \boldsymbol{S}^n_{even}$, such that $L_{\boldsymbol{\mathcal{O}}} \notin \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.*

Theorem 4 applies equally well whether the oracle is preimage-correct or randomized-preimage-correct. So why is it harder to prove Conjecture 1 than Theorem 12? The answer is that Recipe 1 is much easier to use if the optimal witness depends only on a subset of integers. Note randomized-preimage-correct oracles have a one-to-one relationship with a subset of integers, and so the optimal witness only depends on that subset. However for preimage-correct oracles, the optimal witness might depend on some details of the permutation, which is more challenging to handle.

For convenience, we define the complexity class $\mathsf{QCMA}_{\mathsf{exp,poly}}$ to be the analogue of QCMA, in which the quantum verifier is allowed exponential time and space, but receives a polynomial length classical witness. While trivially bounded-error quantum exponential time, $\mathsf{BQEXP} = \mathsf{QCMA}_{\mathsf{exp,poly}}$, in general the query complexity of a $\mathsf{QCMA}_{\mathsf{exp,poly}}$ machine is not the same as the query complexity of a BQEXP machine.

Our proof works as follows. We first show that if there is a QCMA machine that decides $L_{\boldsymbol{\mathcal{O}}}$, for all randomized-preimage-correct oracles $\boldsymbol{\mathcal{O}}$, then there will be a $\mathsf{QCMA}_{\mathsf{exp,poly}}$ machine that decides $L_{\widetilde{\boldsymbol{\mathcal{O}}}}$ for any preimage-correct oracle $\widetilde{\boldsymbol{\mathcal{O}}}$, where, *crucially*, the optimal witness only depends on the pre-image subset of the permutation implemented by the oracle. Then using Recipe 1, we show that there is a language $L_{\widetilde{\boldsymbol{\mathcal{O}}}}$ for a preimage-correct oracle $\widetilde{\boldsymbol{\mathcal{O}}}$ such that no $\mathsf{QCMA}_{\mathsf{exp,poly}}$ machine that can decide the language using an efficient number of queries to $\widetilde{\boldsymbol{\mathcal{O}}}$ (with a witness that only depends on the pre-image subset). This implies that there is no QCMA machine that solves the randomized-preimage-correct oracle problem.

We first prove the reduction from deciding languages on pre-image correct oracles to languages on randomized pre-image correct oracles.

▶ **Lemma 14.** *Given a randomized-preimage-correct oracle $\boldsymbol{\mathcal{O}}$, let $1^n \in L_{\boldsymbol{\mathcal{O}}}$ if $\mathcal{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{pre}(S)}$ with $S \in \boldsymbol{S}^n_{even}$. Given a preimage-correct oracle $\tilde{\boldsymbol{\mathcal{O}}}$ let $1^n \in L_{\widetilde{\boldsymbol{\mathcal{O}}}}$ if $\mathcal{O}_n = \mathcal{P}_\sigma$ with $S_{pre}(\sigma) \in \mathbf{S}^n_{even}$. Then if there is a* QCMA *machine M that decides $L_{\boldsymbol{\mathcal{O}}}$ for every randomized-preimage-correct $\boldsymbol{\mathcal{O}}$, then there is a* $\mathsf{QCMA}_{\mathsf{exp,poly}}$ *machine $\widetilde{M}$ that decides $L_{\widetilde{\boldsymbol{\mathcal{O}}}}$ for every preimage-correct $\tilde{\boldsymbol{\mathcal{O}}}$ such that $\widetilde{M}$ uses at most a polynomial number of queries to $\tilde{\boldsymbol{\mathcal{O}}}$, and on input 1^n takes as input a classical witness w that depends only on $S_{pre}(\sigma)$.*

Proof Sketch. (Full proof in Appendix C.) Given a permutation σ, we can obtain all permutations σ' such that $S_{\text{pre}}(\sigma') = S_{\text{pre}}(\sigma)$ by first applying σ, and then permuting the first N elements and the last $N^2 - N$ elements separately. Consider a controlled-unitary that, if system A is in state $|i\rangle$, implements the i^{th} in-place permutation of the first N and last $N^2 - N$ elements on system B. If we start with system A in an equal superposition, apply $\mathcal{P}_\sigma$ to B, apply the control to A and B, and then trace out system A, the result is $\mathscr{P}_{S_{\text{pre}}(\sigma)}$ on system A. Thus, given any preimage-correct oracle $\mathcal{P}_\sigma$, we can simulate the randomized-preimage-correct oracle $\mathscr{P}_{S_{\text{pre}}(\sigma)}$.

Using this simulation trick, we can create an algorithm $\tilde{M}$ using a preimage-correct oracle that has the same outcomes as any algorithm M using a randomized-preimage-correct oracle, which uses the oracle the same number of times, and has a witness that only depends on the preimage subset. However, we do not believe the control permutation can be implemented efficiently, and that is why we must consider the class $\mathsf{QCMA}_{\mathsf{exp,poly}}$.

▶ **Lemma 15.** *There exists a preimage-correct $\boldsymbol{\mathcal{O}}$ such that there is no $\mathsf{QCMA}_{\mathsf{exp,poly}}^{\boldsymbol{\mathcal{O}}}$ machine M that decides $L_{\boldsymbol{\mathcal{O}}}$ using a polynomial number of queries, where the classical witness on input 1^n depends only on $S_{pre}(\sigma)$, when $\mathcal{O}_n = \mathcal{P}_\sigma$.*

Note that Lemma 15, combined with the contrapositive of Lemma 14, proves Theorem 12.

To prove Lemma 15, we use Recipe 1. Even though we do not have a true subset-based oracle (the function $g(\mathcal{P}_\sigma) = S_{\text{pre}}(\sigma)$ is not injective), using the constraint that the classical witness depends only on $S_{\text{pre}}(\sigma)$, we can apply the recipe.

Additionally, while Recipe 1 refers to the class QCMA, because we are only making a statement about query complexity (and say nothing about space or time complexity), the approach also applies to the query complexity of $\mathsf{QCMA}_{\mathsf{exp,poly}}$.

We prove steps 2 and 3 of Recipe 1 in Lemmas 16 and 17. These proofs are quite similar to the proofs of Lemmas 10 and 11; the full proofs can be found in Appendix D.

▶ **Lemma 16.** *Let $0 < \alpha < 1/2$ be a constant and $p(\cdot)$ be a polynomial function. Then there exists a positive integer $n^*(p, \alpha)$, such that for every $n > n^*(p, \alpha)$, and every subset family $\mathbf{S} \subset \mathbf{S}^n_{\text{even}}$ such that $|\mathbf{S}| \geq |\mathbf{S}^n_{\text{even}}|2^{-p(n)}$, there exists a subset family $\mathbf{S}_X \subset \mathbf{S}$ such that $\mathbf{S}_X$ is α-distributed. Furthermore the fixed subset S_{fixed} of $\mathbf{S}_X$ contains at most $N/3$ even elements.*

▶ **Lemma 17.** *Let $\mathbf{S}_X$ be the α-distributed set created using the Fixing Procedure from Lemma 16, with fixed subset S_{fixed}. Let $\mathbf{S}_Y = \{S : S \in \mathbf{S}^n_{odd}, S_{fixed} \subset S\}$. Then we can construct an adversary bound to prove that for every quantum algorithm G, there exists permutations $\sigma_x, \sigma_y \in \boldsymbol{\sigma}^n$ with $S_{pre}(\sigma_x) \in \mathbf{S}_X$ and $S_{pre}(\sigma_y) \in \mathbf{S}_Y$, (that depend on G) such that, given oracle access to $\mathcal{P}_{\sigma_x}$ or $\mathcal{P}_{\sigma_y}$, G can not distinguish them with probability $\epsilon > .5$ without using $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right) N^{\alpha/2}$ queries.*

The proof strategy of Lemma 16 (like Lemma 10) involves a Fixing Procedure. However, the details are slightly more complex because we must deal with fixing even and odd elements.

The proof strategy of Lemma 17 is similar to Lemma 11, except we use a more complex relation $\mathbf{R}$ for the adversary bound. The challenge is that for two similar subsets S_x and S_y, there exist permutations σ_x and σ_y that are extremely dissimilar but for which $S_{\text{pre}}(\sigma_x) = S_x$ and $S_{\text{pre}}(\sigma_y) = S_y$. We want to create a relationship $\mathbf{R}$ that connects similar permutations, while only having information about the structure of the related subsets. To address this problem, we note that for any two subsets S_x and S_y, we can create a one-to-one matching between the elements of $\boldsymbol{\sigma}_{\text{pre}}(S_x)$ and the elements of $\boldsymbol{\sigma}_{\text{pre}}(S_y)$ such that each permutation is matched with a similar permutation. Using this one-to-one matching, we create a relationship $\mathbf{R}$ between permutations that inherits the properties of the related subsets.

As an immediate corollary of Theorem 4 and Theorem 12, there exists a randomized-preimage-correct oracle $\boldsymbol{\mathcal{O}}$ and language $L_{\boldsymbol{\mathcal{O}}}$ such that $L \notin \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$ but $L \in \mathsf{QMA}^{\boldsymbol{\mathcal{O}}}$, and so $\mathsf{QMA}^{\boldsymbol{\mathcal{O}}} \not\subseteq \mathsf{QCMA}^{\boldsymbol{\mathcal{O}}}$.

A An Adversary Bound for Permutation Oracles

We will prove Lemma 2:

▶ **Lemma 2.** *Let $\boldsymbol{\sigma} \subset [V] \to [V]$ be a subset of permutations acting on the elements $[V]$. Let $f : \boldsymbol{\sigma} \to \{0,1\}$ be a function of permutations. Let $\boldsymbol{\sigma}_X \subset \boldsymbol{\sigma}$ be a set of permutations such that if $\sigma \in \boldsymbol{\sigma}_X$, then $f(\sigma) = 1$. Let $\boldsymbol{\sigma}_Y \subset \boldsymbol{\sigma}$ be a permutation family such that if $\sigma \in \boldsymbol{\sigma}_Y$ then $f(\sigma) = 0$. Let $R \subset \boldsymbol{\sigma}_X \times \boldsymbol{\sigma}_Y$ be such that*

- *For every $\sigma_x \in \boldsymbol{\sigma}_X$, there exists at least m different $\sigma_y \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$.*
- *For every $\sigma_y \in \boldsymbol{\sigma}_Y$, there exists at least m' different $\sigma_x \in \boldsymbol{\sigma}_X$ such that $(\sigma_x, \sigma_y) \in R$.*
- *Let $l_{x,i}$ be the number of $\sigma_y \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$ and $\sigma_x(i) \neq \sigma_y(i)$. Let $l_{y,i}$ be the number of $\sigma_x \in \boldsymbol{\sigma}_Y$ such that $(\sigma_x, \sigma_y) \in R$ and $\sigma_x(i) \neq \sigma_y(i)$. Then let $l_{max} = \max_{(\sigma_x,\sigma_y)\in R,i} l_{x,i} l_{y,i}$.*

Then given an in-place permutation oracle $\mathcal{P}_\sigma$ for $\sigma \in \boldsymbol{\sigma}$ that acts as $\mathcal{P}_\sigma|i\rangle = |\sigma(i)\rangle$, any quantum algorithm that correctly evaluates $f(\sigma)$ with probability $1-\epsilon$ for every element of $\boldsymbol{\sigma}_X$ and $\boldsymbol{\sigma}_Y$ must use $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right)\sqrt{\frac{mm'}{l_{max}}}$ queries to the oracle.

We note that this is identical to Ambainis' adversary bound for permutations (see Theorem 6 in [6]).

Proof. We assume that we have a control permutation oracle, that acts as

$$\mathcal{P}|x\rangle_C|i\rangle_A|z\rangle_Q = |x\rangle|\sigma_x(i)\rangle|z\rangle \tag{6}$$

where the Hilbert space $\mathcal{H}_C$ has dimension $|\boldsymbol{\sigma}|$,the Hilbert space $\mathcal{H}_A$ has dimension V and is where the permutation is carried out, and $\mathcal{H}_Q$ is a set of ancilla qubits.

Let $|\psi^t\rangle$ be the state of the system immediately after t uses of the control oracle. Let $|\varphi^t\rangle$ be the state of the system immediately before the t^{th} use of the control oracle. Let ρ^t be the reduced state of the system immediately after t uses of the control oracle, where systems A and Q have been traced out. That is, $\rho^t = \mathrm{tr}_{AQ}(|\psi^t\rangle\langle\psi^t|)$. Let $(\rho^t)_{xy}$ be the $(x,y)^{\text{th}}$ element of the density matrix. Then we will track the progress of the following measure:

$$W^t = \sum_{(\sigma_x,\sigma_y)\in R} \left|(\rho^t)_{xy}\right|. \tag{7}$$

Notice that unitaries that only act on the subsystems Q and A do not affect W^t.

If the state before the first use of the oracle is

$$|\psi^0\rangle = \left(\frac{1}{\sqrt{2|\boldsymbol{\sigma}_X|}} \sum_{\sigma_x \in \boldsymbol{\sigma}_X} |x\rangle + \frac{1}{\sqrt{2|\boldsymbol{\sigma}_Y|}} \sum_{\sigma_y \in \boldsymbol{\sigma}_Y} |y\rangle \right) \otimes |\phi\rangle_{AQ}, \tag{8}$$

then following Ambainis (e.g. Theorem 2 [6]), we have that for an algorithm to succeed with probability at least $1-\epsilon$ after T uses of the oracle, we must have

$$W^0 - W^T > \left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right)\sqrt{mm'} \tag{9}$$

Now we calculate how much W^t can change between uses of the oracle. Suppose without loss of generality that

$$|\varphi^t\rangle = \frac{1}{\sqrt{2|\boldsymbol{\sigma}_X|}} \sum_{\sigma_x \in \boldsymbol{\sigma}_X} \sum_{i,z} \alpha_{x,i,z} |x,i,z\rangle_{CAQ} + \frac{1}{\sqrt{2|\boldsymbol{\sigma}_Y|}} \sum_{\sigma_y \in \boldsymbol{\sigma}_Y} \sum_{i,z} \alpha_{y,i,z} |y,i,z\rangle_{CAQ}. \tag{10}$$

Then we have

$$\begin{aligned} |\psi^t\rangle &= \frac{1}{\sqrt{2|\boldsymbol{\sigma}_X|}} \sum_{\sigma_x \in \boldsymbol{\sigma}_X} \sum_{i,z} \alpha_{x,i,z} |x,\sigma_x(i),z\rangle_{CAQ} + \frac{1}{\sqrt{2|\boldsymbol{\sigma}_Y|}} \sum_{\sigma_y \in \boldsymbol{\sigma}_Y} \sum_{i,z} \alpha_{y,i,z} |y,\sigma_y(i),z\rangle_{CAQ} \\ &= \frac{1}{\sqrt{2|\boldsymbol{\sigma}_X|}} \sum_{\sigma_x \in \boldsymbol{\sigma}_X} \sum_{i,z} \alpha_{x,\sigma_x^{-1}(i),z} |x,i,z\rangle_{CAQ} + \frac{1}{\sqrt{2|\boldsymbol{\sigma}_Y|}} \sum_{\sigma_y \in \boldsymbol{\sigma}_Y} \sum_{i,z} \alpha_{y,\sigma_y^{-1}(i),z} |y,i,z\rangle_{CAQ}. \end{aligned} \tag{11}$$

Hence for $(\sigma_x, \sigma_y) \in R$, we have

$$\begin{aligned} (\rho^t)_{xy} &= \frac{1}{2\sqrt{|\boldsymbol{\sigma}_X||\boldsymbol{\sigma}_Y|}} \sum_{i,z} \alpha_{x,\sigma_x^{-1}(i),z} \alpha^*_{y,\sigma_y^{-1}(i),z} \\ (\rho^{t-1})_{xy} &= \frac{1}{2\sqrt{|\boldsymbol{\sigma}_X||\boldsymbol{\sigma}_Y|}} \sum_{i,z} \alpha_{x,i,z} \alpha^*_{y,i,z}, \end{aligned} \tag{12}$$

where $(\cdot)^*$ signifies the complex conjugate. Now we can calculate $W^t - W^{t-1}$:

$$\begin{aligned} W^{t-1} - W^t &= \sum_{(\sigma_x,\sigma_y)\in R} |(\rho^{t-1})_{xy}| - |(\rho^t)_{xy}| \\ &\leq \sum_{(\sigma_x,\sigma_y)\in R} |(\rho^{t-1})_{xy} - (\rho^t)_{xy}|. \end{aligned} \tag{13}$$

From Eq. (12), we see that whenever $\sigma_x^{-1}(i) = \sigma_y^{-1}(i)$, we have a cancellation between the corresponding elements of $(\rho^t)_{xy}$ and $(\rho^{t-1})_{xy}$. However, when $\sigma_x^{-1}(i) \neq \sigma_y^{-1}(i)$, terms do not cancel. To see this more explicitly, we rewrite Eq. (13) as

$$\begin{aligned} W^{t-1} - W^t \leq \\ \frac{1}{2\sqrt{|\boldsymbol{\sigma}_X||\boldsymbol{\sigma}_Y|}} \sum_{(\sigma_x,\sigma_y)\in R} \Bigg| \sum_z \Bigg[\sum_{i:\sigma_x(i)=\sigma_y(i)} \alpha_{x,i,z}\alpha^*_{y,i,z} + \sum_{i:\sigma_x(i)\neq\sigma_y(i)} \alpha_{x,i,z}\alpha^*_{y,i,z} \\ - \sum_{i:\sigma_x^{-1}(i)=\sigma_y^{-1}(i)} \alpha_{x,\sigma_x^{-1}(i),z}\alpha^*_{y,\sigma_y^{-1}(i),z} - \sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} \alpha_{x,\sigma_x^{-1}(i),z}\alpha^*_{y,\sigma_y^{-1}(i),z} \Bigg] \Bigg|. \end{aligned} \tag{14}$$

Consider the sets $T_{x,y} = \{i : \sigma_x(i) = \sigma_y(i)\}$ and $U_{x,y} = \{\sigma_x^{-1}(i) : \sigma_x^{-1}(i) = \sigma_y^{-1}(i)\}$. We will show $U_{x,y} = T_{x,y}$. Suppose $i \in T_{x,y}$. Then $\sigma_x(i) = \sigma_y(i) = i'$, for some i'. But that implies

$\sigma_x^{-1}(i') = \sigma_y^{-1}(i') = i$, so $\sigma_x^{-1}(i') = i \in U_{x,y}$, and thus $T_{x,y} \subset U_{x,y}$. The opposite direction is shown similarly. Therefore, those two sums in Eq. (14) cancel, and, moving the summation over z and i outside the absolute values by the triangle inequality, we are left with

$$W^{t-1} - W^t \leq \frac{1}{2\sqrt{|\boldsymbol{\sigma}_X||\boldsymbol{\sigma}_Y|}} \sum_{z,(\sigma_x,\sigma_y)\in R} \left(\sum_{i:\sigma_x(i)\neq\sigma_y(i)} \left|\alpha_{x,i,z}\alpha^*_{y,i,z}\right| + \sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} \left|\alpha_{x,\sigma_x^{-1}(i),z}\alpha^*_{y,\sigma_y^{-1}(i),z}\right| \right). \tag{15}$$

Now we use the AM-GM to bound the terms in the absolute values:

$$\begin{aligned} W^{t-1} - W^t \leq & \frac{1}{2} \sum_{z,(\sigma_x,\sigma_y)\in R} \left(\sum_{i:\sigma_x(i)\neq\sigma_y(i)} \left(\sqrt{\frac{l_{y,i}}{l_{x,i}}} \frac{|\alpha_{x,i,z}|^2}{2|\boldsymbol{\sigma}_X|} + \sqrt{\frac{l_{x,i}}{l_{y,i}}} \frac{|\alpha^*_{y,i,z}|^2}{2|\boldsymbol{\sigma}_Y|} \right) \right) \\ & + \frac{1}{2} \sum_{z,(\sigma_x,\sigma_y)\in R} \left(\sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} \left(\sqrt{\frac{l_{y,i}}{l_{x,i}}} \frac{\left|\alpha_{x,\sigma_x^{-1}(i),z}\right|^2}{2|\boldsymbol{\sigma}_X|} + \sqrt{\frac{l_{x,i}}{l_{y,i}}} \frac{\left|\alpha^*_{y,\sigma_y^{-1}(i),z}\right|^2}{2|\boldsymbol{\sigma}_Y|} \right) \right) \end{aligned} \tag{16}$$

We now show that for $(\sigma_x, \sigma_y) \in R$,

$$\begin{aligned} \sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} |\alpha_{x,\sigma_x^{-1}(i),z}|^2 &= \sum_{i:\sigma_x(i)\neq\sigma_y(i)} |\alpha_{x,i,z}|^2, \\ \sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} |\alpha_{y,\sigma_y^{-1}(i),z}|^2 &= \sum_{i:\sigma_x(i)\neq\sigma_y(i)} |\alpha_{y,i,z}|^2. \end{aligned} \tag{17}$$

We prove the first equality, and the second is proven similarly. We define

$$\begin{aligned} T'_{x,y} &= [V] \setminus T_{x,y}, \\ U'_{x,y} &= [V] \setminus U_{x,y}. \end{aligned} \tag{18}$$

Looking at the definition of $T_{x,y}$ and $U_{x,y}$, we see that

$$\begin{aligned} T'_{x,y} &= \{i : \sigma_x(i) \neq \sigma_y(i)\} \\ U'_{x,y} &= \{\sigma_x^{-1}(i) : \sigma_x^{-1}(i) \neq \sigma_y^{-1}(i)\}. \end{aligned} \tag{19}$$

We previously showed $T_{x,y} = U_{x,y}$, so we have $T'_{x,y} = U'_{x,y}$. Therefore

$$\sum_{i:\sigma_x^{-1}(i)\neq\sigma_y^{-1}(i)} |\alpha_{x,\sigma_x^{-1}(i),z}|^2 = \sum_{i:U'_{x,y}} |\alpha_{x,j,z}|^2 = \sum_{i:T'_{x,y}} |\alpha_{x,i,z}|^2 \sum_{i:\sigma_x(i)\neq\sigma_y(i)} |\alpha_{x,i,z}|^2. \tag{20}$$

Thus, Eq. (16) becomes

$$W^{t-1} - W^t \leq \sum_{z,(\sigma_x,\sigma_y)\in R} \left(\sum_{i:\sigma_x(i)\neq\sigma_y(i)} \left(\sqrt{\frac{l_{y,i}}{l_{x,i}}} \frac{|\alpha_{x,i,z}|^2}{2|\boldsymbol{\sigma}_X|} + \sqrt{\frac{l_{x,i}}{l_{y,i}}} \frac{|\alpha^*_{y,i,z}|^2}{2|\boldsymbol{\sigma}_Y|} \right) \right). \tag{21}$$

Now we switch the order of summation and then use the definition of $l_{x,i}$ and $l_{y,i}$ to get

$$\begin{aligned} & W^{t-1} - W^t \\ \leq & \sum_{i\in[V],z} \left(\sum_{(\sigma_x,\sigma_y)\in R:\sigma_x(i)\neq\sigma_y(i)} \left(\sqrt{\frac{l_{y,i}}{l_{x,i}}} \frac{|\alpha_{x,i,z}|^2}{2|\boldsymbol{\sigma}_X|} + \sqrt{\frac{l_{x,i}}{l_{y,i}}} \frac{|\alpha^*_{y,i,z}|^2}{2|\boldsymbol{\sigma}_Y|} \right) \right) \\ \leq & \sum_{i\in[V],z} \left(\sum_{\sigma_x\in\boldsymbol{\sigma}_X} \sqrt{l_{x,i} \max_{\sigma_y:(\sigma_x,\sigma_y)\in R} l_{y,i}} \frac{|\alpha_{x,i,z}|^2}{2|\boldsymbol{\sigma}_X|} + \sum_{\sigma_y\in\boldsymbol{\sigma}_Y} \sqrt{l_{y,i} \max_{\sigma_x:(\sigma_x,\sigma_y)\in R} l_{x,i}} \frac{|\alpha^*_{y,i,z}|^2}{2|\boldsymbol{\sigma}_Y|} \right) \end{aligned} \tag{22}$$

Finally, using the definition of l_{max} we have

$$\begin{aligned} W^{t-1} - W^t \leq & \sqrt{l_{max}} \sum_{i\in[V],z} \left(\sum_{x\in\boldsymbol{\sigma}_X} \frac{|\alpha_{x,i,z}|^2}{2|\boldsymbol{\sigma}_X|} + \sum_{\sigma_y\in\boldsymbol{\sigma}_Y} \frac{|\alpha^*_{y,i,z}|^2}{2|\boldsymbol{\sigma}_Y|} \right) \\ \leq & \sqrt{l_{max}}, \end{aligned} \tag{23}$$

where we have used that Eq. (10) is a normalized state. ◀

B Proofs of Lemmas 10 and 11

▶ **Lemma 10.** *Let $0 < \alpha < 1/2$ be a constant and $p(\cdot)$ be a polynomial function. Then there exists a positive integer $n^*(p,\alpha)$, such that for every positive integer $n > n^*(p,\alpha)$, and every subset family $\mathbf{S} \subseteq \mathbf{C}(N^2, N)$ such that $|\mathbf{S}| \geq |\mathbf{C}(N^2,N)|2^{-p(n)}$, there exists a subset family $\mathbf{S}_X \subseteq \mathbf{S}$ such that $\mathbf{S}_X$ is α-distributed with $|S_{fixed}| < .5N$.*

Proof. We prove the existence of $\mathbf{S}'$ by construction. Let $\mathbf{S}$ be any subset family of $\mathbf{C}(N^2,N)$ such that $|\mathbf{S}| \geq |\mathbf{C}(N^2,N)|2^{-p(n)}$. We construct $\mathbf{S}'$ using the following procedure:

Fixing Procedure

1. Set $\mathbf{S}' = \mathbf{S}$, and set $S_{\text{fixed}} = \emptyset$.

2. a. Let $\nu(i)$ be the number of subsets $S \in \mathbf{S}_X$ such that $i \in S$.

b. If there exists some element i for which

$$|\mathbf{S}_X| > \nu(i) \geq |\mathbf{S}_X| N^{-\alpha} \tag{24}$$

set $\mathbf{S}' \leftarrow \{S : S \in \mathbf{S}_X \text{ and } i \in S\}$, set $S_{\text{fixed}} \leftarrow S_{\text{fixed}} \cup i$, and return to step 2(a). Otherwise exit the Fixing Procedure.

The Fixing Procedure by construction will always return a set that satisfies Definition 6. Now we just need to bound the size of S_{fixed}.

Let's suppose that at some point in the Fixing Procedure, for sets $\mathbf{S}'$ and S_{fixed}, we have $.5N$ items fixed. Suppose for contradiction there is some element $i^* \notin S_{\text{fixed}}$ that appears in greater than $N^{-\alpha}$ fraction of $S \in \mathbf{S}'$.

Let us look at the set family $\mathbf{S}'' = \{S : S \in \mathbf{S}', i^* \in S\}$. Because $(S_{\text{fixed}} \cup i^*) \subset S$ for all $S \in \mathbf{S}''$, there are $.5N - 1$ elements in each $S \in \mathbf{S}''$ that can be chosen freely from the remaining $N^2 - .5N - 1$ un-fixed elements. Thus, we have

$$|\mathbf{S}''| \leq \binom{N^2 - .5N - 1}{.5N - 1}. \tag{25}$$

By assumption $|\mathbf{S}''| \geq |\mathbf{S}'|N^{-\alpha}$, so

$$\begin{aligned}
|\mathbf{S}'| &\leq \binom{N^2 - .5N - 1}{.5N - 1} N^{\alpha} \\
&\leq \binom{N^2}{.5N} N^{\alpha} \\
&\leq (2Ne)^{N/2} N^{\alpha} \\
&= 2^{N/2(\log(2e)+\log N)+\log(N)\alpha} \\
&= 2^{O(N)+(N/2)\log N}. \qquad (26)
\end{aligned}$$

However, we can also bound the size of $\mathbf{S}'$ from the Fixing Procedure. Notice that at every step of the Fixing Procedure, the size of $\mathbf{S}'$ is reduced by at most a factor $N^{-\alpha}$. Since we are assuming $.5N$ elements are in S_{fixed}, the Fixing Procedure can reduce the original set $\mathbf{S}$ by at most a factor $N^{-\alpha N/2}$. Since $|\mathbf{S}| \geq |\mathbf{C}(N^2, N)|2^{-p(n)}$, we have that at this point in the Fixing Procedure

$$\begin{aligned}
|\mathbf{S}'| &\geq |\mathbf{C}(N^2, N)|2^{-p(n)} N^{-\alpha N/2} \\
&= \binom{N^2}{N} 2^{-p(n)} N^{-\alpha N/2} \\
&\geq N^N 2^{-p(n)} N^{-\alpha N/2} \\
&= 2^{N\log N - p(n) - \log(N)\alpha N/2} \\
&= 2^{-O(N)+N\log N(1-\alpha/2)}. \qquad (27)
\end{aligned}$$

Notice that as long as $\alpha < 1$, for large enough N (in particular, for $N > 2^{n^*}$ for some positive integer n^*, where n^* depends on α and $p(\cdot)$), the bound of Eq. (27) will be larger than the bound of Eq. (26), giving a contradiction. Therefore, our assumption must have been false, and more than $N/2$ elements can not have been fixed during the Fixing Procedure. Therefore, the final set produced by the Fixing Procedure will satisfy point (2) of Definition 6. ◀

▶ **Lemma 11.** *Suppose $\mathbf{S}_X \subset \mathbf{C}(N^2, N)$ is the α-distributed subset created using the Fixing Procedure of Lemma 10, with fixed subset S_{fixed}. Let $\mathbf{S}_Y = \{S : S \in \mathbf{C}(N^2, 0.99N), S_{fixed} \subset S\}$. Then we can construct an adversary bound to prove that for every quantum algorithm G, there exists $S_x \in \mathbf{S}_X$, and $S_y \in \mathbf{S}_Y$, (that depend on G) such that, given oracle access to $\mathcal{F}_{S_x}$ or $\mathcal{F}_{S_y}$, G can not distinguish them with probability $\epsilon > .5$ without using $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right) N^{\alpha/2}$ queries.*

Proof. Note $\mathbf{S}_Y$ is non-empty, since only $.5N$ elements are in S_{fixed}.

We will use Theorem 6 from [6]. This result is identical to our Lemma 2, except with standard oracles rather than permutation oracles. We define the relation $\mathbf{R}$ as:

$$\mathbf{R} = \{(S_x, S_y) : S_x \in \mathbf{S}_X, S_y \in \mathbf{S}_Y\}. \qquad (28)$$

Notice that each $S_x \in \boldsymbol{S}_X$ is paired with every element of $\mathbf{S}_Y$. Thus $m = |\mathbf{S}_Y|$. Likewise $m' = |\mathbf{S}_X|$.

Now consider $(S_x, S_y) \in \mathbf{R}$. We first consider the case of some element j such that $j \in S_x$ but $j \notin S_y$. By our construction of $\mathbf{S}_Y$, $j \notin S_{\text{fixed}}$. We upper bound $l_{x,j}$, the number of $S_{y'}$ such that $(S_x, S_{y'}) \in \mathbf{R}$ and $j \notin S_{y'}$. We use the trivial upper bound $l_{x,j} \leq |\mathbf{S}_Y|$, which is sufficient for our purposes. Next we need to upper bound $l_{y,j}$, the number of $S_{x'}$ such that

$(S_{x'}, S_y) \in \mathbf{R}$ and $j \in S_x$. Since S_y is paired with every element of $\mathbf{S}_X$ in $\mathbf{R}$, we just need to determine the number of sets in $\mathbf{S}_X$ that contain j. Because $\mathbf{S}_X$ is α-distributed, there can be at most $N^{-\alpha}|\mathbf{S}_X|$ elements of $\mathbf{S}_X$ that contain j. In this case we have

$$l_{x,j} l_{y,j} \leq |\mathbf{S}_X||\mathbf{S}_Y| N^{-\alpha}. \tag{29}$$

We now consider the case that $j \in S_y$ but $j \notin S_x$. (Note this case only occurs when S_{fixed} contains less than $0.99N$ elements.) We upper bound $l_{y,j}$, the number of $S_{x'}$ such that $(S_{x'}, S_y) \in \mathbf{R}$ and $j \notin S_{x'}$. Again, we use the trivial upper bound of $l_{y,j} \leq |\mathbf{S}_X|$, which is sufficient for our analysis. Next we upper bound $l_{x,j}$, the number of $S_{y'}$ such that $(S_x, S_{y'}) \in \mathbf{R}$ and $j \in S_{y'}$. In our choice of $\mathbf{R}$, S_x is paired with every $S_y \in \mathbf{S}_Y$, so we need to count the number of $S \in \mathbf{S}_Y$ that contain j. We have

$$\begin{aligned} l_{x,j} =& \binom{N^2 - S_{\text{fixed}} - 1}{0.99N - S_{\text{fixed}} - 1} \\ =& \frac{0.99N - S_{\text{fixed}}}{N^2 - S_{\text{fixed}}} |\mathbf{S}_Y| \\ \leq& \frac{1}{N} |\mathbf{S}_Y|. \end{aligned} \tag{30}$$

Therefore in this case, we have

$$l_{x,j} l_{y,j} \leq |\mathbf{S}_X||\mathbf{S}_Y| N^{-1}. \tag{31}$$

Looking at Eq. (29) and Eq. (31), we see that because $\alpha < 1$, the bound of Eq. (29) dominates, and so we have that

$$\sqrt{\frac{mm'}{l_{x,j} l_{y,j}}} \geq \sqrt{\frac{|\mathbf{S}_X||\mathbf{S}_Y|}{|\mathbf{S}_X||\mathbf{S}_Y| N^{-\alpha}}} = N^{\alpha/2}. \tag{32}$$

Using the contrapositive of Lemma 2, if an algorithm G makes less than q queries to an oracle $\mathcal{F}_S$ where S is promised to be in $\mathbf{S}_X$ or $\mathbf{S}_Y$, there exists at least one element of $\mathbf{S}_X$ and one element of $\mathbf{S}_Y$ such that the probability of distinguishing between the corresponding oracles less than is $1/2 + \epsilon$, where

$$\frac{1}{2} \sqrt{2 N^{-\alpha/2} q} > \epsilon. \tag{33}$$

Equivalently, there exists at least one element of $\boldsymbol{S}_X$ and one element of $\boldsymbol{S}_Y$ such that in order for $\mathcal{A}$ to distinguish them with constant bias, one requires $\Omega(N^{\alpha/2})$ queries. ◀

C Proof of Lemma 14

▶ **Lemma 14.** *Given a randomized-preimage-correct oracle $\boldsymbol{\mathcal{O}}$, let $1^n \in L_{\boldsymbol{\mathcal{O}}}$ if $\mathcal{O}_n = \mathscr{P}_{\boldsymbol{\sigma}_{pre}(S)}$ with $S \in \boldsymbol{S}^n_{even}$. Given a preimage-correct oracle $\tilde{\boldsymbol{\mathcal{O}}}$ let $1^n \in L_{\tilde{\boldsymbol{\mathcal{O}}}}$ if $\mathcal{O}_n = \mathcal{P}_\sigma$ with $S_{pre}(\sigma) \in \mathbf{S}^n_{even}$. Then if there is a* QCMA *machine M that decides $L_{\boldsymbol{\mathcal{O}}}$ for every randomized-preimage-correct $\boldsymbol{\mathcal{O}}$, then there is a* $\mathsf{QCMA}_{\mathsf{exp,poly}}$ *machine $\widetilde{M}$ that decides $L_{\tilde{\boldsymbol{\mathcal{O}}}}$ for every preimage-correct $\tilde{\boldsymbol{\mathcal{O}}}$ such that $\widetilde{M}$ uses at most a polynomial number of queries to $\tilde{\boldsymbol{\mathcal{O}}}$, and on input 1^n takes as input a classical witness w that depends only on $S_{pre}(\sigma)$.*

Proof. We denote the composition of two CPTP maps with $\circ$, so $\mathscr{E} \circ \mathscr{F}$ means apply $\mathscr{F}$ first, and then $\mathscr{E}$.

For each input 1^n, M applies an algorithm that takes as input a standard basis state. Because S completely characterizes $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}(S)}}$, the optimal witness will depend only on S.

Suppose on input 1^n to M, the algorithm is the following:

$$\mathscr{L}_{AB} \circ (\mathscr{O})_A \circ (\mathscr{U}_t)_{AB} \circ \cdots \circ (\mathscr{U}_2)_{AB} \circ (\mathscr{O})_A \circ (\mathscr{U}_1)_{AB}(|w\rangle\langle w| \otimes |\psi_0\rangle\langle\psi_0|)_{AB} \tag{34}$$

where $|w\rangle\langle w|$ is the witness state (that depends only on S) in the standard basis and $\mathscr{U}_i$ are fixed unitaries and $\mathscr{L}$. The two subspaces A and B refer to the subset where the oracle acts (A) and the rest of the workspace (B). The two subspaces do *not* refer to the tensor product structure of the initial state.

For $i \in [N!(N^2-N)!]$ let $\boldsymbol{\tau}^n = \{\tau_i\}$ be the set of permutations on the elements of $[N^2]$ that do not mix the first N elements with the last $N^2 - N$ elements. Then let $\mathcal{P}_n^{\mathrm{C}}$ be the following control-permutation:

$$\mathcal{P}_n^{\mathrm{C}}|i\rangle|j\rangle = \begin{cases} |i\rangle|\tau_i(j)\rangle \text{ for } i \in [N!(N^2-N)!] \\ |i\rangle|j\rangle \text{ otherwise.} \end{cases} \tag{35}$$

$\mathscr{P}_n^{\mathrm{C}}$ is the respective CPTP map.

$\mathcal{P}_n^{\mathrm{C}}$ is a completely known unitary that is independent of the oracle, however, we do not know how to implement this unitary in polynomial time. This unitary is the reason we consider the class $\mathsf{QCMA}_{\mathsf{exp,poly}}$ in this proof rather than the more standard QCMA. Ultimately, we care about query complexity - not the complexity of the unitaries that occur between the oracle applications.

Let

$$|\chi_n\rangle = \frac{1}{\sqrt{N!(N^2-N)!}} \sum_{i=1}^{N!(N^2-N)!} |i\rangle \tag{36}$$

Then on input 1^n we have $\tilde{M}$ implement the algorithm

$$\begin{aligned} &\mathscr{L}_{AB} \circ (\mathscr{P}_n^{\mathrm{C}})_{C_t A} \circ (\mathscr{O})_A \circ (\mathscr{U}_t)_{AB} \circ \cdots \\ &\quad \circ (\mathscr{U}_2)_{AB} \circ (\mathscr{P}_n^{\mathrm{C}})_{C_1 A} \circ (\mathscr{O})_A \circ (\mathscr{U}_1)_{AB} \left(|\chi_n\rangle\langle\chi_n|_C^t \otimes (|w\rangle\langle w| \otimes |\psi_0\rangle\langle\psi_0|)_{AB}\right) \end{aligned} \tag{37}$$

where $(\mathscr{P}_\tau^{\mathrm{C}})_{C_i A}$ means the $C_i{}^{\mathrm{th}}$ register controls the A^{th} register, and initially, the $C_i{}^{\mathrm{th}}$ register is the i^{th} copy of $|\chi_n\rangle$, and $\mathscr{O}$ is the CPTP version of the oracle $\mathcal{O}$.

Let $\rho_i(\mathscr{O})$ (resp. $\tilde{\rho}_i(\mathcal{O})$) be the state of the system during the algorithm M (resp. $\tilde{M}$) after the i^{th} use of the oracle. Let $\rho_0(\mathscr{O})$ (resp. $\tilde{\rho}_0(\mathcal{O})$) be the initial state of the respective algorithms. Then we will show that

$$\rho_i(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}(S_{\mathrm{pre}}(\sigma))}}) = \mathrm{tr}_{C_1,\ldots,C_t}\left(\tilde{\rho}_i(\mathcal{P}_\sigma)\right). \tag{38}$$

As a consequence of this, the probability distribution of measurement outcome of the two algorithms will be identical.

We prove this by induction. For the initial step, we have

$$\rho_0(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}(S_{\mathrm{pre}}(\sigma))}}) = |w\rangle\langle w| \otimes |\psi_0\rangle\langle\psi_0| \tag{39}$$

while

$$\begin{aligned} \mathrm{tr}_C(\tilde{\rho}_0(\mathcal{P}_\sigma)) &= \mathrm{tr}_C\left(|\chi_n\rangle\langle\chi_n|_C^t \otimes (|w\rangle\langle w| \otimes |\psi_0\rangle\langle\psi_0|)_{AB}\right) \\ &= |w\rangle\langle w| \otimes |\psi_0\rangle\langle\psi_0|. \end{aligned} \tag{40}$$

For the induction step, we need to show

$$\rho_k(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}) = \mathrm{tr}_{C_1,\ldots,C_t}\left(\tilde{\rho}_k(\mathcal{P}_\sigma)\right). \tag{41}$$

Because $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}$ has an equal probability of applying $\mathcal{P}_\sigma$ for each σ such that $S(\sigma) = S$, we have

$$\begin{aligned}\rho_k(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}) =& \mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}\left(\mathcal{U}_k\rho_{k-1}(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))})\mathcal{U}_k^\dagger\right)\\ =& \frac{1}{N!(N^2-N)!}\sum_{i=1}^{N!(N^2-N)!}\mathcal{P}_{\tau_i}\mathcal{P}_\sigma\mathcal{U}_k\rho_{k-1}(\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))})\mathcal{U}_k^\dagger\mathcal{P}_\sigma^\dagger\mathcal{P}_{\tau_i}^\dagger. \end{aligned}\tag{42}$$

On the other hand

$$\begin{aligned}\mathrm{tr}_C\left(\tilde{\rho}_k(\mathcal{P}_\sigma)\right) =& \mathrm{tr}_C\left((\mathcal{P}_\tau^{\mathrm{C}})_{C_kA}\mathcal{P}_\sigma\mathcal{U}_k(\tilde{\rho}_{k-1}(\mathcal{P}_\sigma))\mathcal{U}_k^\dagger\mathcal{P}_\sigma^\dagger(\mathcal{P}_\tau^{\mathrm{C}})_{C_kA}^\dagger\right)\\ =& \frac{1}{N!(N^2-N)!}\sum_{i=1}^{N!(N^2-N)!}\mathcal{P}_{\tau_i}\mathcal{P}_\sigma\mathcal{U}_k\,\mathrm{tr}_C\left(\tilde{\rho}_{k-1}(\mathcal{P}_\sigma)\right)\mathcal{U}_k^\dagger\mathcal{P}_\sigma^\dagger\mathcal{P}_{\tau_i}^\dagger \end{aligned}\tag{43}$$

Now we need to show $\tilde{M}$ decides $L_{\boldsymbol{\mathcal{O}}}$ for a preimage-correct oracle $\boldsymbol{\mathcal{O}}$. Let's consider an input 1^n. Suppose $\mathcal{O}_n = \mathcal{P}_\sigma$, where $S_{\mathrm{pre}}(\sigma) \in \mathbf{S}^n_{\mathrm{even}}$. Then because M decides $L_{\boldsymbol{\mathcal{O}}}$ for any randomized-preimage-correct, there exists a witness w that depends only on $S_{\mathrm{pre}}(\sigma)$ such that when the oracle is $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}$ the output of M is 1 with probability at least $2/3$. Using the same witness w, $\tilde{M}$ will therefore produce output 1 with probability at least $2/3$.

Now consider an input 1^n such that $\mathcal{O}_n = \mathcal{P}_\sigma$ where $S_{\mathrm{pre}}(\sigma) \in \mathbf{S}^n_{\mathrm{odd}}$. Because M decides $L_{\boldsymbol{\mathcal{O}}}$ for a randomized-preimage-correct oracle $\boldsymbol{\mathcal{O}}$, when M is run with the oracle $\mathscr{P}_{\boldsymbol{\sigma}_{\mathrm{pre}}(S_{\mathrm{pre}}(\sigma))}$, for any witness w, M will output 1 with probability at most $1/3$. But because $\tilde{M}$ will have the same probability distribution of outcomes, this means that for any witness w to $\tilde{M}$, with oracle $\mathcal{P}_\sigma$, $\tilde{M}$ will output 1 with probability at most $1/3$. ◀

D Proofs of Lemmas 16 and 17

▶ **Lemma 16.** *Let $0 < \alpha < 1/2$ be a constant and $p(\cdot)$ be a polynomial function. Then there exists a positive integer $n^*(p,\alpha)$, such that for every $n > n^*(p,\alpha)$, and every subset family $\mathbf{S} \subset \mathbf{S}^n_{\mathrm{even}}$ such that $|\mathbf{S}| \geq |\mathbf{S}^n_{\mathrm{even}}|2^{-p(n)}$, there exists a subset family $\mathbf{S}_X \subset \mathbf{S}$ such that $\mathbf{S}_X$ is α-distributed. Furthermore the fixed subset S_{fixed} of $\mathbf{S}_X$ contains at most $N/3$ even elements.*

Proof. We prove the existence of $\mathbf{S}'$ by construction. Let $\mathbf{S}$ be any subset of $\mathbf{S}^n_{\mathrm{even}}$ such that $|\mathbf{S}| \geq |\mathbf{S}^n_{\mathrm{even}}|2^{-p(n)}$. We construct $\mathbf{S}_X$ using the following procedure, which we call the fixing procedure.

Fixing Procedure

1. Set $\mathbf{S}_X = \mathbf{S}$, and set $S_{\mathrm{fixed}} = \emptyset$.
2. **a.** Let $\nu(i)$ be the number of subsets $S \in \mathbf{S}_X$ such that $i \in S$.
   b. If there exists some element i for which

$$|\mathbf{S}_X| > \nu(i) \geq |\mathbf{S}_X|N^{-\alpha} \tag{44}$$

set $\mathbf{S}_X \leftarrow \{S : S \in \mathbf{S}_X \text{ and } i \in S\}$, set $S_{\mathrm{fixed}} \leftarrow S_{\mathrm{fixed}} \cup i$, and return to step 2(a). Otherwise exit the Fixing Procedure.

By construction, $\mathbf{S}_X$ will satisfy Definition 6. Now we need to check that the Fixing Procedure stops before fixing more than $N/3$ even items.

Let's suppose that at some point in the Fixing Procedure, for sets $\mathbf{S}_X$ and S_{fixed}, we have $N/3$ even items fixed. Suppose for contradiction, that at this point, there is some even element i^* such that i^* appears in greater than $N^{-\alpha}$ fraction of $S \in \mathbf{S}_X$. Let's also assume without loss of generality that $|S_{\text{fixed}} \cap \mathbb{Z}_{\text{odd}}| = k_{\text{odd}} \leq N/3$.

Let us look at the set

$$\mathbf{S}'' = \{S : S \in \mathbf{S}_X, i^* \in S\}. \tag{45}$$

Because $(S_{\text{fixed}} \cup i^*) \subset S$ for all $S \in \mathbf{S}''$, there are $N/3 - 1$ even elements that can be freely chosen for $S \in \mathbf{S}''$ and $N/3 - k_{\text{odd}}$ odd elements that can be freely chosen. Thus, we have

$$|\mathbf{S}''| \leq \binom{N^2/2 - N/3 - 1}{N/3 - 1}\binom{N^2/2 - k_{\text{odd}}}{N/3 - k_{\text{odd}}}. \tag{46}$$

By assumption

$$|\mathbf{S}''| \geq |\mathbf{S}_X| N^{-\alpha}, \tag{47}$$

so

$$\begin{aligned}
|\mathbf{S}_X| &\leq \binom{N^2/2 - N/3 - 1}{N/3 - 1}\binom{N^2/2 - k_{\text{odd}}}{N/3 - k_{\text{odd}}} N^{\alpha} \\
&\leq \binom{N^2/2}{N/3}\binom{N^2/2}{N/3} N^{\alpha} \\
&\leq (3Ne/2)^{2N/3} N^{\alpha} \\
&= 2^{2N/3(\log(3e/2) + \log N) + \log(N)\alpha} \\
&= 2^{O(N) + (2N/3)\log N}.
\end{aligned} \tag{48}$$

However, we can also bound the size of $\mathbf{S}_X$ from the Fixing Procedure. Notice that at every step of the Fixing Procedure, the size of $\mathbf{S}_X$ is reduced by at most a factor $N^{-\alpha}$. Since we are assuming $N/3$ even elements are in S_{fixed} and $k_{\text{odd}} \leq N/3$ odd elements are in S_{fixed}, the Fixing Procedure can reduce the original set family $\mathbf{S}$ by at most a factor $N^{-\alpha(2N/3)}$. Since $|\mathbf{S}| \geq |\mathbf{S}^n_{\text{even}}| 2^{-p(n)}$, we have that at this point in the Fixing Procedure

$$\begin{aligned}
|\mathbf{S}_X| &\geq |\mathbf{S}^n_{\text{even}}| 2^{-p(n)} N^{-\alpha(2N/3)} \\
&= \binom{N^2/2}{2N/3}\binom{N^2/2}{N/3} 2^{-p(n)} N^{-\alpha(2N/3)} \\
&\leq (3N/4)^{2N/3} (3N/4)^{N/3} 2^{-p(n)} N^{-\alpha(2N/3)} \\
&= 2^{2N/3(\log(3/4) + \log N) + N/3(\log(3/4) + \log N) - p(n) - \log(N)\alpha 2N/3} \\
&= 2^{N \log N(1 - 2\alpha/3) + N\log(3/4) - p(\log(N))} \\
&= 2^{-O(N) + N\log N(1 - 2\alpha/3)}.
\end{aligned} \tag{49}$$

Notice that as long as $\alpha < 1/2$, for large enough N (in particular, for $N > 2^{n^*}$ for some positive integer n^*, where n^* depends on α and $p(\cdot)$), the bound of Eq. (49) will be larger than the bound of Eq. (48), giving a contradiction. Therefore, our assumption, must have been false, and at this point in the Fixing Procedure, all even elements $i \in [N^2]/S_{\text{fixed}}$ will appear in at most a fraction $N^{-\alpha}$ of $S \in \mathbf{S}_X$. Thus at the next step of the Fixing Procedure, an even element will not be added to S_{fixed}, and the number of even elements in S_{fixed} will stay bounded by $N/3$. The same logic can be reapplied at future steps of the Fixing Procedure, even if additional odd items are added. ◀

▶ **Lemma 17.** *Let $\mathbf{S}_X$ be the α-distributed set created using the Fixing Procedure from Lemma 16, with fixed subset S_{fixed}. Let $\mathbf{S}_Y = \{S : S \in \mathbf{S}^n_{odd}, S_{fixed} \subset S\}$. Then we can construct an adversary bound to prove that for every quantum algorithm G, there exists permutations $\sigma_x, \sigma_y \in \boldsymbol{\sigma}^n$ with $S_{pre}(\sigma_x) \in \mathbf{S}_X$ and $S_{pre}(\sigma_y) \in \mathbf{S}_Y$, (that depend on G) such that, given oracle access to $\mathcal{P}_{\sigma_x}$ or $\mathcal{P}_{\sigma_y}$, G can not distinguish them with probability $\epsilon > .5$ without using $\left(1 - 2\sqrt{\epsilon(1-\epsilon)}\right) N^{\alpha/2}$ queries.*

Proof. Since $\mathbf{S}_X$ is α-distributed, there exists a set S_{fixed} of elements such that $S_{\text{fixed}} \subset S$ for all $S \in \mathbf{S}_X$, where S_{fixed} contains at most $N/3$ odd elements and at most $N/3$ even elements. (Otherwise Condition (2) of Definition 6 will not be satisfied.) We choose

$$\begin{aligned}\boldsymbol{\sigma}_Y &= \{\sigma : S_{\text{pre}}(\sigma) \in \mathbf{S}_Y\},\\ \boldsymbol{\sigma}_X &= \{\sigma : S_{\text{pre}}(\sigma) \in \mathbf{S}_X\}.\end{aligned} \tag{50}$$

We now define the relation $\mathbf{R}$ needed to apply our adversary bound. For each $(S_x, S_y) \in \mathbf{S}_X \times \mathbf{S}_Y$, we will create a one-to-one matching in $\mathbf{R}$ between the elements of $\boldsymbol{\sigma}_{\text{pre}}(S_x)$ and $\boldsymbol{\sigma}_{\text{pre}}(S_y)$. We first choose any element $\sigma^*_x \in \boldsymbol{\sigma}_{\text{pre}}(S_x)$. Then we choose a permutation $\sigma^*_y \in \boldsymbol{\sigma}_{\text{pre}}(S_y)$ such that

- $\forall j \in (S_x \cap S_y), \sigma^*_x(j) = \sigma^*_y(j)$,
- $\forall j \in [N^2] \setminus (S_x \cup S_y), \sigma^*_x(j) = \sigma^*_y(j)$,
- $\forall j \in S_x \setminus (S_x \cap S_y), \exists i \in S_y \setminus (S_x \cap S_y)$ such that $\sigma^*_x(j) = \sigma^*_y(i)$ and $\sigma^*_x(i) = \sigma^*_y(j)$.

Since every permutation corresponding to S_y is in $\boldsymbol{\sigma}_{\text{pre}}(S_y)$, there will always be such a σ^*_y that satisfies the above criterion. We choose $(\sigma^*_x, \sigma^*_y) \in \mathbf{R}$.

For $i \in [N!(N^2 - N)!]$ let $\boldsymbol{\tau}^n = \{\tau_i\}$ be the set of permutations on the elements of $[N^2]$ that do not mix the first N elements with the last $N^2 - N$ elements. By $\sigma_a \circ \sigma_b$, we mean apply first permutation σ_b, and then permutation σ_a. Notice that

$$\begin{aligned}\boldsymbol{\sigma}_{\text{pre}}(S_x) =& \{\tau \circ \sigma^*_x : \tau \in \boldsymbol{\tau}^n\}\\ \boldsymbol{\sigma}_{\text{pre}}(S_y) =& \{\tau \circ \sigma^*_y : \tau \in \boldsymbol{\tau}^n\}.\end{aligned} \tag{51}$$

Furthermore given $\tau \in \boldsymbol{\tau}^n$, we have

- $\forall j \in (S_x \cap S_y), \tau \circ \sigma^*_x(j) = \tau \circ \sigma^*_y(j)$,
- $\forall j \in [N^2] \setminus (S_x \cup S_y), \tau \circ \sigma^*_x(j) = \tau \circ \sigma^*_y(j)$,
- $\forall j \in S_x \setminus (S_x \cap S_y), \exists i \in S_y \setminus (S_x \cap S_y)$ such that $\tau \circ \sigma^*_x(j) = \tau \circ \sigma^*_y(i)$ and $\sigma \circ \sigma^*_x(i) = \sigma \circ \sigma^*_y(j)$.

For every $\tau \in \boldsymbol{\tau}^n$, we set $(\tau \circ \sigma^*_x, \tau \circ \sigma^*_y) \in \mathbf{R}$. In doing so, we create a one-to-one correspondance in $\mathbf{R}$ between the elements of $\boldsymbol{\sigma}_{\text{pre}}(S_x)$ and $\boldsymbol{\sigma}_{\text{pre}}(S_y)$. We then repeat this process for all pairs $(S_x, S_y) \in \mathbf{S}_X \times \mathbf{S}_Y$. The end result is the $\mathbf{R}$ that we will use.

Now we need to analyze the properties of this $\mathbf{R}$. Notice that each $\sigma_x \in \boldsymbol{\sigma}_X$ is paired to exactly one element of $\boldsymbol{\sigma}_{\text{pre}}(S_y)$ for each $S_y \in \mathbf{S}_Y$. Thus $m = |\mathbf{S}_Y|$. Likewise $m' = |\mathbf{S}_X|$.

Now consider $(\sigma_x, \sigma_y) \in \mathbf{R}$. We consider some element j such that $\sigma_x(j) \neq \sigma_y(j)$. We first consider the case that $j \in S_x$. We upper bound $l_{x,j}$, the number of $\sigma_{y'}$ such that $(\sigma_x, \sigma_{y'}) \in \mathbf{R}$ and $\sigma_{y'}(j) \neq \sigma_x(j)$. To simplify analysis, we use the simple upper bound $l_{x,j} \leq |\mathbf{S}_Y|$, which is sufficient for our purposes. Next we need to upper bound $l_{y,j}$, the number of $\sigma_{x'}$ such that $(\sigma_{x'}, \sigma_y) \in \mathbf{R}$ and $\sigma_{x'}(j) \neq \sigma_y(j)$. By our construction of $\mathbf{R}$, we have $j \notin S_y$. Also, by construction, if $j \notin S_y$, $\sigma_{x'}(j) \neq \sigma_y(j)$ if and only if $j \in S_{x'}$. Since σ_y is paired to only one element σ_x for each set S_x, $l_{y,j}$ is bounded by the number of sets

$S_x \in \mathbf{S}_X$ such that $j \in S_x$. Because $\mathbf{S}_X$ is α-distributed, at most a fraction $N^{-\alpha}$ of the sets of $\mathbf{S}_X$ can contain j, so $l_{y,j} \leq |\mathbf{S}_X| N^{-\alpha}$. In this case we have

$$l_{x,j} l_{y,j} \leq |\mathbf{S}_X||\mathbf{S}_Y| N^{-\alpha}. \tag{52}$$

We now consider the case that $j \in S_y$. We upper bound $l_{y,j}$, the number of $\sigma_{x'}$ such that $(\sigma_{x'}, \sigma_y) \in \mathbf{R}$ and $\sigma_{x'}(j) \neq \sigma_y(j)$. To simplify analysis, we use the upper bound of $l_{y,j} \leq |\mathbf{S}_X|$, which is sufficient for our analysis. Next we need to upper bound $l_{x,j}$, the number of $\sigma_{y'}$ such that $(\sigma_x, \sigma_{y'}) \in \mathbf{R}$ and $\sigma_{y'}(j) \neq \sigma_x(j)$. By our construction of $\mathbf{R}$, we have $j \notin S_x$. Also, by construction, if $j \notin S_x$, $\sigma_{y'}(j) \neq \sigma_x(j)$ if and only if $j \in S_{y'}$. Since σ_x is paired to only one element σ_x for each set S_x, $l_{x,j}$ is bounded by the number of sets $S_y \in \mathbf{S}_Y$ such that $j \in S_y$. Suppose S_{fixed} contains k_{even} even elements and k_{odd} odd elements. If j is odd, we have

$$\begin{aligned} l_{x,j} &= \binom{N^2/2 - k_{\text{odd}} - 1}{2N/3 - k_{\text{odd}} - 1} \binom{N^2/2 - k_{\text{even}}}{N/3 - k_{\text{even}}} \\ &\leq \frac{2N/3}{N^2/2 - N/3} |\mathbf{S}_Y|, \end{aligned} \tag{53}$$

while if j is even (in that case, we must have $k_{\text{even}} < N/3$), we have

$$\begin{aligned} l_{x,j} &= \binom{N^2/2 - k_{\text{odd}}}{2N/3 - k_{\text{odd}}} \binom{N^2/2 - k_{\text{even}} - 1}{N/3 - k_{\text{even}} - 1} \\ &\leq \frac{N/3}{N^2/2 - N/3} |\mathbf{S}_Y|, \end{aligned} \tag{54}$$

where we've used that

$$|\mathbf{S}_Y| = \binom{N^2/2 - k_{\text{odd}}}{2N/3 - k_{\text{odd}}} \binom{N^2/2 - k_{\text{even}}}{N/3 - k_{\text{even}}}. \tag{55}$$

Therefore in this case, we have

$$l_{x,j} l_{y,j} = |\mathbf{S}_X||\mathbf{S}_Y| O(N^{-1}). \tag{56}$$

Looking at Eq. (52) and Eq. (56), we see that because $\alpha < 1$, the bound of Eq. (52) dominates, and so we have that

$$\sqrt{\frac{mm'}{l_{x,j} l_{y,j}}} \geq \sqrt{\frac{|\mathbf{S}_X||\mathbf{S}_Y|}{|\mathbf{S}_X||\mathbf{S}_Y| N^{-\alpha}}} = N^{\alpha/2}. \tag{57}$$

Using the contrapositive of Lemma 2, if an algorithm G makes less than q queries to an oracle $\mathcal{O}_{\sigma_x}$ where σ_x is promised to be in $\boldsymbol{\sigma}_X$ or $\boldsymbol{\sigma}_Y$, there exists at least one element of $\boldsymbol{\sigma}_X$ and one element of $\boldsymbol{\sigma}_Y$ such that the probability of distinguishing between the corresponding oracles less than is $1/2 + \epsilon$, where

$$\frac{1}{2} \sqrt{2 N^{-\alpha/2} q} > \epsilon. \tag{58}$$

Equivalently, there exists at least one element of $\boldsymbol{\sigma}_X$ and one element of $\boldsymbol{\sigma}_Y$ such that in order for $\mathcal{A}$ to distinguish them with constant bias, one requires $\Omega(N^{\alpha/2})$ queries. ◀

Timed Network Games with Clocks

Abstract

Network games are widely used as a model for selfish resource-allocation problems. In the classical model, each player selects a path connecting her source and target vertices. The cost of traversing an edge depends on the *load*; namely, number of players that traverse it. Thus, it abstracts the fact that different users may use a resource at different times and for different durations, which plays an important role in determining the costs of the users in reality. For example, when transmitting packets in a communication network, routing traffic in a road network, or processing a task in a production system, actual sharing and congestion of resources crucially depends on time.

In [13], we introduced *timed network games*, which add a time component to network games. Each vertex v in the network is associated with a cost function, mapping the load on v to the price that a player pays for staying in v for one time unit with this load. Each edge in the network is guarded by the time intervals in which it can be traversed, which forces the players to spend time in the vertices. In this work we significantly extend the way time can be referred to in timed network games. In the model we study, the network is equipped with *clocks*, and, as in timed automata, edges are guarded by constraints on the values of the clocks, and their traversal may involve a reset of some clocks. We argue that the stronger model captures many realistic networks. The addition of clocks breaks the techniques we developed in [13] and we develop new techniques in order to show that positive results on classic network games carry over to the stronger timed setting.

1 Introduction

Network games (NGs, for short) [10, 48, 49] constitute a well studied model of non-cooperative games. The game is played among selfish players on a network, which is a directed graph. Each player has a source and a target vertex, and a strategy is a choice of a path that connects these two vertices. The cost a player pays for an edge depends on the *load* on it, namely the number of players that use the edge, and the total cost is the sum of costs of the edges she uses. In *cost-sharing* games, load has a positive effect on cost: each edge has a cost and the players that use it split the cost among them. Then, in *congestion* games[4], load has a negative effect on cost: each edge has a non-decreasing *latency function* that maps the load on the edge to its cost.

One limitation of NGs is that the cost of using a resource abstracts the fact that different users may use the resource at different times and for different durations. This is a real limitation, as time plays an important role in many real-life settings. For example, in a road or a communication system, congestion only affects cars or messages that use a road or a channel simultaneously. We are interested in settings in which congestion affects the quality of service (QoS) or the way a price is shared by entities using a resource at the *same time* (rather than affecting the travel time). For example, discomfort increases in a crowded train (in congestion games) or price is shared by the passengers in a taxi (in cost-sharing games).

The need to address temporal behaviors has attracted a lot of research in theoretical computer science. Formalisms like temporal logic [46] enable the specification of the temporal ordering of events. Its refinement to formalisms like real-time temporal logic [7], interval temporal logic [42], and timed automata (TAs, for short) [6] enables the specification of *real-time* behaviors. Extensions of TAs include *priced timed automata* (PTAs, for short) that assign costs to real-time behaviors. Thus, PTAs are suitable for reasoning about quality of real-time systems. They lack, however, the capability to reason about multi-agent systems in which the players' choices affect the incurred costs.

We study *timed network games* (TNGs, for short) – a new model that adds a time component to NGs. A TNG is played on a *timed-network* in which edges are labeled by *guards* that specify time restrictions on when the edge can be traversed. Similar to NGs, each player has a source and target vertex, but a strategy is now a *timed path* that specifies, in addition to which vertices are traversed, the amount of time that is spent in each vertex. Players pay for staying in vertices, and the cost of staying in a vertex v in a time interval $I \subseteq \mathbb{R}_{\geq 0}$ is affected by the load in v during I. In [13], we studied a class of TNGs that offered a first extension of NGs to a timed variant in which the reference to time is restricted: the guards on the edges refer only to *global* time, i.e., the time that has elapsed since the beginning of the game. In the model in [13], it is impossible to refer to the duration of certain events that occur during the game, for example, it is not possible to express constraints that require staying exactly one time unit in a vertex. Accordingly, we refer to that class as *global TNGs* (GTNGs, for short).

In this work, we significantly extend the way time can be referred to in TNGs. We do this by adding *clocks* that may be reset along the edges, and by allowing the guards on the edges to refer to the values of all clocks. GTNGs can be viewed as a fragment in which there is only a single clock that is never reset. We demonstrate our model in the following example.

[4] The name *congestion games* is sometimes used to refer to games with general latency functions. We find it more appropriate to use it to refer to games with non-decreasing functions.

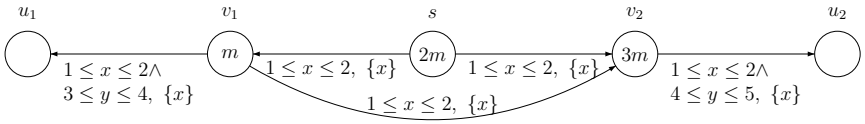

Figure 1 A congestion TNG.

▶ **Example 1.** Consider a setting in which messages are sent through a network of routers. Messages are owned by selfish agents who try to avoid congested routes, where there is a greater chance of loss or corruption. The owners of the messages decide how much time they spend in each router. Using TNGs, we can model constraints on these times, as well as constraints on global events, in particular, arrival time. Note that in some applications, c.f., advertising or security, messages need to patrol the network with a lower bound on their arrival time.

Consider the TNG appearing in Figure 1. The vertices in the TNG model the routers. There are two players that model two agents, each sending a message. The source of both messages is s and the targets are u_1 and u_2, for messages 1 and 2, respectively. The latency functions are described in the vertices, as a function of the load m; e.g., the latency function in v_2 is $\ell_{v_2}(m) = 3m$. Thus, when a single message stays in v_2 the cost for each time unit is 3, and when the two messages visit v_2 simultaneously, the cost for each of them is 6 per unit time. The network has two clocks, x and y. Clock x is reset in each transition and thus is used to impose restrictions on the time that can be spent in each router: since all transitions can be taken when $1 \leq x \leq 2$, a message stays between 1 and 2 time units in a router. Clock y is never reset, thus it keeps track of the global time. The guards on clock y guarantee that message 1 reaches its destination by time 4 but not before time 3 and message 2 reaches its destination by time 5 but not before time 4.

Suppose the first agent chooses the timed path $(s, 2), (v_1, 1), u_1$, thus message 1 stays in s for two time units and in v_1 for one time unit before reaching its destination u_1. Suppose the second agent chooses the path $(s, 2), (v_1, 2), (v_2, 1), u_2$. Note that crossing an edge is instantaneous. Since both messages stay in the same vertices during the intervals $I_1 = [0, 2]$ and $I_2 = [2, 3]$, the load in the corresponding vertices is 2. During interval I_1, each of the agents pays $|I_1| \cdot \ell_s(2) = 2 \cdot 4$ and during I_2, each pays $|I_2| \cdot \ell_{v_1}(2) = 1 \cdot 2$. Message 2 stays in v_1 alone during the interval $[3, 4]$ and in v_2 during the interval $[4, 5]$, for which it pays 1 and 3, respectively. The total costs are thus 10 and 14.

Before we elaborate on our contribution, let us survey relevant works, namely, extensions of NGs with temporal aspects and extensions of timed-automata to games. Extensions of NGs that involve reasoning about time mostly study a cost model in which the players try to minimize the time of arrival at their destinations (c.f., [36, 39, 47, 45]), where, for example, congestion affects the duration of crossing an edge. These works are different from ours since we consider a QoS cost model. An exception is [36], which studies the QoS costs. A key difference in the models is that there, time is discrete and the players have finitely many strategies. Thus, reductions to classical resource allocation games is straightforward while for TNGs it is not possible, as we elaborate below. Games on timed automata were first studied in [11] in which an algorithm to solve timed games with timed reachability objective was given. The work was later generalized and improved [4, 20, 35, 23]. Average timed games, games with parity objectives, mean-payoff games and energy games have also been studied in the context of timed automata [2, 37, 27, 21, 34]. All the timed games above are two-player zero-sum ongoing games. Prices are fixed and there is no notion of load. Also, the questions

studied on these games concern their decidability, namely finding winners and strategies for them. TNGs are not zero-sum games, so winning strategies do not exist. Instead, the problems we study here concern rationality and stability.

The first question that arises in the context of non-zero-sum games is the existence of *stable outcomes*. In the context of NGs, the most prominent stability concept is that of a (pure) *Nash equilibrium* (NE, for short) [43] – a profile such that no player can decrease her cost by unilaterally deviating from her current strategy.[5] Decentralized decision-making may lead to solutions that are sub-optimal for the society as a whole. The standard measures to quantify the inefficiency incurred due to selfish behavior is the *price of stability* (PoS) [10] and the *price of anarchy* (PoA) [38]. In both measures we compare against the *social optimum* (SO, for short), namely a profile that minimizes the sum of costs of all players. The PoS (PoA, respectively) is the best-case (worst-case) inefficiency of an NE; that is, the ratio between the cost of a best (worst) NE and the SO.

The picture of stability and equilibrium inefficiency for standard NGs is well understood. Every NG has an NE, and in fact these games are *potential games* [48], which have the following stronger property: a *best response sequence* is a sequence of profiles $P_1, P_2, \ldots$ such that, for $i \geq 1$, the profile P_{i+1} is obtained from P_i by letting some player deviate and decrease her personal cost. In finite potential games, every best-response sequence converges to an NE. For k-player cost-sharing NGs, the PoS and PoA are $\log k$ and k, respectively [10]. For congestion games with affine cost functions, PoS ≈ 1.577 [29, 1] and PoA $= \frac{5}{2}$ [30].

In [13], we showed that these positive results carry over to GTNGs. A key technical feature of GTNGs is that since guards refer to global time, it is easy to find an upper bound T on the time by which all players reach their destinations. Proving existence of NE follows from a reduction to NGs, using a zone-like structure [5, 18]. The introduction of clocks with resets breaks the direct reduction to NGs and questions the existence of a bound by which the players arrive at their destinations.[6] To see the difficulty in finding such a bound, consider, for example, a cost-sharing game in which all players, on their paths to their targets, need to stay for one time unit in a "gateway" vertex v that costs 1 (see details in Section 6). Assume also that, for $1 \leq i \leq k$, Player i can only reach v in times that are multiples of p_i, for relatively prime numbers $p_1, \ldots, p_k$. The SO is obtained when all players synchronize their visits to v, and such a synchronization forces them to wait till time $p_1 \cdot \ldots \cdot p_k$, which is exponential in the TNG.

The lack of an upper bound on the global time in TNGs demonstrates that we need a different approach to obtain positive results for general TNGs. We show that TNGs are guaranteed to have an NE. Our proof uses a combination of techniques from real-time models and resource allocation games. Recall that a PTA assigns a price to a timed word. We are able to reduce the *best-response* and the *social-optimum* problems to and from the problem of finding cheapest runs in PTAs [19], showing that the problems are PSPACE-complete. Next, we show that TNGs are potential games. Note that since players have uncountably many strategies, the fact that TNGs are potential games does not immediately imply existence of an NE, as a best-response sequence may not be finite. We show that there is a best-response sequence that terminates in an NE. For this, we first need to show the existence of an integral best-response, which is obtained from the reduction to PTAs. Finally, given a TNG, we find a time T such that there exists an NE in which all players reach their destination by time T.

Due to lack of space, some of the proofs appear in the full version [14].

---

[5] Throughout this paper, we consider *pure* strategies, as is the case for the vast literature on NGs.

[6] In the full version we show that even with an upper bound on time, a reduction from TNGs to NGs is not likely.

2 Preliminaries

2.1 Resource allocation games and network games

For $k \in \mathbb{N}$, let $[k] = \{1, \ldots, k\}$. A *resource allocation game* (RAG, for short) is $R = \langle k, E, \{\Sigma_i\}_{i\in[k]}, \{\ell_e\}_{e\in E}\rangle$, where $k \in \mathbb{N}$ is the number of players; E is a set of resources; for $i \in [k]$, the set strategies of Player i is $\Sigma_i \subseteq 2^E$; and, for $e \in E$, the *latency function* $\ell_e : [k] \to \mathbb{Q}_{\geq 0}$ maps a load on e to its cost under this load. A *profile* is a choice of a strategy for each player. The set of profiles of R is $\mathit{profiles}(R) = \Sigma_1 \times \ldots \times \Sigma_k$. For $e \in E$, we define the *load* on e in a profile $P = \langle \sigma_1, \ldots, \sigma_k\rangle$, denoted $\mathit{load}_P(e)$, as the number of players using e in P, thus $\mathit{load}_P(e) = |\{i \in [k] : e \in \sigma_i\}|$. The cost a player pays in profile P, denoted $\mathit{cost}_i(P)$, depends on the choices of the other players. We define $\mathit{cost}_i(P) = \sum_{e\in\sigma_i} \ell_e(\mathit{load}_P(e))$.

Network games (NGs, for short) can be viewed as a special case of RAGs where strategies are succinctly represented by means of paths in graphs. An NG is $\mathcal{N} = \langle k, V, E, \{\langle s_i, u_i\rangle\}_{i\in[k]}, \{\ell_e\}_{e\in E}\rangle$, where $\langle V, E\rangle$ is a directed graph; for $i \in [k]$, the vertices s_i and u_i are the *source* and *target* vertices of Player i; and the latency functions are as in RAGs. The set of strategies for Player i is the set of simple paths from s_i to u_i in $\mathcal{N}$. Thus, in NGs, the resources are the edges in the graph.

We distinguish between two types of latency functions. In *cost-sharing games*, the players that visit a vertex share its cost equally. Formally, every $e \in E$ has a cost $c_e \in \mathbb{Q}_{\geq 0}$ and its latency function is $\ell_e(l) = \frac{c_e}{l}$. Note that these latency functions are decreasing, thus the load has a positive effect on the cost. In contrast, in *congestion games*, the cost functions are non-decreasing and so the load has a negative effect on the cost. Typically, the latency functions are restricted to simple functions such as linear latency functions, polynomials, and so forth.

2.2 Timed networks and timed network games

A *clock* is a variable that gets values from $\mathbb{R}_{\geq 0}$ and whose value increases as time elapses. A *reset* of a clock x assigns value 0 to x. A *guard* over a set C of clocks is a conjunction of *clock constraints* of the form $x \sim m$, for $x \in C$, $\sim \in \{\leq, =, \geq\}$, and $m \in \mathbb{N}$. Note that we disallow guards that use the operators $<$ and $>$ (see Remark 4). A guard of the form $\bigwedge_{x\in C} x \geq 0$ is called *true*. The set of guards over C is denoted $\Phi(C)$. A *clock valuation* is an assignment $\kappa : C \to \mathbb{R}_{\geq 0}$. A clock valuation κ *satisfies* a guard g, denoted $\kappa \models g$, if the expression obtained from g by replacing each clock $x \in C$ with the value $\kappa(x)$ is valid.

A *timed network* is a tuple $\mathcal{A} = \langle C, V, E\rangle$, where C is a set of clocks, V is a set of vertices, and $E \subseteq V \times \Phi(C) \times 2^C \times V$ is a set of directed edges in which each edge e is associated with a guard $g \in \Phi(C)$ that should be satisfied when e is traversed and a set $R \subseteq C$ of clocks that are reset along the traversal of e.

When traversing a path in a timed network, time is spent in vertices, and edges are traversed instantaneously. Accordingly, a *timed path* in $\mathcal{A}$ is a sequence $\eta = \langle \tau_1, e_1\rangle, \ldots, \langle \tau_n, e_n\rangle \in (\mathbb{R}_{\geq 0} \times E)^*$, describing edges that the path traverses along with their traversal times. The timed path η is *legal* if the edges are successive and the guards associated with them are satisfied. Formally, there is a sequence $\langle v_0, t_0\rangle, \ldots, \langle v_{n-1}, t_{n-1}\rangle, v_n \in (V \times \mathbb{R}_{\geq 0})^* \cdot V$, describing the vertices that η visits and the time spent in these vertices, such that for every $1 \leq j \leq n$, the following hold: (1) $t_{j-1} = \tau_j - \tau_{j-1}$, with $\tau_0 = 0$, (2) there is $g_j \in \Phi(C)$ and $R_j \subseteq C$, such that $e_j = \langle v_{j-1}, g_j, R_j, v_j\rangle$, (3) there is a clock valuation κ_j that describes the values of the clocks before the incoming edge to vertex v_j is traversed. Thus, $\kappa_1(x) = t_0$, for all $x \in C$, and for $1 < j \leq n$, we distinguish between clocks that are reset when e_{j-1}

is traversed and clocks that are not reset: for $x \in R_{j-1}$, we define $\kappa_j(x) = t_{j-1}$, and for $x \in (C \setminus R_{j-1})$, we define $\kappa_j(x) = \kappa_{j-1}(x) + t_{j-1}$, and (4) for every $1 \leq j \leq n$, we have that $\kappa_j \models g_j$. We sometimes refer to η also as the sequence $\langle v_0, t_0\rangle, \ldots, \langle v_{n-1}, t_{n-1}\rangle, v_n$.

Consider a finite set $T \subseteq \mathbb{R}_{\geq 0}$ of time points. We say that a timed path η is a *T-path* if all edges in η are taken at times in T. Formally, for all $1 \leq j \leq n$, we have that $\tau_j \in T$. We refer to the time at which η *ends* as the time τ_n at which the destination is reached. We say that η is *integral* if $T \subseteq \mathbb{N}$.

A *timed network game* (TNG, for short) extends an NG by imposing constraints on the times at which edges may be traversed. Formally, $\mathcal{T} = \langle k, C, V, E, \{\ell_v\}_{v\in V}, \langle s_i, u_i\rangle_{i\in[k]}\rangle$ includes a set C of clocks, and $\langle C, V, E\rangle$ is a timed network. Recall that while traversing a path in a timed network, time is spent in vertices. Accordingly, the latency functions now apply to vertices, thus $\ell_v : [k] \to \mathbb{Q}_{\geq 0}$ maps a load on vertex v to its cost under this load. Traversing an edge is instantaneous and is free of charge. A strategy for Player i, for $i \in [k]$, is then a legal timed path from s_i to u_i. We assume all players have at least one strategy.

▶ Remark. A possible extension of TNGs is to allow costs on edges. Since edges are traversed instantaneously, these costs would not be affected by load. Such an extension does not affect our results and we leave it out for sake of simplicity. Another possible extension is allowing strict time guards, which we discuss in Remark 4.

The cost Player i pays in profile P, denoted $cost_i(P)$, depends on the vertices in her timed path, the time spent on them, and the load during the visits. In order to define the cost formally, we need some definitions. For a finite set $T \subseteq \mathbb{R}_{\geq 0}$ of time points, we say that a timed path is a T-strategy if it is a T-path. Then, a profile P is a T-profile if it consists only of T-strategies. Let $t_{max} = \max(T)$. For $t \in T$ such that $t < t_{max}$, let $next_T(t)$ be the minimal time point in T that is strictly larger than t. We partition the interval $[0, t_{\max}]$ into a set Υ of sub-intervals $[m, next_T(m)]$ for every $m \in (T \cup \{0\}) \setminus \{t_{max}\}$. We refer to the sub-intervals in Υ as *periods*. Suppose T is the minimal set such that P is a T-profile. Note that Υ is the coarsest partition of $[0, t_{\max}]$ into periods such that no player crosses an edge within a period in Υ. We denote this partition by Υ_P.

For a player $i \in [k]$ and a period $\gamma \in \Upsilon_P$, let $visits_P(i, \gamma)$ be the vertex that Player i visits during period γ. That is, if $\pi_i = \langle v_0^i, t_0^i\rangle, \ldots, \langle v_{n_i-1}^i, t_{n_i-1}^i\rangle, v_{n_i}^i$ is a legal timed path that is a strategy for Player i and $\gamma = [m_1, m_2]$, then $visits_P(i, \gamma)$ is the vertex v_j^i for the index $1 \leq j < n_i$ such that $\tau_j^i \leq m_1 \leq m_2 \leq \tau_{j+1}^i$, and $visits_P(i, \gamma)$ is the vertex v_0^i if $0 = m_1 \leq m_2 \leq \tau_1^i$. Note that since P is a T-profile, for each period $\gamma \in \Upsilon_P$, the number of players that stay in each vertex v during γ is fixed. Let $load_P(v, \gamma)$ denote this number. Formally $load_P(v, \gamma) = |\{i : visits_P(i, \gamma) = v\}|$. Finally, for a period $\gamma = [m_1, m_2]$, let $|\gamma| = m_2 - m_1$ be the *duration* of γ. Suppose Player i's path ends at time τ^i. Let $\Upsilon_P^i \subseteq \Upsilon_P$ denote the periods that end by time τ_i.

Recall that the latency function $\ell_v : [k] \longrightarrow \mathbb{Q}_{\geq 0}$ maps the number of players that simultaneously visit vertex v to the price that each of them pays per time unit. If $visits_P(i, \gamma) = v$, then the cost of Player i in P, over the period γ is $cost_{\gamma,i}(P) = \ell_v(load_P(v, \gamma)) \cdot |\gamma|$. We define $cost_i(P) = \sum_{\gamma\in\Upsilon_P^i} cost_{\gamma,i}(P)$. The cost of the profile P, denoted $cost(P)$, is the total cost incurred by all the players, i.e., $cost(P) = \sum_{i=1}^{k} cost_i(P)$.

A T-strategy is called an *integral strategy* when $T \subseteq \mathbb{N}$, and similarly for *integral* profile.

A profile $P = \langle \pi_1, \ldots, \pi_k\rangle$ is said to *end* by time τ if for each $i \in [k]$, the strategy π_i ends by time τ. Consider a TNG $\mathcal{T}$ that has a cycle such that a clock x of $\mathcal{T}$ is reset on the cycle. It is not difficult to see that this may lead to $\mathcal{T}$ having infinitely many integral profiles that end by different times. A TNG $\mathcal{T}$ is called *global* if it has a single clock x that is never reset. We use GTNG to indicate that a TNG is global.

As in RAGs, we distinguish between cost-sharing TNGs that have cost-sharing latency functions and congestion TNGs in which the latency functions are non-decreasing.

2.3 Stability and efficiency

Consider a game G. For a profile P and a strategy π of player $i \in [k]$, let $P[i \leftarrow \pi]$ denote the profile obtained from P by replacing the strategy of Player i in P by π. A profile P is said to be a *(pure) Nash equilibrium* (NE) if none of the players in $[k]$ can benefit from a unilateral deviation from her strategy in P to another strategy. Formally, for every Player i and every strategy π for Player i, it holds that $cost_i(P[i \leftarrow \pi]) \geq cost_i(P)$.

A *social optimum* (SO) of a game G is a profile that attains the infimum cost over all profiles. We denote by $SO(G)$ the cost of an SO profile; i.e., $SO(G) = \inf_{P \in profiles(G)} cost(P)$. It is well known that decentralized decision-making may lead to sub-optimal solutions from the point of view of the society as a whole. We quantify the inefficiency incurred due to self-interested behavior by the *price of anarchy* (PoA) [38, 44] and *price of stability* (PoS) [10] measures. The PoA is the worst-case inefficiency of a Nash equilibrium, while the PoS measures the best-case inefficiency of a Nash equilibrium. Note that unlike resource allocation games in which the set of profiles is finite, in TNGs there can be uncountably many NEs, so both PoS and PoA need to be defined using infimum/supremum rather than min/max. Formally,

▶ **Definition 2.** Let $\mathcal{G}$ be a family of games, and let $G \in \mathcal{G}$ be a game in $\mathcal{G}$. Let $\Gamma(G)$ be the set of Nash equilibria of the game G. Assume that $\Gamma(G) \neq \emptyset$.

- The *price of anarchy* of G is $PoA(G) = \sup_{P \in \Gamma(G)} cost(P)/SO(G)$. The *price of anarchy* of the family of games $\mathcal{G}$ is $PoA(\mathcal{G}) = sup_{G \in \mathcal{G}} PoA(G)$.
- The *price of stability* of G is $PoS(G) = \inf_{P \in \Gamma(G)} cost(P)/SO(G)$. The *price of stability* of the family of games $\mathcal{G}$ is $PoS(\mathcal{G}) = sup_{G \in \mathcal{G}} PoS(G)$.

3 The Best-Response and the Social-Optimum Problems

Consider a TNG $\mathcal{T} = \langle k, C, V, E, \{\ell_v\}_{v \in V}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$. In the *best-response problem* (BR problem, for short), we ask how a player reacts to a choice of strategies of the other players. Formally, let $\pi_1, \ldots, \pi_{k-1}$ be a choice of integral[7] strategies for Players $1, \ldots, k-1$ in $\mathcal{T}$. We look for a strategy π_k that minimizes $cost_k(\langle \pi_1, \ldots, \pi_k \rangle)$. The choice of allowing Player k to react is arbitrary and is done for convenience of notation. In the *social optimum problem* (SOPT problem, for short), we seek a profile that maximizes the social welfare, or in other words, minimizes the sum of players' costs.

In this section we describe *priced timed automata* (PTAs, for short) [9, 17] and show that while they are different from TNGs both in terms of the model and the questions asked on it, they offer a useful framework for reasoning about TNGs. In particular, we solve the BR and SOPT problems by reductions to problems about PTAs.

3.1 From TNGs to priced timed automata

A PTA [9, 17] is $\mathcal{P} = \langle C, V, E, \{r_v\}_{v \in V} \rangle$, where $\langle C, V, E \rangle$ is a timed network and $r_v \in \mathbb{Q}_{\geq 0}$ is the *rate* of vertex $v \in V$. Intuitively, the rate r_v specifies the cost of staying in v for a duration of one time unit. Thus, a timed path $\eta = \langle v_0, t_0 \rangle, \ldots, \langle v_n, t_n \rangle, v_{n+1}$ in a PTA has a

[7] We choose integral strategies since strategies with irrational times cannot be represented as part of the input; for strategies that use rational times, the best response problem can be solved with little modification in the proof of Theorem 4.

price, denoted $price(\eta)$, which is $\sum_{0 \leq j \leq n} r_v \cdot t_v$. The size of $\mathcal{P}$ is $|V| + |E|$ plus the number of bits needed in the binary encoding of the numbers appearing in guards and rates in $\mathcal{P}$. [8]

Consider a PTA $\mathcal{P}$ and two vertices s and u. Let $paths(s, u)$ be the set of timed paths from s to u. We are interested in cheapest timed paths in $paths(s, u)$. A priori, there is no reason to assume that the minimal price is attained, thus we are interested in the optimal price, denoted $opt(s, u)$, which we define to be $\inf\{price(\eta) : \eta \in paths(s, u)\}$. The corresponding decision problem, called the *cost optimal reachability problem* (COR, for short) takes in addition a threshold μ, and the goal is to decide whether $opt(s, t) \leq \mu$. Recall that we do not allow the guards to use the operators $<$ and $>$.

▶ **Theorem 3.** *[19, 32] The COR problem is PSPACE-complete for PTAs with two or more clocks. Moreover, the optimal price is attained by an integral path, i.e., there is an integral path $\eta \in paths(s, u)$ with $price(\eta) = opt(s, u)$.*

In Sections 3.2 and 3.3 below, we reduce problems on TNGs to problems on PTAs. The reductions allow us to obtain properties on strategies and profiles in TNGs using results on PTAs, which we later use in combination with techniques for NGs in order to solve problems on TNGs.

3.2 The best-response problem

▶ **Theorem 4.** *Consider a TNG $\mathcal{T}$ with n clocks and integral strategies $\pi_1, \ldots, \pi_{k-1}$ for Players $1, \ldots, k-1$. There is a PTA $\mathcal{P}$ with $n+1$ clocks and two vertices v and u such that there is a one-to-one cost-preserving correspondence between strategies for Player k in $\mathcal{T}$ and timed paths from v to u: for every strategy π_k in $\mathcal{T}$ and its corresponding path η in $\mathcal{P}$, we have $cost_k(\langle \pi_1, \ldots, \pi_k \rangle) = price(\eta)$.*

Proof. We describe the intuition of the reduction and the details can be found in the full version. Consider a TNG $\mathcal{T} = \langle k, V, E, C, \{\ell_v\}_{v \in V}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$, where $C = \{x_1, \ldots, x_m\}$. Let $Q = \langle \pi_1, \ldots, \pi_{k-1} \rangle$ be a choice of timed paths for Players $1, \ldots, k-1$. Note that Q can be seen as a profile in a game that is obtained from $\mathcal{T}$ by removing Player k, and we use the definitions for profiles on Q in the expected manner. Let $T \subseteq \mathbb{Q}$ be the minimal set of time points for which all the strategies in Q are T-strategies. Consider two consecutive time points $a, b \in T$, i.e., there is no $c \in T$ with $a < c < b$. Then, there are players that cross edges at times a and b, and no player crosses an edge at time points in the interval (a, b). Moreover, let t_{max} be the latest time in T, then t_{max} is the latest time at which a player reaches her destination. Let Υ_Q be a partition of $[0, t_{max}]$ according to T. We obtain Υ'_Q from Υ_Q by adding the interval $[t_{\max}, \infty)$.

A key observation is that the load on all the vertices is unchanged during every interval in Υ'_Q. For a vertex $v \in V$ and $\delta \in \Upsilon_Q$, the cost Player k pays per unit time for using v in the interval δ is $\ell_v(load_Q(v, \delta) + 1)$. On the other hand, since all $k-1$ players reach their destination by time t_{max}, the load on v after t_{max} is 0, and the cost Player k pays for using it then is $\ell_v(1)$.

The PTA $\mathcal{P}$ that we construct has $|\Upsilon'_Q|$ copies of $\mathcal{T}$, thus its vertices are $V \times \Upsilon'_Q$. Let $\delta_0 = [0, b] \in \Upsilon'_Q$ be the first interval. We consider paths from the vertex $v = \langle s_k, \delta_0 \rangle$, which is the copy of Player k's source in the first copy of $\mathcal{T}$, to a target u, which is a new vertex we add and whose only incoming edges are from vertices of the form $\langle u_k, \delta \rangle$, namely,

[8] In general, PTAs have rates on transitions and strict time guards, which we do not need here.

the copies of the target vertex u_k of Player k. We construct $\mathcal{P}$ such that each such path η from v to u in $\mathcal{P}$ corresponds to a legal strategy π_k for Player k in $\mathcal{T}$, and such that $cost_k(\langle \pi_1, \ldots, \pi_{k-1}, \pi_k \rangle) = price(\eta)$. The main difference between the copies are the vertices' costs, which depend on the load as in the above. We refer to the n clocks in $\mathcal{T}$ as *local clocks*. In each copy of $\mathcal{P}$, we use the local clocks and their guards in $\mathcal{T}$ as well as an additional *global* clock that is never reset to keep track of global time. Let $\delta = [a, b] \in \Upsilon_Q$ and $\delta' = [b, c] \in \Upsilon'_Q$ be the following interval. Let $\mathcal{T}_\delta$ and $\mathcal{T}_{\delta'}$ be the copies of $\mathcal{T}$ that corresponds to the respective intervals. The local clocks guarantee that a path in $\mathcal{T}_\delta$ is a legal path in $\mathcal{T}$. The global clock allows us to make sure that (1) proceeding from $\mathcal{T}_\delta$ to $\mathcal{T}_{\delta'}$ can only occur precisely at time b, and (2) proceeding from $\langle u_k, \delta \rangle$ in $\mathcal{T}_\delta$ to the target u can only occur at a time in the interval δ. ◀

We conclude with the computational complexity of the BR problem. The decision-problem variant gets as input a TNG $\mathcal{T}$, integral strategies $\pi_1, \ldots, \pi_{k-1}$ for Players $1, \ldots, k-1$, and a value μ, and the goal is to decide whether Player k has a strategy π_k such that $cost_k(\langle \pi_1, \ldots, \pi_k \rangle) \leq \mu$. Theorem 4 implies a reduction from the BR problem to the COR problem and a reduction in the other direction is easy since PTAs can be seen as TNGs with a single player. For one-clock instances, we show that the BR problem is NP-hard by a reduction from the subset-sum problem. Note the contrast with the COR problem in one-clock instances, which is NLOGSPACE-complete [41]. The proof of the following theorem can be found in the full version.

▶ **Theorem 5.** *The BR problem is PSPACE-complete for TNGs with two or more clocks. For one-clock cost-sharing and congestion TNGs it is in PSPACE and NP-hard.*

Proof. We reduce the BR problem to and from the COR problem, which is PSPACE-complete for PTAs with at least two clocks [19]. A PTA can be seen as a one-player TNG, thus the BR problem for TNGs with two or more clocks is PSPACE-hard. For the upper bound, given a TNG $\mathcal{T}$, strategies $Q = \langle \pi_1, \ldots, \pi_{k-1} \rangle$ for Players $1, \ldots, k-1$, and a threshold μ, we construct a PTA $\mathcal{P}$ as in the proof of Theorem 4. Note that the size of $\mathcal{P}$ is polynomial in the size of the input and that $\mathcal{P}$ has one more clock than $\mathcal{T}$. An optimal path in $\mathcal{P}$ is a best response for Player k, and such a path can be found in PSPACE.

The final case to consider is TNGs with one clock. We show that the BR problem is NP-hard for such instances using a reduction from the *subset-sum* problem. The input to that problem is a set of natural numbers $A = \{a_1, \ldots, a_n\}$ and $\mu \in \mathbb{N}$, and the goal is to decide whether there is a subset of A whose sum is μ. We start with the cost-sharing case. The game we construct is a two-player game on a network that is depicted in Figure 2. Player 2 has a unique strategy that visits vertex v_{n+1} in the time interval $[\mu, \mu + 1]$. A Player 1 strategy π corresponds to a choice of a subset of A. Player 1's source is v_1 and her target is u_2. The vertex v_{n+1} is the only vertex that has a cost, which is 1, and the other vertices cost 0. For $1 \leq i \leq n$, Player 1 needs to choose between staying in vertex v_i for a duration of a_i time units, and exiting the vertex through the top edge, or staying 0 time units, and exiting the vertex through the bottom edge. Finally, she must stay in v_{n+1} for exactly one time unit. The cost Player 1 pays for v_{n+1} depends on the load. If she stays there in the global time interval $[\mu, \mu + 1]$, she pays $1/2$, and otherwise she pays 1. Thus, Player 1 has a strategy with which she pays $1/2$ iff there is a subset of A whose sum is μ, and we are done.

The reduction for congestion games is similar. Recall that in congestion games, the cost increases with the load, thus a player would aim at using a vertex together with as few other players as possible. The network is the same as the one used above. Instead of two

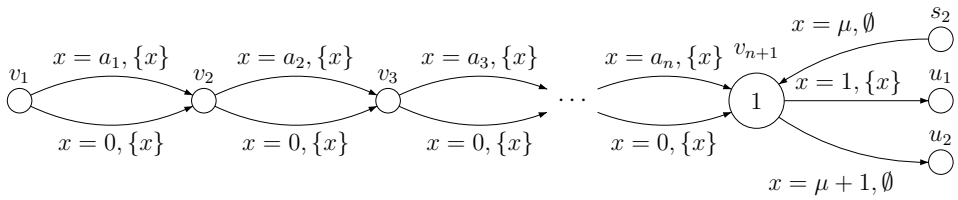

Figure 2 NP-hardness proof of best response problem in one clock TNG.

players, we use three players, where Players 2 and 3 have a unique strategy each. Player 2 must stay in v_{n+1} in the time interval $[0, \mu]$ and Player 3 must stay there during the interval $[\mu + 1, \sum_{1 \leq i \leq n} a_i]$. As in the above, Player 1 has a strategy in which she uses v_{n+1} alone in the time interval $[\mu, \mu + 1]$ iff there is a subset of A whose sum is μ. ◀

3.3 The social-optimum problem

▶ **Theorem 6.** *Consider a TNG $\mathcal{T} = \langle k, C, V, E, \{\ell_v\}_{v \in V}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$. There is a PTA $\mathcal{P}$ with $k \cdot |C|$ clocks, $|V|^k$ vertices, and two vertices $\bar{s}$ and $\bar{u}$ such that there is a one-to-one cost-preserving correspondence between profiles in $\mathcal{T}$ and paths from $\bar{s}$ to $\bar{u}$; namely, for a profile P and its corresponding path η_P, we have $cost(P) = price(\eta_P)$.*

Proof. We describe the intuition of the construction and the details can be found in the full version. Recall that the social optimum is obtained when the players do not act selfishly, rather they cooperate to find the profile that minimizes their sum of costs. Let $\mathcal{T} = \langle k, C, V, E, \{\ell_v\}_{v \in V}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$. We construct a PTA $\mathcal{P}$ by taking k copies of $\mathcal{T}$. For $i \in [k]$, the i-th copy is used to keep track of the timed path that Player i uses. We need k copies of the clocks of $\mathcal{T}$ to guarantee that the individual paths are legal. Recall that the players' goal is to minimize their total cost, thus for each point in time, the price they pay in $\mathcal{P}$ is the sum of their individual costs in $\mathcal{T}$. More formally, consider a vertex $\bar{v} = \langle v_1, \ldots, v_k \rangle$ in $\mathcal{P}$ and let $S_{\bar{v}} \subseteq V$ be the set of vertices that appear in $\bar{v}$. Then, the load on a vertex $v \in S_{\bar{v}}$ in $\bar{v}$ is $load_{\bar{v}}(v) = |\{i : v_i = v\}|$, and the rate of $\bar{v}$ is $\sum_{v \in S_{\bar{v}}} \ell_v(load_{\bar{v}}(v))$. The cost of the social optimum in $\mathcal{T}$ coincides with the price of the optimal timed path in $\mathcal{P}$ from $\langle s_1, \ldots, s_k \rangle$ to the vertex $\langle u_1, \ldots, u_k \rangle$, i.e., the vertices that respectively correspond to the sources and targets of all players. ◀

We turn to study the complexity of the SOPT problem. In the decision-problem variant, we are given a TNG $\mathcal{T}$ and a value μ and the goal is to decide whether there is a profile P in $\mathcal{T}$ with $cost(P) \leq \mu$. Theorem 6 implies a reduction from the SOPT problem to the COR problem, and, as in the BR problem, the other direction is trivial. For one-clock instances, we use the same NP-hardness proof as in the BR problem. The details can be found in the full version.

▶ **Theorem 7.** *The SOPT problem is PSPACE-complete for at least two clocks and it is NP-hard for TNGs with one clock.*

4 Existence of a Nash Equilibrium

The first question that arises in the context of games is the existence of an NE. In [13], we showed that GTNGs are guaranteed to have an NE by reducing every GTNG to an NG. We strengthen the result by showing that every TNG has an NE.

In order to prove existence, we combine techniques from NGs and use the reduction to PTA in Theorem 4. A standard method for finding an NE is showing that a *best-response sequence* converges: Starting from some profile $P = \langle \pi_1, \ldots, \pi_k \rangle$, one searches for a player that can benefit from a unilateral deviation. If no such player exists, then P is an NE and we are done. Otherwise, let π'_i be a beneficial deviation for Player i, i.e., $cost_i(P) > cost_i(P[i \leftarrow \pi'_i])$. The profile $P[i \leftarrow \pi'_i]$ is considered next and the above procedure repeats.

A *potential function* for a game is a function Ψ that maps profiles to costs, such that the following holds: for every profile $P = \langle \pi_1, \ldots, \pi_k \rangle$, $i \in [k]$, and strategy π'_i for Player i, we have $\Psi(P) - \Psi(P[i \leftarrow \pi'_i]) = cost_i(P) - cost_i(P[i \leftarrow \pi'_i])$, i.e., the change in potential equals the change in cost of the deviating player. A game is a *potential game* if it has a potential function. In a potential game with finitely many profiles, since the potential of every profile is non-negative and in every step of a best-response sequence the potential strictly decreases, every best-response sequence terminates in an NE. It is well-known that RAGs are potential games [48] and since they are finite, this implies that an NE always exists.

The idea of our proof is as follows. First, we show that TNGs are potential games, which does not imply existence of NE since TNGs have infinitely many profiles. Then, we focus on a specific best-response sequence that starts from an integral profile and allows the players to deviate only to integral strategies. Finally, we define *normalized TNGs* and show how to *normalize* a TNG in a way that preserves existence of NE. For normalized TNGs, we show that the potential reduces at least by 1 along each step in the best-response sequence, thus it converges to an NE.

▶ **Theorem 8.** *TNGs are potential games.*

Proof. Consider a TNG $\mathcal{T} = \langle k, C, V, E, \{\ell_v\}_{v \in V}, \langle s_i, u_i \rangle_{i \in [k]} \rangle$. Recall that for a profile P, the set of intervals that are used in P is Υ_P. We define a potential function Ψ that is an adaptation of Rosenthal's potential function [48] to TNGs. We decompose the definition of Ψ into smaller components, which will be helpful later on. For every $\gamma \in \Upsilon_P$ and $v \in V$, we define $\Psi_{\gamma,v}(P) = \sum_{j=1}^{load_P(v,\gamma)} |\gamma| \cdot \ell_v(j)$, that is, we take the sum of $|\gamma| \cdot \ell_v(j)$ for all $j \in [load_P(v, \gamma)]$. We define $\Psi_\gamma(P) = \sum_{v \in V} \Psi_{\gamma,v}(P)$, and we define $\Psi(P) = \sum_{\gamma \in \Upsilon_P} \Psi_\gamma(P)$. Let for some $i \in [k]$, we have P' to be a profile that is obtained by an unilateral deviation of Player i to a strictly beneficial strategy π'_i from her current strategy in P, that is $P' = P[i \leftarrow \pi']$ for some $i \in [k]$. In the full version, we show that $\Psi(P) - \Psi(P') = cost_i(P) - cost_i(P')$. ◀

Recall from Theorem 4, that given a TNG, a profile P and an index i, we find the best response of Player i by constructing a PTA. If P is an integral profile, from Theorem 3, we have that the best response of Player i also leads to an integer profile. Thus we have the following lemma.

▶ **Lemma 9.** *Consider a TNG $\mathcal{T}$ and an integral profile P. For $i \in [k]$, if Player i has a beneficial deviation from P, then she has an integral beneficial deviation.*

The last ingredient of the proof gives a lower bound for the difference in cost that is achieved in a beneficial integral deviation for some player $i \in [k]$, which in turn bounds the change in potential.

We first need to introduce a *normalized* form of TNGs. Recall that the latency function in a TNG $\mathcal{T}$ is of the form $\ell_v : [k] \to \mathbb{Q}_{\geq 0}$. In a normalized TNG all the latency functions map loads to natural numbers, thus for every vertex $v \in V$, we have $\ell_v : [k] \to \mathbb{N}$. Constructing a normalized TNG from a TNG is easy. Let L be the least common multiple of the denominators of the elements in the set $\{\ell_v(l) : v \in V \text{ and } l \in [k]\}$. For every latency function ℓ_v and every $l \in [k]$, we construct a new latency function ℓ'_v by $\ell'_v(l) = \ell_v(l) \cdot L$.

Consider a TNG $\mathcal{T}$ and let $\mathcal{T}'$ be the normalized TNG that is constructed from $\mathcal{T}$. It is not hard to see that for every profile P and $i \in [k]$, we have $cost_i(P)$ in $\mathcal{T}'$ is $L \cdot cost_i(P)$ in $\mathcal{T}$. We can thus restrict attention to normalized TNGs as the existence of NE and convergence of best-response sequence in $\mathcal{T}'$ implies the same properties in $\mathcal{T}$. In order to show that a best-response sequence converges in TNGs, we bound the change of potential in each best-response step by observing that in normalized TNGs, the cost a player pays is an integer.

▶ **Lemma 10.** *Let $\mathcal{T}$ be a normalized TNG, $P = \langle \pi_1, \ldots, \pi_k \rangle$ be an integral profile in $\mathcal{T}$, and π_i' be a beneficial integral deviation for Player i, for some $i \in [k]$. Then, $cost_i(P) - cost_i(P[i \leftarrow \pi_i']) \geq 1$.*

We can now prove the main result in this section.

▶ **Theorem 11.** *Every TNG has an integral NE. Moreover, from an integral profile P, there is a best-response sequence that converges to an integral NE.*

Proof. Lemma 9 allows us to restrict attention to integral deviations. Indeed, consider an integral profile P. Lemma 9 implies that if no player has a beneficial integral deviation from P, then P is an NE in $\mathcal{T}$. We start best-response sequence from some integral profile P_I and allow the players to deviate with integral strategies only. Consider a profile P and let P' be a profile that is obtained from P by a deviation of Player i. Recall from Theorem 8 that $cost_i(P) - cost_i(P') = \Psi(P) - \Psi(P')$. Lemma 10 implies that when the deviation is beneficial, we have $\Psi(P) - \Psi(P') \geq 1$. Since the potential is non-negative, the best-response sequence above converges within $\Psi(P_I)$ steps. ◀

▶ Remark. A TNG that allows $<$ and $>$ operators on the guards is not guaranteed to have an NE. Indeed, in a PTA, which can be seen as a one-player TNG, strict guards imply that an optimal timed path may not be achieved. In turn, this means that an NE does not exist. To overcome this issue, we use ϵ-NE, for $\epsilon > 0$; an ϵ-deviation is one that improves the payoff of a player at least by ϵ, and an ϵ-NE is a profile in which no player has a ϵ-deviation. Our techniques can be adapted to show that ϵ-NE exist in TNGs with strict guards. The proof uses the results of [19] that show that an ϵ-optimal timed path exists in PTAs. The proof technique for existence of NE in TNGs with non-strict guards can then be adapted to the strict-guard case.

5 Equilibrium Inefficiency

In this section we address the problem of measuring the degradation in social welfare due to selfish behavior, which is measured by the PoS and PoA measures. We show that the upper bounds from RAGs on these two measures apply to TNGs. For cost-sharing TNGs, we show that the PoS and PoA are at most $\log k$ and k, respectively, as it is in cost-sharing RAGs. Matching lower bounds were given in [13] already for GTNGs. For congestion TNGs with affine latency functions, we show that the PoS and PoA are $1 + \sqrt{(3)}/3 \approx 1.577$ and $\frac{5}{2}$, respectively, as it is in congestion RAGs. Again, a matching lower bound for PoA is shown in [13] for GTNGs, and a matching lower bound for the PoS remains open. Let $\mathcal{F}$ denote a family of latency functions and $\mathcal{F}$-TNGs and $\mathcal{F}$-RAGs denote, respectively, the family of TNGs and RAGs that use latency functions from this family.

▶ **Theorem 12.** *Consider a family of latency functions $\mathcal{F}$. We have $PoS(\mathcal{F}\text{-}TNGs) \leq PoS(\mathcal{F}\text{-}RAGs)$ and $PoA(\mathcal{F}\text{-}TNGs) \leq PoA(\mathcal{F}\text{-}RAGs)$. In particular, the PoS and PoA for cost-sharing TNGs with k players is at most $\log(k)$ and k, respectively, and for congestion TNGs with affine latency functions it is at most roughly 1.577 and $\frac{5}{2}$ respectively.*

Proof. We prove for PoS in cost-sharing games and the other proofs are similar. Consider a TNG $\mathcal{T}$ and let $N^1, N^2, \ldots$ be a sequence of NEs whose cost tends to $c^* = \inf_{P \in \Gamma(\mathcal{T})} cost(P)$. Let O be a social optimum profile in $\mathcal{T}$, which exists due to Theorem 6. Thus, $PoS(\mathcal{T}) = \lim_{j \to \infty} cost(N^j)/\ cost(O)$. We show that each element in the sequence is bounded above by PoS(cost-sharing RAGs), which implies that $PoS(\mathcal{T}) \leq PoS$(cost-sharing RAGs), and hence PoS(cost-sharing TNGs) $\leq PoS$(cost-sharing RAGs). In the full version, for each $j \geq 1$, we construct a RAG $\mathcal{R}_j$ that has $PoS(\mathcal{R}_j) = cost(N^j)/cost(O)$, and since $\mathcal{R}_j$ is a cost-sharing RAG, we have $PoS(\mathcal{R}_j) \leq PoS$(cost- sharing RAGs), and we are done. ◀

6 Time Bounds

Recall that due to resets of clocks, the time by which a profile ends can be potentially unbounded. It is interesting to know, given a TNG, whether there are time bounds within which some interesting profiles like an NE and an SO are guaranteed to exist. Earlier we showed that every TNG is guaranteed to have an integral NE (Theorem 11) and an integral SO (Theorem 6). In this section we give bounds on the time by which such profiles end. That is, given a TNG $\mathcal{T}$, we find $t_{NE}(\mathcal{T}), T_{SO}(\mathcal{T}) \in \mathbb{Q}_{\geq 0}$ such that an integral NE N and an integral SO O exist in $\mathcal{T}$ in which the players reach their destinations by time $t_{NE}(\mathcal{T})$ and $T_{SO}(\mathcal{T})$ respectively.

We start by showing a time bound on an optimal timed path in a PTA, and then proceed to TNGs.

▶ **Lemma 13.** *Consider a PTA $\mathcal{P} = \langle C, V, E, \{r_v\}_{v \in V} \rangle$, and let χ be the largest constant appearing in the guards on the edges of $\mathcal{P}$. Then, for every $s, u \in V$, there is an integral optimal timed path from s to u that ends by time $|V| \cdot (\chi + 2)^{|C|}$.*

Proof. Consider an optimal integral timed path η in $\mathcal{P}$ that ends in the earliest time and includes no loop that is traversed instantaneously. Let $v_0, \ldots, v_n$ be the sequence of vertices that η traverses, and, for $0 \leq i < n$, let κ_i be the clock valuation before exiting the vertex v_i. Since η is integral, κ_i assigns integral values to clocks. Note that since the largest constant appearing in a guard in $\mathcal{P}$ is χ, the guards in $\mathcal{P}$ cannot differentiate between clock values greater than χ. We abstract away such values and define the *restriction* of a clock valuation κ_i to be $\beta_i : C \to (\{0\} \cup [\chi] \cup \{\top\})$ by setting, for $x \in C$, the value $\beta_i(x) = \kappa_i(x)$, when $\kappa_i(x) \leq \chi$, and $\beta_i(x) = \top$, when $\kappa_i(x) > \chi$. Assume towards contradiction that η ends after time $|V| \cdot (\chi + 2)^{|C|}$. Then, there are $0 \leq i < j < n$ such that $\langle v_i, \beta_i \rangle = \langle v_j, \beta_j \rangle$. Let $\eta = \eta_1 \cdot \eta_2 \cdot \eta_3$ be a partition of η such that η_2 is the sub-path between the i-th and j-th indices. Consider the path $\eta' = \eta'_1 \cdot \eta'_3$ that is obtained from η by removing the sub-path η_2. First, note that η' is a legal path. Indeed, the restrictions of the clock valuations in η_1 and η_3 match these in η'_1 and η'_3, that is, $\eta' = \eta_1 \cdot \eta_3$. Second, since we assume that traversing the loop η_2 is not instantaneous, we know that η' ends before η. Moreover, since the rates in $\mathcal{P}$ are non-negative, we have $price(\eta') \leq price(\eta)$, and we reach a contradiction to the fact that η is an optimal timed path that ends earliest. ◀

▶ **Theorem 14.** *For a k-player TNG $\mathcal{T}$ with a set V of vertices and a set C of clocks, there exists an SO that ends by time $\mathcal{O}(|V|^k \cdot \chi^{k|C|})$, where χ is the maximum constant appearing in $\mathcal{T}$. For every $k \geq 1$, there is a k-player (cost-sharing and congestion) TNG $\mathcal{T}_k$ such that $\mathcal{T}_k$ has $\mathcal{O}(k)$ states, the boundaries in the guards in $\mathcal{T}_k$ are bounded by $\mathcal{O}(k \log k)$, and any SO in $\mathcal{T}_k$ requires time $2^{\Omega(k)}$.*

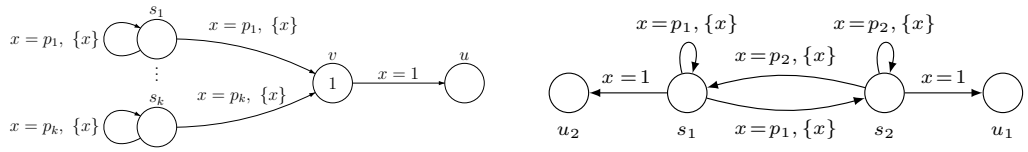

Figure 3 The time required for the SO is not polynomial.

Proof. We start with the upper bound. Consider a TNG $\mathcal{T}$ with a set V of vertices and a set C of clocks. By Theorem 6, we can construct a PTA $\mathcal{P}$ with $|V|^k$ vertices and $k|C|$ clocks such that a social optimum of $\mathcal{T}$ is an optimal timed path in $\mathcal{P}$. Applying Lemma 13, we are done.

We turn to the lower bounds. We show that for every $k \geq 1$, there is a k-player (cost-sharing and congestion) TNG $\mathcal{T}_k$ such that $\mathcal{T}_k$ has $\mathcal{O}(k)$ states, the boundaries in the guards in $\mathcal{T}_k$ are bounded by $\mathcal{O}(k \log k)$, and any SO in $\mathcal{T}_k$ requires time $2^{\Omega(k)}$.

Consider the k-player cost-sharing TNG appearing on the left of Figure 3. Let $p_1, \ldots, p_k$ be relatively prime (e.g., the the first k prime numbers). All the vertices in the TNG have cost 0, except for v, which has some positive cost function. Each player i has to spend one time unit in v in her path from s_i to u. In an SO, all k players spend this one time unit simultaneously, which forces them all to reach v at time $\prod_{1 \leq i \leq k} p_i$. Since the i-th prime number is $O(i \log i)$ and the product of the first i prime numbers is $2^{\Omega(i)}$, we are done. We note that we could define the TNG also with no free vertices, that is vertics with 0 cost, by setting the cost in v to be much higher than those in the source vertices.

For congestion games, the example is more complicated. We start with the case of two players. Consider the congestion TNG appearing on the right of Figure 3. Assume that p_1 and p_2 are relatively prime, $r_{s_1}(1) = r_{s_2}(1) = 0$, and $r_{s_1}(2) = r_{s_2}(2) = 1$. In the SO, the two players avoid each other in their paths from s_i to u_i, and the way to do so is to wait $p_1 \cdot p_2$ time units before the edge from s_i to s_{3-i} is traversed. In the full version,we generalize this example to k players. Again, we could define the TNG with no free vertices. ◀

We proceed to derive a time bound for the existence of an NE. For a TNG $\mathcal{T}$, let $L_{\mathcal{T}} \in \mathbb{N}$ be the smallest number such that multiplying the latency functions by $L_{\mathcal{T}}$ results in a normalized TNG. Recall the $SO(\mathcal{T})$ is the cost of a social optimum in $\mathcal{T}$.

▶ **Theorem 15.** *Consider a TNG $\mathcal{T}$ with k players, played on a timed network $\langle V, E, C \rangle$, and let χ be the maximum constant appearing in a guard. Then, there is an NE in $\mathcal{T}$ that ends by time $\mathcal{O}(\varphi \cdot |V| \cdot \chi^{|C|} + |V|^k \cdot \chi^{k|C|})$, where $\varphi = L_{\mathcal{T}} \cdot SO(\mathcal{T})$ for congestion TNGs and $\varphi = L_{\mathcal{T}} \cdot \log(k) \cdot SO(\mathcal{T})$ for cost-sharing TNGs.*

Proof. Recall the proof of Theorem 11 that shows that every TNG has an integral NE: we choose an initial integral profile P and perform integral best-response moves until an NE is reached. The number of iterations is bounded by the potential $\Psi(P)$ of P. We start the best-response sequence from a social-optimum profile O that ends earliest. By Theorem 14, there is such a profile that ends by time $\mathcal{O}(|V|^k \cdot \chi^{k|C|})$. Let $\varphi = L_{\mathcal{T}} \cdot SO(\mathcal{T})$ in the case of congestion TNGs and $\varphi = L_{\mathcal{T}} \cdot (\ln(k) + 1) \cdot SO(\mathcal{T})$ in the case of cost-sharing TNGs. It is not hard to show that $\Psi(O) \leq \varphi$.

Next, we bound the time that is added in a best-response step. We recall the construction in Theorem 4 of the PTA $\mathcal{P}$ for finding a best-response move. Consider a TNG $\mathcal{T}$ and a profile of strategies P, where, w.l.o.g., we look for a best-response for Player k. Suppose the strategies of Players $1, \ldots, k-1$ take transitions at times $\tau_1, \ldots, \tau_n$. We construct a PTA $\mathcal{P}$

with $n+1$ copies of $\mathcal{T}$. For $1 \leq i \leq n+1$, an optimal path in $\mathcal{P}$ starts in the first copy and moves from copy i to copy $(i+1)$ at time τ_i. We use the additional "global" clock to enforce these transitions. A key observation is that in the last copy, this additional clock is never used. Thus, the largest constant in a guard in the last copy coincides with χ, the largest constant appearing in $\mathcal{T}$. Let η be an optimal path in $\mathcal{P}$ and π_k the corresponding strategy for Player k. We distinguish between two cases. If η does not enter the last copy of $\mathcal{P}$, then it ends before time τ_n, namely the latest time at which a player reaches her destination. Then, the profile $P[k \leftarrow \pi_k]$ ends no later than P. In the second case, the path η ends in the last copy of $\mathcal{P}$. We view the last copy of $\mathcal{P}$ as a PTA. By Lemma 13, the time at which η ends is within $|V| \cdot (\chi+2)^{|C|}$ since its entrance into the copy, which is τ_n. Then, $P[i \leftarrow \pi_k]$ ends at most $|V| \cdot (\chi+2)^{|C|}$ time units after P. To conclude, the best-response sequence terminates in an NE that ends by time $\mathcal{O}(\varphi \cdot |V| \cdot (\chi+2)^{|C|} + |V|^k \cdot \chi^{k|C|})$. ◀

7 Discussion and Future Work

The model of TNGs studied in this paper extends the model of GTNGs introduced in [13] by adding clocks. From a practical point of view, the addition of clocks makes TNGs significantly more expressive than GTNGs and enables them to model the behavior of many systems that cannot be modeled using GTNGs. From a theoretical point of view, the analysis of TNGs poses different and difficult technical challenges. In the case of GTNGs, a main tool for obtaining positive results is a reduction between GTNGs and NGs. Here, in order to obtain positive results we need to combine techniques from NGs and PTAs.

We left several open problems. In Theorem 11, we describe a method for finding an integral NE through a sequence of BR moves. We leave open the complexity of finding an NE in TNGs. For the upper bound, we conjecture that there is a PSPACE algorithm for the problem. For the lower bound, we would need to find an appropriate complexity class of search problems and show hardness for that class. For example, PLS [31], which lies "close" to P, and includes the problem of finding an NE in NGs, consists of search problems in which a local search, e.g., a BR sequence, terminates. Unlike NGs, where a BR can be found in polynomial time, in TNGs, the problem is PSPACE-complete. To the best of our knowledge, complexity classes for search problems that are higher than PLS were not studied. Further we show that the BR and SO problems for one-clock TNGs is in PSPACE and is NP-hard, leaving open the tight complexity.

This work belongs to a line of works that transfer concepts and ideas between the areas of formal verification and algorithmic game theory: logics for specifying multi-agent systems [8, 26], studies of equilibria in games related to synthesis and repair problems [25, 24, 33, 3], and of non-zero-sum games in formal verification [28, 22]. This line of work also includes efficient reasoning about NGs with huge networks [40, 12], an extension of NGs to objectives that are richer than reachability [16], and NGs in which the players select their paths dynamically [15]. For future work, we plan to apply the real-time behavior of TNGs to these last two concepts; namely, TNGs in which the players' objectives are given as a specification that is more general than simple reachability or TNGs in which the players reveal their choice of timed path in steps, bringing TNGs closer to the timed games of [11, 2].

Abstract

The *Consensus-halving* problem is the problem of dividing an object into two portions, such that each of n agents has equal valuation for the two portions. We study the ϵ-approximate version, which allows each agent to have an ϵ discrepancy on the values of the portions. It was recently proven in [13] that the problem of computing an ϵ-approximate Consensus-halving solution (for n agents and n cuts) is PPA-complete when ϵ is *inverse-exponential*. In this paper, we prove that when ϵ is *constant*, the problem is PPAD-hard and the problem remains PPAD-hard when we allow a constant number of additional cuts. Additionally, we prove that deciding whether a solution with $n-1$ cuts exists for the problem is NP-hard.

1 Introduction

Suppose that two families wish to split a piece of land into two regions such that every member of each family believes that the land is equally divided, or suppose that a conference organizer wants to assign the conference presentations to the morning and the afternoon sessions, so that every participant thinks that the two sessions are equally interesting. Is it possible to achieve these objectives? If yes, how can it be done and how efficiently? What if we aim for "almost equal" instead of "equal"?

These real-life problems can be modeled as the *Consensus-halving problem* [27]. More formally, there are n agents and an object to be divided; each agent may have a different opinion as to which part of the object is more valuable. The problem is to divide the object

[1] The author was supported by the ERC Advanced Grant 321171 (ALGAME).
[2] The author was supported by the ERC Advanced Grant 321171 (ALGAME).

into two portions such that each of the n agents believes that the two portions have equal value, according to her personal opinion. The division may need to cut the object into pieces and then label each piece appropriately to include it in one of the two portions.

The importance of the Consensus-halving problem - or to be precise, of its approximate version, where there is an associated precision parameter ϵ - other than the fact that it models real-life problems like the ones described above, lies in in the following fact: It is the first "natural" problem that is *complete* for the complexity class PPA, where "natural" here means that its does not contain a circuit explicitly in its definition; this was proven quite recently by Filos-Ratsikas and Goldberg [13]. PPA is a class of *total search problems* [19] defined in [22], and is a superclass of the class PPAD, which precisely captures the complexity of computing a Nash equilibrium [11, 9]. Therefore, generally speaking, a PPA-hardness result is stronger than a PPAD-hardness result.

Crucially however, the hardness result in [13] requires the precision parameter to be inverse-exponential in the number of agents and does not even provably preclude the possibility of efficient algorithms, if we allow larger discrepancies in the values for the two portions. In this paper, we prove that this is actually not possible[3], by showing that even when the allowed discrepancy is independent of the number of agents, the problem is PPAD-hard. Understanding the problem for increasing values of the discrepancy parameter is quite important in terms of capturing precisely its complexity and resembles closely the series of results establishing hardness of computing a mixed ϵ-Nash equilibrium, from ϵ being inverse-polynomial in [11, 9] to being constant in [26], as well as several other problems (see [26]). Additionally, one could imagine that solutions where constant discrepancies are acceptable are the ones arising in several real-life scenarios, such as splitting land.

1.1 Our results

We are interested in the computational complexity of computing an ϵ-approximate solution to the Consensus-halving problem where ϵ is a constant function of the number of agents, as well as the complexity of deciding whether given an input instance, $n-1$ cuts are sufficient to achieve an ϵ-approximate solution. We discuss our main results below.

- We prove that the problem of finding an ϵ-approximate solution to the Consensus-halving problem for n agents using n cuts is PPAD-hard. Moreover, the problem remains PPAD-hard even if we allow a constant number of additional cuts. The result is established via a reduction from the approximate Generalized Circuit problem [9, 11, 26].
- We prove that it is NP-hard to decide whether or not an ϵ-approximate solution to the Consensus-halving problem for n agents using $n-1$ cuts exists. Using the gadgetry already developed for the PPAD-hardness proof, we establish the result via a reduction from 3-SAT.
- We prove that the problem of finding an ϵ-approximate solution to the Consensus-halving problem for n agents using n cuts is in the computational class PPA; we obtain the result via a reduction to the computational version of Tucker's Lemma [22, 1].

We remark here that an earlier version of this paper actually predated [13], and some of the results in [13] are established by referencing the results in the present paper. Specifically:

[3] Under usual computational complexity assumptions, here that PPAD-hard problems do not admit polynomial-time algorithms.

- While the authors of [13] provide a rather elaborate reduction to establish PPA-hardness of the problem, the inclusion in the class PPA is established with reference to the present paper. In turn, the inclusion result follows from a formalization of the ideas of the algorithms by [27] and [24] and Fan's version of Tucker's Lemma [12, 31].
- In [13], the authors obtain a *computational equivalence* between the *Necklace Splitting* problem [2] and ϵ-approximate Consensus-halving, for ϵ being at least inverse-polynomial. The inverse-polynomial dependence on ϵ implies that PPA-hardness of the former problem does not follow from their hardness result, but PPAD-hardness does follow from their reduction and our main result here.

Due to lack of space, some of the proofs and details are left for the the full version of the paper. Most emphasis is put on the main PPAD-hardness proof of Section 3, which is presented in sufficient detail, and the NP-hardness proof of Section 4. The exposition of the results in Section 5 is limited to higher-level intuition, with full proofs in the full version.

1.2 Related work

The Consensus-halving problem was explicitly formalized and studied firstly by Simmons and Su [27], who proved that a solution with n cuts always exists and constructed a protocol that finds an approximate solution, which allows for a small discrepancy on the values of the two portions. Their proofs are based on one of the most applied theorems in topology, the Borsuk-Ulam Theorem [6] and its combinatorial analogue, known as Tucker's Lemma [31]. The existence of solutions to the problem was already known since [16, 3, 4] but the algorithm in [27] is constructive, in the sense that it actually finds such a solution and furthermore, it does not require the valuations of the players to be additively separable over subintervals, like some of the previous papers do. Actually, for the case of valuations which are probability measures, the existence of a solution with n cuts was known since as early as the 1940s [20] and can also be obtained as an application of the Hobby-Rice Theorem [18] (also see [2]). Despite proposing an explicit protocol however, the authors in [27] do not answer the question of "efficiency", i.e. how fast can a protocol find an (approximate) solution and the running time of their protocol is worst-case exponential-time.[4]

To this end, Filos-Ratsikas and Goldberg [13] recently proved that the problem is PPA-complete, but as we explained in the introduction, the hardness holds only when the precision parameter is inversely exponential. Even more recently, the authors strengthened their result to PPA-completeness of the problem for inversely polynomial precision [14]. However, since our hardness result holds for constant precision, it is not subsumed by neither [13] or [14].

The computational classes PPA (Polynomial Parity Arguments) and PPAD (Polynomial Parity Arguments on Directed graphs) were introduced by Papadimitriou [22] in an attempt to capture the precise complexity of several interesting problems of a topological nature such as computational analogues of Sperner's Lemma [28] and Brouwer's and Kakutani's fixed point theorems [5], which are all known to be in PPAD [22]. Interestingly, Aisenberg et al. [1] recently proved that the search problems associated with the Borsuk-Ulam Theorem and Tucker's Lemma are PPA-complete; this is the starting point for the reduction in [13], but it will also be used for our "in-PPA" result, which complements the hardness result of [13].

Our PPAD-hardness reduction goes via the *Generalized Circuit* problem. Generalized circuits differ from usual circuits in the sense that they can contain cycles, a fact which basically induces a continuous function on the gates, and the solution is guaranteed to exist

[4] The protocol exhaustively iterates through all the vertices of triangulated geometric object, which, to achieve a small discrepancy, has to be exponentially large.

by Brouwer's fixed point theorem. The ϵ-approximate Generalized Circuit problem was implicitly proven to be PPAD-complete for exponentially small ϵ in [11] and explicitly for polynomial small ϵ [9], en route to proving that perhaps the most interesting problem in PPAD, that of computing a mixed-Nash equilibrium, is also complete for the class. The same problem was also used in [10] to prove that finding an approximate competitive equilibrium for the Arrow-Debreu market with linear and non-monotone utilities is PPAD-complete and in [21] to prove that finding an approximate solution of the Competitive Equilibrium with Equal Incomes (CEEI) for indivisible items is PPAD-complete. More recently, Rubinstein [26] showed that computing an ϵ-approximate solution for the Generalized Circuit problem is PPAD-complete for a constant ϵ, which implies that finding an ϵ-approximate Nash equilibrium is PPAD-complete for constant ϵ, in the context of graphical games; we reduce from that version of the problem. This improvement should also lead to stronger hardness results in [10] and [21], as well as other problems that rely on the Generalized Circuit problem.

The Consensus-halving problem is a typical fair division problem that studies how to divide a set of resources between a set of agents who have valuations on the resources, such that some fairness properties are fulfilled. The fair division literature, which dates back to the late 1940s [29], has studied a plethora of such problems, with *chore-division* [23, 15], *rent-partitioning* [17, 7, 30] and the perhaps the most well-known one, *cake-cutting* [8, 25] being notable examples. Note that Consensus-halving is inherently different from cake-cutting, since the objective is that all participants are (approximately) equally satisfied with the solution, and they do not have "ownership" over the resulting pieces.

2 Preliminaries

We represent the object O as a line segment $[0, 1]$. Each agent in the set of agents $N = \{1, \ldots, n\}$ has its own valuation over any subset of interval $[0, 1]$. These valuations are:

- *non-negative and bounded*, i.e. there exists $M > 0$, such that for any subinterval $X \subseteq [0, 1]$, it holds that $0 \leq u_i(X) \leq M$.
- *non-atomic*, i.e. agents have no value on any single point on the interval.

For simplicity, the reader may assume that the valuations are represented as step functions (where agents have constant values over distinct intervals), although this is not necessary for the results to hold.[5]

A set of k cuts $\{t_1, \ldots, t_k\}$, where $0 \leq t_1 \leq \ldots \leq t_k \leq 1$, means that we cut along the points $t_1, \ldots, t_k$, such that the object is cut into $k+1$ pieces $X_i = [t_{i-1}, t_i]$ for $i = 1, \ldots, k+1$, where $t_0 = 0$ and $t_{k+1} = 1$. A labelling of an interval X_i means that we assign a label $\ell \in \{+, -\}$ to X_i, which corresponds to including X_i in a set of intervals, either O_+ or O_-. In case some cuts happen to be on the same point, say $t_{j-1} = t_j$, then the corresponding subinterval X_j is a single point on which agents have no value. We will consider cuts on the same points to be the same cut, e.g. if there is only one such occurrence, we will consider the number of cuts to be $k - 1$.

The Consensus-halving problem is to divide the object O into two portions O_+ and O_-, such that every agent derives equal valuation from the two portions, i.e., $u_i(O_+) =$

[5] The inclusion result actually holds for more general functions, while our hardness results (PPAD-hardness and NP-hardness) hold even for well-behaved functions, such as step functions. We note here that while an exact solution to Consensus-halving generally requires the valuations to be continuous, this is not necessary for the existence of an approximate solution; the algorithm of [27] can find such a solution assuming that valuations are bounded and non-atomic.

$u_i(O_-), \forall i \in N$. The ϵ-approximate Consensus-halving problem allows that each agent has a small discrepancy on the values of the two partitions, i.e., $|u_i(O_+) - u_i(O_-)| < \epsilon$. As discussed in the Introduction, such a solution always exists [27].

We define the following search problem, called (n, k, ϵ)-ConHalving.

▶ **Problem 1.** (n, k, ϵ)-ConHalving.
Input: *The value density functions (valuation functions)* $v_i : O \to R_+, i = 1, \cdots, n$.
Output: *A partition* (O_+, O_-) *with* k *cuts such that* $|u_i(O_+) - u_i(O_-)| \leq \epsilon$.

We will also consider the following decision problem, called $(n, n-1, \epsilon)$-ConHalving. Note that for n agents and $n-1$ cuts, a solution to the ϵ-approximate Consensus-halving problem is not guaranteed to exist.

▶ **Problem 2.** $(n, n-1, \epsilon)$-ConHalving.
Input: *The valensity functions* $v_i : O \to R_+, i = 1, \cdots, n$.
Output: Yes*, if a partition* (O_+, O_-) *with* $n-1$ *cuts such that* $|u_i(O_+) - u_i(O_-)| \leq \epsilon$ *for all agents* $i \in N$ *exists, and* No *otherwise.*

TFNP, PPA and PPAD: Most of the problems that we will consider in this paper belong to the class of *total search problems*, i.e. search problems for which a solution is guaranteed to exist, regardless of the input. In particular, we will be interested in problems in the class TFNP, i.e. total search problems for which a solution is verifiable in polynomial time [19].

An important subclass of TFNP is the class PPAD, defined by Papadimitriou in [22]. PPAD stands for "Polynomial Parity Argument on a Directed graph" and is defined formally in terms of the problem End-Of-Line [22]. The class PPAD is defined in terms of an exponentially large digraph $G = (V, E)$ consisting of 2^n vertices with indegree and outdegree at most 1. An edge between vertices v_1 and v_2 is present in E if and only if the successor $S(v_1)$ of node v_1 is v_2 and the predecessor $P(v_2)$ of node v_2 is v_1. By construction, the point 0^n has indegree 0 and we are looking for a point with outdegree 0, which is guaranteed to exist. Note that the graph is given *implicitly* to the input, through a function that given any vertex v, returns its set of neighbours (predecessor and successor) in polynomial time. PPAD is a subclass of the class PPA ("Polynomial Parity Argument") which is defined similarly, but in terms of an undirected graph in which every vertex has degree at most 2, and given a vertex of degree 1, we are asked to find another vertex of degree 1; the computational problem associated with the class is called Leaf [22] and a problem is the class PPA if it is polynomial-time reducible to Leaf.

The formal definitions of End-Of-Line and Leaf are not required for the results presented in this version and therefore are left for the full version.

2.1 Generalized Circuits

A *generalized circuit* $S = (V, \mathcal{T})$ consists of a set of nodes V and a set of gates $\mathcal{T}$ and let $N = |V|$ and $M = |\mathcal{T}|$. Every gate $T \in \mathcal{T}$ is a 5-tuple $T = (G, v_{in_1}, v_{in_2}, v_{out}, \alpha)$ where

- $G \in \{G_\zeta, G_{\times\zeta}, G_=, G_+, G_-, G_<, G_\vee, G_\wedge, G_\neg\}$ is the type of the gate,
- $v_{in_1}, v_{in_2} \in V \cup \{nil\}$ are the first and second input nodes of the gate or *nil* if not applicable,
- $v_{out} \in V$ is the output node, and $\alpha \in [0, 1] \cup \{nil\}$ is a parameter if applicable,
- for any two gates $T = (G, v_{in_1}, v_{in_2}, v_{out}, \alpha)$ and $T' = (G', v'_{in_1}, v'_{in_2}, v'_{out}, \alpha')$ in $\mathcal{T}$ where $T \neq T'$, they must satisfy $v_{out} \neq v'_{out}$.

Table 1 Gate constraint $T = (G, v_{in_1}, v_{in_2}, v_{out}, \alpha)$.

Gate	Constraint
$(G_\zeta, nil, nil, v_{out}, \alpha)$	$\alpha - \epsilon \leq \mathbf{x}[v_{out}] \leq \alpha + \epsilon$
$(G_{\times\zeta}, v_{in_1}, nil, v_{out}, \alpha)$	$\alpha \cdot \mathbf{x}[v_{in_1}] - \epsilon \leq \mathbf{x}[v_{out}] \leq \alpha \cdot \mathbf{x}[v_{in_1}] + \epsilon$
$(G_=, v_{in_1}, nil, v_{out}, nil)$	$\mathbf{x}[v_{in_1}] - \epsilon \leq \mathbf{x}[v_{out}] \leq \mathbf{x}[v_{in_1}] + \epsilon$
$(G_+, v_{in_1}, v_{in_2}, v_{out}, nil)$	$\mathbf{x}[v_{out}] \in [\min(\mathbf{x}[v_{in_1}] + \mathbf{x}[v_{in_2}], 1) - \epsilon, \min(\mathbf{x}[v_{in_1}] + \mathbf{x}[v_{in_2}], 1) + \epsilon]$
$(G_-, v_{in_1}, v_{in_2}, v_{out}, nil)$	$\mathbf{x}[v_{out}] \in [\max(\mathbf{x}[v_{in_1}] - \mathbf{x}[v_{in_2}], 0) - \epsilon, \max(\mathbf{x}[v_{in_1}] - \mathbf{x}[v_{in_2}], 0) + \epsilon]$
$(G_<, v_{in_1}, v_{in_2}, v_{out}, nil)$	$\mathbf{x}[v_{out}] = \begin{cases} 1 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] < \mathbf{x}[v_{in_2}] - \epsilon; \\ 0 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] > \mathbf{x}[v_{in_2}] + \epsilon. \end{cases}$
$(G_\vee, v_{in_1}, v_{in_2}, v_{out}, nil)$	$\mathbf{x}[v_{out}] = \begin{cases} 1 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 1 \pm \epsilon \text{ or } \mathbf{x}[v_{in_2}] = 1 \pm \epsilon; \\ 0 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 0 \pm \epsilon \text{ and } \mathbf{x}[v_{in_2}] = 0 \pm \epsilon. \end{cases}$
$(G_\wedge, v_{in_1}, v_{in_2}, v_{out}, nil)$	$\mathbf{x}[v_{out}] = \begin{cases} 1 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 1 \pm \epsilon \text{ and } \mathbf{x}[v_{in_2}] = 1 \pm \epsilon; \\ 0 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 0 \pm \epsilon \text{ or } \mathbf{x}[v_{in_2}] = 0 \pm \epsilon. \end{cases}$
$(G_\neg, v_{in_1}, nil, v_{out}, nil)$	$\mathbf{x}[v_{out}] = \begin{cases} 1 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 0 \pm \epsilon; \\ 0 \pm \epsilon, & \text{if } \mathbf{x}[v_{in_1}] = 1 \pm \epsilon. \end{cases}$

Note that generalized circuits extend the standard boolean or arithmetic circuits in the sense that generalized circuits allow cycles in the directed graph defined by the nodes and gates. We define the search problem ϵ-Gcircuit [9, 26].

▶ **Problem 3.** ϵ-Gcircuit

Input: *A generalized circuit* $S = (V, \mathcal{T})$.

Output: *A vector* $\mathbf{x} \in [0,1]^N$ *of values for the nodes, satisfying the conditions from Table 1.*

Note that a solution to ϵ-Gcircuit always exists [9] and hence the problem is well-defined. Also, notice that for the logic gates $G_\vee, G_\wedge$ and $G_\neg$, if the input conditions are not fulfilled, the output is unconstrained, and for the multiplication gate, it holds that $\alpha \in (0, 1]$. ϵ-Gcircuit was proven to be PPAD-complete implicitly or explicitly in [11, 9] for inversely polynomial error ϵ and in [26] for constant ϵ. We state the latter theorem here as a lemma:

▶ **Lemma 1** ([26]). *There exists a constant* $\epsilon > 0$ *such that* ϵ-Gcircuit *is PPAD-complete.*

3 Consensus-Halving with $n + k$ cuts is is PPAD-hard

In this section, we will first prove that finding an approximate partition for Consensus-halving using n cuts is PPAD-hard, even if the allowed discrepancy between the two portions is a constant. We describe the reduction from ϵ-Gcircuit that we will be using for the PPAD-hardness proof. Given an instance $S = (V, \mathcal{T})$ of ϵ-Gcircuit, we will construct an instance of (n, n, ϵ')-ConHalving with $n = 2N$ agents, in which each node $v_i \in V$ of the circuit will correspond to two agents var_i and $copy_i$ and where ϵ' will be defined later. As a matter of convenience in the reduction, we will assume that for every gate $(G, v_{in_1}, v_{in_2}, v_{out}, \alpha)$ in $\mathcal{T}$, v_{in_1}, v_{in_2} and v_{out} are distinct. This does not affect the hardness of the problem as any ϵ-generalized circuit can be converted to this form by use of at most $2N$ additional equality-gates and nodes, and also since an $(\epsilon/2)$-approximate solution to the converted problem can clearly be converted to a solution in the original circuit.

For ease of notation, we consider a Consensus-halving instance on the interval $[0, 6N]$. Let $d_i := 6(i-1)$.

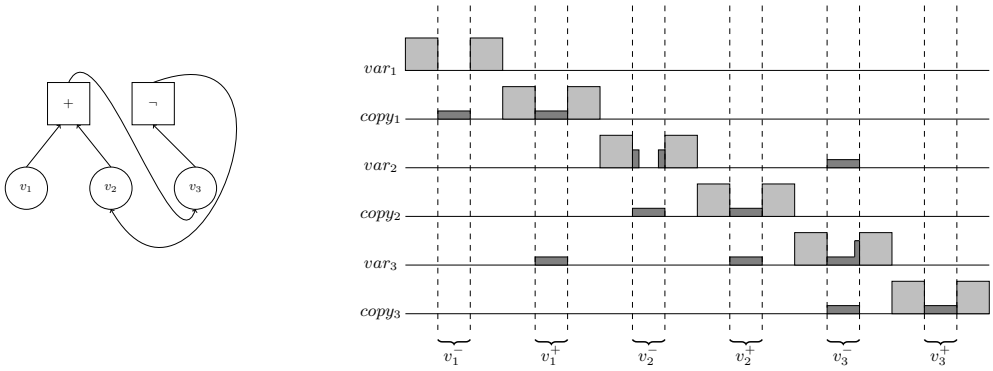

Figure 1 An instance of ϵ-GCIRCUITwith the corresponding construction for (n, ϵ')-CONHALVING.

The two agents var_i and $copy_i$ that we construct for every node v_i have valuations

$$var_i = \begin{cases} border_i(t) + G^\tau(t), & \text{if } v_i \text{ is the output of } \tau \\ border_i(t), & \text{otherwise} \end{cases}$$

$$copy_i = \begin{cases} 4, & t \in [d_i + 3, d_i + 4] \cup [d_i + 5, d_i + 6] \\ 1, & t \in [d_i + 1, d_i + 2] \cup [d_i + 4, d_i + 5] \\ 0, & \text{otherwise} \end{cases}$$

$$\text{where} \quad border_i = \begin{cases} 4, & \text{if } t \in [d_i, d_i + 1] \cup [d_i + 2, d_i + 3] \\ 0, & \text{otherwise} \end{cases}$$

Since each node is the output of at most one gate, var_i is well-defined. Note that apart from the valuation defined by the function G^τ, agents var_i and $copy_i$ only have valuations on the sub-interval $[d_i, d_{i+1}]$, i.e., the agents associated with node v_1 only have valuations on $[0, 6]$, the agents associated with v_2 only on have valuations on $[6, 12]$ and so on. Let $v_i^- := [d_i + 1, d_i + 2]$ and the right and left endpoints respectively be $v_{i,\ell}^-$ and $v_{i,r}^-$, (and analogously for $v_i^+ := [d_i + 3, d_i + 4]$, $v_{i,\ell}^+$ and $v_{i,r}^+$). Now, we are ready to define the functions G^τ according to Table 2. Notice that because of the assumption that the two input nodes and the output node are distinct, the graphs of the functions are as in Table 2. Figure 1 demonstrates an example of a Consensus-halving instance corresponding to a small circuit.

▶ **Lemma 2.** *Given the construction of a* (n, n, ϵ')-CONHALVING *instance above, for* $\epsilon' < \min\{\epsilon/11, 1/40\}$*, a partition with* n *cuts corresponds to a solution to* ϵ-GCIRCUIT*.*

Proof. First observe that since all of the agents var_i and $copy_i$ are constructed to have at least $3/4$ of their valuation on $[d_i, d_i + 3]$ and $[d_i + 3, d_i + 6]$ respectively, there must be at least one cut in each one of those intervals in any ϵ'-approximate solution to Consensus-halving (with $\epsilon' < 1/4$) and therefore any ϵ'-approximate solution to Consensus-halving with $2N$ cuts must have exactly one cut in each interval. Furthermore, since the constructed instance consists of $2N$ agents, by [27], such a partition with $2N$ cuts is guaranteed to exist.

Now consider such a solution $\mathcal{C}$ to (n, n, ϵ')-CONHALVING with $2N$ cuts. For each agent var_i (and associated gate G^τ, if any), since her valuation in v_i^- is at least the same as her valuation outside the interval $[d_i, d_i + 3]$, the cut from $\mathcal{C}$ in $[d_i, d_i + 3]$ must be in $[d_i + 1 - \epsilon', d_i + 2 + \epsilon']$, since $\mathcal{C}$ is a solution to (n, n, ϵ')-CONHALVING. We will assume without loss of generality that the leftmost piece of the partition $\mathcal{C}$ is in O_-. Notice then

Table 2 Agent preferences from gate $\tau = (G, v_{in_1}, v_{in_2}, v_{out}, \alpha)$. For the gate $G_{\times\zeta}$, the figure depicts the case when $\alpha + \epsilon < 1$.

	$G^\tau(t)$	Picture
G_ζ	$\begin{cases} 1 & \text{if } t \in [v^-_{out,\ell} + \alpha - \frac{1}{2}, v^-_{out,\ell} + \alpha + \frac{1}{2}] \\ 0 & \text{otherwise} \end{cases}$	$G_{\times\zeta}$	$\begin{cases} 1 & \text{if } t \in v^+_{in} \\ 1/\alpha & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \min(\alpha + \epsilon, 1)] \\ 0 & \text{otherwise} \end{cases}$	$G_\neg$	$\begin{cases} 1 & \text{if } t \in v^-_{in} \\ 1/2\epsilon & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \epsilon] \\ 1/2\epsilon & \text{if } t \in [v^-_{out,r} - \epsilon, v^-_{out,r}] \\ 0 & \text{otherwise} \end{cases}$	G_+	$\begin{cases} 1 & \text{if } t \in v^+_{in_1} \cup v^+_{in_2} \\ 1 & \text{if } t \in [v^-_{out,\ell}, v^-_{out,r} - \epsilon] \\ 1/\epsilon + 1 & \text{if } t \in [v^-_{out,r} - \epsilon, v^-_{out,r}] \\ 0 & \text{otherwise} \end{cases}$	G_-	$\begin{cases} 1 & \text{if } t \in v^+_{in_1} \cup v^-_{in_2} \\ 1 & \text{if } t \in [v^-_{out,\ell} + \epsilon, v^-_{out,r}] \\ 1/\epsilon + 1 & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \epsilon] \\ 0 & \text{otherwise} \end{cases}$	$G_<$	$\begin{cases} 1 & \text{if } t \in v^+_{in_1} \cup v^-_{in_2} \\ 1/\epsilon & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \epsilon] \\ 1/\epsilon & \text{if } t \in [v^-_{out,r} - \epsilon, v^-_{out,r}] \\ 0 & \text{otherwise} \end{cases}$	$G_\vee$	$\begin{cases} 1 & \text{if } t \in v^+_{in_1} \cup v^+_{in_2} \\ 0.5/\epsilon & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \epsilon] \\ 1.5/\epsilon & \text{if } t \in [v^-_{out,r} - \epsilon, v^-_{out,r}] \\ 0 & \text{otherwise} \end{cases}$	$G_\wedge$	$\begin{cases} 1 & \text{if } t \in v^+_{in_1} \cup v^+_{in_2} \\ 1.5/\epsilon & \text{if } t \in [v^-_{out,\ell}, v^-_{out,\ell} + \epsilon] \\ 0.5/\epsilon & \text{if } t \in [v^-_{out,r} - \epsilon, v^-_{out,r}] \\ 0 & \text{otherwise} \end{cases}$	
that for each node v_i, the piece on the left-hand side of the cut in v_i^- is always in O_- and the piece on the left-hand side of the cut in v_i^+ is always in O_+. Let the location of the cut be $d_i + 1 + t_i^-$ where $t_i^- \in [-\epsilon', 1 + \epsilon']$. Analogously, the same argument holds for agent $copy_i$ and the interval $[d_i + 3 - \epsilon', d_i + 4 + \epsilon']$, and define $t_i^+ \in [-\epsilon', 1 + \epsilon']$ similarly.

Now consider the agent $copy_i$ and the cut at location $d_i + 1 + t_i^-$. If $t_i^- \in [0, 1]$, then since agent $copy_i$ has valuation 1 on interval v_i^-, t_i^- of her valuation will be on a piece in O_- and $1 - t_i^-$ of her valuation will be on a piece in O_+. Then, since $\mathcal{C}$ is a solution to

(n, n, ϵ')-ConHalving, the cut in $d_i+3+t_i^+$ must be placed so that $|t_i^- - t_i^+| \leq \epsilon'/2$; similarly for the cases where $t_i^- \notin [0,1]$. In other words, $copy_i$ ensures that the cut at $d_i + 1 + t_i^-$ is "copied" ϵ'-approximately.

We will interpret the solution $\mathcal{C}$ as a solution to ϵ-Gcircuit in the following way. For each node v_i and each associated cut at $d_i + 1 + t_i^-$ let

$$x_i := \begin{cases} 0 & , \quad t_i^- < 0 \\ t_i^- & , \quad t_i^- \in [0,1] \\ 1 & , \quad t_i^- > 1 \end{cases} \tag{1}$$

and notice

$$|t_i^+ - x_i| \leq 2\epsilon' \quad , \quad |t_i^- - x_i| \leq 2\epsilon' \tag{2}$$

To complete the proof, we just need to argue that these variables satisfy the constraints of the gates of the circuit. Due to lack of space, we will only argue the correctness of some of the gates here; the arguments for the remaining gates follow a similar spirit and are presented in detail in the full version.

Constant gate $\tau = (G_\zeta, nil, nil, v_{out}, \alpha)$. The valuation of agent var_{out} for the intervals $[d_i, d_i + 1 + \alpha]$ and $[d_i + 1 + \alpha, d_i + 3]$ is the same and since the height of the agent's value density function is at least 1 in $[d_i, d_i + 3]$,[6] it holds that $t_{out}^- \in [\alpha - \epsilon', \alpha + \epsilon']$. Then, by Equation 2, it holds that $x_{out} \in [\alpha - 3\epsilon', \alpha + 3\epsilon']$, so for $\epsilon' < \epsilon/3$ the gate constraint is satisfied.

Multiplication-by-scalar gate $\tau = (G_{\times\zeta}, v_{in}, nil, v_{out}, \alpha)$. Notice that for any given cut t_{in}^+ and $1 - \alpha \geq \epsilon$, it holds that $t_{out}^- \in [\alpha t_{in}^+ + \epsilon/2 - \epsilon', \alpha t_{in}^+ + \epsilon/2 + \epsilon']$ as the height of G^τ in v_{out}^- is at least 1. Similarly, for the case $1 - \alpha < \epsilon$ and any given cut t_{in}^+, it holds that $t_{out}^- \in [\alpha t_{in}^+ + (1-\alpha)/2 - \epsilon', \alpha t_{in}^+ + (1-\alpha)/2 + \epsilon']$ as the height of G^τ in v_{out}^- is at least 1. In particular, since $1 - \alpha < \epsilon$, it also holds that $t_{out}^- \in [\alpha t_{in}^+ + \epsilon/2 - \epsilon', \alpha t_{in}^+ + \epsilon/2 + \epsilon']$ for this case as well. Then, by Equation 2, it holds that $x_{out} \in [\alpha t_{in}^+ + \epsilon/2 - 3\epsilon', \alpha t_{in}^+ + \epsilon/2 + 3\epsilon']$ and since $\alpha \leq 1$ it also holds that $x_{out} \in [\alpha x_{in} + \epsilon/2 - 5\epsilon', \alpha x_{in} + \epsilon/2 + 5\epsilon']$, again by Equation 2. Then the gate constraint is satisfied whenever $\epsilon' < \epsilon/10$.

Addition gate$\tau = (G_+, v_{in_1}, v_{in_2}, v_{out}, nil)$. If for the cuts $t_{in_1}^+$ and $t_{in_2}^+$ it holds that $t_{in_1}^+ + t_{in_2}^+ < 1 - \epsilon + 4\epsilon'$ then $t_{out}^- \in [t_{in_1}^+ + t_{in_2}^+ - 5\epsilon', t_{in_1}^+ + t_{in_2}^+ + 5\epsilon']$ as the height of G^τ in v_{out}^- is at least 1. This then implies that $x_{out} \in [x_{in_1}^+ + x_{in_2}^+ - 11\epsilon', x_{in_1}^+ + x_{in_2}^+ + 11\epsilon']$, by Inequality 2. On the other hand, when $t_{in_1}^+ + t_{in_2}^+ \geq 1 - \epsilon + 4\epsilon'$, then by Definition 1, it holds that $x_{in_1} + x_{in_2} \in [1 - \epsilon, 1]$ and clearly $t_{out}^- \in [1 - \epsilon, 1 + \epsilon']$ which by Definition 1 implies that $x_{out} \in [1 - \epsilon, 1]$. The gate constraints are satisfied for $\epsilon' < \epsilon/11$ for each of the cases.

Less-than-equal gate $\tau = (G_<, v_{in_1}, v_{in_2}, v_{out}, nil)$. We will consider three cases, depending on the positions of the cuts $t_{in_1}^+$ and $t_{in_2}^-$. First, when $|t_{in_1}^+ - t_{in_2}^-| < \epsilon - 4\epsilon'$, by Inequality 2 it holds that $|x_{in_1} - x_{in_2}| < \epsilon$ and the output of the gate is unconstrained. When $t_{in_1}^+ - t_{in_2}^- \geq \epsilon - 4\epsilon'$ then by Inequality 2 it holds that $x_{in_1} \geq x_{in_2} + \epsilon$. Additionally, since the height of G^τ in $[v_{out,r}^- - \epsilon, v_{out,r}^-]$ is at least 1, it holds that $t_{out}^- \in [1 - \epsilon, 1 + \epsilon']$, which by Definition 1 implies that $x_{out}^- \in [1 - \epsilon, 1]$ and the gate constraint is satisfied. The argument for the case when $t_{in_2}^- > t_{in_1}^+ - 2\epsilon'$ is completely symmetrical.

Logic OR gate $\tau = (G_\vee, v_{in_1}, v_{in_2}, v_{out}, nil)$. We will consider three cases depending on the position of the cuts $t_{in_1}^+$ and $t_{in_2}^+$. First, when $t_{in_1}^+ + t_{in_2}^+ < 0.4$ it holds that

[6] Notice that the constant gate is the only gate where $border_i$ and G^τ overlap.

$t^-_{out} \in [-\epsilon', \epsilon]$ and hence by Definition 1, it holds that $x_{out} \in [0, \epsilon]$. Furthermore, by Inequality 2 it holds that $x_{in_1} + x_{in_2} < 0.4 + 4\epsilon'$ and for $\epsilon' < 1/40$, it also holds that $x_{in_1}, x_{in_2} < 0.5$ and the gate constraint is satisfied. Next, when $t^+_{in_1} + t^+_{in_2} \in [0.4, 0.8]$ then by Inequality 2, it holds that $x_{in_1}, x_{in_2} \in [0.4 - \epsilon', 0.8 + 4\epsilon']$ and in particular, when $\epsilon' < 1/40$ then it also holds that $x_{in_1} + x_{in_2} \in [0.3, 0.9]$ and the output of the gate in unconstrained. Finally when $t^+_{in_1} + t^+_{in_2} > 0.8$, it holds that $t^-_{out} \in [1 - \epsilon, 1 + \epsilon']$ and hence by Definition 1, we have that $x_{out} \in [1 - \epsilon, 1]$. Furthermore, by Inequality 2 we have that $x_{in_1} + x_{in_2} > 0.8 + 4\epsilon'$ which is greater than 0.9 when $\epsilon' < 1/40$ which implies that at least one of the two inputs is greater than ϵ. In particular, the gate's output lies in $[1 - \epsilon, \epsilon]$ when the inputs are smaller than ϵ or greater than $1 - \epsilon$ and at least one of them is greater than $1 - \epsilon$. This shows that the gate constraint is satisfied.

Given the discussion above, by setting $\epsilon' < \min\{\epsilon/11, 1/40\}$[7], the gate constraints are satisfied, and the vector (x_i) obtained from $\mathcal{C}$ is a solution to ϵ-GCIRCUIT. ◀

Now from Lemma 2, we obtain the following result.

▶ **Theorem 3.** *There exists a constant $\epsilon' > 0$ such that (n, n, ϵ')-CONHALVING is PPAD-hard.*

Proof. Recall that in the proof of Lemma 2, ϵ' was constrained to be at most $\min\{1/40, \epsilon/11\}$ and in particular by Lemma 1, there exists a constant ϵ' that would make the reduction work. Recall however that we "expanded" the instance of (n, ϵ')-CONHALVING from the interval $[a, b]$ to $[0, 6N]$ for convenience, which implies that after rescaling the instance to a constant interval $[a, b]$, the allowed error ϵ' goes down to $O(1/n)$. To get a constant error ϵ', we simply multiply all valuations by N. ◀

Theorem 3 implies that although a solution with n cuts is generally desirable, it might be hard to compute, even for a relatively simple class of valuations like those used in the reduction. In fact, we can extend our results to the more general case of finding a partition with $n + k$ cuts where k is a constant.

▶ **Theorem 4.** *Let k be any constant. Then there exists a constant ϵ' such that $(n, n + k, \epsilon')$-CONHALVING is PPAD-hard.*

Proof. Let $S = (V, \mathcal{T})$ be an instance of ϵ-GCIRCUIT with N nodes, consisting of smaller identical sub-circuits $S_i = (V_i, \mathcal{T}_i)$, for $i = 1, 2, \ldots, k + 1$, with with $N/(k + 1)$ nodes each such that for all $i, j \in [k + 1]$ such that $i \neq j$, it holds that $V_i \cap V_j = \emptyset$. and $\mathcal{T}_i \cap \mathcal{T}_j = \emptyset$. In other words, the circuit S consists of $k + 1$ copies of a smaller circuit S_i that do not have any common nodes or gates. Furthermore, for convenience, assume without loss of generality that for two nodes l and m such that $u_l \in V_i$ and $u_m \in V_j$, with $i < j$, it holds that $l < m$. In other words, the labeling of the nodes is such that nodes in circuits with smaller indices have smaller indices.

Let H be the instance of (n, n, ϵ')-CONHALVING corresponding to the circuit S following the reduction described in the beginning of the section and recall that $n = 2N$ in the construction. Note that according to the convention adopted above for the labeling of the nodes, for $i < j$, the agents corresponding to V_i lie in the interval $[\ell_i, r_i]$, whereas the agents corresponding to V_j lie in the interval $[\ell_j, r_j]$ and $r_i \leq \ell_j$. In other words, agents corresponding to sub-circuits with smaller indices are placed before agents with higher indices, and there is no overlap between agents corresponding to different sub-circuits.

[7] We can in fact assume some $\epsilon \leq 11/40$, as the smaller the ϵ, the harder the problem is, since we are interested in establishing hardness for some constant ϵ.

Now suppose that we have a solution to $(n, n+k, \epsilon')$-ConHalving. Since there is no overlap between valuations corresponding to different sub-circuits, an approximate solution with $n+k$ cuts for the instance H implies that there exists some interval $[\ell_i, r_i]$ corresponding to the set of nodes V_i of sub-circuit S_i, such that at least $n/(k+1)$ cuts lie in $[\ell_i, r_i]$, otherwise the total number of cuts on H would be at least $n+k+1$. Since there are exactly $n/(k+1)$ agents with valuations on $[\ell_i, r_i]$, this would imply an approximate solution for n' agents with n' cuts and the problem reduces to (n, n, ϵ')-ConHalving. ◀

4 Consensus-Halving with $n-1$ cuts is NP-hard

We have proved that the problem of finding an approximate solution with n players and n cuts is PPAD-complete. For n players and $n-1$ cuts however, we no longer have a guarantee that a solution exists. We prove that deciding whether this is the case or not is NP-hard.

▶ **Theorem 5.** *There exists a constant $\epsilon' > 0$ such that $(n, n-1, \epsilon')$-ConHalving is NP-hard.*

Proof. We will first describe the construction that we will use in the reduction. For consistency with the previous section, we will denote the error of the Consensus-halving problem by ϵ' and the error of the (implict) generalized circuits by functions of ϵ. Let $R_\epsilon(S)$ be the construction for the reduction of Section 3, that encodes an ϵ-generalized circuit S into an $(n, n-1, \epsilon')$-ConHalving instance when $\epsilon' < \epsilon/11$. We will reduce from 3-SAT, which is known to be NP-complete.

Let ϕ be any 3-SAT formula with m clauses, $k \leq 3m$ variables $x_1, \ldots, x_k$, and let $\epsilon > 0$ be given. For convenience of notation, let $\delta = \epsilon/11$. We will (implicitly) create a generalized circuit S with the following building blocks:

- k input nodes $x_1, \ldots, x_k$ corresponding to the variables $x_1, \ldots, x_k$.
- k sub-circuits $\text{Bool}(x_i)$ for $i = 1, 2, \ldots, k$ that input the real value $x_i \in [0, 1]$ and output a boolean value $x_i^{bool} \in [0, 4\delta] \cup [1-4\delta, 1]$ (see the lower stage of Figure 2). The allowed error for these circuits will be δ. The implementation of the circuit in terms of the gates of the generalized circuit can be seen in Algorithm 1. Note that the sub-circuit containing all the $\text{Bool}(x_i)$ sub-circuits has at most $4k$ nodes as each $\text{Bool}(x_i)$ sub-circuit could be implemented with one constant gate, one subtraction gate, one addition gate and one equality gate; the latter is to maintain the convention that all inputs to each gate are distinct.
- A sub-circuit $\Phi(x_1^{bool}, \ldots, x_k^{bool})$ that implements the formula ϕ, inputing the boolean variables x_i^{bool} and outputting a value x_{out} corresponding to the value of the assignment plus the error introduced by the approximate gates. The allowed error for this circuit will be 4δ. A pictorial representation of such a circuit can be seen in Figure 2; note that the circuits $\text{Bool}(x_i)$ are also shown in the picture. This circuit has at most $k+3m$ nodes. First, there might be k possible negation gates to negate the input variables. Secondly, for each clause, in order to implement an OR gate of fan-in 3, we need 2 OR gates of fan-in 2, for a total of $2m$ gates for all clauses. Finally, in order to simulate the AND gate with fan-in m, we need m AND gates of fan-in 2. Overall, since $k \leq 3m$, we need at most $6m$ nodes to implement this sub-circuit, using elements of the generalized circuit.
- A sub-circuit $\text{Rebool}(x_1, \ldots, x_k, x_{out})$ that inputs the variables x_i, for $i = 1, 2, \ldots, k$ and the variable x_{out} and computes the function

$$\min(x_{out}, \max(x_1, 1-x_1), \ldots, \max(x_k, 1-x_k)).$$

Algorithm 1 Computing $bool(x)$.

$a \leftarrow x - 1/4$
$bool \leftarrow a + a$

Algorithm 2 Computing $\min(x, y)$ and $\max(x, y)$.

$a \leftarrow x - y$; $b \leftarrow y - x$; $c \leftarrow a + b$
$d \leftarrow c/2$; $\ell \leftarrow (x/2) + (y/2)$
$min \leftarrow \ell - d$; $max \leftarrow \ell + d$

The function can be computed using the gates of the generalized circuit as shown in Algorithm 2. Let x_{out}^{bool} be the output of that sub-circuit with allowed error 4δ. Note that this circuit has at most $16k$ nodes. Each min and max operation requires 8 nodes and we need to do $2k$ such computations overall; k for the k max operations and k to implement the min operation of fan-in k with min operations of fan-in 2. Again, since $k \leq 3m$, this sub-circuit requires at most $48m$ nodes in total.

Following the notation introduced above, let $R_\delta(\text{Bool})$, $R_{4\delta}(\Phi)$ and $R_{4\delta}(\text{Rebool})$ denote the valuations of the agents in the instance of Consensus-halving corresponding to those sub-circuits, according to the reduction described in Section 3. In other words, based on the circuit described above, we create an instance H of Consensus-halving where we have:

- $2k$ agents (as each node corresponds to two agents, var_i and $copy_i$) that correspond to the input variables $x_1, \ldots, x_k$, who are not the output of any gate
- at most $2(4k + k + 3m + 16k)$ nodes corresponding to the internal nodes and the output node of the circuit.
- an additional agent with valuation

$$u_n = \begin{cases} 1, \text{if } t \in [b - 18m\epsilon' - 1, b - 18m\epsilon'] \\ 1, \text{if } t \in [b, b + 1] \\ 0, \text{otherwise} \end{cases}$$

where $[a, b]$ is the interval where the value of x_{out}^{bool} is "read" in the instance of Consensus-halving, i.e. the interval where the cut $t_{out}^{bool}-$ will be placed in the Consensus-halving solution.

Recall Definition 1 from Section 3 and note that as far as agent n is concerned, any cut $t_{out}^{bool}-$ such that $1 - 18m\epsilon \leq x_{out}^{bool} \leq 1$ is a Consensus-halving solution.

We will now argue about the correctness of the reduction. Let n be the number of agents and notice that there are $n - 1$ agents that correspond to the nodes of the circuit and a single agent constraining the value of x_{out}^{bool}. Notice that since the allowed error for the sub-circuit $\text{Rebool}(x_1, \ldots, x_k, x_{out})$ is 4δ, the total additive error of the agents of $R_{4\delta}(\text{Rebool})$ will be at most $4\delta \cdot 48m \leq 18m\epsilon'$.

First, assume that there exists a a solution to ϵ'-approximate Consensus-halving with $n-1$ cuts. By the correctness of the construction of Section 3 and the fact that $\epsilon' < \epsilon/11 = \delta$, the solution encodes a valid assignment to the variables of the generalized circuit S. Due to the valuation of agent n, the output of C must satisfy $x_{out}^{bool} \geq 1 - 18m\epsilon' - \epsilon'$, otherwise the corresponding cut $t_{out}^{bool}-$ could not be a part of a valid solution. Since the total additive error for the circuit $\text{Rebool}(x_1, \ldots, x_k, x_{out})$ is at most $18m\epsilon'$, if we choose $\epsilon' < 1/90m$, it

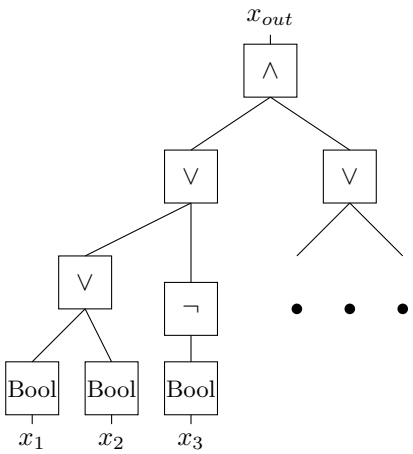

Figure 2 A generalized circuit corresponding to a 3-SAT formula ϕ, where the first clause is $(x_1 \vee x_2 \vee \overline{x_3})$. The nodes of the circuit between different layers are omitted. The layer at the output layer that "restores" the boolean values is also not shown, therefore x_{out} is the outcome of the emulated formula ϕ.

holds that $x_{out}^{bool} \geq 4/5 - \epsilon'$, which implies that $x_{out} \geq 3/4$, by the function implemented by the circuit Rebool$(x_1, \ldots, x_k, x_{out})$. For the same reason, for each $i = 1, \ldots, k$ it holds that $x_i \in [0, 1/4] \cup [3/4, 1]$, and hence the output of Bool(x_i) will lie in $[0, 4\delta] \cup [1 - 4\delta, 1]$, which means that the inputs $x_1^{bool}, \ldots, x_k^{bool}$ to the gates of the sub-circuit $\Phi(x_1^{bool}, \ldots, x_k^{bool})$ will be treated correctly as boolean values by the gates of the circuit (since the allowed error of the sub-circuit is 4δ). Since the circuit $\Phi(x_1^{bool}, \ldots, x_k^{bool})$ computes the boolean operations correctly and $x_{out} \geq 3/4$, the formula ϕ is satisfiable.

For the other direction, assume that ϕ is satisfiable and let $\tilde{x} = (\tilde{x}_1, \ldots, \tilde{x}_k)$ be a satisfying assignment. First we set the values of the variables $x_1, \ldots, x_k$ to 0 or 1 according to $\tilde{x}$ and then we propagate the values up the circuit S using the exact operation of the gates, which by our construction can be encoded to an instance of exact Consensus-halving for the $(n-1)$ agents corresponding to the nodes of S, i.e. the first $n-1$ will be exactly satisfied with the partition resulting from the encoded satisfying assignment. For the n-th agent, again, since the total additive error is bounded by $18m\epsilon'$, the agent will be satisfied with the solution. ◀

5 Consensus-Halving with n cuts is in PPA

In this section, we prove that (n, n, ϵ)-ConHalving is in PPA. As we discussed in the introduction, this result of ours was referenced in [13] to complement the PPA-hardness reduction of the inverse-exponential precision version and obtain PPA-completeness.

▶ **Theorem 6.** (n, n, ϵ)-ConHalving *is in PPA.*

For establishing this result, we construct a reduction from (n, n, ϵ)-ConHalving to the PPA-complete problem Leaf which goes via (n, T)-Tucker the computational version of Tucker's Lemma.

More precisely, to prove that (n, n, ϵ)-ConHalving is in PPA, we follow the main idea of the algorithm provided in [27] for obtaining a Consensus-halving solution: the coordinates of any vertex $\mathbf{x}$ in the unit cross polytope C^n naturally correspond to a partition that uses n cuts on the $[0, 1]$ interval. This is because the coordinates of any vertex $\mathbf{x} \in C^n$ satisfy

$\sum_{i=1}^{n+1} |x_i| = 1$, and a partition with n cuts on $[0,1]$ can be interpreted as partitioning the interval into $n+1$ pieces such that the length of each piece is equal to $|x_i|, i = 1, \ldots, n+1$. Furthermore, if the sign of the i-th coordinate x_i is "+", piece $|x_i|$ is assigned to portion O_+; otherwise it is assigned to portion O_-. We note that the use of the $[0,1]$ interval is for convenience and without loss of generality; for any choice of the interval we could use a a sphere of a different radius.

Given a sub-division of this sphere into small simplices (i.e. a *triangulation*) T of mesh size τ, we label each point of the triangulation by the label of the agent that is most dissatisfied by the corresponding set of cuts (and the sign indicates the direction of the discrepancy). This labelling satisfies the boundary conditions of Tucker's lemma and solutions to (n,T)-Tucker correspond to solutions of (n,n,ϵ)-ConHalving. In simple words, we show that the algorithm of [27] solves the computational version of Consensus-halving, using an algorithm for the computational version of Tucker as a subroutine.

The "in PPA" result is then established by the fact that Tucker is in PPA, i.e. it reduces to Leaf in polynomial time; this was already known from [22], where the problem is defined with respect to a subdivision of a hypercube. Technically, the algorithm of [27] that we use in our reduction requires the problem to be defined on the triangulation of a cross polytope, so one would have to prove that this version of the problem is in PPA as well. While this was already sketched in [22], we also prove it here via explaining how a constructive proof of Fan's combinatorial lemma [12] proposed by Prescott and Su [24] can be converted into a reduction to Leaf. The details along with all the necessary definitions are included in the full version.

6 Conclusion and Future Work

Our work takes an extra step in the direction of capturing the exact complexity of the Consensus-halving problem for all precision parameters. While, as we mentioned in the introduction, the techniques developed in [13] were successfully extended to obtain PPA-hardness of the problem for an inverse-polynomial precision parameter [14], it seems unlikely that they could be applicable when the precision is constant. In that sense, our main result is not implied by [13, 14], neither can it be subsumed by modifications to those reductions, even those involving highly non-trivial alterations. In other words, it seems that a PPA-completeness result for constant precision would require techniques fundamentally different from those used in [13, 14], and one can not even exclude the possibility of the problem being complete for PPAD instead.

Abstract

Prefetching constitutes a valuable tool toward the goal of efficient Web surfing. As a result, estimating the amount of resources that need to be preloaded during a surfer's browsing becomes an important task. In this regard, prefetching can be modeled as a two-player combinatorial game [Fomin et al., *Theoretical Computer Science 2014*], where a surfer and a marker alternately play on a given graph (representing the Web graph). During its turn, the marker chooses a set of k nodes to mark (prefetch), whereas the surfer, represented as a token resting on graph nodes, moves to a neighboring node (Web resource). The surfer's objective is to reach an unmarked node before all nodes become marked and the marker wins. Intuitively, since the surfer is step-by-step traversing a subset of nodes in the Web graph, a satisfactory prefetching procedure would load in cache (without any delay) all resources lying in the neighborhood of this growing subset.

Motivated by the above, we consider the following maximization problem to which we refer to as the *Maximum Rooted Connected Expansion* (MRCE) problem. Given a graph G and a root node v_0, we wish to find a subset of vertices S such that S is connected, S contains v_0 and the ratio $\frac{|N[S]|}{|S|}$ is maximized, where $N[S]$ denotes the *closed neighborhood* of S, that is, $N[S]$ contains all nodes in S and all nodes with at least one neighbor in S.

We prove that the problem is NP-hard even when the input graph G is restricted to be a split graph. On the positive side, we demonstrate a polynomial time approximation scheme for split graphs. Furthermore, we present a $\frac{1}{6}(1-\frac{1}{e})$-approximation algorithm for general graphs based on techniques for the *Budgeted Connected Domination* problem [Khuller et al., *SODA 2014*]. Finally, we provide a polynomial-time algorithm for the special case of interval graphs. Our algorithm returns an optimal solution for MRCE in $\mathcal{O}(n^3)$ time, where n is the number of nodes in G.

1 Introduction

In the evergrowing World Wide Web landscape, browsers compete against each other to offer the best quality of surfing to their users. A key characteristic in terms of quality is the speed attained when retrieving a new page or, in general, resource. Thus, a browser's objective is to minimize latency when moving from one resource to another. One way to achieve this goal is via *prefetching*: when the user lies at a certain Web node, predict what links she is more likely to visit next and preload them in cache so that, when the user selects to visit one of them, the transition appears to be instantaneous. Indeed, the World Wide Web Consortium (W3C) provides standards for prefetching in HTML [16]. Also, besides being nowadays a common practice for popular browsers, prefetching constitutes an intriguing research theme, e.g., see the surveys in [17, 1] for further references.

However, prefetching may come with a high network load cost if employed at a large scale. In other words, there is a trade-off that needs to be highlighted: more prefetching may mean less speed and even delays. For this reason, it becomes essential to acquire knowledge about the maximum number of resources to be prefetched over any potential Web nodes a surfer may visit. In this respect, Fomin et al. [4] define the *Surveillance Game* as a model for worst-case prefetching. The game is played by two players, namely the *surfer* and the *marker*, on a (directed) graph G representing (some view of) the Web graph. The surfer controls a token initially lying at a designated pre-marked start node v_0. In each round, the marker marks, i.e., prefetches, up to k so-far unmarked nodes during her turn and then the surfer chooses to move her token at a neighboring node of its current position. Notice that, once marked, a node always remains marked thereafter. The surfer wins if she arrives at an unmarked node, otherwise the marker wins if she manages to mark the whole graph before such an event occurs. In optimization terms, the quantity under consideration is the *surveillance number*, denoted $sn(G, v_0)$ for a graph G and a start (root) node v_0, which is the minimum number of marks the marker needs to use per round in order to ensure that a surfer walking on G (starting from v_0) never reaches an unmarked node.

A main observation regarding the above game is that the surfer follows some connected trajectory on the graph G. Let S stand for the set of nodes included in this trajectory. The marker's objective is to ensure that all nodes in S or in the neighborhood of S get marked promptly. Let $N[S]$ stand for the *closed neighborhood* of S, i.e., $N[S]$ includes all nodes in S and all nodes with at least one neighbor in S. Fomin et al. prove (Theorem 20 [4]) that, for any graph G and root v_0, it holds $sn(G, v_0) \geq \max\lceil \frac{|N[S]|-1}{|S|} \rceil$, where the maximum is taken over all subsets S that induce a connected subgraph of G containing v_0. Moreover, equality holds in case G is a tree. That is, a ratio of the form $|N[S]|/|S|$ (minus one and ceiling operator removed for clarity) provides a good lower bound and possibly in many occasions a good prediction on the prefetching load necessary to satisfy an impatient Web surfer. Hence, in this paper, we believe it is worth to independently study the problem of determining $\max \frac{|N[S]|}{|S|}$ where the maximum is taken over all subsets S inducing a connected subgraph of G containing v_0. We refer to this problem as the *Maximum Rooted Connected Expansion* problem (shortly MRCE) since we seek to find a connected set S (containing the root v_0) maximizing its *expansion ratio* in the form of $|N[S]|/|S|$.

Except for the prefetching motivation, such a problem can stand alone as an extension to the well-studied family of domination problems. Indeed, we later use connections between our problem and a domination variant in [14] to prove certain results. Finally, notice that removing the root node requirement makes the problem trivial. Let Δ stand for the maximum degree of a given graph G. Then, a solution consisting of a single max-degree node gives

a ratio of $\Delta + 1$. In addition, the ratio is at most $\Delta + 1$, since given any connected set S consisting of k nodes, $|N[S]| \leq (\Delta + 1)k$ due to the fact that each node can contribute at most $\Delta + 1$ new neighbors (including itself).

Related Work. The Surveillance Game was introduced in [4], where it was shown that computing $sn(G, v_0)$ is NP-hard in split graphs, nonetheless, it can be computed in polynomial time in trees and interval graphs. Furthermore, in the case of trees, the MRCE ratio is proved [4] to be equal to $sn(G, v_0)$ and therefore can be computed in polynomial time. In [7], the connected variant of the problem is considered, i.e., when the set of marked nodes is required to be connected after each round. For the corresponding optimization objective, namely the *connected surveillance number* denoted $csn(G, v_0)$, it holds $csn(G, v_0) \leq \sqrt{sn(G, v_0)n}$ for any n-node graph G. The more natural online version of the problem is also considered and (unfortunately) a competitive ratio of $\Omega(\Delta)$ is shown to be the best possible.

A problem closely related to ours (as demonstrated later in Section 4) is the *Budgeted Connected Dominating Set* problem (shortly BCDS), where, given a budget of k, one must choose a connected subset of k nodes with a maximum size of closed neighborhood. This problem is shown to have a $(1 - 1/e)/13$-approximation algorithm (in general graphs) in [14].

Regarding problems dealing with some ratio of quantities, we are familiar with the *isoperimetric number* problem [10], where the objective is to *minimize* $|\partial X|/|X|$ over all node-subsets X, where ∂X denotes the set of edges with exactly one endpoint in X. *Vertex-isoperimetric* variants also exist; see for example [12, 2]. Up to our knowledge, a ratio similar to the MRCE ratio we currently examine has not been considered.

Our Results. We initiate the study for MRCE. We prove that the decision version of MRCE is NP-complete, even when the given graph G is restricted to be a split graph. For the same case, we demonstrate a polynomial-time approximation scheme running in $\mathcal{O}(n^{k+1})$ time with a constant-factor $\frac{k}{k+2}$ guarantee, for any fixed integer $k > 0$. Our algorithm exploits a growth property for MRCE and the special topology of split graphs. Moving on, we provide another algorithm for general graphs, i.e., when no assumption is made on the topology of the given graph besides it being connected. The algorithm is inspired by an approximation algorithm for BCDS [14] and achieves an approximation guarantee of $(1 - 1/e)/6$. Finally, we show that in the case of interval graphs, the MRCE ratio can be computed optimally in $\mathcal{O}(n^3)$ time for any given n-node graph.

Outline. In Section 2, we first define some necessary preliminary graph-theoretic notions and then formally define the MRCE problem. In Section 3, we present our results for split graphs. Later, in Section 4, we give the approximation algorithm for general graphs. Next, in Section 5, we demonstrate the polynomial-time algorithm for interval graphs. Finally, in Section 6 we cite some concluding remarks and further work directions.

2 Preliminaries

A graph G is denoted as a pair $(V(G), E(G))$ of the nodes and edges of G. The graphs considered are simple (neither loops nor multi-edges are allowed), connected and undirected.

Two nodes connected by an edge are called *adjacent* or *neighboring*. The *open neighborhood* of a node $v \in V(G)$ is defined as $N(v) = \{u \in V(G) : \{v, u\} \in E(G)\}$, while the *closed neighborhood* is defined as $N[v] = \{v\} \cup N(v)$. For a subset of nodes $S \subseteq V(G)$, we expand the definitions of open and closed neighborhood as $N(S) = \bigcup_{v \in S}(N(v) \setminus S)$ and $N[S] = N(S) \cup S$.

The degree of a node $v \in V(G)$ is defined as $d(v) = |N(v)|$. The minimum (resp. maximum) degree of G is denoted by $\delta(G) = \min_{v \in V(G)} d(v)$ (resp. $\Delta(G) = \max_{v \in V(G)} d(v)$).

A *clique* is a set of nodes, where there exists an edge between each pair of them. The maximum size of a clique in G, i.e., the *clique number* of G, is denoted by $\omega(G)$.

An *independent set* is a set of nodes, where there exists no edge between any pair of them. The max. size of such a set in G, i.e., the *independence number* of G, is denoted by $\alpha(G)$.

In the results to follow, we consider two specific families of graphs, namely *split* and *interval* graphs. Any necessary preliminary knowledge for these two graph families is given more formally in their corresponding sections.

Finally, let us provide a formal definition of the quantity under consideration and the decision version of the corresponding optimization problem.

▶ **Definition 1.** We define the Maximum Rooted Connected Expansion number for a graph G and a node v_0 as follows, where $Con(G, v_0) := \{S \subseteq V(G) \mid v_0 \in S \text{ and } S \text{ is connected}\}$:

$$MRCE(G, v_0) = \max_{S \in Con(G, v_0)} \frac{|N[S]|}{|S|}$$

▶ **Definition 2** ($\mathcal{MRCE}$)**.** Given a graph G, a node $v_0 \in V(G)$ and two natural numbers a, b, decide whether $MRCE(G, v_0) \geq a/b$.

When the input graph is known to be split, respectively interval, we refer to the corresponding optimization problem as *Split* $\mathcal{MRCE}$, respectively *Interval* $\mathcal{MRCE}$.

3 Split Graphs

In this section, we define split graphs and cite a useful preliminary result regarding their structure. We proceed with our results and prove that *Split* $\mathcal{MRCE}$ is NP-hard, but it can be approximated within a constant factor of $\frac{k}{k+2}$ for any fixed integer $k > 0$.

▶ **Definition 3.** A graph is split if it can be partitioned into a clique and an independent set.

Given the above definition, we denote by (I, C) a partition for a split graph G where I stands for the independent set and C for the clique. However, there may be many different ways to partition a split graph into an independent set and a clique [11].

▶ **Theorem 4** (Follows from Theorem 3.1 [3])**.** *A split graph has at most a polynomial number of partitions into a clique and an independent set. Furthermore, all these partitions can be found in polynomial time.*

3.1 Hardness

We now move onward to investigate the complexity of *Split* $\mathcal{MRCE}$. Initially, let us a define a pair of satisfiability problems we rely on in order to prove NP-hardness.

▶ **Definition 5** (3-$\mathcal{SAT}$)**.** Given a CNF formula ϕ with n variables and m clauses, where each clause is a disjunction of exactly 3 literals, decide whether ϕ is satisfiable.

▶ **Definition 6** (3-$\mathcal{SAT}_{equal}$)**.** Given a CNF formula ϕ with n variables and n clauses, where each clause is a disjunction of exactly 3 literals, decide whether ϕ is satisfiable.

To demonstrate the hardness result in a more presentable way, we employ an auxiliary reduction from 3-$\mathcal{SAT}$ to 3-$\mathcal{SAT}_{equal}$ and then a reduction from 3-$\mathcal{SAT}_{equal}$ to *Split* $\mathcal{MRCE}$.

We recall that 3-$\mathcal{SAT}$ is well-known to be NP-hard, e.g. see [5].

▶ **Lemma 7.** 3-$\mathcal{SAT}_{equal}$ *is NP-hard.*

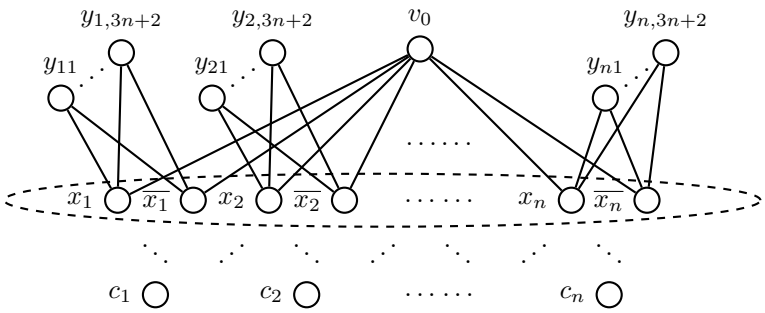

Figure 1 The graph G constructed for the reduction.

The Reduction. Given a 3-$\mathcal{SAT}_{equal}$ formula ϕ, we create a graph G with a node $v_0 \in V(G)$. Let $x_1, x_2, \ldots, x_n$ stand for the variables of ϕ and $c_1, c_2, \ldots, c_n$ for the clauses of ϕ. We construct the graph G in the following way: we place a node v_0, one node per literal $x_i, \overline{x_i}$ ($2n$ nodes in total), one node per clause c_i (n nodes in total) and a set of $3n+2$ "leaf" nodes for each variable (namely y_{ij} for $j = 1, \ldots, 3n+2$) summing up to $(3n+2) \cdot n = 3n^2 + 2n$ "leaf" nodes in total. We call the two nodes $x_i, \overline{x_i}$ a *literal-pair* and each node c_i a *clause-node*. Then, we connect v_0 to each literal node and each literal node to *all* the other literal nodes. Moreover, each literal-node is connected to all the corresponding clause-nodes where it appears in ϕ. Finally, x_i and $\overline{x_i}$ are connected to y_{ij} for all j. It is clear that the construction can be done in polynomial time. Formally, $V(G) = \{v_0\} \cup \{x_i, \overline{x_i} : 1 \le i \le n\} \cup \{c_i : 1 \le i \le n\} \cup \{y_{ij} : 1 \le i \le n, 1 \le j \le 3n+2\}$ and

$$\begin{aligned} E(G) = {} & \{[v_0, x_i] : 1 \le i \le n\} \cup \{[v_0, \overline{x_i}] : 1 \le i \le n\} \cup \\ & \cup \{[x_i, x_j] : 1 \le i, j \le n, i \ne j\} \cup \{[\overline{x_i}, x_j] : 1 \le i, j \le n, i \ne j\} \cup \{[\overline{x_i}, \overline{x_j}] : 1 \le i, j \le n, i \ne j\} \cup \\ & \cup \{[x_i, y_{ij}] : 1 \le i \le n, 1 \le j \le 3n+2\} \cup \{[\overline{x_i}, y_{ij}] : 1 \le i \le n, 1 \le j \le 3n+2\} \cup \\ & \cup \{[x_i, c_j] : x_i \text{ in clause } c_j\} \end{aligned}$$

That is, we get $|V(G)| = 1 + 5n + 3n^2$ and $|E(G)| = 2n + \binom{2n}{2} + 2n(3n+2) + 3n = 8n^2 + 8n$. Figure 1 demonstrates an example of such a construction; the literal-nodes within the dashed ellipsis form a clique.

▶ **Proposition 1.** *G is a split graph.*

Proof. $x_1, \overline{x_1}, x_2, \overline{x_2}, \ldots, x_n, \overline{x_n}$ form a clique; all other nodes form an independent set. ◀

▶ **Claim 1.** *If ϕ is satisfiable, then* $\mathrm{MRCE}(G, v_0) \ge \frac{1+5n+3n^2}{1+n}$.

Proof. Let A stand for a truth assignment under which ϕ is satisfiable. Then, to form a feasible solution for MRCE, we choose a set S including v_0 and these literal-nodes (either x_i or $\overline{x_i}$) whose corresponding literals are set true under A. Therefore, we get $|S| = 1 + n$. Since, in ϕ, each clause is satisfied by at least one literal set true under A, each clause-node c_i is connected to at least one literal-node in S. Moreover, any node y_{ij} is connected to S, since exactly one out of x_i and $\overline{x_i}$ is in S (due to A being a truth assignment). Overall, we see that $|N[S]| = |V(G)| = 1 + 5n + 3n^2$. ◀

▶ **Claim 2.** *If there exists no satisfiable assignment for ϕ, then $MRCE(G, v_0) < \frac{1+5n+3n^2}{1+n}$.*

Proof. Let us first show a proposition to restrict the shape of a feasible MRCE solution. Intuitively, adding any y_{ij} or c_i node does not contribute any new neighbors to the ratio.

Algorithm 1: Approximate Split MRCE.

Input : A split graph $G = (V(G), E(G))$, a node $v_0 \in V(G)$ and a fixed integer $k > 0$

Output : An MRCE solution and its corresponding ratio as a pair

1 $S_{apx} \leftarrow \arg\max_{S \in Con(G,v_0), 1 \leq |S| \leq k+2} |N[S]|/|S|$

2 **return** $(S_{apx}, |N[S_{apx}]|/|S_{apx}|)$

▶ **Proposition 2.** *Adding any y_{ij}, c_i node can only decrease the ratio of a feasible solution.*

The above proposition suggests it suffices to upper-bound potential solutions S containing v_0 and only literal nodes. Below, let $R = \frac{1+5n+3n^2}{1+n}$. To conclude the proof, we show that, if ϕ is unsatisfiable, then the ratio we can obtain is strictly less than R.

If $S = \{v_0\}$, then the ratio we get is $\frac{|N[\{v_0\}]|}{|\{v_0\}|} = \frac{1+2n}{1} < R$ for any $n > 0$.

If S contains v_0 and k literal nodes (any k of them), we distinguish three cases.

- *Case $k \leq n-1$:* For a fixed k, the ratio becomes at most $\frac{1+3n+k(3n+2)}{1+k}$, since at most k families of y nodes are in the neighborhood. We observe $\partial\left(\frac{1+3n+k(3n+2)}{1+k}\right)/\partial k = \frac{1}{(k+1)^2} > 0$ for any $k > 0$. Hence, the worst case is $k = n-1$, which yields a ratio $\frac{1+3n+(n-1)\cdot(3n+2)}{n} = \frac{3n^2+2n-1}{n} < R$ for any $n > 0$.
- *Case $k = n$:* If exactly one node from each literal pair is in S (i.e. S corresponds to a truth assignment), then the ratio becomes at most $\frac{1+3n-1+n(3n+2)}{1+n} < R$, since ϕ is unsatisfiable and therefore any truth assignment leaves at least one uncovered clause node. On the other hand, if there exists at least one literal-pair where both x_i and $\overline{x_i}$ are not in S, then the ratio is at most $\frac{1+3n+(n-1)(3n+2)}{1+n} < R$, since at least one set of $3n+2$ "leaf" nodes are not in $N[S]$.
- *Case $k > n$:* The ratio becomes at most $\frac{|(V(G)|}{1+k} = \frac{1+5n+3n^2}{1+k} < \frac{1+5n+3n^2}{1+n} = R$. ◀

▶ **Theorem 8.** *Split $\mathcal{MRCE}$ is NP-complete.*

3.2 Approximation

We now turn our attention to a polynomial time approximation scheme for *Split $\mathcal{MRCE}$*. Our algorithm is parameterized by any fixed integer $k > 0$ and provides an approximation guarantee of $\frac{k}{k+2}$. Intuitively, the idea is that, given the best MRCE ratio when the set size is restricted to be at most $k+2$, the overall optimal ratio cannot be much better due to a ratio growth property. Additionally, connectivity is ensured due to the special topology of split graphs. Below, the approach is described formally in Algorithm 1. Lemma 9 restricts the structure of a feasible MRCE solution on split graphs and the analysis follows in Theorem 10.

▶ **Lemma 9.** *Let G be a split graph, $v_0 \in V(G)$ the requested root node and (I, C) a partition of G into an independent set I and a clique C where $|C| = \omega(G)$. Any feasible solution for Split $\mathcal{MRCE}$ containing nodes in I can be transformed into another feasible solution with no nodes in I (except maybe for v_0) which achieves a non-decreased MRCE ratio.*

▶ **Theorem 10.** *For any fixed integer $k > 0$, Algorithm 1 runs in $\mathcal{O}(n^{k+1})$ time and returns a $\frac{k}{k+2}$-approximation for Split $\mathcal{MRCE}$.*

Proof. The algorithm computes a maximum value out of all connected subsets of size at most $k+2$, including v_0, and so it runs in $\mathcal{O}(n^{k+1})$ time.

Let S_{opt} stand for an optimal solution for *Split* $\mathcal{MRCE}$. In other words, it holds $S_{opt} \in \arg\max_{S \in Con(G,v_0)} |N[S]|/|S|$. We distinguish two cases based on the size of S_{opt}.

If $|S_{opt}| \leq k+2$, then Algorithm 1 considers S_{opt} and either returns it or another solution achieving the same ratio.

If $|S_{opt}| > k+2$, then consider the following procedure: repeatedly remove from S_{opt} the node with the least contribution in the numerator until k nodes are left. More formally, let us denote $|S_{opt}| = l$ and then $S_{opt} = S_l$. For $i = l-1, \ldots, k$, let $S_i = S_{i+1} \setminus \{u_{i+1}\}$ for some node u_{i+1} that maximizes $|N[S_{i+1} \setminus \{v\}]|$ over all $v \in S_{i+1}$. Equivalently, let $p(v) = |N[S_{i+1}]| - |N[S_{i+1} \setminus \{v\}]|$ denote the number of exclusive neighbors of v in $N[S_{i+1}]$. Then, $u_{i+1} \in \arg\min_{v \in S_{i+1}} p(v)$. Notice that, for any $i = l-1, \ldots, k$, it may be the case that S_i is *not* a feasible MRCE solution, since v_0 may be removed during this process.

Now, let us show that the ratio does not decrease while performing the above process. For any $i \in \{l-1, \ldots, k\}$, let $|N[S_i]| = N_i$ and $|S_i| = n_i$. Assume $\frac{N_{i+1}}{n_{i+1}} > \frac{N_i}{n_i}$. We rewrite the inequality as $\frac{N_{i+1}}{n_{i+1}} > \frac{N_{i+1} - p(u_{i+1})}{n_{i+1}-1}$ which implies $p(u_{i+1}) > \frac{N_{i+1}}{n_{i+1}}$. Since u_{i+1} minimizes the value of $p(\cdot)$, it follows that, for every $v \in S_{i+1}$, $p(v) \geq p(u_{i+1})$. Furthermore, $N_{i+1} \geq \sum_{v \in S_{i+1}} p(v)$ because $N[S_{i+1}]$ includes all exclusive neighbors of each node. Putting everything together, we get $N_{i+1} \geq \sum_{v \in S_{i+1}} p(v) > \sum_{v \in S_{i+1}} \frac{N_{i+1}}{n_{i+1}} = n_{i+1} \frac{N_{i+1}}{n_{i+1}} = N_{i+1}$, a contradiction. Based on this observation, we get $\frac{N_k}{n_k} \geq \frac{N_{k+1}}{n_{k+1}} \geq \ldots \geq \frac{N_l}{n_l} = OPT$, where OPT stands for the optimal MRCE number.

From Lemma 9, we may assume without loss of generality that $S_{opt} \setminus \{v_0\} \subseteq C$. Moreover, due to the removal procedure followed, $S_k \setminus \{v_0\} \subseteq S_{opt} \setminus \{v_0\} \subseteq C$. In the worst case, when $v_0 \in I$ and v_0 has no neighbor in S_k, we form $S' = S_k \cup \{v_0, r\}$ where $r \in N(v_0)$ is a representative of v_0 in the clique C such that $S_k \subseteq N(r)$. Notice that, since $S' \supseteq S_k$, then $N[S'] \supseteq N[S_k]$. Since $|S'| = k+2$, S' is considered by Algorithm 1 and therefore it holds $\frac{|N[S_{apx}]|}{|S_{apx}|} \geq \frac{|N[S']|}{|S'|}$ where S_{apx} is the solution returned by Algorithm 1. Overall, we get the approximation guarantee $\frac{|N[S_{apx}]|}{|S_{apx}|} \geq \frac{|N[S']|}{|S'|} \geq \frac{|N[S_k]|}{k+2} = \frac{k}{k+2}\frac{|N[S_k]|}{k} \geq \frac{k}{k+2}\frac{N_l}{n_l} = \frac{k}{k+2} OPT$. ◀

4 General Graphs

We hereby state a constant-factor approximation algorithm for the general case when the input graph G has no specified structure. Our algorithm and analysis closely follow the work in [14] for the *Budgeted Connected Dominating Set* (shortly BCDS) problem.

In BCDS, the input is a graph G with n vertices and a natural number k and we are asked to return a *connected* subgraph, say S, of at most k vertices of G which maximizes the number of dominated vertices $|N[S]|$. Khuller et al. [14] prove that there is a $(1-1/e)/13$ approximation algorithm for BCDS. In broad lines, their algorithmic idea is to compute a greedy dominating set and its corresponding *profit function* and then obtain a connected subgraph via an approximation algorithm for the *Quota Steiner Tree* (shortly QST) problem.

▶ **Definition 11** ($\mathcal{QST}$). Given a graph G, a node profit function $p : V(G) \to \mathbb{N} \cup \{0\}$, an edge cost function $c : E(G) \to \mathbb{N} \cup \{0\}$ and a quota $q \in \mathbb{N}$, find a subtree T that minimizes $\sum_{e \in E(T)} c(e)$ subject to the condition $\sum_{v \in V(T)} p(v) \geq q$.

Evidently, both MRCE and BCDS require finding a connected subset $S \subseteq V(G)$ with many neighbors. Nonetheless, while in BCDS we only care about maximizing $|N[S]|$, in MRCE we care about maximizing $|N[S]|/|S|$ with the additional demand that $v_0 \in S$. In order to deal with this extra requirement, in this paper, we are going to employ the rooted version of QST, namely the *Rooted Quota Steiner Tree* (shortly RQST) problem.

▶ **Definition 12** ($\mathcal{RQST}$)**.** Given a graph G, a root $v_0 \in V(G)$, a profit function $p : V(G) \to \mathbb{N} \cup \{0\}$, an edge cost function $c : E(G) \to \mathbb{N} \cup \{0\}$ and a quota $q \in \mathbb{N}$, find a subtree T that minimizes $\sum_{e \in E(T)} c(e)$ subject to the conditions $\sum_{v \in V(T)} p(v) \geq q$ and $v_0 \in T$.

Garg [6] gave a 2-approximation algorithm for the (rooted) *k-Minimum Spanning Tree* (shortly k-MST) problem based on the Goemans-Williamson *Prize-Collecting Steiner Tree* approximation algorithm (shortly GW) [8, 9]. Johnson et al. [13] showed that any polynomial-time α-approximation algorithm for (rooted) k-MST, which applies GW, yields a polynomial-time α-approximation algorithm for (rooted) QST. Hence, Theorem 13 below follows.

▶ **Theorem 13** ([6, 13])**.** *There is a* 2*-approximation algorithm for RQST.*

The Algorithm. Algorithm 2, namely the *Greedy Dominating Set* (shortly GDS) algorithm, describes a greedy procedure to obtain a dominating set and a corresponding profit function for the input graph G. At each step, a node dominating the maximum number of the currently undominated vertices is chosen for addition into the dominating set.

Algorithm 3, namely the *Greedy MRCE* algorithm, makes use of GDS to obtain a dominating set for a slightly modified version of G, namely a graph G', which is the same as G with the addition of n^2 leaves to node v_0. Then, the algorithm outputs a connected subset T_i (containing v_0) for any possible size i. Finally, the subset yielding the best MRCE ratio is chosen as our approximate solution.

In terms of notation, we refer to the approximation algorithm implied by Theorem 13 as the 2-$RQST(G, v_0, p, q)$ algorithm with a graph G, a root node $v_0 \in V(G)$, a profit function $p : V(G) \to \mathbb{N} \cup \{0\}$ and a quota q as input. We omit including an edge cost function, since in our case all edges have the same cost, that is, cost 1. Furthermore, let $[n] := \{1, 2, 3, \ldots, n\}$.

Now, consider a connected set S_i of size i (which contains v_0) yielding the maximum number of dominated vertices, i.e. $S_i \in \arg\max_{S:\, S \in Con(G, v_0),\, |S|=i} |N[S]|$. We then denote $OPT_i := |N[S_i]|$ and use it in the quota parameter of 2-$RQST$ at line 4 of Greedy MRCE. Yet, in the general case, we do not know OPT_i and also such a quantity may be hard to compute. To overcome this obstacle, notice that $OPT_i \in [i, n]$ and therefore we could *guess* OPT_i, e.g., by running a sequential or binary search within the loop of Greedy MRCE and then keeping the best tree returned by 2-$RQST$. Notice that such an extra step requires at most a linear time overhead. Therefore, the running time of Greedy MRCE remains polynomial and is dominated by the running time of 2-$RQST$. For presentation purposes, we omit this extra step and assume OPT_i is known for each $i \in [n]$.

In the analysis to follow, we focus on why this specific $(1 - 1/e)OPT_i$ quota is selected and how it leads to a $(1 - 1/e)/6$ approximation factor.

Analysis. Let us consider some step i of the loop in the Greedy MRCE algorithm. Recall that $OPT_i = \max_{S:\, S \in Con(G, v_0),\, |S|=i} |N[S]|$. That is, OPT_i stands for the maximum number of dominated vertices by a connected subset of size i, which contains v_0. In the call to 2-$RQST$, notice that, although OPT_i refers to the graph G and by definition contains v_0, the profit function p (as well as the corresponding greedy dominating set D) stems from running GDS on G'. The reason for this choice is, due to the extra n^2 leaves attached to v_0 in G', to force v_0 into the greedy dominating set D and assign to it the highest profit amongst all nodes. Below, let $S_{i,G'} \in \arg\max_{S:\, S \subseteq V(G),\, |S|=i,\, S \text{ is connected}} |N[S]|$ and $OPT_i^{G'} := |N[S_{i,G'}]|$, i.e., $OPT_{i,G'}$ denotes the maximum number of nodes dominated by a size-i subset of nodes in G'.

▶ **Claim 3.** *For any $i \in [n]$, it holds $v_0 \in S_{i,G'}$.*

Algorithm 2: Greedy Dominating Set (GDS) [14].

Input : A graph $G = (V(G), E(G))$
Output : A dominating set $D \subseteq V(G)$ and a profit function $p : V(G) \to \mathbb{N} \cup \{0\}$

$D \leftarrow \emptyset$
$U \leftarrow V(G)$
foreach $v \in V(G)$ **do**
  $p(v) \leftarrow 0$
end
while $U \neq \emptyset$ **do**
  $w \leftarrow \arg\max_{v \in V(G) \setminus D} |N_U(v)|$ /* $N_U(v) = N[\{v\}] \cap U$ */
  $p(w) \leftarrow |N_U(w)|$
  $U \leftarrow U \setminus N_U(w)$
  $D \leftarrow D \cup \{w\}$
end
return (D, p)

Algorithm 3: Greedy MRCE.

Input : A graph plus node pair (G, v_0)
Output : An MRCE solution S and its corresponding ratio s

Construct G': same as G with extra n^2 leaves attached to v_0
$(D, p) \leftarrow GDS(G')$
foreach $i \in [n]$ **do**
  $T_i \leftarrow 2\text{-}RQST(G, v_0, p, (1 - \frac{1}{e})OPT_i)$
end
Let $i^* = \arg\max_{i \in [n]} |N[T_i]|/|T_i|$
return $(T_{i^*}, |N[T_{i^*}]|/|T_{i^*}|)$

Let us introduce some further notation for the proofs to follow. Let $L_1 = S_{i,G'}$ and $L_2 = N(L_1)$, that is, $OPT_{i,G'} = |L_1 \cup L_2|$. Also, let $L_3 = N(L_2) \setminus L_1$ and $R = V(G) \setminus (L_1 \cup L_2 \cup L_3)$, where R denotes the remaining vertices, i.e., those outside the three layers L_1, L_2, L_3. Let us now consider the intersection of these layers with the greedy dominating set D returned by GDS. Let $L'_j = D \cap L_j$ for $j = 1, 2, 3$ and $D'_i = \{v_1, v_2, \ldots, v_i\}$ denote the first i vertices from $L'_1 \cup L'_2 \cup L'_3$ in the order selected by the greedy algorithm. In order to bound the total profit in D'_i, we define $g_j = \sum_{k=1}^{j} p(v_k)$ as the profit we gain from the first j vertices of D'_i.

▶ **Claim 4** (Variation of Claim 1 in [14]). *It holds* $g_{j+1} - g_j \geq \frac{1}{i}(OPT_{i,G'} - g_j)$.

▶ **Lemma 14** (Variation of Lemma 5.1 in [14]). *There exists a subset* $D'_i \subseteq D$ *of size* i *with total profit at least* $(1 - \frac{1}{e})OPT_i$. *Further,* D'_i *can be connected using at most* $2i$ *Steiner nodes and contains* v_0.

▶ **Theorem 15.** *There exists a* $\frac{1}{6}(1 - \frac{1}{e})$*-approximation for MRCE in general graphs.*

Proof. For each $i \in [n]$, by Lemma 14, there exists a solution of at most $3i$ vertices with profit at least $(1 - \frac{1}{e})OPT_i$. In Algorithm 3, we run 2-*RQST*, therefore obtaining a, connected and including v_0, solution of at most $6i$ vertices with profit at least $(1 - \frac{1}{e})OPT_i$. Let APX_i

stand for the MRCE ratio of the approximate solution corresponding to T_i. Then

$$APX_i \geq \frac{(1-\frac{1}{e})OPT_i}{6i} = \frac{1}{6}\left(1-\frac{1}{e}\right)\frac{OPT_i}{i}$$

Now, let OPT stand for the optimal ratio for MRCE. Then, $OPT = \max_{i\in[n]}\left\{\frac{OPT_i}{i}\right\}$. Let i^* be the solution size returned by Algorithm 3 and $i_0 = \arg\max_{i\in[n]}\left\{\frac{OPT_i}{i}\right\}$. Then, $APX_{i^*} \geq APX_{i_0} \geq \frac{1}{6}\left(1-\frac{1}{e}\right)OPT$, which concludes the proof. ◀

5 Interval Graphs

In this section, we provide an optimal polynomial time algorithm for the special case of *interval graphs*. We commence with some useful preliminaries and then provide the algorithm and its correctness.

Preliminaries. All intervals considered in this section are defined on the real line, closed and non-trivial (i.e., not a single point). Their form is $[\alpha, \beta]$, where $\alpha < \beta$ and $\alpha, \beta \in \mathbb{R}$.

▶ **Definition 16.** A graph is called interval if it is the intersection graph of a set of intervals on the real line.

Following the above definition, each graph node corresponds to a specific interval and two nodes are connected with an edge if and only if their corresponding intervals overlap.

▶ **Definition 17.** Given an interval graph G, a realization of G (namely $I(G)$) is a set of intervals on the real line corresponding to G, where

- for each node $v \in V(G)$, the corresponding interval is given by $I(v) \in I(G)$, and
- for $v, u \in V(G)$, $I(v)$ intersects $I(u)$ if and only if $[v, u] \in E(G)$.

Notice that we can always derive a realization, where *all interval ends are distinct*. Suppose that two intervals share a common end. One need only extend one of them by $\epsilon > 0$ chosen small enough such that neighboring relationships are not altered.

Below, we provide a definition caring for the relative position of two intervals with regards to each other. Building on that, we define a partition of $V(G)$ with respect to the position of the vertices' corresponding intervals apropos of the v_0-interval.

▶ **Definition 18.** Given two intervals $x = [x_l, x_r]$ and $y = [y_l, y_r]$, we denote the following:

- $x \sqsubset y$, i.e. x is contained in y, when $x_l > y_l$ and $x_r < y_r$.
- $x \cap_L y$, i.e. x intersects y to the left, when $x_l < y_l$ and $y_l < x_r < y_r$.
- $x \cap_R y$, i.e. x intersects y to the right, when $x_r > y_r$ and $y_l < x_l < y_r$.
- $x \prec_L y$, i.e. x is strictly to the left of y, when $x_r < y_l$.
- $x \succ_R y$, i.e. x is strictly to the right of y, when $x_l > y_r$.

▶ **Definition 19.** We define the following sets:

- Let $C \coloneqq \{v \in V(G) : I(v_0) \sqsubset I(v)\}$. Notice that $v_0 \notin C$.
- Let $C' \coloneqq \{v \in V(G) : I(v) \sqsubset I(v_0)\}$. Notice that $v_0 \notin C'$.
- Let $C_L \coloneqq \{v \in V(G) : I(v) \cap_L I(v_0)\}$.
- Let $C_R \coloneqq \{v \in V(G) : I(v) \cap_R I(v_0)\}$.
- Let $L \coloneqq \{v \in V(G) : I(v) \prec_L I(v_0)\}$.
- Let $R \coloneqq \{v \in V(G) : I(v) \succ_R I(v_0)\}$.

▶ **Proposition 3.** *$(L, C_L, C', C, \{v_0\}, C_R, R)$ forms a partition of $V(G)$.*

Let us proceed with some useful propositions regarding the form of an optimal solution.

▶ **Proposition 4.** *The addition of any node $v \in C'$ to any feasible Interval $\mathcal{MRCE}$ set does not increase the solution ratio.*

Let us now show that we need only care about a specific subset of C, namely C^*, defined as $C^* := \{v \in C \mid \nexists\, v' \in C : v \neq v' \wedge I(v) \sqsubset I(v')\}$. That is, we restrict ourselves to those vertices whose corresponding intervals contain $I(v_0)$, but are not contained in any other interval. In other words, we are only interested in the intervals that *maximally* contain $I(v_0)$.

▶ **Proposition 5.** *Any feasible Interval $\mathcal{MRCE}$ solution $S \subseteq V(G)$ containing a node $v \in C \setminus C^*$ can be transformed into another feasible solution S', where $v \notin S'$, with at least the same ratio as S.*

The Algorithm. The general idea of the algorithm is to start from the feasible solution $\{v_0\}$ and then consider a family of the best out of all possible expansions, while maintaining feasibility, either moving toward the left or the right in terms of the real line. The key in this approach is that the left and right part of the graph are dealt with *independently* from each other. Of course, special care needs to be taken when other intervals contain $I(v_0)$. During this left/right subroutine, we save a series of possible expansion stop-nodes with maximal ratio. In the end, we conflate each left ratio with each right ratio and pick the combination providing the maximum one. The algorithm is given in Algorithm 4 and the other routines follow in Algorithms 5, 6. We hereby provide a short description for each function.

- *Interval*: This is the main routine. The input is an interval graph G and a starting node $v_0 \in V(G)$. The output is a solution set together with its corresponding ratio. Initially, the algorithm computes a realization $I(G)$, a partition of $V(G)$ and the *core* set C^* as defined in the preliminaries. Then, possible left and right expansions to $\{v_0\}$ are sought. These are combined to get a best solution for this case. Finally, these basic steps are repeated for each $c \in C^*$ and the best are kept in the *Sols* pool. It then suffices to calculate the max out of the best candidate solutions.
- *Expand*: This function is responsible for providing a set of possible expansions either left or right of a starting node. A direction, the starting node, the realization, the node partition and a counter are given as input. The counter serves to save different solutions in a vector, which is returned as output. Notice that the solution vector is *static*, i.e. it can be accessed by any recursive call. The main step of the function is to select a node whose interval intersects the starting interval to the requested direction. At the same time, this interval needs to be the farthest away in this direction, i.e., its left/right endpoint needs to be smaller/greater to any other candidate's. The potential expansion is saved and the function is called recursively with the new node as a start point. The process continues till no further expansion can be made, i.e., the farthest interval is reached. The returned vector does contain a no-expansion solution (case $count = 0$).
- *Combine*: This function takes as input the potential left and right expansions. It then computes a ratio for each possible combination of left and right expansions and outputs the solution and ratio pair attaining the maximum ratio for the given starting node-set.
- *MaxRatio*: This routine simply returns the maximum set-ratio pair out of a set of different such pairs.
- *Ratio*: Simply returns the MRCE ratio for a given set.

Algorithm 4: Interval.

Input : An interval graph plus node pair (G, v_0)
Output : A set-ratio pair (S, s)

$I \longleftarrow Realization(G)$
$P \longleftarrow Partition(G, I)$
$C^* \longleftarrow Core(C, I)$
$L_{sols} \longleftarrow Expand(L, v_0, I, P, 0)$
$R_{sols} \longleftarrow Expand(R, v_0, I, P, 0)$
$Sols \longleftarrow Combine(\{v_0\}, L_{sols}, R_{sols}, G)$
foreach $c \in C^*$ **do**
  $L_{sols} \longleftarrow Expand(L, c, I, P, 0)$
  $R_{sols} \longleftarrow Expand(R, c, I, P, 0)$
  $Sols \longleftarrow Sols \cup \{Combine(\{v_0, c\}, L_{sols}, R_{sols}, G)\}$
end
return $MaxRatio(Sols)$

Algorithm 5: Expand.

Input : A direction, node, realization, partition and counter $(D, v, I, P, count)$
Output : A vector of sets of nodes $Sols$

if $count == 0$ **then**
  $Sols(count) \longleftarrow \{v\}$
end
Pick v' such that $I(v')$ is the farthest interval on direction D with $I(v') \cap_D I(v)$
if $\nexists$ *such a* v' **then**
  return $Sols$
else
  $Sols(count + 1) \longleftarrow Sols(count) \cup \{v'\}$
  return $Expand(D, v', I, P, count + 1)$
end

Algorithm 6: Combine.

Input : A node-set, left/right possible solutions and graph $(S, Left, Right, G)$
Output : A set-ratio pair $(Argmax, Max)$

$(Argmax, Max) \longleftarrow (S, Ratio(S))$
foreach $l \in Left$ **do**
  foreach $r \in Right$ **do**
    if $Ratio(S \cup l \cup r) > Max$ **then**
      $(Argmax, Max) \longleftarrow (S \cup l \cup r, Ratio(S \cup l \cup r))$
    end
  end
end
return $(Argmax, Max)$

Correctness & Complexity. Lemma 20 argues about the fact that the solutions $Expand()$ ignores do not have any effect on optimality. We state the lemma for the *left* expansion case and the reader can similarly adapt it to the right expansion case. Then, we conclude with the optimality and running time of the overall procedure (Theorem 21).

▶ **Lemma 20.** *Let L_{sols} stand for the vector returned by the function call $Expand(L, v, I, P, 0)$ for some node $v \in V(G)$. For any node-set $S \subseteq C_L \cup L \cup \{v\}$ such that $v \in S$ and $S \notin L_{sols}$, there exists a set $S' \in L_{sols}$ such that $Ratio(S') \geq Ratio(S)$.*

▶ **Theorem 21.** *$Interval(G, v_0)$ optimally solves Interval $\mathcal{MRCE}$ in $\mathcal{O}(n^3)$ time.*

6 Conclusion & Further Work

We proved that MRCE is NP-complete for split graphs. We showed that, in this case, the problem admits a polynomial time approximation scheme, whereas for interval graphs we proposed a polynomial-time algorithm. For general graphs, we also gave a constant-factor approximation algorithm by exploring the relation of MRCE with BCDS [14].

The major open question is to improve the approximability of the problem on general graphs without applying BCDS techniques, but using rather MRCE properties. Another open problem is the design of an approximation algorithm for chordal graphs. Towards this direction, we notice that even for chordal graphs with a dominating clique (a superclass of split graphs), equivalently chordal graphs with diameter at most three (Theorem 2.1 [15]), the assumption that only clique nodes need to be included in a solution (Lemma 9) now fails.

Abstract

In this paper we consider what can be computed by a user interacting with a potentially malicious server, when the server performs polynomial-time quantum computation but the user can only perform polynomial-time classical (i.e., non-quantum) computation. Understanding the computational power of this model, which corresponds to polynomial-time quantum computation that can be efficiently verified classically, is a well-known open problem in quantum computing. Our result shows that computing the order of a solvable group, which is one of the most general problems for which quantum computing exhibits an exponential speed-up with respect to classical computing, can be realized in this model.

1 Introduction

First-generation quantum computers will be implemented in the "cloud" style, since only few groups, such as governments or huge companies, will be able to possess such expensive and high-maintenance machines. In fact, IBM has recently opened their 16-qubit machine for a cloud service [34]. In a future when many companies provide their own quantum cloud computing services, a malicious company might emerge who is trying to palm a user off with

a wrong result forged from their fake quantum computer. In addition, even if a fortunate user is interacting with a honest server, some noises in the server's gate operations might change the result. How can a user verify the correctness of the server's quantum computation? If the user has his/her own quantum computer, the user can of course check the server's result, but in this case the user may not need the cloud service in the first place. If the solution of the problem is easily verifiable (e.g., integer factoring), the user can naturally verify the correctness of the server's result, but many problems considered in quantum computing are not believed to have this property. Verifying classically and efficiently a server's quantum computation is indeed in general highly nontrivial.

It is known that if at least two servers, who are entangled but not communicating with each other, are allowed, then any problem solvable in quantum polynomial time can be verified by a classical polynomial-time user who exchanges classical messages with the servers [20, 24, 27]. However, the assumption that servers are not communicating with each other is somehow unrealistic: how can the user guarantee that remote servers are not communicating with each other?

Whether the number of the servers can be reduced to one is a well-known open problem [4]. For certain computational problems solvable in quantum polynomial time, it is known that this can be done. Simon's problem [31] and factoring [30] are trivial examples, since the answer can be directly checked in classical polynomial time. It is known that recursive Fourier sampling [10], which was the first problem that separates efficient quantum and classical computing, can be verified by a polynomial number of message exchanges with a single quantum server [23]. Moreover, it was shown that certain promise problems related to quantum circuits in the second level of the Fourier hierarchy [29] are verifiable by a classical polynomial-time user interacting with a single quantum server who sends only a single message to the user [12, 26].

Our results. In this paper we consider the problem of computing the order, i.e., the number of elements, of a finite group given as a black-box group (the concept of black-box groups is defined in Section 2). This problem is central in computational group theory, especially since the ability of computing the order makes possible to decide membership in subgroups. This problem has also been the subject of several investigations in computational complexity [1, 6, 7, 9, 32, 33]. The seminal result by Babai [6], especially, which put this problem in the complexity class AM, has been one of the fundamental motivations behind the concept of interactive proofs. Note that this is clearly a hard problem for classical computation: it is easy to show that no polynomial-time classical algorithm exists in the black-box setting, even if the input is an abelian group [9].

Most of the known quantum algorithms that achieve exponential speedups with respect to the best known classical algorithms are for group-theoretic problems, and especially problems over abelian groups. Shor's algorithm for factoring [30], for instance, actually computes the order of a cyclic black-box group. Watrous has shown that the group order problem can be solved in quantum polynomial time when the input group is solvable [33]. Since the class of solvable groups, defined in Section 2, is a large[5] class of finite groups that includes all

[5] It is known (see for instance [11]) that

$$\lim_{m\to\infty} \frac{\log \mathcal{G}_s(m)}{\log \mathcal{G}(m)} = 1,$$

where $\mathcal{G}(m)$ denotes the number of finite groups of order at most m and $\mathcal{G}_s(m)$ denotes the number of finite solvable groups of order at most m. It is even conjectured that the quotient $\mathcal{G}_s(m)/\mathcal{G}(m)$ goes to 1 when m goes to infinity, i.e., most finite groups are solvable.

abelian groups, this result significantly generalized Shor's algorithm. Watrous' algorithm can actually be seen as one of the most general results achieving an exponential speedup with respect to classical computation.

In this paper we show that the group order problem over solvable groups is also verifiable with a single server. More formally, in Section 2, where we introduce the relevant model of interactive protocols, we will introduce the notation $\mathrm{IP}[k, \mathrm{qpoly}]$ to denote the class of computational problems that are verifiable by a classical polynomial-time user interacting in k messages with a server who works in quantum polynomial time. Our main result is as follows.

▶ **Theorem 1.** *The solvable group order problem is in the complexity class* $\mathrm{IP}[3, \mathrm{qpoly}]$. *Moreover, if the set of prime factors of the order is also given as input, then the solvable group order problem is in* $\mathrm{IP}[2, \mathrm{qpoly}]$.

This result shows that for this important computational problem, the number of servers can be reduced to one as well, using a small number of messages. Note that assuming, in the second part of Theorem 1, that the set of prime factors of the order is known corresponds to several practical situations. An important example is computing the order of p-groups[6] with p known, which cannot be done in polynomial time in the classical setting [9]. The main open question is whether the number of messages can also be reduced to 2 without any assumption on the prime factors.

Other related works. In addition to the introduction of multiple servers mentioned above, there are other approaches considered in the literature for constructing verification systems for quantum computation.

First, if the user is allowed to be "slightly quantum", any problem solvable in quantum polynomial time can be efficiently verified with a single quantum server. For example, Refs. [2, 14] assume that the user can generate randomly-rotated single-qubit states, and Refs. [13, 16, 25] assume that the user can measure single-qubit states.

Second, since the class BQP (the class of decision problems that can be solved in quantum polynomial-time) is trivially in PSPACE and PSPACE = IP [21, 28], any problem in BQP can be classically verified using generic interactive proof protocols for PSPACE. In such protocols, however, the server has unbounded computational power. A tempting approach is to try to specialize these generic protocols to the class BQP, with the hope that the server's necessary computational power may be reduced. Ref. [3] made an significant first step in this direction.

Finally, it has been shown very recently that assuming that the learning with errors problem is intractable for polynomial-time quantum computation, any problem solvable in quantum polynomial time can be efficiently verified with a single quantum server and a single classical user [22].

2 Preliminaries

In this paper we assume that the reader is familiar with the standard notions of group theory (we refer to, e.g., [18] for a good introduction). All the groups considered will be finite. Given

[6] A (finite) p-group, where p is a prime, is a group of order p^r for some integer $r \geq 1$. A basic result from group theory shows that any p-group is solvable.

a group G, we use $|G|$ to denote its order (i.e., the number of elements in G), and use e to denote its identity element. Given elements $g_1, \ldots, g_r \in G$, we denote $\langle g_1, \ldots, g_r \rangle$ the subgroup of G generated by $g_1, \ldots, g_r$.

Black-box groups. We now describe the model of black-box groups. This concept, in which each group element is represented by a string and each group operation is implemented using an oracle, was first introduced by Babai and Szemerédi [9] to describe group-theoretic algorithms in the most general way, without having to concretely specify how the elements are represented and how groups operations are implemented. Indeed, any efficient algorithm in the black-box group model gives rise to an efficient concrete algorithm whenever the oracle operations can be replaced by efficient procedures. Especially, performing group operations can be done directly on the elements in polynomial time for many natural groups, including permutation groups and matrix groups where the group elements are represented by permutations and matrices, respectively. In the quantum setting, black-box groups have first been considered by Ivanyos et al. [19] and Watrous [32, 33].

A black-box group is a representation of a group G where each element of G is uniquely encoded by a binary string of a fixed length n, which is called the encoding length. The encoding length n is known. In order to be able to express the complexity of black-box group algorithms in terms of the group order $|G|$, and not in terms of the encoding length, we make the standard assumption that $n = O(\log |G|)$. Oracles are available to perform group operations. More precisely, two oracles are available. A first oracle performs the group product: given two strings representing two group elements g and h, the oracle outputs the string representing gh. The second oracle performs inversion: given a string representing an element $g \in G$, the oracle outputs the string representing the element g^{-1}. Note that the two oracles may behave arbitrarily on strings not corresponding to elements in G; this is not a problem since our protocols will never use the oracles on such strings. We say that a group G is input as a black-box if a set of strings representing generators $\{g_1, \ldots, g_s\}$ of G with $s = O(\log |G|)$ is given as input and queries to the oracles can be done at cost 1.[7] The input length is thus $sn = \mathrm{poly}(\log |G|)$.

To be able to take advantage of the power of quantum computation when dealing with black-box groups, the oracles performing the group operations have to be able to deal with quantum superpositions. Concretely, this is done as follows (see [19, 32, 33]). Let $s\colon G \to \{0,1\}^n$ denote the encoding of elements as binary strings. We assume that a quantum oracle V_G is available, such that $V_G(|s(g)\rangle|s(h)\rangle) = |s(g)\rangle|s(gh)\rangle$ for any two elements $g, h \in G$, and behaving in an arbitrary way on other inputs (i.e., strings not in $s(G)$). Another quantum oracle V'_G is also available, such that $V'_G(|s(g)\rangle|s(h)\rangle) = |s(g)\rangle|s(g^{-1}h)\rangle$ for any $g, h \in G$ and again behaving in an arbitrary way on other inputs.

Approximate sampling in black-box groups. Babai [5] proved the following result for general groups, which shows that elements of a black-box group can be efficiently sampled nearly uniformly.

▶ **Theorem 2.** *([5]) Let G be a black-box group. For any $\varepsilon > 0$, there exists a classical randomized algorithm running in time polynomial in $\log(|G|)$ and $\log(1/\varepsilon)$ that outputs an element of G such that each $g \in G$ is output with probability in range $(1/|G| - \varepsilon, 1/|G| + \varepsilon)$.*

[7] The assumption $s = O(\log |G|)$ is standard. Indeed, every group G has a generating set of size $O(\log |G|)$. Additionally, a set of generators of any size can be converted efficiently into a set of generators of size $O(\log |G|)$ by taking random products of elements [5].

Solvable groups. Before discussing solvable groups, let us introduce the following concept of polycyclic generating sequences (see [17] for details).

▶ **Definition 3.** Let G be a group. A polycyclic generating sequence of G is a sequence $(h_1, \ldots, h_t)$ of t elements from G, for some integer t, such that:
1. $\langle h_1, \ldots, h_t \rangle = G$;
2. for each $1 < j \leq t$, the subgroup $\langle h_1, \ldots, h_{j-1} \rangle$ is normal in $\langle h_1, \ldots, h_j \rangle$.

There are many equivalent definitions of solvable groups in the literature (see, e.g., [17] for a thorough discussion). In this paper we will use the following characterization: a finite group is solvable if and only if it has a polycyclic generating sequence. This characterization, which was already used by Watrous [33], is the most convenient for our purpose. As discussed in [33], for any finite solvable group G given as a black box, a polycyclic generating sequence $(h_1, \ldots, h_t)$ with $t = O(\log |G|)$ can be computed classically in polynomial time with high probability using for instance the randomized algorithm by Babai et al. [8].

Watrous showed that the order of a solvable black-box group can be computed in polynomial time in the quantum setting. We state this result in the following theorem.

▶ **Theorem 4.** *([33]) Let G be a solvable group given as a black-box group. There exists a quantum algorithm running in time* $\mathrm{poly}(\log |G|)$ *that outputs $|G|$ with probability at least* $1 - 1/\mathrm{poly}(|G|)$.

Let G be a solvable group and $(h_1, \ldots, h_t)$ be a polycyclic generating sequence of G. In the following we will write $H_j = \langle h_1, \ldots, h_j \rangle$ for each $j \in \{1, \ldots, t\}$, and for convenience write $H_0 = \{e\}$. Since H_j is obtained from H_{j-1} by adding one generator, the factor group H_j/H_{j-1} is cyclic. Let us write its order m_j. Note that the order of G is thus the product $m_1 m_2 \cdots m_t$. A fundamental (and easy to show) property of polycyclic generating sequences is the following: For any $j \in \{1, \ldots, t\}$, any element $h \in H_j$ can be written, in a unique way, as $h = h_1^{a_1} h_2^{a_2} \cdots h_j^{a_j}$ with integers $a_i \in \{0, 1, \ldots, m_i - 1\}$ for $i \in \{1, \ldots, j\}$. We call this sequence $(a_1, \ldots, a_j)$ the decomposition of h over H_j. Watrous [33] showed that the decomposition of any element can be computed efficiently in the quantum setting, which immediately leads to an efficient algorithm for membership testing in the subgroups H_j. We state these two results, separately, in the following theorem.

▶ **Theorem 5.** *([33]) Let G be a solvable group given as a black-box group and let $(h_1, \ldots, h_t)$ be a polycyclic generating sequence of G with $t = O(\log |G|)$. There exist two quantum algorithms $\mathcal{A}_1$ and $\mathcal{A}_2$ running in time polynomial in* $\log |G|$ *as follows.*
- *Algorithm $\mathcal{A}_1$ receives an integer $j \in \{1, \ldots t\}$ and an element $h \in H_j$, and outputs with probability at least* $1 - 1/\mathrm{poly}(|G|)$ *the decomposition of h over H_j.*
- *Algorithm $\mathcal{A}_2$ receives an integer $j \in \{1, \ldots t\}$ and an element $h \in G$, and decides whether $h \in H_j$ or not. The decision is correct with probability at least* $1 - 1/\mathrm{poly}(|G|)$.

Interactive proofs with efficient quantum prover. Interactive proof systems are typically described as protocols for decision problems. In this paper it will be more convenient to consider interactive proofs for computing functions, since we are interested in computing the order of the input group.[8] The definition we give below is inspired by [15].

[8] In order to be completely rigorous, we should actually define this concept for functional problems where the input is represented using oracles (since we are dealing with black-box groups where the group operation is represented by oracles). We nevertheless omit this purely technical point in the exposition.

Let $f : X \to \{0,1\}^*$ be a function, where X is a finite set. We consider protocols between a prover and a verifier, who both receives as input an element $x \in X$ and can exchange classical messages of polynomial length. At the end of the protocol, the verifier outputs either some $y \in \{0,1\}^*$ or one special element $\perp$. We say that the function f has a *k-message polynomial-time interactive proof* if there exists a k-message protocol in which the verifier works in classical polynomial time, such that the following properties hold:

1. (completeness) there is a prover P such that the verifier's output y satisfies $y = f(x)$ with probability at least $2/3$ when interacting with P;
2. (soundness) for any prover P', the verifier's output y satisfies $y \in \{f(x), \perp\}$ with probability at least $2/3$ when interacting with P'.

The prover P in the completeness condition is called the *honest prover*.

The above definition makes no assumption on the computational powers of the provers. Our main definition is obtained by restricting the computational power of the *honest* prover, i.e., the prover P in the completeness condition.

▶ **Definition 6.** A function f is in the class $\mathrm{IP}[k, \mathrm{qpoly}]$ if it has a k-message polynomial-time interactive proof where the honest prover P works in quantum polynomial time.

The notation $\mathrm{IP}[k, \mathrm{qpoly}]$ comes from its definition as a k-message interactive protocol with a prover working in quantum polynomial time (when honest). We stress that in Definition 6 there is no assumption on the computational power of P' for the soundness.

3 2-Message Protocol with Known Prime Factors

In this section we assume that the prime factors of the order of the black-box group G are known. We present a 2-message protocol in this case, which proves the second part of Theorem 1.

3.1 Preliminaries

We will need the following result in our protocol. This result essentially shows how to reduce the computation of the order of a solvable group G to the problem of deciding if its factor groups H_i/H_{i-1} have order 1 or not.

▶ **Theorem 7.** *Let G be a solvable group given as a black-box group. Let $p_1, \ldots, p_\ell$ denote the prime factors of $|G|$ and assume that the set $S = \{p_1, \ldots, p_\ell\}$ is also given as input. There exists a classical algorithm running in time polynomial in $\log|G|$ that outputs elements $h_1, \ldots, h_t \in G$, with $t = \mathrm{poly}(\log|G|)$, and t prime numbers $r_1, \ldots, r_t \in S$ such that, with probability at least $1 - 1/\mathrm{poly}(|G|)$, the following conditions hold:*

- *$(h_1, \ldots, h_t)$ is a polycyclic generating sequence of G;*
- *the order of H_i/H_{i-1} is either 1 or r_i for each $1 \le i \le t$, where we denote $H_i = \langle h_1, \ldots, h_i\rangle$ for $1 \le i \le t$ and $H_0 = \{e\}$.*

Before proving Theorem 7, let us discuss the main idea of the algorithm in this theorem. The approach is to start with an arbitrary polycyclic generating sequence and refine it by replacing each element by decreasing powers of it. Consider for instance the cyclic group of order 12, for which we have $\ell = 2$, $p_1 = 2$, $p_2 = 3$ and $|G| = 12$. Assume that we start with the polycyclic generating sequence (k_1) consisting of a unique element k_1 of order 12. We refine this sequence as (h_1, h_2, h_3) with $h_1 = k_1^{|G|/p_1} = k_1^6$, $h_2 = k_1^{|G|/p_1^2} = k_1^3$ and $h_3 = k_1^{|G|/(p_1^2 p_2)} = k_1$. This is a polycyclic generating sequence with $|H_1/H_0| = 2$, $|H_2/H_1| = 2$ and $|H_3/H_2| = 3$. The difficulty is that naturally we do not know the order $|G|$. Remember nevertheless that

we know the encoding length n of the black-box group, which is an upper bound on $\log_2 |G|$. This means that the quantity $m = p_1^n \times \ldots \times p_\ell^n$ is a multiple of the order $|G|$, and thus we can use the same approach, working with m instead of $|G|$ when refining the original polycyclic generating sequence.

Proof of Theorem 7. Let us consider the function $\lambda\colon \{1,\ldots,\ell\} \times \{1,\ldots,n\} \to \mathbb{Z}$ such that

$$\lambda(i,a) = p_i^{n-a} \times p_{i+1}^n \times \cdots \times p_\ell^n$$

for any $(i,a) \in \{1,\ldots,\ell\} \times \{1,\ldots,n\}$. Now consider the sequence

$$(\lambda(1,1),\ldots,\lambda(1,n),\lambda(2,1),\ldots,\lambda(2,n),\ldots,\lambda(\ell,1),\ldots,\lambda(\ell,n)) \tag{1}$$

consisting of ℓn integers (the integers in the sequence are strictly decreasing). Define the function $\mu\colon \{1,\ldots,\ell n\} \to \mathbb{Z}$ such that $\mu(j)$ is the j-th integer in Sequence (1). Note that $\mu(j-1)/\mu(j) \in S$ for any $j \in \{2,\ldots,\ell n\}$.

We now describe our algorithm that computes the claimed generating sequence.

We first compute a polycyclic generating sequence $(k_1,\ldots,k_{t'})$ of G with $t' = O(\log |G|)$ using the randomized polynomial-time algorithm from [8], already mentioned in Section 2, which succeeds with probability at least $1 - 1/\mathrm{poly}(|G|)$. Let us write $K_{i'} = \langle k_1,\ldots,k_{i'}\rangle$ for each $1 \le i' \le t'$, and $K_0 = \{e\}$.

We now show how to refine the polycyclic generating sequence. For each $i' \in \{1,\ldots,t'\}$, we replace $k_{i'}$ by the sequence of ℓn elements $(k_{i'}^{\mu(1)},\ldots k_{i'}^{\mu(\ell n)})$, which gives a new sequence

$$\left(k_1^{\mu(1)},\ldots,k_1^{\mu(\ell n)},k_2^{\mu(1)},\ldots,k_2^{\mu(\ell n)},\ldots,k_{t'}^{\mu(1)},\ldots,k_{t'}^{\mu(\ell n)}\right), \tag{2}$$

of $\ell n t'$ elements. Sequence (2) is a polycyclic generating sequence of G since $(k_1,\ldots,k_{t'})$ is a polycyclic generating sequence of G and $\mu(\ell n) = 1$. For any $i' \in \{1,\ldots,t'\}$, observe that

$$\left|\langle k_1^{\mu(1)},\ldots,k_{i'}^{\mu(j)}\rangle / \langle k_1^{\mu(1)},\ldots,k_{i'}^{\mu(j-1)}\rangle\right| \in \{1,\mu(j-1)/\mu(j)\} \tag{3}$$

for any $j \in \{2,\ldots \ell n\}$. Similarly for any $i' \in \{2,\ldots t'\}$ we have

$$\left|\langle k_1^{\mu(1)},\ldots,k_{i'}^{\mu(1)}\rangle / \langle k_1^{\mu(1)},\ldots,k_{i'-1}^{\mu(\ell n)}\rangle\right| \in \{1,p_1\}. \tag{4}$$

Let us rename the elements of Sequence (2) as $h_1,\ldots,h_t$, with $t = \ell n t'$. Note that $t = O(\ell(\log|G|)^2) = O((\log|G|)^3)$. Let us write $H_i = \langle h_1,\ldots,h_i\rangle$ for $1 \le i \le t$ and $K_0 = \{e\}$. For each $1 \le i \le t$, the order of H_i/H_{i-1} is either 1 or r_i, where r_i can be determined from Equations (3) and (4). More concretely, r_i is of the form $\mu(j-1)/\mu(j)$ for some j (which can be immediately computed from i) when H_i/H_{i-1} corresponds to the case of Equation (3), and $r_i = p_1$ when H_i/H_{i-1} corresponds to the case of Equation (4). Note that in both cases we have $r_i \in S$, from the property $\mu(j-1)/\mu(j) \in S$ mentioned before. ◀

3.2 The protocol

Let $S = \{p_1,\ldots,p_\ell\}$ denote the set of prime factors of $|G|$, which is given as an additional input. The protocol is given in Figure 1. The main idea is that the verifier can, using Theorem 7, compute by itself a polycyclic generating sequence $(h_1,\ldots,h_t)$ and prime numbers $r_1,\ldots,r_t$ such that $|H_i/H_{i-1}| \in \{1,r_i\}$ for each $1 \le i \le t$. This is done at Step 1 of the protocol. Note that $|G| = \prod_{i=1}^t |H_i/H_{i-1}|$. The purpose of Steps 2-5 is to decide

Input: • a black-box solvable group G with generators $\{g_1, \ldots, g_s\}$
• the set $S = \{p_1, \ldots, p_\ell\}$ of prime factors of $|G|$

1. The verifier uses the algorithm of Theorem 7 to compute elements $h_1, \ldots, h_t$ and prime numbers $r_1, \ldots, r_t \in S$. Let us write $H_i = \langle h_1, \ldots, h_i \rangle$ for each $1 \leq i \leq t$ and $H_0 = \{e\}$.
2. For each $i \in \{1, \ldots, t\}$, the verifier takes a bit $s_i \in \{0, 1\}$ uniformly at random and takes a random element $x_i \in H_{i-1}$ using the algorithm of Theorem 2 with $\varepsilon = 1/2^{2n}$ (where n represents the encoding length of the black-box group).
3. The verifier sends to the prover the elements $h_1, \ldots, h_t$ and, for each $i \in \{1, \ldots, t\}$, the element $h_i^{s_i} x_i$.
4. The prover sends to the verifier bits $b_1, \ldots, b_t$ and integers $a_{i,j}$ for $i \in \{1, \ldots t\}$ and $j \in \{1, \ldots, i-1\}$.
5. For each $i \in \{1, \ldots, t\}$ the verifier does the following:
   5.1 If $h_i = h_1^{a_{i,1}} \cdots h_{i-1}^{a_{i,i-1}}$ then set $\ell_i = 1$;
   5.2 If $h_i \neq h_1^{a_{i,1}} \cdots h_{i-1}^{a_{i,i-1}}$ and $b_i = s_i$ then set $\ell_i = r_i$;
   5.3 If neither of these two conditions holds, then abort the protocol and output $\perp$.
6. The verifier outputs the product of the ℓ_i's.

Figure 1 Our 2-message protocol computing the order of a solvable group when the prime factors of the order are known.

whether $|H_i/H_{i-1}| = 1$ or $|H_i/H_{i-1}| = r_i$, for each $i \in \{1, \ldots, t\}$, by interacting with the prover. More precisely, the verifier interacts with the prover to test, for each i, whether $h_i \in H_{i-1}$ or $h_i \notin H_{i-1}$. This requires testing non-membership in a solvable group with a polynomial-time quantum prover, which is achieved by sending (at Step 3) to the prover the element $h_i^{s_i} x_i$ for a random bit s_i and a random element x_i, and asking the prover to find the chosen bit s_i. These tests enable the verifier to decide which of the two cases holds (at Steps 5.1 and 5.2), and then to compute $|G|$ at Step 6, or to detect cheating (at Step 5.3).

3.3 Analysis of the protocol

We now analyze the protocol of Figure 1. Let $h_1, \ldots, h_t$ be the group elements and $r_1, \ldots, r_t \in S$ be the prime numbers computed at Step 1. The analysis below is done under the assumption that $(h_1, \ldots, h_t)$ is a polycyclic generating sequence of G and $|H_i/H_{i-1}| \in \{1, r_i\}$ for all $i \in \{1, \ldots, t\}$, which is true with probability at least $1 - 1/\text{poly}(|G|)$ from Theorem 7.

Let us first consider the correctness, i.e., showing that there exists a prover (working in quantum polynomial time) who enables the verifier to compute $|G|$ with high probability. This prover acts as follows. For each $i \in \{1, \ldots, t\}$, the prover checks if the element $h_i^{s_i} x_i$ received at Step 3 is in the subgroup H_{i-1}, using Algorithm $\mathcal{A}_2$ of Theorem 5. If the prover learns that this element is in H_{i-1} then the prover applies Algorithm $\mathcal{A}_1$ of Theorem 5 to obtain a decomposition $(a_{i,1}, \ldots, a_{i,i-1})$ of h_i over H_{i-1}, and sends to the verifier the bit $b_i = 0$ and these values $a_{i,1}, \ldots, a_{i,i-1}$. If the prover learns that this element is not in H_{i-1}, then the prover sends to the verifier the bit $b_i = 1$ and arbitrary values $a_{i,1}, \ldots, a_{i,i-1}$.

Let us analyze the verifier's output when interacting with the above prover. If $|H_i/H_{i-1}| = 1$ then we have $h_i \in H_{i-1}$ and thus $h_i^{s_i} x_i \in H_{i-1}$ whatever the value of s_i is. With probability at least $1 - 1/\text{poly}(|G|)$, the prover's message is thus $b_i = 0$ and $a_{i,1}, \ldots, a_{i,i-1}$ corresponding

to the decomposition of h_i over H_{i-1}, and then the verifier sets $\ell_i = 1$. If $|H_i/H_{i-1}| = r_i$ then we have $h_i \notin H_{i-1}$ and thus $h_i^{s_i} x_i \in H_{i-1}$ if and only if $s_i = 0$. With probability at least $1 - 1/\mathrm{poly}(|G|)$, the bit b_i sent by the prover satisfies $b_i = s_i$, and thus the verifier sets $\ell_i = r_i$ (since the second part of the message $a_{i,1}, \ldots, a_{i,i-1}$ cannot correspond to the decomposition of h_i over H_{i-1}). In conclusion, with probability at least $1 - 1/\mathrm{poly}(|G|)$ the output at Step 6 is

$$\prod_{i=1}^{t} \ell_i = \prod_{i=1}^{t} |H_i/H_{i-1}| = |G|.$$

Let us now consider the soundness, i.e., showing that for any prover the verifier outputs either $|G|$ or $\perp$ with high probability. It is clear that if $|H_i/H_{i-1}| = r_i$, then the prover cannot convince the verifier to set $\ell_i = 1$, since there is no set of integers $a_{i,1}, \ldots, a_{i,i-1}$ such that $h_i = h_1^{a_{i,1}} \cdots h_{i-1}^{a_{i,i-1}}$. On the other hand, if $|H_i/H_{i-1}| = 1$ then the prover cannot convince the verifier to set $\ell_i = r_i$ unless the prover is able to decide whether $s_i = 0$ or $s_i = 1$ from the element $h_i^{s_i} x_i$ received, which cannot be done with probability larger than $\frac{1}{2} + \frac{1}{2}\delta$, where

$$\delta = \frac{1}{2} \sum_{h \in H_{i-1}} \left| \Pr_{x_i}[x_i = h] - \Pr_{x_i}[h_i x_i = h] \right|$$

represents the variational distance between the two probability distributions x_i and $h_i x_i$ (seen as distributions over H_{i-1}). We have

$$\begin{aligned}
\delta &\leq \frac{1}{2} \sum_{h \in H_{i-1}} \left| \Pr[x_i = h] - \frac{1}{|H_{i-1}|} \right| + \frac{1}{2} \sum_{h \in H_{i-1}} \left| \Pr[h_i x_i = h] - \frac{1}{|H_{i-1}|} \right| \\
&= \frac{1}{2} \sum_{h \in H_{i-1}} \left| \Pr[x_i = h] - \frac{1}{|H_{i-1}|} \right| + \frac{1}{2} \sum_{h \in H_{i-1}} \left| \Pr[x_i = h_i^{-1} h] - \frac{1}{|H_{i-1}|} \right| \\
&= \sum_{h \in H_{i-1}} \left| \Pr[x_i = h] - \frac{1}{|H_{i-1}|} \right| \\
&\leq |H_{i-1}| \varepsilon \\
&\leq 1/2^n,
\end{aligned}$$

where the second inequality follows from Theorem 2 and the third inequality follows from our choice of ε and the upper bound $|G| \leq 2^n$. Thus, for any fixed i such that $|H_i/H_{i-1}| = 1$, the prover cannot convince the verifier to set $\ell_i = r_i$ with probability greater than $\frac{1}{2} + \frac{1}{2^{n+1}} = 1/2 + 1/\mathrm{poly}(|G|)$. Let us now bound the probability that the verifier's output is either $|G|$ or $\perp$. This corresponds to the probability that the verifier does not output an integer different from the order of G. Note that the verifier can output an integer not equal to the order only if the prover forces the verifier to set $\ell_i \neq |H_i/H_{i-1}|$ for at least one index i. From the above analysis, we know that this can happen with probability at most $1/2 + 1/\mathrm{poly}(|G|)$, i.e., such a cheating is detected by the verifier at Step 5.3 with probability at least $1/2 - 1/\mathrm{poly}(|G|)$, in which case the verifier immediately aborts the protocol and outputs $\perp$. Thus the overall probability that the verifier's output is either $|G|$ or $\perp$ is at least $1/2 - 1/\mathrm{poly}(|G|)$. Note finally that this probability can be amplified to reach the soundness threshold of $2/3$ used in Definition 6 by repeating the protocol of Figure 1 a constant number of times in parallel and deciding the output based on a standard threshold argument.

Input: a black-box solvable group G with generators $\{g_1, \ldots, g_s\}$

0. The prover sends to the verifier the following:
- **a.** a list of t elements $h_1, \ldots, h_t \in G$, for some $t = \text{poly}(\log |G|)$;[9]
- **b.** a list of t prime numbers $r_1, \ldots, r_t$;
- **c.** a list of integers $\alpha_{i,j}$, for $i \in \{1, \ldots, s\}$ and $j \in \{1, \ldots, t\}$;
- **d.** a list of integers $\beta_{i,j}$, for $i \in \{2, \ldots, t\}$ and $j \in \{1, \ldots, i-1\}$;
- **e.** a list of integers $\gamma_{i,j,\ell}$, for $i \in \{2, \ldots, t\}$ and $j, \ell \in \{1, \ldots, i-1\}$.

Let us write $H_i = \langle h_1, \ldots, h_i \rangle$ for each $1 \leq i \leq t$ and $H_0 = \{e\}$.

1. The verifier checks that the following equalities hold:
- **a.** $g_i = h_1^{\alpha_{i,1}} \cdots h_t^{\alpha_{i,t}}$ for all $i \in \{1, \ldots, s\}$;
- **b.** $h_i^{r_i} = h_1^{\beta_{i,1}} \cdots h_{i-1}^{\beta_{i,i-1}}$ for all $i \in \{2, \ldots, t\}$ and $h_1^{r_1} = e$;
- **c.** $h_i h_\ell h_i^{-1} = h_1^{\gamma_{i,1,\ell}} \cdots h_{i-1}^{\gamma_{i,i-1,\ell}}$ for all $i \in \{2, \ldots, t\}$ and all $\ell \in \{1, \ldots, i-1\}$.

If any of these equalities fails, then the verifier aborts the protocol and outputs $\perp$.

2. For each $i \in \{1, \ldots, t\}$, the verifier takes a bit $s_i \in \{0, 1\}$ uniformly at random and takes a random element $x_i \in H_{i-1}$ using the algorithm of Theorem 2 with $\varepsilon = 1/2^{2n}$.

3. The verifier sends, for each $i \in \{1, \ldots, t\}$, the element $h_i^{s_i} x_i$.

4. The prover sends to the verifier bits $b_1, \ldots, b_t$ and integers $a_{i,j}$ for $i \in \{1, \ldots t\}$ and $j \in \{1, \ldots, i-1\}$.

5. For each $i \in \{1, \ldots, t\}$ the verifier does the following:
- 5.1 If $h_i = h_1^{a_{i,1}} \cdots h_{i-1}^{a_{i,i-1}}$ then set $\ell_i = 1$;
- 5.2 If $h_i \neq h_1^{a_{i,1}} \cdots h_{i-1}^{a_{i,i-1}}$ and $b_i = s_i$ then set $\ell_i = r_i$;
- 5.3 If neither of these two conditions holds, then abort the protocol and output $\perp$.

6. The verifier outputs the product of the ℓ_i's.

Figure 2 Our 3-message protocol computing the order of a solvable group.

4 General 3-Message Protocol

In this section we show that when the prime factors of the order of G are not known, we can design a 3-message protocol, which proves the first part of Theorem 1.

4.1 The protocol

Our 3-message protocol, described in Figure 2, is obtained by modifying the protocol of the previous section. More precisely, Step 1 in the protocol of the previous section is replaced by two steps (Steps 0 and 1 in Figure 2): instead of having the verifier compute a polycyclic generating sequence $(h_1, \ldots, h_t)$ using Theorem 7, which requires the knowledge of the set of factors of $|G|$, in the new protocol the prover computes by itself this sequence and sends it at Step 0 to the verifier, who then checks that the sequence is really correct at Step 1. All the other steps 2-6 are exactly the same as for the protocol in Figure 1 (one small exception is Step 3, which is slightly rewritten since the polycyclic generating sequence does not need to be sent to the prover anymore).

4.2 Analysis of the protocol

Let us consider the correctness. In that case the prover first uses the algorithm of Theorem 4 to compute the order $|G|$, then factorizes it using Shor's algorithm [30] and collects the prime factors in a set S. The prover then uses the algorithm of Theorem 7 using the set S as input to obtain group elements $h_1, \ldots, h_t$ and a list of integers $r_1, \ldots, r_t \in S$ such that with probability at least $1 - 1/\text{poly}(|G|)$ the following two conditions hold:

(i) $(h_1, \ldots, h_t)$ is a polycyclic generating sequence of G, with $t = \text{poly}(\log |G|)$,

(ii) the order of H_i/H_{i-1} is either 1 or r_i for each $1 \leq i \leq t$,

where as usual we use the notation $H_i = \langle h_1, \ldots, h_i \rangle$ for any $i \in \{1, \ldots, t\}$ and the convention $H_0 = \{e\}$. These two conditions are equivalent to the following:

(a) $H_t = G$, i.e., $g_i \in H_t$ for each $i \in \{1, \ldots, s\}$;

(b) $h_i^{r_i} \in H_{i-1}$ for each $i \in \{1, \ldots, t\}$;

(c) H_{i-1} is normal in H_i for any $i \in \{2, \ldots, t\}$, i.e., $h_i h_\ell h_i^{-1} \in H_{i-1}$ for any $\ell \in \{1, \ldots, i-1\}$.

Thus, with probability at least $1 - 1/\text{poly}(|G|)$, the prover can compute the following decompositions in quantum polynomial time using Algorithm $\mathcal{A}_1$ of Theorem 5:

- a decomposition $(\alpha_{i,1}, \ldots, \alpha_{i,t})$ of g_i over H_t, for each $i \in \{1, \ldots, s\}$;
- a decomposition $(\beta_{i,1}, \ldots, \beta_{i,i-1})$ of $h_i^{r_i}$ over H_{i-1}, for each $i \in \{2, \ldots, t\}$;
- a decomposition $(\gamma_{i,1,\ell}, \ldots, \gamma_{i,i-1,\ell})$ of $h_i h_\ell h_i^{-1}$ over H_{i-1}, for each $i \in \{2, \ldots, t\}$ and each $\ell \in \{1, \ldots, i-1\}$.

At Step 0, the prover sends all these integers, along with the elements $h_1, \ldots, h_t$ and the primes $r_1, \ldots, r_t$. All the tests performed by the verifier at Step 1 then pass. The analysis of the second part of the protocol (Steps 2-6) is then exactly the same as the analysis of the protocol of Section 3.

The soundness follows by observing that passing the tests performed by the verifier at Step 1 guarantees that Conditions (a)-(c) of the previous paragraph hold. This guarantees that Conditions (i)-(ii) hold as well, and thus the soundness analysis for the second part of the protocol (Steps 2-6) is exactly the same as the analysis of the protocol of Section 3.

[9] Naturally, this is binary strings corresponding to the elements $h_1, \ldots, h_t$ (i.e., the oracle representations of these elements) that are actually sent, not the elements themselves. Note also that, to simplify the exposition, we are assuming that these strings do correspond to elements of G. To deal with a cheating prover that may send strings not corresponding to group elements, we can simply ask the prover to send a certificate of membership in G for each string (such a certificate can be computed in quantum polynomial time using the algorithms of Theorem 5).

On the Complexity of Team Logic and Its Two-Variable Fragment

Martin Lück

lueck@thi.uni-hannover.de

Abstract

We study the logic FO(∼), the extension of first-order logic with team semantics by unrestricted Boolean negation. It was recently shown to be axiomatizable, but otherwise has not yet received much attention in questions of computational complexity. In this paper, we consider its two-variable fragment $\mathrm{FO}^2(\sim)$ and prove that its satisfiability problem is decidable, and in fact complete for the recently introduced non-elementary class TOWER(poly). Moreover, we classify the complexity of model checking of FO(∼) with respect to the number of variables and the quantifier rank, and prove a dichotomy between PSPACE- and ATIME-ALT(exp, poly)-complete fragments. For the lower bounds, we propose a translation from modal team logic MTL to $\mathrm{FO}^2(\sim)$ that extends the well-known standard translation from modal logic ML to FO^2. For the upper bounds, we translate FO(∼) to fragments of second-order logic with PSPACE-complete and ATIME-ALT(exp, poly)-complete model checking, respectively.

1 Introduction

In the past decades, the work of logicians has unearthed a plethora of decidable fragments of first-order logic FO. Many decidability results are rooted in a finite model property: if there exists a (computable) upper bound on the size of minimal models with respect to a class of formulas, and if the logic admits sufficiently feasible model checking, then the question of satisfiability can be settled by exhaustively searching all structures of suitable size. Prominent examples meeting the above criteria are logics with restricted quantifier prefixes, such as the BSR-fragment which contains only $\exists^*\forall^*$-sentences [34]. Others include the monadic class [27], the guarded fragment GF [2], the recently introduced separated fragment SF [36, 37], or the two-variable fragment FO^2 [31, 35, 19], which all are decidable. See also the excellent book by Börger et al. [6] for a comprehensive classification.

The above fragments all have been subject to intensive research with the purpose of further pushing the boundary of decidability. One example is the guarded fixpoint logic, μGF, which extends GF and is 2-EXPTIME-complete [18, 3]. Another is FOC^2, the extension FO^2

with counting quantifiers. Due to an exponential model property, satisfiability is NEXPTIME-complete for both FO^2 and FOC^2 [16, 33].

Another novel and very actively studied formalism is *team semantics*, introduced by Hodges [22]. At its core, it refers to the simultaneous evaluation of formulas on whole *sets* of assignments, called *teams*. This extension is conservative in the sense that the evaluation of singleton teams, which consist of a single assignment, coincides with classical Tarski semantics. Logics with team semantics offer many applications in areas such as statistics, database theory, physics, cryptography and social choice theory (see also Abramsky et al. [1]).

As a prototypical logic with team semantics, Väänänen [38] introduced *dependence logic* D. It extends FO by *dependence atoms* $=(x_1, \dots, x_n, y)$, which intuitively state that the value of y in the team functionally depends on the values of $x_1, \dots, x_n$. With respect to expressive power, D coincides with existential second-order logic. Nonetheless, its two-variable fragment D^2 was recently proved by Kontinen et al. [23] to have a NEXPTIME-complete satisfiability problem due to a satisfiability-preserving translation to FOC^2. However, D is not closed under Boolean negation, and the *validity* problem of D^2 is in fact undecidable [24], and non-arithmetical for full D [38]. By adding a negation operator $\sim$ to D, Väänänen [38] introduced *team logic* TL, which is equivalent to full second-order logic SO [25].

As a generalization of TL, we study the logic $\mathsf{FO}(\sim, \mathcal{D})$ introduced by Galliani [13, 12]. It extends FO under team semantics by a Boolean negation $\sim$ and a set $\mathcal{D}$ of so-called generalized dependence atoms (cf. [26]). We focus on FO-definable atoms, which covers the dependence atom and many other important atoms such as the independence $\perp$ [17] or inclusion atom $\subseteq$ [10]. We abbreviate $\mathsf{FO}(\sim, \emptyset)$ as $\mathsf{FO}(\sim)$. While $\mathsf{FO}(\sim)$ and D have incomparable expressive power, in terms of complexity, $\mathsf{FO}(\sim)$ is much weaker than D. In particular, unlike D it is axiomatizable [29] and its validity problem is complete for the class Σ^0_1 of recursively enumerable sets, as with ordinary FO.

As a new result, we prove in Section 4 that its two-variable fragment $\mathsf{FO}^2(\sim)$ is decidable. More precisely, we show that satisfiability and validity of $\mathsf{FO}^2(\sim)$ are complete for the recently introduced non-elementary complexity class TOWER(poly) [28]. This pushes the "decidability frontier" away from FO^2 into a new direction, and creates the curious situation that the satisfiability problem for $\mathsf{FO}^2(\sim)$ is strictly harder than for D^2, while for validity the exact opposite is the case (cf. Table 1).

On the path to decidability, we also investigate the model checking problem of $\mathsf{FO}(\sim, \mathcal{D})$. In the first-order setting, model checking in team semantics has received only little attention so far, unlike the well-understood propositional [21] and modal [9, 32, 39] variants of team logic and dependence logic. In Section 3 and 6, we fill this gap and show that model checking for $\mathsf{FO}(\sim, \mathcal{D})$ (for "well-behaved" $\mathcal{D}$) is complete for the class ATIME-ALT(exp, poly), i.e., for exponential runtime with polynomially many alternations. This complements the result of Grädel [14] that model checking for D is NEXPTIME-complete.

Finally, we also consider fragments $\mathsf{FO}^n_k(\sim, \mathcal{D})$ which have only n variables and quantifier rank k, and relate them to certain "sparse" fragments of SO which we call $\mathsf{SO}[p]$. We prove that model checking of $\mathsf{SO}[p]$ and $\mathsf{FO}^n_k(\sim, \mathcal{D})$ is only PSPACE-complete, as opposed to unrestricted SO and $\mathsf{FO}^\omega_\omega(\sim, \mathcal{D})$.

Due to space constraints, some proofs are moved to the appendix and marked with $(\star)$, and can also be found in the full version of this paper [30].

Table 1 Complexity of logics with team semantics. Completeness unless stated otherwise. $\mathcal{D}$ is a set of generalized dependency atoms, the superscript refers to the number of variables, and the subscript to the quantifier rank.

2 Preliminaries

The domain of a function f is $\mathsf{dom}\, f$. For $f\colon X \to Y$ and $Z \subseteq X$, $f{\restriction}Z$ is the restriction of f to the domain Z. The power set of X is $\mathfrak{P}(X)$. The cardinality of the natural numbers is ω. The class of recursively enumerable sets (resp. their complements) is Σ^0_1 (resp. Π^0_1).

Given a logic $\mathcal{L}$, the sets of all satisfiable and valid formulas of $\mathcal{L}$ are written $\mathsf{SAT}(\mathcal{L})$ and $\mathsf{VAL}(\mathcal{L})$, respectively. Likewise, the model checking problem $\mathsf{MC}(\mathcal{L})$ contains the tuples (A, φ) such that φ is an $\mathcal{L}$-formula and A is a model of φ.

We assume the reader to be familiar with basic complexity theory and alternating Turing machines [7]. When stating that a problem is hard or complete for a complexity class $\mathcal{C}$, we refer to logspace-computable reductions. In this paper, we require Turing machines that are restricted in both their runtime and their *alternation depth*, as introduced by Berman [4], where the alternation depth is the maximal number of alternations between existential and universal non-determinism that a given machine performs on any computation path.

In what follows, we use the tetration function $\exp_k$, defined by $\exp_0(n) := n$ and $\exp_{k+1}(n) := 2^{\exp_k(n)}$. We write $\exp(n)$ instead of $\exp_1(n)$.

▶ **Definition 2.1.** For $k \geq 0$, ATIME-ALT$(\exp_k, \mathrm{poly})$ is the class of problems decided by an alternating Turing machine with at most $p(n)$ alternations and runtime at most $\exp_k(p(n))$, for a polynomial p.

▶ **Definition 2.2.** TOWER(poly) is the class of problems that are decided by a deterministic Turing machine in time $\exp_{p(n)}(1)$ for some polynomial p.

The reader may verify that both ATIME-ALT$(\exp_k, \mathrm{poly})$ and TOWER(poly) are closed under all Boolean operations and under polynomial time resp. logspace computable reductions.

First-order Team Logic

A vocabulary τ is a set of function symbols f and predicate symbols P, with their respective arity denoted by $\mathsf{arity}(f)$ and $\mathsf{arity}(P)$. τ is called relational if it contains no function symbols. We explicitly state $= \in \tau$ if we permit equality as part of the syntax. For obvious reasons, we require that a vocabulary always contains at least one predicate or $=$.

We fix a set $\mathsf{Var} = \{x_1, x_2, \ldots\}$ of first-order variables. If $\vec{t}$ is a tuple of τ-terms, $\mathsf{Var}(\vec{t})$ is the set of variables appearing in $\vec{t}$. Formulas are interpreted in τ-structures, denoted as pairs $\mathcal{A} = (A, \tau^{\mathcal{A}})$, with the domain A of $\mathcal{A}$ also written $\mathsf{dom}\,\mathcal{A}$. We sometimes identify $\mathcal{A}$ and $\mathsf{dom}\,\mathcal{A}$ if the meaning is clear. If $s\colon X \to \mathcal{A}$, t is a τ-term, and $\mathsf{dom}\, s \supseteq \mathsf{Var}(t)$, then $t\langle s\rangle \in \mathcal{A}$ is the evaluation of t in $\mathcal{A}$ under s. Likewise, if $\vec{t} = (t_1, \ldots, t_n)$, then $\vec{t}\langle s\rangle := (t_1\langle s\rangle, \ldots, t_n\langle s\rangle)$.

A *team* T (in $\mathcal{A}$) is a set of assignments $s\colon X \to \mathcal{A}$, where X is called domain of T. If $X \supseteq \mathsf{Var}(\vec{t})$ and $\vec{t}$ is a tuple of terms, then $\vec{t}\langle T\rangle := \{\vec{t}\langle s\rangle \mid s \in T\}$. If T is a team with domain $X \supseteq Y$, then its restriction to Y is $T{\restriction}Y := \{s{\restriction}Y \mid s \in T\}$. In slight abuse of notation, we sometimes identify a tuple $\vec{x}$ with its underlying set, e.g., write $T{\restriction}\vec{x}$ for $T{\restriction}\{x_1, \ldots, x_n\}$.

If $s\colon X \to \mathcal{A}$ and $x \in \mathsf{Var}$, then $s^x_a\colon X \cup \{x\} \to \mathcal{A}$ is the assignment that maps x to a and $y \in X \setminus \{x\}$ to $s(y)$. If T is a team in $\mathcal{A}$ with domain X, then $f\colon T \to \mathfrak{P}(\mathcal{A}) \setminus \{\emptyset\}$ is called a *supplementing function* of T. It extends (or modifies) T to the *supplementing team* $T^x_f := \{\, s^x_a \mid s \in T, a \in f(s)\,\}$. If $f(s) = A$ is constant, we write T^x_A for T^x_f.

In this paper, we consider generalized dependencies in team semantics (cf. [26, 12]), but restrict ourselves to the special case of FO-definable dependencies. For this reason, in our setting, the definition boils down to the following.

▶ **Definition 2.3** (Dependencies)**.** If P is a predicate and $\tau_P = \{P, =\}$, then a τ_P-FO-formula δ is called *dependency*. Furthermore, if $\mathsf{arity}(P) = k$, then δ is also called *k-ary dependency*.

Let $\mathcal{D} = \{\delta_1, \delta_2, \ldots\}$ be a (possibly infinite) set of dependencies. Then we consider special atoms $A_i\vec{t}$, called *generalized dependency atoms*, to represent the dependencies δ_i in the syntax. The logic τ-$\mathsf{FO}(\sim, \mathcal{D})$ extends τ-FO as follows:

$$\varphi ::= \alpha \mid A_i\vec{t} \mid {\sim}\varphi \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \exists x\, \varphi \mid \forall x\, \varphi,$$

where α is any τ-FO-formula, $\delta_i \in \mathcal{D}$ is a k-ary dependency, $\vec{t}$ is a k-tuple of τ-terms, and $x \in \mathsf{Var}$. For easier distinction, we usually call classical FO-formulas $\alpha, \beta, \gamma, \ldots$ and reserve $\varphi, \psi, \vartheta, \ldots$ for $\mathsf{FO}(\sim, \mathcal{D})$-formulas. If $\vec{t} = (t_1, \ldots, t_n)$ and $\vec{u} = (u_1, \ldots, u_n)$ are tuples of τ-terms, then we use the shorthand $\vec{t} = \vec{u}$ for $\bigwedge_{i=1}^n t_i = u_i$.

From now on, we usually omit τ. The $\sim$-free fragment of $\mathsf{FO}(\sim, \mathcal{D})$ is $\mathsf{FO}(\mathcal{D})$, and we abbreviate $\mathsf{FO}(\sim, \emptyset)$ as $\mathsf{FO}(\sim)$.

▶ **Example 2.4.** Let $\mathsf{dep} := \{\mathsf{dep}_1, \mathsf{dep}_2, \ldots\}$ be defined by

$$\mathsf{dep}_n(R) := \forall x_1 \cdots \forall x_{n-1} \forall y \forall z (Rx_1 \cdots x_{n-1}y \wedge Rx_1 \cdots x_{n-1}z \to y = z).$$

Then dep is set of dependencies, and the corresponding atom $A_n\vec{t}$ is called n-ary *dependence atom* and is also written $=\!(t_1, \ldots, t_n)$. It holds $(\mathcal{A}, T) \vDash =\!(t_1, \ldots, t_n)$ if and only if for all $s, s' \in T$ we have that $t_1\langle s\rangle = t_1\langle s'\rangle, \ldots, t_{n-1}\langle s\rangle = t_{n-1}\langle s'\rangle$ implies $t_n\langle s\rangle = t_n\langle s'\rangle$. Likewise, for the case $n = 1$, the atom $=\!(t)$ means that t is constant, i.e., $t\langle s\rangle = t\langle s'\rangle$ for all $s, s' \in T$.

In this notation, Väänänen's dependence logic D is $\mathsf{FO}(\mathsf{dep})$, and team logic TL is $\mathsf{FO}(\sim, \mathsf{dep})$ [38]. Many other important atoms are FO-definable, such as independence [17], inclusion and exclusion [10] (see also Durand et al. [8]).

If φ is a formula, $\mathsf{Fr}(\varphi)$ and $\mathsf{Var}(\varphi)$ denote the set of free resp. of all variables in φ, with $\mathsf{Fr}(A_i\vec{t}) := \mathsf{Var}(A_i\vec{t}) := \mathsf{Var}(\vec{t})$. If $\mathsf{Fr}(\varphi) = \emptyset$, then φ is called sentence. We write $\varphi(x_1, \ldots, x_n)$ to indicate that $x_1, \ldots, x_n$ are free in φ. The *width* $\mathsf{w}(\varphi)$ of φ is $|\mathsf{Var}(\varphi)|$.

The *quantifier rank* $\mathsf{qr}(\varphi)$ of φ is 0 if φ is atomic, and otherwise defined recursively as $\mathsf{qr}({\sim}\varphi) := \mathsf{qr}(\neg\varphi) := \mathsf{qr}(\varphi)$, $\mathsf{qr}(\varphi \wedge \psi) := \mathsf{qr}(\varphi \vee \psi) := \max\{\mathsf{qr}(\varphi), \mathsf{qr}(\psi)\}$, and $\mathsf{qr}(\exists x\, \varphi) := \mathsf{qr}(\forall x\, \varphi) := \mathsf{qr}(\varphi) + 1$, respectively. The fragment of FO with formulas of width at most n

and quantifier rank at most k is FO^n_k. The corresponding fragments D^n_k, TL^n_k, $\mathsf{FO}^n_k(\sim, \mathcal{D})$, $\mathsf{FO}^n_k(\sim)$ and $\mathsf{FO}^n_k(\mathcal{D})$ are defined analogously.

We evaluate τ-$\mathsf{FO}(\sim, \mathcal{D})$-formulas φ on pairs $(\mathcal{A}, T)$ as follows, where $\mathcal{A}$ is a τ-structure and T a team in $\mathcal{A}$ with domain $X \supseteq \mathsf{Fr}(\varphi)$:

$$
\begin{aligned}
(\mathcal{A}, T) \vDash \varphi \quad &\Leftrightarrow\ \forall s \in T : (\mathcal{A}, s) \vDash \varphi \text{ (in Tarski semantics), for } \varphi \in \mathsf{FO},\\
(\mathcal{A}, T) \vDash A_i \vec{t} \quad &\Leftrightarrow\ \mathcal{A} \vDash \delta_i(\vec{t}\langle T \rangle), \text{ where } \delta_i \in \mathcal{D},\\
(\mathcal{A}, T) \vDash {\sim}\psi \quad &\Leftrightarrow\ (\mathcal{A}, T) \nvDash \psi,\\
(\mathcal{A}, T) \vDash \psi \wedge \theta \ &\Leftrightarrow\ (\mathcal{A}, T) \vDash \psi \text{ and } (\mathcal{A}, T) \vDash \theta,\\
(\mathcal{A}, T) \vDash \psi \vee \theta \ &\Leftrightarrow\ \exists S, U \subseteq T \text{ such that } T = S \cup U, (\mathcal{A}, S) \vDash \psi, \text{ and } (\mathcal{A}, U) \vDash \theta,\\
(\mathcal{A}, T) \vDash \exists x \varphi \ &\Leftrightarrow\ (\mathcal{A}, T^x_f) \vDash \varphi \text{ for some } f \colon T \to \mathfrak{P}(\mathsf{dom}\,\mathcal{A}) \setminus \{\emptyset\},\\
(\mathcal{A}, T) \vDash \forall x \varphi \ &\Leftrightarrow\ (\mathcal{A}, T^x_{\mathsf{dom}\,\mathcal{A}}) \vDash \varphi.
\end{aligned}
$$

A τ-formula φ is *satisfiable* if there exists a τ-structure $\mathcal{A}$ and team T with domain $X \supseteq \mathsf{Fr}(\varphi)$ in $\mathcal{A}$ such that $(\mathcal{A}, T) \vDash \varphi$. Likewise, φ is *valid* if $(\mathcal{A}, T) \vDash \varphi$ for all such τ-structures $\mathcal{A}$ and teams T.

The so-called *locality* property ensures that the truth of a formula, as in classical semantics, depends only on the assignments to variables that occur free in it.

▶ **Proposition 2.5** (Locality). *Let $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$ and $X \supseteq \mathsf{Fr}(\varphi)$. If T is a team in $\mathcal{A}$ with domain $Y \supseteq X$, then $(\mathcal{A}, T) \vDash \varphi$ if and only if $(\mathcal{A}, T{\restriction}X) \vDash \varphi$.*

Proof. Proof by induction on φ. The base case of FO-formulas and the inductive step for $\wedge$, $\vee$, $\exists$ and $\forall$ work similarly to Galliani's proof for inclusion/exclusion logic [10, Theorem 4.22], to which the $\sim$-case can be added in the obvious manner. It remains to consider the dependence atoms $A_i\vec{t}$. As $X \supseteq \mathsf{Fr}(A_i\vec{t}) = \mathsf{Var}(\vec{t})$, clearly $\vec{t}\langle s \rangle = \vec{t}\langle s{\restriction}X \rangle$ for any $s \in T$, and consequently, $\vec{t}\langle T \rangle = \vec{t}\langle T{\restriction}X \rangle$. Hence, $\mathcal{A} \vDash \delta_i(\vec{t}\langle T \rangle)$ iff $\mathcal{A} \vDash \delta_i(\vec{t}\langle T{\restriction}X \rangle)$. ◀

Second-Order Logic

Second-order logic τ-SO (or simply SO) extends τ-FO by second-order quantifiers $\exists f$, $\forall f$, $\exists P$ and $\forall P$ for function and predicate variables. For an SO-formula α, the sets $\mathsf{Var}(\alpha)$ and $\mathsf{Fr}(\alpha)$ refer to all resp. all free variables in α (first-order or second-order). SO is evaluated on pairs $(\mathcal{A}, \mathcal{J})$, where $\mathcal{A}$ is a structure and $\mathcal{J}$ maps first-order variables x to elements $\mathcal{J}(x) \in \mathcal{A}$, function variables f to functions $\mathcal{J}(f) \colon \mathcal{A}^{\mathsf{arity}(f)} \to \mathcal{A}$, and predicate variables P to relations $\mathcal{J}(P) \subseteq \mathcal{A}^{\mathsf{arity}(P)}$. The notation $\mathcal{J}^X_Y$ for a (first-order or second-order) variable X and an element resp. function resp. relation Y is defined as in the first-order setting. Instead of $(\mathcal{A}, \mathcal{J}) \vDash \alpha(X_1, \ldots, X_n)$ and $\mathcal{J}(X_1) = \mathcal{X}_1, \ldots, \mathcal{J}(X_n) = \mathcal{X}_n$, we also write $\mathcal{A} \vDash \alpha(\mathcal{X}_1, \ldots, \mathcal{X}_n)$.

Second-order model checking, $\mathsf{MC}(\mathsf{SO})$, is decidable using a straightforward algorithm: Given a formula α and a finite input structure $\mathcal{A}$, evaluate α in recursive top-down manner, using non-deterministic guesses for the quantified elements, functions and relations, which are of exponential size with respect to $|\mathsf{dom}\,\mathcal{A}|$.

▶ **Proposition 2.6** (⋆). $\mathsf{MC}(\mathsf{SO})$ *is decidable on input $(\mathcal{A}, \mathcal{J}, \alpha)$ in time $2^{n^{\mathcal{O}(1)}}$ and with $|\alpha|$ alternations.*

If the arity of quantified functions and relations is bounded by c, then each quantified function and relation has at most $|\mathsf{dom}\,\mathcal{A}|^c$ elements and hence takes only polynomial space:

▶ **Corollary 2.7.** *Let c-SO be the fragment of SO where all quantified functions and relations have arity at most c. Then $\mathsf{MC}(c\text{-}\mathsf{SO})$ is* PSPACE*-complete.*

3 From FO(∼) to SO: Upper bounds for model checking

In this section, we present upper bounds for the model checking problem of $\mathsf{FO}(\sim, \mathcal{D})$. On that account, we assume all first-order structures $\mathcal{A}$ and teams T to be finite and to have a suitable encoding. Instead of deciding $\mathsf{MC}(\mathsf{FO}(\sim, \mathcal{D}))$ directly, we reduce it to the corresponding problem of second-order logic, $\mathsf{MC}(\mathsf{SO})$. For this purpose, we build on top of a result of Väänänen [38], which roughly speaking states that TL-formulas can efficiently be translated to SO.

However, in Väänänen's original translation [38, Theorem 8.12, p. 159] from TL to SO it is assumed that the truth in a team is preserved when taking subteams (which is not the case if $\sim$ is available), and that all variables in a formula are quantified at most once. However, in fragments $\mathsf{FO}^n(\sim, \mathcal{D})$ of finite width n, re-quantification of variables cannot be avoided in general. In what follows, we adapt the translation accordingly. Furthermore, we extend it to include generalized dependency atoms.

Suppose $\vec{x} = (x_1, \ldots, x_n)$ is a tuple of variables. In order to avoid repetitions of variables, we define the notation $\vec{x};y$ as follows: $\vec{x};y := \vec{x}$ if $y \in \vec{x}$, and $\vec{x};y := (x_1, \ldots, x_n, y)$ if $y \notin \vec{x}$. Let now $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$ such that $\mathsf{Fr}(\varphi) \subseteq \vec{x}$, and R be a n-ary predicate. Then we inductively define the SO-formula $\eta^{\vec{x}}_{\varphi}(R)$ as shown below.

- If φ is a classical first-order formula, then $\eta^{\vec{x}}_{\varphi}(R) := \forall \vec{x}(R\vec{x} \to \varphi)$.
- If $\varphi = A_i(\vec{t})$ and $\delta_i \in \mathcal{D}$ is k-ary, then let $\vec{z} = (z_1, \ldots, z_k)$ be pairwise distinct variables disjoint from $\vec{x}$ and $\eta^{\vec{x}}_{\varphi}(R) := \exists S \forall \vec{z}\,(S\vec{z} \leftrightarrow (\exists \vec{x}\, R\vec{x} \wedge \vec{t} = \vec{z})) \wedge \delta_i(S)$.[1]
- If $\varphi = \sim\psi$, then $\eta^{\vec{x}}_{\varphi}(R) := \neg\eta^{\vec{x}}_{\psi}(R)$.
- If $\varphi = \psi \wedge \theta$, then $\eta^{\vec{x}}_{\varphi}(R) := \eta^{\vec{x}}_{\psi}(R) \wedge \eta^{\vec{x}}_{\theta}(R)$.
- If $\varphi = \psi \vee \theta$, then $\eta^{\vec{x}}_{\varphi}(R) := \exists S\, \exists U\ \forall \vec{x}(R\vec{x} \leftrightarrow (S\vec{x} \vee U\vec{x})) \wedge \eta^{\vec{x}}_{\psi}(S) \wedge \eta^{\vec{x}}_{\theta}(U)$.
- If $\varphi = \exists y\, \psi$, then $\eta^{\vec{x}}_{\varphi}(R) := \exists S \forall \vec{x}((\exists y R\vec{x}) \leftrightarrow (\exists y\, S\vec{x};y)) \wedge \eta^{\vec{x};y}_{\psi}(S)$.
- If $\varphi = \forall y\, \psi$, then $\eta^{\vec{x}}_{\varphi}(R) := \exists S \forall \vec{x}((\exists y R\vec{x}) \leftrightarrow (\exists y\, S\vec{x};y)) \wedge \eta^{\vec{x};y}_{\psi}(S) \wedge \forall \vec{x}(R\vec{x} \to \forall y\, S\vec{x};y)$.

By an inductive proof, the formulas φ and $\eta^{\vec{x}}_{\varphi}(R)$ can be shown equivalent, provided that the team T is represented as a relation $R := \vec{x}\langle T\rangle$:

▶ **Theorem 3.1** (⋆). *Let $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$, let $\vec{x} \supseteq \mathsf{Fr}(\varphi)$ be a tuple of variables, and T be a team in $\mathcal{A}$ with domain $Y \supseteq \vec{x}$. Then $(\mathcal{A}, T) \vDash \varphi$ if and only if $\mathcal{A} \vDash \eta^{\vec{x}}_{\varphi}(\vec{x}\langle T\rangle)$.*

▶ **Definition 3.2.** We call a set $\mathcal{D} = \{\delta_1, \delta_2, \ldots\}$ of dependencies *p-uniform* if there is a polynomial time algorithm that for all i, when given $A_i\vec{t}$, computes δ_i.

▶ **Corollary 3.3.** *Let $\mathcal{D}$ be a p-uniform set of dependencies. Then $\mathsf{MC}(\mathsf{FO}(\sim, \mathcal{D}))$ is decidable on input $(\mathcal{A}, T, \varphi)$ in time $2^{n^{\mathcal{O}(1)}}$ and with $|\varphi|^{\mathcal{O}(1)}$ alternations.*

Proof. First, we compute $\vec{x} := \mathsf{Fr}(\varphi)$, the formula $\eta^{\vec{x}}_{\varphi}$ and the relation $\vec{x}\langle T\rangle$ from φ and T in polynomial time. When translating the atoms $A_i\vec{t}$, we apply the p-uniformity of $\mathcal{D}$. Afterwards, we accept if and only if $\mathcal{A} \vDash \eta^{\vec{x}}_{\varphi}(\vec{x}\langle T\rangle)$. By Proposition 2.6, the latter can be checked by an algorithm with $|\eta^{\vec{x}}_{\varphi}|$ alternations and time exponential in $(\mathcal{A}, \vec{x}\langle T\rangle, \eta^{\vec{x}}_{\varphi})$. In total, this leads to $|\varphi|^{\mathcal{O}(1)}$ alternations and runtime exponential in the size of $(\mathcal{A}, T, \varphi)$. ◀

[1] Note that the "obvious" translation $\eta^{\vec{x}}_{\varphi}(R) := \delta_i(R)$ does not work in general if $A_i(\vec{t})$ contains proper terms. For instance, any team T satisfies $=\!(c)$ for any constant term c, but R represents only $\vec{x}\langle T\rangle$, which might or might not satisfy δ_i. To properly reflect such atoms, we quantify $\vec{t}\langle T\rangle$ in the relation S; in our example, $S = \{(c)\}$ for $T \neq \emptyset$.

Sparse second-order logic

The complexity of the model checking problem of $\mathsf{FO}(\sim, \mathcal{D})$ significantly drops if either the number of variables or the quantifier rank is bounded by an arbitrary constant. To prove this, we introduce a fragment of SO that corresponds to these restricted fragments of $\mathsf{FO}(\sim, \mathcal{D})$. We call this fragment *sparse second-order logic*, based on *sparse quantifiers* $\exists^p$ and $\forall^p$:

$$(\mathcal{A}, \mathcal{J}) \vDash \exists^p P\, \psi \Leftrightarrow \text{there exists } R \subseteq \mathcal{A}^{\mathsf{arity}(P)} \text{ such that } |R| \leq p(|\mathcal{A}|) \text{ and } (\mathcal{A}, \mathcal{J}^P_R) \vDash \psi,$$
$$(\mathcal{A}, \mathcal{J}) \vDash \forall^p P\, \psi \Leftrightarrow \text{for all } R \subseteq \mathcal{A}^{\mathsf{arity}(P)} \text{ such that } |R| \leq p(|\mathcal{A}|) \text{ it holds } (\mathcal{A}, \mathcal{J}^P_R) \vDash \psi,$$

where $p\colon \mathbb{N} \to \mathbb{N}$ and $|\mathcal{A}| := |\mathsf{dom}\, \mathcal{A}| + \sum_{X \in \tau} |X^{\mathcal{A}}|$. In other words, all quantified relations have bounded cardinality relative to the underlying structure. For obvious reasons, there are no sparse function quantifiers.

The logic $\mathsf{SO}[p]$ is now defined as SO, but with only $\exists^p$ and $\forall^p$ as permitted second-order quantifiers. Consider the case where p is bounded by a polynomial. The interpretation of each quantified relation then contains at most $|\mathcal{A}|^{\mathcal{O}(1)}$ tuples. Consequently, on $\mathsf{SO}[p]$-formulas, the recursive model checking algorithm from Proposition 2.6 then runs in polynomial time:

▶ **Corollary 3.4.** *If p is bounded by a polynomial, then $\mathsf{MC}(\mathsf{SO}[p])$ is decidable on input $(\mathcal{A}, \mathcal{J}, \alpha)$ in polynomial time and with $|\alpha|$ alternations.*

It remains to show that the translation from team logic with bounded width or quantifier rank takes place in this fragment of SO. This can be seen as follows. Intuitively, every quantified relation in $\eta^{\vec{x}}_\varphi$ represents either a subteam of an existing team (for the $\vee$-case), or it is a supplementing team (for the $\exists$-case and $\forall$-case). For this reason, the cardinality of the quantified relations grows at most by a factor of $|\mathsf{dom}\, \mathcal{A}|$ for every occurrence of $\vee$, $\exists$ or $\forall$.

Now, for $p\colon \mathbb{N} \to \mathbb{N}$, define the $\mathsf{SO}[p]$-formula $\zeta^{\vec{x},p}_\varphi$ like $\eta^{\vec{x}}_\varphi$, but with all second-order quantifiers replaced by $\exists^p$. The next theorem states that $\zeta^{\vec{x},p}_\varphi$ is an appropriate translation of φ, similarly to $\eta^{\vec{x}}_\varphi$, if φ has sufficiently small width or quantifier rank:

▶ **Theorem 3.5** (⋆). *Let $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$, let $\vec{x} \supseteq \mathsf{Fr}(\varphi)$ be a tuple of variables, and T be a team in $\mathcal{A}$ with domain $Y \supseteq \vec{x}$. If $p(n) \geq |T| \cdot n^{\mathsf{qr}(\varphi)}$ or $p(n) \geq n^{\mathsf{w}(\varphi)}$, then $(\mathcal{A}, T) \vDash \varphi$ if and only if $\mathcal{A} \vDash \zeta^{\vec{x},p}_\varphi(\vec{x}\langle T\rangle)$.*

Proof. By a careful analysis, it can be shown that all second-order quantifiers $\exists S$ in $\eta^{\vec{x}}_\varphi$ can be replaced by $\exists^p S$. See the appendix for details. As then $\eta^{\vec{x}}_\varphi$ and $\zeta^{\vec{x},p}_\varphi$ agree on $(\mathcal{A}, T)$, the claim follows by Theorem 3.1. ◀

▶ **Corollary 3.6.** *Let $\mathcal{D}$ be a p-uniform set of dependencies and $m < \omega$. $\mathsf{MC}(\mathsf{FO}^m_\omega(\sim, \mathcal{D}))$ and $\mathsf{MC}(\mathsf{FO}^\omega_m(\sim, \mathcal{D}))$ are then decidable on input $(\mathcal{A}, T, \varphi)$ in polynomial time with $|\varphi|^{\mathcal{O}(1)}$ alternations.*

Proof. Let $p(n) := n^{m+1}$. Analogously to Corollary 3.3, we reduce both $\mathsf{MC}(\mathsf{FO}^m_\omega(\sim, \mathcal{D}))$ and $\mathsf{MC}(\mathsf{FO}^\omega_m(\sim, \mathcal{D}))$ to $\mathsf{MC}(\mathsf{SO}[p])$. Assume that $(\mathcal{A}, T, \varphi)$ is the input, and that either $\mathsf{w}(\varphi) \leq m$ or $\mathsf{qr}(\varphi) \leq m$. Then the input is mapped to $(\mathcal{A}, \vec{x}\langle T\rangle, \zeta^{p,\vec{x}}_\varphi)$, where $\vec{x} = \mathsf{Fr}(\varphi)$.

- If $\mathsf{w}(\varphi) \leq m$, then $(\mathcal{A}, T) \vDash \varphi$ if and only if $\mathcal{A} \vDash \zeta^{p,\vec{x}}_\varphi(\vec{x}\langle T\rangle)$ by Theorem 3.5.
- If $\mathsf{qr}(\varphi) \leq m$, then w.l.o.g. $|T| \leq |\mathcal{A}|$ (if necessary, pad $\mathcal{A}$ with a dummy predicate in polynomial time). Then $|T| \cdot |\mathcal{A}|^m \leq p(|\mathcal{A}|)$, and we can again apply Theorem 3.5. ◀

4 From $\mathsf{FO}^2(\sim)$ to FO^2: Upper bounds for satisfiability

In this section, we turn to the satisfiability problem of $\mathsf{FO}^2(\sim)$ and prove that it is complete for TOWER(poly) (cf. Definition 2.2). Our approach is to establish a finite model property for $\mathsf{FO}^2(\sim)$. However, instead of constructing a finite model directly, we reduce $\mathsf{FO}^2(\sim)$-formulas to FO^2-formulas, and use the exponential model property of FO^2 [19]. As a first step, we expand $\mathsf{FO}^2(\sim)$-formulas into a specific "disjunctive normal form" over $\wedge$ and $\sim$. Recall that $\vee$ is not the Boolean disjunction, which we instead define via $\varphi \otimes \psi := \sim(\sim\varphi \wedge \sim\psi)$. We also use the abbreviation $\mathsf{E}\beta := \sim\neg\beta$ ("at least one assignment in the team satisfies β").

▶ **Lemma 4.1** ($\star$). *Every τ-$\mathsf{FO}^n_k(\sim)$-formula φ is equivalent to a formula of the form*

$$\psi := \bigotimes_{i=1}^{n} \left(\alpha_i \wedge \bigwedge_{j=1}^{m_i} \mathsf{E}\beta_{i,j} \right)$$

such that $\{\alpha_1, \dots, \alpha_n, \beta_{1,1}, \dots, \beta_{n,m_n}\} \subseteq \tau$-$\mathsf{FO}^n_k$ and $|\psi| \leq \exp_{\mathcal{O}(|\varphi|)}(1)$.

Proof. The proof is by induction on φ, and consists of repeatedly applying the following distributive laws. Here, $\varphi \equiv \psi$ means that φ and ψ are logically equivalent. See the appendix for details.

$$\alpha \wedge \bigwedge_{i=1}^{n} \mathsf{E}\beta_i \equiv \bigvee_{i=1}^{n} (\alpha \wedge \mathsf{E}\beta_i) \qquad \bigvee_{i=1}^{n} (\alpha_i \wedge \mathsf{E}\beta_i) \equiv \Big(\bigvee_{i=1}^{n} \alpha_i\Big) \wedge \bigwedge_{i=1}^{n} \mathsf{E}(\alpha_i \wedge \beta_i)$$

$$(\vartheta_1 \otimes \vartheta_2) \vee \vartheta_3 \equiv (\vartheta_1 \vee \vartheta_3) \otimes (\vartheta_2 \vee \vartheta_3) \qquad \vartheta_1 \vee (\vartheta_2 \otimes \vartheta_3) \equiv (\vartheta_1 \vee \vartheta_2) \otimes (\vartheta_1 \vee \vartheta_3)$$

$$(\vartheta_1 \otimes \vartheta_2) \wedge \vartheta_3 \equiv (\vartheta_1 \wedge \vartheta_3) \otimes (\vartheta_2 \wedge \vartheta_3) \qquad \vartheta_1 \wedge (\vartheta_2 \otimes \vartheta_3) \equiv (\vartheta_1 \wedge \vartheta_2) \otimes (\vartheta_1 \wedge \vartheta_3)$$

$$\exists v\,(\vartheta_1 \otimes \vartheta_2) \equiv (\exists v\,\vartheta_1) \otimes (\exists x\,\vartheta_2) \qquad \exists v\,(\vartheta_1 \vee \vartheta_2) \equiv (\exists v\,\vartheta_1) \vee (\exists v\,\vartheta_2)$$

$$\exists v\,(\alpha \wedge \mathsf{E}\beta) \equiv (\exists v\,\alpha) \wedge \mathsf{E}\,\exists v\,(\alpha \wedge \beta) \qquad \forall v\,(\vartheta_1 \wedge \vartheta_2) \equiv (\forall v\,\vartheta_1) \wedge (\forall v\,\vartheta_2)$$

$$\forall v \sim\vartheta \equiv \sim\forall v\,\vartheta$$

◀

▶ **Theorem 4.2.** *If τ is a relational vocabulary, then every satisfiable $\varphi \in \tau$-$\mathsf{FO}^2(\sim)$ has a model of size $\exp_{\mathcal{O}(|\varphi|)}(1)$.*

Proof. Let $\varphi \in \tau$-$\mathsf{FO}^2(\sim)$ be satisfiable. φ is equivalent to a disjunction of size $\exp_{\mathcal{O}(|\varphi|)}(1)$ as stated in Lemma 4.1. Clearly, this disjunction must have at least one satisfiable disjunct, which is of the form

$$\psi = \alpha \wedge \bigwedge_{i=1}^{m} \mathsf{E}\beta_i,$$

for $\{\alpha, \beta_1, \dots, \beta_m\} \subseteq \tau$-$\mathsf{FO}^2$ and w.l.o.g. $\mathsf{Var}(\psi) \subseteq \{x, y\}$. Let $(\mathcal{A}, T)$ be a model of ψ. For every i, as ψ implies $\mathsf{E}(\alpha \wedge \beta_i)$, there exists $s \in T$ such that $(\mathcal{A}, s) \vDash \alpha \wedge \beta_i$. But then $\mathcal{A}$ also satisfies – in Tarski semantics – the classical FO^2-sentence

$$\gamma := \bigwedge_{i=1}^{m} \exists x\,\exists y\,\alpha \wedge \beta_i,$$

as $s(x)$ and $s(y)$ are witnesses for $\exists x$ and $\exists y$. However, by the exponential model property of FO^2 [19], there exists a model $\mathcal{B}$ of size $2^{\mathcal{O}(|\gamma|)}$ for γ. As for every i there is $\hat{s}_i \colon \{x, y\} \to \mathcal{B}$ such that $(\mathcal{B}, \hat{s}_i) \vDash \alpha \wedge \beta_i$, we conclude $(\mathcal{B}, \{\hat{s}_1, \dots, \hat{s}_m\}) \vDash \psi$ by definition of team semantics. Clearly, this shows that ψ and hence φ has a model of size $\exp_{\mathcal{O}(|\varphi|)}(1)$. ◀

▶ **Corollary 4.3.** *If τ is a relational vocabulary, then* $\mathsf{SAT}(\tau\text{-}\mathsf{FO}^2(\sim))$ *and* $\mathsf{VAL}(\tau\text{-}\mathsf{FO}^2(\sim))$ *are in* TOWER(poly).

Proof. By Corollary 3.6, model checking for $\mathsf{FO}^2(\sim)$ is possible in alternating polynomial time, and hence in deterministic exponential time. The following is a TOWER(poly)-algorithm for $\mathsf{SAT}(\tau\text{-}\mathsf{FO}^2(\sim))$. Given a formula φ, iterate over all interpretations $(\mathcal{A}, T)$ of size $\exp_{\mathcal{O}(|\varphi|)}(1)$ and accept if $(\mathcal{A}, T) \models \varphi$. The algorithm for $\mathsf{VAL}(\tau\text{-}\mathsf{FO}^2(\sim))$ is similar. ◀

5 From MTL to FO²(∼): A team-semantical standard translation

In order to prove the lower bounds for $\mathsf{FO}^2(\sim)$ and $\mathsf{FO}^n_k(\sim)$, we reduce from the corresponding satisfiability, validity and model checking problems of so-called *modal team logic* MTL. This logic was introduced by Müller [32], and extends classical modal logic ML by $\sim$ in the same fashion as $\mathsf{FO}(\sim)$ extends FO.

We fix a countably infinite set Φ of propositions. MTL is defined as follows, where φ denotes an MTL-formula, α an ML-formula, and p a proposition.

$$\varphi ::= \sim\varphi \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \Box\varphi \mid \Diamond\varphi \mid \alpha \qquad\qquad \alpha ::= \neg\alpha \mid \alpha \wedge \alpha \mid \alpha \vee \alpha \mid \Box\alpha \mid \Diamond\alpha \mid p$$

The modal depth $\mathsf{md}(\varphi)$ of φ is defined recursively, i.e., $\mathsf{md}(p) := 0$, $\mathsf{md}(\sim\varphi) := \mathsf{md}(\neg\varphi) := \mathsf{md}(\varphi)$, $\mathsf{md}(\varphi \wedge \psi) := \mathsf{md}(\varphi \vee \psi) := \max\{\mathsf{md}(\varphi), \mathsf{md}(\psi)\}$, and $\mathsf{md}(\Box\varphi) := \mathsf{md}(\Diamond\varphi) := \mathsf{md}(\varphi)+1$. MTL_k is the fragment of MTL with modal depth at most k. The set of propositional variables occurring in $\varphi \in \mathsf{MTL}$ is written $\mathsf{Prop}(\varphi)$.

Let $X \subseteq \Phi$ be finite. Then, a Kripke structure (over X) is a tuple $\mathcal{K} = (W, R, V)$, where W is a set of *worlds* or *points*, (W, R) is a directed graph, and $V\colon X \to \mathfrak{P}(W)$. If $w \in W$, then $(\mathcal{K}, w)$ is called *pointed Kripke structure*.

ML is evaluated on pointed Kripke structures in the classical Kripke semantics, whereas MTL is evaluated on pairs $(\mathcal{K}, T)$, where $\mathcal{K}$ is a Kripke structure and – analogously to the first-order case – $T \subseteq W$ is called *team* (in $\mathcal{K}$). The team $RT := \{v \in W \mid \exists w \in T\colon Rwv\}$ is the *image* of T, and we write Rw instead of $R\{w\}$ for brevity. A successor team of T is a team S such that every $w \in T$ has at least one successor in S, and every $v \in S$ has at least one predecessor in T. The semantics of MTL is now defined as follows:

$$\begin{aligned}
(\mathcal{K}, T) \models \varphi &\;\Leftrightarrow\; \forall w \in T\colon (\mathcal{K}, w) \models \varphi \text{ (in Kripke semantics) for } \varphi \in \mathsf{ML},\\
(\mathcal{K}, T) \models \sim\psi &\;\Leftrightarrow\; (\mathcal{K}, T) \not\models \psi,\\
(\mathcal{K}, T) \models \psi \wedge \theta &\;\Leftrightarrow\; (\mathcal{K}, T) \models \psi \text{ and } (\mathcal{K}, T) \models \theta,\\
(\mathcal{K}, T) \models \psi \vee \theta &\;\Leftrightarrow\; \exists S, U \subseteq T \text{ such that } T = S \cup U,\ (\mathcal{K}, S) \models \psi, \text{ and } (\mathcal{K}, U) \models \theta,\\
(\mathcal{K}, T) \models \Diamond\psi &\;\Leftrightarrow\; \exists S \text{ such that } S \text{ is a successor team of } T \text{ and } (\mathcal{K}, S) \models \psi,\\
(\mathcal{K}, T) \models \Box\psi &\;\Leftrightarrow\; (\mathcal{K}, RT) \models \psi.
\end{aligned}$$

A formula $\varphi \in \mathsf{MTL}$ is satisfiable if $(\mathcal{K}, T) \models \varphi$ for some Kripke structure $\mathcal{K}$ over $X \supseteq \mathsf{Prop}(\varphi)$ and team T in $\mathcal{K}$. Likewise, φ is valid if it is true in every such pair.

The modality-free fragment MTL_0 syntactically coincides with *propositional team logic* PTL [20, 21, 40]. The usual interpretations of the latter, i.e., via sets of Boolean assignments, can easily be simulated by teams in Kripke structures. For this reason, we identify PTL and MTL_0 in this paper.

The following lower bounds due to Hannula et al. [21] are logspace reductions.

▶ **Theorem 5.1** ([21])**.** MC(PTL) *is* PSPACE*-complete.*

▶ **Theorem 5.2** ([21]). $\mathsf{SAT}(\mathsf{PTL})$ *and* $\mathsf{VAL}(\mathsf{PTL})$ *are* ATIME-ALT(exp, poly)*-complete.*

For each increment in modal depth, the complexity of the satisfiability problem increases by an exponential, reaching the non-elementary class TOWER(poly) in the unbounded case:

▶ **Theorem 5.3** ([28]). $\mathsf{SAT}(\mathsf{MTL})$ *and* $\mathsf{VAL}(\mathsf{MTL})$ *are* TOWER(poly)*-complete.* $\mathsf{SAT}(\mathsf{MTL}_k)$ *and* $\mathsf{VAL}(\mathsf{MTL}_k)$ *are* ATIME-ALT($\exp_{k+1}$, poly)*-complete for every* $k < \omega$.

Next, let us demonstrate how MTL can be embedded into $\mathsf{FO}^2(\sim)$. More precisely, we present an extension of the well-known standard translation that embeds modal logic ML into FO^2. The underlying relational vocabulary usually is $\tau_{\mathrm{st}} = (R, P_1, P_2, \ldots)$, where $\mathsf{arity}(R) = 2$ and $\mathsf{arity}(P_i) = 1$ for all i. The translation of an ML-formula α is denoted by $\mathsf{st}_x(\alpha)$ resp. $\mathsf{st}_y(\alpha)$, and is defined by mutual recursion:

$$\begin{aligned}
\mathsf{st}_x(p_i) &:= P_i x \ \text{ for } p_i \in \mathcal{PS} & \mathsf{st}_x(\neg\alpha) &:= \neg\mathsf{st}_x(\alpha)\\
\mathsf{st}_x(\Box\alpha) &:= \forall y\, Rxy \to \mathsf{st}_y(\alpha) & \mathsf{st}_x(\alpha \wedge \beta) &:= \mathsf{st}_x(\alpha) \wedge \mathsf{st}_x(\beta)\\
\mathsf{st}_x(\Diamond\alpha) &:= \exists y\, Rxy \wedge \mathsf{st}_y(\alpha) & \mathsf{st}_x(\alpha \vee \beta) &:= \mathsf{st}_x(\alpha) \vee \mathsf{st}_x(\beta),
\end{aligned}$$

with $\mathsf{st}_y(\alpha)$ defined symmetrically via $\mathsf{st}_x(\alpha)$. The corresponding *first-order interpretation* of a Kripke structure $\mathcal{K} = (W, R', V)$ is the τ_{st}-structure $\mathcal{A}(\mathcal{K})$ defined by $\mathsf{dom}\,\mathcal{A}(\mathcal{K}) = W$, $R^{\mathcal{A}(\mathcal{K})} = R'$ and $P_i^{\mathcal{A}(\mathcal{K})} = V(p_i)$. For a world w, let $w^x \colon \{x\} \to W$ be defined by $w^x(x) = w$.

▶ **Theorem 5.4** (see, e.g., Blackburn et al. [5]). *Let* $(\mathcal{K}, w)$ *be a pointed Kripke structure and* $\alpha \in \mathsf{ML}$. *Then* $(\mathcal{K}, w) \vDash \alpha$ *if and only if* $(\mathcal{A}(\mathcal{K}), w^x) \vDash \mathsf{st}_x(\alpha)$.

Let us now turn to team semantics. On the model side, the first-order interpretation of a team T in a Kripke structure is straightforwardly $T^x := \{\, w^x \mid w \in T \,\}$. For the syntax, we require the additional operator $\hookrightarrow$. It was introduced by Galliani [12] and Kontinen and Nurmi [25] in the first-order setting, but was also adapted to the modal setting [28]. For $\alpha \in \mathsf{ML}$ and $\varphi \in \mathsf{MTL}$, define $\alpha \hookrightarrow \varphi := \neg\alpha \vee (\alpha \wedge \varphi)$. If $(\mathcal{K}, T)$ is a Kripke structure with team, let $T_\alpha := \{\, w \in T \mid (\mathcal{K}, w) \vDash \alpha \,\}$.

▶ **Proposition 5.5.** $(\mathcal{A}, T) \vDash \alpha \hookrightarrow \varphi$ *if and only if* $(\mathcal{A}, T_\alpha) \vDash \varphi$.

Proof. Straightforward. See also Galliani [12, Lemma 16]. ◀

We extend the above translation by an $\sim$-case, and in the $\Box$-case replace $\to$ by $\hookrightarrow$.[2] The standard translation for MTL, denoted by st_x^* resp. st_y^*, then becomes:

$$\begin{aligned}
\mathsf{st}_x^*(\alpha) &:= \mathsf{st}_x(\alpha) \ \text{ for } \alpha \in \mathsf{ML} & \mathsf{st}_x^*(\sim\varphi) &:= \sim\mathsf{st}_x^*(\varphi)\\
\mathsf{st}_x^*(\Box\varphi) &:= \forall y\, Rxy \hookrightarrow \mathsf{st}_y^*(\varphi) & \mathsf{st}_x^*(\varphi \wedge \psi) &:= \mathsf{st}_x^*(\varphi) \wedge \mathsf{st}_x^*(\psi)\\
\mathsf{st}_x^*(\Diamond\varphi) &:= \exists y\, Rxy \wedge \mathsf{st}_y^*(\varphi) & \mathsf{st}_x^*(\varphi \vee \psi) &:= \mathsf{st}_x^*(\varphi) \vee \mathsf{st}_x^*(\psi),
\end{aligned}$$

with $\mathsf{st}_y^*(\varphi)$ again defined symmetrically.

▶ **Theorem 5.6.** *For every Kripke structure* $\mathcal{K}$*, team* T *in* $\mathcal{K}$ *and* $\varphi \in \mathsf{MTL}$ *it holds* $(\mathcal{K}, T) \vDash \varphi$ *if and only if* $(\mathcal{A}(\mathcal{K}), T^x) \vDash \mathsf{st}_x^*(\varphi)$.

Proof. Proof by induction on φ. We omit $\mathcal{K}$ and $\mathcal{A}(\mathcal{K})$ and simply write, e.g., $T \vDash \varphi$.

[2] It is not hard to show that the "classical" translation of $\Box\varphi$ to $\forall y\, Rxy \to \mathsf{st}_y^*(\varphi) = \forall y\, (\neg Rxy \vee \mathsf{st}_y^*(\varphi))$ is unsound under team semantics.

- $\varphi \in \mathsf{ML}$: We have $T \vDash \varphi$ iff $\forall w \in T\colon w \vDash \varphi$ by definition of the semantics of MTL, which by Theorem 5.4 is equivalent to $\forall w^x \in T^x\colon w^x \vDash \mathsf{st}_x(\varphi)$. However, as $\mathsf{st}_x(\varphi) \in \mathsf{FO}$, the latter is equivalent to $T^x \vDash \mathsf{st}_x(\varphi)$ by the semantics of $\mathsf{FO}(\sim)$, and hence $T^x \vDash \mathsf{st}^*_x(\varphi)$.
- $\varphi = \psi \wedge \vartheta$ and $\varphi = {\sim}\psi$ are clear.
- $\varphi = \psi \vee \theta$: Suppose $T \vDash \psi \vee \theta$. Then $T = S \cup U$ such that $S \vDash \psi$ and $U \vDash \theta$. By induction hypothesis, $S^x \vDash \mathsf{st}^*_x(\psi)$ and $U^x \vDash \mathsf{st}^*_x(\theta)$. As $S \cup U = T$, clearly $S^x \cup U^x = T^x$. As a consequence, $T^x \vDash \mathsf{st}^*_x(\psi) \vee \mathsf{st}^*_x(\theta) = \mathsf{st}^*_x(\psi \vee \theta)$.

  For the other direction, suppose $T^x \vDash \mathsf{st}^*_x(\psi \vee \theta) = \mathsf{st}^*_x(\psi) \vee \mathsf{st}^*_x(\theta)$ by the means of some subteams $S' \cup U' = T^x$ such that $S' \vDash \mathsf{st}^*_x(\psi)$ and $U' \vDash \mathsf{st}^*_x(\theta)$. As T^x has domain $\{x\}$, there are unique $S, U \subseteq T$ such that $S' = S^x$ and $U' = U^x$. By induction hypothesis, $S \vDash \psi$ and $U \vDash \theta$. In order to prove $T \vDash \psi \vee \theta$, it remains to show $T \subseteq S \cup U$. For this purpose, let $w \in T$. As then $w^x \in T^x$, as least one of $w^x \in S'$ or $w^x \in U'$ holds. But then $w \in S$ or $w \in U$.
- $\varphi = \Box\psi$: We define subteams S and U of the duplicating team $(T^x)^y_W$ as follows: S contains all "outgoing edges": $S := \{s \in (T^x)^y_W \mid s(y) \in Rs(x)\}$. On the other hand, U contains all "non-edges": $U := \{s \in (T^x)^y_W \mid s(y) \notin Rs(x)\}$. Then clearly $(T^x)^y_W = S \cup U$, $S \vDash Rxy$ and $U \vDash \neg Rxy$. Moreover, the above division of $(T^x)^y_W$ into S and U is the *only* possible splitting of $(T^x)^y_W$ such that $S \vDash Rxy$ and $U \vDash \neg Rxy$.
  By induction hypothesis, clearly $T \vDash \Box\psi \Leftrightarrow (RT)^y \vDash \mathsf{st}^*_y(\psi)$. Moreover, by the above argument, $T^x \vDash \mathsf{st}^*_x(\Box\psi) \Leftrightarrow S \vDash \mathsf{st}^*_y(\psi)$. Consequently, it suffices to show that $(RT)^y$ and S agree on $\mathsf{st}^*_y(\psi)$. This follows from Proposition 2.5, since

$$\begin{aligned}(RT)^y &= \{s\colon \{y\} \to W \mid \exists w \in T : s(y) \in Rw\}\\ &= \{s{\restriction}y \mid s \in (T^x)^y_W \text{ and } s(y) \in Rs(x)\} = S{\restriction}y.\end{aligned}$$

- $\varphi = \Diamond\psi$: Suppose $T \vDash \Diamond\psi$, i.e., $S \vDash \psi$ for some successor team S of T. By induction hypothesis, $S^y \vDash \mathsf{st}^*_y(\psi)$. In order to prove $T^x \vDash \exists y\, Rxy \wedge \mathsf{st}^*_y(\psi)$, we define a supplementing function $f : T^x \to \mathfrak{P}(W) \setminus \{\emptyset\}$ such that $(T^x)^y_f \vDash Rxy \wedge \mathsf{st}^*_y(\psi)$.
  Let $f(w^x) := Rw \cap S$. Then $f(w^x)$ is non-empty for each w, as S is a successor team. Moreover, $(T^x)^y_f \vDash Rxy$. It remains to show that $(T^x)^y_f \vDash \mathsf{st}^*_y(\psi)$ follows from $S^y \vDash \mathsf{st}^*_y(\psi)$. Here, we combine Proposition A.1 and 2.5, since

$$y\langle S^y\rangle = S = \bigcup_{w \in T} Rw \cap S = \bigcup_{w^x \in T^x} f(w^x) = \{s(y) \mid s \in (T^x)^y_f\} = y\langle (T^x)^y_f\rangle.$$

  For the other direction, suppose $T^x \vDash \exists y\, Rxy \wedge \mathsf{st}^*_y(\psi)$ by the means of a supplementing function $f : T^x \to \mathfrak{P}(W) \setminus \{\emptyset\}$ such that $(T^x)^y_f \vDash Rxy \wedge \mathsf{st}^*_y(\psi)$.
  We define $S := \bigcup_{w \in T} f(w^x)$, and first prove that it is a successor team of T, i.e., that every $v \in S$ has a predecessor in T and that every $w \in T$ has a successor in S.
  Let $v \in S$. Then there exists $w \in T$ such that $v \in f(w^x)$. As a consequence, the assignment s given by $s(x) = w$ and $s(y) = v$ is in $(T^x)^y_f$, and hence satisfies Rxy. In other words, v has a predecessor in T. Conversely, if $w \in T$, then $f(w^x)$ is non-empty, i.e., contains an element v. As before, v is a successor of w. Since $v \in f(w^x)$, $v \in S$, so w has a successor in S. By a similar argument as above, $y\langle (T^x)^y_f\rangle = S = y\langle S^y\rangle$, hence $S^y \vDash \mathsf{st}^*_y(\psi)$, and consequently $S \vDash \psi$ by induction hypothesis. ◀

6 Lower bounds

As a first application of the extended standard translation from the previous section, we prove several complexity theoretic lower bounds.

▶ **Lemma 6.1.** $\mathsf{MC}(\tau\text{-}\mathsf{FO}^1_0(\sim))$ *is* PSPACE*-hard if* τ *contains infinitely many predicates.*

Proof. We reduce from $\mathsf{MC}(\mathsf{PTL})$, which is PSPACE-hard by Theorem 5.1. The reduction maps $(\mathcal{K}, T, \varphi)$ to $(\mathcal{A}(\mathcal{K}), T^x, \mathsf{st}^*_x(\varphi))$. W.l.o.g. τ contains unary predicates $P_0, P_1, \ldots$; otherwise they are easily simulated by predicates of higher arity. It is now easy to see that $\mathsf{st}^*_x(\varphi)$ is quantifier-free and contains only the variable x. Moreover, by Theorem 5.6, $(\mathcal{K}, T) \models \varphi$ if and only if $(\mathcal{A}(\mathcal{K}), T^x) \models \mathsf{st}^*_x(\varphi)$. ◀

▶ **Lemma 6.2.** $\mathsf{MC}(\tau\text{-}\mathsf{FO}^\omega_\omega(\sim))$ *is* ATIME-ALT(exp, poly)*-hard for all vocabularies* τ*, even on sentences and for a fixed* τ*-structure* $\mathcal{A}$ *with domain* $\{0,1\}$ *and a fixed team* $\{\emptyset\}$*.*

Proof. Here, we reduce from $\mathsf{SAT}(\mathsf{PTL})$, which is ATIME-ALT(exp, poly)-hard by Theorem 5.2. Given $\varphi \in \mathsf{PTL}$, suppose $\mathsf{Prop}(\varphi) = \{p_1, \ldots, p_n\}$. The idea is that a team of worlds (and their Boolean assignments to $p_1, \ldots, p_n$), are simulated by a team of first-order assignments $s\colon X \to B$, where $X = \{z, x_1, \ldots, x_n\}$ and $B := \{0, 1\}$. Here, the variable z acts as the constant 1, while x_i simulates p_i. For each $b \in B$, define the team $V_b := (\{\emptyset\}^z_{\{b\}})^{x_1}_B \cdots ^{x_n}_B$. In other words, V_b is the n-fold supplemented team of $\{\emptyset\}^z_{\{b\}} = \{\{z \mapsto b\}\}$.

In the remaining proof, we distinguish two cases based on τ. By definition of a vocabulary, either $= \in \tau$, or τ contains a predicate. First, we consider the case $= \in \tau$. We reduce via the mapping $\varphi \mapsto (\mathcal{A}, \{\emptyset\}, \psi)$, where $\mathcal{A}$ is a fixed τ-structure with $\mathsf{dom}\,\mathcal{A} = B$, $\psi := \exists z \forall x_1 \cdots \forall x_n \top \vee \varphi^*$, and φ^* is obtained from φ by replacing each p_i by $x_i = z$. We prove that the reduction is correct, and begin with the following equivalence:

$$\exists U \subseteq V_1 : (\mathcal{A}, U) \models \varphi^* \quad \text{iff} \quad (\mathcal{A}, V_1) \models \top \vee \varphi^* \quad \text{iff} \quad (\mathcal{A}, \{\emptyset\}) \models \psi. \tag{1}$$

Here, "⇒" follows from the semantics of $\vee$ and the definition of ψ. For "⇐", suppose $(\mathcal{A}, \{\emptyset\}) \models \psi$. Then, again by definition of ψ, we have $(\mathcal{A}, U) \models \varphi^*$ for some $U \subseteq V_0 \cup V_1$. In particular, the variable z can take the values 0, 1 or both in U. However, for all $s \in U \cap V_0$, we can simply flip the ones and zeroes of s. This leaves the truth of any atomic formula $x_i = z$ unchanged, and by induction preserves the semantics of φ^*.

Next, we proceed with the correctness of the reduction. Assume that φ is satisfiable, i.e., has a model $(\mathcal{K}, T)$. For each world $w \in T$, define $s_w\colon X \to B$ by $s_w(z) = 1$ and $s_w(x_i) = 1 \Leftrightarrow (\mathcal{K}, w) \models p_i$. Then $(\mathcal{K}, w) \models p_i$ if and only if $(\mathcal{A}, s_w) \models x_i = z$. By induction on the syntax of φ, we obtain $(\mathcal{A}, U) \models \varphi^*$, where $U := \{s_w \mid w \in T\}$. As $U \subseteq V_1$, the equivalence (1) yields $(\mathcal{A}, \{\emptyset\}) \models \psi$. The other direction is similar.

Next, consider the case where $= \notin \tau$; then τ contains a predicate P. We define $\mathcal{A}$ as above, but let $P^{\mathcal{A}} := \{(1, \ldots, 1)\}$. Furthermore, $\psi := \forall x_1 \cdots \forall x_n \top \vee \varphi^*$, and φ^* is now as φ, with p_i replaced by $P(x_i, \ldots, x_i)$. The remaining proof is similar to the previous one. ◀

Clearly, the standard translation of satisfiable formulas is itself satisfiable. A converse result holds as well. Loosely speaking, from a first-order structure (and team) for $\mathsf{st}^*_x(\varphi)$ we can reconstruct a Kripke model (and team) for φ.

▶ **Lemma 6.3.** *If* $\varphi \in \mathsf{MTL}$*, then* φ *is satisfiable if and only if* $\mathsf{st}^*_x(\varphi)$ *is satisfiable.*

Proof. As Theorem 5.6 implies "⇒", we show "⇐". Suppose $(\mathcal{B}, S) \models \mathsf{st}^*_x(\varphi)$. Then $\mathcal{B}$ interprets the binary predicate R and unary predicates $P_1, P_2, \ldots$. By Proposition 2.5, w.l.o.g. S has domain $\{x\}$, i.e., $S = (x\langle S \rangle)^x$. Define now the Kripke structure $\mathcal{K} = (\mathsf{dom}\,\mathcal{B}, R^{\mathcal{B}}, V)$ such that $V(p_i) := P^{\mathcal{B}}_i$. Then clearly $\mathcal{A}(\mathcal{K}) = \mathcal{B}$. By Theorem 5.6, $(\mathcal{K}, x\langle S \rangle) \models \varphi$. ◀

Finally, with the above lower bounds, let us gather the completeness results for the satisfiability, validity and model checking problems.

▶ **Theorem 6.4.** *Let $\mathcal{D}$ be any p-uniform set of dependencies and τ any vocabulary.*

- $\mathsf{MC}(\tau\text{-}\mathsf{FO}^{\omega}_{\omega}(\sim, \mathcal{D}))$ *is* ATIME-ALT(exp, poly)*-complete, with hardness already on sentences and for a fixed τ-structure $\mathcal{A}$ with domain $\{0,1\}$ and a fixed team $\{\emptyset\}$.*
- *If τ contains infinitely many relations and at least one of $k \geq 0, n \geq 1$ is finite, then* $\mathsf{MC}(\tau\text{-}\mathsf{FO}^{n}_{k}(\sim, \mathcal{D}))$ *is* PSPACE*-complete.*

Proof. The upper bounds are due to Corollary 3.3 and 3.6, since alternating polynomial time coincides with PSPACE [7]. The lower bounds are due to Lemma 6.1 and 6.2. ◀

▶ **Corollary 6.5.** $\mathsf{MC}(\tau\text{-}\mathsf{SO})$ *is* ATIME-ALT(exp, poly)*-complete for all vocabularies τ, with hardness already on sentences and with a fixed τ-interpretation $\mathcal{A}$ with* $\mathsf{dom}\,\mathcal{A} = \{0,1\}$.

Proof. The upper bound is by Proposition 2.6. The lower bound is by the previous theorem and reduction from $\mathsf{MC}(\tau\text{-}\mathsf{FO}(\sim))$. Let R be a nullary predicate variable. In the spirit of Corollary 3.3, we map $(\mathcal{A}, \{\emptyset\}, \varphi)$ to $(\mathcal{A}, \emptyset, \exists R\, \eta^{\emptyset}_{\varphi}(R) \wedge R)$, where φ w.l.o.g. is a sentence. ◀

The next theorem settles the complexity of the satisfiability and validity problem of $\mathsf{FO}^2(\sim)$, and provides lower bounds for $\mathsf{FO}^1_0(\sim)$ and $\mathsf{FO}^2_k(\sim)$.

▶ **Theorem 6.6.** *Let τ contain at least one binary predicate, infinitely many unary predicates, and no functions. Then the problems* $\mathsf{SAT}(\tau\text{-}\mathsf{FO}^{n}_{k}(\sim))$ *and* $\mathsf{VAL}(\tau\text{-}\mathsf{FO}^{n}_{k}(\sim))$ *are*

- TOWER(poly)*-complete for $n = 2$ and $k = \omega$,*
- ATIME-ALT($\exp_{k+1}$, poly)*-hard for $n = 2$ and $0 \leq k < \omega$,*
- ATIME-ALT(exp, poly)*-hard for $n = 1$ and $0 \leq k < \omega$.*

Proof. The upper bound for $\tau\text{-}\mathsf{FO}^2(\sim)$ is by Corollary 4.3. For the lower bounds, the mapping $\varphi \mapsto \mathsf{st}^*_x(\varphi)$ is a reduction from $\mathsf{SAT}(\mathsf{MTL})$ resp. $\mathsf{SAT}(\mathsf{MTL}_k)$ (see Theorem 5.3 and Lemma 6.3). Finally, the validity cases follow since the logic is closed under negation. ◀

Let us contrast the above decidable cases with the following negative result, where a single unary dependence atom is added to the logic (cf. p. 4).

▶ **Theorem 6.7.** *There is a vocabulary τ such that* $\mathsf{SAT}(\mathcal{L})$ *is Π^0_1-hard and* $\mathsf{VAL}(\mathcal{L})$ *is Σ^0_1-hard, where $\mathcal{L} = \tau\text{-}\mathsf{FO}^2_2(\sim, \{\mathsf{dep}_1\})$.*

Proof. Kontinen et al. [24] showed that $\mathsf{VAL}(\mathsf{D}^2_2)$ is Σ^0_1-hard, and their reduction in fact uses only unary and binary dependence atoms. Moreover, the binary dependence atom $=\!(x, y)$ can equivalently be rewritten as $\sim(\top \vee (=\!(x) \wedge \sim=\!(y)))$, where $\top$ is an arbitrary tautology. Intuitively, this formula stipulates that every subteam constant in x is also constant in y. This concludes the reduction to $\mathsf{VAL}(\tau\text{-}\mathsf{FO}^2_2(\sim, \{\mathsf{dep}_1\}))$. Again, the proof for the satisfiability problem is analogous. ◀

7 Conclusion

In this paper, we proved that the logic $\mathsf{FO}^2(\sim)$ is complete for the class TOWER(poly) and hence decidable. In particular, it has the finite model property, but exhibits non-elementary succinctness compared to classical FO^2, which enjoys an exponential model property [19].

For $\mathsf{FO}^n_k(\sim, \mathcal{D})$, where $n \geq 1$ and $k \geq 0$, we proved a dichotomy regarding its model checking complexity: It is ATIME-ALT(exp, poly)-complete if $n = k = \omega$, and otherwise PSPACE-complete. This only requires that $\mathcal{D}$ is a p-uniformly FO-definable set of generalized

dependency atoms (cf. Definition 3.2), which covers first-order team logic TL as well as independence [17] and inclusion logic [10] augmented with Boolean negation.

We conclude with some open questions:

- Can the translation from $\mathsf{FO}^n_k(\sim, \mathcal{D})$ to $\mathsf{SO}[p]$ be inverted, i.e., can we translate every $\mathsf{SO}[p]$-formula to $\mathsf{FO}^n_k(\sim, \mathcal{D})$ for suitable n and k? This would be an interesting generalization of the translation from SO to TL given by Kontinen and Nurmi [25].
- What is the exact complexity of $\mathsf{SAT}(\mathsf{FO}^2_k(\sim))$? In the modal setting, every satisfiable MTL_k-formula has a $(k+1)$-fold exponential model. It would be interesting to learn whether the same holds for $\mathsf{FO}^2_k(\sim)$. Due to Corollary 3.6, a positive answer would immediately yield a tight ATIME-ALT$(\exp_{k+1}, \mathrm{poly})$ upper bound.
- It is a well-known fact that the standard translation of an ML-formula is in the two-variable guarded fragment GF^2. It is conceivable to consider a similar fragment $\mathsf{GF}^2(\sim)$ for the standard translation of MTL. Studying the corresponding fragments $\mathsf{GF}^2_k(\sim)$ of bounded quantifier rank could also be a first step towards finding the complexity of $\mathsf{FO}^2_k(\sim)$.

Algorithm 1: Decision procedure for MC(SO).

Algorithm: $\mathsf{check}(\alpha, \mathcal{A}, \mathcal{J})$ for $\alpha \in \tau\text{-SO}$ in negation normal form, a τ-structure $\mathcal{A}$, and a second-order interpretation $\mathcal{J}$ of $\mathsf{Fr}(\alpha)$.

if *α is an atomic formula or the negation of an atomic formula* **then**
  return `true` *if* $(\mathcal{A}, \mathcal{J}) \models \alpha$ *and* `false` *otherwise*;
else if $\alpha = \gamma_1 \vee \gamma_2$ **then** existentially choose $i \in \{1, 2\}$ and let $\alpha := \gamma_i$
else if $\alpha = \gamma_1 \wedge \gamma_2$ **then** universally choose $i \in \{1, 2\}$ and let $\alpha := \gamma_i$
else if $\alpha = \eth X \gamma$ *for* $\eth \in \{\exists, \forall\}$ *and* $X \in \mathsf{Var}(\alpha)$ **then**
  $\alpha := \gamma$
  if $X \in \mathsf{Fr}(\gamma)$ **then**
    if $\eth = \exists$ **then** switch to existential branching **else** switch to universal branching
    if *X is a first-order variable* **then**
      non-deterministically choose $a \in \mathcal{A}$ and let $\mathcal{J}(X) := a$
    else if *X is a function variable* **then**
      non-deterministically choose $F \colon \mathcal{A}^{\mathsf{arity}(X)} \to \mathcal{A}$ and let $\mathcal{J}(X) := F$
    else if *X is a relation variable* **then**
      non-deterministically choose $R \subseteq \mathcal{A}^{\mathsf{arity}(X)}$ and let $\mathcal{J}(X) := R$
return $\mathsf{check}(\alpha, \mathcal{A}, \mathcal{J}{\restriction}\mathsf{Fr}(\alpha))$

A Appendix

Proof of Proposition 2.6

▶ **Proposition 2.6.** MC(SO) *is decidable on input* $(\mathcal{A}, \mathcal{J}, \alpha)$ *in time* $2^{n^{\mathcal{O}(1)}}$ *and with* $|\alpha|$ *alternations.*

Proof. W.l.o.g., $\neg$ appears in α only in front of atomic formulas, and $\mathsf{dom}\,\mathcal{J} = \mathsf{Fr}(\alpha)$. Let $A := \mathsf{dom}\,\mathcal{A}$. We abbreviate

$$|\mathcal{J}| := \sum_{\substack{X \in \mathsf{dom}\,\mathcal{J} \\ X \text{ second-order}}} |\mathcal{J}(X)|,$$

i.e., the sum of the cardinalities of functions and relations in $\mathcal{J}$. Since for any second-order variable X it holds $|\mathcal{J}(X)| \leq |A|^{\mathsf{arity}(X)} \leq |A|^{|\alpha|}$, and furthermore $|\mathsf{dom}\,\mathcal{J}| = |\mathsf{Fr}(\alpha)| \leq |\alpha|$, the sum $|\mathcal{J}|$ is at most $|\alpha| \cdot |A|^{|\alpha|}$.

Now we run Algorithm 1. It performs at most $|\alpha|$ recursive calls, and clearly at most $|\alpha|$ alternations. Furthermore, the i-th recursive call is of the form $\mathsf{check}(\alpha_i, \mathcal{A}, \mathcal{J}_i)$ with $|\alpha_i| \leq |\alpha|$ and, by the same argument as before, $|\mathcal{J}_i| \leq |\alpha| \cdot |A|^{|\alpha|}$. For this reason, it is easy to see that the overall runtime is polynomial in $|\mathcal{J}|$ and $|A|^{|\alpha|}$, and consequently exponential in the input size. ◀

Proofs of Theorem 3.1 and 3.5

We require the next propositions in order to prove Theorem 3.1 and 3.5.

▶ **Proposition A.1.** *Let $\mathcal{A}$ be a structure, $\vec{t}$ a tuple of terms, and $X \supseteq \mathsf{Fr}(\vec{t})$. For $i \in \{1,2\}$, let T_i be a team in $\mathcal{A}$ with domain $X_i \supseteq X$. Then $T_1{\restriction}X = T_2{\restriction}X$ implies $\vec{t}\langle T_1\rangle = \vec{t}\langle T_2\rangle$. Furthermore, for any tuple $\vec{x} \subseteq X$ of variables, $\vec{x}\langle T_1\rangle = \vec{x}\langle T_2\rangle$ iff $T_1{\restriction}\vec{x} = T_2{\restriction}\vec{x}$.*

Proof. For the first part of the proposition, assume $T_1{\restriction}X = T_2{\restriction}X$. Exploiting symmetry, we only show that $\vec{t}\langle T_1\rangle \subseteq \vec{t}\langle T_2\rangle$. Hence, let $\vec{a} \in \vec{t}\langle T_1\rangle$ be arbitrary. Then $\vec{a} = \vec{t}\langle s\rangle$ for some $s \in T_1$. By assumption, there is $s' \in T_2$ such that $s{\restriction}X = s'{\restriction}X$. Since $\mathsf{Fr}(\vec{t}) \subseteq X$, clearly $\vec{t}\langle s\rangle = \vec{t}\langle s'\rangle$. Consequently, $\vec{a} \in \vec{t}\langle T_2\rangle$.

For the second part, suppose $\vec{x}\langle T_1\rangle = \vec{x}\langle T_2\rangle$ and let $s \in T_1{\restriction}\vec{x}$ be arbitrary. We show $s \in T_2{\restriction}\vec{x}$, which again suffices due to symmetry. Clearly, $s = s'{\restriction}\vec{x}$ for some $s' \in T_1$. Then $\vec{x}\langle s\rangle = \vec{x}\langle s'\rangle \in \vec{x}\langle T_1\rangle = \vec{x}\langle T_2\rangle$, and consequently, $\vec{x}\langle s\rangle \in \vec{x}\langle T_2\rangle$. But then $\vec{x}\langle s\rangle = \vec{x}\langle s''\rangle$ for some $s'' \in T_2$, which implies $s = s''{\restriction}\vec{x}$, and hence $s \in T_2{\restriction}\vec{x}$. ◀

▶ **Proposition A.2.** *Let $\mathcal{A}$ be a structure, $\vec{x}$ a tuple of variables, and $V := \{s\colon \vec{x} \to \mathcal{A}\}$. Then $\mathfrak{P}(V)$ is the set of all teams in $\mathcal{A}$ with domain $\vec{x}$, and the mapping $r\colon S \mapsto \vec{x}\langle S\rangle$ is an order isomorphism between $(\mathfrak{P}(V), \subseteq)$ and $(\mathfrak{P}((\mathsf{dom}\,\mathcal{A})^{|\vec{x}|}), \subseteq)$.*

Proof. Let $n := |\vec{x}|$. Clearly, every team with domain $\vec{x}$ is in $\mathfrak{P}(V)$. It is easy to show that r is surjective: Given $A \subseteq (\mathsf{dom}\,\mathcal{A})^n$, define the team $S := \{s \in V \mid \vec{x}\langle s\rangle \in A\}$. Then $r(S) = \vec{x}\langle S\rangle = \{\vec{x}\langle s\rangle \mid s \in V \text{ and } \vec{x}\langle s\rangle \in A\} = A$.

Moreover, r preserves $\subseteq$ in both directions: Suppose $S \subseteq S'$ and let $\vec{a} = (a_1, \dots, a_n) \in r(S)$ be arbitrary. We show $\vec{a} \in r(S')$, which proves $r(S) \subseteq r(S')$. Since $\vec{a} \in r(S) = \vec{x}\langle S\rangle$, there exists $s \in S$ such that $\vec{x}\langle s\rangle = \vec{a}$. By assumption, $s \in S'$. Consequently, $\vec{a} \in \vec{x}\langle S'\rangle = r(S')$.

Conversely, suppose $r(S) \subseteq r(S')$ and let $s \in S$ be arbitrary. As $\vec{x}\langle s\rangle \in r(S) \subseteq r(S') = \vec{x}\langle S'\rangle$, there exists an assignment $s' \in S'$ such that $\vec{x}\langle s\rangle = \vec{x}\langle s'\rangle$. However, as $\mathsf{dom}\,s = \mathsf{dom}\,s' = \vec{x}$, necessarily $s = s'$, i.e., $s \in S'$. As $S \subseteq S' \Leftrightarrow r(S) \subseteq r(S')$, and r is surjective, we conclude that r is also injective and hence an order isomorphism. ◀

As an alternative definition of supplementing functions, Galliani [11] coined the term *x-variations*, which are teams that "agree" on all variables but x:

▶ **Proposition A.3.** *Let T be a team with domain X and S a team with domain $X \cup \{x\}$ (with possibly $x \in X$), and let $X' := X \setminus \{x\}$. Then $S{\restriction}X' = T{\restriction}X'$ if and only if there is a supplementing function f such that $S = T^x_f$.*

Proof. Let $\mathcal{A}$ be the underlying structure.

"⇒": Suppose $S{\restriction}X' = T{\restriction}X'$. First, we show that for every $s' \in S$ there is $s \in T$ such that $s' = s^x_a$ for some a. By assumption, $s'{\restriction}X' = s{\restriction}X'$ for some $s \in T$. But then $s' = s^x_{s'(x)}$. We define the function $f(s) := \{\, a \in \mathcal{A} \mid s^x_a \in S \,\}$, and prove that it is a supplementing function of T. Here, it suffices to show that $f(s) \neq \emptyset$ for all $s \in T$, i.e., that for every $s \in T$ there exists $a \in \mathcal{A}$ such that $s^x_a \in S$. This follows again by $S{\restriction}X' = T{\restriction}X'$. Moreover, $T^x_f = \{s^x_a \mid s \in T, a \in f(s)\} = \{s^x_a \mid s \in T, s^x_a \in S\}$, which equals S by the above argument.

"⇐": First, we show "⊆", i.e., that $s \in T{\restriction}X'$ for arbitrary $s \in S{\restriction}X'$. By definition, for such s we have $s = s'{\restriction}X'$ for some $s' \in S$. Since $S = T^x_f$, there exists $s'' \in T$ and $a \in \mathcal{A}$ such that $s' = (s'')^x_a$. As $x \notin X'$, we have $s = s'{\restriction}X' = s''{\restriction}X' \in T{\restriction}X'$, as desired.

For the other direction, "⊇", let $s \in T{\restriction}X'$ be arbitrary. Then $s = s'{\restriction}X'$ for some $s' \in T$. As $S = T^x_f$, there exists some $s'' \in S$ and $a \in \mathcal{A}$ such that $s'' = (s')^x_a$. Again we have $s = s'{\restriction}X' = s''{\restriction}X'$, i.e., $s \in S{\restriction}X'$. ◀

▶ **Lemma A.4.** *Let T have domain $\vec{x}$ and S have domain $\vec{x} \cup \{y\}$ (with possibly $y \in X$), and let $X' := \vec{x} \setminus \{y\}$. Then $T{\restriction}X' = S{\restriction}X'$ if and only if $\mathcal{A} \vDash \pi(\vec{x}\langle T\rangle, \vec{x};y\langle S\rangle)$, where $\pi(T,S) := \forall\vec{x}((\exists y T\vec{x}) \leftrightarrow (\exists y S\vec{x};y))$.*

Proof. First, let us consider the case $y \notin X$, i.e., $X' = X$. Then:

$$\begin{aligned}
&T{\restriction}X' = S{\restriction}X' \\
\Leftrightarrow\ &\vec{x}\langle T\rangle = \vec{x}\langle S\rangle && \text{(by Proposition A.1)} \\
\Leftrightarrow\ &\forall \vec{a} : (\vec{a} \in \vec{x}\langle T\rangle \Leftrightarrow \exists b : (\vec{a}, b) \in (\vec{x}; y)\langle S\rangle) && \text{(since } T \text{ has domain } \vec{x}) \\
\Leftrightarrow\ &\mathcal{A} \vDash \pi(\vec{x}\langle T\rangle, \vec{x};y\langle S\rangle) && \text{(since } \exists y T\vec{x} \equiv T\vec{x})
\end{aligned}$$

Next, assume $y \in X$ and w.l.o.g. $y = x_n$. Then $\vec{x};y = \vec{x}$ and $X' = \{x_1, \dots, x_{n-1}\}$. Let $\vec{x}' = (x_1, \dots, x_{n-1})$. Analogously as before, we have:

$$\begin{aligned}
&T{\restriction}X' = S{\restriction}X' \\
\Leftrightarrow\ &\vec{x}'\langle T\rangle = \vec{x}'\langle S\rangle \\
\Leftrightarrow\ &\forall \vec{a} : \big((\exists b : (\vec{a}, b) \in \vec{x}\langle T\rangle) \Leftrightarrow (\exists b : (\vec{a}, b) \in \vec{x};y\langle S\rangle)\big) \\
\Leftrightarrow\ &\mathcal{A} \vDash \pi(\vec{x}\langle T\rangle, \vec{x};y\langle S\rangle)
\end{aligned}$$

◀

▶ **Theorem 3.1.** *Let $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$, let $\vec{x} \supseteq \mathsf{Fr}(\varphi)$ be a tuple of variables, and T be a team in $\mathcal{A}$ with domain $Y \supseteq \vec{x}$. Then $(\mathcal{A}, T) \vDash \varphi$ if and only if $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(\vec{x}\langle T\rangle)$.*

Proof. Note that $(\mathcal{A}, T) \vDash \varphi \Leftrightarrow (\mathcal{A}, T{\restriction}\vec{x}) \vDash \varphi$ by Proposition 2.5, and $\vec{x}\langle T\rangle = \vec{x}\langle T{\restriction}\vec{x}\rangle$. For this reason, we can assume that T has domain $\vec{x}$. The proof is now by induction on φ.

- If φ is first-order, clearly $(\mathcal{A}, T) \vDash \varphi$ iff $\mathcal{A} \vDash \varphi(\vec{a})$ for all $\vec{a} \in \vec{x}\langle T\rangle$ iff $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(\vec{x}\langle T\rangle)$.
- If $\varphi = A_i(\vec{t})$ and $\delta_i \in \mathcal{D}$ is a k-ary dependency, then $(\mathcal{A}, T) \vDash A_i(\vec{t})$ iff $\mathcal{A} \vDash \delta_i(\vec{t}\langle T\rangle)$. We prove that this is again equivalent to $\mathcal{A} \vDash \exists S\, \rho(\vec{x}\langle T\rangle, S) \wedge \delta_i(S)$, where $\rho(R, S) := \forall \vec{z}\,(S\vec{z} \leftrightarrow (\exists \vec{x}\, R\vec{x} \wedge \vec{t} = \vec{z}))$.
  It suffices to show that $\mathcal{A} \vDash \rho(\vec{x}\langle T\rangle, S)$ if and only if $S = \vec{t}\langle T\rangle$. As it is straightforward that $\mathcal{A} \vDash \rho(\vec{x}\langle T\rangle, \vec{t}\langle T\rangle)$ holds, let us focus on the direction from left to right. Recall that $\vec{x} \cap \{z_1, \dots, z_k\} = \emptyset$ and that the z_i are pairwise distinct. On that account, suppose $\mathcal{A} \vDash \rho(\vec{x}\langle T\rangle, S)$ and $\vec{a} = (a_1, \dots, a_k) \in \mathcal{A}^k$. By definition of the formula, $\vec{a} \in S$ iff $\mathcal{A} \vDash \exists \vec{x}\, R\vec{x} \wedge \vec{t} = \vec{a}$. However, this is the case iff $\vec{t}\langle s\rangle = \vec{a}$ for some $s \in T$, i.e., $\vec{a} \in \vec{t}\langle T\rangle$.
- The cases $\varphi = {\sim}\psi$ and $\varphi = \psi \wedge \theta$ immediately follow by induction hypothesis.
- If $\varphi = \psi \vee \theta$, then by induction hypothesis, $(\mathcal{A}, T) \vDash \varphi$ iff there are $S, U \subseteq T$ such that $T = S \cup U$ and $\mathcal{A} \vDash \eta_\psi^{\vec{x}}(\vec{x}\langle S\rangle) \wedge \eta_\theta^{\vec{x}}(\vec{x}\langle U\rangle)$. Let $R := \vec{x}\langle T\rangle$.
  Then due to Proposition A.2, the above is equivalent to the existence of $P, Q \subseteq \mathcal{A}^n$ such that $R = P \cup Q$ and $\mathcal{A} \vDash \eta_\psi^{\vec{x}}(P) \wedge \eta_\theta^{\vec{x}}(Q)$, and consequently to $\mathcal{A} \vDash \exists S \exists U \forall \vec{x}(R\vec{x} \leftrightarrow (S\vec{x} \vee U\vec{x})) \wedge \eta_\psi^{\vec{x}}(S) \wedge \eta_\theta^{\vec{x}}(U)$.
- If $\varphi = \exists y\, \psi$, by Proposition A.3, then $(\mathcal{A}, T) \vDash \varphi$ iff $(\mathcal{A}, S) \vDash \psi$ for some team S with domain $\vec{x} \cup \{y\}$ such that $T{\restriction}X' = S{\restriction}X'$, where $X' := \vec{x} \setminus \{y\}$. By Lemma A.4 and by induction hypothesis, this is the case iff $(\mathcal{A}, \vec{x}\langle T\rangle) \vDash \exists S \forall \vec{x}((\exists y R\vec{x}) \leftrightarrow (\exists y S\vec{x}; y)) \wedge \eta_\psi^{\vec{x};y}(S)$.
- The case $\varphi = \forall y\, \psi$ is proven analogously to $\exists$. The additional clause $(R\vec{x} \to \forall y\, S\vec{x};y)$ ensures that the supplementing function is constant and $f(s) = \mathsf{dom}\,\mathcal{A}$. ◀

▶ **Theorem 3.5.** *Let $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$, let $\vec{x} \supseteq \mathsf{Fr}(\varphi)$ be a tuple of variables, and T be a team in $\mathcal{A}$ with domain $Y \supseteq \vec{x}$. If $p(n) \geq |T| \cdot n^{\mathsf{qr}(\varphi)}$ or $p(n) \geq n^{\mathsf{w}(\varphi)}$, then $(\mathcal{A}, T) \vDash \varphi$ if and only if $\mathcal{A} \vDash \zeta_\varphi^{\vec{x},p}(\vec{x}\langle T\rangle)$.*

Proof for $p(n) \geq |T| \cdot n^{\mathsf{qr}(\varphi)}$. Assume $\mathcal{A}$, T as above, let $m := \mathsf{qr}(\varphi)$ and $p(n) \geq n^m$. The idea is to show that $\eta_\varphi^{\vec{x}}$ and $\zeta_\varphi^{\vec{x},p}$ agree on $(\mathcal{A}, \mathcal{J})$ for all "sufficiently sparse" $\mathcal{J}$ (cf. Theorem 3.1). Formally, let $\ell \leq m$ and let $(\mathcal{A}, \mathcal{J})$ be a second-order interpretation such that

$|\mathcal{J}(R)| \leq |T| \cdot |\mathcal{A}|^\ell$ for all relations $R \in \mathsf{dom}\,\mathcal{J}$. Then we prove for all $\varphi \in \mathsf{FO}(\sim, \mathcal{D})$ with $\mathsf{qr}(\varphi) \leq m - \ell$ and $\vec{x} \supseteq \mathsf{Fr}(\varphi)$ that $(\mathcal{A}, \mathcal{J}) \vDash \eta_\varphi^{\vec{x}}$ if and only if $(\mathcal{A}, \mathcal{J}) \vDash \zeta_\varphi^{\vec{x},p}$. For $\ell = 0$, this yields the theorem, since $|\vec{x}\langle T\rangle| \leq |T| \cdot |\mathcal{A}|^0$.

The proof is by induction on φ. We distinguish the following cases.

- If $\varphi \in \mathsf{FO}$, then there is nothing to prove, as $\eta_\varphi^{\vec{x}} = \zeta_\varphi^{\vec{x},p}$.
- If $\varphi = \sim\psi$ or $\varphi = \psi \wedge \theta$, then the inductive step is clear.
- If $\varphi = A_i\vec{t}$ for some k-ary $\delta_i \in \mathcal{D}$, then $\zeta_\varphi^{\vec{x},p}(R) = \exists^p S\, \rho(R,S)$ and $\eta_\varphi^{\vec{x}}(R) = \exists S\, \rho(R,S)$, where

$$\rho(R,S) = \forall \vec{z}\,(S\vec{z} \leftrightarrow (\exists \vec{x}\, R\vec{x} \wedge \vec{t} = \vec{z}\,)) \wedge \delta_i(S).$$

  We show that $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(R)$ implies $\mathcal{A} \vDash \zeta^{\vec{x},p}(R)$, as the other direction is trivial.
  On that account, suppose $\mathcal{A} \vDash \rho(R,S)$ for some $S \subseteq \mathcal{A}^k$. We prove that necessarily $|S| \leq |R|$ by constructing some injective $f\colon S \to R$. Then $\mathcal{A} \vDash \exists^p S\, \rho(R,S)$, as by assumption, $|S| \leq |R| \leq |T| \cdot |\mathcal{A}|^\ell \leq |T| \cdot |\mathcal{A}|^m \leq p(|\mathcal{A}|)$.
  We define f as follows. For every $\vec{a} \in S$, let $f(\vec{a})$ be some $\vec{b} \in R$ such that $\vec{t}\langle\{\vec{x} \mapsto \vec{b}\}\rangle = \vec{a}$. By $\rho(R,S)$, such $\vec{b}$ must exist. Clearly, f is injective.
- If $\varphi = \psi \vee \theta$, then $\zeta_\varphi^{\vec{x},p}(R) = \exists^p S\, \exists^p U\, \rho$ and $\eta_\varphi^{\vec{x}}(R) = \exists S\, \exists U\, \rho'$, where

$$\rho(R,S,U) = \forall\vec{x}(R\vec{x} \leftrightarrow (S\vec{x} \vee U\vec{x})) \wedge \zeta_\psi^{\vec{x},p}(S) \wedge \zeta_\theta^{\vec{x},p}(U),$$
$$\rho'(R,S,U) = \forall\vec{x}(R\vec{x} \leftrightarrow (S\vec{x} \vee U\vec{x})) \wedge \eta_\psi^{\vec{x}}(S) \wedge \eta_\theta^{\vec{x}}(U).$$

  Suppose $|R| \leq |T| \cdot |\mathcal{A}|^\ell$ and $\mathsf{qr}(\varphi) \leq m - \ell$. Clearly $\mathsf{qr}(\psi), \mathsf{qr}(\theta) \leq \mathsf{qr}(\varphi)$.
  Let $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(R)$, i.e., $\mathcal{A} \vDash \rho'(R,S,U)$ for some $S, U \subseteq \mathcal{A}^{|\vec{x}|}$.
  It is easy to see that ρ' forces $|S|, |U| \leq |R|$. Since $|R| \leq |T| \cdot |\mathcal{A}|^\ell$ by assumption, we can apply the induction hypothesis to $\eta_\psi^{\vec{x}}(S)$ and $\eta_\theta^{\vec{x}}(U)$ and derive $\mathcal{A} \vDash \rho(R,S,U)$ from $\mathcal{A} \vDash \rho'(R,S,U)$. Since in particular $|S|, |U| \leq p(|\mathcal{A}|)$, we conclude $\mathcal{A} \vDash \zeta_\varphi^{\vec{x},p}(R)$. The other direction is trivial due to the inductivion hypothesis, since $\rho(R,S)$ entails $\rho'(R,S)$.
- If $\varphi = \exists y\, \psi$, then $\zeta_\varphi^{\vec{x},p}(R) = \exists^p S\, \rho(R,S)$ and $\eta_\varphi^{\vec{x}}(R) = \exists S\, \rho'(R,S)$, where

$$\rho(R,S) = \forall\vec{x}((\exists y R\vec{x}) \leftrightarrow (\exists y\, S\vec{x};y)) \wedge \zeta_\psi^{\vec{x};y,p}(S),$$
$$\rho'(R,S) = \forall\vec{x}((\exists y R\vec{x}) \leftrightarrow (\exists y\, S\vec{x};y)) \wedge \eta_\psi^{\vec{x};y}(S).$$

  Suppose $|R| \leq |T| \cdot |\mathcal{A}|^\ell$ and $\mathsf{qr}(\varphi) \leq m - \ell$. We show that $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(R)$ implies $\mathcal{A} \vDash \zeta_\varphi^{\vec{x},p}(R)$. The other direction is then again similar.
  Assuming $\mathcal{A} \vDash \eta_\varphi^{\vec{x}}(R)$, there exists $S \subseteq \mathcal{A}^{|\vec{x};y|}$ such that $\mathcal{A} \vDash \rho'(R,S)$. As a first step, we erase unnecessary elements from S. Note that S occurs in ρ' only in atomic formulas $S\vec{x};y$, i.e., with a fixed argument tuple $\vec{x};y$. Let $(v_1, \ldots, v_r) := \vec{x};y$. If now $v_i = v_j$ for some $1 \leq i < j \leq r$, then every tuple $(a_1, \ldots, a_r)$ with $a_i \neq a_j$ can be safely deleted from S. Formally, if $S^* := \vec{x};y\langle V\rangle \cap S$, where $V = \{s\colon \vec{x} \cup \{y\} \to \mathcal{A}\}$ is the full team with domain $\vec{x} \cup \{y\}$, then $\mathcal{A} \vDash \rho'(R,S)$ if and only if $\mathcal{A} \vDash \rho'(R,S^*)$, which can be shown by straightforward induction.
  Note that $\mathsf{qr}(\psi) = \mathsf{qr}(\varphi) - 1 \leq m - (\ell+1)$. Consequently, to apply the induction hypothesis, we prove $|S^*| \leq |R| \cdot |\mathcal{A}| \leq |T| \cdot |\mathcal{A}|^{\ell+1}$ by presenting some injective $f\colon S^* \to R \times \mathcal{A}$.
  If $y \notin \vec{x}$, let f be the identity, as ρ' ensures that $(\vec{a}, b) \in S^*$ implies $\vec{a} \in R$. However, if $y \in \vec{x}$, then we define $f(\vec{a})$ as follows. By construction, $\vec{a} \in S^*$ equals $\vec{x}\langle s\rangle$ for some $s\colon \vec{x} \to \mathcal{A}$. Again by ρ', there is $\hat{s}\colon \vec{x} \to \mathcal{A}$ such that $\vec{x}\langle\hat{s}\rangle \in R$ and $s = \hat{s}^y_{s(y)}$. Let now $f(\vec{a}) := (\vec{x}\langle\hat{s}\rangle, s(y))$. Then f is injective.

Hence, by induction hypothesis, we can replace $\eta^{\vec{x}}_{\varphi}$ by $\zeta^{\vec{x},p}_{\varphi}$ and obtain $\mathcal{A} \vDash \rho(R, S^*)$. Since $|S^*| \leq |\mathcal{A}|^{\ell+1} \leq p(|\mathcal{A}|)$, we obtain $\mathcal{A} \vDash \exists^p S\, \rho(R, S)$.

- The case $\varphi = \forall y\, \psi$ is proven similarly to $\varphi = \exists y\, \psi$. ◀

Proof for $p(n) \geq n^{\mathsf{w}(\varphi)}$. We can apply the same argument as in the $\exists$-case of the previous proof. Suppose S is a second-order variable. Then S appears in $\eta^{\vec{x}}_{\varphi}$ only in atomic formulas of the form $S\vec{t}$ for a fixed $\vec{t}$. Accordingly, it suffices to let $\exists S$ range over subsets of $\vec{t}\langle V\rangle$, where $\vec{y} := \mathsf{Var}(\vec{t})$ and $V := \{s \colon \vec{y} \to \mathcal{A}\}$.

(We consider terms $\vec{t}$ instead of only variables to account for the translations of dependencies, where S can have terms as arguments.)

Since $\vec{y}$ contains at most $\mathsf{w}(\varphi)$ distinct variables, $|V| \leq |\mathcal{A}|^{\mathsf{w}(\varphi)} \leq p(|\mathcal{A}|)$. Consequently, every second-order quantifier $\exists S$ can be replaced by $\exists^p S$, which implies $\mathcal{A} \vDash \eta^{\vec{x}}_{\varphi}(\vec{x}\langle T\rangle) \Leftrightarrow \mathcal{A} \vDash \zeta^{\vec{x},p}_{\varphi}(\vec{x}\langle T\rangle)$. ◀

Proof of Lemma 4.1

▶ **Lemma A.5.** *The following laws hold for* $\mathsf{FO}(\sim)$*:*

$$\alpha \wedge \bigwedge_{i=1}^{n} \mathsf{E}\beta_i \equiv \bigvee_{i=1}^{n} (\alpha \wedge \mathsf{E}\beta_i) \tag{2}$$

$$\bigvee_{i=1}^{n} (\alpha_i \wedge \mathsf{E}\beta_i) \equiv \left(\bigvee_{i=1}^{n} \alpha_i\right) \wedge \bigwedge_{i=1}^{n} \mathsf{E}(\alpha_i \wedge \beta_i) \tag{3}$$

$$(\vartheta_1 \owedge \vartheta_2) \vee \vartheta_3 \equiv (\vartheta_1 \vee \vartheta_3) \owedge (\vartheta_2 \vee \vartheta_3) \tag{4}$$

$$\vartheta_1 \vee (\vartheta_2 \owedge \vartheta_3) \equiv (\vartheta_1 \vee \vartheta_2) \owedge (\vartheta_1 \vee \vartheta_3) \tag{5}$$

$$\exists x\, (\vartheta_1 \owedge \vartheta_2) \equiv (\exists x\, \vartheta_1) \owedge (\exists x\, \vartheta_2) \tag{6}$$

$$\exists x\, (\vartheta_1 \vee \vartheta_2) \equiv (\exists x\, \vartheta_1) \vee (\exists x\, \vartheta_2) \tag{7}$$

$$\exists x\, (\alpha \wedge \mathsf{E}\beta) \equiv (\exists x\, \alpha) \wedge \mathsf{E}\, \exists x\, (\alpha \wedge \beta) \tag{8}$$

$$\forall x\, (\vartheta_1 \wedge \vartheta_2) \equiv (\forall x\, \vartheta_1) \wedge (\forall x\, \vartheta_2) \tag{9}$$

$$\forall x \sim\vartheta \equiv \sim\forall x\, \vartheta \tag{10}$$

Proof. For (2), (3) and (7), see Lück [29, Lemma 4.13, 4.14 and D.1], respectively. For (4)–(6), see Galliani [13, Proposition 5]. For (9)–(10), see Väänänen [38, Chapter 8].

For (8), the direction "$\vDash$" is clear, as $\alpha \wedge \mathsf{E}\beta$ implies both α and $\mathsf{E}(\alpha \wedge \beta)$. For the converse direction, suppose $(\mathcal{A}, T) \vDash \exists x \alpha$ and $(\mathcal{A}, \hat{s}) \vDash \exists x(\alpha \wedge \beta)$ for some $\hat{s} \in T$. Then there are $f \colon T \to \mathfrak{P}(\mathcal{A}) \setminus \{\emptyset\}$ and $b \in \mathcal{A}$ such that $(\mathcal{A}, T^x_f) \vDash \alpha$ and $(\mathcal{A}, \hat{s}^x_b) \vDash \alpha \wedge \beta$. Define $g(\hat{s}) = f(\hat{s}) \cup \{b\}$ and $g(s) = f(s)$ for $s \in T \setminus \{\hat{s}\}$. Then $T^x_g = T^x_f \cup \{s^x_b\}$. Consequently, $(\mathcal{A}, T^x_g) \vDash \alpha \wedge \mathsf{E}\beta$, hence $(\mathcal{A}, T) \vDash \exists x\, (\alpha \wedge \mathsf{E}\beta)$. ◀

▶ **Lemma 4.1.** *Every τ-$\mathsf{FO}^n_k(\sim)$-formula φ is equivalent to a formula of the form*

$$\psi := \bigovee_{i=1}^{n} \left(\alpha_i \wedge \bigwedge_{j=1}^{m_i} \mathsf{E}\beta_{i,j} \right)$$

such that $\{\alpha_1, \ldots, \alpha_n, \beta_{1,1}, \ldots, \beta_{n,m_n}\} \subseteq \tau$-$\mathsf{FO}^n_k$ *and* $|\psi| \leq \exp_{\mathcal{O}(|\varphi|)}(1)$.

In what follows, *disjunctive normal form* (DNF) refers to formulas in the above form.

Proof. We construct the formula ψ by induction on φ. In each inductive step, it grows at most exponentially.

- If φ is a Boolean combination of FO_k^n-formulas (i.e., over $\sim$ and $\wedge$), then we obtain a DNF of size $\leq |\varphi| \cdot 2^{|\varphi|}$ similarly as for ordinary propositional logic.
- If $\varphi = \vartheta_1 \vee \vartheta_2$ for ϑ_1, ϑ_2 in DNF, then

$$\begin{aligned}
\varphi &= \bigovee_{i=1}^{n} \left(\alpha_i \wedge \bigwedge_{j=1}^{m_i} \mathsf{E}\beta_{i,j}\right) \vee \bigovee_{i=1}^{k} \left(\gamma_i \wedge \bigwedge_{j=1}^{\ell_i} \mathsf{E}\delta_{i,j}\right) \\
&\equiv \bigovee_{i=1}^{n} \bigvee_{j=1}^{m_i} (\alpha_i \wedge \mathsf{E}\beta_{i,j}) \vee \bigovee_{i=1}^{k} \bigvee_{j=1}^{\ell_i} (\gamma_i \wedge \mathsf{E}\delta_{i,j}) && \text{(Lemma A.5, (2))} \\
&\equiv \bigovee_{\substack{1\leq i_1 \leq n \\ 1 \leq i_2 \leq k}} \bigvee_{j=1}^{m_{i_1}} (\alpha_{i_1} \wedge \mathsf{E}\beta_{i_1,j}) \vee \bigvee_{j=1}^{\ell_{i_2}} (\gamma_{i_2} \wedge \mathsf{E}\delta_{i_2,j}) && \text{(Lemma A.5, (4) and (5))} \\
&\equiv \bigovee_{i=1}^{n\cdot k} \bigvee_{j=1}^{o_i} (\mu_{i,j} \wedge \mathsf{E}\nu_{i,j}) && \text{(for some } \mu_{i,j}, \nu_{i,j} \in \mathsf{FO}_k^n\text{)} \\
&\equiv \bigovee_{i=1}^{n\cdot k} \Big(\bigvee_{j=1}^{o_i} \mu_{i,j}\Big) \wedge \bigwedge_{j=1}^{o_i} \mathsf{E}(\mu_{i,j} \wedge \nu_{i,j}), && \text{(Lemma A.5, (3))}
\end{aligned}$$

where the final DNF has size polynomial in $|\vartheta_1| + |\vartheta_2| \leq |\varphi|$.
- If $\varphi = \exists x\, \vartheta$ for ϑ in DNF, then

$$\begin{aligned}
\varphi &\equiv \exists x \bigovee_{i=1}^{n} \bigvee_{j=1}^{m_i} (\alpha_i \wedge \mathsf{E}\beta_{i,j}) && \text{(Lemma A.5, (2))} \\
&\equiv \bigovee_{i=1}^{n} \bigvee_{j=1}^{m_i} \exists x\, (\alpha_i \wedge \mathsf{E}\beta_{i,j}) && \text{(Lemma A.5, (6) and (7))} \\
&\equiv \bigovee_{i=1}^{n} \bigvee_{j=1}^{m_i} \Big((\exists x\, \alpha_i) \wedge \mathsf{E}\exists x\, (\alpha_i \wedge \beta_{i,j})\Big) && \text{(Lemma A.5, (8))} \\
&\equiv \bigovee_{i=1}^{n} \Big(\bigvee_{j=1}^{m_i} \exists x\, \alpha_i\Big) \wedge \bigwedge_{j=1}^{m_i} \mathsf{E}\exists x\, (\alpha_i \wedge \beta_{i,j})), && \text{(Lemma A.5, (3))}
\end{aligned}$$

which is again a DNF of polynomial size.
- Finally, the $\forall$ case is by repeated application of (9) and (10) of Lemma A.5. ◀

A Tight Analysis of the Parallel Undecided-State Dynamics with Two Colors

Abstract

The *Undecided-State Dynamics* is a well-known protocol for distributed consensus. We analyze it in the parallel $\mathcal{PULL}$ communication model on the complete graph with n nodes for the *binary* case (every node can either support one of *two* possible colors, or be in the undecided state).

An interesting open question is whether this dynamics is an efficient *Self-Stabilizing* protocol, namely, starting from an arbitrary initial configuration, it reaches consensus *quickly* (i.e., within a polylogarithmic number of rounds). Previous work in this setting only considers initial color configurations with no undecided nodes and a large *bias* (i.e., $\Theta(n)$) towards the majority color.

In this paper we present an *unconditional* analysis of the Undecided-State Dynamics that answers to the above question in the affirmative. We prove that, starting from *any* initial configuration, the process reaches a monochromatic configuration within $\mathcal{O}(\log n)$ rounds, with high probability. This bound turns out to be tight. Our analysis also shows that, if the initial configuration has bias $\Omega(\sqrt{n \log n})$, then the dynamics converges toward the initial majority color, with high probability.

1 Introduction

Simple local mechanisms for *Consensus* problems in distributed systems recently received a lot of attention [2, 1, 18, 19, 28, 31]. In one of the basic versions of the consensus problem the system consists of anonymous entities (*nodes*) each one initially supporting a *color* out of a finite set of colors Σ. Nodes run elementary operations and interact by exchanging messages. A *Consensus Protocol* is a local procedure that makes the system converge to a *monochromatic* configuration, where all nodes support the same color. Consensus has to be *valid*, i.e., the "winning" color must be one of those initially supported by at least one node. A crucial property of a consensus protocol is *self-stabilization* [6, 18, 30]: Informally, if the system is "perturbed" by some external event and moved to an arbitrary configuration, then the protocol must bring the system back to a valid consensus and, moreover, once the system reaches consensus, it must remain in that configuration forever, unless a further external event takes place[2]. Self-stabilizing consensus processes are fundamental building-blocks that play an important role in coordination tasks and self-organizing behavior in population systems [11, 13, 19, 29].

We study the consensus problem in the $\mathcal{PULL}$ *communication model* [12, 17, 24] where, at every round, each active node of a communication network contacts one neighbor uniformly at random to pull information. A natural consensus protocol in this model is the *Undecided-State Dynamics*[3] (for short, the *U-Dynamics*) in which the state of a node can be either a color or the *undecided state*. When a node is activated, it pulls the state of a random neighbor and updates its state according to the following updating rule (see Table 1): If a colored node pulls a different color from its current one, then it becomes undecided, while in all other cases it keeps its color; moreover, if the node is in the undecided state then it will take the state of the pulled neighbor.

The U-Dynamics has been previously studied in both *sequential* [2] and *parallel* [4] models: Informally, in the former only one random node is activated at every round and it updates its state according to the local rule, while in the latter all nodes are activated at every round and they update their state, synchronously.

As for the sequential model[4], [2] provides an unconditional analysis showing (among other results) that the U-Dynamics is a self-stabilizing protocol for *binary* consensus (i.e., when $|\Sigma| = 2$) in the complete graph with n nodes. They show the convergence time is $\mathcal{O}(n \log n)$ (and, thus, work per node is $\mathcal{O}(\log n)$), *with high probability*[5]. This result also clarifies the algorithmic interest for this process. Indeed, the U-Dynamics can be seen as a variant of the popular *Voter Model* [9, 23, 26] where every active node simply takes the color it pulls at every round. On one hand, the Voter Model uses minimal number of node states (i.e. $|\Sigma|$) and takes $\Theta(n)$ work per node to reach consensus (see for instance [25]). On the other hand, the U-Dynamics exponentially improves the work complexity by using one additional state, only. Further motivations on the U-Dynamics are discussed in Subsection 1.2.

We remark that the stochastic process induced by the parallel dynamics significantly departs from the one induced by the sequential dynamics. As a simple evidence of such qualitative differences, observe that, starting from a configuration with no undecided nodes,

---

[2] Notice that, according to previous work [6, 18], we require self-stabilization to hold *with high probability*.

[3] In some previous papers [31] on the binary case ($|\Sigma| = 2$), this protocol has been also called the *Third-State Dynamics*. We here prefer the term "undecided" since it also holds for the non-binary case and, moreover, the term well captures the role of this additional state.

[4] [2] in fact considers the *Population-Protocol* model which is, in our specific context, equivalent to the sequential $\mathcal{PULL}$ model.

[5] As usual, we say that an event $\mathcal{E}_n$ holds *w.h.p.* if $\mathbf{P}(\mathcal{E}_n) \geqslant 1 - n^{-\Theta(1)}$.

in the parallel case the system might end up in the *non-valid*, monochromatic configuration where all nodes are undecided (this would happen if, for example, at the first round every node pulled a node with the other color). On the other hand, it is easy to see that in the sequential case the process always ends up in a monochromatic configuration with no undecided nodes, unless it starts from a configuration with all nodes undecided. The crucial difference lies in the random number of nodes that may change color at every round: In the sequential model, this is at most one[6], while in the parallel one, *all* nodes may change state in one round and, for most phases of the process, the expected number of changes is indeed linear in n. The above difference is one of the main reasons why no general techniques are currently available to extend any quantitative analysis for the sequential process to the corresponding parallel one (and vice versa). In particular, the analysis in [2] strongly uses the fact that only one node can change state in one round in order to derive a suitable supermartingale argument to bound the stopping time of the process. It thus fully covers the case of sequential interaction models, but it is not helpful to understand the evolution of the U-Dynamics process on any interaction model in which the number of nodes that may change state in one round is not bounded by some absolute constant.

As for the parallel $\mathcal{PULL}$ model, while it is easy to verify that the U-Dynamics achieves consensus in the complete graph (with high probability), the convergence time of this dynamics is still an interesting open issue, even in the binary case. Indeed, in [4] the authors analyze the U-Dynamics in the parallel $\mathcal{PULL}$ model on the complete graph for any number $k = o(n^{1/3})$ of colors. However, their analysis requires the initial configuration to have a relatively-large *bias* $s = c_1 - c_2$ between the size c_1 of the (unique) initial plurality and the size c_2 of the second-largest color. More in details, in [4] it is assumed that $c_1 \geqslant \alpha c_2$, for some absolute constant $\alpha > 1$ and, thus, this condition for the binary case would result into requiring a very-large initial bias, i.e., $s = \Theta(n)$. This analysis clearly does not show that the U-Dynamics efficiently solves the binary consensus problem, mainly because it does not manage *balanced* initial configurations.

1.1 Our results

We prove that, starting from any color configuration[7] on the complete graph, the U-Dynamics reaches a monochromatic configuration (thus consensus) within $\mathcal{O}(\log n)$ rounds, with high probability. This bound is tight since, for some (in fact, a large number of) initial configurations, the process requires $\Omega(\log n)$ rounds to converge.

Not assuming a large initial bias of the majority color significantly complicates the analysis. Indeed, the major technical issues arise from the analysis of *balanced* initial configurations where the system "needs" to *break symmetry* without having a strong expected drift towards any color. Previous analysis of this phase consider either *sequential* processes of interacting particles that can be modeled as *birth-and-death* chains [2] or parallel processes whose local rule is fully symmetric w.r.t. the states/colors of the nodes (such as majority rules) [6, 18]. The U-Dynamics process falls neither in the former nor in the latter scenario: It works in parallel rounds and the role of the undecided nodes makes the local rule not symmetric. We believe this issue has a *per-se* scientific interest since symmetry-breaking phenomena yielded by simple and local mechanisms plays a central role in key aspects of population systems [10] and, more generally, in the emerging field of natural algorithms [13].

[6] This number actually becomes 2 if the sequential communication model activates a random edge per round, rather than one single node [2].

[7] Our analysis also considers initial configurations with undecided nodes.

Informally speaking, in Section 4 we deal with almost-balanced starting configurations. By devising a coupling to a "simplified" pruned process, we show that the analysis of this *symmetry-breaking* phase essentially reduces to the analysis of a specific regime where the number q of undecided nodes remains a suitable constant fraction of n *until* the magnitude of the bias s reaches $\Omega(\sqrt{n \log n})$: In other words, during this regime, with very high probability the system never jumps to almost-balanced configurations having either too many or too few undecided nodes. This fact is crucial for two main reasons: Along this regime, (i) the *variance* of the bias s is large (i.e. $\Theta(n)$) and (ii) whenever the bias s is $\Omega(\sqrt{n})$, its drift turns out to be *exponential* with non-negligible, increasing probability (w.r.t. s itself). Then, we prove a variant of a general Lemma [18] that provides a logarithmic bound on the hitting time of Markov chains satisfying Properties (i) and (ii) above.

The symmetry-breaking phase terminates when the U-Process reaches some configuration having a bias $s = \Omega(\sqrt{n \log n})$. Then we prove that, starting from *any* configuration having that bias, the process reaches consensus within $\mathcal{O}(\log n)$ rounds, with high probability. Even though our analysis of this "majority" part of the process is based on standard concentration arguments, it must cope with some *non-monotone* behavior of the key random variables (such as the bias and the number of undecided nodes at the next round): Again, this is due to the non-symmetric role played by the undecided nodes. A good intuition about this "non-monotone" process can be gained by looking at the mutually-related formulas giving the expectation of such key random variables (see Equations (1)-(3)). Our refined analysis shows that, during this majority phase, the winning color never changes and, thus, the U-Dynamics also ensures Plurality Consensus in logarithmic time whenever the initial bias is $s = \Omega(\sqrt{n \log n})$.

Interestingly enough, we also show that configurations with $s = \mathcal{O}(\sqrt{n})$ exist so that the system may converge toward the minority color with non-negligible probability.

1.2 Further motivation and related work

On the U-Dynamics. The interest in the U-Dynamics arises in fields beyond the borders of Computer Science and it seems to have a key-role in important biological processes modeled as so-called chemical reaction networks [11, 19]. For such reasons, the convergence time of this dynamics has been analyzed on different communication models [2, 3, 4, 27, 31]. As previously mentioned, the U-Dynamics has been analyzed in the parallel $\mathcal{PULL}$ model in [4] and their results concern the evolution of the process for the multi-color case when there is a significant initial bias (as a protocol for plurality consensus).

As for the sequential model, the U-Dynamics has been introduced and analyzed in [2] on the complete graph. They prove that this dynamics, with high probability, converges to a valid consensus within $\mathcal{O}(n \log n)$ activations and, moreover, it converges to the majority whenever the initial bias is $\omega\left(\sqrt{n \log n}\right)$.

Still concerning the sequential model, [27] recently analyzes, besides other protocols, the U-Dynamics in arbitrary graphs where in the initial configuration each node samples uniformly at random one out of two colors. In this (average-case) setting, they prove that the system converges to the initial majority color with higher probability than the initial minority one. They also give results for special classes of graphs where the minority can win with large probability if the initial configuration is chosen in a suitable way. Their proof for this result relies on an exponentially-small upper bound on the probability that a certain minority can win in the complete graph (see [27] for more details). In [3, 7, 20, 31], the same dynamics for the binary case has been analyzed in other sequential communication models.

On some other consensus dynamics. Recently, further simple consensus protocols have been deeply analyzed in several papers, thus witnessing the high interest of the scientific community on such processes [2, 5, 9, 11, 15, 16, 18, 31].

The parallel 3-Majority is a protocol where at every round, each node picks the colors of three random neighbors and updates its color according to the majority rule (taking the first one or a random one to break ties). The authors of [5] assume that the bias is $\Omega(\min\{\sqrt{2k}, (n/\log n)^{1/6}\} \cdot \sqrt{n \log n})$. Under this assumption, they prove that consensus is reached with high probability in $\mathcal{O}(\min\{k, (n/\log n)^{1/3}\} \cdot \log n)$ rounds, and that this is tight if $k \leqslant (n/\log n)^{1/4}$. The first result without bias [6] restricts the number of initial colors to $k = \mathcal{O}(n^{1/3})$. Under this assumption, they prove that 3-Majority reaches consensus with high probability in $\mathcal{O}((k^2(\log n)^{1/2} + k \log n) \cdot (k + \log n))$ rounds. Very recently, such result has been generalized to the whole range of k in [8].

In [18] the authors provide an analysis of the *3-median* rule, in which every node updates its value to the median of its current value and the values of two randomly chosen neighbors. They show that this dynamics converges to an almost-agreement configuration (which is even a good approximation of the global median) within $\mathcal{O}(\log k \cdot \log\log n + \log n)$ rounds, w.h.p. It turns out that, in the binary case, the median rule is equivalent to the 2-Choices dynamics, a variant of 3-Majority, thus their result implies that this is a stabilizing consensus protocol with $\mathcal{O}(\log n)$ convergence time. As mentioned earlier, our analysis borrows a hitting-time bound on general Markov chains from [18].

Very recently, [22] provides an optimal bound $\Theta(k \log n)$ for the 2-Choices dynamics on the complete graph even under some dynamic adversary. In [15, 16], the authors consider the 2-Choices dynamics for plurality consensus in the binary case (i.e. $k = 2$). For random d-regular graphs, [15] proves that all nodes agree on the majority color in $\mathcal{O}(\log n)$ rounds, provided that the bias is $\omega(n \cdot \sqrt{1/d + d/n})$. The same holds for arbitrary d-regular graphs if the bias is $\Omega(\lambda_2 \cdot n)$, where λ_2 is the second largest eigenvalue of the transition matrix. In [16], these results are extended to general expander graphs.

1.3 Structure of the paper

In Section 2, we provide some preliminaries and an informal description of the expected evolution of the U-Process. In Section 3, we formally state the main results of this paper and describe an outline of the corresponding proofs. Section 4 is devoted to the description of the tight analysis of the symmetry-breaking phase. The analysis of the "majority" phase of the process is given in Section 5. Conclusions and some open questions are discussed in Section 6. Due to lack of space, all the omitted proofs can be found in the full-version of the paper [14].

2 Preliminaries

We analyze the parallel version of the dynamics called U-Dynamics in the (uniform) $\mathcal{PULL}$ model on the complete graph: Starting from an initial configuration where every node supports a color, i.e. a value from a set Σ of k possible colors[8], at every round, each node u pulls the color of a randomly-selected neighbor v. If the color of node v differs from its own color, then node u enters in an *undecided* state (an extra state with no color). When a

[8] W.l.o.g. we can define $\Sigma = [k]$ where $[k] = \{1, 2, \cdots, k\}$.

Table 1 The update rule of the U-Dynamics where $i, j \in [k]$ and $i \neq j$.

$u \backslash v$	undecided	color i	color j
undecided	undecided	i	j
i	i	i	undecided
j	j	undecided	j

node is in the undecided state and pulls a color, it gets that color. Finally, a node that pulls either an undecided node or a node with its own color remains in its current state.

In this paper we consider the case in which there are two possible colors (say color `Alpha` and color `Beta`). Let us name $\mathcal{C}$ the space of all possible configurations and observe that, since the graph is complete, a configuration $\mathbf{x} \in \mathcal{C}$ is uniquely determined by fixing the number of `Alpha`-colored nodes and the number of `Beta`-colored ones, say $a(\mathbf{x})$ and $b(\mathbf{x})$, respectively.

It is convenient to give names also to two other quantities that will appear often in the analysis: The number $q(\mathbf{x}) = n - a(\mathbf{x}) - b(\mathbf{x})$ of undecided nodes and the difference $s(\mathbf{x}) = a(\mathbf{x}) - b(\mathbf{x})$ called the *bias* of $\mathbf{x}$. Notice that any two of the quantities $a(\mathbf{x}), b(\mathbf{x}), q(\mathbf{x})$, and $s(\mathbf{x})$ uniquely determine the configuration. When it will be clear from the context, we will omit $\mathbf{x}$ and write a, b, q, and s instead of $a(\mathbf{x}), b(\mathbf{x}), q(\mathbf{x})$, and $s(\mathbf{x})$.

Observe that the U-Dynamics defines a finite-state Markov chain $\{\mathbf{X}_t\}_{t \geqslant 0}$ with state space $\mathcal{C}$ and three absorbing states, namely, $q = n$, $a = n$, and $b = n$. We call *U-Process* the random process obtained by applying the U-Dynamics starting at a given state. Once we fix the configuration $\mathbf{x}$ at round t of the process, i.e. $\mathbf{X}_t = \mathbf{x}$, we use the capital letters A, B, Q, and S to refer to the random variables $a(\mathbf{X}_{t+1}), b(\mathbf{X}_{t+1}), q(\mathbf{X}_{t+1})$, $s(\mathbf{X}_{t+1})$.

From the definition of U-Dynamics it is easy to calculate the following expected values (see also Section 3 in [4]):

$$\mathbf{E}\left[A \mid \mathbf{X}_t = \mathbf{x}\right] = a\left(\frac{a+2q}{n}\right), \tag{1}$$

$$\mathbf{E}\left[Q \mid \mathbf{X}_t = \mathbf{x}\right] = \frac{q^2+2ab}{n}, \tag{2}$$

$$\mathbf{E}\left[S \mid \mathbf{X}_t = \mathbf{x}\right] = \frac{a(a+2q)}{n} - \frac{b(b+2q)}{n} = s\left(1+\frac{q}{n}\right). \tag{3}$$

2.1 The expected evolution of the U-Process

Equations (1)-(3) can be used to have a preliminary intuitive idea on the expected evolution of the U-Process. From (3) it follows that the bias s increases exponentially, in expectation, as long as the number q of undecided nodes is a constant fraction of n (say, $q \geqslant \delta n$, for some positive constant δ). By rewriting (2) in terms of q and s we have that

$$\mathbf{E}\left[Q \mid \mathbf{X}_t = \mathbf{x}\right] = \frac{q^2+2ab}{n} = \frac{2q^2+(n-q)^2-s^2}{2n} \geqslant \frac{n}{3} - \frac{s^2}{2n}, \tag{4}$$

where in the inequality we used the fact that the minimum of $2q^2 + (n-q)^2$ is achieved at $q = \frac{n}{3}$ and its value is $\frac{2}{3}n^2$. From (4) it thus follows that, as long as the magnitude of the bias is smaller than a constant fraction of n (say $s < \frac{2}{3}n$), the expected number of undecided nodes will be larger than a constant fraction of n at the next round (say, $\mathbf{E}\left[Q \mid \mathbf{X}_t = \mathbf{x}\right] \geqslant \frac{n}{9}$).

When the magnitude of the bias s reaches $\frac{2}{3}n$, it is easy to see that the expected number of nodes with the *minority* color decreases exponentially. Indeed, suppose w.l.o.g. that `Beta`

is the minority color and rewrite (1) for B and in terms of b and s. We get

$$\mathbf{E}\left[B \mid \mathbf{X}_t = \mathbf{x}\right] = b\left(\frac{b+2q}{n}\right) = b\left(1 - \frac{2s+3b-n}{n}\right). \tag{5}$$

Hence, when $s > \frac{2}{3}n$ we have that $\mathbf{E}\left[B \mid \mathbf{X}_t = \mathbf{x}\right] \leqslant \frac{2}{3}b$.

The above sketch of the analysis *in expectation* would suggest that the process should end up in a monochromatic configuration within $\mathcal{O}(\log n)$ rounds. Indeed, in Theorem 2 we prove that this is what happens with high probability (w.h.p., from now on) when the process starts from a configuration that already has some bias, namely $s = \Omega(\sqrt{n \log n})$.

When the process starts from a configuration with a smaller bias, the analysis *in expectation* looses its predictive power. As an extreme example, observe that when $a = b = \frac{n}{3}$ the system is "in equilibrium" according to (1)-(3). However, the equilibrium is "unstable" and the symmetry is broken by the *variance* of the process (as long as $s = o(\sqrt{n})$) and by the increasing drift towards majority (as soon as $s > \sqrt{n}$). As mentioned in the Introduction, the analysis of this *symmetry-breaking* phase is the key technical contribution of the paper and it will be described in Section 4. This analysis will show that, starting from any initial configuration, the system reaches a configuration where the magnitude of the bias is $\Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds, w.h.p.

3 Main results and the digraph of the U-Process' phases

As informally discussed in the introduction, we prove the two following results characterizing the evolution of the U-Dynamics on the synchronous $\mathcal{PULL}$ model in the complete graph.

▶ **Theorem 1** (Consensus). *Let the U-Process start from any configuration in $\mathcal{C}$. Then the process converges to a (valid) monochromatic configuration within $\mathcal{O}(\log n)$ rounds, w.h.p. Furthermore, if the initial configuration has at least one colored node (i.e. $q \leqslant n-1$), then the process converges to a configuration such that $|s| = n$, w.h.p.*

▶ **Theorem 2** (Plurality consensus). *Let γ be any positive constant. Assume that the U-Process starts at any biased configuration such that $|s| \geqslant \gamma\sqrt{n \log n}$ and assume w.l.o.g. the majority color is* `Alpha`*. Then the process converges to the monochromatic configuration with $a = n$ within $\mathcal{O}(\log n)$ rounds, w.h.p. Furthermore, the result is almost tight in a twofold sense: (i) An initial configuration exists, with $|s| = \Omega(\sqrt{n \log n})$, such that the process requires $\Omega(\log n)$ rounds to converge w.h.p. and (ii) there is an initial configuration with $|s| = \Theta(\sqrt{n})$ such that the process converges to the minority color with constant probability.*

Outline of the two proofs. The two theorems above are consequences of our refined analysis[9] of the evolution of the U-Process. The analysis is organized into a set of possible process phases, each of them is defined by specific ranges of parameters q and s. A high-level description of this structure is shown in Fig. 1 where every rectangular region represents a subset of configurations with specific ranges of s and q and it is associated to a specific phase. In details, let γ be any positive constant, then the regions are defined as follows: H_1 is the set of configurations such that $s \leqslant \gamma\sqrt{n \log n}$ and $q \geqslant \frac{1}{2}n$; H_2 is the set of configurations

[9] We remark that our analysis focuses on asymptotic bounds and it does not definitely optimize the corresponding constants: However, using technicalities and loosing readability, all such constants can be largely improved.

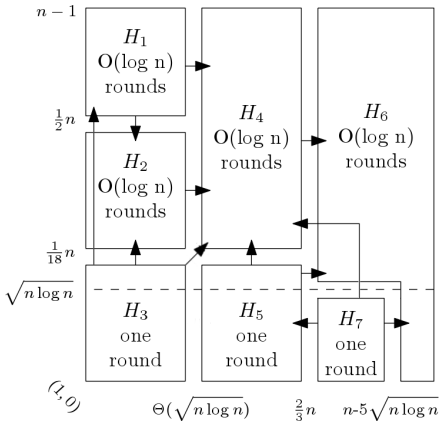

Figure 1 $\{H_1, \ldots, H_7\}$ is the considered partitioning of the configuration space $\mathcal{C}$. On the x axis we represent the bias s, on the y axis the number of undecided nodes q. Missing arrows are transitions that have negligible probabilities.

such that $s \leqslant \gamma\sqrt{n\log n}$ and $\frac{1}{18}n \leqslant q \leqslant \frac{1}{2}n$; H_3 is the set of configurations such that $s \leqslant \gamma\sqrt{n\log n}$ and $q \leqslant \frac{1}{18}n$. H_4 is the set of configurations such that $\gamma\sqrt{n\log n} \leqslant s \leqslant \frac{2}{3}n$ and $q \geqslant \frac{1}{18}n$; H_5 is the set of configurations such that $\gamma\sqrt{n\log n} \leqslant s \leqslant \frac{2}{3}n$ and $q \leqslant \frac{1}{18}n$; H_7 is the set of configurations such that $\frac{2}{3}n \leqslant s \leqslant n - 5\sqrt{n\log n}$ and $q \leqslant \sqrt{n\log n}$. H_6 is the set of configurations such that $s \geqslant \frac{2}{3}n$ minus H_7.

For each region, Fig. 1 specifies our upper bound on the exit time of the corresponding phase, while black arrows represent the phase transitions which may happen with non-negligible probability.

Observe that the scheme highlighted in Fig. 1 can be seen as a directed acyclic graph G having a single sink, H_6, that is reachable from any other region. We remark that, starting from certain configurations, a monochromatic state may be reached via different paths in G. This departs from previous analysis of consensus processes [4, 5, 18] in which the phase transition graph is essentially a path.

We now outline the proofs of the two main results of this paper.

Outline of the Proof of Theorem 2. Consider an initial configuration $\mathbf{x}$ such that $s(\mathbf{x}) \geqslant \gamma\sqrt{n\log n}$, for some positive constant γ, and assume w.l.o.g. that the majority color in $\mathbf{x}$ is `Alpha`. We first show that, if the initial configuration $\mathbf{x}$ is in H_4, then the bias grows exponentially fast and thus the process enters in H_6 within $\mathcal{O}(\log n)$ rounds. Then we prove that, once in H_6, the process ends in the monochromatic configuration where $a = n$ within $\mathcal{O}(\log n)$ rounds, w.h.p. All the other cases "reduce" to the above ones in at most two rounds. Indeed, we show that, starting from any configuration in H_5, the process falls into H_4 or H_6 in one round and that, starting from any configuration in H_7, the process falls into H_4, H_5 or H_6 in one round. As for the tightness of the result stated in the second part of the theorem, we have that the lower bound (Claim (i)) on the convergence time is an immediate consequence of Claim (ii) of Lemma 12, while the second claim, concerning the lower bound on the initial bias, is proved in the full version of the paper [14].

Outline of the Proof of Theorem 1. We first observe that the configuration where all nodes are undecided (i.e. $q = n$) is an absorbing state of the U-Process and thus, for this initial configuration, Theorem 1 trivially holds. In Section 4, we will show that, starting from any *balanced* configuration, i.e. with $s = o(\sqrt{n\log n})$, the U-Process "breaks symmetry"

reaching a configuration $\mathbf{y}$ with $s(\mathbf{y}) = \Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds, w.h.p. Then, the thesis easily follows by applying Theorem 2 with initial configuration $\mathbf{y}$. As for the symmetry-breaking phase, in Lemma 3 we prove that, if the process starts from a configuration in H_1 or H_3 (see Figure 1), then after $\mathcal{O}(\log n)$ rounds either the bias between the two colors becomes $\Omega(\sqrt{n \log n})$ or the system reaches some configuration in H_2, w.h.p. In Lemma 8 we then prove that, if the process is in a configuration in H_2, then the bias s will become $\Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds, w.h.p.

4 Symmetry breaking

In this section we show that, starting from any (almost-) balanced configuration, i.e. those with $s = o(\sqrt{n \log n})$, the U-Process "breaks symmetry" reaching a configuration with $s = \Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds, w.h.p. This part of our analysis is organized as follows.

In Lemma 3 we prove that, if the process starts at a configuration in H_1 or H_3 (see Figure 1), i.e., when the number of undecided nodes is either smaller than $n/18$ or larger than $n/2$, then, after $\mathcal{O}(\log n)$ rounds, either the bias between the two colors already gets magnitude $\Omega(\sqrt{n \log n})$ or the system reaches some configuration in H_2 (i.e., a configuration where the number of undecided nodes is between $n/18$ and $n/2$). In Lemma 8 we then prove that, if the process is in a configuration in H_2, then the bias between the two colors will get magnitude $\Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds, w.h.p.

▶ **Lemma 3** (Phases H_1 and H_3: Starters)**.**

- *Starting from any configuration $\boldsymbol{x} \in H_3$, the U-Process reaches a configuration $\boldsymbol{X}' \in (H_1 \cup H_2 \cup H_4)$ in one round, w.h.p.*
- *Starting from any configuration $\boldsymbol{x} \in H_1$, the U-Process reaches a configuration $\boldsymbol{X}' \in (H_2 \cup H_4)$ within $\mathcal{O}(\log n)$ rounds, w.h.p.*

If the system lies in a configuration of H_2, we need more complex probabilistic arguments to prove that the bias between the two colors reaches $\Omega(\sqrt{n \log n})$ within $\mathcal{O}(\log n)$ rounds w.h.p. We will make use of the following bound on the hitting time of any Markov chain having suitable drift properties. This result is a variant of Claim 2.9 in [18] that requires a new proof.

▶ **Lemma 4.** *Let $\{X_t\}_{t \in \mathbb{N}}$ be a Markov Chain with finite state space Ω and let $f : \Omega \mapsto [0, n]$ be a function that maps states to integer values. Let c_3 be any positive constant and let $m = c_3 \sqrt{n} \log n$ be a target value. Assume the following properties hold:*

1. *For any positive constant h, a positive constant $c_1 < 1$ exists such that, for any $x \in \Omega$ with $f(x) < m$, it holds that*

$$\mathbf{P}\left(f(X_{t+1}) < h\sqrt{n} | X_t = x\right) < c_1\,,$$

2. *Two positive constants ε, c_2 exist such that, for any $x \in \Omega$ with $f(x) < m$, it holds that*

$$\mathbf{P}\left(f(X_{t+1}) < (1+\varepsilon) f(X_t) | X_t = x\right) < e^{-c_2 f(x)^2/n}\,.$$

Then the process reaches a state x such that $f(x) \geqslant m$ within $\mathcal{O}(\log n)$ rounds, w.h.p.

Proof. We first define a set of hitting times $T = \{\tau(i)\}_{i \in \mathbb{N}}$ where

$$\tau(i) = \inf_{t \in \mathbb{N}} \{t : t > \tau(i-1), f(X_t) \geqslant h\sqrt{n}\}$$

setting $\tau(0) = 0$. By Hypothesis (1), for every $i \in \mathbb{N}$, the expectation of $\tau(i)$ is finite. Then we define the following stochastic process which is a subsequence of $\{X_t\}_{t\in\mathbb{N}}$: $\{R_i\}_{i\in\mathbb{N}} = \{X_{\tau(i)}\}_{i\in\mathbb{N}}$. Observe that $\{R_i\}_{i\in\mathbb{N}}$ is still a Markov Chain. Indeed, let $\{x_1, \dots, x_{i-1}\}$ a set of states in Ω:

$$
\begin{aligned}
&\mathbf{P}\left(R_i = x | R_{i-1} = x_{i-1} \wedge \cdots \wedge R_1 = x_1\right) \\
&= \mathbf{P}\left(X_{\tau(i)} = x | X_{\tau(i-1)} = x_{i-1} \wedge \cdots \wedge X_{\tau(1)} = x_1\right) \\
&= \sum_{t(i)\wedge\cdots\wedge t(0)\in\mathbb{N}} \mathbf{P}\left(X_{t(i)} = x | X_{t(i-1)} = x_{i-1} \wedge \cdots \wedge X_{t(1)} = x_1\right) \\
&\quad \cdot \mathbf{P}\left(\tau(i) = t(i) \wedge \tau(i-1) = t(i-1) \wedge \cdots \wedge \tau(1) = t(1)\right) \\
&= \sum_{t(i)\wedge\cdots\wedge t(0)\in\mathbb{N}} \mathbf{P}\left(X_{t(i)} = x | X_{t(i-1)} = x_{i-1}\right) \\
&\quad \cdot \mathbf{P}\left(\tau(i) = t(i) \wedge \tau(i-1) = t(i-1) \wedge \cdots \wedge \tau(1) = t(1)\right) \\
&= \mathbf{P}\left(X_{\tau(i)} = x | X_{\tau(i-1)} = x_{i-1}\right) = \mathbf{P}\left(R_i = x | R_{i-1} = x_{i-1}\right).
\end{aligned}
$$

By definition the state space of R is $\{x \in \Omega : f(x) \geqslant h\sqrt{n}\}$. Moreover Hypothesis (2) still holds for this new Markov Chain. Indeed:

$$
\begin{aligned}
&\mathbf{P}\left(f(R_{i+1}) < (1+\varepsilon) f(R_i) | R_i = x\right) \\
&= 1 - \mathbf{P}\left(f(R_{i+1}) \geqslant (1+\varepsilon) f(R_i) | R_i = x\right) \\
&= 1 - \mathbf{P}\left(f(X_{\tau(i+1)}) \geqslant (1+\varepsilon) f(X_{\tau(i)}) | X_{\tau(i)} = x\right) \\
&\leqslant 1 - \mathbf{P}\left(f(X_{\tau(i+1)}) \geqslant (1+\varepsilon) f(X_{\tau(i)}) \wedge \tau(i+1) = \tau(i) + 1 | X_{\tau(i)} = x\right) \\
&= 1 - \mathbf{P}\left(f(X_{\tau(i)+1}) \geqslant (1+\varepsilon) f(X_{\tau(i)}) | X_{\tau(i)} = x\right) \\
&= 1 - \mathbf{P}\left(f(X_{t+1} \geqslant (1+\varepsilon) f(X_t) | X_t = x\right) < e^{-c_2 f(x)^2/n}.
\end{aligned}
$$

These two properties are sufficient to study the number of rounds required by the new Markov Chain $\{R_i\}_{i\in\mathbb{N}}$ to reach the target value m. Indeed, by defining the random variable $Z_i = \frac{f(R_i)}{\sqrt{n}}$ and considering the following "potential" function, $Y_i = \exp(\frac{m}{\sqrt{n}} - Z_i)$ we can compute its expectation at the next round as follows. Let us fix any state $x \in \Omega$ such that $h\sqrt{n} \leqslant f(x) < m$ and define $z = \frac{f(x)}{\sqrt{n}}$ and $y = \exp(\frac{m}{\sqrt{n}} - z)$. We get:

$$
\begin{aligned}
\mathbf{E}\left[Y_{i+1} | R_i = x\right] &\leqslant \mathbf{P}\left(f(R_{i+1}) < (1+\varepsilon) f(x)\right) e^{m/\sqrt{n}} \\
&\quad + \mathbf{P}\left(f(R_{i+1}) \geqslant (1+\varepsilon) f(x)\right) e^{m/\sqrt{n} - (1+\varepsilon)z} \\
\text{(from Hypothesis (2))} \quad &\leqslant e^{-c_2 z^2} \cdot e^{m/\sqrt{n}} + 1 \cdot e^{m/\sqrt{n} - (1+\varepsilon)z} \qquad (6) \\
&= e^{m/\sqrt{n} - c_2 z^2} + e^{m/\sqrt{n} - z - \varepsilon z} \\
&= e^{m/\sqrt{n} - z}(e^{z - c_2 z^2} + e^{-\varepsilon z}) \leqslant e^{m/\sqrt{n} - z}(e^{-2} + e^{-2}) \qquad (7) \\
&< \frac{e^{m/\sqrt{n} - z}}{e} < \frac{y}{e},
\end{aligned}
$$

where in (7) we used that z is always at least h and thanks to Hypothesis (1) we can choose a sufficiently large h. By applying the Markov inequality and iterating the above bound, we get:

$$
\mathbf{P}\left(Y_i > 1\right) \leqslant \frac{\mathbf{E}\left[Y_i\right]}{1} \leqslant \frac{\mathbf{E}\left[Y_{i-1}\right]}{e} \leqslant \cdots \leqslant \frac{\mathbf{E}\left[Y_0\right]}{e^{\tau_R}} \leqslant \frac{e^{m/\sqrt{n}}}{e^i}.
$$

We observe that if $Y_i \leqslant 1$ then $R_i \geqslant m$, thus by setting $i = m/\sqrt{n} + \log n = (c_3+1)\log n$, we get:

$$\mathbf{P}\left(R_{(c_3+1)\log n} < m\right) = \mathbf{P}\left(Y_{(c_3+1)\log n} > 1\right) < \frac{1}{n}. \tag{8}$$

Our next goal is to give an upper bound on the hitting time $\tau_{(c_3+1)\log n}$. Note that the event "$\tau_{(c_3+1)\log n} > c_4 \log n$" holds if and only if the number of rounds such that $f(X_t) \geqslant h\sqrt{n}$ (before round $c_4 \log n$) is less than $(c_3+1)\log n$. Thanks to Hypothesis (1), at each round t there is at least probability $1 - c_1$ that $f(X_t) \geqslant h\sqrt{n}$. This implies that, for any positive constant c_4, the probability $\mathbf{P}\left(\tau_{(c_3+1)\log n} > c_4 \log n\right)$ is bounded by the probability that, within $c_4 \log n$ independent Bernoulli trials, we get less than $(c_3+1)\log n$ successes, where the success probability is at least $1 - c_1$. We can thus choose a sufficiently large c_4 and apply the multiplicative form of the Chernoff bound (see e.g. Theorem 1.1 in[21]) and obtain:

$$\mathbf{P}\left(\tau_{(c_3+1)\log n} > c_4 \log n\right) < \frac{1}{n}. \tag{9}$$

We are now ready to prove the Lemma using (8) and (9), indeed:

$$\begin{aligned}
\mathbf{P}\left(\exists t \leqslant c_4 \log n : X_t \geqslant m\right) &> \mathbf{P}\left(R_{(c_3+1)\log n} \geqslant m \wedge \tau_{(c_3+1)\log n} \leqslant c_4 \log n\right) \\
&= 1 - \mathbf{P}\left(R_{(c_3+1)\log n} < m \vee \tau_{(c_3+1)\log n} > c_4 \log n\right) \\
&\geqslant 1 - \mathbf{P}\left(R_{(c_3+1)\log n} < m\right) - \mathbf{P}\left(\tau_{(c_3+1)\log n} > c_4 \log n\right) \\
&> 1 - \frac{2}{n}.
\end{aligned}$$

Hence, choosing a suitable big c_4, we have shown that in $c_4 \log n$ rounds the process reaches the target value m, w.h.p. ◀

The basic idea would be to apply the above lemma to the U-Process with $f(X_t) = |s(X_t)|$ in order to get an upper bound on the number of rounds needed to reach a configuration having bias $\Omega(\sqrt{n \log n})$. To this aim, we first show that, for any configuration in H_2, Properties 1 and 2 in Lemma 4 are satisfied.

▶ **Claim 5.** *Let $\boldsymbol{x} \in \mathcal{C}$ be any configuration such that $\frac{n}{18} \leqslant q(\boldsymbol{x}) \leqslant \frac{n}{2}$ and $|s(\boldsymbol{x})| < c_4\sqrt{n}\log n$ for any positive constant c_4, then it holds:*

1. *for any constant $h > 0$ a constant $c_1 < 1$ exists such that $\mathbf{P}\left(|S| < h\sqrt{n} \mid \boldsymbol{X}_t = \boldsymbol{x}\right) < c_1$,*
2. *two positive constants c_2, ε exist such that $\mathbf{P}\left(|S| \geqslant (1+\varepsilon)s \mid \boldsymbol{X}_t = \boldsymbol{x}\right) \geqslant 1 - e^{-c_2 s^2/n}$.*

It is important to observe that the above claim ensures Properties 1 and 2 of Lemma 4 whenever $\frac{1}{18}n \leqslant q \leqslant \frac{1}{2}n$. Unfortunately, Lemma 4 requires such properties to hold for *any* (almost-)balanced configuration: If $q = n - o(n)$, Property 1 does not hold, while Property 2 is not satisfied if $q = o(n)$. In order to manage this issue, in Subsection 4.1, we define a *pruned* process, a variant of U-Process where it is possible to apply Lemma 4. Then, in Subsection 4.2 we show a coupling between the U-Process and the pruned one.

4.1 The pruned process

The helpful, key point is that, starting from any configuration $\mathbf{x} \in H_2$, the probability that the process goes in one of those "bad" configurations with $q < \frac{1}{18}n$ or $q \geqslant \frac{1}{2}n$ is negligible (see Claim 7). Thus, intuitively speaking, all the configurations *actually visited* by the process

before leaving H_2 do satisfy Lemma 4. In order to make this intuitive argument rigorous, in what follows, we define a suitably *pruned* process by removing from H_2 all the *unwanted* transitions.

Let $\bar{s} \in [n]$ and $\mathbf{z}(\bar{s})$ be the configuration such that $s(\mathbf{z}(\bar{s})) = \bar{s}$ and $q(\mathbf{z}(\bar{s})) = \frac{1}{2}n$. Let $p_{\mathbf{x},\mathbf{y}}$ be the probability of a transition from the configuration $\mathbf{x}$ to the configuration $\mathbf{y}$ in the U-Process. We define a new stochastic process: The U-Pruned-Process. The U-Pruned-Process behaves exactly like the original process but every transition from a configuration $\mathbf{x} \in H_2$ to a configuration $\mathbf{y}$ such that $q(\mathbf{y}) < \frac{1}{18}n$ or $q(\mathbf{y}) > \frac{1}{2}n$ now have probability $p'_{\mathbf{x},\mathbf{y}} = 0$. Moreover, for any $\bar{s} \in [n]$, starting from any configuration $\mathbf{x} \in H_2$, the probability of reaching the configuration $\mathbf{z}(\bar{s})$ is:

$$p'_{\mathbf{x},\mathbf{z}(\bar{s})} = p_{\mathbf{x},\mathbf{z}(\bar{s})} + \sum_{\mathbf{y}:\left(q(\mathbf{y})<\frac{1}{18}n \vee q(\mathbf{y})>\frac{1}{2}n\right) \bigwedge s(\mathbf{y})=\bar{s}} p_{\mathbf{x},\mathbf{y}}.$$

Finally, all the other transition probabilities remain the same.

Observe that, since the U-Pruned-Process is defined in such a way it has exactly the same marginal probability of the original process with respect to the random variable s, then Claim 5 holds for the U-Pruned-Process as well. Thus, we can choose constants h, c_1, c_2, ε such that the two properties of Lemma 4 are satisfied.

▶ **Corollary 6.** *Starting from any configuration $\boldsymbol{x} \in H_2$, the U-Pruned-Process reaches a configuration $\boldsymbol{X}' \in H_4$ within $\mathcal{O}(\log n)$ rounds, w.h.p.*

4.2 Back to the original process

The definition of the U-Pruned-Process suggests a natural coupling between the original process and the pruned one: If the two processes are in different states then they act independently, while, if they are in the same configuration $\mathbf{x}$, they move together unless the U-Process goes in a configuration $\mathbf{y}$ such that $q(\mathbf{y}) < \frac{1}{18}n$ or $q(\mathbf{y}) > \frac{1}{2}n$. In that case the U-Pruned-Process goes in $\mathbf{z}(s(\mathbf{y}))$. Using this coupling, we first show that, if the two processes are in the same configuration, the probability that they get separated is negligible.

▶ **Claim 7.** *For every configuration $\boldsymbol{x} \in H_2$, the probability that the number of undecided nodes in the next round of the U-Process is not between $n/18$ and $n/2$ is*

$$\mathbf{P}\left(q(\boldsymbol{X}_{t+1}) \notin \left[\frac{n}{18}, \frac{n}{2}\right] \mid \boldsymbol{X}_t = \boldsymbol{x}\right) \leqslant e^{-\Theta(n)}.$$

Then, thanks to the above claim, we can show that the H_2 exit time of the pruned procedure stochastically dominates the H_2 exit time of the original process. Thus, using Corollary 6, we get the main result of this section.

▶ **Lemma 8** (Phase H_2)**.** *Starting from any configuration $\boldsymbol{x} \in H_2$, the U-Process reaches a configuration $\boldsymbol{X}' \in H_4$ within $\mathcal{O}(\log n)$ rounds, w.h.p.*

5 Convergence to the majority

In this section we state the key technical lemmas we use to prove our second main result, namely Theorem 2, which essentially establishes that, starting from any sufficiently-biased configuration, the U-Process converges to the monochromatic configuration where all nodes support the initial majority color within $\Theta(\log n)$ rounds, w.h.p.

The proofs of the technical lemmas, as well as the almost-tightness result on the minimal magnitude of the initial bias stated in Theorem 2, can be found in the full version of the paper [14].

Phases H_5 and H_7 (Starters II)

We show that if the process is in a configuration where the number of the undecided nodes is relatively small with respect to the bias, then in the next round the number of the undecided nodes becomes large while the bias does not decrease too much, w.h.p. This essentially implies that if the process starts in H_5 then in the next round the process moves to a configuration belonging to H_4 or H_6 (Lemma 9), while if it starts in H_7 then in the next round it moves to H_4 or H_5 or H_6 (Lemma 10).

▶ **Lemma 9** (Phase H_5). *Starting from any configuration $\boldsymbol{x} \in H_5$ with $a > b$, the U-Process reaches a configuration $\boldsymbol{X}' \in (H_4 \cup H_6)$ with $a > b$ in one round, w.h.p.*

▶ **Lemma 10** (Phase H_7). *Starting from any configuration $\boldsymbol{x} \in H_7$ with $a > b$, the U-Process reaches a configuration $\boldsymbol{X}' \in (H_4 \cup H_5 \cup H_6)$ with $a > b$ in one round, w.h.p.*

Phase H_4 (Age of the undecideds)

We first show that, under some parameter ranges including H_4 (and hence when the number of the undecideds are large enough), the growth of the bias is exponential.

▶ **Claim 11.** *Let γ be any positive constant and $\boldsymbol{x} \in \mathcal{C}$ be any configuration such that $s \geqslant \gamma\sqrt{n \log n}$ and $q \geqslant \frac{1}{18}n$. Then, it holds that $s\,(1 + 1/36) < S < 2s$, w.h.p.*

The above result allows us to prove the following bounds on the time the process requires to reach Phase H_6.

▶ **Lemma 12** (Phase H_4). *Let $\boldsymbol{x} \in H_4$ be a configuration with $a > b$. Then, (i) starting from $\boldsymbol{x}$, the U-Process reaches a configuration $\boldsymbol{X}' \in H_6$ with $a > b$ within $\mathcal{O}(\log n)$ rounds, w.h.p. Moreover, (ii) an initial configuration $\boldsymbol{y} \in H_4$ exists such that the U-Process stays in H_4 for $\Omega(\log n)$ rounds, w.h.p.*

Phase H_6 (Majority takeover)

This is the phase in which, due to the large bias, the nodes converge to the majority color within a logarithmic number of rounds. We first prove that the number of nodes that support the minority color decreases exponentially fast and that the bias is preserved round by round. Then, when $b \leqslant 2\sqrt{n \log n}$, the number of undecided nodes starts to decrease exponentially fast as well. At the very end, when there are only few nodes (i.e., $\mathcal{O}(\sqrt{n \log n})$) that do not support the majority color yet, the minority color disappears in few steps and thus the U-Process converges to majority within $\mathcal{O}(\log n)$ rounds

▶ **Lemma 13** (Phase H_6). *Starting from any configuration $\boldsymbol{x} \in H_6$ with $a > b$, the U-Process ends in the monochromatic configuration where $a = n$ within $\mathcal{O}(\log n)$ rounds, w.h.p.*

6 Conclusions

We provided a full analysis of the U-Dynamics in the parallel $\mathcal{PULL}$ model for the binary case showing it is an efficient self-stabilizing consensus protocol. Besides giving tight bounds on the convergence time, our set of results well-clarifies the main aspects of the process

evolution and the crucial role of the undecided nodes in each phase of this evolution. An interesting open question is that of considering the same process in the multi-color case and to derive bounds on the time required to break symmetry from balanced configurations, as well. Finally, we believe that our analysis can be suitably adapted in order to show that the U-Dynamics efficiently stabilizes to a valid consensus "regime" [10] even in the presence of a dynamic adversary that can change the state of a subset of nodes of size $o(\sqrt{n})$ provided that the initial number of colored nodes is $\Omega(\sqrt{n})$.

Abstract

We construct a fixed parameter algorithm parameterized by d and k that takes as an input a graph G' obtained from a d-degenerate graph G by complementing on at most k arbitrary subsets of the vertex set of G and outputs a graph H such that G and H agree on all but $f(d,k)$ vertices.

Our work is motivated by the first order model checking in graph classes that are first order interpretable in classes of sparse graphs. We derive as a corollary that if $\mathcal{G}$ is a graph class with bounded expansion, then the first order model checking is fixed parameter tractable in the class of all graphs that can obtained from a graph $G \in \mathcal{G}$ by complementing on at most k arbitrary subsets of the vertex set of G; this implies an earlier result that the first order model checking is fixed parameter tractable in graph classes interpretable in classes of graphs with bounded maximum degree.

1 Introduction

The work presented in this paper is motivated by the line of research on algorithmic metatheorems, general algorithmic results that guarantee the existence of efficient algorithms for wide classes of problems. The most classical example of such a result is the celebrated theorem of Courcelle [2] asserting that every monadic second order property can be model checked in linear time in every class of graphs with bounded tree-width; further results of this kind can be found in the survey [17]. Specifically, our motivation comes from the first order model checking in sparse graph classes and attempts to extend these results to classes of dense graphs with structural properties close to sparse graph classes.

The two very classical algorithms for the first order model checking in sparse graph classes are the linear time algorithm of Seese [24] for graphs with bounded maximum degree and the linear time algorithm of Frick and Grohe [10] for planar graphs, which can also be adapted

to an almost linear time algorithm for graphs with locally bounded tree-width. These results were extended to many other classes of sparse graphs, in particular to graphs locally excluding a minor by Dawar, Grohe and Kreutzer [5] and to the very general graph classes with bounded expansion, which were introduced in [18–21], by Dawar and Kreutzer [6] (see [14] for further details) and, independently, by Dvořák, Král' and Thomas [7, 8]. This line of research ultimately culminated with the result of Grohe, Kreutzer and Siebertz [15], who proved that the first order model checking is fixed-parameter tractable in nowhere-dense classes of graphs by giving an almost linear time algorithm for this problem when parameterized by the class and the property.

The results that we have just mentioned concern classes of sparse graphs. While they cannot be extended to all somewhere-dense classes of graphs, see e.g. [8], it is still possible to hope for proving tractability results for dense graphs that possess structural properties making first order model checking feasible. For example, a well-known theorem of Courcelle, Makowsky and Rotics [4] on monadic second order model checking in classes of graphs with bounded clique-width implies that first order model checking is tractable for classes of graphs with bounded clique-width; in relation to the results that we present further, it is interesting to note that graph classes that can be first order interpreted in classes of graphs with bounded clique-width also have bounded clique-width [3, Corollary 7.38]). Another approach is studying graphs defined by geometric means [9, 13, 16]. The approach that we are interested in here lies in considering graph classes derived from sparse graph classes by first order interpretations as in [11, 12]; the definition of a first order interpretation can be found in Section 2.

Specifically, we are motivated by the following very general folklore conjecture.

▶ **Conjecture 1.** *The first order model checking is fixed parameter tractable in $I(\mathcal{G})$ when parameterized by a graph class $\mathcal{G}$ with bounded expansion, a simple first order graph interpretation scheme I and a first order property to be tested.*

The first step towards this conjecture was obtained in [11], where it was shown that Conjecture 1 holds for classes of graphs with bounded maximum degree.

▶ **Theorem 2.** *The first order model checking is fixed parameter tractable in $I(\mathcal{G})$ when parameterized by a class $\mathcal{G}$ of graphs with bounded maximum degree, a simple first order graph interpretation scheme I and a first order property to be tested.*

A combinatorial characterization of classes of graphs interpretable in graph classes of bounded expansion was given in [12]. However, the characterization does not come with an efficient algorithm to compute the corresponding decomposition. So, Conjecture 1 remains open. The approach taken in this paper can be seen as complementary to the one used in [12] since we attempt to directly reverse the effect of the first order interpretation.

To motivate our approach, we sketch the proof of Theorem 2 from [11]. The core of the proof lies in considering first order graph interpretation schemes I where the vertex sets of G and $I(G)$ are the same and constructing an algorithm that recovers a graph H from $I(G)$ such that the graphs G and H have the same vertex set and they agree on most of the edges. We now describe the approach from [11] phrased in the terminology used in this paper.

We start with introducing additional notation. A *pattern* is a graph R that may contain loops and it does not contain a pair of adjacent twins that both have loops, or a pair of non-adjacent twins that neither of them has a loop, i.e., a graph that has no non-trivial induced endomorphism. To make our exposition more transparent, we will further refer to vertices of patterns as to *nodes* and generally denote them by u with different subscripts

and superscripts; vertices of graphs that are not patterns will generally be denoted by v with different subscripts and superscripts. Let G be a graph, R a pattern and $(V_u)_{u \in V(R)}$ a partition of the vertices of G into parts indexed by the nodes of R. The graph G^R is the graph with the same vertex set as G such that if $v, v' \in V(G)$, $v \in V_u$ and $v' \in V_{u'}$, then vv' is an edge in G^R if and only if either vv' is an edge of G and uu' is not an edge of R or vv' is not an edge of G or uu' is an edge of R. Alternatively, we may define the graph G^R to be the graph obtained from G by complementing all edges inside sets V_u for each node u with a loop and between sets V_u and $V_{u'}$ for each edge uu' of R. Note that the graph G^R depends on the chosen partition of the vertex set of G; this partition will always be clear from the context.

A very simple example of the introduced notion is a pattern R that consists of a single node u with a loop. For every graph G, there is only one single class partition of $V(G)$, i.e., $V_u = V(G)$, and G^R is then the complement of G. Similarly, if R has two vertices u and u' and the edges uu (loop) and uu', and the vertex set of a graph G is partitioned into sets V_u and $V_{u'}$, then G^R is obtained from G by complementing all edges inside V_u and all edges between V_u and $V_{u'}$.

We now continue with the exposition of the proof of Theorem 2 from [11]. Simple first order graph interpretation schemes of graphs with bounded maximum degree are very closely linked to patterns as given in the next proposition, which directly follows from Gaifman's theorem [11]. The proposition essentially says that for every integer d and interpretation scheme I, there exist a pattern R and an integer D such that the graph $I(G)$ for any graph G with maximum degree d is equal to H^R for a suitable graph H with maximum degree D; note that R and D depend on I and d only.

▶ **Proposition 3.** *Let $\mathcal{G}_d$ be the class of graphs of maximum degree d and I a simple first order graph interpretation scheme. There exists an integer D and a pattern R such that for every graph $I(G)$ obtained from $G \in \mathcal{G}_d$ there exists a graph $H \in \mathcal{G}_D$ and a partition $(V_u)_{u \in V(R)}$ of the vertex set of H such that the graphs $I(G)$ and H^R are the same.*

This characterization of graphs that can be interpreted in a class of graphs with bounded maximum degree is then combined with the following "recovery" algorithm, which is implicit in [11], to get a proof of Theorem 2. Note the algorithm $\mathcal{A}$ from Theorem 4 has two parameters, one controls the complexity of the structure of a graph and the other controls the complexity of its transformation.

▶ **Theorem 4.** *There exists an algorithm $\mathcal{A}$ that is fixed parameter with respect to an integer parameter D and a pattern R and has the following property: for all D and R, there exist an integer D' and a pattern R' such that the algorithm $\mathcal{A}$ takes as an input a graph G^R, where G is a graph with maximum degree at most D, and outputs a graph H such that G^R and $H^{R'}$ are the same and the maximum degree of H is at most D'.*

One of our main results is an extension of Theorem 4 to classes of d-degenerate graphs. Note that such graph classes include classes with bounded expansion concerned by Conjecture 1. This may look like an innocent extension of Theorem 4 at the first sight. However, the proof of Theorem 4 relies on the fact that the degrees of any two vertices of G^R that are contained in the same part V_u, $u \in V(R)$, differ by at most $2d$, i.e., it is easy to recognize vertices that belong to the same part. This is far from being true in the setting of d-degenerate graphs, which leads to a need for a much finer analysis of the structure of an input graph.

▶ **Theorem 5.** *There exists an algorithm $\mathcal{A}$ that is fixed parameter with respect to integer parameters d and K and has the following property: for all d and K, there exists an integer m such that the algorithm $\mathcal{A}$ takes as an input a graph G^R and integers d and K, where G is a d-degenerate graph and R is a K-node pattern (both unknown to $\mathcal{A}$), and outputs a graph H such that G and H agree on all but at most m vertices. In particular, the graph H is $(d+m)$-degenerate.*

We next present a corollary of Theorem 5, which we believe to be of independent interest. First observe that complementing edges between two subsets V and V' of the vertex set of G is equivalent to complementing on the following three subsets of vertex set: $V \cup V'$, V and V'. Hence, the graph G^R is obtained from G by complementing on at most $K + \binom{K}{2}$ subsets of vertices of G, where K is the number of nodes of R. In the other direction, if a graph H is obtained from G by complementing on at most k subsets of vertices, there exists a pattern R with at most 2^k nodes such that $H = G^R$. Hence, Theorem 5 implies the following.

▶ **Corollary 6.** *There exists an FPT algorithm $\mathcal{A}$ with the following property: for every integer d and an integer k, there exists an integer m such that the algorithm $\mathcal{A}$ takes as an input a graph G' obtained from a d-degenerate graph G by complementing on at most k subsets of the vertex set of G and outputs a graph H such that G and H agree on all but at most m vertices.*

In relation to the first order model checking, Corollary 6 yields the following theorem, which we prove in Section 4.

▶ **Theorem 7.** *Let $\mathcal{G}$ be a graph class with bounded expansion and let $\mathcal{G}^k$ be the class containing all graphs that can obtained from a graph $G \in \mathcal{G}$ by complementing on at most k subsets of the vertex set of G. For every k, the first order model checking is fixed parameter tractable on $\mathcal{G}^k$.*

Observe that Proposition 3 implies the following: if $\mathcal{G}$ is a class of graphs with bounded maximum degree and I is a simple first order graph interpretation scheme, then $I(\mathcal{G}) \subseteq \mathcal{G}_D^k$ for some integers D and k, where $\mathcal{G}_D$ is the class of all graphs with maximum degree at most D. Hence, Theorem 7 gives an alternative proof of Theorem 2. On the other hand, since Proposition 3 does not hold in the setting of graph classes with bounded expansion, Theorems 5 and 7 do not yield an analogous result in this more general setting, which is concerned by Conjecture 1; we discuss further details in Section 5.

2 Preliminaries

In this section, we briefly introduce the notation used throughout the paper, and present the concepts that we need further.

Graphs considered in this paper are simple, i.e., they do not contain loops or parallel edges unless stated otherwise. If G is a graph, then $V(G)$ denotes the set of its vertices. The *neighborhood* of a vertex v in a graph G, denoted by $N_G(v)$, is the set of all vertices adjacent to v. The *degree* of a vertex v of a graph G is the size of its neighborhood, and the *relative degree* of v with respect to a subset $X \subseteq V(G)$ is the number of the neighbors of v in X. If G is a graph and W a subset of its vertices, then the subgraph of G *induced* by W, denoted by $G[W]$, is the subgraph of G with the vertex set W such that two vertices are adjacent in $G[W]$ if and only if they are adjacent in G. Finally, a graph G is *d-degenerate*, if its vertices can be ordered in such a way that each vertex has at most d of its neighbors preceding it.

Let G be a graph. Two vertices v and v' of G are *twins* if every vertex w different from v and v' is adjacent to either both v and v' or none of them. The binary relation of "being a twin" on $V(G)$ is an equivalence relation; we will call the equivalence classes of this relation *twin-classes*. Note that each twin-class induces either a complete subgraph or an empty subgraph of G.

A graph G' is an *r-shallow minor* of a graph G if it can be obtained from a subgraph of G by contracting vertex-disjoint subgraphs of radii at most r (and removing arising loops and parallel edges). We say that a graph class $\mathcal{G}$ has *bounded expansion* if $\mathcal{G}$ is monotone, i.e., closed under taking subgraphs, and there exists a function $f : \mathbb{N} \to \mathbb{N}$ such that the average degree of every r-shallow minor of any graph from G is at most $f(r)$. As we have already mentioned, examples of classes of graphs with bounded expansion are classes of graphs with bounded maximum degree and minor-closed classes of graphs. The latter include classes of graphs with bounded tree-width or graphs embeddable in a fixed surface.

If G is a graph, then a K-apex of G is a graph obtained by at adding at most K vertices to G and joining them to the remaining vertices and between themselves arbitrarily. The next proposition easily follows from the basic results on classes of graphs with bounded expansion; see e.g. [22, Chapter 5] for further details.

▶ **Proposition 8.** *Let $\mathcal{G}$ be a class of graph with bounded expansion, and let K be a positive integer. The class of graphs formed by K-apices of graphs from $\mathcal{G}$ has bounded expansion.*

Finally, a *simple first order interpretation scheme* I consists of a pair of formulas $\psi_V(x)$ and $\psi_E(x, y)$. If G is a graph, then the graph $I(G)$ has vertex set equal to the set $\{v \in V(G) \mid G \models \psi_V(x)\}$, i.e., it is the subset of vertices x of G such that $\psi_V(x)$ holds, and two vertices u and v of $I(G)$ are adjacent iff $G \models \psi_E(u, v) \vee \psi_E(v, u)$.

3 Recovering degenerate graphs

This section is devoted to the proof of Theorem 5, one of our two main results. We need to start with introducing additional notation that will be used in our analysis of complemented graphs. Let G be a graph. Two subsets X and Y of the vertex set $V(G)$ are *k-similar* if their symmetric difference is at most k, i.e., $|X \triangle Y| \leq k$. We say that two vertices of G are *k-similar* if their neighborhoods are k-similar, and we define the *k-similarity graph* of G to be the graph with the vertex set $V(G)$ where two vertices are adjacent if they are k-similar.

Further fix a pattern R and a partition $(V_u)_{u \in V(R)}$ of $V(G)$. If u is a node of R, then the *u-perfect* set is the union of the sets $V_{u'}$ where the union is taken over all neighbors u' of u in R. Note that the u-perfect set includes V_u iff u has a loop. A subset X of the vertex set of G is *(u, k)-perfect* if it is k-similar to the u-perfect set, and a vertex of G is *(u, k)-perfect* if its neighbors in G^R form a *(u, k)-perfect* set. In particular, when saying that a vertex of G is *(u, k)-perfect*, this always concerns its neighborhood in G^R or in the induced subgraph of G^R.

Our goal is to approximately recover graph G from G^R given the size K of R and assuming that G is d-degenerate. We achieve this by finding a partition of $V(G^R)$ that approximates the partition of $(V_u)_{u \in V(R)}$ of $V(G)$. To find the approximate partition, we use (u, k)-perfect vertices introduced above: if we identify a (u, k)-perfect vertex for each class V_u of $(V_u)_{u \in V(R)}$, then the structure of the neighborhoods of these vertices leads to a good approximation of the partition $(V_u)_{u \in V(R)}$. The structural lemmas presented in the next subsection lead to a simple condition (Lemma 11) that allows us to find a (u, C)-perfect vertex in the input graph, where the constant C depends on d and K only. The presented structural results are then be used to design Algorithm 1, which outputs an approximation of the graph G.

3.1 Structural results

In this subsection, we present structural results on complemented graphs. These results will be used in the next subsection to analyze our algorithm. We start with observing that most vertices of each substantially large part are almost perfect.

▶ **Lemma 9.** *Let R be a K-node pattern, G a d-degenerate graph with a vertex partition $(V_u)_{u\in V(R)}$, and M the maximum size of a part V_u, $u \in V(R)$. If a part V_u, $u \in V(R)$, contains at least $\frac{M}{4K}$ vertices, then it contains at least $\left(1-\frac{1}{10K}\right)|V_u|$ vertices that are $(u, 80dK^3)$-perfect.*

Proof. Fix a node u such that the size of the part V_u is at least $\frac{M}{4K}$, and observe that a vertex v of V_u is $(u, 80dK^3)$-perfect if and only if its degree in G is at most $80dK^3$. Hence, we need to show that at least $\left(1-\frac{1}{10K}\right)|V_u|$ vertices of V_u have degree at most $80dK^3$.

Suppose that more than $\frac{1}{10K}|V_u|$ vertices of V_u have degree strictly larger than $80dK^3$. This implies that the sum of the degrees of the vertices of V_u is strictly larger than

$$8dK^2|V_u| \geq 2dKM\ .$$

This is impossible since G contains at most $dn \leq dKM$ edges in total and thus the sum of the degrees of all vertices of G is at most $2dKM$. The statement of the lemma now follows. ◀

The next lemma shows that almost all vertices with similar neighborhoods must belong to the same part.

▶ **Lemma 10.** *Let R be a K-node pattern and G a d-degenerate graph with a vertex partition $(V_u)_{u\in V(R)}$ such that each V_u contains at least $330dK^3$ vertices. For every $W \subseteq V(G)$, there exists a node $u \in V(R)$ such that all but at most $330dK^4$ vertices with their neighborhoods $(160dK^3)$-similar to W in G^R belong to V_u.*

Proof. Suppose that the statement is false and fix a set W that violates the statement. This implies that there are two different nodes u and u' such that each of the sets V_u and $V_{u'}$ contains at least $330dK^3$ vertices with $(160dK^3)$-similar to W in G^R. Indeed, take a node $u \in V(R)$ such that V_u contains the largest number of vertices with their neighborhoods $(160dK^3)$-similar to W in G^R; note that V_u contains at least $330dK^3$ such vertices (otherwise, any node u would satisfy the statement of the lemma since there would be at most $330dK^4$ such vertices in total). Since the set W violates the statement, there are at least $330dK^4$ vertices with their neighborhoods $(160dK^3)$-similar to W in G^R that do not belong to V_u. This implies that there exists a node $u' \in V(R)$ such that $V_{u'}$ also contains at least $330dK^3$ such vertices.

To simplify our notation, fix n to be $330dK^3$. Choose an n-vertex subset A of V_u such that their neighborhoods are $(160dK^3)$-similar to W and an n-vertex subset A' of $V_{u'}$ such that their neighborhoods are $(160dK^3)$-similar to W. Observe that any two vertices in $A \cup A'$ are $(320dK^3)$-similar.

We next distinguish three cases based on whether the nodes u and u' have loops in R and whether they are adjacent in R.

- **At least one of the two nodes, say u, has a loop, and R does not contain the edge uu'.**
  The subgraph $G[A \cup A']$ contains at most $2dn$ edges, which yields that the sum of the degrees of the vertices of $G[A \cup A']$ is at most $4dn$. We next compare relative degrees of the vertices of $A \cup A'$ with respect to A in G^R. Since the neighbors of the vertices of A' in A are the same in $G[A \cup A']$ and in $G^R[A \cup A']$, the sum of the relative degrees of

the vertices of A' with respect to A is at most $4dn$. On the other hand, the sum of the relative degrees of the vertices of A in $G^R[A \cup A']$ is at least $n(n-1) - 4dn$. Since any two vertices in $A \cup A'$ are $(320dK^3)$-similar in G^R and thus in $G^R[A \cup A']$, their relative degrees in G^R with respect to A differ by at most $320dK^3$. Consequently, the sums of the relative degrees of the vertices of A and those of A' with respect to A in G^R can differ by at most $320dK^3n$. However, the difference of these two sums is at least

$$n(n-1) - 8dn = n(n-1-8d) \geq n(330dK^3 - 1 - 8d) \geq 321dK^3n > 320dK^3n \,.$$

- **At least one of the two nodes, say u, does not have a loop, and R contains the edge uu'.**
  An analogous argument to that used in the first case yields that the sum of the relative degrees of the vertices of A with respect to A in G^R is at most $4dn$ and the sum of the relative degrees of the vertices of A' with respect to A in G^R is at least $n^2 - 4dn$. Consequently, the difference of these two sums is at least $n^2 - 8dn > 320dK^3n$ while it cannot exceed $320dK^3n$.
- **The nodes u and u' either both have loops and are adjacent or both do not have a loop and are non-adjacent in R.**
  Since R is a pattern, there must exist a node u'', which is different from u and u', such that either uu'' is not an edge and $u'u''$ is an edge, or vice versa. By symmetry, we can assume the former to be the case. Let A'' be a set of n vertices contained in $V_{u''}$. The number of edges between A and A'' in G is at most $2dn$. Hence, the sum of the relative degrees of the vertices of A with respect to A'' is at most $2dn$ both in G and in G^R. On the other hand, the sum of the relative degrees of the vertices of A' with respect to A'' is at most $2dn$ in G, and thus at least $n^2 - 2dn$ in G^R. Since any two vertices of $A \cup A'$ are $(320dK^3)$-similar, their relative degrees with respect to A'' in G^R can differ by at most $320dK^3$. Consequently, the sums of the relative degrees of the vertices of A and A' can differ by at most $320dK^3n$. However, the difference of the two sums is at least $n^2 - 4dn > 320dK^3n$.

In each of the three cases, we have obtained a contradiction, which concludes the proof of the lemma. ◀

To prove the next lemma, we need to introduce some additional notation. Let G be a graph, R a pattern, $(V_u)_{u \in V(R)}$ a partition of $V(G)$, and U a subset of the nodes of R. The graph $R \setminus U$ need not be a pattern but there is a unique pattern to that $R \setminus U$ has an induced homomorphism. This pattern can be obtained as follows. Let R' be $R \setminus U$. As long as R' contains either two adjacent twins u and u' that both have loops or two non-adjacent twins u and u' that none of them has a loop, identify the nodes u and u' and merge the parts V_u and $V_{u'}$. The resulting pattern R_0 is called the *reduction* of $R \setminus U$; the reduction R_0 is uniquely determined by the pattern R and the set U. If W is the union of V_u with $u \notin U$, then the new parts V_u indexed by $u \in V(R_0)$ form a partition of the vertex set $G[W]$. This partition is called the *reduced partition* and it is easy to observe that the graphs $G^R[W]$ and $G[W]^{R_0}$ are the same.

▶ **Lemma 11.** *Let R be a K-node pattern and G a d-degenerate graph with a vertex partition $(V_u)_{u \in V(R)}$. If G has at least $1100dK^5$ vertices, then the vertex of the maximum degree in the $(160dK^3)$-similarity graph of G^R is $(u, 570dK^4)$-perfect for some $u \in V(R)$.*

Proof. Let u_M be the node of R such that V_{u_M} is the largest part of the partition $(V_u)_{u \in V(R)}$ and let M be its size, i.e., $M = |V_{u_M}|$. Observe that $M \geq 1100dK^4$. By Lemma 9, V_{u_M} contains at least $\left(1 - \frac{1}{10K}\right) M \geq \frac{9M}{10}$ vertices that are $(u_M, 80dK^3)$-perfect. All these vertices

are mutually adjacent in the $(160dK^3)$-similarity graph of G^R, which implies that the maximum degree of the $(160dK^3)$-similarity graph of G^R is at least $9M/10-1$. Let w be the vertex of the maximum degree in the $(160dK^3)$-similarity graph of G^R, W the neighborhood of w in G^R, and W_s the neighborhood of w in the $(160dK^3)$-similarity graph. Note that $|W_s| \geq 9M/10-1$ and each vertex of W_s is $(160dK^3)$-similar to w in G^R.

Let U' be the set of the nodes $u \in V(R)$ such that $|V_u| \leq 330dK^3$, and let V' be the union of the parts V_u with $u \in U'$. Observe that $|V'| \leq 330dK^4$. Let R_0 be the reduction of $R \setminus U'$, and let G_0 be the graph $G \setminus V'$ with the reduced partition $V_{0,u}$, $u \in V(R_0)$. Observe that $G_0^{R_0} = G^R \setminus V'$ and each part $V_{0,u}$, $u \in V(R_0)$, has at least $330dK^3$ vertices. Further, let $W_0 = W \setminus V'$, and note that W_0 is the neighborhood of w in $G_0^{R_0}$ and that each vertex of $W_s \setminus V'$ is $(160dK^3)$-similar to w in $G_0^{R_0}$.

We now apply Lemma 10 to the graph G_0 with the pattern R_0 and the set W_0. The lemma implies that there exists a node u_0 of R_0 such that there are at most $330dK^4$ vertices outside V_{0,u_0} with their neighborhood $(160dK^3)$-similar to W_0 in $G_0^{R_0}$. Hence, the set $W_s \subseteq V(G)$ contains at most $660dK^4$ vertices that are not contained in V_{0,u_0}: all such vertices are contained in V' or are $(160dK^3)$-similar to w in $G_0^{R_0}$. It follows that the part V_{0,u_0} contains at least $9M/10-1-660dK^4 \geq 9M/10-661dK^4 \geq M/4$ vertices of W_s. In particular, the part V_{0,u_0} contains at least $M/4$ vertices in total.

By Lemma 9, the part V_{0,u_0} contains at least $\left(1-\frac{1}{10K}\right)|V_{0,u_0}|$ vertices that are $(u_0, 80dK^3)$-perfect with respect to the graph G_0 and the pattern R_0, i.e., there are at most $\frac{|V_{0,u_0}|}{10K} \leq M/10$ vertices of V_{0,u_0} that are not $(u_0, 80dK^3)$-perfect. Hence, there is a vertex v that is contained in $W_s \cap V_{0,u_0}$ and that is $(u_0, 80dK^3)$-perfect with respect to the graph G_0 and the pattern R_0.

Since the vertex v is $(u_0, 80dK^3)$-perfect with respect to the graph G_0 and the pattern R_0, there exists a node $u \in V(R)$ such that the vertex v is $(u, 80dK^3+|V'|)$-perfect with respect to the graph G and the pattern R, i.e., v is $(u, 80dK^3+330dK^4)$-perfect. Since the vertex v is contained in W_s, i.e., it is a neighbor of w in the $(160dK^3)$-similarity graph, we get that the vertex w is $(u, 240dK^3+330dK^4)$-perfect. Since $240dK^3+330dK^4 \leq 570dK^4$, the lemma now follows. ◀

3.2 Algorithm

We are now ready to present an algorithm that can be used to recover the original d-degenerate graph G from the graph G^R where R is an a priori unknown K-pattern. The algorithm is given as Algorithm 1. The algorithm takes the graph G^R as an input and outputs a graph F that differs from the perfect blow-up E^R of the pattern R only on constantly many vertices, where E is the graph with the vertex set $V(G)$ and no edges. Algorithm 1 is analyzed in the next lemma.

▶ **Lemma 12.** *Let R be a K-node pattern and G a d-degenerate graph with a vertex partition $(V_u)_{u \in V(R)}$. Suppose that Algorithm 1 is applied for $H = G^R$, d and K, and the algorithm outputs a graph F. There exists a subset U of at most $4000dK^6$ vertices of H such that the graph $F \setminus U$ and $E^R \setminus U$ are the same, where E is the empty graph with the vertex set $V(H)$.*

Proof. Let W_i be the set W at the point when the set S_i is fixed by Algorithm 1, and let k be the final value of this variables at the end of the algorithm. Further let W_0 be the set W at the end of the algorithm. By Lemma 11, the set S_i is $(u_i, 570dK^4)$-perfect in $H[W_i]$ for some $u_i \in V(R)$. Note that the set S_i is $(u_i, 570dK^4)$-perfect in $H[W_j]$ for every $j = i+1, \ldots, k$, since this property cannot be affected by deleting vertices. At the point when the set S_i

Algorithm 1: Algorithm producing an approximation of the perfect blow-up of an unknown K-node pattern.

Input: a graph H, integers d and K
Output: a graph F on the vertex set $V(H)$
$W := V(H)$;
F :=empty graph on the vertex set $V(H)$;
$k := 0$;
$\mathcal{S} := \emptyset$;
while $|W| \geq 1100dK^5$ **do**
  if $\exists\, v \in W$ *s.t.* $N_{H[W]}(v)$ *is* $(1140dK^4)$*-similar to a set* $S_i \cap W$, $S_i \in \mathcal{S}$ **then**
    $W := W \setminus \{v\}$;
    join v in F to all the vertices of $S_i \cap W$;
  else
    v :=max. degree vertex in the $(160dK^3)$-similarity graph of $H[W]$;
    $k := k + 1$;
    S_k :=the neighbors of v in $H[W]$;
    add S_k to $\mathcal{S}$;
output F.

was fixed, the set S_i was not $(1140dK^4)$-similar to any of the sets $S_1 \cap W_i, \ldots, S_{i-1} \cap W_i$. It follows that the nodes $u_1, \ldots, u_k$ are mutually distinct, which implies $k \leq K$.

Let T_i be the set of at most $570dK^4$ vertices of $H[W_i]$ such that S_i is u_i-perfect in $H[W_i \setminus T_i]$, and let $T = T_1 \cup \cdots \cup T_k$. Further, for each node $u \in V(R)$, let V'_u be the last $1143dK^4$ vertices of $V_u \setminus T$ removed by Algorithm 1 from the set W if such vertices exist; otherwise, let $V'_u = V_u \setminus (T \cup W_0)$. Note that $|V'_u| \leq 1143dK^4$ in either of the cases.

Consider the point when the algorithm removes a vertex $v \in V_u$ from the set W because the neighborhood of v is $(1140dK^4)$-similar to the set $S_i \cap W$, where W is the value of the variable at the time of the removal of v. We say that the vertex v is u'*-erroneous* for $u' \in V(R)$ if at least one of the vertices of $V_{u'} \setminus (V'_{u'} \cup T \cup W_0)$ has not yet been removed from W and

- either uu' is an edge of R but $V'_{u'}$ and S_i are disjoint, or
- uu' is not an edge of R but $V'_{u'}$ is a subset of S_i.

Note that it can be the case that the nodes u and u' in the above definition coincide, and a vertex v can be u'-erroneous for several choices of u'. Also note that if v is u'-erroneous, then $V_{u'} \setminus (V'_{u'} \cup T \cup W_0) \neq \emptyset$, which implies that $|V'_{u'}| = 1143dK^4$. Let $V_{u,u'}$ be the set of vertices of $V_u \setminus (V'_u \cup T)$ that are u'-erroneous.

The set U will contain the following vertices:

- at most $1100dK^5$ vertices contained in W_0,
- at most $k \cdot 570dK^4 \leq 570dK^5$ vertices contained in T,
- at most $K \cdot 1143dK^4 \leq 1143dK^5$ vertices contained in the set V'_u, $u \in V(R)$, and
- the vertices of all sets $V_{u,u'}$, $u, u' \in V(R)$.

We next show that each of the sets $V_{u,u'}$ contains at most $1143dK^4$ vertices, which would imply that the size of U does not exceed $4000dK^6$.

Set $n = 1143dK^4$ to simplify the notation, and suppose that there exists a set $V_{u,u'}$ containing more than n vertices for some $u, u' \in V(R)$ (possibly $u = u'$). Let X be a subset of $V_{u,u'}$ containing exactly n vertices. Note that that if $u = u'$, the sets X and $V'_{u'}$ are disjoint because all vertices of $V'_{u'}$ are removed from W after those of X. We first consider the case

that uu' is not an edge of R, which includes the case that $u = u'$ and u does not have a loop. Since the vertices of X are u'-erroneous, the set $V'_{u'}$ contains n vertices and all vertices of $V'_{u'}$ are removed from W later than the vertices of X, the d-degeneracy of G implies that the number of edges between X and $V'_{u'}$ in G is at most $2dn$. When a vertex $v \in X$ is removed from W by Algorithm 1, it is adjacent to at least $|V'_{u'}| - 1140dK^4 \geq 3dK^4$ vertices of $V'_{u'}$ in $H = G^R$ since the neighborhood of v is $(1140dK^4)$-similar to S_i and $V'_{u'} \subseteq S_i$. Hence, the number of edges between X and $V'_{u'}$ in $H = G^R$ is at least $3dK^4 n \geq 3dn$. However, the edges between the vertices of X and those of $V'_{u'}$ are the same in G and G^R, which is impossible.

The other case that we need to consider is that when uu' is an edge of R; this case also includes the case that $u = u'$ and u has a loop. The arguments are analogous to the first case but we include them for completeness. We again observe that the number of edges between X and $V'_{u'}$ in G is at most $2dn$. When a vertex $v \in X$ is removed from W, it is adjacent to at most $1140dK^4$ vertices of $V'_{u'}$ in $H = G^R$ since its neighborhood is $(1140dK^4)$-similar to S_i and the sets S_i and $V'_{u'}$ are disjoint. It follows that each vertex $v \in X$ is adjacent to at least $|V'_{u'}| - 1140dK^4 \geq 3dK^4$ vertices of $V'_{u'}$ in G. This implies that the number of edges between X and $V'_{u'}$ in G is at least $3dK^4 n \geq 3dn$, which is again impossible.

To complete the proof of the lemma, we need to show that the graphs $F \setminus U$ and $E^R \setminus U$ are the same. Let v and v' be two vertices of $V(H) \setminus U$ such that $v \in V_u$ and $v' \in V_{u'}$. By symmetry, we can assume that v is removed before v'. Suppose that the vertex v was removed by Algorithm 1 because the neighborhood of v in $H[W]$ was $(1140dK^4)$-similar to a set S_i where W is the value of the set at the time of the removal of v from W. Since the vertex v' does not belong to U, it is not contained in $V'_{u'} \cup W_0 \cup T$, which implies that $V'_{u'} \subseteq (V_{u'} \cap W) \setminus T$. Further, since the set S_i is u_i-perfect in $H[W \setminus T]$, the set S_i either contains $(V_{u'} \cap W) \setminus T$ or is disjoint from $(V_{u'} \cap W) \setminus T$. Since v is not u'-erroneous, the former happens if and only if uu' is an edge in R, and the latter happens otherwise. Hence, the vertices v and v' are joined by an edge in F if and only if uu' is an edge of R. ◀

Lemma 12 yields the proof of Theorem 5 as follows.

Proof of Theorem 5. Fix d and K, and set $m = 4000dK^6$. Let G_0 be the input graph, and suppose that G is the d-degenerate graph and R is the K-node pattern such that $G_0 = G^R$. Note that both G and R are not given to the algorithm $\mathcal{A}$.

The algorithm $\mathcal{A}$ applies Algorithm 1 to the graph G_0 and integers d and K, and Algorithm 1 outputs a graph F. By Lemma 12, the graphs E^R and F agree on all but at most m vertices, where E is the empty graph on the same vertex set as G_0. The algorithm $\mathcal{A}$ then outputs the graph $G_0 \triangle F$, i.e., the graph with the same vertex set as G_0 and with the edge set that is the symmetric difference of the edge sets of G_0 and F. Observe that the graph $G = G^R \triangle E^R$ and the output graph $G_0 \triangle F = G^R \triangle F$ differ exactly where the graphs E^R and F differ. It follows that the output graph $G_0 \triangle F$ and the graph G agree on all but at most m vertices, which implies that the output graph $G_0 \triangle F$ is $(d + m)$-degenerate. ◀

4 FO model checking

In this section, we prove Theorem 7, which is our second main result, and also discuss first order model checking in graphs obtained by complementing parts of degenerate graphs. We start with proving Theorem 7.

Proof of Theorem 7. Fix a graph class $\mathcal{G}$ with bounded expansion and an integer k, and set $K = 2^k$. Since the graph class $\mathcal{G}$ has bounded expansion, there exists an integer d such that every graph in $\mathcal{G}$ is d-degenerate. Set $m = 4000dK^6$ and let $\mathcal{H}$ be the graph class that

contain all m-apices of subgraphs of graphs contained in $\mathcal{G}$. By Proposition 8, the graph class $\mathcal{H}$ has bounded expansion.

Let G' be a graph obtained from a graph $G \in \mathcal{G}$ by complementing on at most k subsets of the vertex set of G, and let V be the common vertex set of G and G'. Note that there exists a K-node pattern R (which can be chosen independently of G and G' but this fact is not needed in our proof) and a partition $(V_u)_{u \in V(R)}$ of the vertex set V such that $G' = G^R$. Apply Algorithm 1 to G', d and K, and let F be the output graph. Since the graphs F and E^R, where E is the empty graph on the vertex set V, coincide on all but at most m vertices by Lemma 12, there exists a $(K+m)$-node pattern R_F such that $F = E^{R_F}$ for a suitable partition $(V'_u)_{u \in V(R_F)}$ of the vertex set V. Moreover, the pattern R_F and the partition $(V'_u)_{u \in V(R_F)}$ can be efficiently constructed: the at most $K+m$ twin-classes of the graph F form the partition $(V'_u)_{u \in V(R_F)}$ and the partition into twin-classes uniquely determine the pattern.

Let H be the graph with the vertex set V and the edge set being the symmetric difference of the edge sets of G' and F. Observe that $H^{R_F} = G'$. By Lemma 12, the graphs G and H agree on all but at most m vertices, which implies that the graph H belongs to the class $\mathcal{H}$. The application of the pattern R_F to H can be simulated by viewing the partition $(V'_u)_{u \in V(R_F)}$ as a vertex $(K+m)$-coloring and encoding the application of the pattern R_F by a first order formula. In particular, there exists a simple first order graph interpretation scheme I of $(K+m)$-vertex colored graphs such that $I(H) = G'$. Since there are only finitely many choices of R_F (because the number of nodes of R_F is bounded) and it is possible to use disjoint sets of colors to encode applications of different patterns R_F, there exists such an interpretation scheme I that is universal for all patterns R_F. The fixed parameter tractability of the first order model checking in $\mathcal{G}^k$ is now implied by the fixed parameter tractability of the first order model checking in graph classes with bounded expansion that contain graphs vertex-colored by a bounded number of colors, which directly follows from the results of [6–8]. ◀

The first order model checking in d-degenerate graphs is hard from the point of fixed parameter tractability, however, many parameterized problems that are hard for general graphs become fixed parameter tractable when restricted to d-degenerate graphs. Two prominent examples of such problems are the k-clique problem, which asks whether the input graph contains a complete subgraph with k vertices, and the k-independent set problem, which asks whether the input graph contains k independent vertices. Both these problems are fixed parameter tractable when parameterized by d and k.

To explore hopes of extending the fixed parameter tractability results for d-degenerate graphs to classes of graphs obtained by complementing d-degenerate graphs, we provide a brief analysis of the fixed parameter tractability of the k-clique problem in graphs obtained from d-degenerate graphs by applying patterns In the rest of this section, $\mathcal{G}_d$ denotes the class of d-degenerate graphs and $\mathcal{G}_d^R$ for a pattern R will be the class of all graphs that can be obtained from a graph $G \in \mathcal{G}_d$ by applying the pattern R, i.e., the class of all graphs G^R for $G \in \mathcal{G}_d$. We start with considering the parameterization by both R and k, where the problem turns out to be tractable for $d = 1$ and hard for $d \geq 2$ as given in the following two propositions.

▶ **Proposition 13.** *The k-clique problem in the class $\mathcal{G}_1^R$ is fixed parameter tractable when parameterized by a pattern R and an integer k.*

Proof. The class $\mathcal{G}_1$ of 1-degenerate graphs is the class of all forests. Recall that a rank-width of a graph G is defined as the minimum r such that there exists a tree T with leaves one-to-one

corresponding to the vertices of G such that each edge e of T determines a vertex cut (A, B) of G (A and B are the vertices assigned to the leaves of the two components of $T \setminus e$) such that the adjacency matrix of the cut (A, B) has rank at most r. It is not hard to see that each forest has rank-width at most one. Next observe that if the adjacency matrix of a vertex cut (A, B) in a graph G has rank r, then the adjacency matrix of the cut (A, B) in G^R has rank at most $r + K$. Consequently, if G is a graph with rank-width r and R is a K-node pattern, then the rank-width of G^R is at most $r + K$. We conclude that all graphs contained in the class $\mathcal{G}_1^R$ have bounded rank-width, which implies that all graphs contained in the class $\mathcal{G}_1^R$ have bounded clique-width [23]. Since monadic second order model checking is fixed parameter tractable in classes of graphs with bounded clique-width [4], the statement of the proposition follows. ◀

▶ **Proposition 14.** *The k-clique problem in the class $\mathcal{G}_2^R$ is $W[1]$-hard when parameterized by a pattern R and an integer k.*

Proof. We present a reduction from the multicolored k-clique problem, which is a well-known $W[1]$-hard problem. The multicolored k-clique problem asks whether a given k-partite graph contains a clique of order k. Let G be an arbitrary k-partite graph, let $V_1, \ldots, V_k$ be its vertex parts, and let H be the graph obtained from G by subdividing each edge. Note that H can be viewed as a $\left(k + \binom{k}{2}\right)$-partite graph with parts $V_1, \ldots, V_k$ and parts V_{ij}, $1 \leq i < j \leq k$, formed by vertices of degree two associated with edges between the parts V_i and V_j in the graph G. Let R be a pattern with $k + \binom{k}{2}$ nodes u_i, $1 \leq i \leq k$, and u_{ij}, $1 \leq i < j \leq k$, such that R has no loops but all pairs of nodes of R are joined edges except for pairs u_i and u_{ij} and pairs u_j and u_{ij}, $1 \leq i < j \leq k$. Set $V_{u_i} = V_i$, $1 \leq i \leq k$, and $V_{u_{ij}} = V_{ij}$, $1 \leq i < j \leq k$; this yields a vertex partition $(V_u)_{u \in V(R)}$ of the graph H. The graph H^R is a $\left(k + \binom{k}{2}\right)$-partite graph. Note that if $k \geq 4$, then H^R contains a clique with $k + \binom{k}{2}$ vertices if and only if H contains a subdivision of a clique with k vertices. Consequently, if $k \geq 4$, then G contains a clique with k vertices if and only if H^R contains a clique with $k + \binom{k}{2}$ vertices. Since H is a 2-degenerate graph, the proposition now follows. ◀

Proposition 14 leaves it open whether the k-clique problem is fixed parameter tractable when d and R are fixed and k is the parameter. We address this affirmatively in the next proposition.

▶ **Proposition 15.** *For every integer d and every pattern R, the k-clique problem in the class $\mathcal{G}_d^R$ is fixed parameter tractable when parameterized by k.*

Proof. We present an algorithm that decides whether a graph $H \in \mathcal{G}_d^R$ contains a complete subgraph with k vertices. In view of Theorem 5 and Lemma 12, we may assume (at the expense of considering a larger integer d and a larger pattern R) that the algorithm is given a graph $G \in \mathcal{G}_d$, a pattern R and a vertex partition $(V_u)_{u \in V(R)}$ such that $H = G^R$. If R contains a node u with a loop such that $|V_u| > dk$, then H contains a complete subgraph with k vertices: indeed, since the subgraph $G[V_u]$ is $(d+1)$-colorable, $G[V_u]$ contains an independent set of at least k vertices; this set forms a complete subgraph in $H = G^R$. Hence, we may assume that the following holds for every node u of R: u has no loop or $|V_u| \leq dk$.

We next observe that $H[V_u]$ contains at most $\max\{2^{dk}, 2^d|V_u|\}$ (not necessarily inclusion-wise maximal) complete subgraphs. Indeed, if $|V_u| \leq dk$, then there are at most 2^{dk} subsets of V_u and the claim follows. Otherwise, u has no loop and $G[V_u] = H[V_u]$ and the claim follows since $H[V_u]$ is d-degenerate. Let $\mathcal{C}_u$ be the set of all complete subgraphs of $H[V_u]$ (including the one with no vertices, i.e., the one induced by the empty set). The algorithm

now tests all possible combinations of subgraphs from $\mathcal{C}_u$, $u \in V(R)$, whether they form a complete subgraph in H. This identifies all complete subgraphs of H. The running time of the algorithm is bounded by the product of the sizes of the set $\mathcal{C}_u$, $u \in V(R)$, i.e., the algorithm runs in time $O\left(2^{dkK} n^{K+O(1)}\right)$, where n is the number of vertices of the input graph H and K is the number of nodes of the pattern R. ◀

5 Conclusion

Our results have been motivated by the characterization of graphs that are first interpretable in graphs with bounded maximum degree as given in Proposition 3. While we were able to translate Theorem 4 to the setting of Conjecture 1 and even the more general setting of degenerate graphs, Proposition 3 fails to extend to the setting of Conjecture 1, which we now outline. Consider a class $\mathcal{G}$ of all star forests, one of the simplest classes of sparse graphs with unbounded maximum degree, and also consider the simple first order graph interpretation scheme I such that two vertices in $I(G)$ are joined by an edge iff their distance in a graph G is at most two. The graph class $I(\mathcal{G})$ contains all graphs G such that each component of G is a complete graph. Let $\mathcal{H}$ be a graph class and R a pattern such that $I(\mathcal{G}) \subseteq \mathcal{H}^R$, where $\mathcal{H}^R$ is the class of graphs H^R, $H \in \mathcal{H}$. Let K be the number of nodes of R and consider a graph $G \in \mathcal{G}$ formed by $k \cdot K$ stars each with $k \cdot K - 1$ leaves for an integer $k \geq K + 1$. The graph $I(G)$ consists of $k \cdot K$ cliques each having $k \cdot K$ vertices; let $C_1, \ldots, C_{k \cdot K}$ be the vertex sets of the k cliques forming the graph $I(G)$. Suppose that $I(G) = H^R$ for a graph $H \in \mathcal{H}$ and a vertex partition $(V_u)_{u \in V(R)}$ of H. There exist a node u such that $|V_u \cap C_i| \geq k$ for at least two different indices i; by symmetry we can assume that $|V_u \cap C_1| \geq k$ and $|V_u \cap C_2| \geq k$. If the node u has a loop in R, then the graph H contains all edges between $V_u \cap C_1$ and $V_u \cap C_2$, i.e., H contains a complete bipartite subgraph with parts of sizes k. If the node u does not have a loop in R, then $H[V_u \cap C_1]$ is a complete subgraph with k vertices, i.e., H contains a complete bipartite subgraph with parts of sizes $\lfloor k/2 \rfloor$. We conclude that the graph class $\mathcal{H}$ contains graphs with arbitrary large complete bipartite subgraphs; this implies that the graph class $\mathcal{H}$ does not have bounded expansion.

In view of the results presented in Section 4, it is natural to wonder about the fixed parameter tractability of other important graph problems. One of such problems is the k-dominating set problem, which asks whether the input graph contains k vertices such that each vertex of the graph is one of these k vertices or adjacent to at least one of them. The k-dominating set problem is known to be fixed parameter tractable for d-degenerate graphs [1] when parameterized by d and k. However, we were not able to resolve the fixed parameter complexity of the k-dominating set problem in graphs obtained by complementing vertex subsets of d-degenerate graphs and even the following particular case seems to be challenging.

▶ **Problem 16.** *Is the k-dominating set problem in the complements of d-degenerate graphs fixed parameter tractable when parameterized by d and k?*

Abstract

We apply average-case complexity theory to physical problems modeled by continuous-time dynamical systems. The computational complexity when simulating such systems for a bounded time-frame mainly stems from trajectories coming close to complex singularities of the system. We show that if for most initial values the trajectories do not come close to singularities the simulation can be done in polynomial time on average. For Hamiltonian systems we relate this to the volume of "almost singularities" in phase space and give some general criteria to show that a Hamiltonian system can be simulated efficiently on average. As an application we show that the planar circular-restricted three-body problem is average-case polynomial-time computable.

1 Introduction

Many phenomena in nature can be modeled by continuous-time dynamical systems. Analyzing such phenomena is usually done by simulating the evolution of a system with digital computers. It is therefore crucial to better understand the computational properties of dynamical systems. One of the most basic questions one can ask about such a system is given the state of the system at some time t_0 what will be the state at some time $t > t_0$, i.e., to simulate the evolution for a finite time-frame.

The extended Church-Turing thesis is the statement that any physical computation device can be simulated efficiently with a Turing machine. While the thesis might be incompatible with quantum computation, at least for classical (non-quantum) physical computation the assumption seems reasonable. Thus, it should be possible to simulate trajectories of dynamical systems for problems in (classical) physics for a bounded time-frame efficiently as nature already provides an efficient "computation device". However, accurate numerical simulation of dynamical systems can be very hard. For example, Miller pointed out the difficulties when integrating the famous gravitational N-body problem [16]. The N-body problem is the problem of predicting the motion of N point masses under their mutual gravitational attraction. For a moderate number N of point masses, the main difficulty arises because close encounters of particles cause instabilities. Indeed, two particles colliding leads to a singularity in the analytic function describing the dynamics. On the other hand, Saari could show that at least for $N \leq 4$ singularities are rare in the sense that the set of initial values leading to singularities has Lebesgue measure zero [21, 22] (for $N > 4$ this is an open problem). Thus, a possible resolution to the inconsistency with the extended Church-Turing thesis might be that hard instances are extremely rare in nature and therefore it is possible to do the simulation efficiently on typical inputs. For further discussion on the extended Church-Turing thesis in classical physics, see e.g. [26].

The theory of real number computation based on a realistic model of approximation is known as *computable analysis*. Using this model, computational complexity theory can be applied to real functions [7, 8]. Simulating a continuous-time dynamical system corresponds to solving an initial value problem (IVP) for systems of ordinary differential equations. There are already several results on the computational complexity of solving IVPs in computable analysis. In particular, if the right-hand side function f of the equation $\dot{y} = f(y)$ is polynomial-time computable and Lipschitz-continuous, the unique solution y can be computed in PSPACE and can be hard for this class [6, 4]. On the other hand, for analytic right-hand side function the solution is also a polynomial-time computable function [18, 9]. However, this formulation does not really capture the notion of what is usually understood by simulating a dynamical system, as it is assumed that the solution exists on the whole time interval and only takes values in a known compact set, and there are several hidden factors depending on the function and the initial value that heavily influence the efficiency in practice.

Instead of fixing the initial value, it is therefore more natural to study the complexity of the function mapping initial values and time to the corresponding solution. This, however, poses the problem that the worst-case complexity for most interesting systems is unbounded. Indeed, it is quite obvious that the simulation should take longer the closer a trajectory approaches a singularity of the system as then higher precision is required. Nonetheless, the system might behave well for most initial values in the sense that the trajectory does stay far away from any singularities. We would then expect efficient simulation to be possible on typical inputs.

In this paper we want to formalize this intuition. In classical complexity theory, the notion of being efficiently computable on typical inputs is usually captured by *average-case complexity theory*, which often provides a more significant measure of the performance of an algorithm than worst-case complexity when the hard instances are rare. However, finding the right notion of average-case complexity poses some subtle difficulties. A structural theory of average-case complexity for discrete problems was introduced by Levin [13]. Schröder, Steinberg and Ziegler recently extended Levin's definition of average-case complexity to problems on real numbers [23].

In this paper we use their definition to show that many physical problems are indeed efficiently solvable on average. We first give a short introduction to the model of computation in Section 2 and define the most important notions that we need in the rest of the paper. In Section 3 we formalize a parameterized result for IVPs with analytic right-hand side. We show that restricted to a compact domain where the dynamics take place the solution can be computed in time polynomial in the output precision and a natural parameter depending on the function and the domain. In Section 4 we use this to show that if the "probability of trajectories to get close to complex singularities of the system" is small and if the right-hand side function can be evaluated efficiently on points not close to singularities, the simulation can be done in polynomial time on average. We then focus on a special case of dynamical systems that play an important role in classical physics, the Hamiltonian systems, and show that there is a simple way to bound the above probability in terms of the volume of singularities in phase-space. Finally, we apply our theorem to show that a special case of the three-body problem, the planar circular restricted three-body problem, can be simulated in polynomial time on average.

2 Computability and complexity in analysis

Computable Analysis extends classical computability theory to deal with uncountable quantities such as real numbers. The theory already dates back to Turing [24] with later important contributions for example by Grzegorczyk [3] and Lacombe [12]. The rigorous study of complexity in this model was initiated by Ko and Friedman [8]. In this section we briefly summarize the most important definitions. For a more detailed overview the reader is referred, e.g., to Weihrauch's monograph [25].

2.1 Computing real numbers and functions

Classically, computability is typically defined using Turing machines or an equivalent model of computation. Turing machines compute functions from finite strings to finite strings, that is, functions $F : \Sigma^* \to \Sigma^*$ for some fixed finite alphabet Σ. While computations over discrete objects like natural numbers, rational numbers or graphs can be defined by choosing an appropriate encoding for these objects as finite strings, the set of reals is uncountable and it is therefore impossible to find such an encoding. On the other hand, any real number can be approximated with arbitrarily small error by rational numbers. A real number x can therefore be encoded by a function that gives arbitrary exact approximations of x. More formally: A function $\varphi : \Sigma^* \to \Sigma^*$ is called a *name* for a real number $x \in \mathbb{R}$ if it maps strings of length n to the binary encoding of some integer z such that $\left|x - \frac{z}{2^n}\right| \leq 2^{-n}$. Any real number has infinitely many different names. We say x is *computable* if it has a computable name.

Similarly, a function $f : \mathbb{R} \to \mathbb{R}$ is computable if there is a computable function mapping names of x to names of $f(x)$, i.e., an algorithm that computes approximations of the output $f(x)$ with arbitrary precision while having access to arbitrary exact approximations of the input x. Such computation on names can be formally defined using oracle machines. Oracle machines can make queries to an oracle, a function $\varphi : \Sigma^* \to \Sigma^*$, during the computation. When making such a query the string w on a special tape, the so-called oracle tape, is replaced by the value of $\varphi(w)$ in a single time-step. We denote the oracle machine M with oracle φ by M^φ. M^φ again computes a function $\Sigma^* \to \Sigma^*$. A computable real function can then be defined as follows: A partial function $f :\subseteq \mathbb{R} \to \mathbb{R}$ is computable if there is an oracle machine M such that whenever φ is a name for $x \in \operatorname{dom} f$ the machine M^φ computes a name

for $f(x)$. The machine can behave arbitrarily on elements outside the domain of the function. The definition can be easily generalized to multidimensional functions $f :\subseteq \mathbb{R}^n \to \mathbb{R}^m$ by allowing multiple oracle and output tapes.

The running time $T_M(\varphi, w)$ for an oracle machine M with oracle $\varphi : \Sigma^* \to \Sigma^*$ and input $w \in \Sigma^*$ is defined as the number of steps the machine makes. If the machine M computes a real function $f : \mathbb{R} \to \mathbb{R}$ we can thus define the (worst-case) running time $T_M(x, n) \in \mathbb{N} \cup \{\infty\}$ of M for an argument $x \in \mathbb{R}$ and output precision $n \in \mathbb{N}$ as an upper bound of $T_M(\varphi, 0^n)$ over all names φ for x. We further say that a computable function $f : \mathbb{R} \to \mathbb{R}$ has (worst-case) time-complexity $T : \mathbb{N} \to \mathbb{N}$ if $T_M(x, n) \leq T(n)$ for all $x \in \operatorname{dom} f$ and that f is polynomial-time computable if T is a polynomial. Thus, the time-complexity of a real function is given in terms of the number of steps necessary to approximate the solution up to precision 2^{-n} depending on the output precision $n \in \mathbb{N}$.

Most work in real complexity theory restricts $\operatorname{dom} f$ to be a fixed compact set as this makes sure that a (finite) complexity bound exists. A more general theory taking into account the "size" of an oracle can be found in [5].

In this paper we sometimes use the notation that f is computable on some maximal domain $\operatorname{dom} f$ and *uniformly* allows some time-bound on a restricted subset of the domain. By this we mean that there is a single algorithm to compute f on its domain and the running time of this algorithm can be bounded on this subset.

2.2 Average-case complexity for real functions

Worst-case complexity as defined above has the disadvantage that the cost can be dominated by a small number of instances. A problem that can be solved efficiently on most inputs might thus still be hard from the perspective of computational complexity. *Average-case complexity* studies the average running time of an algorithm over all inputs and often gives a more realistic measure for the efficiency of an algorithm. Similarly to the class $\mathcal{P}$ in worst-case complexity we would like to have a class of average-case polynomial-time problems that we consider as "efficient on average". This notion should fulfill some basic robustness criteria. For example, composition of an average-case polynomial-time computable function with a worst-case polynomial-time computable function should still be computable in polynomial time on average. However, already in the discrete case this robustness property is not fulfilled by the most intuitive definitions. A definition that resolves this problem was given by Levin [13]. Schröder, Steinberg and Ziegler [23] recently extended Levin's notion to real number computations:

▶ **Definition 1.** Let (X, Σ, μ) denote a probability space and $T : X \times \mathbb{N} \to [0, \infty]$ a measurable function. We say that T is polynomial-time on average if there is some $\varepsilon > 0$ such that the function

$$n \mapsto \frac{1}{n} \int_X (T(x, n))^\varepsilon \, d\mu \tag{1}$$

is bounded by some constant $c > 0$.

If an algorithm runs in polynomial-time on average, there is a high probability that it runs in polynomial-time for a randomly selected input as by Markov's inequality for any $k > 0$ it is

$$\Pr[\, T(x, n) \geq k n^{\frac{1}{\varepsilon}} \,] \leq \frac{c}{k^\varepsilon}.$$

In this paper we only consider the case where $X \subseteq \mathbb{R}^d$, Σ is the Borel algebra over $\mathbb{R}^d$ and $\mu(A) = \frac{\lambda(A)}{\lambda(X)}$ where λ denotes the Lebesgue measure on $\mathbb{R}^d$.

3 Complexity of simulating dynamical systems

Dynamical systems are used to describe the evolution of a system over time. A dynamical system on the reals can be formally defined as follows:

▶ **Definition 2.** A dynamical system is a triple (X, T, Φ) of a non-empty set $X \subset \mathbb{R}^d$ called the *phase space*, a time set $T \subseteq \mathbb{R}$ and a (partial) function $\Phi :\subseteq X \times T \to X$ called *evolution operator* satisfying

1. $\Phi(x, 0) = x$, and
2. $\Phi(\Phi(x, t_1), t_2) = \Phi(x, t_1 + t_2)$

for $x \in X$ and all $t_1, t_2 \in T$ such that $(x, t_1), (\Phi(x, t_1), t_2) \in \operatorname{dom} \Phi$.

A point $x \in X$ is also called a *state* of the system and $\Phi(x_0, t)$ the state at time t (w.r.t. the initial value x_0). For a fixed initial value x_0 the function $\Phi(x_0, \cdot)$ is called *trajectory* through x_0. In this paper we only consider continuous-time systems where the time set is some real interval and the evolution operator is continuously differentiable with respect to time. The dynamics of such a system can be described by the solution of a system of autonomous first-order ODEs

$$\dot{y} = f(y), \quad y(t_0) = y_0 \tag{2}$$

for some function $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ and $y_0 \in \mathbb{R}^d$.

We call Equation (2) an *initial value problem* (IVP) with initial value y_0. The corresponding solution function $y : \mathbb{R} \to \mathbb{R}^d$ of the IVP gives a trajectory of the system. We sometimes also write $y(t; t_0, y_0)$ for the solution function with initial value $y(t_0) = y_0$ to make the dependency on the initial value explicit.

In the following, we use multi-index notation for tuples of non-negative integers $\beta = (\beta_1, \ldots, \beta_d)$, i.e., for $\beta \in \mathbb{N}^d$ and $x \in \mathbb{R}^d$ it is $|\beta| = \beta_1 + \cdots + \beta_d$, $\beta! = \beta_1! \ldots \beta_d!$, $x^\beta = x_1^{\beta_1} \ldots x_d^{\beta_d}$ and $D^\beta f = D_1^{\beta_1} \ldots D_d^{\beta_d} f$.

A function $f : U \to \mathbb{R}$ for $U \subseteq \mathbb{R}^d$ open is called *analytic* if for each $x_0 \in U$ there is an open neighborhood $V \subseteq U$ of x_0 such that for all $x \in V$ the power series expansion

$$\sum\nolimits_{\beta \in \mathbb{N}^d} a_\beta (x - x_0)^\beta$$

converges to $f(x)$. A function $f : D \to \mathbb{R}$ on a (possibly) non-open domain D is called analytic if it can be extended to an analytic function on some open domain $U \supseteq D$.

We further say a function $f : D \to \mathbb{R}^m, f(x) = (f_1(x), \ldots, f_m(x))$ is analytic if each of the component functions $f_1, \ldots, f_d : D \to \mathbb{R}$ are analytic. Any function analytic on some subset $D \subseteq \mathbb{R}^d$ can be extended to a complex analytic function on an open set $G \subseteq \mathbb{C}^d$. In this paper we only consider IVPs where the right-hand side function f is analytic. By the Cauchy-Kowalevski theorem the solution function y of such an IVP is again analytic.

3.1 Parameterized complexity for analytic initial value problems

Most results on IVPs in computable analysis assume the initial value to be fixed. In this work, however, we want to consider the average complexity over all initial values. We therefore first need to formalize how exactly the complexity of the solution depends on the chosen initial value. More formally, assume that we allow initial values from some set $A \subseteq \mathbb{R}^d$. We want to give a complexity bound for the solution function $Y :\subseteq A \times [0, 1] \to \mathbb{R}^d, (y_0, t) \mapsto y(t; 0, y_0)$ that maps initial values at time 0 and time $t \in [0, 1]$ to the solution of the initial value

problem at time t. Note that the restriction that the time is between 0 and 1 is somehow arbitrary. However, for the average-case analysis in the following chapter it is reasonable to assume that the time is bounded as there is no natural choice for a distribution on time.

The domain of Y are tuples $(y_0, t) \in A \times [0,1]$ where the solution with initial value y_0 exists up to time t. As this domain is not necessarily compact, we can not expect to find a simple complexity bound on the whole domain. However, we can subdivide the domain into subsets depending on some natural parameter of the system and give a complexity not only in terms of the output precision n but also in terms of an additional integer parameter. That is, we want to say that there is a uniform algorithm that computes the function on its whole domain and if we restrict the domain to some subset this algorithm runs in time polynomial in the output precision n and some parameter depending on the subset. We formalize this in the following definition.

▶ **Definition 3.** Let $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^e$ be a computable real function and let $D = \bigcup_{i \in I} D_i$ be some (fixed) partition of its domain with index set I. We say f is C-polynomial-time computable for a function $C : I \to \mathbb{N}$ if there is an oracle machine M that

1. computes f on all inputs $x \in D$, and
2. there is a polynomial $p : \mathbb{N} \to \mathbb{N}$ such that on inputs $x \in D_i$ the machine outputs a 2^{-n} approximation of $f(x)$ after at most $p(C(i) + n)$ steps.

We will usually partition the domain in terms of some positive real parameter α and use the short-hand notation "f is α^{-1}-polynomial-time computable on D_α". Formally, this means that f is C-polynomial-time computable w.r.t. the partition of the domain $D = \bigcup_{\alpha > 0} D_\alpha$ and the function $C : \mathbb{R}^+ \to \mathbb{N},\ C(\alpha) = \lceil \alpha^{-1} \rceil$.

Assume we are given an initial value problem (2) and the right-hand side function f is analytic on some compact $K \subseteq \operatorname{dom} f$. Then there is some integer C_K such that the bound

$$\left| D^\beta f(x) \right| \leq C_K^{|\beta|+1} \beta! \tag{3}$$

holds for all $\beta \in \mathbb{N}^d$ and $x \in K$ [10]. On the other hand, if for some $y_0 \in \operatorname{dom} f$ the solution exists up to time T then $y([0,T])$ is a compact subset of the domain. Thus, restricting f to this set suffices to compute the solution.

We usually can not assume that f is polynomial-time computable on its whole domain since its values can be unbounded. On the other hand on any compact subset $K \subseteq \operatorname{dom} f$ of the domain, C_K is an upper bound for the values of f. It is therefore a reasonable assumption that f is C-polynomial-time computable where C denotes a function that assigns each compact subset $K \subseteq \operatorname{dom} f$ an integer C_K as in Equation (3).

For simplicity let us from now assume that $T = 1$, i.e., we only consider initial values for which the solution exists up to time 1. The following theorem characterizes the complexity of the solution in terms of the parameterization given by C.

▶ **Theorem 4.** *Assume $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ is analytic and computable. Let $D_0 \subseteq D$ be some subset of initial values $y_0 \in D$ such that the solution y to the IVP (2) with initial value y_0 exists for all $t \in [0,1]$. For each $y_0 \in D_0$ let further $K(y_0) := y([0,1]; 0, y_0)$ and $D' := \bigcup_{y_0 \in D_0} K(y_0)$. Assume there is a function $C : D_0 \to \mathbb{N}$ such that*

- *f restricted to D' is C-polynomial-time computable, and*
- *$C(y_0)$ is a derivative bound for f on $K(y_0)$ as in (3).*

Then there exists a C-polynomial-time computable function $Z : \mathbb{R}^d \times [0,1] \times \mathbb{N} \to \mathbb{R}^d$ such that $Z(y_0, t, C(y_0)) = Y(y_0, t)$ for all $y_0 \in D_0$ and $t \in [0,1]$. That is, Z computes Y when given $C(y_0)$ as additional information.

Note that in general it is not possible to effectively get the parameter $C(y_0)$ from the function [2, 20]. Thus, in the above theorem we have to provide it as an additional input. For most natural systems, however, it is usually easy to get an upper bound for the parameter. We therefore assume that we can effectively get the parameter for the rest of the paper.

The main idea of the proof is that a simple power series based approach suffices to compute a local solution on some small time interval $[t_0, t_0 + \delta]$ in time polynomial in $n + C(y_0)$ (see e.g. [17]). To get a solution on a bigger interval this algorithm can be iterated several times. To show theorem 4 it therefore suffices to show that polynomially in $C(y_0)$ many iterations suffice and that it suffices to compute the intermediate values in each iteration with polynomial precision. The proof of the theorem is very similar to the proof of a recent result by Bournez, Graça and Pouly [1] for polynomial ODEs over unbounded time. We therefore chose to omit the details here. However, as both the statement and notation of our theorem are quite different from theirs, we included a proof in the appendix for completeness.

4 Average-case complexity for dynamical systems

While theorem 4 gives a very general characterization for the complexity of simulating initial value problems, it is usually not very useful as the complexity bound can differ for each initial value y_0. In general there is no way around this as the trajectories for distinct initial values can be quite different. On the other hand, it might be the case that most trajectories behave nicely in the sense that they stay far away from singularities of the system. In that case, we would like to say that the simulation can "usually" be done efficiently. This notion can be made formal using average-case complexity.

Such an average-case analysis, however, requires that we can get a bound on the probability for a trajectory to come close to a singularity. Usually, there is no easy way to assign such a probability. On the other hand, if the system has the special property that the volume of subsets of phase-space is preserved over time then a small volume of singularities in phase space indicates that the set of initial values coming close to singularities is also small. A large class of dynamical systems that have this property are *Hamiltonian systems*.

A d degree-of-freedom (time-independent) Hamiltonian system is a $2d$-dimensional dynamical system $\dot{y} = f(y)$ where the state can be split into two variables $y(t) = (q(t), p(t))$ for smooth functions $q, p : \mathbb{R} \to \mathbb{R}^d$ that satisfy the system of $2d$ first order ordinary differential equations

$$\dot{q}(t) = \frac{\partial H(p,q)}{\partial p}, \quad \dot{p}(t) = -\frac{\partial H(p,q)}{\partial q} \tag{4}$$

for some smooth, real-valued function $H : \mathbb{R}^{2d} \to \mathbb{R}$. The functions q and p are called the *position* and *momentum* of the system and H is called the *Hamiltonian*. We only consider time-independent systems where the Hamiltonian is constant over time and therefore is sometimes also called the *energy* of the system.

4.1 Average-case complexity for Hamiltonian system

In this chapter we define some criteria under which a given Hamiltonian system can be simulated in polynomial time on average. Here, it is more natural to formalize the results in terms of distance to complex singularities of a complex analytic extension instead of a derivative bound. We first (independently of the system being Hamiltonian or not) formalize the notion of a point being close to a (complex) singularity of an analytic function.

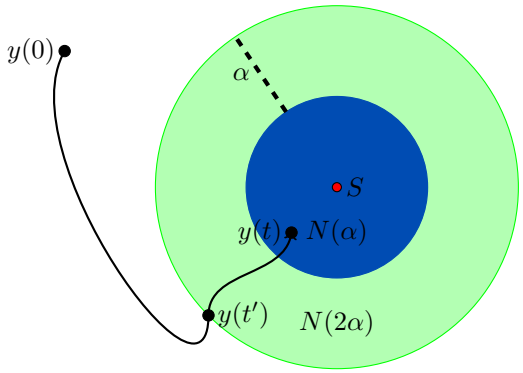

Figure 1 An α-singularity is a state of the system where the distance to a singularity is at most α. If the distance at time $t = 0$ is at least 2α and there is an α-singularity at time $t > 0$ there has to be some time t' when $y(t')$ is 2α close to the singularity. While the distance is between 2α and α the velocity is bounded which can be used to bound the minimum time the particle has to spend in the green region.

▶ **Definition 5.** Let $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ analytic. For any $\alpha > 0$ and $A \subseteq D$ we define the following sets:

1. $G(\alpha)$ is the set of points $x \in D$ such that there is a complex analytic extension $\widetilde{f}$ of f that is analytic on all $z \in \mathbb{C}^d$ with $|x - z| \leq \alpha$,
2. $N(\alpha) := D \setminus G(\alpha)$,
3. $R_A \subseteq D$ is the set of points reachable from A in time $t \leq 1$, i.e., $x \in R_A$ if there is $y_0 \in A$ and $t \in [0, 1]$ such that $y(t; 0, y_0) = x$,
4. $G_A(\alpha) := G(\alpha) \cap R_A$ and $N_A(\alpha) := N(\alpha) \cap R_A$,
5. $A(\alpha) := \{y_0 \in A : y(t; 0, y_0) \in G(\alpha) \text{ for all } t \in [0, 1]\}$,
6. $B(\alpha) := A \setminus A(\alpha)$.

We call a point $x \in N(\alpha)$ an *α-singularity*, $x \in A(\alpha)$ an *α-good* initial value (*α-bad* for $x \in B(\alpha)$) and points in R_A *reachable points*.

If we restrict the initial values to be contained in a set A and the volume of $B(\alpha)$ is small in comparison to A and if the growth of f behaves "nicely" on $G(\alpha)$ then the simulation can be done in polynomial time on average:

▶ **Theorem 6.** *Let $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ analytic and computable. Consider the solution function Y to the IVP (2) restricted to a bounded subset of initial values $A \subseteq D$. Assume that there is some polynomial $m : \mathbb{N} \to \mathbb{N}$ such that $\left|\tilde{f}\right| \leq m(\alpha^{-1})$ holds for any point in $G_A(\frac{\alpha}{2})$ and that f on $G_A(\alpha)$ is α^{-1}-polynomial-time computable. Then*

1. *Y is α^{-1}-polynomial-time computable on initial values in $A(\alpha)$, and*
2. *If there is additionally some constant $\gamma > 0$ such that $\frac{\lambda(B(\alpha))}{\lambda(A)} \leq \alpha^{\gamma}$ then Y can be computed in polynomial time on average (w.r.t. the restriction of d-dimensional Lebesgue measure to A).*

Proof. We show how to apply theorem 4 to prove the first part of the theorem. Let us first show that the polynomial m can be used to get a derivative bound on $G(\alpha)$.

Assume $\left|\tilde{f}(z)\right| \leq M(\alpha)$ for all $z \in G(\frac{\alpha}{2})$ for a function M with $M(\alpha) \geq \frac{2}{\alpha}$. For $z_0 \in G(\alpha)$, consider the polydisc $D = \prod_{i=1}^{d} D_i$ with $D_i := \{z \in \mathbb{C} : |z_{0,i} - z| \leq \frac{\alpha}{2}\}$. Now, $\tilde{f}$ is analytic

on D by the definition of $G(\alpha)$. Furthermore $\left|\tilde{f}\right|$ is bounded on D by $M(\alpha)$. By Cauchy's integral formula it follows

$$\begin{aligned}\left|D^\beta f(z_0)\right| &= \left|\frac{\beta!}{(2\pi i)^d}\int_{\xi_1\in\partial D_1}\cdots\int_{\xi_d\in\partial D_d}\frac{f(\xi_1,\ldots,\xi_d)}{(\xi_1-z_{0,1})^{\beta_1+1}\cdots(\xi_d-z_{0,d})^{\beta_d+1}}\right| d\xi_1\cdots d\xi_d \\ &\leq \frac{\beta!}{(2\pi)^d}\left(2\pi\frac{\alpha}{2}\right)^d\frac{M(\alpha)}{(\frac{\alpha}{2})^{\beta+d}} = \beta!M(\alpha)\left(\frac{2}{\alpha}\right)^\beta.\end{aligned}$$

Therefore, $\left|D^\beta f(z_0)\right| \leq \beta!M(\alpha)^{|\beta|+1}$ for all $z_0 \in G(\alpha)$. As we assume that the set of initial values is bounded and $t \in [0,1]$, it further follows that the absolute value of points in $G_A(\alpha)$ is bounded by a linear function in $M(\alpha)$. Thus we can apply theorem 4 using the partition of the domain into sets $K_\alpha = G_A(\alpha)$ which concludes the proof of the first part of the theorem.

For the second part let μ be the restriction of the Lebesgue measure to A, i.e., $\mu(B) = \frac{\lambda(B)}{\lambda(A)}$ for all measurable subsets $B \subseteq A$. Let further $A_i = A(2^{-(i+1)}) \setminus A(2^{-i})$, i.e., A_i contains the initial values where the minimum distance to a complex singularity for any $t \in [0,1]$ is between 2^{-i} and $2^{-(i+1)}$. Since $A_i \subseteq B(2^{-i})$ it holds $\lambda(A_i) \leq \lambda(B(2^{-i}))$ and by assumption $\mu(A_i) \leq 2^{-i\gamma}$. On the other hand A_i is contained in $A(2^{-(i+1)})$ thus by the first part of the theorem and the assumption on the time bound of f it follows that Y is computable on initial values in A_i in time $u(n+2^i)$ for a polynomial u. Since $A = \bigcup_{i=0}^\infty A_i$ it holds

$$\int_A \frac{1}{n}T(x,n)^\varepsilon d\mu \leq \frac{1}{n}\sum_{i=0}^\infty \mu(A_i)T(A_i,n)^\varepsilon \leq \frac{1}{n}\sum_{i=0}^\infty 2^{-i\gamma}u(n+2^i)^\varepsilon$$

Let m be the highest coefficient in the polynomial u then for $\varepsilon \leq \frac{\gamma}{2m}$ the sum converges and thus $\int_A \frac{1}{n}T(x,n)^\varepsilon d\mu$ is bounded. ◀

Theorem 6 holds even if the system is not Hamiltonian, but usually there is no simple way to get a bound for the measure for the second part of the theorem. For Hamiltonian systems, on the other hand, we can exploit the fact that they preserve phase-space volume over time (this is known as Liouville's theorem). Thus, there is a relation between the volume $\lambda(A(\alpha))$ of initial values leading to almost singularities and the volume $\lambda(N_A(\alpha))$ of almost singularities in phase-space.

Saari uses a similar idea to show that for the three-body problem the set of initial values leading to collisions has measure 0. However, for our application we need a stronger quantification of how the measure correlates to the distance of the particles. The main difficulty is that almost singularities can occur at any time $t \in [0,1]$. Thus, theoretically we would have to consider infinitely many "copies" of $N_A(\alpha)$, one for each possible time. Saari manages to replace this by only countably infinite many copies which suffices to show that the set of initial values leading to collisions has measure zero. However, this approach does does not suffice to give a bound for α-singularities with $\alpha > 0$. We therefore need a slightly more complicated idea to show that finitely many copies suffice in our case. Note, however, that Saari's result holds for unbounded time while our idea is based on the time being bounded. In fact, a generalization of our result to unbounded time turns out to be false [27].

Let us now state our main theorem. As the property of preserving phase-space volume is in fact the only attribute we use about Hamiltonian systems, we can formulate the theorem in terms of the bigger class of volume-preserving (sometimes also called conservative) dynamical systems.

▶ **Theorem 7.** *Let $\dot{y} = f(y)$ be a volume-preserving dynamical system with $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ computable and analytic and let $A \subseteq D$ be a bounded subset of initial values. Assume that*

- *f is α^{-1}-polynomial-time computable on α-good initial values $y_0 \in G_A(\alpha)$,*
- *for all $\alpha > 0$ the measure of α-bad subsets of phase space is bounded by $\lambda(N_A(\alpha)) \leq \alpha^\gamma$ for some $\gamma > 0$,*
- *$\left|\widetilde{f}\right|$ is bounded by $M_\alpha := M(\lceil \alpha^{-1} \rceil)$ for a polynomial $M : \mathbb{N} \to \mathbb{N}$ on $N(2\alpha) \setminus N(\alpha)$.*

Then

1. *$\lambda(B(\alpha)) \leq \left(\frac{2M_\alpha}{\alpha} + 1\right)\lambda(N_A(2\alpha))$*
2. *The solution function $Y :\subseteq A \times [0,1] \to \mathbb{R}^d$ is polynomial-time computable on average.*

Proof. We only prove the first part. The second part then follows by applying theorem 6. For any $t \in [0,1]$ let $B_t(\alpha) \subseteq A$ be the subset of initial values that lead to an α-singularity at time t, i.e., $y_0 \in B_t(\alpha)$ iff $y(t; 0, y_0) \in N(\alpha)$. As the system is volume-preserving it holds $\lambda(B_t(\alpha)) \leq \lambda(N_A(\alpha))$ for all t and α. Obviously, $B(\alpha) = \bigcup_{t\in[0,1]} B_t(\alpha)$.

We now show that we can replace the infinite union by a union of finitely many slightly bigger sets. Let $y(0) \in B_t(\alpha)$ for some $t \in [0,1]$, i.e., $y(0)$ is an initial value such that $y(t) \in N(\alpha)$. If $y(0) \in N(2\alpha)$ then it holds that $y(0) \in B_0(2\alpha)$ by definition. Otherwise there has to be some time $t' > 0$ where $y(t') \in N(2\alpha) \setminus N(\alpha)$ for the first time (see Fig. 1). As for any $z \in N(2\alpha) \setminus N(\alpha)$ by assumption $\left|\tilde{f}(z)\right| \leq M_\alpha$. It follows that for any $s \in [t', t' + \frac{\alpha}{M_\alpha}]$ the difference of the state at time t' and the state at time s can be at most α, i.e., $y(s) \in G(\alpha)$. In particular, if $y(0) \in G(2\alpha)$ and for some $t \in [0,1]$ it holds that $y(t) \in N(\alpha)$ then there is some non-trivial time interval $[t_1, t_2]$ of length at least $\frac{\alpha}{M_\alpha}$ such that $y(s) \in N(2\alpha) \setminus N(\alpha)$ for all $s \in [t_1, t_2]$. Therefore, $[t_1, t_2]$ contains some multiple t^* of $\frac{\alpha}{2M_\alpha}$. In particular, $y(t^*) \in N(2\alpha)$ and thus by definition $y(0) \in B_{t^*}(2\alpha)$. This shows that for the finite subset $\{t_k\}_k \subset [0,1]$ of multiples of $\frac{\alpha}{2M\alpha}$ it holds that $B(\alpha) \subseteq \bigcup_{t_k} B_{t_k}(2\alpha)$. By applying the fact that the system is volume-preserving it holds $\lambda(B_{t_k}(2\alpha)) \leq \lambda(N_A(2\alpha))$ and thus the statement follows. ◀

4.2 Average-case complexity for the restricted three-body problem

As an application of theorem 7 we show that the solution of the restricted three-body problem can be computed in polynomial-time on average. The classical three-body problem is the problem of predicting the motion of three point masses under their mutual gravitational attraction. An important special case is that we assume that one particle P_3 has much smaller mass than the other two P_1 and P_2. In that case P_3 does not influence the motion of P_1 and P_2 significantly. The problem can therefore be simplified by assuming that P_3 is massless. The motion of the heavy particles can then be seen as a two-body problem. A further simplification can be achieved by assuming that the heavy particles move on a circular orbit around their common center of mass and P_3 only moves in the plane defined by P_1 and P_2. This problem is known as the *planar circular restricted three-body problem*. In spite of being much simpler than the general problem, the restricted problem shares many of the properties of the N-body problem that makes it interesting for our analysis. In particular, the restricted problem is a Hamiltonian dynamical system where the equation of motion is given by an analytic initial value problem. There is no general closed form solution and the motion can be chaotic [15]. The restricted three-body problem has been studied extensively by mathematicians and engineers.

By choosing appropriate units of measurement and a rotating coordinate system, the system can be brought in a simpler, normalized form only depending on a single parameter $\mu \in (0, 0.5]$. The masses of the particles P_1 and P_2 in the new units are given by μ and $1 - \mu$, respectively. The position of the heavy particles in the rotating coordinate system remains

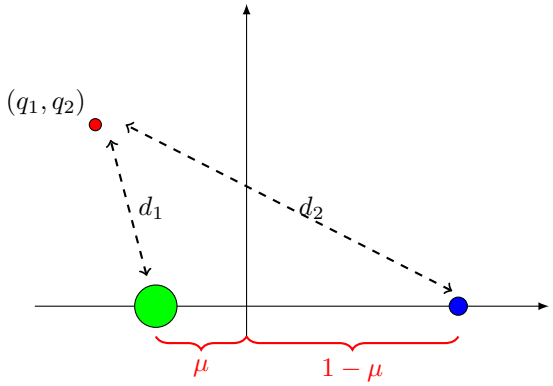

Figure 2 The planar circular restricted three-body problem in normalized form. P_1 and P_2 are fixed at position $(-\mu, 0)$ and $(1-\mu, 0)$. They have masses $1-\mu$ and μ and influence the motion of the massless particle P_3 at position (q_1, q_2).

fixed at $(-\mu, 0)$ and $(1-\mu, 0)$. We use $q = (q_1, q_2)$ to describe the coordinates of P_3 relative to that coordinate system (see Figure 2). A full derivation for the transformations as well as formulas to translate a solution for the normalized system to a solution for the non-modified system can e.g. be found in [11].

In Hamiltonian form the IVP can be written in terms of position $q \in \mathbb{R}^2$ and moment $p \in \mathbb{R}^2$ as

$$H(p,q) = \frac{1}{2}\|p\|^2 + q_2 p_1 - q_1 p_2 - \frac{\mu}{d_1} - \frac{1-\mu}{d_2} \tag{5}$$

where $d_1 := \sqrt{(q_1+\mu)^2 + q_2^2}$ and $d_2 := \sqrt{(q_1+\mu-1)^2 + q_2^2}$. This defines a dynamical system with phase space $\Gamma \subseteq \mathbb{R}^4$. We sometimes also consider the velocity of the particle given by $v(t) = (p_1(t) + q_2(t), p_2(t) - q_1(t))$ instead of the moment.

We assume that we start the simulation with initial values in the set A of points q_0, p_0 with $|q_0| \leq 1$ and $|p_0| \leq 1$. We first make the additional assumption that the energy is bounded by some constant $h > 0$, i.e., it holds $|H(q_0, p_0)| \leq h$. We denote the subset of initial values satisfying this bound by A_h.

In this problem, an α-singularity corresponds to the situation where P_3 gets close to either P_1 or P_2. Note that the absolute value of the moments tend to infinity when approaching a singularity. A bound on the volume of α-singularities in phase-space is given by the following lemma.

▶ **Lemma 8.** *For any $\alpha \in [0, 0.5]$, the Lebesgue measure of $N_{A_h}(\alpha)$ is given by $\lambda(N_{A_h}(\alpha)) \leq 8\pi^2 h \alpha^2$.*

Proof. We show that for the set $N_1(\alpha)$ of points coming close to P_1 it holds that $\lambda(N_1(\alpha)) \leq \pi^2 h \alpha^2$. Then the claim follows as $N_{A_h}(\alpha) = N_1(\alpha) \cup N_2(\alpha)$. We first change to a new coordinate system (x, v) in terms of position and velocity of the particle such that P_1 is at the origin (note that this change preserves volume). The Hamiltonian of the problem in these coordinates can be written as

$$E(x,v) = \frac{1}{2}\|v\|^2 - \frac{1}{2}\|x\|^2 + x_1\mu - \frac{\mu}{\|x\|} - \frac{1-\mu}{d_2} - 0.5\mu^2$$

Let $\Gamma \subseteq \mathbb{R}^4$ the phase-space of the problem. Γ can be parameterized in terms of the position

and the energy E by

$$\Phi : (E, r, \varphi, \psi) \;\mapsto\; \big(r\cos(\varphi), r\sin(\varphi), R(E, r, \varphi)\cos(\psi), R(E, r, \varphi)\sin(\psi)\big) \tag{6}$$

with

$$R(E, r, \varphi) := \sqrt{2E + \mu^2 - 2\mu r\cos(\varphi) + \frac{2\mu}{r} + \frac{2-2\mu}{d_2} + r^2} \tag{7}$$

It is $N_1(\alpha) \subseteq \Phi(G)$ with $G := [-h, h] \times [0, \alpha] \times [0, 2\pi) \times [0, 2\pi)$. Thus the volume can be bounded by

$$\lambda(N_1(h, \alpha)) \;\le\; \int_{\Phi(G)} dq_1\, dq_2\, dv_1\, dv_2 \;=\; \int_G |\det(\mathrm{D}\,\Phi)|\, dr\, dh\, d\varphi\, d\psi \;=\; 4\pi^2 \cdot \alpha^2 \cdot h.$$

The last equality holds since $\det(\mathrm{D}\,\Phi) = r$. ◀

It further holds that a bound on the energy implies that both the position and the velocity of the particle are bounded as long as the particle does not get close to one of the singularities.

▶ **Lemma 9.** *For any $q, v \in G(\alpha) \cap A_h$ it holds $\|q\| \le 2h + 10$ and $\|v\| \le \sqrt{(2h+11)^2 + \frac{1}{\alpha}}$.*

Proof. Assume $d_1 \ge \alpha$ and $d_2 \ge \alpha$. The Hamiltonian in terms of the velocity is given by

$$H(v, q) = \frac{1}{2}\|v\|^2 - \frac{\mu}{d_1} - \frac{1-\mu}{d_2} - \frac{1}{2}\|q\|^2.$$

Thus the bound on the Hamiltonian implies the bound

$$\|v\|^2 \le 2h + |q|^2 + \frac{2}{\alpha} \tag{8}$$

on the velocity.

Now assume $\|q\| \ge 2$ then both $d_1 \ge 1$ and $d_2 \ge 2$ and thus $\|v\|^2 \le 2h + |q|^2 + 2$ holds. Let $h' = \max(h, 2)$ then $\|v\| \le h' + \|q\|$. Now consider for $n \ge 1$ the subsets U_n where $n-1 \le \|q\| \le n$. For $n \ge 3$, $(q, v) \in U_n$ implies that $\|v\| \le h' + n$. In particular the minimum time to get from U_n to U_{n+1} is $t_n := \frac{1}{h'+n}$. As for the initial values $\|q\| \le 2$ the minimum time needed to reach a state where $\|q\| \ge N$ is bounded by

$$T_N := \sum_{i=3}^{N} \frac{1}{h' + n} = \mathcal{H}_{N+h'+3} - \mathcal{H}_{h'+3}$$

where $\mathcal{H}_N := \sum_{k=1}^{N} \frac{1}{k}$ denotes the N-th *harmonic number*. By the well known bound

$$\gamma + \log(N) \le \mathcal{H}_N \le \gamma + \log(N+1)$$

it holds

$$T_N \ge \log\left(\frac{N + h' + 3}{h' + 4}\right).$$

As the time is bounded by 1 it follows that $\|q\| \le 2h' + 6 \le 2h + 10$. Inserting this back into (8) yields

$$\|v\| \le \sqrt{2h + (2h+10)^2 + \frac{2}{\alpha}}$$

from which the claim follows. ◀

From this it can be easily followed that the right-hand side function of the ODE system is computable in time polynomial in $\lceil \alpha^{-1} \rceil$ and h and that a polynomial bound in those terms holds for complex analytic extensions of the function on $N(2\alpha) \setminus N(\alpha)$.

As for initial values it holds that the magnitude of both position and moment are bounded by 1, it follows from the Equation for the Hamiltonian (5) that high energy can only be due to particles being already close at time 0. In particular for α-good initial values the following bound on the Hamiltonian holds.

▶ **Lemma 10.** *Assume* $\|q\| \leq 1$, $\|p\| \leq 1$ *and* $q, p \notin N(\alpha)$ *then* $H(p,q) \leq 3 + \frac{2}{\alpha}$.

Thus the above polynomial bounds can all be stated only in terms of α. In particular all conditions in theorem 7 are satisfied and thus the problem is polynomial-time computable on average:

▶ **Theorem 11.** *Simulating the restricted three-body problem for time* $t \leq 1$ *for initial values* p_0, q_0 *with* $|p_0| \leq 1$, $|q_0| \leq 1$ *is possible in polynomial time on average.*

5 Conclusion

We applied a recent definition of average-case complexity in analysis to problems in classical physics. We gave some general conditions which show that a continuous-time system can be computed efficiently on average. For the important special case of Hamiltonian systems, we showed that a simpler approach based on the volume of almost singularities in phase-space usually suffices. We applied our theory to the planar circular restricted three-body problem and showed that it indeed can be computed in polynomial time on average. The same can easily be done for some other simple dynamical systems.

However, our theory does not easily generalize to some other more complicated systems like the classical N-body problem as bounding the volume of singularities in phase space is more complicated for these systems. While we think that most systems in nature can indeed be simulated efficiently and that a similar result holds for, e.g., the general N-body problem it is unlikely that our approach can be easily adapted to this case as for $N > 4$ it is not even known if the set of initial conditions leading to singularities has measure zero.

Nonetheless, we hope that we can at least extend our theory to the general three-body problem and some other interesting problems in future work.

A Proof of Theorem 4

The proof consists of two parts. We first show that the local solution on some small interval with length polynomial in $C(y_0)^{-2}$ can be computed in $C(y_0)$-polynomial time. We then show that iterating the algorithm for the local solution until reaching time $t = 1$ can still be done within this complexity bound.

A.1 Computing a local solution

We formulate the complexity result for the local solution as the following Lemma.

▶ **Lemma 12.** *Let $D \subseteq \mathbb{R}^d$ analytic and computable. Then there is an algorithm that given an initial $y_0 \in \mathbb{R}^d$, time $t \in \mathbb{R}$ and an integer $C \in \mathbb{N}$ such that C is a derivative bound for f on the closed ball $\overline{B_C(y_0)}$ of radius $\frac{1}{C}$ around y_0 returns the solution $y(t)$ to the IVP (2) for any t with $|t - t_0| \leq \frac{1}{2(d+1)C^2}$. Assume f is C-polynomial-time computable on $\overline{B_C(y_0)}$ then so is y for all t that satisfy the above bound.*

Proof. Cauchy's existence theorem guarantees that the solution exists and is analytic on this time-interval. The polynomial-time result has in principle already been shown, e.g., by Moiske and Müller [17]. The main idea is to first compute the coefficients of the power series of f around t_0. Müller [19] showed that with the above bounds for any $\beta \in \mathbb{N}^d$ the coefficient a_β is computable in time polynomial in $n + C + |\beta|$. Further, if the power series of f around y_0 can be computed in time $T_f(n + |\beta|)$ then the k-th coefficient of the power series $(b_k)_{k\in\mathbb{N}}$ of any of the d components $y_1, \ldots, y_d$ of solution function y around t_0 can be computed from the power series of f in time $\mathrm{O}(k^d T_f(n + k^d))$.

For any $i = 1, \ldots, d$, the solution $y_i(t)$ for small enough t can then be approximated by summing up the truncated power series $\sum_{i=0}^{N} b_i(t - t_0)^i$ for some $N \in \mathbb{N}$. It can be shown that $|b_i| \leq (d + 1)^i C^{2i}$. Therefore for any t with $|t - t_0| \leq \frac{1}{2(d+1)C^2}$ it suffices to sum up $\mathrm{O}(n)$ coefficients to make the truncation error less than $2^{-(n+1)}$. To additionally make the approximation error less than $2^{-(n+1)}$ and thereby the total error less than 2^{-n} it suffices to approximate each b_i with error less than $2^{-(2n+1)}$. ◀

A.2 Extending to a global solution

We now prove the theorem by iterating the local solution algorithm. Let us first summarize the assumptions:

1. The right-hand side function $f : D \subseteq \mathbb{R}^d \to \mathbb{R}^d$ is analytic and computable,
2. The solution $y(t) := y(t; 0, y_0)$ exists for all time $t \in [0, 1]$,
3. Restricted to the set $K := y([0, 1]; 0, y_0)$ the integer C is a derivative-bound for f, i.e., $\left|D^\beta f(x)\right| \leq C^{|\beta|+1}\beta!$ for all $x \in K$,
4. The algorithm computing f gives a 2^{-n} approximation of $f(x)$ in time $poly(n + C)$ on any $x \in K$.

Note that each $x \in K$ is bounded by $|x| \leq C$ as it is in the image of y.

We want to show that iteratively using the local solution algorithm yields a polynomial-time algorithm mapping initial values $y_0 \in K$ and time $t \in [0, 1]$ to the solution $y(t)$ at time t.

Algorithm 1 Solving Initial Value Problems.

function SOLVE_IVP(f, y_0, t, n, C)
  $t_{curr} \leftarrow 0$
  $y_{curr} \leftarrow \text{APPROX}(y_0, m)$
  $h \leftarrow \frac{1}{2(d+1)C^2}$

  while $t_{curr} + h \leq t$ **do**
    $y_{curr} \leftarrow \text{LOCALSOLUTION}(y_{curr}, h, m, C)$
    $t_{curr} \leftarrow t_{curr} + h$
  return $\text{LOCALSOLUTION}(f, y_{curr}, t - t_{curr}, m, C)$

For this it suffices to show that we can always reach time 1 in polynomially many iterations and that it suffices to approximate all intermediate values with polynomial precision. For simplicity we fix the index i of the solution function y_i and simply denote it by y. By lemma 12 we can assume that there is an algorithm `LocalSolution` that computes for inputs $y_0 \in K$, $t \in [0,1]$ and $C, n \in \mathbb{N}$ with $t \leq \frac{1}{2(d+1)C^2}$ a rational approximation $q \in \mathbb{Q}$ such that $|y(t; t_0, y_0) - q| \leq 2^{-n}$. For a suitable choice of the intermediate precision parameter m Algorithm 1 computes an approximation q to the solution at any time $t \in [0,1]$ such that $|y(t; t_0, y_0) - q| \leq 2^{-n}$. It remains to show that m can be chosen to be polynomial in $n + C$. The algorithm makes at most $2(d+1)C^2$ steps to reach any time $t \in [0,1]$.

Let us first consider the error when computing the local solution y_{i+1} from y_i. There are two types of errors. The first one is due to the local solution algorithm only returning an approximation to the real solution with precision 2^{-m}. The second kind of error arises because of the accumulated error in y_i: Instead of solving the IVP problem with initial value y_i we use an approximation z_i of y_i as initial value. To bound the second kind of error we use the following fact:

▶ **Lemma 13.** *Assume $f : \mathbb{R}^d \to \mathbb{R}^d$ fulfills the conditions above. Then each component function $f_i : \mathbb{R}^d \to \mathbb{R}$ is Lipschitz-continuous on K with Lipschitz-constant $L = \sqrt{d}C^2$.*

Proof. This simply follows from the fact that all partial derivatives of f are bounded by C^2. ◀

This can be used to get a bound on the local error.

▶ **Lemma 14.** *Assume f fulfills the conditions above. Let $y_0, z_0 \in K$ be initial condition with $\|y_0 - z_0\|_\infty \leq \varepsilon$. Then for all $t < \frac{1}{2(d+1)C^2}$ it is $|y(t; y_0) - y(t; z_0)| \leq 2\varepsilon$.*

Proof. It holds that $y(t; y_0) = y_0 + \int_0^t |f(\mathbf{y}(\tau))|$. Thus

$$
\begin{aligned}
&|y(t; y_0) - y(t; z_0)| \\
&\leq |y_0 - z_0|_\infty + \int_0^t |f(y(\tau; y_0)) - f(y(\tau; z_0))| \, d\tau \\
&\leq \varepsilon + \int_{t_0}^t L \, |y(\tau; y_0) - y(\tau; z_0)| \, d\tau
\end{aligned}
$$

By Grönwall's Lemma [14, Chapter 1, Theorem 8.1] it follows that

$$|y(t; y_0) - y(t; z_0)| \leq \varepsilon e^{Lt}.$$

For $t \leq \frac{1}{2(d+1)C^2} \leq \frac{\sqrt{d}}{2(d+1)L}$ it then holds

$$|y(t;y_0) - y(t;z_0)| \leq \varepsilon e^{\frac{\sqrt{d}}{2(d+1)}} \leq 2\varepsilon. \qquad \blacktriangleleft$$

It is now easy to compute the total error for the algorithm depending on the parameter m for the intermediate precision.

▶ **Lemma 15.** *Assume algorithm 1 needs N iterations to reach the final time t. The total error E is bounded by $E \leq 2^{N+1-m}$.*

Proof. Let E_k be the error of y_{curr} after k iterations of the while-loop in Algorithm 1. It is $E_0 \leq 2^{-m}$ and $E_{k+1} \leq 2E_k + 2^{-m}$. It follows by induction that $E_N \leq 2^{N+1-m} - 2^{-m}$. ◀

Since the maximum number of iterations is bounded by $N = 2(d+1)C^2$ to achieve precision 2^{-n} it suffices to choose $m \geq n + 2(d+1)C^2 + 1$ which proves the theorem.

Generalized Budgeted Submodular Set Function Maximization

Abstract

In this paper we consider a generalization of the well-known budgeted maximum coverage problem. We are given a ground set of elements and a set of bins. The goal is to find a subset of elements along with an associated set of bins, such that the overall cost is at most a given budget, and the profit is maximized. Each bin has its own cost and the cost of each element depends on its associated bin. The profit is measured by a monotone submodular function over the elements.

We first present an algorithm that guarantees an approximation factor of $\frac{1}{2}\left(1-\frac{1}{e^{\alpha}}\right)$, where $\alpha \leq 1$ is the approximation factor of an algorithm for a sub-problem. We give two polynomial-time algorithms to solve this sub-problem. The first one gives us $\alpha = 1-\epsilon$ if the costs satisfies a specific condition, which is fulfilled in several relevant cases, including the unitary costs case and the problem of maximizing a monotone submodular function under a knapsack constraint. The second one guarantees $\alpha = 1-\frac{1}{e}-\epsilon$ for the general case. The gap between our approximation guarantees and the known inapproximability bounds is $\frac{1}{2}$.

We extend our algorithm to a bi-criterion approximation algorithm in which we are allowed to spend an extra budget up to a factor $\beta \geq 1$ to guarantee a $\frac{1}{2}\left(1-\frac{1}{e^{\alpha\beta}}\right)$-approximation. If we set $\beta = \frac{1}{\alpha}\ln\left(\frac{1}{2\epsilon}\right)$, the algorithm achieves an approximation factor of $\frac{1}{2}-\epsilon$, for any arbitrarily small $\epsilon > 0$.

1 Introduction

The Maximum Coverage (MC) is a fundamental combinatorial optimization problem which has several applications in job scheduling, facility locations and resource allocations [14, Ch. 3], as well as in influence maximization [17]. In the classical definition we are given a ground set X, a collection S of subsets of X with unit cost, and a budget k. The goal is selecting a subset $S' \subseteq S$, such that $|S'| \leq k$, and the number of elements of X covered by S' is maximized. A natural greedy algorithm starts with an empty solution and iteratively adds a set with maximum number of uncovered elements until k sets are selected. This algorithm has an approximation of $1 - \frac{1}{e}$ [20] and such result is tight given the inapproximability result due to Feige [11]. An interesting special case of the problem where this inapproximability result does not hold is when the size of the sets in S is small. In the maximum h-coverage, h denotes the maximum size of each set in S. This problem is APX-hard for any $h \geq 3$ [16] (notice that when $h = 2$ it is the maximum matching problem), while a simple polynomial local search heuristic has an approximation ratio very close to $\frac{2}{h}$ [4]. A polynomial time algorithm with approximation factor of $\frac{5}{6}$ is possible for the case when $h = 3$ [5]. In the Budgeted Maximum Coverage (BMC) problem, which is an extension of the maximum coverage, the cost of the sets in S are arbitrary, and thus a solution is feasible if the overall cost of the selected subset $S' \subseteq S$ is at most k. In [18], the authors present a polynomial time (greedy) algorithm with approximation factor of $1 - \frac{1}{e}$. In the Generalized Maximum Coverage (GMC) problem every set $s \in S$ has a cost $c(s)$, and every element $x \in X$ has a different weight and cost that depend on which set covers it. In [7], a polynomial time (greedy) algorithm with approximation factor of $1 - \frac{1}{e} - \epsilon$, for any $\epsilon > 0$, has been shown.

In all the above problems the profit of a solution is given by the sum of the weights of the covered elements. An important and studied extension is adopting a nonnegative, nondecreasing, submodular function f, which assigns a profit to each subset of elements. In the Submodular set Function subject to a Knapsack Constraint maximization (SFKC) problem we have a cost $c(x)$ for any element $x \in X$, and the goal is selecting a set $X' \subseteq X$ of elements that maximizes $f(X')$, where f is a monotone submodular function subject to the constraint that the sum of the costs of the selected elements is at most k. This problem admits a polynomial time algorithm that is $\left(1 - \frac{1}{e}\right)$-approximation [23]. Since the MC problem is a special case of SFKC problem, such result is tight. A more general setting was considered in [15], where the authors consider the following problem called Submodular Cost Submodular Knapsack (SCSK): given a set of elements $V = \{1, 2, \ldots, n\}$, two monotone non-decreasing submodular functions g and f ($f, g : 2^V \to \mathbb{R}$), and a budget b, the goal is finding a set of elements $X \subseteq V$ that maximizes the value $g(X)$ under the constraint that $f(X) \leq b$. They show that the problem cannot be approximated within any constant bound. Moreover, they give a $1/n$ approximation algorithm and mainly focus on bi-criterion approximation.

In this paper we consider the Generalized Budgeted submodular set function Maximization problem (GBSM) that is not captured by any of the above settings. We are given a ground set of elements X, a set of bins S, and a budget k. The goal is to find a subset of elements along with an associated set of bins such that the overall costs of both is at most a given budget and the profit is maximized. Each bin has its own cost, while the cost of each element depends on its associated bin. Finally, the profit is measured by a monotone submodular function over the elements.

We emphasize that the problem considered here is not a special case of the GMC problem, since we consider any monotone submodular functions for the profits. Moreover, it is possible to show that our cost function is not submodular and hence our problem is not a special

case of SCSK. Finally, our setting extends the SFKC problem, given that, the cost of an element is not fixed like in SFKC, but instead depends on the bin used for covering it.

In addition to its theoretical appeal, our setting is motivated by the adaptive seeding problem, which is an algorithmic challenge motivated by influence maximization in social networks [1, 22]. In its non-stochastic version, the problem is to select amongst certain accessible nodes in a network, and then select amongst neighbors of those nodes, in order to maximize a global objective function. In particular, given a set X and its neighbors $N(X)$ there is a monotone submodular function defined on $N(X)$, and the goal is to select $t \leq k$ elements in X connected to a set of size at most $k - t$ for which the submodular function has the largest value. Our setting is an extension of it since we consider more general costs.

1.1 Our results

In Section 3 we present an algorithm that guarantees an approximation factor of $\frac{1}{2}\left(1 - \frac{1}{e^{\alpha}}\right)$ for GBSM. Here, α is the approximation factor of an algorithm used to select a subset of elements whose ratio between marginal increment in the objective function and marginal cost is maximum. We give two polynomial-time algorithms to solve this sub-problem. In particular, in Section 4 we propose an algorithm that gives us $\alpha = 1 - \epsilon$ if the costs satisfy a specific condition. This latter is fulfilled in several relevant cases including the unitary costs case and the problem of maximizing a monotone submodular function under a knapsack constraint. In Section 5 we propose an algorithm that guarantees $\alpha = 1 - \frac{1}{e} - \epsilon$ for the general case.

The gap between our approximation guarantees and the known inapproximability bounds, i.e. the $1-\frac{1}{e}$ hardness for the MC problem [11] and the $1-\frac{1}{e^{1-\frac{1}{e}}}$ hardness for the non-stochastic adaptive seeding problem with knapsack constraint [21], is $\frac{1}{2}$, unless $P = NP$.

In Section 6, we extend our algorithm to a bi-criterion approximation algorithm in which we are allowed to spend an extra budget up to a factor β. An algorithm gives a $[\rho, \beta]$ bi-criterion approximation for GBSM if it is guaranteed to obtain a solution (S', X') such that $f(X') \geq \rho f(X^*)$ and $c(S', X') \leq \beta k$, where X^* is the optimal solution. We denote by β the extra-budget we are allowed to use in order to obtain a better approximation factor. Our algorithm guarantees a $\left[\frac{1}{2}\left(1 - \frac{1}{e^{\alpha\beta}}\right), \beta\right]$-approximation. If we set $\beta = \frac{1}{\alpha}\ln\left(\frac{1}{2\epsilon}\right)$, the algorithm achieves an approximation factor of $\frac{1}{2} - \epsilon$, for any arbitrarily small $\epsilon > 0$.

Due to space constraints, some of the proofs have been omitted and will appear in a full version of the paper.

1.2 Related work

Maximum coverage and submodular set function maximization are important problems. In the literature, besides the above mentioned ones, there are many other papers dealing with related issues. For instance, in the maximum coverage with group budgeted constraints, the set S is partitioned into groups, and the goal is to pick k sets from S to maximize the cardinality of their union with the restriction that at most one set can be picked from each group. In [6], the authors propose a $\frac{1}{2}$-approximation algorithms for this problem, and smaller constant approximation algorithm for the cost version. In the ground-set-cost budgeted maximum coverage problem, given a budget and a hypergraph, where each vertex has a non-negative cost and a non-negative profit, we want to select a set of hyperedges such that the total cost of the covered vertices is at most the budget and the total profit of all covered vertices is maximized. This problem is strictly harder than budgeted max coverage. The difference of our problem to the budgeted maximum coverage problem is that

the costs are associated with the covered vertices instead of the selected hyperedges. In [24], the authors obtain a $\frac{1}{2}\left(1-\frac{1}{\sqrt{e}}\right)$-approximation algorithm for graphs (which means having sets of size 2) and an FPTAS if the incidence graph of the hypergraph is a forest (i.e. the hypergraph is Berge-acyclic).

Maximizing submodular set function is another important research topic. The general version of the problem is: given a set of elements and a monotone submodular function, the goal is to find the subset of elements that gives the maximum value, subjected to some constraints. The case when the subset of elements must be an independent set of the matroid over the set of elements has been considered in [3], where the authors show an optimal randomized $\left(1-\frac{1}{e}\right)$-approximation algorithm. A simpler algorithm has been proposed in [13]. The case of multiple k matroid constraints has been considered in [19], where the authors give a $\frac{1}{k+\epsilon}$-approximation. An improved result appeared in [26]. Finally, unconstrained (resp. constrained) general non-monotone submodular maximization, have been considered in [2, 12] (resp. [25]).

Another related topic is the adaptive seeding problem in which the aim is to select amongst a set X of nodes of a network, called the *core*, and then adaptively selecting amongst the neighbors $N(X)$ of those nodes as they become accessible in order to maximize a submodular function of the selected nodes in $N(X)$ [1, 22]. An approximation algorithm with ratio $\left(1-\frac{1}{e}\right)^2$ has been proposed in [1]. In the adaptive seeding with knapsack constraints problem, nodes in X and in $N(X)$ are associated with a cost and the aim is to maximize the objective function while respecting a budget constraint. In this case, an $\left(1-\frac{1}{e}\right)\left(1-\frac{1}{e^{1-\frac{1}{e}}}\right)$-approximation algorithm is known [21]. In the non-stochastic version of these problems, all the nodes in $N(X)$ become accessible with probability one. Even in this case it is not possible to approximate an optimal solution within a factor greater than $\left(1-\frac{1}{e^{1-\frac{1}{e}}}\right)$, unless $P=NP$. A similar problem in which the core is made of the whole network and the network can be augmented by adding edges according to a given cost function has been shown to admit a 0.0878-approximation algorithm [9]. Finally, in [8, 10] the authors consider the problem where the core is made of a give set of nodes and the network can be augmented by adding edges incident only to the nodes in the core. In the unit-cost version of the problem where the cost of adding any edge is constant and equal to 1 the problem is NP-hard to be approximated within a constant factor greater than $1-(2e)^{-1}$. Then they provide a greedy approximation algorithm that guarantees an approximation factor of $1-\frac{1}{e}-\epsilon$, where ϵ is any positive real number. Then, they study the more general problem where the cost of edges is in $[0,1]$ and propose an algorithm that achieves an approximation guarantee of $1-\frac{1}{e}$ combining greedy and enumeration technique.

2 Preliminaries

We are given a set X of n elements and a set S of m bins. Let us denote the cost of a bin $s\in S$ by $c(s)\in\mathbb{R}_{\geq 0}$. For each bin $s\in S$ and element $x\in X$, we denote by $c(s,x)$ the cost of associating x to s. Given a budget $k\in\mathbb{R}_{\geq 0}$, and a monotone submodular function $f:2^X\to\mathbb{R}_{\geq 0}$[1], our goal is to find a subset X' of X and a subset $S'\neq\emptyset$ of S such that $c(S',X')=\sum_{s\in S'}c(s)+\sum_{x\in X'}\min_{s\in S'}c(s,x)\leq k$, and $f(X')$ is maximum. We call this problem the Generalized Budgeted submodular set function Maximization problem (GBSM).

[1] For a ground set X, a function $f:2^X\to\mathbb{R}_{\geq 0}$ is submodular if for any pair of sets $S\subseteq T\subseteq X$ and for any element $x\in X\setminus T$, $f(S\cup\{x\})-f(S)\geq f(T\cup\{x\})-f(T)$.

Our problem generalizes several well-known problems. Indeed, by setting $c(s,x) = \infty$, we do not allow the association of element x to bin s, while by setting $c(s,x) = 0$ we allow to assign element x to bin s with no additional cost. Moreover, we relax the constraints related to the association of elements to bins by setting $c(s) = 0$ for each $s \in S$, and $c(s_1,x) = c(s_2,x)$, for each $s_1, s_2 \in S$ and $x \in X$. By suitably combining these conditions we can capture the following problems: budgeted maximum coverage problem [18]; non-stochastic adaptive seeding problem [1] (also with knapsack constraints [21]); monotone submodular set function subject to a knapsack constraint maximization [23].

Let us consider a partial solution (S', X'). Given a set $T \subseteq X \setminus X'$, we denote by $c_{\min}(T)$ the minimum cost of associating the elements in T with a single bin in S, considering that the cost of bins in S' has been already paid, formally:

$$c_{\min}(T) = \min_{s \in S} \left\{ c_{S'}(s) + \sum_{x \in T} c(s,x) \right\},$$

where $c_{S'}(s) = c(s)$ if $s \notin S'$, and $c_{S'}(s) = 0$ if $s \in S'$. We call $c_{\min}(T)$ the *marginal cost* of T with respect to the partial solution (S', X'). We define $s_{\min}(T)$ as the bin $s \in S$ needed to cover T with cost $c_{\min}(T)$. Moreover, we denote by $\bar{c}(T)$ the cost of associating the elements in T to $s_{\min}(T)$, $\bar{c}(T) = c_{\min}(T) - c_{S'}(s_{\min}(T))$.

The *marginal increment* of $T \subseteq X$ with respect to the partial solution (S', X') is defined as $f(X' \cup T) - f(X')$. To simplify the notation, we use $g(T) = f(X' \cup T) - f(X')$ to denote the marginal increment.

In the algorithm in the next section, we will look for subsets of X that maximize the ratio between the marginal increment and the marginal cost with respect to some partial solution. In the following we define a family of subsets of X containing a set that approximates such maximal ratio. Given a partial solution (S', X'), we denote by $\mathcal{F}$ the family of subsets T of X that can be associated to bins in $S' \cup \{s\}$, for some single bin $s \in S$, with a cost such that $c(S' \cup \{s_{\min}(T)\}, T) \leq k$, formally $\mathcal{F} = \left\{ T \in 2^{X \setminus X'} \mid c(S' \cup \{s_{\min}(T)\}, T) \leq k \right\}$. A sub-family of $\mathcal{F}$ is an *α-list* with respect to (S', X') if it contains a subset T whose ratio between marginal increment and marginal cost is at least α times the optimal such ratio amongst all the subsets $\mathcal{F}$. Formally, $L \subseteq \mathcal{F}$ is an α-list with respect to (S', X') if

$$\max \left\{ \frac{g(T)}{c_{\min}(T)} \mid T \in L, c_{\min}(T) > 0 \right\} \geq \alpha \cdot \max \left\{ \frac{g(T)}{c_{\min}(T)} \mid T \in \mathcal{F}, c_{\min}(T) > 0 \right\}.$$

Note that the sets that maximize the above formula are not necessarily singletons due to the bin opening cost. Moreover, the algorithm given in the next section build partial solutions (S', X') in such a way that $c_{\min}(T) > 0$, for each $T \in \mathcal{F}$.

3 Greedy Algorithm

In this section we give an algorithm that guarantees a $\frac{1}{2}\left(1 - \frac{1}{e^{\alpha}}\right)$-approximation to the GBSM problem, if we assume that we can compute, in polynomial time, an α-list of polynomial size. In the next sections we will give two algorithms to compute such lists for bounded values of α.

The pseudo-code is reported in Algorithm 1. In the first step (line 3) we add all zero-cost bins to the solution. Then, the algorithm finds two candidate solutions. The first one is found at lines 4–11 with a greedy strategy as follows. The algorithm iteratively constructs a partial solution (S', X') by adding a subset $\hat{T}$ to X' and a bin $s_{\min}(\hat{T})$ to S'. In particular, at

6 Build an α-list L w.r.t. (S', X');
7 $\hat{T} := \arg\max_{T \in L} \frac{f(X' \cup T) - f(X')}{c_{\min}(T)}$;
8 **if** $c(S' \cup \{s_{\min}(\hat{T})\}, X' \cup \hat{T}) \leq k$ **then**
9 $S' := S' \cup \{s_{\min}(\hat{T})\}$;
10 $X' := X' \cup \hat{T}$;
11 **until** $c(S' \cup \{s_{\min}(\hat{T})\}, X' \cup \hat{T}) > k$ or $X' = X$;
12 **if** $f(\hat{T}) \geq f(X')$ **then**
13 $S' := S' \cup \{s_{\min}(\hat{T})\}$;
14 $X' := \hat{T}$;
15 **return** (S', X');

each iteration, it first adds all the elements that can be associated to S' with cost 0 (line 5). Then, it selects a subset $\hat{T}$ that maximizes the ratio between the marginal increment and the marginal cost amongst the elements of an α-list L. Here, we assume that we have an algorithm to compute an α-list L w.r.t. (S', X') (see line 6). In the next sections, we will show how to compute L in polynomial time for some bounded α. The algorithm stops when adding the element with the maximum ratio would exceed the budget k or when $X' = X$. Without loss of generality, we can assume that at each iteration, the sets in the α-list L do not contain any element in X', since such elements do not increase the value of the marginal increment and possibly increase the marginal cost. This implies that at each iteration of the greedy procedure at least a new element in X is added to X' and then the number of iterations is $O(n)$.

Let (S_G, X_G) be the first candidate solution computed at the end of the greedy procedure. The second candidate solution (lines 12–14) is computed by using the set $\hat{T}$ that is discarded in the last iteration of the greedy procedure because adding $\{s_{\min}(\hat{T})\}$ and $\hat{T}$ to (S_G, X_G) would exceed the budget. Indeed, the second candidate solution is $(S_G \cup \{s_{\min}(\hat{T})\}, \hat{T})$. Note that this solution is feasible because $\hat{T}$ is contained in the α-list L computed in the last iteration of the greedy algorithm. Therefore, by definition of α-list, $c(S_G \cup \{s_{\min}(\hat{T})\}, \hat{T}) \leq k$.

The algorithm returns one of the two candidate solutions that maximizes the objective function.

The computational complexity of Algorithm 1 is $O(n \cdot (|L_{\max}| + cl))$, where $L_{\max}$ is the largest α-list computed and cl is the computational complexity of the algorithm at line 6. In the next sections we will show that our algorithms construct the α-lists in such a way that both $|L_{\max}|$ and cl are polynomially bounded in the input size.

In what follows we analyze the approximation ratio of Algorithm 1. The proof generalizes known arguments for monotone submodular maximization, see e.g. [7, 18, 23].

We give some additional definitions that will be used in the proof. We denote an optimal solution by (S^*, X^*). Let us consider the iterations executed by the greedy algorithm. Let $l + 1$ be the index of the iteration in which an element in the α-list is not added to X'

because it violates the budget constraint[2]. For $i = 1, 2, \ldots, l$, we define X'_i and S'_i as the sets X' and S' at the end of the i-th iteration of the algorithm, respectively. Moreover, let $X'_{l+1} = X'_l \cup \{\hat{T}\}$ and $S'_{l+1} = S'_l \cup \{s_{\min}(\hat{T})\}$, where $\hat{T}$ is the element selected at line 7 of iteration $l+1$ (see Algorithm 1). Let c_i be the value of $c_{\min}(\hat{T})$ as computed at iteration i of the greedy algorithm. The next lemma will be used in the proof of Theorem 2.

▶ **Lemma 1.** *After each iteration $i = 1, 2, \ldots, l+1$,*

$$f(X'_i) \geq \left(1 - \prod_{j=1}^{i}\left(1 - \alpha\frac{c_j}{k}\right)\right) f(X^*).$$

Armed with Lemma 1, we can prove Theorem 2.

▶ **Theorem 2.** *Algorithm 1 guarantees an approximation factor of $\frac{1}{2}\left(1 - \frac{1}{e^\alpha}\right)$ for GBSM.*

Proof. We observe that since (S'_{l+1}, X'_{l+1}) violates the budget, then $c(S'_{l+1}, X'_{l+1}) > k$. Moreover, for a sequence of numbers $a_1, a_2, \ldots, a_n$ such that $\sum_{\ell=1}^{n} a_\ell = A$, the function $\left[1 - \prod_{i=1}^{n}\left(1 - \frac{a_i \cdot \alpha}{A}\right)\right]$ achieves its minimum when $a_i = \frac{A}{n}$ and that $\left[1 - \prod_{i=1}^{n}\left(1 - \frac{a_i \cdot \alpha}{A}\right)\right] \geq 1 - \left(1 - \frac{\alpha}{n}\right)^n \geq 1 - e^{-\alpha}$. Therefore, by applying Lemma 1 for $i = l+1$ and observing that $\sum_{\ell=1}^{l+1} c_\ell = c(S'_{l+1}, X'_{l+1})$, we obtain:

$$f(X'_{l+1}) \geq \left[1 - \prod_{\ell=1}^{l+1}\left(1 - \frac{c_\ell \cdot \alpha}{k}\right)\right] f(X^*) \tag{1}$$

$$> \left[1 - \prod_{\ell=1}^{l+1}\left(1 - \frac{c_\ell \cdot \alpha}{c(S'_{l+1}, X'_{l+1})}\right)\right] f(X^*) \tag{2}$$

$$\geq \left[1 - \left(1 - \frac{\alpha}{(l+1)}\right)^{l+1}\right] f(X^*) \geq \left(1 - \frac{1}{e^\alpha}\right) f(X^*). \tag{3}$$

Since, by submodularity, $f(X'_{l+1}) \leq f(X'_l) + f(\hat{T})$, where $\hat{T}$ is the set selected at iteration $l+1$, we get

$$f(X'_l) + f(\hat{T}) \geq \left(1 - \frac{1}{e^\alpha}\right) f(X^*).$$

Hence, $\max\{f(X'_l), f(\hat{T})\} \geq \frac{1}{2}\left(1 - \frac{1}{e^\alpha}\right) f(X^*)$. The theorem follows by observing that $\hat{T}$ is the set selected as the second candidate solution at lines 12–14 of Algorithm 1. ◀

4 Computing an α-list for a particular case

In this section, we give a polynomial time algorithm to find a $(1-\epsilon)$-list with respect to a partial solution (S', X') for the particular case in which, for a given parameter $\epsilon \in (0, 1)$, the following condition holds:

$$\sum_{x \in T} c(s, x) \geq \frac{1}{\epsilon} c(s), \tag{4}$$

[2] We can assume that this iteration exists, as otherwise the algorithm is able to select $X' = X$, which is the optimum.

for each $s \in S$ and for each $T \subseteq X$ such that $|T| = \frac{1}{\epsilon}$. We observe that this condition is fulfilled for any $\epsilon \in (0,1)$ in the case in which $c(s) = 1$ and $c(s,x) \geq 1$, for each $s \in S$ and for each $x \in X$, which generalizes the non-stochastic adaptive seeding problem [1]. Indeed, in this case $\sum_{x \in T} c(s,x) \geq |T| = \frac{1}{\epsilon} c(s)$, for each $s \in S$ and for each $T \subseteq X$, such that $|T| = \frac{1}{\epsilon}$.

We give a simple algorithm that returns a $(1-\epsilon)$-list with respect to a partial solution (S', X'). The algorithm works as follows: build a list which contains all the subsets T of $X \setminus X'$ such that $|T| \leq \frac{1}{\epsilon}$ and $c(S' \cup \{s_{\min}(\hat{T})\}, \hat{T}) \leq k$.

Plugging this algorithm into line 6 of Algorithm 1, we can guarantee an approximation factor of $\frac{1}{2}\left(1 - \frac{1}{e}\right) - \epsilon'$, where $\epsilon' = \frac{1}{2e}\left(e^{\epsilon} - 1\right)$ for GBSM.

We observe that the case in this section contains the problem of maximizing a submodular set function under a knapsack constraint as a special case. Indeed, it is enough to set $c(s) = 0$, for each $s \in S$, and $c(s_1, x) = c(s_2, x)$, for each $s_1, s_2 \in S$ and $x \in X$. Note that in this case Condition 4 is satisfied for any $\epsilon \in (0,1)$. A special case of submodular set function maximization is the maximum coverage problem, and since this latter is NP-hard to be approximated within a factor greater than $\left(1 - \frac{1}{e}\right)$ [11], then the gap between the approximation factor of our algorithm and the best achievable one in polynomial time is $\frac{1}{2}$, unless $P = NP$.

It is easy to see that the computational complexity required by the algorithm in this section is $O(n^{\frac{1}{\epsilon}})$ and that $|L_{\max}| = O(n^{\frac{1}{\epsilon}})$.

In what follows, we assume that any set T^* that maximizes the ratio between marginal increment and marginal cost has size greater than $\frac{1}{\epsilon}$, as otherwise the α-list returned by our algorithm would contain such set. The following two technical lemmata will be used in the analysis of the algorithm.

▶ **Lemma 3.** *Given a monotone submodular set function $f : 2^X \to \mathbb{R}_{\geq 0}$, then, for any $X' \subseteq X$, the function $g(T) = f(X' \cup T) - f(X')$ is monotone and submodular.*

▶ **Lemma 4.** *Let us consider a monotone submodular set function $f : 2^X \to \mathbb{R}_{\geq 0}$ and a cost function $c : 2^X \to \mathbb{R}_{\geq 0}$ such that $c(T) = \sum_{x \in T} c(\{x\})$, for each $T \subseteq X$. For each set $T \subseteq X$, if T_y denotes the subset of T such that $\frac{f(T_y)}{c(T_y)}$ is maximum and $|T_y| = y$, then $\frac{f(T)}{c(T)} \leq \frac{f(T_y)}{c(T_y)}$, for any $y \leq |T|$.*

The next theorem shows the approximation ratio of the algorithm. The main idea is to consider the subset $\hat{T}$ that maximizes the ratio between the marginal increment and marginal cost in L and to derive a series of inequalities to lead us state that this value is greater than the ratio given by the optimal subset T^* times the factor $(1-\epsilon)$. We first compare the ratio computed for $\hat{T}$ with that for $T^*_{\frac{1}{\epsilon}}$ that is a subset of cardinality $\frac{1}{\epsilon}$ of maximal ratio, then, by rewriting the marginal cost formula according to its definition and by exploiting Lemmata 3 and 4, and Condition (4) we compare this ratio to that given by the subset T^* and this last inequality concludes the theorem.

▶ **Theorem 5.** *If for each $T \subseteq X$ such that $|T| = \frac{1}{\epsilon}$ and for each $s \in S$ we have $\sum_{x \in T} c(s,x) \geq \frac{1}{\epsilon} c(s)$, then the list L made of all the subsets of $X \setminus X'$ of size at most $\frac{1}{\epsilon}$ and cost at most k is a $(1-\epsilon)$-list.*

Proof. We recall that $g(T) = f(X' \cup T) - f(X')$. Given a subset T of $X \setminus X'$, we denote by T_y a subset of T such that $|T_y| = y$ and $\frac{f(T_y)}{c(T_y)}$ is maximum. Let T^* be the subset of $X \setminus X'$ that maximizes the ratio between the marginal increment and the marginal cost. Let $\hat{T}$ be

the element of L that maximizes $\frac{g(\hat{T})}{c_{\min}(\hat{T})}$. Since $|\hat{T}| \leq \frac{1}{\epsilon}$, then

$$\frac{g(\hat{T})}{c_{\min}(\hat{T})} \geq \frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{c_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)} = \frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{c_{S'}\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right) + \bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)}.$$

By the hypothesis of the theorem, $\bar{c}\left(T^*_{\frac{1}{\epsilon}}\right) \geq \frac{1}{\epsilon} c\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right)$, moreover, $c\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right) \geq c_{S'}\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right)$ and then $c_{S'}\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right) \leq \epsilon \bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)$. Therefore,

$$\frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{c_{S'}\left(s_{\min}\left(T^*_{\frac{1}{\epsilon}}\right)\right) + \bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)} \geq \frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{\epsilon\bar{c}\left(T^*_{\frac{1}{\epsilon}}\right) + \bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)} = \frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{(\epsilon+1)\bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)}.$$

Since f is monotone and submodular, then, by Lemma 3, also $g\left(T^*_{\frac{1}{\epsilon}}\right)$ is submodular. By Lemma 4 follows that

$$\frac{g\left(T^*_{\frac{1}{\epsilon}}\right)}{(\epsilon+1)\bar{c}\left(T^*_{\frac{1}{\epsilon}}\right)} \geq \frac{g(T^*)}{(\epsilon+1)\bar{c}(T^*)}.$$

We now focus on the denominator, and we obtain that:

$$\frac{1}{(\epsilon+1)\bar{c}(T^*)} = \frac{1+\epsilon-\epsilon}{(\epsilon+1)\bar{c}(T^*)} = \frac{1}{\bar{c}(T^*)} - \frac{\epsilon}{(\epsilon+1)\bar{c}(T^*)} \geq \frac{1}{\bar{c}(T^*) + c_{S'}(s_{\min}(T^*))} - \frac{\epsilon}{\epsilon\bar{c}(T^*) + \bar{c}(T^*)}.$$

By applying the hypothesis $\bar{c}(T^*) \geq \frac{1}{\epsilon} c(s_{\min}(T^*))$, it follows that:

$$\frac{1}{\bar{c}(T^*) + c_{S'}(s_{\min}(T^*))} - \frac{\epsilon}{\epsilon\bar{c}(T^*) + \bar{c}(T^*)} \geq \frac{1}{\bar{c}(T^*) + c_{S'}(s_{\min}(T^*))} - \frac{\epsilon}{c(s_{\min}(T^*)) + \bar{c}(T^*)} \geq \frac{1}{\bar{c}(T^*) + c_{S'}(s_{\min}(T^*))} - \frac{\epsilon}{\bar{c}(T^*) + c_{S'}(s_{\min}(T^*))} = \frac{1-\epsilon}{c_{\min}(T^*)}.$$

To conclude:

$$\frac{g(\hat{T})}{c_{\min}(\hat{T})} \geq (1-\epsilon)\frac{g(T^*)}{c_{\min}(T^*)}.$$ ◀

5 Computing an α-list for the general case

In this section we give a polynomial time algorithm that builds a $\left(1-\frac{1}{e}\right)(1-\epsilon)$-list with respect to a partial solution (S', X'), for any $\epsilon \in (0,1)$. Using this algorithm as routine at line 6 of Algorithm 1, we can guarantee an approximation factor of

$$\frac{1}{2}\left(1 - \frac{1}{e^{\left(1-\frac{1}{e}\right)(1-\epsilon)}}\right)$$

for GBSM. We observe that this case generalizes the non-stochastic adaptive seeding with knapsack constraints problem, which cannot be approximated within a factor greater than

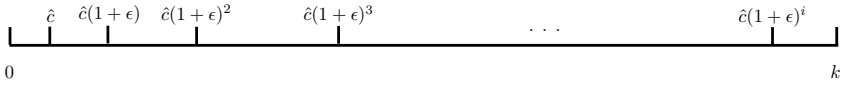

Figure 1 Growth of the budget B_i in the inner cycle of the algorithm.

$\left(1-\frac{1}{e^{1-\frac{1}{e}}}\right)$, unless $P=NP$ [21]. Then, the gap between the approximation factor of our algorithm and the best achievable one in polynomial time is $\frac{1}{2}$, unless $P=NP$.

In the algorithm of this section we make use of a procedure called `GreedyMaxCover` to maximize the value of a monotone submodular function $g: 2^X \to \mathbb{R}_{\geq 0}$, given a certain budget and costs associated to the elements of X. It is well-known that there exists a polynomial-time procedure that guarantees a $\left(1-\frac{1}{e}\right)$-approximation for this problem [23].

Let us denote by $\hat{c}$ the minimum possible positive value of functions $c(s)$ and $c(s,x)$, amongst all elements x and bins s, i.e. $\hat{c}=\min\{\min\{c(s): s\in S, c(s)>0\}, \min\{c(s,x): s\in S, x\in X, c(s,x)>0\}\}$.

The main idea is to build an α-list L which contains approximate solutions to the problem of maximizing a monotone submodular set function subject to a knapsack constraint in which the budget increases by a factor $1+\epsilon$ starting from $\hat{c}$, and the cost of the elements are given by the cost of associating them to a single bin. In particular, we consider $q=\left\lfloor \log_{1+\epsilon}\left(\frac{k}{\hat{c}}\right)\right\rfloor+1$ different budgets B_i that iteratively increase by a factor $1+\epsilon$, i.e. $B_0=\hat{c}$ and $B_i=(1+\epsilon)B_{i-1}$, for $i=1,\ldots,q$. Moreover we define $B_{q+1}=k$. For each $i=0,\ldots,q+1$ and for each bin $s\in S$, we apply procedure `GreedyMaxCover` with ground set X, budget B_i, and the cost of associating the elements to bin s as cost function. Then, we add the set returned by `GreedyMaxCover` to L. In this way we consider a budget that is at most a factor $1+\epsilon$ greater than the cost of an optimal solution and the solution returned by `GreedyMaxCover` for this budget has a value that is at most $1-\frac{1}{e}$ times smaller than that of the optimal solution.

The pseudo-code of the algorithm is reported in Algorithm 2. The outer cycle at lines 2–11 iteratively selects a bin s in S and finds a list of sets of elements assigned to bin s. The inner cycle at lines 4–8, at each iteration i, calls procedure `GreedyMaxCover` which uses g as function to maximize, $\hat{c}(1+\epsilon)^i - c_{S'}(s)$ as budget and the cost of associating the elements to bin s as cost function (to compute this costs, we only pass s as a parameter to `GreedyMaxCover`). The budget is increased by a factor $(1+\epsilon)$ until $\hat{c}(1+\epsilon)^i \geq k$. Finally the algorithm runs `GreedyMaxCover` with the full budget k. See Figure 1 for an illustration.

We call q the value of i at the end of the last iteration in the inner cycle of the algorithm. Let T_j be the set in L that maximizes the ratio between $g(T_j)$ and its assigned budget, that is:

$$T_j = \arg\max\left\{\frac{g(T_i(s))}{B_i} : s\in S, i=0,1,\ldots,q+1\right\}. \tag{5}$$

In order to bound the approximation ratio, we consider $\bar{X}^*$ as the set with the optimal ratio $\frac{g(\bar{X}^*)}{c_{\min}(\bar{X}^*)}$ amongst any possible subset of items. Let B_l be the smallest value of B_i, for $i\in\{0,1,\ldots,q+1\}$, that is greater than or equal to the cost of an optimal solution, that is the smallest B_l such that $B_l \geq c_{\min}(\bar{X}^*)$. See figure 2 for an illustration. We call T_l^* the set in L that has the highest ratio $\frac{g(T_l)}{B_l}$ amongst those computed by `GreedyMaxCover` with budget B_l, i.e. $T_l^* = \max\left\{\frac{g(T_l(s))}{B_l} : s\in S\right\}$. We also denote the set that maximizes $g(X_l^*)$ with budget B_l by X_l^*.

The idea of the approximation analysis is that an optimal solution $\bar{X}^*$ has a value of g that is at most $g(X_l^*)$ and a cost that is at most $1+\epsilon$ times smaller than B_l, while the number of iterations remains polynomial since the size of the intervals grows exponentially.

Algorithm 2: Exponential Budget Greedy.

Input : $S, X, S', X', k, \epsilon$
Output : L

$L := \emptyset$;
foreach $s \in S$ **do**
  $i := 0$;
  while $\hat{c}(1+\epsilon)^i < k$ **do**
    $B_i := \hat{c}(1+\epsilon)^i$;
    $T_i(s) := \texttt{GreedyMaxCover}(X, s, B_i - c_{S'}(s))$;
    $L := L \cup \{T_i(s)\}$;
    $i := i + 1$
  $B_i := k$;
  $T_i(s) := \texttt{GreedyMaxCover}(X, s, B_i - c_{S'}(s))$;
  $L := L \cup \{T_i(s)\}$;
return L;

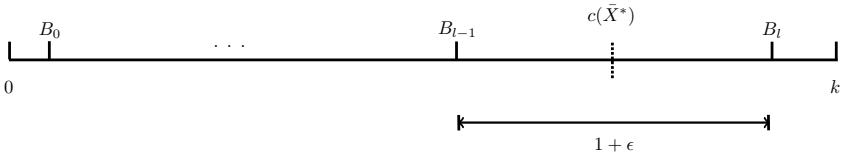

Figure 2 Notation used in Theorem 6.

The next two theorems show the bounds on approximation ratio, computational complexity and size of L.

▶ **Theorem 6.** *The list L built by Algorithm 2, is a $\left(1-\frac{1}{e}\right)(1-\epsilon)$-list.*

Proof. Since, by construction, $c_{\min}(T_j) \leq B_j$, and, by Equation 5, $\frac{g(T_j)}{B_j}$ is maximum, then

$$\frac{g(T_j)}{c_{\min}(T_j)} \geq \frac{g(T_j)}{B_j} \geq \frac{g(T_l^*)}{B_l}.$$

Procedure `GreedyMaxCover` guarantees a $\left(1-\frac{1}{e}\right)$-approximation, then

$$\frac{g(T_l^*)}{B_l} \geq \left(1-\frac{1}{e}\right)\frac{g(X_l^*)}{B_l}.$$

Moreover, since function g is monotone and $c_{\min}(\bar{X}^*) \leq B_l$, then $g(X_l^*) \geq g(\bar{X}^*)$, and therefore:

$$\left(1-\frac{1}{e}\right)\frac{g(X_l^*)}{B_l} \geq \left(1-\frac{1}{e}\right)\frac{g(\bar{X}^*)}{B_l}.$$

We defined B_l as the smallest value of B_i that is at least $c_{\min}(\bar{X}^*)$, this implies that $B_{l-1} \leq c_{\min}(\bar{X}^*)$. Moreover the ratio between B_l and B_{l-1} is $1+\epsilon$. It follows that $B_l \leq (1+\epsilon)c_{\min}(\bar{X}^*)$, which implies:

$$\left(1-\frac{1}{e}\right)\frac{g(\bar{X}^*)}{B_l} \geq \left(1-\frac{1}{e}\right)\left(\frac{1}{1+\epsilon}\right)\frac{g(\bar{X}^*)}{c_{\min}(\bar{X}^*)} \geq \left(1-\frac{1}{e}\right)(1-\epsilon)\frac{g(\bar{X}^*)}{c_{\min}(\bar{X}^*)}$$

Algorithm 3: Bi-criterion Algorithm.

Input : S, X
Output : S', X'

1 $S' := \emptyset$;
2 $X' := \emptyset$;
3 **foreach** $s \in S$ s.t. $c(s) = 0$ **do** $S' := S' \cup \{s\}$;
4 **repeat**
5 **foreach** $x \in X \setminus X'$ s.t. $c(s', x) = 0$ and $s' \in S'$ **do** $X' := X' \cup \{x\}$;
6 Build an α-list L w.r.t. (S', X');
7 $\hat{T} := \arg\max_{T \in L} \frac{f(X' \cup T) - f(X')}{c_{\min}(T)}$;
8 **if** $c(S' \cup \{s_{\min}(\hat{T})\}, X' \cup \hat{T}) \leq \beta k$ **then**
9 $S' := S' \cup \{s_{\min}(\hat{T})\}$;
10 $X' := X' \cup \hat{T}$;
11 **until** $c(S' \cup \{s_{\min}(\hat{T})\}, X' \cup \hat{T}) > \beta k$ or $X' = X$;
12 **if** $f(\hat{T}) \geq f(X')$ **then**
13 $S' := S' \cup \{s_{\min}(\hat{T})\}$;
14 $X' := \hat{T}$;
15 **return** (S', X');

The last inequality holds since $\frac{1}{1+\epsilon} = 1 - \frac{\epsilon}{1+\epsilon} \geq 1 - \epsilon$, for any $\epsilon > 0$, and this concludes the proof. ◀

▶ **Theorem 7.** *Algorithm 2 requires* $O\left(\frac{1}{\epsilon} m \cdot gr(n) \cdot \log \frac{k}{\hat{c}}\right)$ *computational time, where* $gr(n)$ *is the computational time of* `GreedyMaxCover`*, and* $|L_{\max}| = O\left(\frac{1}{\epsilon} m \log \frac{k}{\hat{c}}\right)$.

Proof. The outer for cycle requires m iterations. We now bound the number q of iteration of the inner cycle of the algorithm. By the exit condition of the cycle, we have: $\hat{c} \cdot (1+\epsilon)^q < k$, which is equivalent to: $q < \log_{1+\epsilon}\left(\frac{k}{\hat{c}}\right)$. Since for $\epsilon < 1$, $\log_{1+\epsilon}\left(\frac{k}{\hat{c}}\right) = O\left(\frac{1}{\epsilon} \log \frac{k}{\hat{c}}\right)$, the statement follows. ◀

We observe that $O(\log \frac{k}{\hat{c}})$ is polynomially bounded in the size of the input.

6 Bi-criterion approximation algorithm

In this section we extend the results given in Section 3 providing a bi-criterion approximation algorithm that guarantees a $\frac{1}{2}\left(1 - \frac{1}{e^{\alpha\beta}}\right)$-approximation to the GBSM problem, if we allow an extra budget up to a factor $\beta \geq 1$. We notice that, if $\beta = 1$, i.e. we do not increase the budget, the approximation factor is $\frac{1}{2}\left(1 - \frac{1}{e^{\alpha}}\right)$, while if $\beta = \frac{1}{\alpha} \ln\left(\frac{1}{2\epsilon}\right)$ the algorithm achieves an approximation factor of $\frac{1}{2} - \epsilon$, for any arbitrarily small $\epsilon > 0$.

The algorithm is slightly different from Algorithm 1 and it is reported in Algorithm 3. In this algorithm, we allow to exceed the given budget k by a factor β. In particular we modify lines 8 and 11, admitting a greater budget respect to Algorithm 1.

In the next theorem we show the approximation ratio of this algorithm.

▶ **Theorem 8.** *There exists an algorithm that guarantees a* $\left[\frac{1}{2}\left(1 - \frac{1}{e^{\alpha\beta}}\right), \beta\right]$ *bi-criterion approximation for GBSM, for any* $\beta \geq 1$.

It is possible to prove the theorem by using the same argument as in Theorem 2, by taking into account the new budget βk. We also exploit the fact that Lemma 1 also holds when considering the budget βk.

7 Conclusion

In this paper we defined a new challenging problem which leads to many open problems and new research questions, we referred to it as the generalized budgeted submodular set function maximization problem.

The main open problem is to close the gap between the known hardness result of $1 - \frac{1}{e^\alpha}$, where $\alpha = 1$ for the MC problem [11] and $\alpha = 1 - \frac{1}{e}$ for the non-stochastic adaptive seeding problem with knapsack constraint problem [21], and our approximation bound of $\frac{1}{2}\left(1 - \frac{1}{e^\alpha}\right)$. One possibility to get rid of the $\frac{1}{2}$ factor could be to use the partial enumeration technique exploited in specific subproblems (e.g. budgeted maximum coverage problem [18] and monotone submodular set function subject to a knapsack constraint maximization problem [23]). However, this requires that each greedy step selects a single element of X, to be added to a partial solution X', while our greedy algorithm selects a subset of $X \setminus X'$ that maximizes the ratio between its marginal increment in the objective function and its marginal cost. Note that this set can contain more than one element in order to ensure that the ratio is non-increasing at each iteration of the greedy algorithm, which is needed to apply the analysis in [18] and [23].

Other research directions, that deserve further investigation, include the study of the GBSM considering different cost functions and also different objective functions where the profit given by an element x depends on the bin s which it is associated with. It would be interesting also to analyse GBSM in the case that each bin $s \in S$ has its own budget k to use in order to maximize the objective function.

Abstract

Given a subset of states S of a deterministic finite automaton and a word w, the preimage is the subset of all states that are mapped to a state from S by the action of w. We study the computational complexity of three problems related to the existence of words yielding certain preimages, which are especially motivated by the theory of synchronizing automata. The first problem is whether, for a given subset, there exists a word extending the subset (giving a larger preimage). The second problem is whether there exists a word totally extending the subset (giving the whole set of states) – it is equivalent to the problem whether there exists an avoiding word for the complementary subset. The third problem is whether there exists a word resizing the subset (giving a preimage of a different size). We also consider the variants of the problem where an upper bound on the length of the word is given in the input. Because in most cases our problems are computationally hard, we additionally consider parametrized complexity by the size of the given subset. We focus on the most interesting cases that are the subclasses of strongly connected, synchronizing, and binary automata.

1 Introduction

A deterministic finite complete (semi)automaton $\mathscr{A}$ is a triple (Q, Σ, δ), where Q is the set of *states*, Σ is the input *alphabet*, and $\delta\colon Q \times \Sigma \to Q$ is the *transition function*. We extend δ to a function $Q \times \Sigma^* \to Q$ in the usual way. Throughout the paper, by n we always denote the number of states $|Q|$.

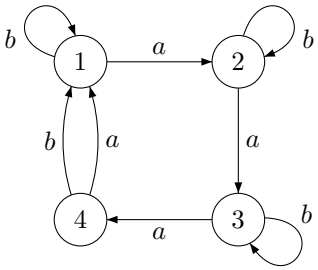

Figure 1 The Černý automaton with 4 states.

When the context automaton is clear, given a state $q \in Q$ and a word $w \in \Sigma^*$, we write shortly $q \cdot w$ for $\delta(q, w)$. Given a subset $S \subseteq Q$, the *image* of S under the action of a word $w \in \Sigma^*$ is $S \cdot w = \delta(S, w) = \{q \cdot w \mid q \in S\}$. The *preimage* is $S \cdot w^{-1} = \delta^{-1}(S, w) = \{q \in Q \mid q \cdot w \in S\}$. If $S = \{q\}$, then we usually simply write $q \cdot w^{-1}$.

We say that a word w *compresses* a subset S if $|S \cdot w| < |S|$, avoids S if $(Q \cdot w) \cap S = \emptyset$, *extends* S if $|S \cdot w^{-1}| > |S|$, and *totally extends* S if $S \cdot w^{-1} = Q$. A subset S is *compressible*, *avoidable*, *extensible*, and *totally extensible*, if there is a word that respectively compresses, avoids, extends and totally extends it.

▶ Remark. A word $w \in \Sigma^*$ is avoiding for $S \subseteq Q$ if and only if w is totally extending for $Q \setminus S$.

Fig. 1 shows an example automaton. For $S = \{2, 3\}$, the shortest compressing word is aab, and we have $\{2, 3\} \cdot aab = \{1\}$, while the shortest extending word is ba, and we have $\{2, 3\} \cdot (ba)^{-1} = \{1, 2\} \cdot b^{-1} = \{1, 2, 4\}$.

In fact, the preimage of a subset under the action of a word can be smaller than the subset. In this case, we say that a word *shrinks* the subset (not to be confused with compressing when the image is considered). For example, in Fig. 1, subset $\{1, 4\}$ is shrank by b to subset $\{4\}$.

Note that shrinking a subset is equivalent to extending its complement. Similarly, a word totally extending a subset also shrinks its complement to the empty set.

▶ Remark. $|S \cdot w^{-1}| > |S|$ if and only if $|(Q \setminus S) \cdot w^{-1}| < |Q \setminus S|$, and $S \cdot w^{-1} = Q$ if and only if $(Q \setminus S) \cdot w^{-1} = \emptyset$.

Therefore, avoiding a subset is equivalent to shrinking it to the empty set.

The *rank* of a word w is the cardinality of the image $Q \cdot w$. A word of rank 1 is called *reset* or *synchronizing*, and an automaton that admits a reset word is called *synchronizing*. Also, for a subset $S \subseteq Q$, we say that a word $w \in \Sigma^*$ such that $|S \cdot w| = 1$ *synchronizes* S.

Synchronizing automata serve as transparent and natural models of various systems in many applications in different fields, such as coding theory, DNA-computing, robotics, testing of reactive systems, and theory of information sources. They also reveal interesting connections with symbolic dynamics, language theory, group theory, and many other parts of mathematics. For a detailed introduction to the theory of synchronizing automata we refer the reader to the survey [31], and for a review of relations with coding theory to [16] and [8].

The famous Černý conjecture [11], which was formally stated in 1969 during a conference ([31]), is one of the most longstanding open problems in automata theory, and is the central problem in the theory of synchronizing automata. It states that a synchronizing automaton has a reset word of length at most $(n-1)^2$. Besides the conjecture, algorithmic issues are also important. Unfortunately, the problem of finding a *shortest* reset word is computationally hard [12, 21], and also its length approximation remains hard [13]. We also refer to surveys [24, 31] about algorithmic issues and the Černý conjecture.

Our general motivation comes from the fact that words compressing and extending subsets play a crucial role in synchronization automata. In fact, all known algorithms finding a reset word as intermediate steps use finding words that either compresses or extends a subset (e.g. [1, 7, 12, 18, 22]). Moreover, probably all proofs of upper bounds on the length of the shortest reset words use bounding the length of words that compress (e.g. [2, 7, 9, 12, 14, 27, 29, 32]) or extend (e.g. [3, 4, 7, 17, 26, 27]) some subsets.

In this paper, we study several natural problems related to preimages. Our goal is to provide a systematic view of their computational complexity and solve several open problems.

1.1 Compressing a Subset

The complexities of problems related to compressing a subset have been well studied.

It is known that given an automaton $\mathscr{A}$ and a subset $S \subseteq Q$, determining whether there is a word that synchronizes it is PSPACE-complete [23]. The same holds even for strongly connected binary automata [33].

On the other hand, checking whether the automaton is synchronizing (whether there is a word that synchronizes Q) can be solved in $\mathcal{O}(|\Sigma|n^2)$ time and space [11, 12, 31] and in $\mathcal{O}(n)$ average time and space for the random binary case [6]. To this end, we just verify whether all pairs of states are compressible. Using the same algorithm, we can determine whether a given subset is compressible.

Deciding whether there exists a synchronizing word of a given length is NP-complete [12] (cf. [21] for the complexity of the corresponding functional problems), even if the given automaton is binary. There exist stronger results, such as NP-completeness of this problem when the automaton is Eulerian and binary [34], which immediately implies that for the class of strongly connected automata the complexity is the same.

However, deciding whether there exists a word that only compresses a subset still can be solved in $\mathcal{O}(|\Sigma|n^2)$ time, as for every pair of states we can compute a shortest word that compresses the pair.

The problems have been also studied in other settings than DFAs. We refer to [20, 23] for the cases of NFA and PDFA (*partial deterministic finite automata*), and to [15] for the partial observability setting. Finally, in [10] the problem of reachability of a given subset in a DFA has been studied.

1.2 Extending a Subset and Our Contributions

In contrast to the problems related to images (compression), the complexity of the problems related to preimages has not been well studied. In the paper, we fill this gap. We study three families of problems. As we noted before, extending is equivalent to shrinking the complement, hence we deal only with the extending word problems.

Extending words: Our first family of problems is the question whether there exists an extending word (Problems 1, 7, 9, 13, 16, 22).

This is motivated by the fact that finding such a word is the basic step of the so-called *extension method* of finding a reset word that is used in many proofs and also some algorithms. The extension method of finding a reset word is to start from some singleton $S_0 = \{q\}$, and iteratively find extending words $w_1, \ldots, w_k$ such that $|S_0 \cdot w_1^{-1} \cdots w_i^{-1}| > |S_0 \cdot w_1^{-1} \cdots w_{i-1}^{-1}|$ for $1 \leq i \leq k$, and where final $S_0 \cdot w_1^{-1} \cdots w_k^{-1} = Q$. For finding a short reset word one needs to bound the lengths of the extending words. For instance, by showing that in the case of Eulerian automata there are always extending words of length at most n, which implies the upper bound $(n-2)(n-1)+1$ on the length of the shortest reset words for this class [17]. In this case, a polynomial algorithm for finding extending words has been proposed in [7].

Table 1 Computational complexity of decision problems in classes of automata. Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$ with n states and a subset $S \subseteq Q$, is there a word $w \in \Sigma^*$ such that:

Subclass of automata	All automata	Strongly connected	Synchronizing	Str. con. and synch.
$\lvert S \cdot w\rvert = 1$ (reset word)	PSPACE-c [23, 33]		$\mathcal{O}(1)$	$\mathcal{O}(1)$
$\lvert S \cdot w\rvert < \lvert S\rvert$ (compressing word)	$\mathcal{O}(\lvert\Sigma\rvert n^2)$ [11, 31]		$\mathcal{O}(1)$	$\mathcal{O}(1)$
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$ (Problem 1)	PSPACE-c (Thm. 3)		PSPACE-c (Prop. 5)	$\mathcal{O}(1)$
$S \cdot w^{-1} = Q$ (Problem 2)	PSPACE-c (Thm. 3)		$\mathcal{O}(\lvert\Sigma\rvert n)$ (Thm. 6)	$\mathcal{O}(1)$
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$, $\lvert S\rvert \leq k$ (Problem 9)	$\mathcal{O}(\lvert\Sigma\rvert n^k)$ (Prop. 10)		$\mathcal{O}(\lvert\Sigma\rvert n^k)$ (Prop. 10)	$\mathcal{O}(1)$
$S \cdot w^{-1} = Q$, $\lvert S\rvert \leq k$ (Problem 11)	$\mathcal{O}(\lvert\Sigma\rvert(n^3 + n^k))$ (Prop. 12)		$\mathcal{O}(\lvert\Sigma\rvert n)$ (Thm. 6)	$\mathcal{O}(1)$
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$, $\lvert S\rvert \geq n - k$ (Problem 16, $k \geq 2$)	PSPACE-c (Thm. 19)	Open	PSPACE-c (Thm. 19)	$\mathcal{O}(1)$
$S \cdot w^{-1} = Q$, $\lvert S\rvert \geq n - k$ (Problem 17, $k \geq 2$)	$\mathcal{O}(n^3 + \lvert\Sigma\rvert n^k)$ (Thm. 21)		$\mathcal{O}(\lvert\Sigma\rvert n)$ (Thm. 6)	$\mathcal{O}(1)$
$S \cdot w^{-1} = Q$, $\lvert S\rvert = n - 1$ (Problem 18)	$\mathcal{O}(\lvert\Sigma\rvert n^2)$ (Thm. 20)		$\mathcal{O}(\lvert\Sigma\rvert)$	$\mathcal{O}(1)$
$\lvert S \cdot w^{-1}\rvert \neq \lvert S\rvert$ (Problem 27)	$\mathcal{O}(\lvert\Sigma\rvert n^3)$ (Thm. 29)		$\mathcal{O}(1)$	$\mathcal{O}(1)$

Totally extending words and avoiding: We study the problem whether there exists a totally extending word (Problems 2, 8, 11, 14, 17, 23). The question about the existence of a totally extending word is equivalent to the question about the existence of an avoiding word for the complementary subset.

Totally extending words themselves can be viewed as a generalization of reset words: a word totally extending a singleton to the whole set of states Q is a reset word. If we are not interested in bringing the automaton into one particular state but want it to be in any of the states from a specified subset, then it is exactly the question about totally extending word for our subset. In view of applications of synchronization, this can be particularly useful when we deal with non-synchronizing automata, where reset words cannot be applied.

Avoiding word problem is a recent concept that is dual to synchronization: instead of being in some states, we want to not be in them. A quadratic upper bound on the length of the shortest avoiding words of a single state have been established in [27], where avoiding words were also used to improve the best known upper bound on the length of the shortest reset words. The computational complexity of the problems related to avoiding, both a single state or a subset, have not been established, which is another motivation to study

Table 2 Computational complexity of decision problems in classes of automata. Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$ with n states, a subset $S \subseteq Q$, and an integer ℓ given in binary form, is there are a word $w \in \Sigma^*$ of length $\leq \ell$ such that:

Subclass of automata	All automata	Strongly connected	Synchronizing	Str. con. and synch.
$\lvert S \cdot w\rvert = 1$ (reset word)	PSPACE-c [23, 33]		NP-c [12]	NP-c [34]
$\lvert S \cdot w\rvert < \lvert S\rvert$ (compressing word)	$\mathcal{O}(\lvert\Sigma\rvert n^2)$ [12]		$\mathcal{O}(\lvert\Sigma\rvert n^2)$ [12]	$\mathcal{O}(\lvert\Sigma\rvert n^2)$ [12]
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$ (Problem 7)	PSPACE-c (Subsec. 2.1)		PSPACE-c (Subsec. 2.1)	NP-c (Thm. 25)
$S \cdot w^{-1} = Q$ (Problem 8)	PSPACE-c (Subsec. 2.1)		NP-c (Cor. 26)	NP-c (Cor. 26)
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$, $\lvert S\rvert \leq k$ (Problem 13)	$\mathcal{O}(\lvert\Sigma\rvert n^k)$ (Prop. 10)		$\mathcal{O}(\lvert\Sigma\rvert n^k)$ (Prop. 10)	$\mathcal{O}(\lvert\Sigma\rvert n^k)$ (Prop. 10)
$S \cdot w^{-1} = Q$, $\lvert S\rvert \leq k$ (Problem 14)	NP-c (Prop. 15)		NP-c (Prop. 15)	NP-c (Prop. 15)
$\lvert S \cdot w^{-1}\rvert > \lvert S\rvert$, $\lvert S\rvert \geq n - k$ (Problem 22, $k \geq 2$)	PSPACE-c (Thm. 19)	Open	PSPACE-c (Thm. 19)	NP-c (Cor. 26)
$S \cdot w^{-1} = Q$, $\lvert S\rvert \geq n - k$ (Problem 23, $k \geq 2$)	NP-c (Cor. 26)		NP-c (Cor. 26)	NP-c (Cor. 26)
$S \cdot w^{-1} = Q$, $\lvert S\rvert = n - 1$ (Problem 24)	NP-c (Thm. 25)		NP-c (Thm. 25)	NP-c (Thm. 25)
$\lvert S \cdot w^{-1}\rvert \neq \lvert S\rvert$ (Problem 28)	$\mathcal{O}(\lvert\Sigma\rvert n^3)$ (Thm. 29)		$\mathcal{O}(\lvert\Sigma\rvert n^3)$ (Thm. 29)	$\mathcal{O}(\lvert\Sigma\rvert n^3)$ (Thm. 29)

totally extending words. We give a special attention to the problem of avoiding one state and a small subset of states (totally extending a large subset), since they seem to be most important in view of their applications (and as we show, the complexity grows with the size of the subset to avoid).

Resizing: Shrinking a subset is dual to extending, i.e. shrinking a subset means extending its complement. Therefore, the complexity immediately transfers from the previous results. However, in Section 5 we consider the problem of determining whether there is a word whose inverse action results in a subset having a different size, that is, either extends the subset or shrinks it (Problems 27, 28).

Interestingly, in contrast with the computationally difficult problems of finding a word that extends the subset and finding a word that shrinks the subset, for this variant there exists a polynomial algorithm finding a shortest resizing word in all cases.

We can mention that in some cases extending and shrinking words are related, and it may be enough to find either one. For instance, this is used in the so-called *averaging trick*, which appears in several proofs (e.g. [7, 17, 25]).

Summary: For all the problems we consider the subclasses of strongly connected, synchronizing, and binary automata. Also, we consider the problems where an upper bound on the length of the word is additionally given in binary form in the input. Since in most cases, the problems are computationally hard, in Section 3 and Section 4 we consider parameterized complexity by the size of the given subset.

Table 1 and Table 2 summarize our results together with known results about compressing words. For the cases where a polynomial algorithm exists, we put the time complexity of the best one known. All the hardness results hold also in the case of a binary alphabet.

2 Extending a Subset in General

We deal with the following problems:

▶ **Problem 1** (Extensible subset). *Given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$, is S extensible?*

▶ **Problem 2** (Totally extensible subset). *Given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$?*

▶ **Theorem 3.** *Problem 1 and Problem 2 are PSPACE-complete even if $\mathscr{A}$ is strongly connected.*

Proof idea. To solve both problems in NPSPACE, we just guess the length of a (totally) extending word and then subsequently its letters, storing only the current subset all the time.

For PSPACE-hardness, we perform a reduction from the problem of determining whether an intersection of regular languages given as DFAs is non-empty [19]. We create one instance for both problems that consists of a strongly connected automaton and a subset S extensible if and only if it is also totally extensible, which is simultaneously equivalent to the non-emptiness of the intersection of the given regular languages. ◀

We ensure that both problems remain PSPACE-complete in the case of a binary alphabet, which follows from the following theorem.

▶ **Theorem 4.** *Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$, we can construct in polynomial time a binary automaton $\mathscr{A}' = (Q', \{a', b'\}, \delta')$ and a subset $S' \subseteq Q'$ such that:*
(1) *$\mathscr{A}$ is strongly connected if and only $\mathscr{A}'$ is strongly connected;*
(2) *S' is extensible in $\mathscr{A}'$ if and only if S is extensible in $\mathscr{A}$;*
(3) *S' is totally extensible in $\mathscr{A}'$ if and only if S is totally extensible in $\mathscr{A}$.*

Proof idea. Let $\Sigma = \{a_1, \ldots, a_k\}$. We reduce $\mathscr{A}$ to a binary automaton $\mathscr{A}'$ that consists of k copies of $\mathscr{A}$. The first letter a acts in an i-th copy as the letter a_i in $\mathscr{A}$. The second letter b acts cyclically on these copies. Then we define S' to contain the states from S in the first copy and all states from the other copies. ◀

Now we consider the subclass of synchronizing automata.

▶ **Proposition 5.** *When the automaton is binary and synchronizing, Problem 1 remains PSPACE-complete.*

Proof idea. We just add a sink state z and a letter which synchronizes $\mathscr{A} = (Q, \Sigma, \delta)$ to z. Additionally, a standard tree-like binarization is suitably used to obtain a binary automaton that preserves extensibility of the subset. ◀

▶ **Theorem 6.** *When the automaton is synchronizing, Problem 2 can be solved in $\mathcal{O}(|\Sigma|n)$ time and is NL-complete.*

Proof idea. Since $\mathscr{A}$ is synchronizing, the problem reduces to checking whether there is a state $q \in S$ reachable from every state: It is well known that a synchronizing automaton has precisely one strongly connected *sink* component that is reachable from every state. If S does not contain a state from the sink component, then every preimage of S also does not contain these states. The problem can be solved in $\mathcal{O}(|\Sigma|n)$ time, since the states of the sink component can be determined in linear time by Tarjan's algorithm [28]. ◀

Note that in the case of strongly connected synchronizing automaton, both problems have a trivial solution, since every non-empty proper subset of Q is totally extensible (by a suitable reset word); thus they can be solved in constant time, assuming that we can check the size of the given subset and the number of states in constant time.

2.1 Bounded Length of the Word

We turn our attention to the variants in which an upper bound on the length of word w is also given.

▶ **Problem 7** (Extensible subset by short word). *Given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$, and an integer ℓ given in binary form, is S extensible by a word of length at most ℓ?*

▶ **Problem 8** (Totally extensible subset by short word). *Given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$, and an integer ℓ given in binary form, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$ of length at most ℓ?*

Obviously, these problems remain PSPACE-complete (also when the automaton is strongly connected and binary), as we can set $\ell = 2^n$, which bounds the number of different subsets of Q. In this case, both the problems are reduced respectively to Problem 1 and Problem 2.

When the automaton is synchronizing, Problem 8 is NP-complete, which will be shown in Corollary 26. Of course, Problem 7 remains PSPACE-complete for a synchronizing automaton by the same argument as in the general case.

3 Extending Small Subsets

The complexity of extending problems rely on the size of the given subset. Variable subset size is essential for hardness. In the proof of PSPACE-hardness in Theorem 3 the used subsets and simultaneously their complements may grow with an instance of the reduced problem, and it is known that the problem of the emptiness of intersection can be solved in polynomial time if the number of given DFAs is fixed. Here we study the computational complexity of the extending problems when the size of the subset is not larger than a fixed k.

▶ **Problem 9** (Extensible small subset). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$ with $|S| \leq k$, is there a word extending S?*

▶ **Proposition 10.** *Problem 9 can be solved in $\mathcal{O}(|\Sigma|n^k)$ time.*

Proof. We build the k-subsets automaton $\mathscr{A}^{\leq k} = (Q^{\leq k}, \Sigma, \delta^{\leq k}, S_0, F)$, where $Q^{\leq k} = \{A \subseteq Q \colon |A| \leq k\}$ and $\delta^{\leq k}$ is naturally defined by the image of δ on a subset. Let the set of initial states be $I = \{A \in Q^{\leq k} \colon |A \cdot a^{-1}| > |S| \text{ for some } a \in \Sigma\}$, and the set of final states be the set of all subsets of S. A final state can be reached from an initial state if and only if S is extensible in $\mathscr{A}$. We can simply check this condition by a BFS. The size (number of states and edges) of this automaton is bounded by $\mathcal{O}(|\Sigma|n^k)$, so the procedure takes this time. ◀

▶ **Problem 11** (Totally extensible small subset). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$ with $|S| \leq k$, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$?*

For $k = 1$ Problem 2 is equivalent to checking if the automaton is synchronizing to the given state, thus can be solved in $\mathcal{O}(|\Sigma|n^2)$ time. For larger k we have the following:

▶ **Proposition 12.** *Problem 11 can be solved in $\mathcal{O}(|\Sigma|(n^3 + n^k))$ time.*

Proof. Let u be a word of the minimal rank in $\mathscr{A}$. We can find such a word and compute the image $Q \cdot u$ in $\mathcal{O}(|\Sigma|n^3)$ time, using e.g. the algorithm from [12].

For each $w \in \Sigma^*$ we have $S \cdot w^{-1} = Q$ if and only if $Q \cdot w \subseteq S$. We can meet the required condition for w if and only if $(Q \cdot u) \cdot w \subseteq S$. Surely $|(Q \cdot u) \cdot w| = |(Q \cdot u)|$. The desired word does not exist if the minimal rank is larger than $|S| = k$. Otherwise, we can build the subset automaton $\mathscr{A}^{\leq |Q \cdot u|}$ (similarly as in the proof of Proposition 10). The initial subset is $Q \cdot u$. If some subset of S is reachable by a word w, then the word uw totally extends S in $\mathscr{A}$. Otherwise, S is not totally extensible. Reachability can be checked in at most $\mathcal{O}(|\Sigma|n^k)$ time. However, if the rank r of u is less than k, the algorithm takes only $\mathcal{O}(|\Sigma|n^r)$ time. ◀

3.1 Bounded Length of the Word

We also have the two variants of the above problems when an upper bound on the length of the word is additionally given.

▶ **Problem 13** (Extensible small subset by short word). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$ with $|S| \leq k$, and an integer ℓ given in binary form, is there a word extending S of length at most ℓ?*

Problem 13 can be solved by the same algorithm in a Proposition 10, since the procedure can find a shortest extending word.

▶ **Problem 14** (Totally extensible small subset by short word). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$ with $|S| \leq k$, and an integer ℓ given in binary form, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$ of length at most ℓ?*

▶ **Proposition 15.** *For every k, Problem 14 is NP-complete, even if the automaton is simultaneously strongly connected, synchronizing, and binary.*

Proof. The problem is in NP, as the shortest extending words have length at most $\mathcal{O}(n^3 + n^k)$ (since words of this length can be found by the procedure from Proposition 12).

When we choose S of size 1, the problem is equivalent to finding a reset word that maps every state to the state in S. In [34] it has been shown that for Eulerian automata that are simultaneously strongly connected, synchronizing, and binary, deciding whether there is a reset word of length at most ℓ is NP-complete. Moreover, in this construction, if there exists a reset word of this length, then it maps every state to one particular state s_2 (see [34, Lemma 2.4]). Therefore, we can set $S = \{s_2\}$, and thus Problem 14 is NP-complete. ◀

4 Extending Large Subsets

We consider here the case when the subset S contains all except at most a fixed number of states k.

▶ **Problem 16** (Extensible large subset). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$ with $|Q \setminus S| \leq k$, is there a word extending S?*

▶ **Problem 17** (Totally extensible large subset). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$ with $|Q \setminus S| \leq k$, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$?*

Problem 17 is equivalent to deciding the existence of an avoiding word for a subset S of size $\leq k$. Note that both problems are equivalent for $k = 1$, which is the problem of avoiding a single given state. Their properties will also turn out to be different than in the case of $k \geq 2$. We give a special attention to this problem and study it separately.

▶ **Problem 18** (Avoidable state). *Given $\mathscr{A} = (Q, \Sigma, \delta)$ and a state $q \in Q$, is there a word $w \in \Sigma^*$ such that $q \notin Q \cdot w$?*

The following result may be a bit surprising, in view of that it is the only case where the general problem remains equally hard when the subset size is bounded. We state that the first problem remains PSPACE-complete for all $k \geq 2$, although the problem remains open for strongly connected automata.

▶ **Theorem 19.** *Problem 16 is PSPACE-hard for every $k \geq 2$ and $|\Sigma| \geq 2$ even if the given automaton is synchronizing.*

Proof idea. We show a reduction from PSPACE-complete Problem 2 (Thm. 3). Our obtained automaton is ternary and synchronizing with a sink state e'.

We reduce the alphabet to two letters by an application of the Theorem 4 to Problem 16. The reduction in the proof keeps the size of complement set the same, so we can apply it. Furthermore, we identify all copies of the sink state e', which ensures that it remains synchronizing. ◀

Now, we focus on totally extending words for large subsets, which we study in terms of avoiding small subsets. First we provide a complete characterization of single states that are avoidable:

▶ **Theorem 20.** *Let $\mathscr{A} = (Q, \Sigma, \delta)$ be a strongly connected automaton. For every $q \in Q$, state q is avoidable if and only if there exists $p \in Q \setminus \{q\}$ and $w \in \Sigma^*$ such that $q \cdot w = p \cdot w$.*

Proof. Let p and w be the state and the word from the theorem for a given state q. Since the automaton is strongly connected, there is a word w' such that such that $(p \cdot w) \cdot w' = (q \cdot w) \cdot w' = p$. For each subset $S \subseteq Q$ such that $p \in S$ we have $p \in S \cdot ww'$. Moreover, if $q \in S$ then $|S \cdot ww'| < |S|$, because $\{q, p\} \cdot ww' = \{p\}$. If q is not avoidable, then all subsets $Q \cdot (ww'), Q \cdot (ww')^2, \ldots$ contain q and they form an infinite sequence of subsets of decreasing cardinality, which is a contradiction.

Now consider the other direction. Suppose for a contradiction that q is avoidable, but there is no state $p \in Q \setminus \{q\}$ such that $\{q, p\}$ can be compressed. Let u be a word of the minimal rank in $\mathscr{A}$, and v be a word that avoids q. Then $w = uv$ has the same rank and also avoids q. Let $\sim$ be the equivalence relation defined by

$$p_1 \sim p_2 \iff p_1 \cdot w = p_2 \cdot w.$$

The equivalence class $[p]_\sim$ for $p \in Q$ is $(p \cdot w) \cdot w^{-1}$. There are $|Q/\!\sim| = |Q \cdot w|$ equivalence classes and one of them is $\{q\}$, since q does not belong to a compressible pair of states. For every state $p \in Q$, we know that $|(Q \cdot w) \cap [p]_\sim| \leq 1$, because $[p]_\sim$ is compressed by w to a singleton and $Q \cdot w$ cannot be compressed by any word. Note that every state $r \in Q \cdot w$ belongs to some class $[p]_\sim$. From the equality $|Q/\!\sim| = |Q \cdot w|$ we conclude that for every class $[p]_\sim$ there is a state $r \in (Q \cdot w) \cap [p]_\sim$, thus $|(Q \cdot w) \cap [p]_\sim| = 1$. In particular, $1 = |(Q \cdot w) \cap [q]_\sim| = |(Q \cdot w) \cap \{q\}|$. This contradicts that w avoids q. ◀

Note that if $\mathscr{A}$ is not strongly connected, then every state from a strongly connected component that is not a sink can be avoided. If a state belongs to a sink component, then we can consider the sub-automaton of this sink component, and by Theorem 20 we know that given $q \in Q$, it is sufficient to check whether q belongs to a compressible pair of states. Hence, Problem 18 can be solved using the well-known algorithm [12] computing the pair automaton and performing a breadth-first search with inverse edges on the pairs of states. It works in $\mathcal{O}(|\Sigma|n^2)$ time and $\mathcal{O}(n^2 + |\Sigma|n)$ space.

We note that in a synchronizing automaton all states are avoidable except a *sink state*, which is a state q such that $q \cdot a = q$ for all $a \in \Sigma$. We can check this condition and hence verify if a state is avoidable in a synchronizing automaton in $\mathcal{O}(|\Sigma|)$ time.

The above algorithm does not find an avoiding word but checks avoidability indirectly. For larger subsets than singletons, we construct another algorithm finding a word avoiding the subset, which also generalizes the idea from Theorem 20. From the following theorem, it follows that Problem 17 for $k \geq 2$ can be solved in polynomial time.

▶ **Theorem 21.** *Let $\mathscr{A} = (Q, \Sigma, \delta)$, let r be the minimum rank in $\mathscr{A}$ over all words, and let $S \subseteq Q$ be a subset of size $\leq k$. We can find a word w such that $(Q \cdot w) \cap S = \emptyset$ or verify that it does not exist in $\mathcal{O}(n^3 + |\Sigma|(n^2 + n^{\min(r,k)}))$ time and $\mathcal{O}(n^2 + n^{\min(r,k)} + |\Sigma|n)$ space. Moreover the length of w is bounded by $\mathcal{O}(n^3 + n^{\min(r,k)}))$.*

Proof. Similarly to the proof of Theorem 20, let u be a word of the minimal rank r in $\mathscr{A}$ and let $\sim$ be the equivalence relation on Q defined by

$$p_1 \sim p_2 \iff p_1 \cdot u = p_2 \cdot u.$$

The equivalence class $[p]_\sim$ for $p \in Q$ is the set $(p \cdot u) \cdot u^{-1}$. There are $|Q/\!\sim| = |Q \cdot u|$ equivalence classes.

Now, we are going to show the following characterization: S is avoidable if and only if there exist a subset $Q' \subseteq Q \cdot u$ of size $|S/\!\sim|$ and a word w' such that $(Q' \cdot w') \cap ([s]_\sim \setminus S) \neq \emptyset$ for each $s \in S$.

Suppose that S is avoidable, and let w' be an avoiding word for S. Then the word $w = uw'$ also avoids S. Observe that w has rank r as u has. For every state $p \in Q$, we know that $|(Q \cdot w) \cap [p]_\sim| \leq 1$, because $[p]_\sim$ is compressed by u to a singleton and $Q \cdot w$ cannot be compressed by any word. Note that every state $q \in Q \cdot w$ belongs to some class $[p]_\sim$. From the equality $|Q/\sim| = |Q \cdot u| = |Q \cdot w|$ we conclude that for every class $[p]_\sim$ there is a unique state $q_{[p]_\sim} \in (Q \cdot w) \cap [p]_\sim$.

Then for every state $s \in S$, we have $q_{[s]_\sim} \in [s]_\sim \setminus S$, because w avoids S and $q_{[s]_\sim} \in Q \cdot w$. Notice that $[s]_\sim \cap S$ can contain more than one state, so the set $\{q_{[s]_\sim} \mid s \in S\}$ has size $|S/\!\sim|$, which is not always equal to $|S|$. Therefore, there exists a subset $Q' \subseteq Q \cdot u$ of size $|S/\!\sim|$ such that $Q' \cdot w' = \{q_{[s]_\sim} \mid s \in S\}$. Now, we know that for every $s \in S$ we have $q_{[s]_\sim} \in Q' \cdot w'$ and $q_{[s]_\sim} \in [s]_\sim \setminus S$. We conclude that, if S is avoidable, then there exist a subset $Q' \subseteq Q \cdot u$ of size $|S/\!\sim|$ and a word w' such that $(Q' \cdot w') \cap ([s]_\sim \setminus S) \neq \emptyset$ for every $s \in S$.

Conversely, suppose that there is a subset $Q' \subseteq Q \cdot u$ of size $|S/\!\sim|$ and a word w' such that $(Q' \cdot w') \cap ([s]_\sim \setminus S) \neq \emptyset$ for every $s \in S$. Since in the image $Q \cdot uw'$ there is exactly one state in each equivalence class, we have $((Q \cdot u) \setminus Q') \cdot w' \subseteq Q \setminus \bigcup_{s \in S}([s]_\sim) \subseteq Q \setminus S$, and by the assumption, $(Q' \cdot w') \cap S = \emptyset$. Therefore, we get that uw' is an avoiding word for S.

This characterization gives us Alg. 1 to find w or verify that S cannot be avoided.

Alg. 1 first finds a word u of the minimal rank. This can be done by iterative compressing the subset as long as possible by the algorithm from [12], which works in $\mathcal{O}(n^3 + |\Sigma|n^2)$ time and $\mathcal{O}(n^2 + |\Sigma|n)$ space. For every subset $Q' \subseteq Q \cdot u$ of size $z = |S/\!\sim|$ the algorithm checks

Algorithm 1 Avoiding a subset.

Require: Automaton $\mathscr{A}(Q, \Sigma, \delta)$ and a subset $S \subseteq Q$.
1: Find a word u of the minimal rank.
2: Compute $|S/\!\sim|$.
3: **for all** $Q' \subseteq Q \cdot u$ of size $|S/\!\sim|$ **do**
4: **if** there is a word w' such that $(Q' \cdot w') \cap ([s]_\sim \setminus S) \neq \emptyset$ for each $s \in S$ **then**
5: **return** uw'.
6: **end if**
7: **end for**
8: **return** "S is unavoidable".

whether there is a word w' mapping Q' to avoid S, but using its $\sim$-classes. This can be done by constructing the automaton $\mathscr{A}^z(Q^z, \Sigma, \delta^z)$, where δ^z is δ naturally extended to z-tuples of states, and checking whether there is a path from Q' to a subset containing a state from each class $[s]_\sim$ but avoiding the states from S. Note that since Q' cannot be compressed, every reachable subset from Q' has also size $|Q'|$. The number of states in this automaton is $\binom{n}{z} \in \mathcal{O}(n^z)$. Also, note that we have to visit every z-tuple only once during a run of the algorithm, and we can store it in $\mathcal{O}(n^z + |\Sigma|n)$ space. Therefore, the algorithm works in $\mathcal{O}(n^3 + |\Sigma|(n^2 + n^z))$ time and $\mathcal{O}(n^2 + n^z + |\Sigma|n)$ space.

The length of u is bounded by $\mathcal{O}(n^3)$, and the length of w' is at most $\mathcal{O}(n^z)$. Note that $z = |S/\!\sim| \leq \min(r, |S|)$, where r is the minimal rank in the automaton. ◀

4.1 Bounded Length of the Word

We now turn our attention to the variants of the problems where an upper bound on the length of the word is given.

▶ **Problem 22** (Extensible large subset by short word). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$ with $|Q \setminus S| \leq k$, and an integer ℓ given in binary form, is there a word extending S of length at most ℓ?*

▶ **Problem 23** (Totally extensible large subset by short word). *For a fixed $k \in \mathbb{N}$, given $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$ with $|Q \setminus S| \leq k$, and an integer ℓ given in binary form, is there a word $w \in \Sigma^*$ such that $S \cdot w^{-1} = Q$ of length at most ℓ?*

As before, both problems for $k = 1$ are equivalent to the following:

▶ **Problem 24** (Avoidable state by short word). *Given $\mathscr{A} = (Q, \Sigma, \delta)$, a state $q \in Q$, and an integer ℓ given in binary form, is there a word $w \in \Sigma^*$ such that $q \notin Q \cdot w$ of length at most ℓ?*

Problem 22 for $k \geq 2$ obviously remains PSPACE-complete. By the following theorem, we show that Problem 24 is NP-complete, which then implies NP-completeness of Problem 23 for every $k \geq 1$ (by Corollary 26).

▶ **Theorem 25.** *Problem 24 is NP-complete, even if the automaton is simultaneously strongly connected, synchronizing, and binary.*

Proof idea. The problem is in NP, because we can non-deterministically guess a word w as a certificate, and verify $q \notin Q \cdot w$ in $\mathcal{O}(|\Sigma|n)$ time. If the state q is avoidable, then the length of the shortest avoiding words is at most $\mathcal{O}(n^2)$ [27]. Then we can guess an avoiding word w of at most quadratic length and compute $Q \cdot w$ in $\mathcal{O}(n^3)$ time.

To prove NP-hardness, we show a reduction from the problem of determining the reset threshold in the specific subclass of automata constructed in the Eppstein's proof of [12, Theorem 8], which is known to be NP-complete. The reduction has two steps. First, we construct a strongly connected synchronizing ternary automaton for which deciding about the length of an avoiding word is equivalent to determining the existence of a reset word in the original automaton. Then, based on the ideas from [5] we turn the automaton into a binary one that still has the desired properties. ◀

As a corollary from Theorem 25 and Theorem 21, we complete the results.

▶ **Corollary 26.** *Problem 23 is NP-complete, Problem 8 is NP-complete when the automaton is synchronizing, and Problem 22 is NP-complete when the automaton is strongly connected and synchronizing. They remain NP-complete when the automaton is simultaneously strongly connected, synchronizing, and binary.*

5 Resizing a Subset

▶ **Problem 27** (Resizable subset)**.** *Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$ and a subset $S \subseteq Q$, is there a word $w \in \Sigma^*$ such that $|S \cdot w^{-1}| \neq |S|$?*

▶ **Problem 28** (Resizable subset by short word)**.** *Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$, and an integer ℓ given in binary form, is there a word $w \in \Sigma^*$ such that $|S \cdot w^{-1}| \neq |S|$ of length at most ℓ?*

In contrast to the cases $|S \cdot w^{-1}| > |S|$ and $|S \cdot w^{-1}| < |S|$, there exists a polynomial time algorithm for both these problems.

▶ **Theorem 29.** *Given an automaton $\mathscr{A} = (Q, \Sigma, \delta)$, a subset $S \subseteq Q$, there exists an algorithm working in $\mathcal{O}(|\Sigma|n^3)$ time (assuming constant time arithmetic of integers whose values are bounded by $\mathcal{O}(2^n)$) that computes a shortest word w such that $|S \cdot w^{-1}| \neq |S|$ or verifies that there is no such word. Moreover, the length of the shortest such words is a at most $n - 1$.*

Proof idea. We construct a reduction to the problem of multiplicity equivalence of NFAs and apply the algorithm from [30] with an improvement to achieve the desired complexity[4]. ◀

The running time $\mathcal{O}(|\Sigma|n^3)$ of the algorithm is quite large (and may require large arithmetic), and it is an interesting open question whether there is a faster algorithm for Problems 27 and 28.

We note that Problem 27 becomes trivial when the automaton is synchronizing: A word resizing the subset exists if and only if $S \neq \emptyset$ and $S \neq Q$, because if w is a reset word and $\{q\} = Q \cdot w$, then $S \cdot w^{-1}$ is either Q when $q \in S$ or $\emptyset$ when $q \notin S$. This implies that there exists a faster algorithm in the sense of expected running time when the automaton over an at least binary alphabet is drawn uniformly at random:

▶ Remark. The algorithm from [6] checks in expected $\mathcal{O}(n)$ time (regardless of the alphabet size, which is not fixed) whether a random automaton is synchronizing, and it is synchronizing with probability $1 - \Theta(1/n^{0.5|\Sigma|})$ (for $|\Sigma| \geq 2$). Then only if it is not synchronizing we

[4] In a previous version of our proof we presented our own algorithm having $\mathcal{O}(|\Sigma|n^3)$ time complexity under the assumption of performing arithmetic computations in constant time. We thank one of the anonymous reviewers that suggested a shortcut by reducing to multiplicity equivalence of NFAs.

have to use the algorithm from Theorem 29. Thus, Problem 28 can be solved for a random automaton in the expected time

$$\mathcal{O}(|\Sigma|n^3) \cdot \Theta(1/n^{0.5|\Sigma|}) + \mathcal{O}(n) = \mathcal{O}(|\Sigma|n^{3-0.5|\Sigma|}) \leq \mathcal{O}(n^2).$$

Note that the bound is independent on the alphabet size, and this is because a random automaton with a growing alphabet is more likely to be synchronizing, so less likely we need to use Theorem 29.

Abstract

We study the Constraint Satisfaction Problem CSP($\mathbb{A}$), where $\mathbb{A}$ is first-order definable in $(\mathbb{Z}; +, 1)$ and contains $+$. We prove such problems are either in P or NP-complete.

1 Introduction

A *constraint satisfaction problem* (CSP) is a computational problem where the input consists of a finite set of variables and a finite set of constraints, and where the question is whether there exists a mapping from the variables to some fixed domain such that all the constraints are satisfied. When the domain is finite, and arbitrary constraints are permitted in the input, the CSP is NP-complete. However, when only constraints for a restricted set of relations are allowed in the input, it might be possible to solve the CSP in polynomial time. The set of relations that is allowed to formulate the constraints in the input is often called the *constraint language*. The question as to which constraint languages give rise to polynomial-time solvable CSPs has been the topic of intensive research over the past years. It was conjectured by Feder and Vardi [14] that CSPs for constraint languages over finite domains have a complexity dichotomy: they are in P or are NP-complete. This conjecture has recently been proved [12, 25].

A famous CSP over an infinite domain is the feasibility question for Integer Programs. It is of great importance in practice and theory of computing, and NP-complete. In order to obtain a systematic understanding of polynomial-time solvable restrictions and variations of this problem, Jonsson and Lööw [15] proposed to study the class of CSPs where the constraint language $\mathbb{A}$ is definable in *Presburger arithmetic*; that is, consists of relations that have a first-order definition over $(\mathbb{Z}; <, +, 1)$. Equivalently, each relation $R(x_1, \ldots, x_n)$ in $\mathbb{A}$ can be defined by a disjunction of conjunctions of the atomic formulas of the form $p \leq 0$ where p is a linear polynomial with integer coefficients and variables from $\{x_1, \ldots, x_n\}$. The constraint satisfaction problem for $\mathbb{A}$, denoted by $\mathrm{CSP}(\mathbb{A})$, is the problem of deciding whether a given conjunction of formulas of the form $R(y_1, \ldots, y_n)$, for some n-ary R from $\mathbb{A}$, is satisfiable in $\mathbb{A}$. By appropriately choosing such a constraint language $\mathbb{A}$, a great variety of problems over the integers can be formulated as $\mathrm{CSP}(\mathbb{A})$. Several constraint languages $\mathbb{A}$ over the integers are known where the CSP can be solved in polynomial time. Among the most famous of these is Linear Diophantine Equations, namely $\mathrm{CSP}(\mathbb{Z}; +, 1)$. The first polynomial-time algorithms for the satisfiability of linear Diophantine equation systems have been discovered by Frumkin and, independently, Sieveking and von zur Gathen. Kannan and Bachem [17] presented a method based on first computing the Hermite Normal Form of the matrix given by the linear system (see discussion in the text-book of Schrijver [23]). Further improvements have been made in [13, 24, 19]. In the present parlance, $\mathrm{CSP}(\mathbb{Z}; <, +, 1)$ is Integer Program feasibility itself. However, a complete complexity classification for the CSPs of Jonsson-Lööw languages appears to be a very ambitious goal.

Among the classes of constraint language that fall into the framework of Jonsson and Lööw are the *distance CSPs* of [5, 10] and the *temporal CSPs* of [8]. Temporal CSPs are those whose constraint language is first-order definable in $(\mathbb{Q}; <)$ and *discrete temporal CSPs* are those whose constraint languages is first-order definable in $(\mathbb{Z}; <)$. The classification for discrete temporal CSPs represents the join of the work on temporal CSPs and distance CSPs, and has only recently been accomplished [4].

Moving away from the discrete and non-dense, $(\mathbb{Q}; <)$ is not the only structure for which constraint languages that are first-order expansions have had their CSPs classified. The situation for such expansions of the language of linear programming, $(\mathbb{Q}; <, +, 1)$ was settled in [6]. Perhaps, more interesting for us is the simplified situation in which only first-order expansions of $(\mathbb{Q}; +)$ are considered, in [7]. Most recently, the work [16] delivers a classification for all first-order definitions in $(\mathbb{Q}; <, +, 1)$ that contain $+$, thus properly extending the result from [6]. In these works, the class of relations quantifier-free definable in Horn CNF plays a key role. In this context, the atomic relations are inequalities and equalities, and each clause may have no more than one equality or inequality. That is, additional disjuncts in clauses must be disequalities. For first-order expansions of $(\mathbb{Q}; +)$, the tractable constraint languages are precisely those that are quantifier-free Horn definable on $(\mathbb{Q}; +)$ [7].

However, the integers behave very differently from the rationals or reals and even simple types of Horn definitions engender intractable constraint languages, as documented in [15]. This article shows, depending on one's perspective, [un]surprisingly, that the tractability frontier for first-order definitions of $(\mathbb{Z}; +, 1)$, containing $+$, coincides with that for first-order expansions of $(\mathbb{Q}; +)$. Under a mild technical assumption on $\mathbb{A}$, either all of its relations are quantifier-free Horn definable, in the expansion of $(\mathbb{Z}; +, 1)$ associated with its quantifier elimination, and $\mathrm{CSP}(\mathbb{A})$ is solvable in P; or $\mathrm{CSP}(\mathbb{A})$ is NP-complete. From this we obtain the following dichotomy result.

▶ **Theorem 1.** *Let $\mathbb{A}$ be an expansion of $(\mathbb{Z}; +)$ by finitely many relations with a first-order definition in $(\mathbb{Z}; +, 1)$. Then $\mathrm{CSP}(\mathbb{A})$ is in P or NP-complete.*

Other related work

This work forms part of a growing body addressing infinite-domain CSPs. One line of that work concerns ω-categorical and finitely-bounded constraint languages and the other line considers constraint languages over ordinary structures of arithmetic. The two lines overlap in the foundational work on temporal CSPs [8]. The outstanding other result in the first line is [11] and recent progress can be seen in [3, 1]. The importance of the latter line is discussed in the survey [9].

The CSP for certain finite groups were studied already in the seminal [14]. $(\mathbb{Z}; +, 0)$ is a group *par excellence* and our work takes inspiration from that paper. One of our hardness results uses its Theorem 34 and our tractable cases include the situation when all relations are subgroups, or cosets of subgroups, of powers of $\mathbb{Z}$ (cf. [14], Theorem 33). However, not all first-order expansions of $(\mathbb{Z}; +, 1)$ are related to groups, and we have other sources of tractability too.

2 Preliminaries

We say a relational structure $\mathbb{A}$ is *first-order definable in* $(\mathbb{Z}; +, 1)$ (or a *first-order reduct of*$(\mathbb{Z}; +, 1)$ if it is over domain $\mathbb{Z}$ with relations specified by first-order formulas over $(\mathbb{Z}; +, 1)$. An *endomorphism* of $\mathbb{A}$ is a map $h\colon \mathbb{Z} \to \mathbb{Z}$ such that for every relation R of $\mathbb{A}$ and every tuple $(a_1, \dots, a_k) \in \mathbb{Z}^k$, we have $\mathbf{a} \in R \Rightarrow h(\mathbf{a}) \in R$. We say that h is a *self-embedding* if the implication is an equivalence.

A formula over a relational signature σ is *primitive positive (pp)* if it is of the form $\exists x_1, \dots, x_k(\psi_1 \wedge \dots \wedge \psi_m)$ where each ψ_i is an atomic relation built from σ. Note that 0 is pp-definable in $(\mathbb{Z}; +)$. A *sentence* is a formula without free variables.

The *constraint satisfaction problem* for a structure $\mathbb{A}$ with finite relational signature σ, denoted CSP($\mathbb{A}$), is the following computational problem.

Input: A primitive positive σ-sentence Φ.
Question: $\mathbb{A} \models \Phi$?

All CSPs will be defined over strictly relational signatures, thus in this context $+$ must be considered a ternary relation and 1 a constant or singleton unary relation, depending on taste. Since we also use $+$ with its common meaning of binary operation, we concede guilt for overloading. However, the two uses will never conflict in meaning, so we will not dwell further on the matter. If $\mathbb{A}$ is first-order definable in $(\mathbb{Z}; <, +, 1)$ then CSP($\mathbb{A}$) is in NP (this is noted e.g. in [15]).

A *linear equation* is a formula of the form $\sum_{i=1}^{n} a_i x_i = b$ with $a_1, \dots, a_n, b \in \mathbb{Z}$, whose free variables are $\{x_1, \dots, x_n\}$. A *modular linear equation* is a formula of the form $\sum_{i=1}^{n} a_i x_i = b \bmod c$ with $a_1, \dots, a_n, b, c \in \mathbb{Z}$. Let $\mathcal{L}_{(\mathbb{Z};+,1)}$ be the infinite relational language containing a relation symbol for each linear equation and modular linear equation. For convenience, we consider first-order logic to have native symbols for $\top$ (true) and $\bot$ (false). It is well-known that $(\mathbb{Z}; +, 1)$ admits quantifier elimination in the language $\mathcal{L}_{(\mathbb{Z};+,1)}$ (see [21], or [18, Corollary 3.1.21] for a more modern treatment). Call an $\mathcal{L}_{(\mathbb{Z};+,1)}$-formula *standard* if it does not contain a negated modular linear equation. Every $\mathcal{L}_{(\mathbb{Z};+,1)}$-formula is equivalent to a standard $\mathcal{L}_{(\mathbb{Z};+,1)}$-formula, since a negated modular linear equation is equivalent to a disjunction of modular linear equations (i.e., $k \neq b \bmod c \Leftrightarrow \bigvee_{0 \leq a \leq c, a \neq b} k = a \bmod c$). We say that an equation *appears* in a formula if it is a positive or negative literal in that formula.

Any subgroup G of $\mathbb{Z}^k$ can be given by a finite set of *generators*, i.e., k-tuples $\mathbf{g}^1, \dots, \mathbf{g}^m$, such that for every $\mathbf{g} \in G$, there are $\lambda_1, \dots, \lambda_m \in \mathbb{Z}$ such that $\mathbf{g} = \sum_i \lambda_i \mathbf{g}^i$, where we

write $\lambda \cdot \mathbf{g}$ for $(\lambda g_1, \dots, \lambda g_k)$. A *coset* of a subgroup G of $\mathbb{Z}^k$ is any set of the form $\mathbf{a} + G := \{\mathbf{a} + \mathbf{g} \mid \mathbf{g} \in G\}$, where $\mathbf{a} \in \mathbb{Z}^k$. By moving to a standard formula, we are in a position to deduce the following.

▶ **Proposition 2.** *Suppose R is a unary relation first-order definable in $(\mathbb{Z}; +, 1)$. Then R has the form $(R^\circ \cup R^+) \setminus R^-$, where R° is a finite union of cosets of nontrivial subgroups of $\mathbb{Z}$, and R^+ and R^- are finite disjoint sets of integers.*

Proof. Consider a disjunction φ of equations (possibly negated and modular equations). If this disjunction contains a negated equation $ax \neq c$, then φ defines a relation that contains $\mathbb{Z} \setminus \{c/a\}$ and is therefore as in the statement. Otherwise, φ contains only positive linear equation and modular equations, and the relation that φ defines is clearly of the form $R^\circ \cup R^+$ for some finite set R^+ and some union R° of nontrivial subgroups of $\mathbb{Z}$.

Consider a quantifier-free formula φ in conjunctive normal form defining R. Each conjunct defines a relation of the right form, per the previous paragraph. It is easily checked that a conjunction of relations of this form is again a relation of the form $(R^\circ \cup R^+) \setminus R^-$, so that we have proved that every quantifier-free formula with one free variables defines a relation of the right form. The proposition then follows from quantifier-elimination. ◀

Note that if $R^+ \cap R^\circ = \emptyset$ and $R^- \subset R^\circ$, then R^+, R^-, and R° are unique. We use the terminology with this convention for all unary relations R that are first-order definable in $(\mathbb{Z}; +, 1)$ throughout the article.

▶ **Definition 3.** Let φ be an $\mathcal{L}_{(\mathbb{Z};+,1)}$-formula. We say that φ is *Horn* if it is a conjunction of clauses of the form

$$\bigvee_{i=1}^{n} \neg\varphi_i \vee \varphi_0$$

where $\varphi_1, \dots, \varphi_n$ are linear equations and φ_0 is a linear or a modular linear equation.

▶ **Example 4.** Singletons, cofinite unary relations, and cosets of subgroups of $\mathbb{Z}^n$ are examples of Horn-definable relations.

3 Cores

If $\mathbb{A}$ is a first-order expansion of $(\mathbb{Z}; +)$, note that its endomorphisms are precisely of the form $x \mapsto \lambda x$ for some $\lambda \in \mathbb{Z}$. Therefore, we view in the following $\mathrm{End}(\mathbb{A})$ as a subset of $\mathbb{Z}$, where the monoid structure on $\mathrm{End}(\mathbb{A})$ implies that as a subset of $\mathbb{Z}$, it is closed under multiplication and contains 1. We say that $\mathbb{A}$ is a core if all its endomorphisms are self-embeddings, and that $\mathbb{B}$ is a core of $\mathbb{A}$ if $\mathbb{A}$ and $\mathbb{B}$ are homomorphically equivalent and $\mathbb{B}$ is a core.

▶ **Lemma 5.** *Let $\mathbb{A}$ be first-order definable in $(\mathbb{Z}; +, 1)$, and suppose that $\mathbb{A}$ contains $+$. There exists a structure which is a core of $\mathbb{A}$, and which is either a 1-element structure or first-order definable in $(\mathbb{Z}; +, 1)$ and containing $+$.*

Proof. If $0 \in \mathrm{End}(\mathbb{A})$ then the lemma is clearly true ($\mathbb{A}$ being homomorphically equivalent to the substructure of $\mathbb{A}$ induced by $\{0\}$), so let us assume that $0 \notin \mathrm{End}(\mathbb{A})$. Similarly we can assume that $\mathrm{End}(\mathbb{A}) \not\subseteq \{-1, 1\}$, otherwise $\mathbb{A}$ is already a core. For a quantifier-free formula ψ and an integer λ, define ψ/λ by induction on ψ as follows:

- if ψ is $\sum \lambda_i x_i = c$ and λ divides c, then ψ/λ is $\sum \lambda_i x_i = c/\lambda$,
- if ψ is $\sum \lambda_i x_i = c$ and λ does not divide c, then ψ/λ is $\bot$,

- if ψ is $\sum \lambda_i x_i = c \bmod d$ and $\ell := \gcd(\lambda, d)$ divides c, then ψ/λ is $\sum \lambda_i x_i = ec/\ell \bmod d/\ell$ where e is the inverse of λ/ℓ modulo d/ℓ,
- if ψ is $\sum \lambda_i x_i = c \bmod d$ and $\ell := \gcd(\lambda, d)$ does not divide c, then ψ/λ is $\bot$,
- extend to boolean combinations in the obvious fashion.

Note that for every tuple $\mathbf{a}$, we have that $\mathbf{a}$ satisfies ψ/λ iff $\lambda \cdot \mathbf{a}$ satisfies ψ. Indeed, if ψ is a linear equation then this is clear. Similarly, it is clear if ψ is a modular equation and $\ell := \gcd(\lambda, d)$ does not divide c. Suppose that ψ is a modular equation and $\ell := \gcd(\lambda, d)$ divides c. If $\sum \lambda\lambda_i x_i = c \bmod d$ then $\lambda/\ell \cdot (\sum \lambda_i x_i) = qd/\ell + c/\ell$ so that $e\lambda/\ell \cdot (\sum \lambda_i x_i) = (eq) \cdot d/\ell + ec/\ell$, where e is the inverse of λ/ℓ modulo d/ℓ and $q \in \mathbb{Z}$. We therefore obtain $\sum \lambda_i x_i = ec/\ell \bmod d/\ell$. Conversely if $\sum \lambda_i x_i = ec/\ell \bmod d/\ell$ then $\sum \lambda\lambda_i x_i = (\lambda e)c/\ell + (\frac{\lambda}{\ell} q)d = c \bmod d$.

Let ψ be any quantifier-free $\mathcal{L}_{(\mathbb{Z};+,1)}$-formula and suppose that $|\lambda| > 1$. The only cases where some magnitudes of the integers on the right-hand sides of terms in the formula ψ do not decrease by forming ψ/λ is when ψ only contains literals either of the form $\sum \lambda_i x_i = 0$ or of the form $\sum \lambda_i x_i = c \bmod d$ with λ and d coprime. Therefore, the sequence $\psi_0, \psi_1, \psi_2, \ldots$ where ψ_0 is ψ and where ψ_{i+1} is ψ_i/λ for some $\lambda \in \mathrm{End}(\mathbb{A})$ with $|\lambda| > 1$ reaches in a finite number of steps a fixpoint where all the literals are either of the form $\sum \lambda_i x_i = 0$ or are modular equations whose modulus d is such that λ and d are coprime. Let $n \geq 1$ be such that for every ψ defining a relation of $\mathbb{A}$, the formula ψ_n is a fixpoint. Let $\mathbb{B}$ be the structure whose domain is $\mathbb{Z}$ and whose relations are $+$ and the relations defined by ψ_n for each ψ defining a relation of $\mathbb{A}$.

We claim that $\mathbb{B}$ is homomorphically equivalent to $\mathbb{A}$ and is a core. The first claim is clear, since $\mathbb{B}$ is isomorphic to the structure obtained from $\mathbb{A}$ by successive applications of endomorphisms $x \mapsto \lambda \cdot x$ (in particular $\mathbb{B}$ embeds into $\mathbb{A}$). Let now $x \mapsto \lambda \cdot x$ be an endomorphism of $\mathbb{B}$, and suppose that $\mathbf{a}$ is a tuple in a relation R of $\mathbb{B}$. Then we have that $\lambda \cdot \mathbf{a}$ in R since $x \mapsto \lambda \cdot x$ is an endomorphism. Conversely, note that λ is coprime to d or else we would not have reached a fixed point in the previous stage. Thus, $\lambda^{\varphi(d)} = 1 \bmod d$, where $\varphi(d)$ here is the totient of d. It follows then that $\lambda^{\varphi(d)}\mathbf{a} = \mathbf{a} \bmod d$. Suppose $\lambda\mathbf{a} \in R$, then by applying $\varphi(d) - 1$ times an endomorphism, we derive $\lambda^{\varphi(d)}\mathbf{a} \in R$. It follows that $\mathbf{a} \in R$, for both the cases that atoms are of the form $\sum \lambda_i x_i = 0$ or are modular equations whose modulus d is such that λ and d are coprime. Hence, $x \mapsto \lambda \cdot x$ is an embedding of $\mathbb{A}$. ◀

We order the standard formulas lexicographically with respect to (in this order)

1. the number of non-Horn clauses,
2. the number of literals in clauses with at least two literals,
3. the number of all literals, and
4. the sum of the absolute values of all numbers appearing in an equation.

This order is used in a number of statements and proofs throughout the text, e.g., in Proposition 6, Lemma 17, and Theorem 18. A standard formula is *minimal* if no smaller formula is equivalent to it.

The following properties follow from the construction of cores in the previous proof.

▶ **Proposition 6.** *Let $\mathbb{A}$ be first-order definable in $(\mathbb{Z}; +, 1)$, and suppose that $\mathbb{A}$ contains $+$ and is a core. Let $\lambda \in \mathrm{End}(\mathbb{A})$. Let R be a relation of $\mathbb{A}$ and let φ be a minimal standard formula defining R.*

- *If $\sum \lambda_i x_i = c$ is a linear equation appearing in φ, then $c = 0$ or $|\lambda| = 1$.*
- *If $\sum \lambda_i x_i = c \bmod d$ is a modular linear equation in φ, then λ and d are coprime.*

Moreover, if $\mathrm{End}(\mathbb{A}) = 1 + d\mathbb{Z}$ for some $d \geq 2$, then every relation of $\mathbb{A}$ can be expressed with a minimal formula in which all modular linear equations are modulo a divisor of d.

Proof. The two items are clear from the proof of Lemma 5. For the last statement, let d' be a modulus appearing in a minimal definition of a relation of $\mathbb{A}$. By the second item, we have that d' and $1 + kd$ are coprime, for all $k \in \mathbb{Z}$. Let ℓ be such that $\ell d = -1 \bmod \frac{d'}{\gcd(d,d')}$. If d' and $1 + \ell d$ are coprime, there exist $u, v \in \mathbb{Z}$ such that $ud' + v(1 + \ell d) = 1$. Taking this equation modulo $\frac{d'}{\gcd(d,d')}$ we obtain $0 = 1 \bmod \frac{d'}{\gcd(d,d')}$, so that $\gcd(d, d') = d'$ and d' divides d. ◀

4 Hardness

Our sources of hardness come from *pp-interpretations*, that we define now. A structure $\mathbb{B}$ is said to be *one-dimensional pp-interpretable* in $\mathbb{A}$ if there exists a partial surjective map $h\colon A \to B$, called the *coordinate map*, such that the inverse image of every relation of $\mathbb{B}$ (including the equality relation and the unary relation B) under h has a pp-definition in A. Formally, we require that for every k-ary relation R of $\mathbb{B}$, there exists a pp-formula $\varphi_R(x_1, \dots, x_k)$ in the language of $\mathbb{A}$ such that

$$\mathbb{A} \models \varphi_R(a_1, \dots, a_k) \Leftrightarrow \mathbb{B} \models R(h(a_1), \dots, h(a_k))$$

holds for all $a_1, \dots, a_k \in A$. This requirement for the equality relation of $\mathbb{B}$ and the unary relation B implies that the kernel of h and its domain have a pp-definition in $\mathbb{A}$. It is well-known that if $\mathbb{B}$ is pp-interpretable in $\mathbb{A}$, then $\mathrm{CSP}(\mathbb{B})$ reduces in polynomial time to $\mathrm{CSP}(\mathbb{A})$.

4.1 The fully modular case

One of the sources of hardness for our problems are expansions of the *general subgroup problem* from [14]. The general subgroup problem of a finite abelian group G is the CSP of $(G; +)$ expanded with a k-ary relation for every coset $\mathbf{a} + H$, where H is a subgroup of G^k. It is known that this problem is solvable in polynomial time (under some reasonable encoding of the input); in modern parlance, this follows from the fact that the operation $(x, y, z) \mapsto x - y + z$ is a Maltsev polymorphism of the template. Feder and Vardi [14, Theorem 34] proved that the problem becomes NP-hard if the template is further expanded by any other relation.

The general subgroup problem of $\mathbb{Z}/d\mathbb{Z}$ can be viewed as a CSP of a first-order reduct of $(\mathbb{Z}; +, 1)$ whose relations are defined by quantifier-free formulas only containing modular linear equations. This motivates the following definition.

▶ **Definition 7.** A relation $R \subseteq \mathbb{Z}^k$ is called *fully modular* if it is definable by a conjunction of disjunctions of modular linear equations, in which case we can even assume that all the modular linear equations involved in such a definition of R have the same modulus $d \geq 1$.

▶ **Proposition 8.** *Let $\mathbb{A}$ be a finite-signature core which is first-order definable in $(\mathbb{Z}; +, 1)$ and contains $+$. Suppose that $\mathbb{A}$ has a fully modular relation that is not Horn-definable. Then $\mathrm{CSP}(\mathbb{A})$ is NP-complete.*

Proof. Let R be a relation of $\mathbb{A}$ that is not Horn-definable and fully modular, and let $d \geq 1$ be such that R can be defined with only linear equalities modulo d. Let $\mathbb{A}/d\mathbb{A}$ be the structure with domain $\mathbb{Z}/d\mathbb{Z}$ containing the ternary relation $+$ as well as a relation S' for every relation S of arity k of $\mathbb{A}$, defined by

$$S' = \{(a_1, \dots, a_k) \mid \exists q \in \mathbb{Z} : (qd + a_1, \dots, qd + a_k) \in S\}.$$

Note that $\mathbb{A}/d\mathbb{A}$ is pp-interpretable in $\mathbb{A}$: the coordinate map is the canonical projection $x \mapsto x \bmod d$, whose kernel is pp-definable by the formula $\varphi_=(x,y) := \exists z(x - y = dz)$. As a consequence, $\mathrm{CSP}(\mathbb{A}/d\mathbb{A})$ reduces in logarithmic space to $\mathrm{CSP}(\mathbb{A})$. Moreover, if $\mathbb{A}$ is a core then $\mathbb{A}/d\mathbb{A}$ is also a core. It follows from general principles [2, Proposition 3.3] that $\mathrm{CSP}(\mathbb{A}/d\mathbb{A}, 1)$ reduces to $\mathrm{CSP}(\mathbb{A}/d\mathbb{A})$ and so to $\mathrm{CSP}(\mathbb{A})$. Note that every coset of a subgroup of $(\mathbb{Z}/d\mathbb{Z})^k$ is pp-definable in $(\mathbb{A}/d\mathbb{A}, 1)$ and that if R is not Horn-definable then R' is not a coset of a subgroup. It follows from Theorem 34 in the bible [14] that $\mathrm{CSP}(\mathbb{A})$ is NP-complete. ◀

4.2 The unary case

In order to prove Theorem 1, we now focus on the case of *parametrised unary relations*.

▶ **Definition 9** (Compatibility). Let $\Lambda \subseteq \mathbb{Z} \setminus \{0\}$ be a set containing 1. We say that a set $\{S_\lambda\}_{\lambda\in\Lambda}$ of subsets of $\mathbb{Z}$ that are definable in $(\mathbb{Z}; +, 1)$ is *compatible* if there exist disjoint finite sets $A, B \subseteq \mathbb{Z}$ such that

- $S_\lambda = (S_\lambda^\circ \cup \lambda \cdot A) \setminus \lambda \cdot B$ for all $\lambda \in \Lambda$ and
- for all $d \geq 1$ and $c \in \{0, \dots, d-1\}$, we have $c + d\mathbb{Z} \subseteq S_1^\circ \Leftrightarrow \lambda c + d\mathbb{Z} \subseteq S_\lambda^\circ$.

▶ **Definition 10** (Uniform pp-definability). Let $\mathbb{A}$ be a first-order reduct of $(\mathbb{Z}; +, 1)$. We say that $\{S_\lambda\}_{\lambda\in\Lambda}$ is *uniformly pp-definable in* $\mathbb{A}$ if there exists a pp-formula $\theta(x, y)$ such that $a \in S_\lambda$ if, and only if, $\mathbb{A} \models \theta(\lambda, a)$.

Note that the definition of being uniformly pp-definable implies that Λ has a pp-definition in $\mathbb{A}$, for $\exists y.\, \theta(x, y)$ is a pp-definition. Let $S \subseteq \mathbb{Z}^2$ be a binary relation that is pp-definable in $\mathbb{A}$. Then the family $\{S_\lambda\}_{\lambda\in\Lambda}$ where $\Lambda := \{a \in \mathbb{Z} \mid (a, b) \in S \text{ for some } b \in \mathbb{Z}\} \subseteq \mathbb{Z} \setminus \{0\}$ and $S_\lambda := \{a \in \mathbb{Z} \mid (\lambda, a) \in S\}$ is uniformly pp-definable in $\mathbb{A}$. But even if S contains a tuple of the form $(1, b)$ and no tuple of the form $(0, b)$, it might not necessarily satisfy the compatibility condition, as illustrated in the following example.

▶ **Example 11.** Let $S = \{(a, b) \in \mathbb{Z}^2 \mid a \neq 0 \wedge (a = b \vee a = 2b)\}$. Then $\Lambda = \mathbb{Z} \setminus \{0\}$, and for $\lambda \in \Lambda$ we have $S_\lambda = \{\lambda\}$ if $\lambda = 1 \bmod 2$ and $S_\lambda = \{\lambda, \frac{\lambda}{2}\}$ if $\lambda = 0 \bmod 2$. Therefore, the compatibility condition is not satisfied by $\{S_\lambda\}_{\lambda\in\Lambda}$.

In the following proof, we write 1-in-3-SAT for $\mathrm{CSP}(\{0, 1\}; \{(1, 0, 0), (0, 1, 0), (0, 0, 1)\})$. It is well-known that this problem is NP-complete ([22]; for a proof see [20]).

▶ **Lemma 12.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ containing $+$. If $\{S_\lambda\}_{\lambda\in\Lambda}$ is a compatible set of unary relations that is uniformly pp-definable in $\mathbb{A}$ and if $1 < |S_\lambda| < \infty$ for all $\lambda \in \Lambda$, then $\mathrm{CSP}(\mathbb{A})$ is NP-hard.*

Proof. Since every S_λ is finite, one sees that $S_\lambda = \lambda \cdot A$ for the finite set A coming from the compatibility condition. Let $m_1 := \min(A)$ and $m_2 := \min(A \setminus \{m_1\})$. The formula

$$\exists \lambda(x + y + z = (m_2 - m_1)\lambda \wedge x + m_1\lambda \in S_\lambda \wedge y + m_1\lambda \in S_\lambda \wedge z + m_1\lambda \in S_\lambda \wedge \lambda \in \Lambda)$$

defines the ternary relation consisting of $(a, b, c) \in \mathbb{Z}^3$ such that $a, b, c \in \{0, m_2 - m_1\}$ and exactly one of a, b, c is equal to $m_2 - m_1$. Note that this formula is in the language of $\mathbb{A}$, since $\{S_\lambda\}_{\lambda\in\Lambda}$ is uniformly pp-definable and in particular Λ is pp-definable in $\mathbb{A}$. This gives an interpretation of 1-in-3-SAT in $\mathbb{A}$, using the map $h\colon \{0, m_2 - m_1\} \to \{0, 1\}$ such that $h(0) = 0$ and $h(m_2 - m_1) = 1$. Therefore, $\mathrm{CSP}(\mathbb{A})$ is NP-hard. ◀

▶ **Proposition 13.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ that contains $+$ and is a core. Let $\{S_\lambda\}_{\lambda\in\Lambda}$ be a compatible family that is uniformly pp-definable in $\mathbb{A}$ such that for every $\lambda \in \Lambda$ the set S_λ is not Horn-definable. Then* CSP($\mathbb{A}$) *is NP-hard.*

Proof. Let $A, B \subset \mathbb{Z}$ be finite such that $S_\lambda = (S_\lambda^\circ \cup \lambda \cdot A) \setminus (\lambda \cdot B)$ for all $\lambda \in \Lambda$. Since S_λ is not Horn-definable, we have $|S_\lambda| > 1$ for all $\lambda \in \Lambda$. If S_λ is finite for every $\lambda \in \Lambda$, then CSP($\mathbb{A}$) is NP-hard by Lemma 12. Therefore, we can assume that $S_\lambda^\circ \neq \emptyset$ for some $\lambda \in \Lambda$, and the second compatibility condition implies that S_λ° is infinite for all $\lambda \in \Lambda$. Let $d \geq 1$ be such that S_λ° is a union of cosets of $d\mathbb{Z}$ for all $\lambda \in \Lambda$. Write $S_1^\circ = \bigcup_{i=1}^n c_i + d\mathbb{Z}$, with $c_i \in \{0, \dots, d-1\}$.

If $n \in \{2, \dots, d-1\}$, we claim that we can pp-define a fully modular relation that is not Horn-definable. Indeed, let $\theta(x, y)$ be a formula that defines $\{S_\lambda\}_{\lambda\in\Lambda}$. Note that

$$\chi(x, y) := \theta(x, y) \wedge \theta(x, y + dx) \wedge \cdots \wedge \theta(x, y + \max(A \cup B)dx)$$

holds precisely on the pairs (λ, a) such that $a \in S_\lambda^\circ$: since x is forced to be in Λ by θ, a satisfying assignment gives a nonzero value λ to x. Thus, if all of $y, y + d\lambda, \dots, y + \max(A \cup B)d\lambda$ are in S_λ, then they all must be in the modular part S_λ°. The relation T that χ defines is fully modular and is such that $T_\lambda = S_\lambda^\circ$ and in particular T is not Horn-definable. It follows from Proposition 8 that CSP($\mathbb{A}$) is NP-hard.

Otherwise, the set S_λ° consists of a single coset of $d\mathbb{Z}$ for all $\lambda \in \Lambda$, and this coset is $\lambda c_1 + d\mathbb{Z}$ by the compatibility condition on $\{S_\lambda\}_{\lambda\in\Lambda}$. Since S_λ° is assumed to not be Horn-definable, A must contain an element a. We claim that we can define another family of unary relations where the unary relations are finite and not singletons. Indeed, consider the formula

$$\psi(x, y) := \exists z\, (\theta(x, y) \wedge \theta(x, z) \wedge y + z = (c_1 + a)x)$$

and let $T \subseteq \mathbb{Z}^2$ be the relation that it defines. First, note that $\psi(\lambda, c_1)$ and $\psi(\lambda, a)$ hold for all $\lambda \in \Lambda$, so that $|T_\lambda| > 1$. We claim that T_λ is finite. Since $A \cap S_1^\circ = \emptyset$, one has $a \neq c_1 \bmod d$. Consequently, $c_1 + a \neq 2c_1 \bmod d$ and $(c_1 + a)\lambda \neq 2c_1\lambda \bmod d$. The equation $y + z = (c_1 + a)\lambda$ therefore forces that one of y and z is in $\lambda \cdot A$. Since A is finite, there are only finitely many pairs satisfying this condition, thus showing that $1 < |T_\lambda| < \infty$. It follows from Lemma 12 that CSP($\mathbb{A}$) is NP-hard. ◀

As a corollary we obtain a simple-to-state condition implying that CSP($\mathbb{A}$) is NP-hard (Corollary 16). The corollary relies on the fact that End($\mathbb{A}$), being identified with a subset of $\mathbb{Z}$, can be pp-defined in $\mathbb{A}$. We prove this in the next lemma.

▶ **Lemma 14.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ that contains $+$. Then the set* End($\mathbb{A}$) *has a pp-definition in $\mathbb{A}$ that is additionally quantifier-free.*

Proof. Let E be the set of all the formulas $R(a_1 \cdot x, \dots, a_r \cdot x)$ for R in the language of $\mathbb{A}$ and $(a_1, \dots, a_r) \in R$. We then have that $\mathbb{A} \models E(\lambda)$ iff $\lambda \in$ End($\mathbb{A}$). We now show that there exists a finite subset $F \subseteq E$ that defines the same set of integers.

For each relation R of $\mathbb{A}$, fix a standard definition φ_R in conjunctive normal form of R in $(\mathbb{Z}; +, 1)$. Let M be the largest absolute value of a constant appearing in φ_R. Consider the finite family $\mathcal{F}$ of equations $\sum \mu_i x_i = m$, where $\sum \mu_i x_i = m'$ is some equation appearing in φ_R and $|m| \leq M$, together with all the equations $\sum \mu_i x_i = c \bmod d$ where $\sum \mu_i x_i = c' \bmod d$ is a modular equation appearing in φ_R and $c \in \{0, \dots, d-1\}$. For each subset of $\mathcal{F}$ that is satisfiable by a tuple in R, pick a tuple $\mathbf{b} \in R$ satisfying the formulas in this subset and add this tuple to a set $\mathcal{S}$. Repeat this operation for every relation of $\mathbb{A}$, and let $\mathcal{S}$ be the finite set of tuples (of possibly different arities) that we obtain. Finally, let F be the subset of E where only the formulas associated with tuples from $\mathcal{S}$ are kept.

We claim that F defines $\mathrm{End}(\mathbb{A})$. Since $F \subseteq E$, it suffices to show that every λ satisfying F is an endomorphism of $\mathbb{A}$. Let $\lambda \in \mathbb{Z}$ satisfy F, and let $\mathbf{a} \in R$ be a tuple in some relation of $\mathbb{A}$. Let $\mathbf{b} \in \mathcal{S}$ be such that $\mathbf{b}$ satisfies exactly the same equations in $\mathcal{F}$ as $\mathbf{a}$. By construction, $\lambda\mathbf{b} \in R$ so that in each clause of φ_R, some equation is satisfied by $\lambda\mathbf{b}$. We show that $\lambda\mathbf{a}$ satisfies the same equations, so that $\lambda\mathbf{a} \in R$. If $\lambda = 0$, then $\lambda\mathbf{b} = \lambda\mathbf{a}$ so that $\lambda\mathbf{a} \in R$. Suppose now that $\lambda \neq 0$. Let $\sum \mu_i x_i = c$ be a linear equation that is satisfied by $\lambda\mathbf{b}$. Then necessarily λ divides c, so that $\mathbf{b}$ satisfies $\sum \mu_i x_i = \frac{c}{\lambda}$ and $|\frac{c}{\lambda}| \leq |c| \leq M$, so that $\sum \mu_i x_i = \frac{c}{\lambda}$ is an equation in $\mathcal{F}$. Consequently, $\mathbf{a}$ also satisfies this equation and $\lambda\mathbf{a}$ satisfies $\sum \mu_i x_i = c$. The proof for modular linear equations is similar. This proves that λ is an endomorphism of $\mathbb{A}$ and concludes the proof. ◀

▶ **Lemma 15.** *Let $R \subseteq \mathbb{Z}$ be first-order definable over $(\mathbb{Z}; +, 1)$ such that $(\mathbb{Z}; +, R)$ is a core.*
- *If $R^+ \neq \emptyset$, then $\{1\}$ or $\{1, -1\}$ is pp-definable in $(\mathbb{Z}; +, R)$.*
- *If $R^+ = \emptyset$, then $R^- = \emptyset$ or $R = \mathbb{Z} \setminus \{0\}$.*

Proof. Let n be such that R° is a union of n cosets of $d\mathbb{Z}$, i.e.,

$$R^\circ = \bigcup_{i=1}^{n} c_i + d\mathbb{Z}.$$

Let us prove the first item. By Lemma 14, it suffices to prove that the only possible endomorphisms of the structure $(\mathbb{Z}; +, R)$ are $x \mapsto \lambda \cdot x$ with $\lambda \in \{1, -1\}$. Suppose that $x \mapsto \lambda \cdot x$ is an endomorphism. Then $\lambda \neq 0$ since the structure is a core, so suppose that $|\lambda| > 1$. Let a be the maximal element of R^+, and note that in particular $a + d \notin R$ (it cannot be in R^+ because of the maximality assumption, and cannot be equal to any c_i modulo d). Then $a \in R$, so $\lambda^q a \in R$ for all $q \in \mathbb{N}$. In particular, if q is such that $\lambda^q > \max(R^+ \cup R^-)$ we obtain $\lambda^q a \in R^\circ$. This means that $\lambda^q a = c_i \bmod d$ for some $i \in \{1, \ldots, n\}$. Finally, $\lambda^q(a + d) = \lambda^q a + \lambda^q d = c_i \bmod d$, so that $\lambda^q(a + d) \in R$. This implies that $x \mapsto \lambda^q \cdot x$ is not an embedding, contradicting the core assumption on $(\mathbb{Z}; +, R)$.

Let us now prove the second item. Let b be some element of R^-. We must have $b = c_i \bmod d$ for some $i \in \{1, \ldots, n\}$ since $R^- \subset R^\circ$. Note that the map $x \mapsto (d + 1)x$ is an endomorphism of $(\mathbb{Z}; +, R)$, so it has to be an embedding. It follows that $(d + 1)^m \cdot b \notin R$ for any m. Suppose that b is not 0. Choose m so that $(d + 1)^m \cdot |b| > \max_{e \in R^-} |e|$ so that $(d + 1)^m \cdot b \notin R^-$. But $(d + 1)^m b = c_i \bmod d$, a contradiction. It follows that $R^- \subseteq \{0\}$, which concludes the proof. ◀

▶ **Corollary 16.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ which contains $+$ and is a core. If $\mathrm{End}(\mathbb{A})$ is not Horn-definable, then $\mathrm{CSP}(\mathbb{A})$ is NP-hard. Moreover, if $\mathrm{End}(\mathbb{A})$ is Horn-definable, then it is either $\{1\}$, $\mathbb{Z} \setminus \{0\}$, or $1 + d\mathbb{Z}$ for some $d \geq 2$.*

Proof. Lemma 14 implies that $R := \mathrm{End}(\mathbb{A})$ has a quantifier-free pp-definition in $\mathbb{A}$. We first prove that $(\mathbb{Z}; +, R)$ is a core. Indeed, let λ be an endomorphism of $(\mathbb{Z}; +, R)$. Since $1 \in R$, we obtain that $\lambda \in R$, so that $x \mapsto \lambda x$ is a self-embedding of $\mathbb{A}$ by the fact that $\mathbb{A}$ is a core. Since R is has a quantifier-free definition over $\mathbb{A}$, it follows that $x \mapsto \lambda x$ is also a self-embedding of $(\mathbb{Z}; +, R)$.

First consider the case that R is not Horn-definable. If $R^+ \neq \emptyset$ then Lemma 15 implies that $\{1\}$ or $\{1, -1\}$ are pp-definable in $(\mathbb{Z}; +, R)$. All endomorphisms of $\mathbb{A}$ must preserve this set, so $\mathrm{End}(\mathbb{A}) = R = \{1, -1\}$ or $\mathrm{End}(\mathbb{A}) = R = \{1\}$; since R is no Horn-definable, we must even have $R = \{1, -1\}$. But then the family $\{S_\lambda\}_{\lambda \in \{-1,1\}}$ with $S_{-1} = S_1 = \{1, -1\}$ is uniformly definable and compatible, the conditions being satisfied for $A = \{-1, 1\}$ and $B = \emptyset$:

- $S_1 = A = S_{-1}$;
- $S_1^\circ = S_{-1}^\circ = \emptyset$.

Then Proposition 13 applied to S_λ implies that CSP($\mathbb{A}$) is NP-hard.

If $R^+ = \emptyset$ then Lemma 15 implies that $R^- = \emptyset$ or that $R = \mathbb{Z} \setminus \{0\}$. In the latter case, R would be Horn, contrary to the assumptions, so $R^- = \emptyset$. In this case, R is fully modular, but not Horn definable, so NP-hardness of CSP($\mathbb{A}$) follows from Proposition 8. This shows the first part of the statement.

Finally, consider the case that R is Horn-definable. If $R^+ = \emptyset$ then Lemma 15 implies that $R = \mathbb{Z} \setminus \{0\}$, and we are done, or $R^- = \emptyset$, in which case $R = 1 + d\mathbb{Z}$ for some $d \geq 2$ and we are also done. Otherwise, $R^+ \neq \emptyset$ and Lemma 15 implies that $\{1\}$ or $\{1, -1\}$ is pp-definable in $(\mathbb{Z}; +, R)$. ◀

4.3 Arbitrary arities

We finally present the hardness proof in the general case where the structure contains a relation that is not Horn-definable. The strategy is to cut from a non-Horn relation R a uniformly definable family $\{S_\lambda\}_{\lambda \in \Lambda}$ of lines for which each S_λ is not Horn-definable. In a second step, we ensure that we get a family satisfying the compatibility condition, and we conclude using Proposition 13. Call a formula φ in conjunctive normal form *reduced* if removing any literal or clause from φ yields a formula that is not equivalent to φ. Note that minimal formulas are necessarily reduced.

▶ **Lemma 17.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ which contains $+$ and is a core. Suppose that $\mathbb{A}$ contains a relation R that is not Horn-definable. Then* CSP($\mathbb{A}$) *is NP-hard, or $\mathbb{A}$ pp-defines a relation that is not Horn-definable and that has a minimal definition containing a non-Horn clause ψ such that:*

- *no negated linear equation is in ψ,*
- *at least one linear equation is in ψ.*

Proof. Let φ be a standard minimal definition of R in conjunctive normal form, and let ψ be a clause of φ that is not Horn. From Corollary 16, we can suppose that End($\mathbb{A}$) is $\{1\}$, $\mathbb{Z} \setminus \{0\}$, or $1 + d\mathbb{Z}$ for $d \geq 2$. This implies that either $\{1\}$ is pp-definable or, by Proposition 6, all the linear equations appearing in φ are homogeneous.

We can assume that ψ does not contain any negative literal, per the assumption that φ is minimal: indeed, consider the relation R' defined by the formula

$$\varphi' := \varphi \wedge \sum \lambda_i x_i = c \tag{†}$$

where $\sum \lambda_i x_i \neq c$ is in ψ. Either $c = 0$, in which case the relation R' defined by (†) is pp-definable in $\mathbb{A}$, or $\{1\}$ is pp-definable in $\mathbb{A}$ and R' is pp-definable in $\mathbb{A}$, too. The relation R' is not Horn-definable, and when we reduce the definition φ' of R' we obtain a formula that has fewer literals in clauses that contain more than one literal, in contradiction to the minimality of φ.

If ψ contains a linear equation then we are done. Otherwise, ψ only contains modular linear equations. If End($\mathbb{A}$) $= \mathbb{Z} \setminus \{0\}$ then by Proposition 6 any modulus of a modular linear equation appearing in ψ would have to be coprime with every nonzero integer, which is impossible. Therefore, End($\mathbb{A}$) is $\{1\}$ or $1 + d\mathbb{Z}$ for $d \geq 2$. In the latter case, we can assume by Proposition 6 that all the modular linear equations in ψ are modulo a divisor of d. In the former case, let d be a common multiple of all the moduli appearing in a modular linear equation in ψ. Consider the structure $\mathbb{A}/d\mathbb{A}$ defined in Proposition 8. The relation T

obtained from R in this structure is not a coset of a subgroup H of $(\mathbb{Z}/d\mathbb{Z})^k$ (where k is the arity of R): otherwise this coset is definable by a conjunction θ of modular linear equations modulo a divisor of d. Replacing ψ by θ in φ would produce a smaller definition of R, a contradiction to the minimality of φ. Moreover, $(\mathbb{A}/d\mathbb{A}, 1)$ is pp-interpretable in $\mathbb{A}$: in the two cases that $\mathrm{End}(\mathbb{A}) = \{1\}$ and $\mathrm{End}(\mathbb{A}) = 1 + d\mathbb{Z}$, the preimage of $\{1\}$ under the canonical projection $x \mapsto x \bmod d$ is pp-definable in $\mathbb{A}$. We conclude as in Proposition 8 that $\mathrm{CSP}(\mathbb{A})$ is NP-hard. ◀

▶ **Theorem 18.** *Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ which contains $+$ and is a core. Suppose that $\mathbb{A}$ contains a relation that is not Horn-definable. Then* $\mathrm{CSP}(\mathbb{A})$ *is NP-hard.*

Proof. From Lemma 17, we can suppose that $\mathbb{A}$ pp-defines a relation R that is not Horn-definable, that has a reduced standard definition φ containing a non-Horn clause ψ with at least one linear equation (L) and no negated linear equation. Since ψ is not Horn, it contains at least another equation (L'), possibly modular. Let $(a_1, \ldots, a_n)$ satisfy φ and only (L) in ψ. Such a tuple exists by the assumption that φ is reduced. Similarly, let $(b_1, \ldots, b_n)$ satisfy φ and only (L') in ψ. Let S be the binary relation such that $(\lambda, t) \in S$ if, and only if, $\lambda \in \mathrm{End}(\mathbb{A})$ and $t(\mathbf{a} - \mathbf{b}) + \lambda\mathbf{b}$ is in R. Note that $\mathbf{a}$ and $\mathbf{b}$ being fixed, S is pp-definable over $\mathbb{A}$. Therefore, we obtain a family $\{S_\lambda\}_{\lambda \in \Lambda}$ that is uniformly definable in $\mathbb{A}$, where $\Lambda = \mathrm{End}(\mathbb{A})$. Clearly, $1 \in \Lambda$, and $\Lambda \subseteq \mathbb{Z} \setminus \{0\}$ and $0, \lambda \in S_\lambda$. Moreover, note that

$$S_\lambda \cap \lambda \cdot \mathbb{Z} = \lambda \cdot S_1 \tag{‡}$$

holds for all $\lambda \in \mathrm{End}(\mathbb{A})$. Indeed:

$$\begin{aligned} t \in S_1 &\Leftrightarrow t(\mathbf{a} - \mathbf{b}) + \mathbf{b} \in R \\ &\Leftrightarrow \lambda t(\mathbf{a} - \mathbf{b}) + \lambda\mathbf{b} \in R && \text{because } \mathbb{A} \text{ is a core} \\ &\Leftrightarrow \lambda t \in S_\lambda. \end{aligned}$$

We prove that for all $\lambda \in \mathrm{End}(\mathbb{A})$ the relation S_λ is not Horn-definable. Since $0, \lambda \in S_\lambda$, it suffices to prove that S_λ omits infinitely many multiples of λ, and by (‡) it suffices to prove that $\ell \notin S_1$ for infinitely many ℓ. Let ℓ be such that $\ell = 1 \bmod d'$, for every modulus d' appearing in ψ. We claim that $\ell(\mathbf{a} - \mathbf{b}) + \mathbf{b}$ does not satisfy any modular linear equation in ψ. Indeed, let $\sum_i \sigma_i x_i = c \bmod d'$ be such a modular linear equation. Then we have

$$\sum_i \sigma_i(\ell(a_i - b_i) + b_i) = c \bmod d' \Leftrightarrow \sum_i \sigma_i a_i = c \bmod d',$$

which is a contradiction to the choice of $\mathbf{a}$ since $\mathbf{a}$ only satisfies (L) in ψ and (L) is assumed to be non-modular. Consider now a linear equation $\sum \sigma_i x_i = c$ in ψ. This equation is satisfied by $\ell(\mathbf{a} - \mathbf{b}) + \mathbf{b}$ if, and only if

$$\ell \cdot \sum_i \sigma_i(a_i - b_i) = c - \sum_i \sigma_i b_i\,. \tag{⋆}$$

Suppose first that $\sum \sigma_i(a_i - b_i) = 0$. Then (⋆) is satisfied if, and only if, we have $\sum \sigma_i b_i = c = \sum \sigma_i a_i$. This implies that both $\mathbf{a}$ and $\mathbf{b}$ satisfy the equation; this is a contradiction to our choice of the vectors $\mathbf{a}$ and $\mathbf{b}$, so that $\ell(\mathbf{a} - \mathbf{b}) + \mathbf{b}$ does not satisfy (⋆). Suppose now that $\sum \sigma_i(a_i - b_i) \neq 0$. If $\ell > |c - \sum \sigma_i b_i|$, it is then clear that (⋆) is not satisfied. Therefore, for infinitely many ℓ, the tuple $\ell(\mathbf{a} - \mathbf{b}) + \mathbf{b}$ does not satisfy any literal in ψ and $\ell \notin S_1$.

Let $\theta(x,y)$ be a minimal reduced standard definition of S. By inspection of the formula θ, one finds that S^+_λ and S^-_λ consist of points of the form $-\frac{a\lambda}{b}$, where $ax+by=0$ is an equation in θ. Note that since a and b are taken coprime by the minimality of θ, if b divides $a\lambda$ then b divides λ. Let $m := \mathrm{lcm}\{|b| : ax+by=0 \text{ is an equation in } \theta\}$, and note that $m\mathbb{Z}\cap\Lambda$ is not empty by the previous remark. Let $T \neq \emptyset$ be the binary relation defined by $\theta(m\cdot x, y)$. For all $\lambda \in \mathrm{End}(\mathbb{A})$, the set T_λ is not Horn-definable and of the form $(T^\circ_\lambda \cup (\lambda\cdot P)) \setminus (\lambda \cdot Q)$, where P and Q are finite sets that are independent of λ and $T^\circ_\lambda = S^\circ_{m\lambda}$. For the family of relations $\{T_\lambda\}_{\lambda\in\mathrm{End}(\mathbb{A})}$ to satisfy the compatibility condition, it remains to prove that $c+d\mathbb{Z}\subseteq T^\circ_1$ if, and only if, $\lambda c+d\mathbb{Z}\subseteq T^\circ_\lambda$, for all $d\geq 1$ and $c\in\{0,\dots,d-1\}$. Suppose that $c+d\mathbb{Z}\subseteq T^\circ_1$ for some $d\geq 1$ and suppose that the cosets of T°_λ are cosets of $d'\mathbb{Z}$. By Proposition 6, λ and d' are coprime. Therefore, there exists $\mu\in\mathbb{Z}$ such that $\lambda\mu = 1 \bmod d'$. We have $c+d\mu\mathbb{Z}\subseteq T^\circ_1$, because d divides $d\mu$. It follows that $\lambda c+\lambda d\mu\mathbb{Z}\subseteq T^\circ_\lambda$. Now, let $x\in\lambda c+d\mathbb{Z}$, say $x=\lambda c+qd$. Then we have $x=\lambda c+q\lambda\mu d \bmod d'$. Note that $\lambda c+q\lambda\mu d\in\lambda c+\lambda d\mu\mathbb{Z}\subseteq T^\circ_\lambda$. Since the cosets in T°_λ are cosets of $d'\mathbb{Z}$, we obtain that $x\in T^\circ_\lambda$ and consequently that $\lambda c+d\mathbb{Z}\subseteq T^\circ_\lambda$. Conversely, if $\lambda c+d\mathbb{Z}\subseteq T^\circ_\lambda$ then $\lambda c+d\lambda\mathbb{Z}\subseteq T^\circ_\lambda$, because d divides $d\lambda$. Since $\mathbb{A}$ is a core, $x\mapsto\lambda\cdot x$ is a self-embedding of $\mathbb{A}$, so that $c+d\mathbb{Z}\subseteq T^\circ_1$.

To conclude, the family of compatible relations $\{T_\lambda\}_{\lambda\in\mathrm{End}(\mathbb{A})}$ is uniformly pp-definable in $\mathbb{A}$ and consists of non-Horn relations. By Proposition 13, we obtain that $\mathrm{CSP}(\mathbb{A})$ is NP-hard. ◀

We illustrate our proofs in some examples below.

▶ **Example 19.** Consider the binary relation

$$S = \{(\lambda,t) \mid (\lambda = 1 \bmod 4 \wedge t = 1 \bmod 4) \vee (\lambda = 3 \bmod 4 \wedge t = 3 \bmod 4) \vee t = 0\}.$$

One sees that the set of endomorphisms of $\mathbb{A} := (\mathbb{Z};+,S)$ is equal to $\mathrm{End}(\mathbb{A}) := 1+2\mathbb{Z}$. Moreover, S is not Horn-definable. For every $\lambda\in\mathrm{End}(\mathbb{A})$, one has $S_\lambda = \{0\}\cup(\lambda+4\mathbb{Z})$. When λ is fixed, one can define a finite set by $\exists y(x\in S_\lambda \wedge y\in S_\lambda \wedge x+y=\lambda)$, which defines $\{0,\lambda\}$. One then obtains a reduction from 1-in-3-SAT by $\exists x,y,z\in\{0,\lambda\} : x+y+z\in\{0,\lambda\}$. Finally, by existentially quantifying over $\lambda\in\mathrm{End}(\mathbb{A})$ we obtain a reduction from 1-in-3-SAT to $\mathrm{CSP}(\mathbb{Z};+,S)$.

▶ **Example 20.** Let $R := \{0\}\cup(1+3\mathbb{Z})\cup(2+3\mathbb{Z})$ and $K = 1+3\mathbb{Z}$. Note that Proposition 13 does not apply to $\mathrm{CSP}(\mathbb{Z};+,R)$ since $(\mathbb{Z};+,R)$ is not a core (we have $0\in\mathrm{End}(\mathbb{Z};+,R)$). Neither does Corollary 16 apply to $\mathrm{CSP}(\mathbb{Z};+,R,K)$ since $\mathrm{End}(\mathbb{Z};+,R,K)=K$, which is clearly Horn-definable in $(\mathbb{Z};+,R,K)$. But one obtains hardness of $\mathrm{CSP}(\mathbb{Z};+,R,K)$ by Theorem 18. Indeed, pick $a=0$ (satisfying the linear equation $x=0$ in the definition of R) and $b=1$ (satisfying the modular linear equation $x=1 \bmod 3$ in the definition of R), and define the relation $S=\{(\lambda,t)\mid\lambda\in K\wedge\lambda-t\in S\}$. Note that for all $\lambda\in K$, we have $S_\lambda=\{\lambda\}\cup 3\mathbb{Z}\cup(2+3\mathbb{Z})$. The formula $\exists w(w\in K\wedge S(\lambda,t)\wedge S(\lambda,t+3w))$ defines the relation $T=\{(\lambda,t)\mid\lambda=1 \bmod 3\wedge(t=0 \bmod 3\vee t=2 \bmod 3)\}$, which is fully modular and not Horn-definable. Proposition 8 implies that $\mathrm{CSP}(\mathbb{Z};+,R,S)$ is NP-hard.

5 Tractability

In this section we show the following.

▶ **Proposition 21.** *Let $\mathbb{A}$ be a structure with finite relational signature, domain $\mathbb{Z}$, and whose relations have quantifier-free Horn definitions over $(\mathbb{Z};+,1)$. Then there is an algorithm that solves CSP($\mathbb{A}$) in polynomial time.*

This result follows from the following more general result.

▶ **Theorem 22.** *Let φ be a quantifier-free Horn formula over $(\mathbb{Z}; +)$, allowing parameters from $\mathbb{Z}$ represented in binary. Then there exists a polynomial-time algorithm to decide whether φ is satisfiable over $(\mathbb{Z}; +)$.*

The proof of Theorem 22 can be found at the end of this section. We first show how to derive Proposition 21.

Proof of Proposition 21. The input of CSP($\mathbb{A}$) consists of a primitive positive sentence whose atomic formulas are of the form $R(x_1, \ldots, x_k)$ where R is quantifier-free Horn definable over $\mathcal{L}_{(\mathbb{Z};+,1)}$. Since $\sum_{i=1}^{n} a_i x_i = b \bmod c$ is equivalent to $\sum_{i=1}^{n} a_i x_i = b + ck$, where k is a new integer variable, we can as well assume that the input to our problem consists of a set of Horn clauses over $(\mathbb{Z}; +, 1)$. This is tacitly the process of quantifier introduction, the converse of quantifier elimination. Then apply Theorem 22. ◀

Our algorithm for the proof of Theorem 22 uses two other well-known algorithms:

1. a polynomial-time algorithm for satisfiability of linear diophantine equations, i.e., the subproblem of the computational problem from Theorem 22 where the input only contains atomic formulas (see, e.g., [23]).
2. a polynomial-time algorithm to compute the rank of a matrix over $\mathbb{Q}$; this allows us in particular to decide whether a given linear system of equalities implies another equality over the rationals (this is standard, using Gaussian elimination; again, see [23] for a discussion of the complexity).

These two algorithms can be combined to obtain the following.

▶ **Lemma 23.** *There is a polynomial-time algorithm that decides whether a given system Φ of linear diophantine equations implies another given diophantine equation ψ over $\mathbb{Z}$.*

Proof. First, use the first algorithm above to test whether Φ has a solution over $\mathbb{Z}$. If no, return yes (false implies everything). If yes, we claim that Φ implies ψ over $\mathbb{Q}$ (which can be tested by the second algorithm above) if and only if Φ implies ψ over the integers. Clearly, if every rational solution of Φ satisfies ψ, then so does every integer solution. Suppose now that there exists a rational solution α to Φ which does not satisfy ψ. Also take an integer solution β to Φ. Then on the line L that goes through α and β there are infinitely many integer points. If infinitely many points on a line satisfy ψ, then all points of the line must satisfy ψ. Since $\alpha \in L$ does not satisfy ψ it follows that an integer point on L does not satisfy ψ, i.e., Φ does not imply ψ over the integers. ◀

Given the two mentioned algorithms, our procedure for the proof of Theorem 22 is basically an implementation of positive unit clause resolution. It takes the same form as the algorithm presented in [7] for satisfiability over the rationals.

Proof. We follow the proof of Proposition 3.1 from [7]. We first discuss the correctness of the algorithm.

When $\mathcal{U}$ logically implies φ (which can be tested with the algorithm from Lemma 23) then the negative literal $\neg\varphi$ is never satisfied and can be deleted from all clauses without affecting the set of solutions. Since this is the only way in which literals can be deleted from clauses, it is clear that if one clause becomes empty the instance is unsatisfiable.

If the algorithm terminates with *satisfiable*, then no negation of an inequality is implied by $\mathcal{U}$. If r is the rank of the linear equation system defined by $\mathcal{U}$, we can use Gaussian

```
// Input: a set of Horn-clauses C over (ℤ; +) with parameters.
// Output: satisfiable if C is satisfiable in (ℤ; +), unsatisfiable otherwise
Let U be clauses from C that only contain a single positive literal.
If U is unsatisfiable then return unsatisfiable.
Do
    For all negative literals ¬φ in clauses from C
        If U implies φ, then delete the negative literal ¬φ from all clauses in C.
    If C contains an empty clause, then return unsatisfiable.
    If C contains a clause with a single positive literal ψ, then add {ψ} to U.
Loop until no literal has been deleted
Return satisfiable.
```

Figure 1 An algorithm for satisfiability of Horn formulas with parameters over $(\mathbb{Z}; +)$.

elimination to eliminate r of the variables from all literals in the remaining clauses. For each of the remaining inequalities, consider the sum of absolute values of all coefficients. Let S be one plus the maximum of this sum over all the remaining inequalities. Then setting the i-th variable to S^i satisfies all clauses. To see this, take any inequality, and assume that i is the highest variable index in this inequality. Order the inequality in such a way that the variable with highest index is on one side and all other variables on the other side of the $\neq$ sign. The absolute value on the side with the i-th variable is at least S^i. The absolute value on the other side is less than $S^i - S$, since all variables have absolute value less than S^{i-1} and the sum of all coefficients is less than $S - 1$ in absolute value. Hence, both sides of the inequality have different absolute value, and the inequality is satisfied. Since all remaining clauses have at least one inequality, all constraints are satisfied.

Now let us address the complexity of the algorithm. With appropriate data structures, the time needed for removing negated literals $\neg\varphi$ from all clauses when φ is implied by $\mathcal{U}$ is linearly bounded in the input size since each literal can be removed at most once. ◀

6 Conclusion

We are finally in position to prove the main result.

Proof of Theorem 1. Let $\mathbb{A}$ be a finite-signature first-order reduct of $(\mathbb{Z}; +, 1)$ that $\mathbb{A}$ contains $+$. By Lemma 5 there exists a core $\mathbb{B}$ of $\mathbb{A}$. If $\mathbb{B}$ has only one element then CSP($\mathbb{B}$) and CSP($\mathbb{A}$) are trivially in P. Otherwise, $\mathbb{B}$ is itself first-order definable in $(\mathbb{Z}; +, 1)$ and contains $+$ by Lemma 5, and the statement follows from Theorem 18 and Proposition 21. ◀

Abstract

Many networking applications require timely access to recent network measurements, which can be captured using a sliding window model. Maintaining such measurements is a challenging task due to the fast line speed and scarcity of fast memory in routers. In this work, we study the impact of allowing *slack* in the window size on the asymptotic requirements of sliding window problems. That is, the algorithm can dynamically adjust the window size between W and $W(1+\tau)$ where τ is a small positive parameter. We demonstrate this model's attractiveness by showing that it enables efficient algorithms to problems such as Maximum and General-Summing that require $\Omega(W)$ bits even for constant factor approximations in the exact sliding window model. Additionally, for problems that admit sub-linear approximation algorithms such as Basic-Summing and Count-Distinct, the slack model enables a further asymptotic improvement.

The main focus of the paper is on the widely studied Basic-Summing problem of computing the sum of the last W integers from $\{0, 1 \ldots, R\}$ in a stream. While it is known that $\Omega(W \log R)$ bits are needed in the exact window model, we show that approximate windows allow an *exponential* space reduction for constant τ.

Specifically, for $\tau = \Theta(1)$, we present a space lower bound of $\Omega(\log(RW))$ bits. Additionally, we show an $\Omega(\log(W/\epsilon))$ lower bound for $RW\epsilon$ additive approximations and a $\Omega(\log(W/\epsilon) + \log\log R)$ bits lower bound for $(1+\epsilon)$ multiplicative approximations. Our work is the first to study this problem in the exact and additive approximation settings. For all settings, we provide memory optimal algorithms that operate in *worst case* constant time. This strictly improves on the work of [14] for $(1+\epsilon)$-multiplicative approximation that requires $O(\epsilon^{-1}\log(RW)\log\log(RW))$ space and performs updates in $O(\log(RW))$ worst case time. Finally, we show asymptotic improvements for the Count-Distinct, General-Summing and Maximum problems.

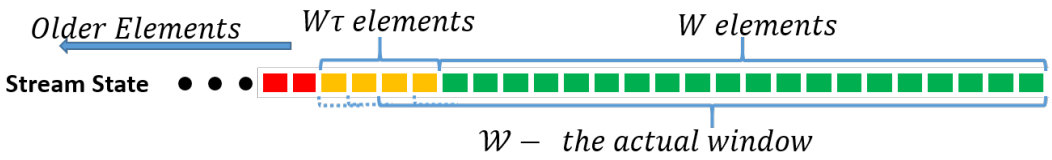

Figure 1 We need to answer each query with respect to a τ-slack window that must include the last W items, but may or may not consider a suffix of the previous $W\tau$ elements.

1 Introduction

Network algorithms in diverse areas such as traffic engineering, load balancing and quality of service [2, 9, 21, 24, 31] rely on timely link measurements. In such applications recent data is often more relevant than older data, motivating the notions of *aging* and *sliding window* [6, 11, 15, 25, 27]. For example, a sudden decrease in the average packet size on a link may indicate a SYN attack [26]. Additionally, a load balancer may benefit from knowing the current utilization of a link to avoid congestion [2].

While conceptually simple, conveying the necessary information to network algorithms is a difficult challenge due to current memory technology limitations. Specifically, DRAM memory is abundant but too slow to cope with the line rate while SRAM memory is fast enough but has a limited capacity [10, 13, 29]. Online decisions are therefore realized through space efficient data structures [7, 8, 16, 17, 4, 23, 28, 30] that store measurement statistics in a concise manner. For example, [16, 28] utilize probabilistic counters that only require $O(\log\log N)$ bits to approximately represent numbers up to N. Others conserve space using variable sized counter encoding [17, 23] and monitoring only the frequent elements [6].

Basic-Summing is one of the most basic textbook examples of such approximated sliding window stream processing problems [14]. In this problem, one is required to keep track of the sum of the last W elements, when all elements are non-negative integers in the range $\{0, 1, \ldots, R\}$. The work in [14] provides a $(1+\epsilon)$-multiplicative approximation of this problem using $O\left(\frac{1}{\epsilon}\cdot\left(\log^2 W + \log R\cdot(\log W + \log\log R)\right)\right)$ bits. The amortized time complexity is $O(\frac{\log R}{\log W})$ and the worst case is $O(\log W + \log R)$. In contrast, we previously showed an $RW\epsilon$-additive approximation with $\Theta\left(\frac{1}{\epsilon} + \log W\epsilon\right)$ bits [3].

Sliding window counters (approximated or accurate) require asymptotically more space than plain stream counters. Such window counters are prohibitively large for networking devices which already optimize the space consumption of plain counters.

This paper explores the concept of *slack*, or approximated sliding window, bridging this gap. Figure 1 illustrates a "window" in this model. Here, each query may select a *τ-slack window* whose size is between W (the green elements) and $W(1+\tau)$ (the green plus yellow elements). The goal is to compute the sum with respect to this chosen window.

Slack windows were also considered in previous works [14, 27] and we call the problem of maintaining the sum over a slack window Slack Summing. Datar et al. [14] showed that constant slack reduces the required memory from $O(\frac{1}{\epsilon}\cdot\left(\log^2 W + \log R\cdot(\log W + \log\log R)\right))$ to $O(\epsilon^{-1}\log(RW)\log\log(RW))$. For τ-slack windows they provide a $(1+\epsilon)$-multiplicative approximation using $O(\epsilon^{-1}\log(RW)(\log\log(RW) + \log\tau^{-1}))$ bits.

Table 1 Comparison of Basic-Summing algorithms. Our contributions are in bold. All algorithms process elements in constant time except for the rightmost column where both update in $O(\log(RW))$ time. We present matching lower bounds to all our algorithms.

	Exact Sum	Additive Error	Multiplicative Error	
$\tau = \Theta(1)$	$\mathbf{\Theta(\log(RW))}$	$\mathbf{\Theta(\log(W/\epsilon))}$	$\mathbf{\Theta(\log(W/\epsilon) + \log\log R)}$	$O(\epsilon^{-1}\log(RW)\log\log(RW))$ [14]
Exact Window	$\Theta(W \log R)$	$\Theta(\epsilon^{-1} + \log W)$ [3]	$O(\epsilon^{-1}\log^2(RW))$ [22]	$O(\epsilon^{-1}\log RW \log(W \log R))$ [14]

Our Contributions

This paper studies the space and time complexity reductions that can be attained by allowing *slack* – an error in the window size. Our results demonstrate exponentially smaller and asymptotically faster data structures compared to various problems over exact windows. We start with deriving lower bounds for three variants of the Basic-Summing problem – when computing an exact sum over a slack window, or when combined with an additive and a multiplicative error in the sum. We present algorithms that are based on dividing the stream into $W\tau$-sized blocks. Our algorithms sum the elements within each block and represent each block's sum in a cyclic array of size τ^{-1}. We use multiple compression techniques during different stages to drive down the space complexity. The resulting algorithms are space optimal, substantially simpler than previous work, and reduce update time to $O(1)$.

For exact Slack Summing, we present a lower bound of $\Omega(\tau^{-1}\log(RW\tau))$ bits. For $(1+\epsilon)$ multiplicative approximations we prove an $\Omega\big(\log(W/\epsilon) + \tau^{-1}(\log(\tau/\epsilon) + \log\log(RW))\big)$ bits bound when $\tau = \Omega\left(\frac{1}{\log RW}\right)$. We show that $\Omega(\tau^{-1}\log\lfloor 1+\tau/\epsilon\rfloor + \log(W/\epsilon))$ bits are required for $RW\epsilon$ additive approximations.

Next, we introduce algorithms for the Slack Summing problem, which asymptotically reduce the required memory compared to the sliding window model. For the exact and additive error versions of the problem, we provide memory optimal algorithms. In the multiplicative error setting, we provide an $O\big(\tau^{-1}\left(\log\epsilon^{-1} + \log\log(RW\tau)\right) + \log(RW)\big)$ space algorithm. This is asymptotically optimal when $\tau = \Omega(\log^{-1} W)$ and $R = \text{poly}(W)$. It also asymptotically improves [14] when $\tau^{-1} = o(\epsilon^{-1}\log(RW))$. We further provide an asymptotically optimal solution for constant τ, even when $R = W^{\omega(1)}$. All our algorithms are deterministic and operate in worst case constant time. In contrast, the algorithm of [14] works in $O(\log RW)$ worst case time.

To exemplify our results, consider monitoring the average bandwidth (in bytes per second) passed through a router in a 24 hours window, i.e., $W \triangleq 86400$ seconds. Assuming we use a 100GbE fiber transceiver, our stream values are bounded by $R \approx 2^{34}$ bytes. If we are willing to withstand an error of $\epsilon = 2^{-20}$ (i.e., about $16KBps$), the work of [3] provides an additive approximation over the sliding window and requires about 120KB. In contrast, using a 10 minutes slack ($\tau \triangleq \frac{1}{144}$), our algorithm for **exact** Slack Summing requires only 800 bytes, 99% less than approximate summing over exact sliding window. For the same slack size, the algorithm of [14] requires more space than our **exact** algorithm even for a large 3% error. Further, if we also allow the same additive error ($\epsilon = 2^{-20}$), we provide an algorithm that requires only 240 bytes - a reduction of more than 99.8% !

Table 1 compares our results for the important case of constant slack with [14]. As depicted, our *exact* algorithm is faster and more space efficient than the multiplicative approximation of [14]. Comparing our multiplicative approximation algorithm to that of [14], we present *exponential* space reductions in the dependencies on ϵ^{-1} and R, with an asymptotic reduction in W as well. We also improve the update time from $O(\log(RW))$ to $O(1)$.

Finally, we apply the slack window approach to multiple streaming problems, including Maximum, General-Summing, Count-Distinct and Standard-Deviation. We show that, while some of these problems cannot be approximated on an exact window in sub-linear space (e.g. maximum and general sum), we can easily do so for slack windows. In the count distinct problem, a constant slack yields an asymptotic space reduction over [11, 19].

2 Preliminaries

For $\ell \in \mathbb{N}$, we denote $[\ell] \triangleq \{0, 1, \ldots, \ell\}$. We consider a stream of data elements $x_1, x_2, \ldots, x_t$, where at each step a new element $x_i \in [R]$ is added to S. A *W-sized window* contains only the last W elements: $x_{t-W+1} \ldots x_t$. We say that $\mathcal{F}$ is a *τ-slack W-sized window* if there exists $c \in [W\tau - 1]$ such that $\mathcal{F} = x_{t-(W+c)+1} \ldots x_t$. For simplicity, we assume that τ^{-1} and $W\tau$ are integers. Unless explicitly specified, the base of all logs is 2.

Algorithms for the Slack Summing problem are required to support two operations:

1. Update(x_t) Process a new element $x_t \in [R]$.
2. Output () Return a pair $\langle \widehat{S}, c \rangle$ such that $c \in \mathbb{N}$ is the slack size and $\widehat{S}$ is an estimation of the last $W + c$ elements sum, i.e., $S \triangleq \sum_{k=t-(W+c)+1}^{t} x_k$.

We consider three types of algorithms for Slack Summing:

1. **Exact algorithms:** an algorithm $\mathbb{A}$ solves (W, τ)-Exact Summing if its Output returns $\langle \widehat{S}, c \rangle$ that satisfies $0 \leq c < W\tau$ and $\widehat{S} = S$.
2. **Additive algorithms:** we say that $\mathbb{A}$ solves (W, τ, ϵ)-Additive Summing if its Output function returns $\langle \widehat{S}, c \rangle$ that satisfies $0 \leq c < W\tau$ and $|S - \widehat{S}| < RW\epsilon$.
3. **Multiplicative algorithms:** $\mathbb{A}$ solves (W, τ, ϵ)-Multiplicative Summing if its Output returns $\langle \widehat{S}, c \rangle$ satisfying $0 \leq c < W\tau$ and $\frac{S}{1+\epsilon} < \widehat{S} \leq S$ if $S > 0$, and $\widehat{S} = 0$ otherwise.

3 Lower Bounds

In this section, we analyze the space required for solving the Slack Summing problems. Intuitively, our bounds are derived by constructing a set of inputs that any algorithm must distinguish to meet the required guarantees. There are two tricks that we frequently use in these lower bounds. The first is setting the input such that the slack consists only of zeros, and thus the algorithm must return the desired approximation of the remaining window. The next is using a "cycle argument" – consider two inputs x and $x \cdot y$ for $x, y \in \{0, 1, \ldots, R\}^*$. If both lead to the same memory configuration, so do such xy^k for any $k \in \mathbb{N}$. Thus, if there is a k such that no single answer approximates x and xy^k well, then x and xy had to lead to separate memory configurations in the first place.

3.1 (W, τ)-Exact Summing

We start by proving lower bounds on the memory required for exact Slack Summing.

▶ **Lemma 1.** *Any deterministic algorithm $\mathbb{A}$ that solves the (W, τ)-Exact Summing problem must use at least $\lceil \log(RW(W+1)/2 + 1) \rceil \geq \lfloor \log(RW^2) \rfloor$ bits.*

Proof. Consider the following language

$$L_{E_1} \triangleq \left\{ 0^{W\tau+i} \sigma R^{W-i-1} 0^j \mid i, j \in [W-1], i \geq j, \sigma \in ([R] \setminus \{0\}) \right\} \cup \{0^{W+W\tau}\}.$$

That is, L_{E_1} contains a word with $W + W\tau$ consecutive zeros and the rest of the words in L_{E_1} are composed of these components in this order:

- $W\tau + i$ zeros for some $i \in [W-1]$.
- a non zero symbol σ.
- $W - i - 1$ repetitions of the maximal symbol (R).
- j zeros for some $j \in [i]$.

Our lower bound stems from the observation that every word in L_{E_1} must lead to a different state. The language size is: $|L_{E_1}| = 1 + \sum_{i=0}^{W-1} R(i+1) = 1 + RW(W+1)/2$. Therefore, the number of required bits is at least: $\lceil \log |L_{E_1}| \rceil > \left(\log(RW^2) - 1\right)$. Further, this number is an integer and therefore at least $\left\lfloor \log(RW^2) \right\rfloor$ bits are required.

First, notice that the word composed of $W + W\tau$ zeros requires a unique configuration as $\mathbb{A}$ must return 0 after processing that word. In contrast, it must not return 0 after processing any other word as there is at least a single R within the last W elements.

Let $w_1, w_2 \in L_{E_1}$ be two different words that are not all-zeros. We need to show that w_1 and w_2 require different memory configuration.

By definition of L_{E_1}, $w_1 = 0^{W\tau+i_1}\sigma_1 R^{W-i_1-1}0^{j_1}$ and $w_2 = 0^{W\tau+i_2}\sigma_2 R^{W-i_2-1}0^{j_2}$. Observe that the last W elements of w_1, w_2 are $0^{i_1-j_1}\sigma_1 R^{W-i_1-1}0^{j_1}$ and $0^{i_2-j_2}\sigma_1 R^{W-i_2-1}0^{j_2}$ respectively and that both are preceded with at least $W\tau$ zeros. If $i_1 \neq i_2$ or $\sigma_1 \neq \sigma_2$, then $\sigma_1 + R \cdot (W - i_1 - 1) \neq \sigma_2 + R \cdot (W - i_2 - 1)$ and thus $\mathbb{A}$ cannot return the same count for both, regardless of the slack, as it is all zeros ib both w_1 and w_2.

Next, assume that $i_1 = i_2$, $\sigma_1 = \sigma_2$ and that without loss of generality $j_1 < j_2$. This means that both w_1 and w_2 have the same count.

Since $j_1 < j_2$, w_1 is a strict prefix of w_2, i.e., $w_2 = w_1 \cdot 0^{j_2-j_1}$. Assume by contradiction that after processing w_1, w_2 $\mathbb{A}$ reaches the same memory configuration. Since $\mathbb{A}$ is deterministic, this means that it must reach the same configuration after seeing $w_1 \cdot 0^{z(j_2-j_1)}$ for any integer z. By choosing $z = W(1+\tau)$, we get that the algorithm reaches this configuration once again while the entire window consists of zeros. This is a contradiction since $\sigma_1, \sigma_2 \neq 0$, and the algorithm cannot answer both w_1 and $w_1 \cdot 0^{z(j_2-j_1)}$ correctly. ◀

We now use Lemma 1 to show the following lower bound on (W,τ)-Exact Summing algorithms:

▶ **Theorem 2.** *Any deterministic algorithm $\mathbb{A}$ that solves the (W,τ)-Exact Summing problem must use at least* $\max\left\{\left\lfloor \log\left(RW^2\right)\right\rfloor, \left\lceil \left\lceil \tau^{-1}/2 \right\rceil \log\left(RW\tau+1\right)\right\rceil\right\}$ *bits.*

Proof. Lemma 1 shows a $\left\lfloor \log\left(RW^2\right)\right\rfloor$ bound. We proceed with showing a lower bound $\left\lceil \left\lceil \tau^{-1}/2 \right\rceil \log\left(RW\tau+1\right)\right\rceil$ bits. Consider the following languages:

$$L_{E_2} \triangleq \left\{0^{W\tau+i}\sigma R^{W\tau-i-1} \mid i \in [W\tau-1], \sigma \in [R]\right\},$$
$$\overline{L_{E_2}} \triangleq \left\{w_1 \cdot w_2 \cdots w_{\lceil \tau^{-1}/2 \rceil} \mid \forall i : w_i \in L_{E_2}\right\}.$$

Notice that $|\overline{L_{E_2}}| = (RW\tau+1)^{\lceil \tau^{-1}/2 \rceil}$ since each of the words in L_{E_2} has a distinct sum of literals, and each number in $\{0, 1, \ldots, RW\tau\}$ is the sum of a word. We show that each input in $\overline{L_{E_2}}$ must be mapped into a distinct memory configuration. Let $S_1 \triangleq w_{1,1} \cdot w_{2,1} \cdots w_{\lceil \tau^{-1}/2 \rceil,1}$, $S_2 \triangleq w_{1,2} \cdot w_{2,2} \cdots w_{\lceil \tau^{-1}/2 \rceil,2}$ be two distinct inputs in $\overline{L_{E_2}}$ such that $\forall i : w_{i,1}, w_{i,2} \in L_{E_2}$. Denote $\chi \triangleq \max\left\{i \in \left[\left\lceil \tau^{-1}/2 \right\rceil\right] \mid w_{i,1} \neq w_{i,2}\right\}$ – the last place in which S_1 differs from S_2; also, denote $w_{\chi,1} \triangleq 0^{W\tau}a, w_{\chi,2} \triangleq 0^{W\tau}b$. Consider the sequences $S_1^* = S_1 \cdot 0^{2W\tau(\chi-1/2)}$ and $S_2^* = S_2 \cdot 0^{2W\tau(\chi-1/2)}$. Notice that the last W elements windows for S_1^*, S_2^* are $a \cdot w_{\chi+1,1} \cdots w_{\lceil \tau^{-1}/2 \rceil,1} \cdot 0^{2W\tau(\chi-1/2)}$ and $b \cdot w_{\chi+1,2} \cdots w_{\lceil \tau^{-1}/2 \rceil,2} \cdot 0^{2W\tau(\chi-1/2)}$ respectively, and that the preceding $W\tau$ elements of both are all zeros. An illustration of the setting appears in Figure 2. By our choice of χ, we have that the sum of the last W elements of S_1^*

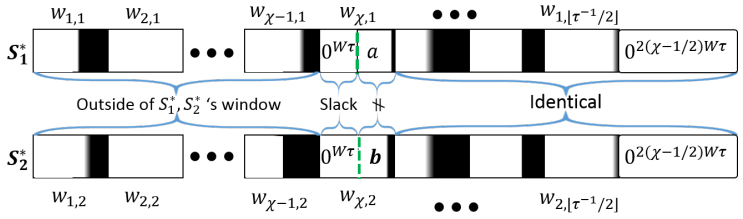

Figure 2 An illustration of the $\lceil\tau^{-1}/2\rceil\log(RW\tau+1)$ lower bound setting. If we assume that after seeing $w_{1,1}\cdot w_{2,1}\cdots w_{\lceil\tau^{-1}/2\rceil,1}$ we reach the same configuration as after processing $w_{1,2}\cdot w_{2,2}\cdots w_{\lceil\tau^{-1}/2\rceil,2}$, then we provide a wrong answer for at least one of S_1^*, S_2^*.

and S_2^* is different, and since the slack is all zeros, no answer is correct on both. Finally, note that this implies that S_1, S_2 had to reach different configurations, as otherwise $\mathbb{A}$ would reach the same configuration after processing the additional $2W\tau(\chi-1/2)$ zeros. ◀

3.2 (W,τ,ϵ)-Additive Summing

Next, Theorem 3 shows a lower bound for additive approximations of Slack Summing.

▶ **Theorem 3.** *For $\epsilon<1/4$, any deterministic algorithm $\mathbb{A}$ that solves the (W,τ,ϵ)-*Additive Summing *problem requires* $\max\left\{\log(W/\epsilon)-O(1),\left\lceil\lceil\tau^{-1}/2\rceil\log\lfloor\tau/2\epsilon+1\rfloor\right\rceil\right\}$ *bits.*

Before we prove Thorem 3, we start with a simpler lower bound.

▶ **Lemma 4.** *Let $\epsilon<1/4$. Any deterministic algorithm that solves the (W,τ,ϵ)-*Additive Summing *problem must use at least* $\log(W/\epsilon)-O(1)$ *bits.*

Proof. Denote by $rep(x)\triangleq(x \mod R)\cdot R^{\lfloor x/R\rfloor}$ a sequence in $\{\sigma R^*\mid\sigma\in[R]\}$ whose sum is x. Next, consider the following languages:

$$L_{A_1}\triangleq\{rep(k\cdot 2RW\epsilon)\mid k\in[\lfloor 1/4\epsilon\rfloor]\setminus\{0\}\};\qquad \overline{L_{A_1}}\triangleq 0^{W+W\tau}\cdot L_{A_1}\cdot\{0^q\mid q\in[\lfloor W/2\rfloor]\}.$$

First, notice that $|L_{A_1}|=\lfloor 1/4\epsilon\rfloor$ and that all words in L_{A_1} have length of at most $W/2$. This means that $|\overline{L_{A_1}}|=\lfloor 1/4\epsilon\rfloor\lfloor W/2+1\rfloor>\lfloor W/8\epsilon\rfloor$.

We now show that every word in $\overline{L_{A_1}}$ must have a dedicated memory configuration, thereby implying a $\lceil\log\lfloor W/8\epsilon\rfloor\rceil$ bits bound. Let $w_1=0^{W+W\tau}\cdot x_1\cdot 0^{q_1}$ and $w_2=0^{W+W\tau}\cdot x_2\cdot 0^{q_2}$ be two distinct words in $\overline{L_{A_1}}$ such that $x_1,x_2\in L_{A_1}$ and $q_1,q_2\in\lfloor W/2\rfloor$. If $x_1\neq x_2$, then their most recent W elements differ by more than $2RW\epsilon$ and there is no output that is correct for both. Note that the slack of both w_1 and w_2 is all zeros. Hence, w_1 and w_2 require different memory configurations.

Assume that $x_1=x_2$ and that by contradiction both w_1 and w_2 reached the same memory configuration. Since $w_1\neq w_2$ and $x_1=x_2$, then $q_1\neq q_2$ and without loss of generality $q_1<q_2$. This implies that w_1 is a prefix of w_2 so that $w_2=w_1\cdot 0^{q_2-q_1}$. Thus, $\mathbb{A}$ enters the shared configuration after reading w_1 and revisits it after reading $0^{q_2-q_1}$. $\mathbb{A}$ is a deterministic algorithm and therefore it reaches the same configuration also for the following word: $w_1\cdot 0^{(W+W\tau)(q_2-q_1)}$. In that word, the last $W+W\tau$ elements are all zeros while the sum of the last W elements in w_1 is at least $2RW\epsilon$. Hence, there is no return value that is correct for both w_1 and $w_1\cdot 0^{(W+W\tau)(q_2-q_1)}$. ◀

We are now ready to prove Theorem 3. The theorem says that for $\epsilon<1/4$, any deterministic algorithm $\mathbb{A}$ that solves the (W,τ,ϵ)-Additive Summing problem requires $\max\left\{\log(W/\epsilon)-O(1),\left\lceil\lceil\tau^{-1}/2\rceil\log\lfloor\tau/2\epsilon+1\rfloor\right\rceil\right\}$ bits.

Proof. Lemma 4 shows that $\mathbb{A}$ must use at least $\log(W/\epsilon) - O(1)$ bits. Given $x \in [RW\tau]$, we denote by $rep(x) \triangleq 0^{2W\tau - \lfloor x/R \rfloor - 1} \cdot (x \mod R) \cdot R^{\lfloor x/R \rfloor}$ a sequence of the following form: $\left\{0^{W\tau+i}\sigma R^{W\tau-i-1} \mid i \in [W\tau - 1], \sigma \in [R]\right\}$ whose sum is x. We consider the following languages:

$$L_{A_2} \triangleq \{rep(k \cdot 2RW\epsilon) \mid k \in [\lfloor \tau/2\epsilon \rfloor]\}; \qquad \overline{L_{A_2}} \triangleq \left\{w_1 \cdot w_2 \cdots w_{\lceil \tau^{-1}/2 \rceil} \mid \forall i : w_i \in L_{A_2}\right\}.$$

Our goal is to show that no two words in $\overline{L_{A_2}}$ have the same memory configuration. Let $S_1, S_2 \in \overline{L_{A_2}}$ so that $S_1 \neq S_2$. Denote $S_1 \triangleq w_{1,1} \cdot w_{2,1} \cdots w_{\lfloor \tau^{-1}/2 \rfloor,1}$ and $S_2 \triangleq w_{1,2} \cdot w_{2,2} \cdots w_{\lfloor \tau^{-1}/2 \rfloor,2}$, while $\forall i : w_{i,1}, w_{i,2} \in L_{A_2}$. We denote $\chi \triangleq \max\{i \mid w_{i,1} \neq w_{i,2}\}$ – the last place in which S_1 differs from S_2.

Next, consider the following sequences: $S_1^* = S_1 \cdot 0^{2W\tau(\chi-1/2)}$ and $S_2^* = S_2 \cdot 0^{2W\tau(\chi-1/2)}$. The last $W + W\tau$ elements in S_1^* are $w_{\chi,1} \cdots w_{\lceil \tau^{-1}/2 \rceil,1} \cdot 0^{2W(\chi-1/2)\tau}$ and in S_2^* $w_{\chi,2} \cdots w_{\lceil \tau^{-1}/2 \rceil,2} \cdot 0^{2W(\chi-1/2)\tau}$. Additionally, the $W\tau$ elements slack in both S_1^* and S_2^* are all zeros. Now, since the sum of $w_{\chi,1}$ and $w_{\chi,2}$ must differ by at least $2RW\epsilon$, no number can approximate both with less than $RW\epsilon$ error. ◀

3.3 (W, τ, ϵ)-Multiplicative Summing

In this section, we show lower bounds for multiplicative approximations of Slack Summing. We start with Lemma 5, whose proof appears in the full version of this paper [5].

▶ **Lemma 5.** *For $\epsilon < 1/4$, any deterministic algorithm $\mathbb{A}$ for the (W, τ, ϵ)-Multiplicative Summing problem requires at least $\log(W/\epsilon) + \log\log(RW\epsilon) - O(1)$ memory bits.*

To extend our multiplicative lower bound, we use the following fact:

▶ **Fact 1.** *For any $x \neq 1, y \in \mathbb{R}$, the sequence $\{c_i\}_{i=1}^{\infty}$, defined as* $c_n \triangleq \begin{cases} 1 & \text{n} = 1 \\ x \cdot c_{n-1} + y & \text{otherwise} \end{cases}$ *can be represented using a closed form as $c_n = x^{n-1} + y \cdot \frac{x^n - 1}{x - 1}$.*

Next, let $k \in \mathbb{N}$ and $\psi, \epsilon \in \mathbb{R}$, such that $\psi \geq 2$, $\epsilon > 0$, $k \geq 1$; consider the integer sequence

$$a_{n,k} \triangleq \begin{cases} 1 & \text{n} = 1 \\ \left\lceil (1+\epsilon)\left(a_{n-1,k} + \sum_{i=1}^{k-1} \psi^i\right)\right\rceil & \text{otherwise.} \end{cases}$$

Using the fact above, we show the following lemma:

▶ **Lemma 6.** *For every integer $n \geq 1$ we have $a_{n,k} \leq 4\epsilon^{-1}(1+\epsilon)^{n+1}\psi^{k-1}$.*

Proof. To apply Fact 1, we define an upper bounding sequence $\{b_{i,k}\}_{i=1}^{\infty}$ as follows:

$$b_{n,k} \triangleq \begin{cases} 1 & \text{n} = 1 \\ (1+\epsilon)\left(b_{n-1,k} + \sum_{i=1}^{k-1} \psi^i\right) + 1 & \text{otherwise.} \end{cases}$$

Thus, we can rewrite the n'th element of the sequence as:

$$b_{n,k} = (1+\epsilon)^{n-1} + \tfrac{(1+\epsilon)^n - 1}{(1+\epsilon) - 1}\left((1+\epsilon)\textstyle\sum_{i=1}^{k-1} \psi^i + 1\right).$$

We can now use this representation to derive an upper bound of $b_{n,k}$:

$$\begin{aligned} b_{n,k} &= (1+\epsilon)^{n-1} + \left((1+\epsilon)\textstyle\sum_{i=1}^{k-1} \psi^i + 1\right)\tfrac{(1+\epsilon)^n - 1}{(1+\epsilon) - 1} \\ &\leq (1+\epsilon)^{n-1} + \left((1+\epsilon)2\psi^{k-1}\right)\frac{(1+\epsilon)^n - 1}{\epsilon} \leq 4\epsilon^{-1}(1+\epsilon)^{n+1}\psi^{k-1}. \end{aligned}$$

Finally, since $a_{n,k} \leq b_{n,k}$ for any n, k, we conclude that $a_{n,k} \leq 4\epsilon^{-1}(1+\epsilon)^{n+1}\psi^{k-1}$. ◀

We now define the integer set I_k as $I_k \triangleq \left\{a_{n,k} \mid a_{n,k} \leq \psi^k\right\}$, and proceed to bound $|I_k|$.

▶ **Lemma 7.** *For any $k \geq 1$ we have $|I_k| \geq \epsilon^{-1} \ln(\psi\epsilon/4) - 1$.*

Proof. Clearly, the cardinality of I_k is the largest n for which $a_{n,k} \leq \psi^k$. According to Lemma 6, we have that $a_{n,k} \leq 4\epsilon^{-1}(1+\epsilon)^{n+1}\psi^{k-1}$, and thus:

$$\begin{aligned}|I_k| &= \arg\max\left\{n \mid 4\epsilon^{-1}(1+\epsilon)^{n+1}\psi^{k-1} \leq \psi^k\right\} \\ &\geq \log_{1+\epsilon}(\psi\epsilon/4) - 1 = \frac{\ln(\psi\epsilon/4)}{\ln(1+\epsilon)} - 1 \geq \epsilon^{-1}\ln(\psi\epsilon/4) - 1.\end{aligned}$$ ◀

We proceed with a stronger lower bound for non-constant τ values.

▶ **Lemma 8.** *For $\frac{1}{2\log(RW)-8} \leq \tau \leq 1$, any deterministic algorithm $\mathbb{A}$ that solves (W,τ,ϵ)-*Multiplicative Summing *requires at least $\Omega\left(\tau^{-1}\left(\log(\tau/\epsilon) + \log\log(RW)\right)\right)$ bits.*

Proof. We use $rep(x) \triangleq (x \mod R) \cdot R^{\lfloor x/R \rfloor}$ to denote a sequence in $\{\sigma R^* \mid \sigma \in [R]\}$ that has a sum of x. For an integer set I_k, we denote $rep(I_k) \triangleq \{rep(x) \mid x \in I_k\}$. We now choose the value of ψ to be $\psi \triangleq \sqrt[\lceil \tau^{-1}/2 \rceil]{RW/8}$; notice that $\psi \geq 2$ as required. Next, consider:

$$\begin{aligned}\overline{L_{M,2}} &\triangleq 0^W \cdot 0^{W\tau} \cdot rep(I_{\lceil \tau^{-1}/2 \rceil}) \cdot 0^{W\tau} \cdot rep(I_{\lceil \tau^{-1}/2 \rceil - 1}) \cdots 0^{W\tau} \cdot rep(I_1) \\ &= \left\{0^W \cdot w_1 \cdot w_2 \cdots w_{\lceil \tau^{-1}/2 \rceil} \mid \forall i : w_i \in \left\{0^{W\tau} \cdot rep(x) \mid x \in I_{\lceil \tau^{-1}/2 \rceil + 1 - i}\right\}\right\}.\end{aligned}$$

That is, every word in the $\overline{L_{M,2}}$ language consists of a concatenation of words $w_1, \ldots, w_{\lceil \tau^{-1}/2 \rceil}$, such that every w_i starts with $W\tau$ zeros followed by a string representing an integer in $I_{\lceil \tau^{-1}/2 \rceil + 1 - i}$, which is defined above. According to Lemma 7 we have that

$$\begin{aligned}\log(|\overline{L_{M,2}}|) &\geq \log\left(\left(\epsilon^{-1}\ln(\psi\epsilon/4) - 1\right)^{\lceil \tau^{-1}/2 \rceil}\right) \\ &= \lceil \tau^{-1}/2 \rceil \left(\log\epsilon^{-1} + \log\log(\psi\epsilon) - O(1)\right) \\ &= \Omega\left(\tau^{-1}\left(\log\epsilon^{-1} + \log\log\left(\sqrt[\lceil \tau^{-1}/2 \rceil]{RW/8} \cdot \epsilon\right)\right)\right) \\ &= \Omega\left(\tau^{-1}\left(\log\epsilon^{-1} + \log\left(\frac{\log(RW/8)}{\lceil \tau^{-1}/2 \rceil} + \log\epsilon\right)\right)\right) \\ &= \Omega\left(\tau^{-1}\left(\log(\tau/\epsilon) + \log\log(RW)\right)\right).\end{aligned}$$

Next, we show that every two words in $\overline{L_{M,2}}$ must reach different memory configurations, thereby implying a $\Omega\left(\log\left(|\overline{L_{M,2}}|\right)\right)$ bits lower bound. Let $S_1 \neq S_2 \in \overline{L_{M,2}}$ such that $S_1 = 0^W \cdot w_{1,1} \cdots w_{\lceil \tau^{-1}/2 \rceil,1}$, $S_2 = 0^W \cdot w_{1,2} \cdots w_{\lceil \tau^{-1}/2 \rceil,2}$, and $\forall i \in \left\{1, \ldots, \lceil \tau^{-1}/2 \rceil\right\} j \in \{1,2\} : w_{i,j} \in \left\{0^{W\tau} \cdot rep(x) \mid x \in I_{\lceil \tau^{-1}/2 \rceil + 1 - i}\right\}$. We next assume by contradiction that S_1 and S_2 leads $\mathbb{A}$ to the same memory configuration. Let $\chi \in \left\{1, \ldots, \lceil \tau^{-1}/2 \rceil\right\}$ such that $w_{\chi,1} \neq w_{\chi,2}$. Since $\mathbb{A}$ reaches an identical configuration after reading S_1, S_2, and as it is deterministic, $\mathbb{A}$ must reach the same configuration when processing $S_1 \cdot 0^{2W\tau(\chi - 1/2)}$ and $S_2 \cdot 0^{2W\tau(\chi - 1/2)}$. Next, observe that for every $k \in \{1, \ldots, \lceil \tau^{-1}/2 \rceil\}$, the representation length of any of its words is bounded by $\lceil \psi^k/R \rceil$. Thus, the length of a word in

$$\left\{w_1 \cdot w_2 \cdots w_{\lceil \tau^{-1}/2 \rceil} \mid \forall i : w_i \in \left\{0^{W\tau} \cdot rep(x) \mid x \in I_{\lceil \tau^{-1}/2 \rceil + 1 - i}\right\}\right\} \text{ is at most}$$

$$\sum_{k=1}^{\lceil \tau^{-1}/2 \rceil} \lceil W\tau + \psi^k/R \rceil \leq \lceil \tau^{-1}/2 \rceil (W\tau + 1) + 2\psi^{\lceil \tau^{-1}/2 \rceil}/R$$
$$= \lceil \tau^{-1}/2 \rceil (W\tau + 1) + 2W/8 \leq 3W/4 + \lceil \tau^{-1}/2 \rceil + W\tau \leq W + W\tau.$$

Now, since every word $w_{i,j}$ starts with a sequence of $W\tau$ zeros, the slack size chosen by the algorithm is irrelevant and the sums the algorithm must estimate are $\sum_{i=\chi}^{\lceil \tau^{-1}/2 \rceil} s(w_{i,1})$ and $\sum_{i=\chi}^{\lceil \tau^{-1}/2 \rceil} s(w_{i,2})$, where $s(w_{i,j})$ is simply the sum of the symbols in $w_{i,j}$. Note that $s(w_{\chi,1})$ and $s(w_{\chi,2})$ are integers in $I_{\lceil \tau^{-1}/2 \rceil + 1 - \chi}$. We assume without loss of generality that $s(w_{\chi,1}) < s(w_{\chi,2})$ (i.e., $s(w_{\chi,1}) < s(w_{\chi,2}) \in I_{\lceil \tau^{-1}/2 \rceil + 1 - \chi}$). Finally, it follows that

$$\sum_{i=\chi}^{\lceil \tau^{-1}/2 \rceil} s(w_{i,1}) \leq s(w_{\chi,1}) + \sum_{i=\chi+1}^{\lceil \tau^{-1}/2 \rceil} \max(I_{\lceil \tau^{-1}/2 \rceil + 1 - i}) \leq s(w_{\chi,1}) + \sum_{k=1}^{\chi-1} \psi^k \leq \frac{s(w_{\chi,2})}{1+\epsilon},$$

where the last inequality follows from the definition of $I_{\lceil \tau^{-1}/2 \rceil + 1 - \chi}$. Thus, no $\widehat{S}$ value is correct for both $S_1 \cdot 0^{2W\tau(\chi - 1/2)}$ and $S_2 \cdot 0^{2W\tau(\chi - 1/2)}$. ◀

Finally, we combine Lemma 5 and Lemma 8 to obtain the following lower bound:

▶ **Theorem 9.** *For* $\epsilon < 1/4$, $\frac{1}{2\log(RW)-8} \leq \tau \leq 1$, *any deterministic algorithm for the* (W, τ, ϵ)-Multiplicative Summing *problem requires at least*

$$\Omega\big(\log(W/\epsilon) + \tau^{-1}(\log(\tau/\epsilon) + \log\log(RW))\big) \text{ bits.}$$

4 Upper Bounds

In this section, we introduce solutions for the Slack Summing problems. In general, all our algorithms have a structure that consists of a subset of the following, where "rounding" has a different meaning for the exact, additive and multiplicative variants:

- Round the arriving item.
- Add the item into a counter y and round the counter.
- If a $W\tau$-sized *block* ends, store it as a compressed representation of y. Sometimes we propagate the compression error to the following block; otherwise, we zero y.
- Use the block values and y to construct an estimation for the sum.

A key idea in our additive and multiplicative algorithms is to introduce rounding errors but maintain the accountability trail so that they do not snowball and exceed the desired guarantees. In the additive algorithm, our *double rounding* technique asymptotically improves over running $1/\tau$ separate plain stream (insertion only) algorithm instances.

4.1 (W, τ)-Exact Summing

We divide the stream into $W\tau$-sized blocks and sum the number of arriving elements in each block with a $\lceil \log(RW\tau + 1) \rceil$ bits counter. We maintain the sum of the current block in a variable called y, c maintains the number of elements within the current block, and i is the current block number. The variable b is a cyclic buffer of τ^{-1} blocks. Every $W\tau$ steps, we assign the value of y to the oldest block (b_i) and increment i. Intuitively, we "forget" b_i when its block is no longer part of the window. To satisfy queries in constant time, we also maintain the sum of all active counters in a $\lceil \log(RW(1+\tau)+1) \rceil$-bits variable named B. Algorithm 1 provides pseudocode for the described algorithm. We now analyze the memory consumption of Algorithm 1.

Algorithm 1 (W,τ)-Exact Summing Algorithm.

Initialization: $y=0, b=\bar{0}, B=0, i=0, c=0$.
function Update(x)
  $y \leftarrow y+x$
  $c \leftarrow (c+1) \mod W\tau$
  if $c=0$ **then** ▷ End of block
    $B \leftarrow B-b_i+y$
    $b_i \leftarrow y$
    $y \leftarrow 0$
    $i \leftarrow (i+1) \mod \tau^{-1}$
function Output
  return $\langle B+y, c\rangle$

▶ **Theorem 10.** *Algorithm 1 uses* $(\tau^{-1}+1)\lceil\log(RW\tau+1)\rceil+\log\left(RW^2\right)+O(1)$ *bits.*

Proof. y takes $\lceil\log(RW\tau+1)\rceil$ bits; B requires $\lceil\log(RW+1)\rceil$; i adds $\left\lceil\log\tau^{-1}\right\rceil$ bits, while c needs $\lceil\log W\tau\rceil$ bits. Finally, b is a τ^{-1}-sized array of counters, each allocated with $\lceil\log(RW\tau+1)\rceil$ bits. Overall, it uses $(\tau^{-1}+1)\lceil\log(RW\tau+1)\rceil+\log\left(RW^2\right)+4$ bits. ◀

We conclude that Algorithm 1 is asymptotically optimal.

▶ **Theorem 11.** *Let* $\mathcal{B} \triangleq \max\left\{\left\lfloor\log\left(RW^2\right)\right\rfloor, \left\lceil\left\lceil\tau^{-1}/2\right\rceil\log(RW\tau+1)\right\rceil\right\}$ *be the* (W,τ)-Exact Summing *lower bound of Theorem 2. Algorithm 1 uses at most* $\mathcal{B}(4+o(1))$ *memory bits.*

Theorem 11 shows that Algorithm 1 is only x4 larger than the lower bound. In the full version of this paper [5], we show that in some cases we can get considerably closer to the lower bound.

Finally, in the full version of this paper [5] we show that Algorithm 1 is correct.

4.2 (W,τ,ϵ)-Additive Summing

We now show that additional memory savings can be obtained by combining slackness with an additive error. First, we consider the case where $\tau \le 2\epsilon$. In [3], we proposed an algorithm that sums over (exact) W elements window using the optimal $\Theta(\epsilon^{-1}+\log W)$ bits, with an additive error of $RW\epsilon$. Next, notice that if an algorithm solves (W,τ,ϵ)-Additive Summing, it also solves $(W,\tau,\tau/2)$-Additive Summing; hence, we can apply Theorem 3 to conclude that it requires $\Omega(\tau^{-1}+\log W)=\Omega(\epsilon^{-1}+\log W)$. Thus, we can run the algorithm from [3] and remain asymptotically memory optimal with no slack at all!

Henceforth, we assume that $\tau > 2\epsilon$; we present an algorithm for the problem using a 2-*stage rounding* technique. When a new item arrives, we scale it by R and then round the results to $O(\log\epsilon^{-1})$ bits. As in Section 4.1, we break the stream into non-overlapping blocks of size $W\tau$ and compute the sum of each block separately. However, we now sum the rounded values rather than the exact input, with a $O(\log\frac{W\tau}{\epsilon})$-bits counter denoted y. Once the block is completed, we *round its sum* such that it is represented with $O(\log\frac{\tau}{\epsilon})$ bits. Note that this second rounding is done for the entire block's sum while we still have the "exact" sum of rounded fractions. Thus, we *propagate* the second rounding error to the following block. An illustration of our algorithm appears in Figure 3. Here, $\text{Round}_v(z)$ refers to rounding a fractional number $z \in [0,1]$ into the closest number $\widetilde{z}$ such that $2^v \cdot \widetilde{z} \in \mathbb{N}$. Algorithm 2 provides pseudo code for the algorithm, which uses the following variables:

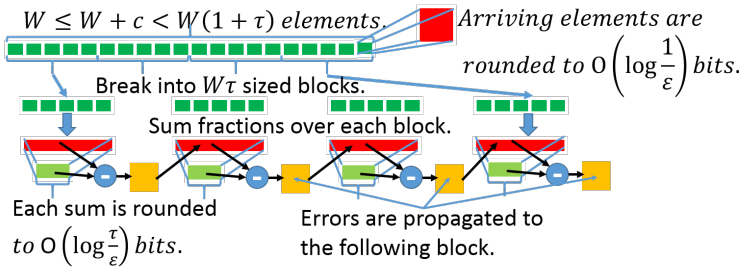

Figure 3 An illustration of our 2-stage rounding technique. Arriving elements are rounded to $\left(\left\lceil \log \epsilon^{-1} \right\rceil + 1\right)$ bits. We then sum the rounded fractions of each block and round the resulting sum into $\left\lceil \log \frac{\tau}{\epsilon} \right\rceil$ bits. The second rounding error is propagated to the next block.

Algorithm 2 (W, τ, ϵ)-ADDITIVE SUMMING Algorithm.

Initialization: $y = 0, b = 0, B = 0, i = 0, c = 0$.
1: **function** UPDATE(x)
2: $x' \leftarrow \text{Round}_{\upsilon_1}\left(\frac{x}{R}\right)$ ▷ Round $\left(\frac{x}{R}\right)$ such that $x' \cdot 2^{\upsilon_1} \in \mathbb{N}$
3: $y \leftarrow y + x'$
4: $c \leftarrow (c+1) \mod W\tau$
5: **if** $c = 0$ **then** ▷ End of block
6: $B \leftarrow B - b_i$
7: $b_i \leftarrow \text{Round}_{\upsilon_2}(\frac{y}{W\tau})$ ▷ Replace the value for the block that has left the window.
8: $B \leftarrow B + b_i$
9: $y \leftarrow y - W\tau \cdot b_i$
10: $i \leftarrow (i+1) \mod \tau^{-1}$
11: **function** OUTPUT
12: **return** $\langle R \cdot (W\tau \cdot B + y), c \rangle$

1. y - a fixed point variable that uses $\lceil \log W\tau \rceil + 1$ bits to store its integral part and additional $\upsilon_1 \triangleq \left\lceil \log \epsilon^{-1} \right\rceil + 1$ bits for storing the fractional part.
2. b - a cyclic array that contains τ^{-1} elements, each of which takes $\upsilon_2 \triangleq \left\lceil \log \frac{\tau}{\epsilon} \right\rceil$ bits.
3. B - keeps the sum of elements in b and is represented using $\log\left(\tau^{-1}\left\lceil \log \frac{\tau}{\epsilon} \right\rceil + 1\right)$ bits.
4. i - the index variable used for tracking the oldest block in b.
5. c - a variable that keeps the offset within the $W\tau$ sized block.

We now analyze the memory consumption of Algorithm 2.

▶ **Theorem 12.** *Algorithm 2 uses* $\tau^{-1} \log\left(\frac{\tau}{\epsilon}\right)(1 + o(1)) + 2\log(W/\epsilon)$ *bits.*

Proof. y requires $\log\left(\frac{W\tau}{\epsilon}\right) + O(1)$ bits; b requires another $\tau^{-1}\left\lceil \log\left(\frac{\tau}{\epsilon}\right)\right\rceil$; B takes additional $\log\left(\tau^{-1}\left\lceil \log \frac{\tau}{\epsilon} \right\rceil + 1\right)$ bits; i adds $\left\lceil \log \tau^{-1} \right\rceil$ bits, while and c is represented with $\lceil \log W\tau \rceil$ bits. Overall, the space requirement is $\tau^{-1}\left\lceil \log\left(\frac{\tau}{\epsilon}\right)\right\rceil(1 + o(1)) + 2\log(W/\epsilon)$ bits. ◀

▶ **Corollary 13.** *Let* $\mathcal{B} \triangleq \max\left\{\log(W/\epsilon) - O(1), \left\lceil \lceil \tau^{-1}/2 \rceil \log \lfloor \tau/2\epsilon + 1 \rfloor \right\rceil\right\}$ *be the* (W, τ, ϵ)-ADDITIVE SUMMING *space lower bound of Theorem 3, then Algorithm 2 uses* $\mathcal{B} \cdot (4 + o(1))$ *bits.*

Finally, Theorem 14 shows that Algorithm 2 is correct. The proof is deferred to the full version of this paper [5].

▶ **Theorem 14.** *Algorithm 2 solves the* (W, τ, ϵ)-ADDITIVE SUMMING *problem.*

Algorithm 3 (W, τ, ϵ)-Multiplicative Summing Algorithm.

function Output
  return $\langle B + y, c \rangle$

4.3 (W, τ, ϵ)-Multiplicative Summing

In this section, we present Algorithm 3 that provides a $(1+\epsilon)$ multiplicative approximation of the Slack Summing problem. Compared to Algorithm 1, we achieve a space reduction by representing each sum of $W\tau$ elements using $O(\log\log(RW\tau) + \log\epsilon^{-1})$ bits. Specifically, when a block ends, if its sum was y, we store $\rho = \left\lfloor \log_{(1+\epsilon/2)} y \right\rfloor$ (we allow a value of $-\infty$ for ρ if $y = 0$). To achieve $O(1)$ Output, we also store an approximate window sum B, which is now a *fixed point* fractional variable with $O(\log RW)$ bits for its integral part and additional $O(\log\epsilon^{-1})$ bits for storing a fraction. To update B's value for a new ρ, we *round down* the value of $(1+\epsilon)^{\rho}$. Specifically, for a real number x, we denote $(x)_{\downarrow} \triangleq \lfloor x \cdot k \rfloor / k$, for $k \triangleq \lceil \frac{4}{\epsilon} \rceil$. Our pseudo code appears in Algorithm 3. The algorithm requires $O\left(\tau^{-1}\left(\log\log(RW\tau) + \log\epsilon^{-1}\right) + \log RW\right)$ bits of space and is memory optimal when $R = W^{O(1)}$ and $\tau = \Omega\left(\frac{1}{\log RW}\right)$.

The full analysis of Algorithm 3 is deferred to the full version of this paper [5]. Next, we present an alternative (W, τ, ϵ)-Multiplicative Summing algorithm that achieves optimal space consumption for $\tau = \Theta(1)$, regardless of the value of R.

Improved (W, τ, ϵ)-Multiplicative Summing for for $\tau = \Theta(1)$

Algorithm 4 is more space efficient than Algorithm 3 but has a query time of $O(\tau^{-1})$. For $\tau = \Theta(1)$, Algorithm 4 is memory optimal *and* supports constant time queries even if $R = W^{\omega(1)}$; for this case, Algorithm 3 requires $\Omega(\log R)$ bits which is sub optimal.

Intuitively, we shave the $\Omega(\log R)$ bits from the space requirement of Algorithm 3 using an approximate representation for our y variable and by not keeping the B variable that allowed $O(1)$ time queries regardless of the value of τ. To avoid using $\Omega(\log R)$ bits in y, we use a *fixed point* representation in which $O(\log\epsilon^{-1} + \log\log(RW\tau))$ bits are allocated for its integral part and another $O(\log W\tau)$ for the fractional part. The goal of y is still to approximate the sum of the elements within a block, but now we aim for the sum to be approximately $(1+\epsilon/3)^y$. Whenever a block ends, we store only the integral part of y in our cyclic array b to save space. When queried, we compute an estimate for the sum using all of the values in b, which makes our query procedure take $O(\log\tau^{-1})$ time. To use the fixed point structure of y, we use the operator $(\cdot)_{\underline{\Downarrow}}$ that rounds a real number x into $(x)_{\underline{\Downarrow}} \triangleq \lfloor x \cdot W\tau \rfloor / W\tau$. We denote $\log_{(1+\epsilon/3)}(0) = -\infty, (-\infty)_{\underline{\Downarrow}} = -\infty, \lfloor -\infty \rfloor = -\infty$ and $(1+\epsilon/3)^{-\infty} = 0$.

Algorithm 4 (W, τ, ϵ)-Multiplicative Summing Algorithm for $\tau = \Theta(1)$.

Initialization: $y = -\infty, b = \bar{0}, i = 0, c = 0$.
1: **function** Update(x)
2: $y \leftarrow \left(\log_{(1+\epsilon/3)}\left(x + (1+\epsilon/3)^y\right)\right)_{\underline{\Downarrow}}$
3: $c \leftarrow (c+1) \mod W\tau$
4: **if** $c = 0$ **then** ▷ End of block
5: $b_i \leftarrow \lfloor y \rfloor$
6: $y \leftarrow -\infty$
7: $i \leftarrow (i+1) \mod \tau^{-1}$
8: **function** Output
9: **return** $\left\langle (1+\epsilon/3)^y + \sum_{i=0}^{\tau^{-1}-1}(1+\epsilon/3)^{b_i}, c \right\rangle$

In the full version of this paper [5], we prove the following theorem:

▶ **Theorem 15.** *For $\tau = \Theta(1)$, Algorithm 4 processes elements and answers queries in $O(1)$ time, uses $O(\log(W/\epsilon) + \log\log R)$ bits, and is asymptotically optimal.*

4.4 The Mean of a Slack Window

For some applications there is value in knowing the *mean* of a slack window. For example, a load balancer may be interested in the average transmission throughput. In exact windows, the sum and the mean can be derived from each other as the window size is constant. In slack windows, the window size changes but our algorithms also return the current slack offset $0 \leq c < W\tau$. That is, by dividing $\widehat{S}$ by $W + c$ we get an estimation of the mean (we assume that stream size is larger than W). Specifically, Algorithm 1 provides the exact mean; Algorithm 2 approximates it with $R\epsilon$ additive error, while Algorithm 3 yields a $(1+\varepsilon)$ multiplicative approximation.

5 Other Measurements over Slack Windows

We now explore the benefits of the slack model for other problems.

Maximum. While maintaining the maximum of a sliding window can be useful for applications such as anomaly detection [26, 21], tracking it over an exact window is often infeasible. Specifically, any algorithms for a maximum over an (exact) window must use $\Omega\left(W \log\left(R/W\right)\right)$ bits [14]. The following theorem shows that we can get a much more efficient algorithm for slack windows. The proof appears in the full version of this paper [5] Observe the the following bounds match for τ values that are not too small ($\tau = R^{\Omega(1)-1}$).

▶ **Theorem 16.** *Tracking the maximum over a slack window deterministically requires $O\left(\tau^{-1}\log R\right)$ and $\Omega\left(\tau^{-1}\log R\tau\right)$ bits.*

Standard-Deviation. Building on the ability of our summing algorithms to provide the size of the slack window that they approximate, we can compute standard deviations over slack windows. Intuitively, the standard deviation of the window can be expressed as

$$\sigma_{\overline{W}} \triangleq \sqrt{\frac{\sum_{x\in\overline{W}}(x - m_{\overline{W}})^2}{\left|\overline{W}\right| - 1}} = \sqrt{\frac{\sum_{x\in\overline{W}} x^2 - 2m_{\overline{W}}\sum_{x\in\overline{W}} x + \overline{W}\cdot m_{\overline{W}}^2}{\left|\overline{W}\right| - 1}} = \sqrt{\frac{\sum_{x\in\overline{W}} x^2 - \overline{W}\cdot m_{\overline{W}}^2}{\left|\overline{W}\right| - 1}},$$

there $\overline{W}$ is the slack window and $m_{\overline{W}}$ is its mean. We can then use two slack summing instances to track $\sum_{x\in\overline{W}} x^2$ and $m_{\overline{W}} = |\overline{W}|^{-1}\sum_{x\in\overline{W}} x$. This gives us an algorithm that computes the exact standard deviation over slack windows using $O(\tau^{-1}\log(RW\tau))$ space. Similarly, by using approximate rather than exact summing solutions we can compute a $(1+\epsilon)$ multiplicative approximation for the standard deviation using $O\big(\tau^{-1}\big(\log\epsilon^{-1} + \log\log(RW\tau)\big) + \log W\big)$ bits, or an $R\epsilon$-additive approximation using $O(\tau^{-1}\log\left(\frac{\tau}{\epsilon}\right) + \log W)$ space. We expand on this further in the full version of this paper [5].

General-Summing. General-Summing is similar to Basic-Summing, except that the integers can be in the range $\{-R,\ldots,R\}$. That is, we now allow for negative elements as well. Datar et al. [14] proved that General Sum requires $\Omega(W)$ bits, even for $R=1$ and constant factor approximation. In contrast, our exact summing algorithm from section 4.1 trivially generalizes to General-Summing and allows exact solution over slack windows.

Count-Distinct. Estimating the number of **distinct** elements in a stream is another useful metric. In networking, the packet header is used to identify different flows, and it is useful to know how many distinct of them are currently active. A sudden spike in the number of active flows is often an indication of a threat to the network. It may indicate the propagation of a worm or virus, port scans that are used to detect vulnerabilities in the system and even *Distributed Denial of Service (DDoS)* attacks [12, 18, 20].

Here, we have studied the memory reduction that can be obtained by following a similar flow to our summing algorithms – we break the stream into $W\tau$ sized blocks and run the state of the art approximation algorithm on each block separately. Luckily, count distinct algorithms are *mergable* [1]. That is, we can merge the summaries for each block to obtain an estimation of the number of distinct items in the union of the blocks. In the full version of this paper [5], we show that this approach yields an algorithm with superior space and query time compared to the state of the art algorithms for counting distinct elements over sliding windows [11, 19]. Formally, we prove the following theorem.

▶ **Theorem 17.** *For $\tau=\Theta(1)$ and any fixed $m>0$, there exists an algorithm that uses $O(m)$ space, performs updates in constant time and answers queries in time $O(m)$, such that the result approximates a window whose size is in $[W, W(1+\tau)]$; the resulting estimation is asymptotically unbiased and has a standard deviation of $\sigma = O(\frac{1}{\sqrt{m}})$. State of the art approaches for exact windows [11, 19] require $O(m\log(W/m))$ space and $O(m\log(W/m))$ time per query for a similar standard deviation.*

6 Discussion

In this work we have explored the slack window model for multiple streaming problems. We have shown that it enables asymptotic space and time improvements. Particularly, introducing slack enables logarithmic space exact algorithms for certain problems such as Maximum and General-Summing. In contract, these problems do not admit sub-linear space *approximations* in the exact window model. Even in problems that do have sub-linear space approximations such as Standard-Deviation and Count-Distinct, adding slack asymptotically improves the space requirement and allows for constant time updates.

Much of our work has focused on the classic Basic-Summing problem. Based on our findings, we argue that allowing a slack in the window size is an attractive approximation axis as it enables greater space reductions compared to an error in the sum. As an example, for a fixed ϵ value, computing a $(1+\epsilon)$-multiplicative approximation requires $\Omega(\log(RW)\log W)$

space [14]. Conversely, a $(1+\tau)$ multiplicative error in the window size, for a constant τ, allows summing using $\Theta(\log(RW))$ bits – same as in summing W elements without sliding windows! Given that for exact windows randomized algorithms have the same asymptotic complexity as deterministic ones [3, 14], we expect randomization to have limited benefits for slack windows as well.

Abstract

We introduce and study a game variant of the classical spanning-tree problem. Our *spanning-tree game* is played between two players, MIN and MAX, who alternate turns in jointly constructing a spanning tree of a given connected weighted graph G. Starting with the empty graph, in each turn a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges form a spanning tree in G. The goal of MIN is to minimize the weight of the resulting spanning tree and the goal of MAX is to maximize it. A strategy for a player is a function that maps each forest in G to an edge that is not yet in the forest and does not close a cycle.

We show that while in the classical setting a greedy approach is optimal, the game setting is more complicated: greedy strategies, namely ones that choose in each turn the lightest (MIN) or heaviest (MAX) legal edge, are not necessarily optimal, and calculating their values is NP-hard. We study the approximation ratio of greedy strategies. We show that while a greedy strategy for MIN guarantees nothing, the performance of a greedy strategy for MAX is satisfactory: it guarantees that the weight of the generated spanning tree is at least $\frac{w(MST(G))}{2}$, where $w(MST(G))$ is the weight of a maximum spanning tree in G, and its approximation ratio with respect to an optimal strategy for MAX is $1.5 + \frac{1}{w(MST(G))}$, assuming weights in $[0, 1]$. We also show that these bounds are tight. Moreover, in a stochastic setting, where weights for the complete graph K_n are chosen at random from $[0, 1]$, the expected performance of greedy strategies is asymptotically optimal. Finally, we study some variants of the game and study an extension of our results to games on general matroids.

1 Introduction

The fundamental *minimum (respectively, maximum) spanning tree problem* receives as an input a connected edge-weighted undirected graph and searches for a spanning tree, namely an acyclic subgraph that connects all vertices, with a minimum (respectively, maximum) weight. The problem can be solved efficiently [19, 26]. It has attracted much attention, has led to a lot of research on algorithms, and has many applications [28, 10, 14].

We introduce and study a natural game variant of the classical problem. Our *spanning-tree game* is played between two players, MIN and MAX, who alternate turns in jointly constructing a spanning tree of a given connected weighted graph $G = \langle V, E, w \rangle$. Starting with the empty graph, in each turn a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges form a spanning tree in G, that is, after $|V| - 1$ turns. The goal of MIN is to minimize the weight of the resulting spanning tree and the goal of MAX is to maximize it. A *strategy* for a player is a function that maps each forest in G to one of its legal moves, namely, it maps a forest $F \subseteq E$ to an edge $e \in E \setminus F$ such that $F \cup \{e\}$ is also a forest. Given two strategies π_{max} and π_{min}, we define the *outcome* of π_{max} and π_{min} as the spanning tree obtained when MAX and MIN follow π_{max} and π_{min}, respectively, in a turn-based game in which MAX moves first. The *value* of a strategy π_{max} of MAX is the minimum over all strategies π'_{min} of MIN of the weight of the spanning tree that is the outcome of the game in which MAX follows π_{max} and MIN follows π'_{min}. Then, an optimal strategy for MAX is a strategy with a maximum value. Thus, an optimal strategy for MAX is one that obtains the maximal value against the most hostile behavior (intuitively, the "most minimizing" strategy) of MIN. The value of a strategy for MIN is defined dually. In particular, an optimal strategy for MIN is one that obtains the minimal value against the "most maximizing" strategy for MAX. In this paper we focus on values of strategies of MAX. Indeed, unless we bound the ratio between the weights of the heaviest and lightest edges in the graph, we cannot bound the "damage" that MAX can cause MIN, namely the ratio between the performance of min strategies and the minimum spanning tree, making the study of the game setting from the viewpoint of MIN less interesting.

▶ **Example 1.** Consider the weighted graph G appearing in Figure 1 (a). The weight of G's (unique, in this example) maximum spanning tree is 33 (see (b)). An optimal strategy for MAX chooses in its first two moves the edges with weights 5 and 4, leading, against an optimal strategy of MIN, to the spanning tree of weight 31 appearing in (c).

The transition from the classical *one-player* setting of the spanning-tree problem to a *two-player* setting corresponds to a transition from *closed systems*, which are completely under our control, to *open systems*, in which we have to contend with adversarial environments. Such a transition has been studied in computer science in logic [8, 27], complexity [6], and

temporal reasoning [23], and it attracts growing attention now in *algorithmic game theory*, cf. [24]. Our work here studies this transition in graph theory. For the basic problem of reachability, the two-player setting has given rise to *alternating graph reachability* [8]. We find it very interesting to study how other basic problems and concepts in graph algorithms evolve when we shift to a two-player setting [20]. Several graph games of this type were previously studied. For example, consider the general setting in which MAX and MIN alternately claim edges of a graph G while making sure the graph they build together satisfies some monotone decreasing property. The *Turán numbers* and *Saturation numbers* refer to the number of edges that can be claimed while the property is maintained [13, 17]. Likewise, researchers have studied the *game chromatic number* of G, namely the smallest k for which MIN has a strategy to color all vertices in a game in which MAX and MIN alternately properly color the vertices of G using the colors $\{1, \ldots, k\}$ [1]. Finally, a game variant of the *maximum-flow problem*, where the algorithm can direct the flow only in a subset of the vertices is studied in [21].

Before we continue to describe our results, let us survey several games that have been studied and are based on minimum or maximum spanning trees. In the *cooperative minimum cost spanning tree game* [7, 2], the cost allocation between users of a minimum spanning tree is considered. Different properties of this cooperative game have been studied, such as the core and the nucleolus [15, 16], the Shapley value [18], and more [11]. The *Stackelberg minimum spanning tree game* [4, 5] is a one-round two-player network pricing game. The game is played on a graph, whose edges are colored either red or blue, with the red edges having a given fixed cost. The first player chooses an assignment of prices to the blue edges, and the second player then buys the cheapest possible minimum spanning tree, using any combination of red and blue edges. The goal of the first player is to maximize the total price of purchased blue edges. *Shannon's switching game* is another related two-player game. Two players take turns coloring the edges of an arbitrary graph. One player has the goal of connecting two distinguished vertices by a path of edges of her color. The other player aims to prevent this by using her color instead (or, equivalently, by erasing edges) [22, 3].

The classical maximum spanning-tree problem can be solved efficiently. Indeed, the forests embodied in a graph induce a *matroid* [25], and thus a greedy approach is optimal. Accordingly, in Kruskal's algorithm [19] for the maximum spanning-tree problem, the edges are chosen in a greedy manner, where in each step an edge with a maximum weight that does not close a cycle is added.

We study greedy strategies in the spanning-tree game. There, MAX always chooses an edge with a maximum weight that does not close a cycle. We first show that the game setting is indeed more complicated. First, greedy strategies are not necessarily optimal. For example, in the graph from Example 1, a greedy strategy for MAX chooses in its first three moves the edges with weight 8, 7, and 6, leading to the spanning tree of weight 27 appearing in Figure 1 (d). In addition, we show that given a strategy for MAX, it is NP-complete to calculate its value, and NP-hardness holds already for greedy strategies. Subsequently, we turn to study how well greedy strategies for MAX perform. We evaluate them with respect to the value of the maximum spanning tree, and with respect to the value of an optimal strategy for MAX. We analyze both the general and stochastic settings. We view our findings in both evaluations as good news. Indeed, greedy strategies for MAX ensure surprisingly tight approximations in all cases.

It is not hard to see that the value of any greedy strategy for MAX is at least half the weight of a maximum spanning tree. Indeed, the tree generated by such a strategy includes at least the heavier half of the set of edges that are chosen by a greedy algorithm in the classical

setting. Much harder is the study of the approximation ratio of a greedy strategy for MAX with respect to an optimal strategy for her. We show that when the weight of the maximum spanning tree tends to infinity, the approximation ratio tends to 1.5. More formally, assuming that the weights are normalized to values in $[0, 1]$ (note that such a normalization does not affect the ratio between the values of different strategies), we show an approximation ratio of $1.5 + \frac{1}{w(MST(G))}$, where $w(MST(G))$ is the weight of a maximum spanning tree of G. We show that our results are tight: for every odd integer $n \geq 1$, there exists a weighted graph $G = \langle V, E, w\rangle$ with $w(MST(G)) = 2n$, such that the value of the greedy strategy for MAX is n, whereas the value of an optimal strategy is $\lceil \frac{n}{2} \rceil + n$. Thus, the ratio between the maximal spanning tree and the value of the greedy strategy is 2, and the ratio between the values of the optimal and the greedy strategies is $1.5 + \frac{1}{w(MST(G))}$. We also show that, unlike the case of greedy strategies of MAX, one cannot bound the approximation ratio of greedy strategies of MIN. As we elaborate in Section 7, since the set of forests that are subgraphs of a given graph form the family of independent sets of a matroid, many of our results go beyond the spanning-tree problem and apply to matroids in a game setting.

We then study the approximation ratio of greedy strategies for MAX in a stochastic setting. Namely, we study the game played on complete graphs whose edge-weights are chosen by a uniform distribution over $[0, 1]$. Building on results of [12] regarding the weight of maximum and minimum spanning trees in such randomly weighted graphs, we are able to show that, in this setting, the approximation ratio of any greedy max strategy is asymptotically almost surely (a.a.s., for brevity) 1. Thus, while in the worst case the approximation ratio is 2 with respect to a maximum spanning tree and it tends to 1.5 with respect to an optimal strategy, it is a.a.s. 1 when we choose the edge-weights uniformly at random.

Finally, we study two variants of the setting. First, a finer definition of an approximation ratio, where performance of a strategy for MAX is examined with respect to all strategies of MIN, and second, a two-turn variant of the game, where MAX first chooses a forest of size k, for a parameter k of the game, and then MIN completes the forest to a spanning tree.

2 Preliminaries

2.1 Graphs and Weighted Graphs

An undirected *graph* is a pair $G = \langle V, E\rangle$, where V is a finite set and E is a set of pairs of elements of V. We refer to the elements of V as *vertices* and to the elements of E as *edges*. A graph may contain parallel edges. A *path* in G is a sequence of vertices $v_1, v_2, \ldots, v_k$ such that $\langle v_i, v_{i+1}\rangle \in E$ for all $1 \leq i < k$. A *cycle* in G is a path $v_1, v_2, \ldots, v_k$ for which $v_1 = v_k$. A graph $G = \langle V, E\rangle$ is *connected* if for every two vertices $v, v' \in V$, there is a path between v and v' in G. A *tree* is a connected graph with no cycles. A *forest* is a graph with no cycles, namely a collection of trees. A *spanning tree of* G is a tree $\langle V, T\rangle$, for a subset $T \subseteq E$. Note that the size of a spanning tree is $n - 1$. When the set V of vertices is clear from the context, we describe trees and forests by their sets of edges only.

A *weighted graph* $G = \langle V, E, w\rangle$ augments a graph with a weight function $w : E \to \mathbb{R}^+$. We extend w to subsets of E in the expected way, i.e., $w : 2^E \to \mathbb{R}^+$ is such that for all $A \subseteq E$, we have $w(A) = \sum_{e\in A} w(e)$. In the *maximum spanning tree* problem, we are given a weighted graph G and seek a spanning tree for G of a maximum weight. Note that G may have several maximum spanning trees. By abuse of notation, we use $MST(G)$ to denote any maximum spanning tree of G.

2.2 Matroids

A finite matroid $\mathcal{M}$ is a pair $\langle E, \mathcal{I} \rangle$, where E is a finite set (called *the ground set*) and $\mathcal{I}$ is a family of subsets of E (called *the independent sets*) that satisfies the following three properties: (1) $\mathcal{I}$ is not empty, (2) *The hereditary property*: If $X \in \mathcal{I}$ and $Y \subseteq X$, then $Y \in \mathcal{I}$, and (3) *The independent set exchange property*: If X and Y are in $\mathcal{I}$ and $|X| > |Y|$, then there is an element $x \in X \setminus Y$ such that $Y \cup \{x\}$ is in $\mathcal{I}$.

For a graph $G = \langle V, E \rangle$, let $\mathcal{F}_G$ be the set of forests in G. The pair $\langle E, \mathcal{F}_G \rangle$ is a matroid and is called *the cycle matroid of* G (see, e.g., [25]).

2.3 The Spanning-Tree Game

We consider a game variant of the maximum spanning tree problem: there are two players, MAX and MIN, who alternate turns in jointly constructing a spanning tree of a given weighted graph. Starting with the empty graph, in each turn, a player chooses an edge that does not close a cycle in the forest that has been generated so far and adds it to that forest. The game ends when the chosen edges are forming a spanning tree, that is, after $n-1$ turns. The goal of MIN is to minimize the weight of the resulting spanning tree and the goal of MAX is to maximize it. Formally, we have the following.

Let $G = \langle V, E, w \rangle$ be a weighted graph, and let $\mathcal{F}_G$ be the set of all forests $F \subseteq E$. A *configuration* in the *spanning-tree game* is a forest $F \in \mathcal{F}_G$. Let $M : \mathcal{F}_G \to 2^E$ be a function that maps a configuration F to the set of all legal moves for a player when the game is in F. Formally, $M(F) = \{e \in E \setminus F : \text{ the graph } \langle V, F \cup \{e\} \rangle \text{ has no cycles}\}$.

A *strategy* for a player is a function $\pi : \mathcal{F}_G \to E$ that maps each configuration to one of its legal moves. Thus, for all $F \in \mathcal{F}_G$, we have $\pi(F) \in M(F)$. If $M(F) = \emptyset$ (that is, when F is already a spanning tree), then $\pi(F)$ is undefined.[3] Given two strategies π_{max} and π_{min}, we define the *outcome* of π_{max} and π_{min}, denoted $T(\pi_{max}, \pi_{min})$, as the spanning tree obtained when MAX and MIN follow π_{max} and π_{min}, respectively, in a turn-based game in which MAX moves first. Formally, $T(\pi_{max}, \pi_{min}) = \{e_1, \ldots, e_{n-1}\}$ is such that for all $1 \leq i \leq n-1$, the following holds.

$$e_i = \begin{cases} \pi_{max}(\{e_1, e_2, \ldots, e_{i-1}\}) & \text{if } i \text{ is odd,} \\ \pi_{min}(\{e_1, e_2, \ldots, e_{i-1}\}) & \text{if } i \text{ is even.} \end{cases}$$

We use $w(\pi_{max}, \pi_{min})$ to denote the weight of $T(\pi_{max}, \pi_{min})$. Thus, $w(\pi_{max}, \pi_{min}) = w(T(\pi_{max}, \pi_{min}))$.

We refer to a strategy for MAX as a *max strategy* and to a strategy for MIN as a *min strategy*. Note that MAX moves when the current configuration has an even number of edges, and MIN moves when the configuration has an odd number of edges. Let $\mathcal{F}_G^{even}$ and $\mathcal{F}_G^{odd}$ be the subsets of $\mathcal{F}_G$ that contain forests of even and odd sizes, respectively. Let Π_{max} and Π_{min} be the set of all possible strategies for the MAX and MIN players, respectively. By the above, Π_{max} contains strategies $\pi_{max} : \mathcal{F}_G^{even} \to E$ and Π_{min} contains strategies

[3] We could have defined π to return a special signal, say $\perp$, in this case, but we ignore it and assume that the game ends after $n-1$ rounds, so there is no need to apply a strategy from configurations that are spanning trees.

$\pi_{min} : \mathcal{F}_G^{odd} \to E$.[4] We evaluate a max strategy π_{max} by its performance against a best (that is, most minimizing) min strategy. Formally, we define the *value* of a max strategy by

$$val_{max}(\pi_{max}) = \min\{w(\pi_{max}, \pi_{min}) : \pi_{min} \in \Pi_{min}\}.$$

Since the number of strategies is finite, the above expression always has a minimum and is thus well defined. Dually, we evaluate a min strategy π_{min} by its performance against a best (that is, most maximizing) max strategy. Formally, we define the value of a min strategy by $val_{min}(\pi_{min}) = \max\{w(\pi_{max}, \pi_{min}) : \pi_{max} \in \Pi_{max}\}$. Our study here focuses on max strategies. Essentially, our choice follows from the fact that, unlike the case of max strategies, one cannot bound the ratio between the outcome of an optimal or a greedy min strategy and the minimum spanning tree. Intuitively, it follows from the fact that the performance of strategies is strongly related to our ability to guarantee a favorable outcome even if we can control only half of the choices. Such a control guarantees that MAX can add to the spanning tree at least half of the heaviest edges in a maximum spanning tree. Such a control also guarantees that MIN can add to the spanning tree at least half of the lightest edges in a minimum spanning tree. Without, however, a bound on the ratio between the heaviest and lightest edge, such a guarantee is not of much help. In the full version, we motivate this choice further and present some results on min strategies.

The following lemma is an easy useful observation on the amount of control MAX and MIN have on the outcome of the game.

▶ **Lemma 2.** *Let $G = \langle V, E, w\rangle$ be a weighted graph and let F be a forest of G. Then,* MAX *has a strategy to ensure that the outcome includes at least $\lceil |F|/2 \rceil$ edges of F, and* MIN *has a strategy to ensure that the outcome includes at least $\lfloor |F|/2 \rfloor$ edges of F.*

Proof. We prove our claim for MIN; the proof for MAX is analogous. It suffices to show that, in each of his first $\lfloor |F|/2 \rfloor$ moves, MIN can claim an edge of F. For every $1 \leq i \leq \lfloor |F|/2 \rfloor$, let $e_1, \ldots, e_{2i-1}$ denote the edges claimed by both players up until MIN's i-th move. In his i-th move, MIN claims an arbitrary edge $e_{2i} \in F \setminus \{e_1, \ldots, e_{2i-1}\}$ such that $\{e_1, \ldots, e_{2i-1}, e_{2i}\}$ spans a forest. Such an edge e_{2i} exists since $|F| > 2i - 1 = |\{e_1, \ldots, e_{2i-1}\}|$ and both F and $\{e_1, \ldots, e_{2i-1}\}$ are forests of G, i.e., independent sets in its cycle matroid. ◀

2.4 Optimal and Greedy Strategies

We define the following strategies:

- An *optimal max strategy* is a strategy $\pi^*_{max} \in \Pi_{max}$ such that for every strategy $\pi_{max} \in \Pi_{max}$, we have $val_{max}(\pi^*_{max}) \geq val_{max}(\pi_{max})$. Such a strategy necessarily exists as the number of max strategies is finite.
- Similarly, $\pi^*_{min} \in \Pi_{min}$ is an *optimal min strategy*, if for every strategy $\pi_{min} \in \Pi_{min}$, we have $val_{min}(\pi^*_{min}) \leq val_{min}(\pi_{min})$.
- A strategy $g_{max} \in \Pi_{max}$ is a *greedy strategy* for MAX if for every configuration $F \in \mathcal{F}_G^{even}$, it holds that $g_{max}(F)$ is a heaviest edge in $M(F)$. Formally, for every configuration $F \in \mathcal{F}_G^{even}$, we have $g_{max}(F) \in \{e \in M(F) : w(e) = \max\{w(e') : e' \in M(F)\}\}$.

[4] Formally, by our definition of a strategy, every strategy for MAX and every strategy for MIN should have a well-defined legal move for every configuration in $\mathcal{F}_G$. We have chosen to restrict the definition of such strategies only to the configurations they might actually encounter during play. For completeness, one can define them for all the remaining configurations arbitrarily or, again, by using the symbol $\perp$. Also, note that strategies are *positional*, in the sense they ignore the way in which configurations have been obtained. It is easy to see that memoryfull strategies are not stronger in the spanning-tree game.

▶ Remark. There may be several optimal and greedy strategies but, from now on, for each weighted graph G we define π^*_{min}, π^*_{max}, and g_{max} as one of the strategies that satisfy the corresponding conditions and, sometimes, write "the optimal min strategy" or "the greedy max strategy". Moreover, when evaluating the performance of a greedy strategy, we consider the worst case. That is, the value of a greedy strategy is $\min\{val_{max}(g_{max}) : g_{max} \text{ is a greedy strategy in } \Pi_{max}\}$.

2.5 On the Complexity of Evaluating Strategies for MAX

Recall that the maximum spanning-tree problem can be solved in polynomial time. A possible way of computing π^*_{min} and π^*_{max} is by solving a Minmax problem, which requires exponential time. We show here that the game setting is indeed more complex than the classical one-player setting. In fact, even evaluating the value of a symbolically given max strategy is co-NP-complete, and the co-NP lower bound holds also for greedy strategies.

▶ **Theorem 3.** *Let π_{max} be a max strategy given by a linear ordering $e_1, \ldots, e_{|E|}$ of the edges in E, where π_{max} chooses in each step the edge e_j with the minimal index j for which e_j is a legal move. Let k be an integer. Deciding whether $val_{max}(\pi_{max}) > k$ is co-NP-complete. Furthermore, it is co-NP-hard already when π_{max} is a worst greedy strategy for* MAX*, that is, a greedy strategy with the lowest value.*

Proof. First, if $val_{max}(\pi_{max}) \leq k$ then there is a polynomial witness that includes the edges that MIN chooses in each turn, such that the weight of the outcome is at most k. Hence the membership in co-NP.

We now show the lower bound. Let $G = \langle V, E\rangle$ be a graph, let $S \subseteq V$, and let k be an integer. The Steiner-tree problem, namely, deciding whether there is a tree of size at most k in G that spans S, is NP-hard. We show a reduction from the Steiner tree problem. We construct a weighted graph $G' = \langle V', E', w'\rangle$ as follows. Let u_0 be a vertex in V. The set V' is obtained from V by adding k new vertices, namely $V' = V \cup \{u_1, \ldots, u_k\}$. The set E' is obtained from E by adding the edges $\{\langle u_i, u_{i+1}\rangle : 0 \leq i < k\} \cup (S \times S)$, where parallel edges are allowed. That is, an edge $e \in S \times S$ is added even if it already appears in E. For every $e \in E$ we define $w'(e) = 0$, and for every new edge $e \in E' \setminus E$ we define $w'(e) = 1$. Let π_{max} be a max strategy in which MAX first chooses edges in $\{\langle u_i, u_{i+1}\rangle : 0 \leq i < k\}$, and when it is not possible anymore she chooses edges in $S \times S$, and when it is not possible anymore she chooses edges in E. We prove that there is a tree in G that spans S and has size at most k iff $val_{max}(\pi_{max}) \leq k$. Assume that there is a tree in G that spans S and has size at most k. We denote this tree by T. Then, while MAX chooses edges in $\{\langle u_i, u_{i+1}\rangle : 0 \leq i < k\}$, MIN can choose all the edges of T and thus ensure that MAX will not be able to choose edges in $S \times S$ later. Since the edges $\{\langle u_i, u_{i+1}\rangle : 0 \leq i < k\}$ appear in every spanning tree, the value of π_{max} is k.

Assume now that there is no tree in G that spans S and has size at most k. Thus, after all the edges in $\{\langle u_i, u_{i+1}\rangle : 0 \leq i < k\}$ are chosen, there are still edges in $S \times S$ that MAX can choose, and therefore the value of π_{max} is strictly larger than k.

Finally, note that the strategy π_{max} is a worst greedy strategy for MAX, and hence the problem is co-NP-hard already for this case. ◀

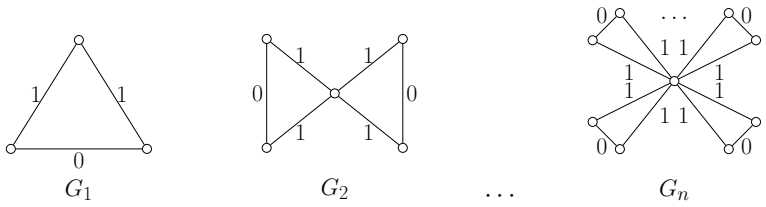

Figure 2 A sequence of weighted graphs $G_1, G_2, \ldots$ such that G_n satisfies $n = val_{max}(g_{max}) = val_{max}(\pi^*_{max}) = \frac{1}{2} \cdot w(MST(G_n))$.

3 The Performance of Optimal and Greedy Strategies w.r.t. the Maximum Spanning Tree

In the game setting, MAX has a chance to choose only half of the edges in the spanning tree. It is thus not surprising that the outcome of an optimal strategy may be only half of the weight of an MST. Below we formalize this intuition, and show that the half-ratio may be obtained already by a greedy strategy (Theorem 4) and that this upper bound is tight (Theorem 5).

▶ **Theorem 4.** *For every weighted graph G, we have that $val_{max}(g_{max}) \geq \frac{1}{2} \cdot w(MST(G))$.*

Proof. Let $G = \langle V, E, w \rangle$, and let $\langle e_1, \ldots, e_{n-1} \rangle$ be a vector of the edges of some maximum spanning tree of G, where $w(e_i) \geq w(e_{i+1})$ for every $1 \leq i < n-1$. Consider the game on G in which MAX plays according to g_{max} and MIN plays according to some strategy π_{min}. For every $1 \leq j \leq \lceil (n-1)/2 \rceil$, let x_j denote the edge of G that MAX chooses in her j-th move. For every $1 \leq j \leq \lfloor (n-1)/2 \rfloor$, let y_j denote the edge of G that MIN chooses in his j-th move. Our goal is to prove that

$$\sum_{j=1}^{\lceil (n-1)/2 \rceil} w(x_j) + \sum_{j=1}^{\lfloor (n-1)/2 \rfloor} w(y_j) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j).$$

We prove that, in fact, already $\sum_{j=1}^{\lceil (n-1)/2 \rceil} w(x_j) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j)$. Since all edge-weights are non-negative, this implies our goal.

To see this, consider an integer $0 \leq k < (n-1)/2$. Note that $|\{x_1, \ldots x_k, y_1, \ldots, y_k\}| = 2k < 2k+1 = |\{e_1, \ldots, e_{2k+1}\}|$. Since, moreover, $\{x_1, \ldots x_k, y_1, \ldots, y_k\}$ and $\{e_1, \ldots, e_{2k+1}\}$ are independent sets of a matroid (namely, the cycle matroid of G), there exists some edge $e \in \{e_1, \ldots, e_{2k+1}\} \cap M(\{x_1, \ldots x_k, y_1, \ldots, y_k\})$. Since MAX plays according to the greedy strategy, it must be that $w(x_{k+1}) \geq w(e) \geq w(e_{2k+1})$. Hence, $\sum_{j=1}^{\lceil (n-1)/2 \rceil} w(x_j) \geq \sum_{j=0}^{\lceil (n-1)/2 \rceil - 1} w(e_{2j+1}) \geq \frac{1}{2} \cdot \sum_{j=1}^{n-1} w(e_j)$, and the statement follows. ◀

▶ **Theorem 5.** *For every $n \geq 1$, there is a weighted graph G_n such that $n = val_{max}(\pi^*_{max}) = \frac{1}{2} \cdot w(MST(G_n))$. In fact, for G_n we also have $val_{max}(g_{max}) = n$.*

Proof. See the weighted graphs $G_1, G_2, \ldots$ in Figure 2. Note that $MST(G_n)$ includes all the edges with weight 1, and that MIN can ensure that all the edges with weight 0 are chosen. ◀

4 The Performance of Greedy Strategies w.r.t. Optimal Ones

In this section we study the performance of the greedy max strategy in comparison to the optimal max strategy. We first define formally what it means for two strategies to approximate each other.

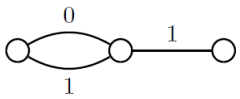

Figure 3 $val_{max}(g_{max}) = 1$ whereas $val_{max}(\pi^*_{max}) = 2$.

4.1 Approximating Strategies

Given a weighted graph $G = \langle V, E, w\rangle$, consider two max strategies $\pi_{max}, \pi'_{max} \in \Pi_{max}$ and a factor $\alpha \geq 1$. We say that π_{max} is an *α-max-approximation* of π'_{max} if

$$val_{max}(\pi_{max}) \geq 1/\alpha \cdot val_{max}(\pi'_{max}).$$

That is, intuitively, π'_{max} is at most α times better than π_{max}, where, in both cases, we assume that MIN follows an optimal min strategy.

The *max competitive ratio* of a strategy $\pi_{max} \in \Pi_{max}$ is then the smallest factor α such that π_{max} is an α-max approximation of π^*_{max}. Namely, $\frac{val_{max}(\pi^*_{max})}{val_{max}(\pi_{max})}$.

▶ Remark (Universal Approximation). We could have defined strategy approximations in a different way, by stating that π_{max} is an α-max-approximation of π'_{max} if for every strategy $\pi_{min} \in \Pi_{min}$, we have that $w(\pi_{max}, \pi_{min}) \geq \frac{1}{\alpha} \cdot w(\pi'_{max}, \pi_{min})$. We refer to such an approximation as *α-max universal approximation*. Intuitively, while in α-max-approximation the performance of the two max strategies is examined with respect to optimal (possibly different from each other) min strategies, in α-max universal approximation the performance is examined with respect to every min strategy – the same min strategy against both max strategies. In the full version, we show that α-max universal approximation is strictly finer than α-max approximation. That is, for all $\pi_{max}, \pi'_{max} \in \Pi_{max}$ and $\alpha \geq 1$, if π_{max} is an α-max universal approximation of π'_{max}, then π_{max} is an α-max approximation of π'_{max}, yet possibly π_{max} is an α-max approximation of π'_{max} but it is not an α-max universal approximation of π'_{max}. Moreover, working with a max universal approximation, the competitive ratio of the greedy strategy with respect to the optimal strategy is 2, higher than the ratio we prove in Theorem 7, when working with a max approximation.

4.2 The Competitive Ratio of Greedy Max Strategies

We turn to study the max competitive ratio of the greedy strategy. For convenience, we assume that the weight function w is normalized so that $\max\{w(e) : e \in E\} = 1$. It is easy to see that such a normalization is always possible and does not change the ratio of the weights of any two spanning trees.

▶ **Theorem 6.** *The max competitive ratio of the greedy strategy is* 2.

Proof. We first prove that g_{max} is a 2-max approximation. By Theorem 4, we have $2 \cdot val_{max}(g_{max}) \geq w(MST(G))$. In addition, as no max strategy can perform better than the weight of a maximum spanning tree, we have that $w(MST(G)) \geq val_{max}(\pi_{max})$ for all $\pi_{max} \in \Pi_{max}$. Hence, $val_{max}(g_{max}) \geq \frac{1}{2} \cdot val_{max}(\pi_{max})$ for all $\pi_{max} \in \Pi_{max}$, and we are done.

Next, in order to prove that the factor 2 is tight, consider the graph in Figure 3. It is easy to see that while an optimal max strategy would choose first the parallel edge with weight 1, leading to a spanning tree of weight 2, a greedy strategy may choose first the edge on the right, leading to a spanning tree of weight 1. ◀

4.3 A Tighter Analysis

While showing tightness in the general case, the lower-bound proof in Theorem 6 is based on a graph with a maximum spanning tree of a very small weight. In this section we show that g_{max} approximates π^*_{max} better when $w(MST(G))$ is large.

▶ **Theorem 7.** *Let $G = \langle V, E, w\rangle$ be a weighted graph, and assume that the weights in G are normalized such that the maximum weight of an edge in E is 1. Then, g_{max} is a $1.5 + \frac{1}{w(MST(G))}$-max-approximation of π^*_{max}.*

Proof. We start with a brief description of the main idea of the proof. Let $\langle e_1, \ldots, e_{n-1}\rangle$ be the edges claimed by MAX and MIN in this order when MAX follows a greedy strategy g_{max} and MIN follows a strategy π_{min} that is optimal against g_{max}. Using the fact that g_{max} is a greedy strategy, we will show that MIN has a strategy π'_{min} such that, when pitted against an optimal strategy π^*_{max} of MAX (in fact, against any max strategy), it ensures that the weight of the resulting spanning tree is at most $(1.5 + 1/w(MST(G))) \cdot \sum_{i=1}^{n-1} w(e_i)$. Note that π'_{min} might not be an optimal min strategy, but this only makes the proven result stronger. The heart of the argument is that as long as MAX can claim high (in comparison to what she claimed when she followed g_{max}) weight edges, MIN can claim quite a few low (in comparison to what he claimed when he followed π_{min}) weight edges.

We proceed to the formal proof. Let $\pi_{min} \in \Pi_{min}$ be a min strategy for which $val_{max}(g_{max}) = w(g_{max}, \pi_{min})$. Let $\langle e_1, \ldots, e_{n-1}\rangle$ be a vector of edges of $T(g_{max}, \pi_{min})$, where, for every $1 \leq i \leq n-1$, if i is odd, then e_i is chosen by MAX in her $((i+1)/2)$-th move, and if i is even, then e_i is chosen by MIN in his $(i/2)$-th move. Let $E_{odd} = \{e_1, e_3, \ldots, e_b\}$, where $b = n - 1 - (n \mod 2)$, be the edges chosen by MAX, and let $E_{even} = \{e_2, e_4, \ldots, e_a\}$, where $a = n - 2 + (n \mod 2)$, be the edges chosen by MIN. Let $d_1 > \ldots > d_k$ be the distinct weights of the edges in E_{odd}, and let $t_1, \ldots, t_k$ be positive integers such that E_{odd} contains exactly t_i edges of weight d_i for every $1 \leq i \leq k$. Let $t'_0 = 0$ and, for every $1 \leq i \leq k$, let $t'_i = t'_{i-1} + 2t_i$. Thus, $t'_i = \sum_{j=1}^{i} 2t_j$. Note that, for every $1 \leq i \leq k$, the edges of E_{odd} whose weight is d_i are $\{e_{t'_{i-1}+1}, e_{t'_{i-1}+3}, \ldots, e_{t'_i-1}\}$. For example, $w(e_1) = w(e_3) = \ldots = w(e_{2t_1-1}) = d_1$, and $w(e_{2t_1+1}) = w(e_{2t_1+3}) = \ldots = w(e_{2t_1+2t_2-1}) = d_2$. Since the weights in G are normalized so that the maximum weight of an edge in G is 1 and since g_{max} is greedy, we have that $d_1 = 1$.

We argue that MIN has a strategy π'_{min} with which he can ensure that, by deviating from the greedy strategy g_{max}, MAX does not greatly improve the weight of the tree she builds with him. We define the strategy π'_{min} as follows. Consider a forest $F_m = \{e'_1, e'_2, \ldots, e'_m\} \in \mathcal{F}^{odd}_G$, where $m < \lfloor \frac{n-1}{2} \rfloor$. Let $0 \leq i < k$ be the unique integer for which $\frac{t'_i}{2} \leq m < \frac{t'_{i+1}}{2}$. Then, $\pi'_{min}(F_m)$ is an arbitrary edge in $M(F_m) \cap \{e_2, e_4, \ldots, e_{t'_{i+1}}\}$; by definition, this is a legal move. Moreover, by the independent set exchange property of the cycle matroid of G, such an edge exists. For example, if $m < t_1$, then $\pi'_{min}(F_m)$ is an arbitrary edge of $\{e_2, e_4, \ldots, e_{2t_1}\}$ that was not chosen earlier and does not close a cycle with F_m.

Since $val_{max}(\pi^*_{max}) \leq w(\pi^*_{max}, \pi'_{min})$, it suffices to prove that $\frac{w(\pi^*_{max}, \pi'_{min})}{val_{max}(g_{max})} \leq 1.5 + \frac{1}{w(MST(G))}$. For an integer t, let $V^t_1, \ldots, V^t_{s_t}$ be the vertex sets of the connected components induced by the forest $\{e_1, \ldots, e_t\}$. Let E^t denote the set of edges of G that are contained in some connected component of $\{e_1, \ldots, e_t\}$, that is, $\langle u, v\rangle \in E^t$ if and only if there exists some $1 \leq i \leq s_t$ such that $u, v \in V^t_i$. Note that every forest in G contains at most $\sum_{j=1}^{s_t}(|V^t_j| - 1) = t$ edges of E^t.

Let $E' = \{e'_1, \ldots, e'_{n-1}\}$ denote the edge set of $T(\pi^*_{max}, \pi'_{min})$. Note that by the description of the strategy π'_{min}, for every $1 \leq i < k$, the forest $\{e'_1, e'_2, \ldots, e'_{t'_i/2}\}$ contains at least $\lfloor \frac{t'_i/2}{2} \rfloor$ edges from $E^{t'_i} \cap E_{even}$. Since $E' \cap E^{t'_i}$ contains at most t'_i edges, it follows that

$E' \cap E^{t'_i}$ contains at most $t'_i - \lfloor \frac{t'_i/2}{2} \rfloor = \lceil 1.5 \cdot \frac{t'_i}{2} \rceil$ edges from $E \setminus E_{even}$. Note that for every edge $e \notin E^{t'_i}$, we have that $w(e) \leq d_{i+1}$. Indeed, otherwise MAX would have chosen $e_{t'_i+1}$ such that $w(e_{t'_i+1}) > d_{i+1}$. Hence, $E' \setminus E_{even}$ contains at most $1.5 \cdot \frac{t'_i}{2} + 0.5$ edges from $\{e \in E : w(e) > d_{i+1}\}$.

We now show that $E' \setminus E_{even}$ contains at most $1.5 \cdot \frac{t'_k}{2} + 0.5$ edges. Assume first that $n-1$ is even and thus $t'_k = n-1$. The forest $\{e'_1, e'_2, \ldots, e'_{t'_k/2}\}$ contains at least $\left\lfloor \frac{t'_k/2}{2} \right\rfloor$ edges from E_{even}. Since E' contains t'_k edges, it follows that E' contains at most $t'_k - \lfloor \frac{t'_k/2}{2} \rfloor = \lceil 1.5 \cdot \frac{t'_k}{2} \rceil$ edges from $E \setminus E_{even}$. Hence, $E' \setminus E_{even}$ contains at most $1.5 \cdot \frac{t'_k}{2} + 0.5$ edges. Now, assume that $n-1$ is odd and thus $t'_k = n$. Note that E' contains at least $\lfloor \frac{\lfloor \frac{n-1}{2} \rfloor}{2} \rfloor = \lfloor \frac{0.5n-1}{2} \rfloor$ edges from E_{even}. Therefore, the size of $E' \setminus E_{even}$ is at most $n-1-\lfloor \frac{0.5n-1}{2} \rfloor = \lceil n-1-\frac{0.5n-1}{2} \rceil = \lceil \frac{3n}{4} - 0.5 \rceil \leq \lceil \frac{3n}{4} \rceil = \lceil 1.5 \cdot \frac{t'_k}{2} \rceil \leq 1.5 \cdot \frac{t'_k}{2} + 0.5$.

Since for every $1 \leq i < k$ the forest $E' \setminus E_{even}$ contains at most $1.5 \cdot \frac{t'_i}{2} + 0.5$ edges from $\{e \in E : w(e) > d_{i+1}\}$, and since $E' \setminus E_{even}$ contains at most $1.5 \cdot \frac{t'_k}{2} + 0.5$ edges, then the total weight of $E' \setminus E_{even}$ is at most $d_1(1.5 \cdot \frac{t'_1}{2} + 0.5) + \sum_{i=2}^{k} d_i \cdot [(1.5 \cdot \frac{t'_i}{2} + 0.5) - (1.5 \cdot \frac{t'_{i-1}}{2} + 0.5)] = d_1(1.5t_1 + 0.5) + \sum_{i=2}^{k} d_i \cdot (1.5t_i) = 0.5d_1 + \sum_{i=1}^{k} 1.5t_i d_i$.

We are now ready to bound $\frac{w(\pi^*_{max}, \pi'_{min})}{val_{max}(g_{max})}$ from above.

$$
\begin{aligned}
\frac{w(\pi^*_{max}, \pi'_{min})}{val_{max}(g_{max})} &= \frac{w(E')}{w(E_{even}) + \sum_{i=1}^{k} t_i d_i} \leq \frac{w(E_{even}) + w(E' \setminus E_{even})}{w(E_{even}) + \sum_{i=1}^{k} t_i d_i} \\
&\leq \frac{w(E_{even}) + 0.5d_1 + \sum_{i=1}^{k} 1.5t_i d_i}{w(E_{even}) + \sum_{i=1}^{k} t_i d_i} = \frac{w(E_{even}) + \sum_{i=1}^{k} t_i d_i + \sum_{i=1}^{k} 0.5t_i d_i + 0.5d_1}{w(E_{even}) + \sum_{i=1}^{k} t_i d_i} \\
&\leq 1 + \frac{\sum_{i=1}^{k} 0.5t_i d_i + 0.5d_1}{\sum_{i=1}^{k} t_i d_i} = 1.5 + \frac{0.5d_1}{\sum_{i=1}^{k} t_i d_i} \leq 1.5 + \frac{0.5}{0.5 \cdot w(MST(G))} \\
&= 1.5 + \frac{1}{w(MST(G))}.
\end{aligned}
$$

The last inequality follows from the fact $\sum_{i=1}^{k} t_i d_i \geq 0.5 \cdot w(MST(G))$ (see proof of Theorem 4) and $d_1 = 1$. ◀

The following theorem asserts that the approximation ratio given in Theorem 7 is tight.

▶ **Theorem 8.** *Let $n \geq 1$ be an odd integer. There exists a weighted graph G_n with $w(MST(G_n)) = 2n$ and with a maximum edge weight of 1, such that $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = 1.5 + \frac{1}{w(MST(G))}$.*

Proof. We define $G_n = \langle V, E, w \rangle$ as follows. First, let $V = V_1 \cup V_2$, where $V_1 = \{v_0, v_1, \ldots, v_n\}$ and $V_2 = \{v_0, u_1, \ldots, u_n\}$. Note that the vertex v_0 appears in both V_1 and V_2. Then, let $E = E_1 \cup E_2$ where $E_1 = \{\langle v_i, v_{i+1} \rangle : 0 \leq i \leq n-1\}$ and $E_2 \subseteq V_2 \times V_2$ is the disjoint union of two spanning trees T_0 and T_1 on the vertices of V_2. It is not hard to see that such two spanning trees always exist. For $n \leq 2$, one needs parallel edges, as in G_1, which appears in Figure 3. For $n \geq 3$, the graph G_n appears in Figure 4, where the edges in T_1 are solid, and these in T_0 are dashed.

For every edge $e \in E_1 \cup T_1$ we have $w(e) = 1$ and for every edge $e \in T_0$ we have $w(e) = 0$. The edges in E_1 must be contained in every spanning tree of G_n. Therefore, if m edges from T_1 are chosen during the game for some $m \leq n$, then the outcome of the game is $m + n$.

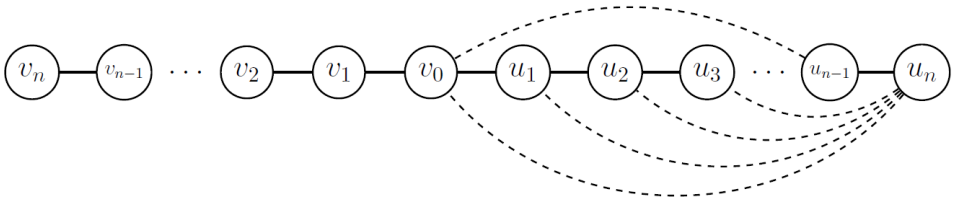

Figure 4 The graph G_n with $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = 1.5 + \frac{1}{w(MST(G_n))}$.

Thus, an optimal strategy π^*_{max} is to have as many edges from T_1 as possible. Hence, by Lemma 2 we have $val_{max}(\pi^*_{max}) = \lceil \frac{n}{2} \rceil + n$. In the strategy g_{max}, MAX chooses only the n edges in E_1, and hence $val_{max}(g_{max}) = n$.

Since n is odd, we have $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = \frac{\lceil \frac{n}{2} \rceil + n}{n} = \frac{\frac{n}{2}+0.5+n}{n} = 1.5 + \frac{1}{2n} = 1.5 + \frac{1}{w(MST(G_n))}$. ◀

5 A Stochastic Setting

The weighted graphs $\{G_n : n \in \mathbb{N}\}$ depicted in Figure 2 form an infinite family of games in which g_{max} is an optimal strategy for MAX. In this section we prove that g_{max} is not far from being optimal in a very natural and general case.

▶ **Theorem 9.** *Consider the weighted graph $G = \langle V, E, w \rangle$, where $V = [n]$, $E = \binom{[n]}{2}$, and $\{w(e) : e \in E\}$ are independent random variables, each having a uniform distribution over $[0, 1]$. Then, asymptotically almost surely (a.a.s., for brevity)*

$$\lim_{n\to\infty} \frac{val_{max}(g_{max})}{val_{max}(\pi^*_{max})} = 1.$$

The main ingredient in our proof of Theorem 9 is the following result, which is an immediate corollary of the main result of [12] (see also [9] and the many references therein).

▶ **Theorem 10.** *For $n \geq 1$, consider the complete graph with n vertices K_n, and let $\{X_e : e \in E(K_n)\}$ be independent random variables, each having a uniform distribution over $[0, 1]$. Let Y_m (respectively, Y_M) denote the weight of a minimum (respectively, maximum) spanning tree. Then*

(a) $\lim_{n\to\infty} Pr(Y_m \leq 1.21) = 1$.

(b) $\lim_{n\to\infty} Pr(Y_M \geq n - 2.21) = 1$.

Proof of Theorem 9. It readily follows from Theorem 4 and Part (b) of Theorem 10 that a.a.s. $val_{max}(g_{max}) \geq (n - 2.21)/2$. Let T be a spanning tree with weight at most 1.21; such a tree exists a.a.s. by Part (a) of Theorem 10. It follows by Lemma 2 that MIN has a strategy to ensure that the tree he builds with MAX contains at least $\lfloor |T|/2 \rfloor = \lfloor (n-1)/2 \rfloor$ edges of T. The weight of the tree they build is thus at most $1.21 + \lceil (n-1)/2 \rceil \leq (n + 2.42)/2$. Hence, a.a.s.

$$\lim_{n\to\infty} \frac{val_{max}(g_{max})}{val_{max}(\pi^*_{max})} \geq \lim_{n\to\infty} \frac{(n - 2.21)/2}{(n + 2.42)/2} = 1$$

as claimed. ◀

6 A Two-Turn Variant of the Spanning-Tree Game

In this section we study a variant of the game in which the players alternate turns only once. Formally, we have the following. A *game* is a pair $\langle G, k\rangle$, where $G = \langle V, E, w\rangle$ is a weighted graph with n vertices and $1 \leq k \leq n-1$ is an integer. In a game on $\langle G, k\rangle$, first MAX chooses a forest $F \subseteq E$ of size k. Then, MIN complements F to a spanning tree of G by choosing $n-1-k$ edges. MAX wants to maximize the weight of the resulting spanning tree and MIN aims to minimize it. Let $g_{max} \subseteq E$ be a strategy for MAX in which she chooses a forest of size k with a maximum weight, that is, MAX chooses a forest in a greedy manner. Note that while we still use the notation which was introduced in Subsection 2.4 (e.g., g_{max}), the definition of a strategy is different in this setting. A strategy π_{max} of MAX is simply the edge set of some forest of G of size k. Similarly, a strategy π_{min} for MIN is a function that, given a forest F of size k, returns a forest F' of size $n-1-k$ such that $F \cup F'$ is a spanning tree.

▶ **Theorem 11.** *Let $\langle G, k\rangle$ be a game, where $G = \langle V, E, w\rangle$ and $|V| = n$. Then, $val_{max}(g_{max}) \geq \frac{k}{n-1} \cdot w(MST(G))$.*

Proof. Let $T = \{e_1, \ldots, e_{n-1}\}$, where $w(e_1) \geq \ldots \geq w(e_{n-1})$, be an MST obtained by complementing g_{max} in a greedy manner. That is, $g_{max} = \{e_1, \ldots, e_k\}$. Note that for every $k < i \leq n-1$ we have $w(e_i) \leq w(e_k)$. Therefore, $w(MST(G)) = w(T) = w(\{e_1, \ldots, e_k\}) + w(\{e_{k+1}, \ldots, e_{n-1}\}) \leq w(g_{max}) + (n-k-1) \cdot w(e_k)$. Since $w(e_k) \leq \frac{1}{k} \cdot w(g_{max})$, we have $w(MST(G)) \leq w(g_{max}) + (n-k-1) \cdot \frac{1}{k} \cdot w(g_{max}) = \frac{n-1}{k} \cdot w(g_{max}) \leq \frac{n-1}{k} \cdot val_{max}(g_{max})$. ◀

▶ **Theorem 12.** *Let $\langle G, k\rangle$ be a game, where $G = \langle V, E, w\rangle$ and $|V| = n$. Then, g_{max} is a 2-max-approximation.*

Proof. Let π_{min} be a strategy for which $val_{max}(g_{max}) = w(g_{max}, \pi_{min})$ and let $T = T(g_{max}, \pi_{min})$. Let π^*_{max} be an optimal strategy for MAX. Consider the strategy π'_{min} of MIN in which π^*_{max} is complemented to a spanning tree as follows. Since $|\pi^*_{max}| = k$ and $|T| = n-1$, MIN can choose $n-1-k$ edges from T due to the independent set exchange property of the cycle matroid of G. For such a strategy π'_{min}, we have $val_{max}(\pi^*_{max}) \leq w(\pi^*_{max}, \pi'_{min}) \leq w(\pi^*_{max}) + w(T)$. Since g_{max} is a forest of maximum weight among all forests of G with k edges, it follows that $w(\pi^*_{max}) \leq w(g_{max})$, and thus $val_{max}(\pi^*_{max}) \leq w(g_{max}) + w(T) \leq 2 \cdot w(T) = 2 \cdot val_{max}(g_{max})$. ◀

The following result is a straightforward consequence of Theorems 11 and 12.

▶ **Corollary 13.** *Let $\langle G, k\rangle$ be a game, where $G = \langle V, E, w\rangle$ and $|V| = n$. Then, g_{max} is a $\min\{2, \frac{n-1}{k}\}$-max-approximation.*

In the following theorem we show that the approximation ratio in Corollary 13 is tight.

▶ **Theorem 14.** *Let $n > 1$ and $1 \leq k \leq n-1$ be integers. There exists a game $\langle G, k\rangle$, where $G = \langle V, E, w\rangle$ and $|V| = n$, such that $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = \min\{2, \frac{n-1}{k}\}$, where π^*_{max} is an optimal strategy for MAX in G.*

Proof. Let $V = V_1 \cup V_2$, where $V_1 = \{v_0, v_1, \ldots, v_k\}$ and $V_2 = \{v_0, u_1, \ldots, u_{n-1-k}\}$. Note that the vertex v_0 appears in both V_1 and V_2. Let $E = E_1 \cup E_2$, where $E_1 = \{\langle v_i, v_{i+1}\rangle : 0 \leq i \leq k-1\}$ and $E_2 = E(T_0) \cup E(T_1)$, where T_0 and T_1 are edge-disjoint spanning trees of $G[V_2]$ (we allow parallel edges in E_2). For every edge $e \in E_1 \cup T_1$ we set $w(e) = 1$ and for every edge $e \in T_0$ we set $w(e) = 0$. Note that if MAX chooses m edges in T_1 for some $m \leq n-1-k$, then MIN can choose $n-1-k-m$ edges in T_0 due to the independent set

exchange property of the cycle matroid of G. The edges of E_1 must be contained in every spanning tree of G. Therefore, if MAX chooses m edges from T_1, then the outcome of the game is $m+k$. Thus, the optimal strategy π^*_{max} contains as many edges from T_1 as possible, namely, $\min\{k, n-1-k\}$ edges from T_1. The strategy g_{max} contains the k edges in E_1, and therefore $val_{max}(g_{max}) = k$.

If $k \leq \frac{n-1}{2}$ then π^*_{max} contains k edges from T_1 and hence we have $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = \frac{2k}{k} = 2 = \min\{2, \frac{n-1}{k}\}$. If $k > \frac{n-1}{2}$ then π^*_{max} contains $n-1-k$ edges from T_1 and hence we have $\frac{val_{max}(\pi^*_{max})}{val_{max}(g_{max})} = \frac{n-1}{k} = \min\{2, \frac{n-1}{k}\}$. ◀

7 Discussion

We studied a game variant of the classic maximum spanning-tree problem. Both the classic problem and our spanning-tree game can be generalized in a straightforward way to all matroids. In the game setting, given a weighted matroid $M = \langle E, \mathcal{I}, w\rangle$, MAX and MIN alternate turns in claiming elements of E while ensuring that the set of elements claimed so far by both players is in $\mathcal{I}$. The game is over as soon as the set of claimed elements is a basis B of M. MAX aims to maximize the total weight of B and MIN aims to minimize it. It is not hard to show that all of our results (with the exception of Theorem 9, which deals only with weighted complete graphs) apply in this more general setting. The only non-trivial generalization is that of one specific point in the proof of Theorem 7, which we explain below.

When defining E^t, instead of relying on the connected components of the forest $\{e_1, \ldots, e_t\}$, one can use the rank function[5] r of the matroid. That is, $E^t = \{e \in E : r(\{e\} \cup \{e_1, \ldots, e_t\}) = r(\{e_1, \ldots, e_t\})\}$. It then readily follows from the definitions of r and of E^t that $|B \cap E^t| \leq t$ holds for every $B \in \mathcal{I}$.

The graph depicted in Figure 3, which is used to show that, in general, the competitive ratio of greedy strategies is 2, contains parallel edges. One then wonders whether the competitive ratio of greedy strategies is better than 2 under the assumption that the graph on which the game is played is simple. At the moment we only know that this ratio is between 5/3 and 2. One can also consider graphs that are not only simple, but have a large girth[6]. The intuition behind this is that, in order to prevent MAX from claiming a certain edge, MIN must ensure that claiming it closes a cycle, and this seems harder if all cycles are long. Moreover, when the girth is 2, i.e., there are parallel edges, we know that the competitive ratio is 2. On the other hand, when the game is played on a tree, i.e., the girth is infinite, the competitive ratio is trivially 1. This shows that increasing the girth does decrease (in some way) the competitive ratio of greedy strategies from 2 to 1.

Finally, our game is a special case of the so-called *biased game*, in which MAX claims p edges per turn and then MIN claims q edges per turn, where p and q are positive[7] integers that are allowed to grow with n. It would be interesting to study how changing the parameters p and q would affect our results.

---

[5] The rank function of a matroid $M = \langle E, \mathcal{I}\rangle$ is a mapping $r : 2^E \to \mathbb{N}$ that maps each subset A of E to the size of a largest independent set it contains; i.e., $r(A) = \max\{|B| : B \subseteq A, B \in \mathcal{I}\}$.

[6] The girth of a graph G is the length of a shortest cycle in G. If G is a forest, then its girth is defined to be ∞.

[7] In fact, by allowing $p = 0$ (respectively, $q = 0$) we get the original minimum (resp., maximum) spanning tree problem for which greedy strategies are optimal regardless of the value of q (resp., p).

Abstract

A temporal graph can be viewed as a sequence of static graphs indexed by discrete time steps. The vertex set of each graph in the sequence remains the same; however, the edge sets are allowed to differ. A natural problem on temporal graphs is the Temporal Exploration problem (TEXP): given, as input, a temporal graph $\mathcal{G}$ of order n, we are tasked with computing an *exploration schedule* (i.e., a temporal walk that visits all vertices in $\mathcal{G}$), such that the time step at which the walk arrives at the last unvisited vertex is minimised (we refer to this time step as the *arrival time*). It can be easily shown that general temporal graphs admit exploration schedules with arrival time no greater than $O(n^2)$. Moreover, it has been shown previously that there exists an infinite family of temporal graphs for which any exploration schedule has arrival time $\Omega(n^2)$, making these bounds tight for general TEXP instances. We consider restricted instances of TEXP, in which the temporal graph given as input is, in every time step, of maximum degree d; we show an $O(\frac{n^2}{\log n})$ bound on the arrival time when d is constant, and an $O(d \log d \cdot \frac{n^2}{\log n})$ bound when d is given as some function of n.

1 Introduction

A natural generalisation of the static, undirected graph is one by which a notion of time is introduced to the edge set. Such a generalisation provides a flexible tool for the modelling of problems/scenarios of a dynamic nature; particularly those which incorporate some temporal aspect into their structure. Informally, a *temporal graph* can be viewed as a graph whose edges are allowed to change over time. Time, herein, refers to an interval comprised of discrete time steps; the model we consider sees a temporal graph as an ordered sequence of static graphs indexed by the steps in this time interval (we call the number of steps contained in the interval the *lifetime* of the graph). In each graph of the sequence, the edge set may differ, whilst the vertex set remains constant. Additionally, we require that the edges that appear in each time step originate from some pre-specified static graph, which we call the *underlying graph*. It is this potential for the edges connecting the vertices in the graph to change over time that allows us to model problems, scenarios and systems in which the relationships between entities can evolve. Various "dynamic graph" models exist; they, and the problems defined on them, have been explored in a number of other studies. For an

overview we refer the reader to [9] and [4]. Since the addition of an element of dynamicity fundamentally makes temporal graphs different from their static predecessors, it is clear that the development of new techniques for their analysis (and for the analysis of problems defined upon them) is required. In this paper, we take an algorithmic standpoint, and consider a restricted case of the problem of computing a walk around a temporal graph that visits all vertices by the earliest time step possible.

1.1 Contribution

This paper considers the problem of Temporal Exploration, or TEXP (defined originally in [10] by Michail and Spirakis), which asks that, given a temporal graph $\mathcal{G}$, we compute an *exploration schedule* (i.e., a walk visiting each vertex in $\mathcal{G}$ at least once) such that the time step at which the last unvisited vertex is reached is minimal amongst all possible schedules (we call this time step the *arrival time*). In [10], Michail and Spirakis gave an $O(dn)$ upper bound on the arrival time of exploration schedules for arbitrary temporal graphs, where d is the *dynamic diameter* of the graph. Erlebach et al. [5] observed that, in general temporal graphs that are connected in every step, d can be at most $n-1$, implying an $O(n^2)$ bound on arrival times in the worst case. Moreover, they provide an explicit construction of an infinite family of graphs for which any exploration schedule has arrival time $\Omega(n^2)$, making these bounds tight for general instances of TEXP. We note that this construction is, as far as we are aware, the only one that has been shown to require this many steps for exploration; this, coupled with the fact that all graphs within this family contain a vertex of high degree $(n-1)$ in each time step, motivates our examination of the problem when restricted to instances in which the temporal graph is of maximum degree d in every time step. Further, provided in [5] is a construction of a degree-bounded family of graphs (with planar underlying graphs), such that each graph in the family is of maximum degree 2 in every time step. They prove $\Omega(n \log n)$ arrival times of any exploration schedule for any graph in this family. No better bound than the general $O(n^2)$ bound is known for the arrival time of exploration schedules for degree-bounded temporal graphs. We make the first step towards narrowing this large gap by showing that, for any graph contained within the class of degree-bounded temporal graphs, one can guarantee that there exists an exploration schedule, W, such that the arrival time of W is $O(d \log d \cdot \frac{n^2}{\log n})$ when d is given as some function of n, and $O(\frac{n^2}{\log n})$ when d is constant.

1.2 Related work

A number of previous studies have considered how standard results, problems and definitions are affected when viewed in the context of a variety of dynamic graph models. For example, it was found by Berman in [1] that the vertex variant of Menger's theorem does not hold when applied to a particular model of dynamic graphs (termed *scheduled networks*), in which each edge is assigned both an arrival and departure time. On the other hand, Kempe et al. showed in [7] that, under this same model, there is a class of temporal graphs for which the vertex variant of Menger's theorem does hold – they show this by means of a forbidden minor characterisation.

As well as their previously mentioned results, Kempe et al. [7] showed that it is *NP*-complete to decide whether or not there exist two vertex-disjoint, *time-respecting* paths (i.e., each edge in the path is traversed during a time step that is strictly greater than the previous edge) between a given source and sink. Under a similar model, Bui-Xuan et al. [3] consider the problems of computing an s-t path in a temporal graph that is *shortest* (minimal number

of edges), *foremost* (arrives at t at the earliest possible time step) or *fastest* (the time spent between traversing the first and last edges in the path is minimal), showing that there are a number of natural path parameters one might wish to optimise when considering dynamic graphs.

In [8], Mertzios et al. consider a temporal graph model in which each edge, e, is labelled with the set of time steps during which e appears in the graph. They specify a polynomial-time algorithm for the problem of computing a foremost path between two given vertices, and, complementing the work in [1] and [7], present a temporal analogue of Menger's theorem which holds for general graphs adhering to their model.

Brodén et al. [2] study a temporal analogue of the TSP problem, in which the graph is a complete graph in every step, and a cost belonging to the set $\{1, 2\}$ is assigned to each edge; additionally, these costs can change in each time step. They assume that the costs of the edges can change at most k times over the course of the graph's lifetime, and manage to provide a polynomial-time approximation algorithm with approximation ratio $2 - \frac{2}{3k}$. In [10], Michail and Spirakis also considered this model, showing the general problem to be *APX*-hard, whilst improving on the results of [2] with a $(1.7 + \varepsilon)$-approximation algorithm.

Under the same model as [8], Michail and Spirakis [10] formally introduced the problem of Temporal Exploration, showing that the general problem of deciding whether a temporal graph admits any valid exploration schedule is *NP*-complete if the graph is not assumed to be connected in each time step. They suggested making the assumption that the graph is connected in every step. Erlebach et al. [5] further studied the TEXP problem under this assumption. In addition to their previously mentioned results, they obtained an $O(n^{1-\varepsilon})$-inapproximability result, for any $\varepsilon > 0$, ruling out the possibility of any constant-factor approximation algorithms. Additionally, they considered the problem of TEXP when the input graph is subject to various structural restrictions: amongst other things, they proved $O(n)$ arrival times for temporal graphs in which the underlying graph is a cycle; $O(n^{1.5}k^2 \log n)$ arrival times for underlying graphs of treewidth k; and $O(n \log^3 n)$ arrival times for underlying graphs that are $2 \times n$ grids. From a different angle, they also considered a model in which the edges of the graph are present in each step with a particular probability, or appear with a certain regularity.

In [6], Fluschnik et al. considered the *NP*-hard problem of Temporal (s, z)-Separation, in which we are are asked to separate two vertices, s and z, in a given temporal graph, by removing from it a minimal number of vertices. Similarly to [5], they showed that there are a number of restricted graph classes for which Temporal (s, z)-Separation becomes easier, and a number for which the problem remains hard to solve; for example they showed that the problem becomes fixed-parameter tractable when parameterised by $k + l$, where k is the size of a solution, and l is the longest temporal path in the input graph. Negatively, they showed that for graphs in which at most one edge is present in every time step, the problem remains *NP*-hard.

2 Preliminaries

In this section, we introduce those definitions key to formulating the general problem of Temporal Exploration.

▶ **Definition 1** (Temporal graph)**.** We represent a temporal graph, $\mathcal{G}$, with *underlying graph*, $G = (V, E)$, using an ordered sequence of static graphs: $\mathcal{G} = \langle G_1, G_2, ..., G_\tau \rangle$. Further, we let the set $V(\mathcal{G}) = V$ and $|V| = n$. The subscripts $i \in \{1, 2, ..., \tau\}$ indexing the graphs in the

sequence are the discrete *time steps* 1 to τ, where τ is known as the *lifetime* of $\mathcal{G}$. Each G_i represents the structure of $\mathcal{G}$ in time step i. More precisely, $G_i = (V, E_i)$ is a subgraph of G; in particular, $V(G_i) = V(G)$, $E_i \subseteq E$, for all $1 \leq i \leq \tau$.

▶ **Definition 2** (Temporal walk)**.** A temporal walk W through a temporal graph $\mathcal{G}$ is given as an alternating sequence of vertices and edge-time pairs,

$$W = v_0, (e_0, i_0), v_1, (e_1, i_1), v_2, ..., v_{k-1}, (e_{k-1}, i_{k-1}), v_k,$$

that starts at vertex v_0 and ends at vertex v_k. Additionally, we require that $i_0 < i_1 < ... < i_{k-1}$, so that an agent following W can traverse at most one edge per time step. Each edge-time pair, (e_j, i_j), denotes the traversal of edge $e_j = \{v_j, v_{j+1}\}$ at timestep i_j. For such a traversal to be possible, e_j must be present in graph G_{i_j}, i.e. $e_j \in E_{i_j}$. We say that a walk, W, *departs* at time $i_0 = \delta(W)$ and *arrives* at time $i_{k-1} + 1 = \alpha(W)$, and may refer to the time steps $\delta(W)$ and $\alpha(W)$ as the *departure* and *arrival* times of W, respectively. Finally, let $t_0 \leq \delta(W)$ be an arbitrary time step, and assume that an agent waits at vertex v_0 for $\delta(W) - t_0$ time steps before traversing edge e_0; we refer to the difference, $|W| = \alpha(W) - t_0$, as the *duration* of W.

The following result is implied by Lemma 1 in [5]. It provides an upper bound on the number of time steps it might take to reach one vertex from another in a temporal graph that is connected in every time step.

▶ **Lemma 3** (Erlebach, Hoffmann and Kammer [5])**.** *Let $\mathcal{G}$ be a temporal graph with vertex set V, and assume $\mathcal{G}$ is connected in each step. Then an agent situated at any vertex $u \in V$ at any time $t \leq \tau - n$ can reach any other vertex $v \in V$ in at most $|V| - 1 = n - 1$ steps, i.e., by time step $t + n - 1$.*

▶ **Definition 4** (Exploration schedule)**.** We say that a walk, W, is an *exploration schedule* if, for all $v \in V(\mathcal{G})$, there exists some $v_i \in W$ such that $v = v_i$. Additionally, W is said to be *foremost* if it reaches the n-th unique vertex $v \in V(\mathcal{G})$ at time $\alpha(W)$, and if there exists no other temporal walk W', such that $\alpha(W') < \alpha(W)$.

▶ **Definition 5** (Temporal walk concatenation)**.** We define two temporal walks, W and W', to be *compatible under concatenation* if the departure time of W' is greater than or equal to the arrival time of W (i.e., $\delta(W') \geq \alpha(W)$), and W' departs from the same vertex at which W arrives. The result of their concatenation is the walk obtained by following W, then following W' directly after.

▶ **Problem** (Temporal Exploration)**.** An instance of the general Temporal Exploration (TEXP) problem is given as a pair $(\mathcal{G}, s)$, where $\mathcal{G} = \langle G_1, G_2, ..., G_\tau \rangle$ is an arbitrary temporal graph with lifetime $\tau \geq |V(\mathcal{G})|^2 = n^2$ (in order to ensure that there exist feasible solutions for any instance), and $s \in V(\mathcal{G})$ is a start vertex. The problem then asks for a temporal walk, W, such that W is an exploration schedule, W is foremost, and W departs from vertex s. We make the additional assumption that the graph is connected in each step; without this it could happen that there exists no valid exploration schedule.

We note that since (as part of any instance of the TEXP problem) we are given a temporal graph, $\mathcal{G} = \langle G_1, G_2, ..., G_\tau \rangle$, any candidate algorithm for the problem knows, in advance, the structure of the graph in each step of its lifetime (and therefore knows the dynamic structure of the temporal graph's edge set in advance). The following section introduces those definitions specific to the proof of our main result.

3 Exploring degree-bounded temporal graphs

We now turn our attention to restricted instances of the Temporal Exploration problem, in which the input graph is of bounded degree in each time step. We proceed by introducing those definitions central to the proof of our main result.

▶ **Definition 6** (Temporal graph of bounded degree)**.** Let $\mathcal{G}^d = \langle G_1^d, G_2^d, ..., G_\tau^d \rangle$ be a temporal graph of order $|V(\mathcal{G}^d)| = n$, and *lifetime* τ. It is said that the degree of $\mathcal{G}^d$ is bounded by d if, for all i, $\max_{v \in V(G_i^d)} \deg_{G_i^d}(v) \leq d$. We note that d may be given as a constant, or as some function of n.

(Note that we do not place any restriction on the underlying graph of $\mathcal{G}^d$.) Consider now a partitioning of the vertex set, $V(\mathcal{G}^d)$, of a degree-bounded temporal graph, $\mathcal{G}^d$, into distinct parts T and L, such that $T \cup L = V(\mathcal{G}^d)$. We refer to the set T as the *terminal* set, containing $|T| = k$ terminal vertices $u \in T$, and L as the *leftover* set, containing the $|L| = n - k$ leftover vertices $v \in L$. The set T of terminals will contain, initially, the set of all unvisited vertices in $\mathcal{G}^d$, whilst the set L will contain the specified start vertex, s. Our aim is to form $\Omega(\frac{k}{d})$ disjoint ordered pairs of terminal vertices, (u, u'), such that there is a temporal walk through $\mathcal{G}^d$ that departs from u, arrives at u', and has duration no longer than $O(\frac{dn}{k})$. In doing so, we obtain a subset $T' \subseteq T$ of terminals which are arrived at by such a walk; by setting $T = T'$, moving all terminals not reachable by such a walk into L, and forming pairs amongst those $u \in T$ again, we obtain a new collection of walks, each of which can be concatenated with exactly one of the walks obtained from the previous application. Repeated application of this process will form the basis of our overall exploration approach, eventually enabling us to explore $\Theta(\log_d n)$ vertices in $O(dn)$ steps. The following definitions will prove useful in showing this – in each of them we consider an arbitrary temporal graph, $\mathcal{G}$, during a time period starting at time step t, and ending at time step t':

▶ **Definition 7** (Reachable set)**.** The reachable set of a vertex, $x \in V(\mathcal{G})$, is the set $R_x(t, t') = \{y \in V(\mathcal{G}) \mid$ there exists a walk from x to y starting at time l and ending at time l', with $t \leq l \leq l' \leq t'\}$. If t and t' are made clear, or are deducible from the context, we simply write R_x, rather than $R_x(t, t')$.

▶ **Definition 8** (Reachable pair)**.** We call an ordered pair of terminal vertices, $(u, u') \in T \times T$, a *reachable pair* if $u' \in R_u(t, t')$ (with $1 \leq t \leq t' \leq \tau$) and $u \neq u'$. When it is clear from the context, we may simply refer to a reachable pair as a *pair*. We also say that a reachable pair is *formed* in the step $t' - 1$, in which u' is added to $R_u(t, t')$.

▶ **Definition 9** (Home set)**.** We define a *home set* of a leftover vertex, $v \in L$, to be a set $H_v(t, t')$ of terminal vertices such that, for any terminal vertex u, the condition $u \in H_v(t, t')$ implies the following: $v \in R_u(t, t')$, and u does not already belong to a reachable pair. As such, there exist temporal walks in $\mathcal{G}$ departing from all $u \in H_v(t, t')$ and arriving at v. Again, we write H_v rather than $H_v(t, t')$ when t and t' are clear from the context.

Note that Definition 9 does not define home sets in a unique way. It only requires that $u \in H_v(t, t')$ implies $v \in R_u(t, t')$, but there is no requirement that all vertices u that satisfy $v \in R_u(t, t')$ are included in the home set. We will specify how to construct home sets in a certain way, and the home sets resulting from our construction will have the additional property that they contain at most two vertices. The purpose of home sets and the details of their construction will become clear in the proof of Lemma 13.

▶ **Definition 10** (Spread of a terminal vertex)**.** We refer to the number of home sets that a particular terminal vertex $u \in T$ belongs to as the *spread* of u.

As previously discussed, we first wish to show that in a degree-bounded temporal graph, $\mathcal{G}^d$, enough disjoint reachable pairs are formed during any period of $O(\frac{dn}{k})$ time steps (here we take k to be the number of terminals contained in T at the start of the time period we are considering). To achieve this, we introduce the following potential function, which tracks the number of terminals that each leftover vertex has contained within its respective home set. By first showing that we can increase the value of this potential function by a large enough amount in each of the $O(\frac{dn}{k})$ considered steps, we will be able to prove that $\Omega(\frac{k}{d})$ disjoint reachable pairs can be found during those same steps.

▶ **Definition 11** (Potential function, ϕ)**.** Consider an arbitrary time step t, and let i be the current time step ($1 \leq t \leq i \leq \tau$). Further, let L_0, L_1, L_2 be the sets of leftover vertices $v \in L$, such that $|H_v(t,i)| = 0$, $|H_v(t,i)| = 1$, and $|H_v(t,i)| = 2$, respectively. In other words, L_0, L_1 and L_2 are the sets of leftover vertices that have 0, 1 and 2 terminals contained in their home sets at time i. Clearly, $L = L_0 \cup L_1 \cup L_2$ at any time, since the home sets we consider grow to a size no larger than 2. We denote by P_v^i the *potential value* of vertex v at time i, and define it for all i as follows:

$$P_v^i = \begin{cases} 1, & \text{if } v \in L_0 \text{ (at time } i) \\ 2, & \text{if } v \in L_1 \text{ (at time } i) \\ 3, & \text{if } v \in L_2 \text{ (at time } i). \end{cases}$$

Given this, we introduce our potential function, ϕ, taking as argument a bounded-degree temporal graph, $\mathcal{G}^d$:

$$\phi_t^i(\mathcal{G}^d) = \sum_{v \in L} P_v^i,$$

so that $\phi_t^i(\mathcal{G}^d)$ is the sum of the values, P_v^i, during time step i ($t \leq i \leq \tau$), given that we began tracking the value of ϕ at time t. When t is clear from the context, we may refer to $\phi_t^i(\mathcal{G}^d)$ at arbitrary i ($t \leq i \leq \tau$) as $\phi^i(\mathcal{G}^d)$ or, if i is clear from the context, as $\phi(\mathcal{G}^d)$ or ϕ.

▶ **Observation 12.** If we assume that we begin tracking the value of our potential function from some time t, such that no $v \in L$ belongs to the reachable set of any $u \in T$ at time t, then initially, $\phi^t(\mathcal{G}^d) = |L|$. Further to this, $P_v^i \leq 3$ for any $v \in L$, and $|L| \leq |V(\mathcal{G}^d)|$. Therefore, $\phi^i(\mathcal{G}^d) \leq 3|V(\mathcal{G}^d)| = 3n$ for any $t \leq i \leq \tau$.

We note that when a reachable pair (u, u') is formed, then both $u, u' \in T$ are no longer considered as candidates for further reachable pairs (since we require our pairs to be disjoint). Therefore, we remove u and u' from T and place them into L. As a result, it is possible for the number of leftover vertices to grow over the course of time, allowing for larger potential values in future time steps. Moreover, in order to increase our potential in any given step, we must be able to find terminal vertices that can be added to the home set of a leftover vertex in that step.

By Definition 9, $u \in H_v$ implies that u does not already belong to any reachable pair. It therefore follows that the forming of a pair in $\mathcal{G}^d$ can also cause the potential to drop, since we are required to remove u and u' from all home sets that they are contained within. Whilst some decrease in potential is inevitable, it is important that we ensure that the decrease is not too large in any single step. If the home sets of many leftover vertices contain the same terminal, and that terminal goes on to form a pair, then it will be removed from all of these home sets, possibly generating a large drop in potential. If this type of behaviour occurs too often, it might happen that we are unable to obtain a large enough amount of potential in total, and as a result, not be able to form the required amount of reachable pairs. This issue is fully addressed by Lemma 13 in the following subsection.

3.1 Exploration method

Following the discussion above, all is in place to fully describe our overall approach to computing exploration schedules (in degree-bounded temporal graphs) that are guaranteed to have arrival time $O(d \log d \cdot \frac{n^2}{\log n})$. We begin by showing that it is possible to obtain a potential increase of $\frac{k-2p}{2d}$ in any given time step, where p is the number of pairs that have already been formed between vertices in T. For the following, assume that we have fixed a time step t, and that we consider $\mathcal{G}^d$ from time t onwards.

▶ **Lemma 13.** *Consider a degree-bounded temporal graph, $\mathcal{G}^d$, in an arbitrary timestep i, whose vertex set has been partitioned into sets T (terminals) and L (leftovers), which initially contained $|T| = k$ and $|L| = n - k$ vertices, respectively. Additionally, assume that $p \leq \frac{k-2}{2}$ reachable pairs of terminal vertices have been formed already (including those pairs formed in step i). Then, it is possible to obtain a potential increase of at least $\frac{k-2p}{2d}$ in time step i.*

Proof. Observe that, since there are already p pairs formed amongst the terminals $u \in T$, there are exactly $k - 2p$ terminals that remain in T, i.e. $|T| = k - 2p$ (since any two terminals forming a pair become leftover vertices once the pair is formed). As $p \leq \frac{k-2}{2}$ implies $k - 2p \geq 2$, we know that there are still at least 2 terminals. We wish to find at least $\frac{k-2p}{2d}$ disjoint paths, such that each path has terminals as its endpoints, and that every other vertex in the path is a leftover vertex (we will refer to such a path as a *terminal path*). Let G_i^d denote the form of $\mathcal{G}^d$ during the i-th time step; we proceed by computing a spanning tree S_i of G_i^d, selecting an arbitrary leaf, r, as S_i's root, and forming paths in a bottom-up fashion via a greedy procedure. More specifically, we consider each vertex, $x \in S_i$, in reverse level order, so that we first examine those vertices that are furthest away from r, followed by those vertices second furthest away from r, and so on, until every x has been processed. On examining a vertex x, we consider the subtree of S_i rooted at x: if it contains 2 or more terminals that do not already belong to a path, we arbitrarily select two and take the path joining them in S_i to be one of our terminal paths, discarding the remaining terminals in that subtree. We claim that in this way, we use exactly 2 terminals for each path we form, and discard at most $d - 2$ terminals whenever we form a single path. To see this, observe that each vertex in S_i has at most $d - 1$ children (since r is a leaf), and consider the situation in which the vertex we are currently processing, x, is a terminal of degree d. If each of the subtrees rooted at x's children contains exactly one terminal, then we will only be able to form one path, which must have x and one of the other $d - 1$ terminals (each of which lies alone in one of the subtrees rooted at x's children) as its endpoints – the remaining $d - 2$ terminals will be discarded. This follows from the fact that if more than one terminal lay in the subtree rooted at any of x's children, then they must already belong to a path; otherwise they would have already been discarded, as per our procedure. Therefore, on forming any path in S_i, we "use up" at most d terminals (2 terminals for the path, and at most $d - 2$ terminals are discarded). Observe now that, on processing r, it may also happen that there is a single unmatched terminal, y, in the subtree rooted at r; in this case, y will be discarded. As a result, it follows that we are able to find at least $\frac{k-2p-1}{d}$ disjoint terminal paths in S_i. Moreover, $\frac{k-2p-1}{d} \geq \frac{k-2p}{2d}$ for $d > 0$ and $p \leq \frac{k-2}{2}$, which can be easily checked. Since $k - 2p \geq 2$ precisely when $p \leq \frac{k-2}{2}$, it follows that we are able to form at least $\frac{k-2p}{2d}$ disjoint terminal paths in S_i, as required.

Now, given a set of terminal paths obtained by following the aforedescribed method, we wish to show that, per each path, we can obtain a $+1$ increase in potential. We require a way of doing so that ensures that not only are we able to increase the potential by a large enough

amount in every step, but that we are able to ensure the drop in potential experienced in any particular time step is limited. Specifically, we require a procedure with the following properties:

1. We can obtain a potential increase of +1 within any given terminal path.
2. For a single execution of our procedure on a given terminal path, we want the spread of exactly one of the path's endpoints to increase by 1, and the spread of the terminal at the opposite end of the path to remain the same.

Property **(1)** ensures that we are able to guarantee a potential increase of $\frac{k-2p}{2d}$ in each time step. Property **(2)** limits the number of home sets that any terminal vertex $u \in T$ can be added to in any particular step to 1. To this end, we specify now our procedure, demonstrating that both properties **(1)** and **(2)** are satisfied by the actions performed within each individual case.

▶ **Procedure** (Obtain-Potential)**.** Consider an arbitrary time step, t, from which we began tracking the value of $\phi(\mathcal{G}^d)$. The input to the procedure is a terminal path, $Q_i \subseteq S_i$ (we omit the i from this notation from here onwards), obtained by applying the aforedescribed greedy procedure to $\mathcal{G}^d$ in step $i \geq t$ (i.e., by applying the greedy procedure to the graph G_i^d). Let u and u' be the endpoints of Q. We proceed as follows: arbitrarily select one of u or u' (for argument's sake we select u), and begin examining the set $H_{v_j}(t,i)$ (again, we will omit the arguments from this notation) for every $v_j \in Q$ in the order in which they appear in Q (from u to u'). Let the x-th and last leftover vertex that we examine where $H_{v_j} = \{u\}$ be known as v_x; the vertex we examine next will be known as v_{x+1}. We note that since, by our earlier assumption, all pairs that will form in step i have already been formed, the existence of such a v_x is guaranteed in all but one case. If u is adjacent to the vertex $v_1 \in Q$ such that $H_{v_1} \supseteq \{u^*\}$ with $u^* \neq u$, then clearly a pair is formed; a contradiction, since the greedy procedure for forming terminal paths does not consider terminals that already belong to pairs. Similarly, if $v_x = v_{|Q|-1}$, then $H_{v_{|Q|-1}} = \{u\}$ and u and u' form a pair in that step; again, a contradiction. Thus, the exceptional case, in which there is no such v_x, occurs when $H_{v_1} = \emptyset$: here, we can instantly obtain our potential increase for Q by adding u to H_{v_1}, whilst still satisfying properties **(1)** and **(2)**. With these exceptions dealt with, we now distinguish between two main cases:

- **(i) Case 1: $H_{v_x} \cap H_{v_{x+1}} = \emptyset$.** We distinguish between two subcases:
  - **(i) Case 1.1: $H_{v_{x+1}} \neq \emptyset$.** Select an arbitrary u^* in $H_{v_{x+1}}$ and add u^* to H_{v_x}, giving our +1 potential increase (satisfying property **(1)**). We note that this is possible since $u^* \in H_{v_{x+1}}$ implies that $v_{x+1} \in R_{u^*}$, in which case an agent could move from u^* to v_{x+1}, and from v_{x+1} to v_x. It is therefore valid to select u^* from the home set of a vertex adjacent to v_x and add it to v_x's home set since, by definition, v_x would be added to R_{u^*} in that step regardless.
    In the event that $u^* \notin \{u, u'\}$, remove u^* from $H_{v_{x+1}}$, and add u to $H_{v_{x+1}}$; this ensures that the potential associated with v_{x+1} does not decrease, whilst additionally ensuring that the spread of u^* does not increase with respect to Q (satisfying property **(2)**).
  - **(ii) Case 1.2: $H_{v_{x+1}} = \emptyset$.** In this case, we add u to $H_{v_{x+1}}$, giving our +1 potential increase (property **(1)**), whilst ensuring that only u is added to the home set of exactly one leftover vertex in Q (property **(2)**).
- **(ii) Case 2: $H_{v_x} \cap H_{v_{x+1}} \neq \emptyset$.** Again, we distinguish between two subcases:
  - **(i) Case 2.1: $u' \in H_{v_{x+1}}$.** Since $u' \in H_{v_{x+1}}$, we can simply add u' to H_{v_x} and we are done – this gets us our required +1 potential increase (property **(1)**), whilst

also satisfying property **(2)**, since the only terminal that is added to a home set within Q is one of Q's endpoints, u'.

(ii) **Case 2.2: $u' \notin H_{v_{x+1}}$.** Select an arbitrary $u^* \in H_{v_{x+1}}$ (with $u^* \neq u, u'$), add u^* to H_{v_x}, and remove u^* from $H_{v_{x+1}}$. Now, continue following Q in the same direction, repeating the above process some $y-1$ times, until in the y-th iteration we examine a vertex v_{x+y+1}, such that $u \notin H_{v_{x+y+1}}$. More generally, in the j-th iteration, we check the set H_{x+j+1}, select from it an arbitrary $u^* \neq u$, add u^* to $H_{v_{x+j}}$, and remove u^* from $H_{v_{x+j+1}}$. By removing u^* from $H_{v_{x+j+1}}$, we ensure that the spread of u^* does not increase with respect to Q, satisfying property **(2)** for all iterations 1 through $y-1$ (notice that in each of these iterations, our potential value stays the same, since whenever we add a terminal to one leftover vertex's home set, we remove that terminal from another home set). If it happens that $H_{v_{x+j+1}} = \{u\}$ (i.e., we cannot select $u^* \neq u$), then we do not add any u^* to $H_{v_{x+j}}$ in that iteration; clearly property **(2)** is still satisfied in this situation. Once we begin the y-th iteration, if it happens that the set $H_{v_{x+y+1}} = \emptyset$, we simply add u to $H_{v_{x+y+1}}$ and we are done – in this case, both properties are trivially satisfied. Otherwise, select an arbitrary u^* from $H_{v_{x+y+1}}$, add u^* to $H_{v_{x+y}}$ (increasing the potential value of v_{x+y}), and remove u^* from $H_{v_{x+y+1}}$. Finally, add u to $H_{v_{x+y+1}}$; this uses the fact that $H_{v_{x+y}}$ is guaranteed to contain terminal u, and so we replace u^* with u, ensuring that the potential of vertex v_{x+y+1} does not decrease, whilst still ensuring that property **(2)** is satisfied, since only vertex u's spread has increased by exactly 1. It is this final step that ensures property **(1)** is satisfied, since we increased the potential value of v_{x+y} in this iteration, but did not decrease the potential value of v_{x+y+1}.

The lemma follows by applying the greedy procedure (for forming $\frac{k-2p}{2d}$ disjoint terminal paths) in G_i^d, and supplying each path as input to the Obtain-Potential procedure. ◀

▶ **Lemma 14.** *Let $\mathcal{G}^d$ be a degree-bounded temporal graph with a vertex set partitioned into parts T and L. Let t be the time at which tracking of the potential function began (so that $\phi^t(\mathcal{G}^d) = |L|$), and let i be the current time step. Then, the forming of a single reachable pair of terminal vertices, (u, u'), can cause the potential value to drop by at most $2l$, where $l = i - t$ is the number of steps that passed since we began tracking the value of $\phi(\mathcal{G}^d)$.*

Proof. Consider the specification of our Obtain-Potential procedure and note that, during any time step i (with $t \leq i \leq \tau$), each terminal vertex can belong to at most one disjoint terminal path, and that exactly one of the vertices in $\{u, u'\}$ (that form the endpoints of each terminal path) has its spread increase by 1. It is clear that when a reachable pair of terminal vertices (u, u') is formed, the worst case scenario is the following: both u and u' were added to the home set of a single leftover vertex in each of the l steps that have passed since time t. The lemma follows by observing that this scenario will result in an overall drop in potential of $2l$, since, by Definition 9, u and u' will be removed from the home set of all those leftover vertices $v \in L$ for which they belong to the set $H_v(t, i)$. ◀

▶ **Lemma 15.** *Let $\mathcal{G}^d$ be a degree-bounded temporal graph with an underlying graph of order n, and let $V(\mathcal{G}^d)$ be partitioned into parts T and L, with $|T| = k$ and $|L| = n - k$. Then in $10 \cdot \frac{dn}{k}$ steps, at least $\frac{k}{20d}$ disjoint reachable pairs of terminal vertices are formed.*

Proof. Consider $\mathcal{G}^d$ from time t onwards and assume that the opposite of our claim is true, so that less than $\frac{k}{20d}$ reachable pairs are formed in the space of $10 \cdot \frac{dn}{k}$ steps (i.e. less than $\frac{k}{20d}$ reachable pairs are formed within the time range t to $t + 10 \cdot \frac{dn}{k}$). Then, by the end of the

$(t + 10 \cdot \frac{dn}{k})$-th step, there are at least $k - 2 \cdot \frac{k}{20d} = k - \frac{k}{10d} = \frac{10dk-k}{10d} = k \cdot \frac{(10d-1)}{10d} \geq 0.9k$ (for all $d \geq 1$) terminal vertices that have not yet formed a pair with another terminal vertex. It follows then, by Lemma 13, that the value of $\phi(\mathcal{G}^d)$ increases by at least $\frac{0.9k}{2d} \cdot \frac{10dn}{k} = \frac{9kdn}{2dk} = \frac{9n}{2} = 4.5n$ over those $10 \cdot \frac{dn}{k}$ steps. By Lemma 14, over the same period, the potential can decrease by at most $\frac{k}{20d} \cdot 2 \cdot \frac{10dn}{k} = \frac{k}{20d} \cdot \frac{20dn}{k} = \frac{20dkn}{20dk} = n$, since, by our earlier assumption, fewer than $\frac{k}{20d}$ pairs are formed. From this, it follows that the potential at the end of those $10 \cdot \frac{dn}{k}$ steps is at least $4.5n - n = 3.5n$. But this is a contradiction since, by Observation 12, $\phi^i(\mathcal{G}^d) \leq 3n$ for any $t \leq i \leq \tau$; the lemma follows. ◀

▶ **Lemma 16.** *Consider a degree-bounded temporal graph, $\mathcal{G}^d$, in an arbitrary time step, t, and let the vertices in $V(\mathcal{G}^d)$ be divided into parts T and L, with $|T| = k$ and $|L| = n - k$ at the beginning of time t. Then, there exists at least one vertex $v \in T$ such that an agent positioned at v at the start of time t can explore $\Theta(\log_d k)$ terminal vertices in $O(dn)$ steps.*

Proof. By application of Lemma 15 to part T, we are able to form at least $\frac{k}{20d}$ disjoint reachable pairs of terminal vertices in the space of $10 \cdot \frac{dn}{k}$ time steps. As a result, we obtain a set of $\frac{k}{20d}$ temporal walks, each of which has exactly one such reachable pair constituting its endpoints, with no walk taking any longer than $10 \cdot \frac{dn}{k}$ steps. At the end of these $\frac{k}{20d}$ walks are exactly $\frac{k}{20d}$ unique (since the pairs are disjoint) terminal vertices. We proceed by taking this smaller set of terminals as our new T and reapplying Lemma 15 at time $t + 10 \cdot \frac{dn}{k}$; as a result, we obtain $\frac{k/20d}{20d} = k/(20d)^2$ new walks, each of which has endpoints that form a reachable pair, and each of which takes no longer than $10 \cdot \frac{dn}{k/20d}$ steps. Notice now that since, via our second application of Lemma 15, we formed pairs amongst only those terminals that were reachable via one of the walks obtained from our initial application of Lemma 15, there are now at least $k/(20d)^2$ walks of length at most $\frac{10dn}{k} + \frac{10dn}{k/(20d)}$, each of which visits three terminal vertices; in other words, we are able to concatenate some walk obtained by our first application of Lemma 15, with some walk obtained by our second application, to construct a walk that visits three terminals. In this fashion, we claim that we are able to construct a walk that visits $\Theta(\log_d k)$ terminals.

Generally speaking, the i-th application of Lemma 15 produces at least $k/(20d)^i$ disjoint pairs of reachable unvisited vertices, in each of which one vertex can reach the other via a walk of length at most $10 \cdot (dn)/(k/(20d)^{i-1})$. Since each time we reapply Lemma 15, it is applied only to those terminals that are reachable via a walk computed by the previous application, it follows that there must be a sequence of i walks, one resulting from each application of Lemma 15, that can be concatenated (in the order in which they were produced) to form a walk that visits exactly $i + 1$ terminals (two terminals are visited by the first computed walk, then an additional terminal is explored by the walk obtained by each successive application). Observe that we are able to repeatedly apply Lemma 15 to T exactly $\lfloor \log_{20d} k \rfloor$ times until no more pairs can be formed in T. By taking the i-th application of Lemma 15 to be the $\lfloor \log_{20d} k \rfloor$-th such application, it is clear that an agent following a walk constructed via the discussed concatenation method can explore $\lfloor \log_{20d} k \rfloor + 1 = \Theta(\log_d k)$ terminals. All that remains to be shown is that the length of any temporal walk, W, constructed in this way is of duration at most $O(dn)$. By our earlier discussion, a reachable pair of unvisited vertices, (u, u'), found as a result of the i-th application of Lemma 15, are separated by a walk with duration no longer than $10 \cdot dn/(k/(20d)^{i-1})$. Given that we apply Lemma 15 $\lfloor \log_{20d} k \rfloor$ times in order to obtain each of the shorter walks that are then concatenated to obtain W, we derive the following summation to bound the overall duration of W from above:

$$\sum_{i=0}^{\lfloor \log_{20d} k \rfloor} \left(10 \cdot \frac{dn}{k/(20d)^i}\right) = \frac{10dn}{k} \cdot \sum_{i=0}^{\lfloor \log_{20d} k \rfloor} (20d)^i \leq \frac{10dn}{k} \cdot 2k = O(dn),$$

as required. ◀

▶ **Theorem 17.** *Let $\mathcal{G}^d$ be a degree-bounded temporal graph of order $|V(\mathcal{G}^d)| = n$. Then there exists an exploration schedule, W_{exp}, starting from a given vertex, s, such that W_{exp}'s arrival time, $\alpha(W_{exp})$, is $O(d \log d \cdot \frac{n^2}{\log n})$.*

Proof. Let the current time step be $t = 1$, and let $V(\mathcal{G}^d)$ be partitioned into sets T and L, with $|T| = k$ and $|L| = n - k$ at time t (for $k = n - 1$, since s is already explored). Initially, we wish to explore $\Theta(\log_d k)$ vertices during the first $O(dn)$ steps. To achieve this, we begin by constructing a temporal walk, W_1, with departure time $\delta(W_1) = t = 1$. Let W_1 be the product of concatenating two walks, X_1 and Y_1, in that order. We note that it is not guaranteed that s will be at the start of any walk computed via our first application of Lemma 16: therefore, we set X_1 to be of duration n, and apply Lemma 16 to $\mathcal{G}^d$ at time $\delta(W_1) + |X_1| = \delta(W_1) + n$, initially setting $T = V(\mathcal{G}^d) - \{s\}$, and $L = \{s\}$, so that $T \cup L = V(\mathcal{G}^d)$. The walk resulting from that application of Lemma 16 will be known as Y_1. In this way, we ensure, by Lemma 3 (Lemma 1 in [5]), that there is enough time for an agent to move, via X_1, from s to whichever vertex Y_1 departs from. Since $|X_1| = n$, $|Y_1| = O(dn)$ (by Lemma 16), and, X_1 and Y_1 are compatible under walk concatenation, we are able to obtain the walk, W_1, of duration $|W_1| = n + O(dn) = O(dn)$, that explores $\Theta(\log_d k)$ unique vertices.

We wish to apply the above process repeatedly, until only $k \leq \frac{n}{\log_{20d} n}$ vertices remain to be explored in $\mathcal{G}^d$. This can be achieved by constructing temporal walks W_i, such that each W_i is the concatenation of two walks X_i and Y_i. Let $\alpha(W_{i-1})$ be the arrival time of walk W_{i-1}. Each X_i is a walk with duration n and departure time $\delta(X_i) = \alpha(W_{i-1})$, that departs from the last vertex of W_{i-1}, and arrives at the first vertex of Y_i. We then define Y_i to be the temporal walk, exploring $\Theta(\log_d k)$ vertices, obtained via the i-th application of Lemma 16. We perform this i-th such application at time $\delta(W_{i-1}) + |X_i| = \delta(W_{i-1}) + n$, setting

$$T = V(\mathcal{G}^d) - (\{s\} \cup V(Y_1) \cup V(Y_2) \cup \ldots \cup V(Y_{i-1})),$$

$L = V(\mathcal{G}^d) - T$ and $k = |T|$. Taking W_i to be the result of concatenating X_i and Y_i (in that order), it follows that each walk W_i departs from the last vertex of W_{i-1}, and so we can continually concatenate each W_i in the order that they are produced. The concatenation of each W_i explores an additional $\Theta(\log_d k)$ vertices; we continue this process until the number of unexplored vertices is less than or equal to $\frac{n}{\log_{20d} n}$.

In order to show now that our overall approach to exploration always produces schedules with arrival time $O(d \log d \cdot \frac{n^2}{\log n})$, we first show that $\log_{20d} k = \Theta(\log_d n)$ whenever we apply Lemma 16. As stated previously, we repeatedly apply the process discussed above until $k \leq \frac{n}{\log_{20d} n}$. This implies that whenever we apply Lemma 16, $k > \frac{n}{\log_{20d} n}$, giving that

$$\log_{20d} k > \log_{20d}(\frac{n}{\log_{20d} n}) = \log_{20d} n - \log_{20d} \log_{20d} n = \Theta(\log_d n).$$

From this, we can conclude that the duration of any W_i produced in the aforedescribed manner visits $\Theta(\log_d n)$ vertices. Since we initially explore at least $n - \frac{n}{\log_{20d} n} = O(n)$ vertices using this method, it follows that we require the concatenation of $O(n)/\Theta(\log_d n)$ W_i's, each of which is of duration $|W_i| = O(dn)$. Let the walk, resulting from the repeated concatenation of our W_i, be W^1_{exp}; it follows that W^1_{exp} explores at least $n - \frac{n}{\log_{20d} n}$ vertices in at most

$$O(dn) \cdot \frac{O(n)}{\Theta(\log_d n)} = O(d \cdot \frac{n^2}{\log_d n})$$

time steps. To deal with the remaining $\frac{n}{\log_{20d} n}$ vertices: let W_x be the last walk we produce via an application of Lemma 16, and assume it has arrival time $\alpha(W_x)$; clearly, W^1_{exp} has arrival

time $\alpha(W^1_{exp}) = \alpha(W_x) = O(d \cdot \frac{n^2}{\log_d n})$. We apply Lemma 3 (Lemma 1 in [5]), computing a walk, W^2_{exp}, which starts at time $\alpha(W^1_{exp})$, and spends a total time of $O(n)$ steps visiting each of the remaining vertices. This gives W^2_{exp} a total duration of $O(n) \cdot \frac{n}{\log_{20d} n} = O(\frac{n^2}{\log_d n})$ steps. Now, since W^1_{exp} has respective departure and arrival times $\delta(W^1_{exp}) = 1$ and $\alpha(W^1_{exp})$, and W^2_{exp} departs at time $\alpha(W^1_{exp})$ from the vertex at which W^1_{exp} ends, it follows that they are compatible under walk concatenation. The result of their concatenation is a walk, W_{exp}, such that W_{exp}'s arrival time is:

$$\alpha(W_{exp}) = |W^1_{exp}| + |W^2_{exp}| = O(d \cdot \frac{n^2}{\log_d n}) + O(\frac{n^2}{\log_d n}) = O\Big(d \cdot \frac{n^2}{\frac{\log n}{\log d}}\Big) = O\Big(d \log d \cdot \frac{n^2}{\log n}\Big),$$

and the theorem follows. ◀

From the above, it follows that whenever $d \log d = o(\log n)$, then a degree-bounded temporal graph $\mathcal{G}^d$ admits exploration schedules with arrival time $o(n^2)$. Moreover, Theorem 17 implies the following corollary:

▶ **Corollary 18.** *Let $\mathcal{G}^d$ be a temporal graph whose maximum degree in every step is at most $d \geq 2$, and d is constant. Additionally, let s be a specified start vertex. Then there exists an exploration schedule, W_{exp}, which starts at vertex s and explores all vertices in $\mathcal{G}^d$, such that the arrival time of W_{exp} is $O(\frac{n^2}{\log n})$.*

We remark that our proof is constructive and implies a polynomial-time algorithm computing an exploration schedule with arrival time $O(d \log d \cdot \frac{n^2}{\log n})$, and thus also an $O(d \log d \cdot \frac{n}{\log n})$-approximation algorithm for the TEXP problem when restricted to temporal graphs of bounded-degree.

4 Conclusion

Linear arrival times for the exploration of any static, undirected graph can be easily achieved by means of a depth-first search. The additional layer of complexity in the structure of temporal graphs, brought about by the potential for time-variance in the edge set, means that their exploration is not such a simple task: exploration schedules of general temporal graphs can require $\Theta(n^2)$ time steps.

Complementing previous results, which suggest that subjecting our input temporal graph to certain structural restrictions can improve arrival times, we have shown that by requiring the maximum degree in each time step to be bounded by d, one can guarantee arrival times of $O(d \log d \cdot \frac{n^2}{\log n})$. These results directly suggest a number of further questions: we would like to close the gap between the upper and lower bounds for exploring general degree-bounded temporal graphs – we suspect that there exists an upper bound lower than the one presented here, but it may also be the case that the current lower bound of $\Omega(n \log n)$ can be improved upon. The study of further restricted temporal graph classes, in order to establish bounds on the amount of time needed to explore them, remains an interesting question; for example, one might consider the class of temporal graphs in which only a constant number of edges are allowed to differ from each time step to the next.

A further question might ask precisely which structural properties a graph must possess in order for it to admit exploration schedules with arrival time $o(n^2)$? – it would be interesting to classify the graphs that can be explored in time strictly less than quadratic under these terms. Establishing how the computational complexity of TEXP changes whilst the problem is restricted to particular classes of graphs also presents an interesting direction; for which classes does the problem remain *NP*-hard to solve optimally, and how well can we approximate solutions for these restricted cases?

A number of other related questions also remain open. An example of one we find particularly interesting is as follows: how much quicker can general temporal graphs be explored if we allow an agent exploring the graph to make a move across two edges per time step, rather than one? We remark that the construction requiring $\Theta(n^2)$ steps to explore (given in [5]) requires only $O(n)$ steps in this two-move model. Establishing bounds for this model could provide further insight into the exploration of temporal graphs under the model considered throughout this paper.

Abstract

We consider the *Minimum Dominating Set* (MDS) problem on the intersection graphs of geometric objects. Even for simple and widely-used geometric objects such as rectangles, no sub-logarithmic approximation is known for the problem and (perhaps surprisingly) the problem is NP-hard even when all the rectangles are "anchored" at a diagonal line with slope -1 (Pandit, CCCG 2017). In this paper, we first show that for any $\epsilon > 0$, there exists a $(2+\epsilon)$-approximation algorithm for the MDS problem on "diagonal-anchored" rectangles, providing the first $O(1)$-approximation for the problem on a non-trivial subclass of rectangles. It is not hard to see that the MDS problem on "diagonal-anchored" rectangles is the same as the MDS problem on "diagonal-anchored" L-*frames*: the union of a vertical and a horizontal line segment that share an endpoint. As such, we also obtain a $(2 + \epsilon)$-approximation for the problem with "diagonal-anchored" L-frames. On the other hand, we show that the problem is APX-hard in case the input L-frames intersect the diagonal, or the horizontal segments of the L-frames intersect a vertical line. However, as we show, the problem is linear-time solvable in case the L-frames intersect a vertical as well as a horizontal line. Finally, we consider the MDS problem in the so-called "edge intersection model" and obtain a number of results, answering two questions posed by Mehrabi (WAOA 2017).

1 Introduction

Minimum Dominating Set (MDS) is an NP-hard problem in graph theory and discrete optimization. Given a graph $G = (V, E)$, the objective of the MDS problem is to compute a minimum-size subset $V' \subseteq V$ such that every vertex not in V' is adjacent to at least one vertex in V'. For general graphs, it is known that a greedy algorithm for MDS achieves an $O(\log |V|)$-factor approximation and within a constant factor this is the best one can hope for, unless P=NP [28]. As such, the problem has been extensively studied on many subclasses of graphs, one of which is the intersection graphs of geometric objects in the plane [12, 23, 17, 16, 24, 27]. Here, each vertex of the graph is in one-to-one correspondence with a geometric object in the plane and two vertices are adjacent if and only if the corresponding objects have a non-empty intersection.

In this paper, we consider the approximability and hardness of the MDS problem on the intersection graphs of geometric objects. The MDS problem is known to admit PTASes on disk graphs [17] and the intersection graphs of non-piercing[2] objects [19]. On the other hand, it is NP-hard to obtain a $o(\log |V|)$-approximation in polynomial time for sufficiently complicated shapes, e.g. rectilinear polygons [15, 16]. However, even for simple shapes such as axis-parallel rectangles no sub-logarithmic approximation is known. The only approximation for rectangles we are aware of is due to Erlebach et al. [16] who gave an $O(c^3)$-approximation on rectangles with aspect-ratio at most c. In fact, the problem is APX-hard [16] on rectangles, and (perhaps surprisingly) the problem is shown to be NP-hard even on diagonal-anchored rectangles [27]; that is, the intersection of every rectangle and a diagonal line with slope -1 is exactly one corner of the rectangle. See Figure 1(a) for an example. However, to the best of our knowledge no sub-logarithmic approximation is known even in this case. We note that optimization problems on "diagonal-intersecting" geometric objects have been studied before through the lenses of approximation algorithms; e.g. maximum independent set [9, 5, 22] and minimum hitting set [9, 8, 25].

Our results. In this paper, we first give a $(2+\epsilon)$-approximation algorithm for the MDS problem on diagonal-anchored rectangles, providing the first $O(1)$-approximation for the problem on a non-trivial subclass of rectangles.

▶ **Theorem 1.** *For any $\epsilon > 0$, there exists a $(2 + \epsilon)$-approximation algorithm for the* MDS *problem on diagonal-anchored rectangles.*

To prove Theorem 1, we first divide the problem into two subproblems and then give a PTAS for the subproblems using the *local search technique* [6, 26]. Each such subproblem involves diagonal-anchored rectangles that lie on only one side of the diagonal. The key to obtain our PTAS is in showing a planar drawing of a bipartite graph that is required for the analysis of the local search algorithm. We note that, even in these simpler cases the problem remains sufficiently challenging due to the geometry of the rectangles, and the existing schemes are not useful to obtain a near-optimal solution. For example, the local search analyses for non-piercing objects in [19] do not hold here, as the diagonal-anchored rectangles can still "pierce" each other.

It is not hard to see that the MDS problem on "diagonal-anchored" rectangles is the same as the MDS problem on "diagonal-anchored" L-*frames* [5]. An L-frame is the union of a vertical and a horizontal line segment that share an endpoint (*corner*). Indeed, each

[2] Two connected objects A and B are called non-piercing if both $A \setminus B$ and $B \setminus A$ are connected.

rectangle in the input can be replaced by a diagonal-anchored L-frame without altering the underlying intersection graph. Thus, a dominating set for the instance with the L-frames is also a dominating set for the original instance with rectangles, and vice versa. Hence, we also obtain a $(2+\epsilon)$-approximation for the problem with diagonal-anchored L-frames. For the MDS problem on general L-frames, the only approximation we are aware of is due to Mehrabi [24] who gave an $O(1)$-approximation algorithm when every two L-frames intersect in at most one point. Asinowski et al. [1] proved that every circle graph is an intersection graph of L-frames. Since MDS is APX-hard on circle graphs [10], the problem is also APX-hard on L-frames.

Note that, by definition, we can have four different *types* of L-frames depending on the two endpoints that define the corner. Considering the problem on L-frames we extend the APX-hardness result in the general case to two constrained cases. First, we show that the problem does not admit a $(1+\epsilon)$-approximation for any $\epsilon > 0$ on "diagonal-intersecting" L-frames (see Figure 1(b) for an example).

▶ **Theorem 2.** *The* MDS *problem is* APX*-hard on* L*-frames when every* L*-frame intersects a diagonal line.*

As the construction in proving Theorem 2 shows, the theorem holds even if the input consists of only one type of L-frames and all intersection points of the L-frames lie on only one side of the diagonal. This is in contrast to the diagonal-anchored L-frames case where we obtain a PTAS . We also show that one cannot hope for a $(1+\epsilon)$-approximation for any $\epsilon > 0$ even when all the L-frames intersect a vertical line; see Figure 1(c) for an example. We refer to these L-frames as *vertical-intersecting* L-frames.

▶ **Theorem 3.** *The* MDS *problem is* APX*-hard on vertical-intersecting* L*-frames even if all the* L*-frames intersect the vertical line from one side. Moreover, the problem is* NP*-hard even if for each* L*-frame, the horizontal and vertical segments have the same length.*

Moreover, we show that the APX-hardness of Theorem 3 is almost tight in the sense that the problem admits a polynomial-time algorithm on L-frames, where each L-frame intersects a vertical line and a horizontal line. See Figure 1(d) for an example. Note that, all the L-frames in the input are of the same type.

▶ **Theorem 4.** *The* MDS *problem is linear-time solvable on* L*-frames that intersect a vertical line and a horizontal line.*

To prove Theorem 4, we show that this class of graphs are the same as permutation graphs for which given the permutation of the vertices, the MDS problem can be solved in linear time [7]. As given a set of L-frames that intersect a vertical line and a horizontal line, the corresponding permutation can be computed in linear time, the theorem follows.

While the standard notion of intersection dates back to 1970s, Golumbic et al. [18] introduced the notion of *edge intersection* of L-frames. In this model, two L-frames are considered adjacent if and only if they overlap in strictly more than a single point in the plane. More formally, the L-frames corresponding to the vertices of the graph are drawn on a grid and two vertices are adjacent in the graph if and only if their corresponding L-frames share at least one grid edge; see Figure 1(e) for an example. To distinguish between the two models we will explicitly refer the edge intersection model whenever discussing a result on this model. Otherwise, we always mean the standard intersection model.

For the edge intersection model, there is a 4-approximation algorithm for MDS on L-frames [4, 20]. Moreover, the problem was recently shown to be APX-hard by Mehrabi [24],

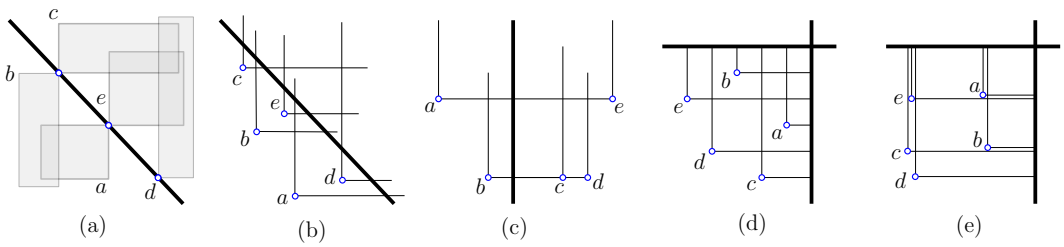

Figure 1 A graph $G = (\{a, b, c, d, e\}, E)$ with five different representations, where $E = \{(a, b), (a, e), (b, c), (c, d), (c, e), (d, e)\}$.

where two "types" of L-frames are needed for the construction. He left open whether the problem remains APX-hard when the input consists of only one type of L-frames or when the L-frames intersect a vertical line. We answer both questions affirmatively.

▶ **Theorem 5.** *In the edge intersection model, the* MDS *problem on* L*-frames of a single type is hard to approximate within a factor of 1.1377 even if all the* L*-frames intersect a vertical line from one side.*

Furthermore, we show that even intersecting two lines does not help: the MDS problem is NP-hard on L-frames in the edge intersection model even if every L-frame intersects a vertical line and a horizontal line. Observe that this is in contrast to the existence of the linear-time algorithm of Theorem 4 under the standard intersection model.

Organization. In Section 2, we give some definitions and revisit some necessary background. We prove Theorems 1 and 2 in Section 3. The proofs of Theorems 3 and 4 are given in Section 4. Finally, we show the results for the edge intersection model in Section 5 and conclude the paper in Section 6. Throughout this paper, the proofs of lemmas and theorems marked with $(*)$ are given in the full version of the paper due to space constraints.

2 Preliminaries

We denote the x- and y-coordinates of a point p by $x(p)$ and $y(p)$, respectively. For two points p and q, we denote the Euclidean distance between p and q by $\texttt{dist}(p, q)$. Given a graph $G = (V, E)$, we denote the L-frame corresponding to a vertex $u \in V(G)$ by $\mathsf{L}(u)$; we use u and $\mathsf{L}(u)$ interchangeably. We denote the corner of an L-frame l by $\texttt{cor}(l)$.

Local search. Consider an optimization problem in which the objective is to compute a feasible subset S' of a ground set S whose cardinality is minimum over all such feasible subsets of S. Moreover, it is assumed that computing some initial feasible solution and determining whether a subset $S' \subseteq S$ is a feasible solution can be done in polynomial time. The local search algorithm for a minimization problem is as follows. Fix some parameter k, and let A be some initial feasible solution for the problem. In each iteration, if there are $A' \subseteq A$ and $M \subseteq S \setminus A$ such that $|A'| \leq k$, $|M| < |A'|$ and $(A \setminus A') \cup M$ is a feasible solution, then set $A := (A \setminus A') \cup M$ and re-iterate. The algorithm returns A and terminates when no such local improvement is possible.

Clearly, the local search algorithm runs in polynomial time. Let $\mathcal{B}$ and $\mathcal{R}$ be the solution returned by the algorithm and an optimal solution, respectively. We can assume that $\mathcal{B} \cap \mathcal{R} = \emptyset$; otherwise, we can remove the common elements of $\mathcal{B}$ and $\mathcal{R}$ and analyze the

algorithm with the new sets, which guarantees that the approximation factor of the original instance is upper bounded by that of the new sets. The following result establishes the connection between local search technique and obtaining a PTAS.

▶ **Theorem 6** ([6, 26]). *Consider the solutions $\mathcal{B}$ and $\mathcal{R}$ for a minimization problem, and suppose that there exists a planar bipartite graph $H = (\mathcal{B} \cup \mathcal{R}, E)$ that satisfies the local exchange property, which is as follows: for any subset $\mathcal{B}' \subseteq \mathcal{B}$, $(\mathcal{B} \setminus \mathcal{B}') \cup N_H(\mathcal{B}')$ is a feasible solution, where $N_H(\mathcal{B}')$ denotes the set of neighbours of $\mathcal{B}'$ in H. Then, the local search algorithm yields a* PTAS *for the problem.*

3 Diagonal-intersecting Rectangles

In this section, we prove Theorems 1 and 2. To prove Theorem 1, we first give a PTAS for the problem when the rectangles are anchored at the diagonal from only one side and will then prove the theorem by applying the PTAS twice.

Recall the class of intersection graphs of diagonal-anchored rectangles is same as that of diagonal-anchored L-frames [5]. As such, to simplify the presentation of the result, we prove Theorem 1 for L-frames.

3.1 PTAS

Suppose that we are given a set of L-frames each of which is anchored at the diagonal from above; let $G = (V, E)$ be the corresponding graph. Consider any two L-frames L_1 and L_2 that intersect each other. We say that L_1 and L_2 are *coincident* if $x(\mathtt{cor}(\mathsf{L}_1))$=$x(\mathtt{cor}(\mathsf{L}_2))$. L_1 is said to intersect L_2 from left (resp. from below) if $x(\mathtt{cor}(\mathsf{L}_1)) \leq x(\mathtt{cor}(\mathsf{L}_2))$ (resp. $x(\mathtt{cor}(\mathsf{L}_1)) \geq x(\mathtt{cor}(\mathsf{L}_2))$). Notice that L_1 intersects L_2 from left if and only if L_2 intersects L_1 from below.

Consider the MDS problem on G and run the local search algorithm with $k := c/\epsilon$ for some constant c. Let $\mathcal{B}$ be the solution returned by the local search algorithm and $\mathcal{R}$ denote an optimal solution. Consider the bipartite graph $H = (\mathcal{B} \cup \mathcal{R}, E')$ in which the edge set E' is defined as follows. For any vertex $u \in V$, consider the set of all L-frames in $\{\mathcal{B} \cup \mathcal{R}\}$ that intersect $\mathsf{L}(u)$ and let (b_i, r_j), where $b_i \in \mathcal{B}$ and $r_j \in \mathcal{R}$, be a pair for which $\mathtt{dist}(\mathtt{cor}(b_i), \mathtt{cor}(r_j))$ (i.e., the Euclidean distance between their corners) is minimum over all such pairs. Then, $(b_i, r_j) \in E'$. We call u a *witness* vertex for the pair (b_i, r_j).

In the following, we show that H is planar (Lemma 7–11) and will then prove that H satisfies the local exchange property (Lemma 12). Then, by Theorem 6, our local search algorithm yields a PTAS for the problem on G. To distinguish between the edges of G and those of H, we refer to the edges of H as *arcs*. Let $b_i \in \mathcal{B}$ and $r_j \in \mathcal{R}$ such that $(b_i, r_j) \in E'$. We say that (b_i, r_j) is a *top arc* if there is a witness u for (b_i, r_j), such that *both* $\mathsf{L}(b_i)$ and $\mathsf{L}(r_j)$ intersect $\mathsf{L}(u)$ from left; choose one such u arbitrarily and denote $\mathsf{L}(u)$ by $\mathsf{w}(b_i, r_j)$. Otherwise, if there is a witness v for (b_i, r_j), such that *both* $\mathsf{L}(b_i)$ and $\mathsf{L}(r_j)$ intersect $\mathsf{L}(v)$ from below, (b_i, r_j) is a *down arc*; choose one such v arbitrarily and denote $\mathsf{L}(v)$ by $\mathsf{w}(b_i, r_j)$. Otherwise, for any witness w of (b_i, r_j), $\mathsf{L}(b_i)$ and $\mathsf{L}(r_j)$ intersect w from different sides; we call (b_i, r_j) a *mixed arc*, and choose one such w arbitrarily and denote $\mathsf{L}(w)$ by $\mathsf{w}(b_i, r_j)$.

Drawing of H. To draw H, we map u to $\mathtt{cor}(u)$ on the diagonal D for all $u \in \mathcal{B} \cup \mathcal{R}$. To draw the arcs of H, the idea is to draw each arc either above or below the diagonal depending on whether it is a top arc or a down arc, respectively. A mixed arc is drawn in such a way

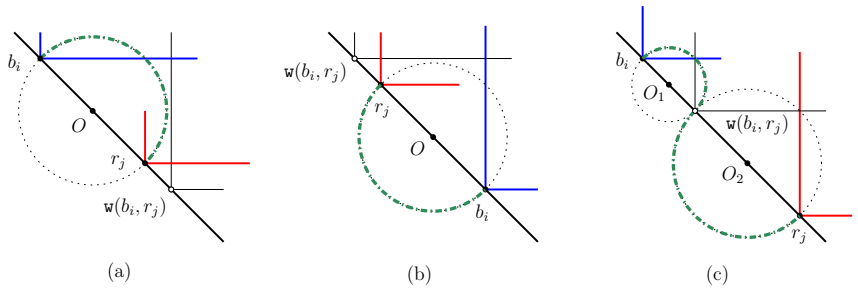

Figure 2 Drawing of (a) a top arc, (b) a down arc, and (c) a mixed arc.

that some part of the arc is drawn above and some part is drawn below the diagonal (and, hence crosses the diagonal). We next give the details of each case.

Let $b_i \in \mathcal{B}$ and $r_j \in \mathcal{R}$ such that $(b_i, r_j) \in E'$ and assume w.l.o.g. that $x(\mathtt{cor}(b_i)) < x(\mathtt{cor}(r_j))$. Moreover, let

$$O := \left(\frac{x(\mathtt{cor}(b_i)) + x(\mathtt{cor}(r_j))}{2}, \frac{y(\mathtt{cor}(b_i)) + y(\mathtt{cor}(r_j))}{2}\right),$$

and consider the circle C centred at O with radius $\mathtt{dist}(\mathtt{cor}(b_i), \mathtt{cor}(r_j))/2$. If the arc (b_i, r_j) is a top arc (resp., down arc), then we draw it on the half circle of C that lies above the diagonal D (resp., that lies below the diagonal D) starting from $\mathtt{cor}(b_i)$ and ending at $\mathtt{cor}(r_j)$; see Figure 2(a) – (b) for an illustration. A mixed arc is drawn in a slightly different way. For a mixed arc (b_i, r_j), assume w.l.o.g. that $\mathsf{L}(b_i)$ intersects $\mathtt{w}(b_i, r_j)$ from left while $\mathsf{L}(r_j)$ intersects $\mathtt{w}(b_i, r_j)$ from below. Notice that $x(\mathtt{cor}(b_i)) < x(\mathtt{cor}(\mathtt{w}(b_i, r_j))) < x(\mathtt{cor}(r_j))$. To draw (b_i, r_j), let

$$O_1 := \left(\frac{x(\mathtt{cor}(b_i)) + x(\mathtt{cor}(\mathtt{w}(b_i, r_j)))}{2}, \frac{y(\mathtt{cor}(b_i)) + y(\mathtt{cor}(\mathtt{w}(b_i, r_j)))}{2}\right),$$

$$O_2 := \left(\frac{x(\mathtt{cor}(\mathtt{w}(b_i, r_j))) + x(\mathtt{cor}(r_j))}{2}, \frac{y(\mathtt{cor}(\mathtt{w}(b_i, r_j))) + y(\mathtt{cor}(r_j))}{2}\right),$$
