Our main result is a polynomial time algorithm for the following problem. Given a matroid with uncertainty areas and a query cost function on its elements, find the set of elements of minimum total cost that we need to simultaneously query such that, no matter their revelation, the resulting instance admits a uniformly optimal base. We also provide combinatorial characterizations of all uniformly optimal bases, when one exists; and of all sets of queries that can be performed so that after revealing the corresponding weights the resulting instance admits a uniformly optimal base.

1 Introduction

We study fundamental combinatorial optimization problems on weighted structures where the numerical data is uncertain but it can be queried at a cost. We focus on the problem of finding a minimum weight base of a matroid under uncertainty, a problem that includes finding the smallest k elements of a list and the minimum spanning tree (MST) problem. In our setting, for every element e of the matroid we know a set $\mathcal{A}(e)$, called uncertainty area, of possible values that contains its real weight w_e. We can reveal this real weight by paying some query cost c_e. We assume that the queries are done in a non-adaptive way, or equivalently, that all the elements queried reveal their values at the same time. A set of elements F is a *feasible query* if for every possible revelation of the weights of F it is possible to compute a minimum weight base T of the resulting instance. The task of the *Minimum Cost Query Problem on Matroids* is to determine a minimum-cost feasible query.

(a) The empty set is feasible. **(b)** Only the full set is feasible. **(c)** Any 2-set is feasible.

Figure 1 Feasible queries.

To better illustrate this, consider the problem of computing an MST of a triangle graph in three possible situations as shown in Figure 1. In the first situation, the edges with areas $[0, 2]$ and $[1, 3]$ always form an MST, so we don't need to query any element. In this case we say that the matroid (the graph) admits a *uniformly optimal basis*, that is, a basis (a spanning tree) having minimum weight for every possible realization of the elements' weights. In the second situation, all edges have uncertainty area $[0, 1]$ and the only feasible query is the entire set of edges. For if we only query two edges, we could be in a situation where both have weight $1/2$. With that information we cannot compute an MST: if the unqueried edge e had weight 0, then e must be in the MST. However, if it had weight 1, then e cannot be in an MST. In the last situation, all uncertainty areas are finite: they have two elements $\{0, 1\}$. Here, every set of size two is feasible. Indeed, if both elements reveal a weight of 0, then they form an MST. Otherwise, the set obtained by deleting any edge with weight 1 is an MST.

Paper outline and results

In Section 2 we give formal definitions and show a simple but strong result: the uniformly optimal bases (UOB) of an uncertainty matroid form the bases of a second matroid. In Section 3 we extend the classic MST red and blue rules to uncertainty matroids, introducing the concept of *colored* elements, and study their properties. We then show that an uncertainty matroid admits a UOB if and only if all its elements are colored, and use this to give a combinatorial description of the matroid of uniformly optimal bases. We provide polynomial time algorithms for testing the existence of a UOB and for finding one if it exists. In Section 4 we study the minimum cost feasible query problem in detail. By using our coloring framework we construct a partition of the elements into groups that characterize minimal feasible queries. We show that every minimal feasible query set is formed by taking the first group (denoted as the core) completely and by deleting exactly one element from each other group. Our main result is an algorithm to find this partition that we use to fully solve the minimum cost feasible query problem on matroids. Unlike related work on the MST, the uncertainty areas in our setting can be arbitrary sets of real numbers, and not just intervals. Our algorithms only assume access to an independence oracle for the matroid, and a very mild type of access to the uncertainty areas. At the end of our study we show that the interval uncertainty area case is special, as there is a unique minimal size feasible query. We also relate the solutions for the MST with $\{0, 1\}$-areas case with the 2-connected components of the graph.

Related Work

Traditional research in optimization with uncertain data mostly focuses on finding solutions whose value is good, either in the worst case (robust optimization) or in some probabilistic sense (stochastic optimization), without gaining new information about the uncertain data. Our problem contributes to the *query model setting*, a different approach that has gained some strength in the last years. In this model one assumes that the algorithm can learn the

exact value of an uncertain input data by paying some query cost in order to solve a certain problem P (e.g., determining the MST of a graph). The aim is to minimize the cost of the queries while guaranteeing that an exact/approximate solution can be computed. Work in this area (see [3] for a survey) falls into three main categories:

Adaptive online. In this setting, the algorithm can query elements one by one, using the information revealed until a certain step to guide the decision of the next element to query. Even though algorithms for this version can be analyzed with a traditional worst-case approach (e.g., minimizing the depth of the decision tree associated to the algorithm's strategy), most of the work in this setting prefers to measure performance in terms of competitive analysis, comparing the number of queries an algorithm makes with the minimum number of queries that an adversary algorithm (that knows the real values beforehand) would make in order to verify that an answer is correct. Probably the first one to consider this model is Kahan [9] who provide optimal online algorithms to compute *all the elements* achieving the maximum, median and minimum gap of a list of closed intervals. Feder et al. [7] devise optimal online competitive algorithms to determine the numerical *value* of the median, and more generally, the K-th top element of the list within some prescribed tolerance. Bruce et al. [1] introduce a general method, called the *witness algorithm*, for adaptive online problems with open intervals and singletons uncertainty areas. They apply this method to geometric problems such as finding all maximum points in the plane from a family with uncertain coordinates. Erlebach et al. [5] studied the MST problem under two types of uncertainty, the edge uncertainty one (which is the same as ours) and the vertex uncertainty setting, in which the graph is complete, the vertices are points in the plane whose coordinates are uncertain, and the weight of an edge is the distance between its endpoints. They get 2 and 4 competitive algorithms, respectively, for both types of uncertainty, under open intervals and singletons areas, which is optimal for deterministic algorithms. The algorithm for edge uncertainty, denoted as U-RED, was later extended by Erlebach, Hoffmann and Kammer [4] to the minimum weight base problem on matroids achieving an optimal 2 competitive algorithm. Megow, Meißner and Skutella [13] show that by using randomization one can do better, lowering the competitive ratio down to $1 + 1/\sqrt{2}$. They also studied the non-uniform cost case. Gupta et al. [8] studied variants where queries return refined estimates of the areas, instead of a single value.

Verification. The verification problem is the one the offline adversary of the previous setting has to solve. That is, given both the uncertainty areas and a family of assumed real values, to determine the minimum number of queries one has to make so that, if the values obtained from the queries and the assumed values coincide, then no more queries are needed in order to obtain an optimal solution. Charalambous and Hoffman [2] show that the verification problem for maximal points in the plane is NP-hard for uncertainty areas of size at most 2. Erlebach and Hoffmann [3] show that the verification problem of MST with (open interval and singleton) uncertainty in the edges is in P, while that for vertex uncertainty is NP-hard.

Non-adaptive online. This setting encompasses our work and is sometimes called the *offline* problem. In it, an algorithm must determine a set F of queries to perform simultaneously, in order to have enough information to solve the problem. The only conceptual difference between the non-adaptive online problem and the verification one, is that in the latter, the algorithm can make use of the real values of the elements to guide the decision of which queries to perform, while in the former, that information is not available. Feder et al. [7] provide optimal algorithms for finding the K-th top element of a list up to additive tolerance.

Later, Feder et al. [6] consider the problem of finding the shortest s-t path on a DAG with closed-intervals uncertainty on the edges. They show that determining the length of the shortest s-t path within a given additive error is neither in NP nor in co-NP unless NP=co-NP, and provide exact algorithms for some special cases. To the best of our knowledge, the MST and, more generally, the matroid case have not been considered before this work.

Further related work. A common approach to deal with closed-interval uncertainty for a problem, without querying extra information, is to find a solution that minimizes the maximal regret, that is, the difference between the (real) weight of the chosen solution and the weight of the best solution that could have been picked had the true weights been known. Zero maximal regret bases and uniformly optimal bases of a matroid coincide. In the context of the MST problem, Yaman et al. [16] characterize trees with zero regret when they exists. In [10], Kaspersky and Zielinsky give a 2-approximation algorithm for the minmax regret problem on general matroids with interval data, and in [11] they give algorithms to find zero maximal regret bases. It is worth noting that all these results assume interval areas on the elements, while we allow for arbitrary uncertainty areas.

2 Preliminaries – Uniformly Optimal Bases

We assume familiarity with basic concepts in matroid theory such as bases, independent sets, span, circuit, cocircuits and duality, contraction, deletion and matroid connectivity. For an introduction and specific results, we refer to Oxley's book [14]. However, most of this paper can be understood by having the graphic matroid of a connected graph in mind. This is a matroid whose elements are the edges. The bases, independent sets, circuits and cocircuits, are the spanning trees, forests, cycles and minimal edge cut-sets, respectively. An element e is in the span (cospan) of a set F if there is a circuit (cocircuit) in $F \cup \{e\}$ containing e. We also use the standard notation $X + e$ and $X - e$ to denote $X \cup \{e\}$ and $X \setminus \{e\}$.

▶ **Definition 1** (Uncertainty Matroid). *An uncertainty matroid is a pair $(\mathcal{M}, \mathcal{A})$ where $\mathcal{M} = (E, \mathcal{I})$ is a matroid and $\mathcal{A}\colon E \to 2^{\mathbb{R}} \setminus \{\emptyset\}$ is a function mapping each element $e \in E$ in the ground set to a nonempty set $\mathcal{A}(e)$ of real numbers denoted the uncertainty area of e. We denote $\inf \mathcal{A}(e)$ by L_e and $\sup \mathcal{A}(e)$ by U_e.*

If $\mathcal{A}(e)$ is a singleton, we say that the element e is *certain*, otherwise, we say it is *uncertain*. If all the elements are certain, then we can identify $\mathcal{A}$ with the associated weight function $w\colon E \to \mathbb{R}$, such that $\mathcal{A}(e) = \{w_e\}$ so that $(\mathcal{M}, w)$ becomes a weighted matroid.

▶ Remark 2. For our algorithms, we assume access to matroid $\mathcal{M}$ via an independence oracle. We also need a very mild access to the uncertainty areas. More precisely, we assume that both L_e and U_e are known for every element, and that for every pair of (not necessarily distinct) elements e and f we can test if $(L_e, U_e) \cap \mathcal{A}(f)$ is empty in constant time. A polynomial time algorithm will, therefore, only use a polynomial number of calls to the independence oracle and to the uncertainty areas. Furthermore, for simplicity we will assume that all the infima and suprema L_e and U_e are finite. Otherwise we can apply a suitable strictly increasing function mapping the reals to a bounded set (such as arctan), and work in its image instead.

Intuitively, an uncertainty matroid models the situation in which we do not know the actual weight of every element e in the matroid, but we do know a set $\mathcal{A}(e)$ containing it. We can learn the actual weight of e by querying it. In this work we are concerned with non-adaptive (simultaneous) queries. The new uncertainty area function obtained after querying a subset of elements will be called a *revelation* of $\mathcal{A}$. The formal definition is below.

▶ **Definition 3** (Revelations and realizations). *Let $X \subseteq E$. A revelation of X in $(\mathcal{M}, \mathcal{A})$ is a function $\mathcal{B}\colon E \to 2^{\mathbb{R}} \setminus \{\emptyset\}$ such that:*

(i) *$\forall e \in X$, $\mathcal{B}(e) = \{b_e\} \subseteq \mathcal{A}(e)$ is a singleton, and*

(ii) *$\forall e \in E \setminus X$, $\mathcal{B}(e) = \mathcal{A}(e)$.*

In particular, $(\mathcal{M}, \mathcal{B})$ is also an uncertainty matroid. A realization *is a revelation of the entire ground set E. The collection of all revelations of X in $(\mathcal{M}, \mathcal{A})$ is denoted by $\mathcal{R}(X, \mathcal{A})$.*

Suppose we want to compute a minimum weight basis of a matroid, but we only know uncertainty areas for its elements. In certain situations (e.g., Figure 1 (a)), we can find sets that are optimal bases for every realization, we call them uniformly optimal bases.

▶ **Definition 4** (Uniformly optimal bases). *A set $T \subseteq E$ is a uniformly optimal basis of $(\mathcal{M}, \mathcal{A})$ (or simply, an $\mathcal{A}$-basis) if for every realization w, T is a minimum weight basis (a w-basis).*

Recall that a nonempty family of sets form the bases of a matroid if and only if they satisfy the strong basis exchange axiom. Our first basic result is the following:

▶ **Lemma 5.** *Let $\mathfrak{B}$ be the collection of all uniformly optimal bases of $(\mathcal{M}, \mathcal{A})$. Suppose $\mathfrak{B} \neq \emptyset$ and let T_1 and T_2 be two sets in $\mathfrak{B}$. If e is an element in $T_1 \setminus T_2$ then:*

(i) *e is certain, and*

(ii) *strong basis exchange holds, i.e., there is an element f in $T_2 \setminus T_1$ such that both $T_1 - e + f$ and $T_2 - f + e$ are in $\mathfrak{B}$.*

In particular, if $\mathfrak{B} \neq \emptyset$, then $\mathfrak{B}$ is the set of bases of a matroid, that we denote by $\mathtt{mat}(\mathcal{M}, \mathcal{A})$

Proof. Let $e \in T_1 \setminus T_2$. By strong basis exchange of $\mathcal{M}$, there is an element $f \in T_2 \setminus T_1$ such that both $T_1 - e + f$ and $T_2 + e - f$ are bases of $\mathcal{M}$. Assume first by contradiction that e is uncertain, then there is a realization $w \in \mathcal{R}(E, \mathcal{A})$ such that $w_e \neq w_f$. If $w_e > w_f$ then $w(T_1 - e + f) < w(T_1)$ contradicting the fact that T_1 is uniformly optimal. On the other hand, if $w_e < w_f$ then $w(T_2 + e - f) < w(T_2)$ contradicting that T_2 is uniformly optimal. We conclude not only that e is certain, but also that in every realization $w_f = w_e$. In particular, for every realization w, $w(T_1 - e + f) = w(T_1) = w(T_2) = w(T_2 - f + e)$, i.e. both $T_1 - e + f$ and $T_2 - f + e$ are uniformly optimal bases. ◀

3 Blue and red rules for uncertainty matroids

By Lemma 5, we conclude that if an uncertain element e is in some uniformly optimal basis then it is in *every* uniformly optimal basis. Our next task is to characterize the set of uncertain elements that are in every uniformly optimal basis. Now it is useful to remember the classic blue and red rules for computing an MST. An edge of a weighted graph is called blue if it is in at least one MST, and it is called red if it is outside at least one MST. Virtually every algorithm for the MST work in steps: if it detects a red edge from the current graph, it deletes it from the graph, and if it detects a blue edge then it adds it to the solution and contracts it. The following definitions extend the coloring notion to uncertainty matroids.

▶ **Definition 6** (Blue and red elements). *An element $e \in E$ is blue (resp. red) if for every realization $w \in \mathcal{R}(E, \mathcal{A})$ there exists a w-basis T such that $e \in T$ (resp. $e \notin T$). We say that e is colored if e is red or blue (or both at the same time), otherwise we say that e is uncolored.*

Note that e is blue (resp. red) on $(\mathcal{M}, \mathcal{A})$ if and only if e is blue (resp. red) on $(\mathcal{M}, w)$ for every realization $w \in \mathcal{R}(E, \mathcal{A})$. Standard matroid arguments show that for any such w, if an element e is any heaviest element of a circuit, then it avoids some w-basis (i.e., it is red on $(\mathcal{M}, w)$), and if it is the unique heaviest element, then it cannot be in a w-basis (i.e., it is

not blue on $(\mathcal{M}, w)$). Blue elements in graphs / matroids with interval uncertainty areas have been studied before under the name of strong edges [16] or necessarily optimal elements [11]. We start with a basic result on colored elements, they are preserved under revelations.

▶ **Lemma 7.** *Let $X \subseteq E$ and $\mathcal{B} \in \mathcal{R}(X, \mathcal{A})$. If e is blue (resp. red) in $(\mathcal{M}, \mathcal{A})$, then it is blue (resp. red) in $(\mathcal{M}, \mathcal{B})$.*

Proof. Suppose e is blue in $(\mathcal{M}, \mathcal{A})$ and consider any $w \in \mathcal{R}(E, \mathcal{B})$. Since $\mathcal{R}(E, \mathcal{B}) \subseteq \mathcal{R}(E, \mathcal{A})$ we get that there exists some w-basis T such that $e \in T$, implying that e is blue in $(\mathcal{M}, \mathcal{B})$. The proof works analogously if e is red in $(\mathcal{M}, \mathcal{A})$. ◀

We can characterize blue and red elements of an uncertainty matroid using its span and cospan functions[2] of a set X in the matroid $\mathcal{M}$ (resp., in the dual matroid $\mathcal{M}^*$). The span and cospan of a set can be computed using a polynomial number of calls to the independence oracle.

▶ **Lemma 8.** *Let $F(e) = \{f \in E - e : L_f < U_e\}$ and $F^*(e) = \{f \in E - e : L_e < U_f\}$.*
(i) *$e \in E$ is blue if and only if $e \notin \operatorname{span} F(e)$.*
(ii) *$e \in E$ is red if and only if $e \notin \operatorname{cospan} F^*(e)$.*
In particular, we can test in polynomial time if any element is blue, red, both or none.

▶ Remark 9. Proofs involving blue and red elements follow the same main ideas. Most of the time we only consider the blue case, since the red case follows by *duality arguments*. More precisely, consider the dual matroid $\mathcal{M}^*$ with inverted uncertainty area function $-\mathcal{A}(e) = \{-x \colon x \in \mathcal{A}(e)\}$. Since the bases of $\mathcal{M}^*$ are complements of the bases of $\mathcal{M}$ we also get that the uniformly optimal bases of $(\mathcal{M}, \mathcal{A})$ are the complements of those in $(\mathcal{M}^*, -\mathcal{A})$, that the red elements in $(\mathcal{M}, \mathcal{A})$ are the blue elements of $(\mathcal{M}^*, -\mathcal{A})$ and vice versa.

Proof of Lemma 8. We only prove (i), since (ii) follows by duality arguments using that $F^*(e)$ is the analogue of $F(e)$ for $(\mathcal{M}^*, -\mathcal{A})$.

Let e be a blue element and let $K = \min_{f \in F(e)} (U_e - L_f) > 0$. For each $f \in E - e$ choose $\varepsilon_f \in [0, K/2)$ such that $L_f + \varepsilon_f \in \mathcal{A}(f)$. In a similar way, choose $\varepsilon_e \in [0, K/2)$ such that $U_e - \varepsilon_e \in \mathcal{A}(e)$. Consider the realization $w \in \mathcal{R}(E, \mathcal{A})$ given by $w_f = \begin{cases} U_e - \varepsilon_e & \text{if } f = e, \\ L_f + \varepsilon_f & \text{if } f \neq e. \end{cases}$

By construction, for every $f \in F(e)$, $w_f < w_e$. Suppose now that $e \in \operatorname{span} F(e)$. Then, there exists a circuit $C \subseteq F(e) + e$ such that e is the unique heaviest (with respect to w) element of C. This implies that e is outside every w-basis, which contradicts that e was blue.

Now let e be an element outside $\operatorname{span} F(e)$ and suppose that e is not blue. Then, there exists a realization $w \in \mathcal{R}(E, \mathcal{A})$ such that e is not in any w-basis. Choose T to be any w-basis and let C be the fundamental circuit[3] of $T + e$. As $e \notin \operatorname{span} F(e)$ we have that $C - e \not\subseteq F(e)$. Select any $f \in (C - e) \setminus F(e)$, then: $w_f \geq L_f \geq U_e \geq w_e$. We conclude that $T - f + e$ is a w-basis that contains e, which is a contradiction. ◀

Even though certain elements can be blue and red at the same time (e.g., in a circuit in which every element has the same weight every element has both colors), this is not possible for uncertain ones as shown by the next lemma whose proof is deferred to the full version.

---

[2] We recall that $\operatorname{span}(X)$ for $X \subseteq E$ is the unique maximal set $U \supseteq X$ with the same rank as X and $\operatorname{cospan}(X)$ is its span in the dual matroid. The span and cospan of a set in a matroid are related by the expression $\operatorname{cospan}(X) = X \cup \{e \in E : e \notin \operatorname{span}[(E - e) \setminus X]\}$

[3] Recall that if T is a basis and e an element, the fundamental circuit C of $T + e$ is the only circuit of $T + e$. For any $f \in C$, $T - f + e$ is a basis.

▶ **Lemma 10.** *If e is red and blue, then e is certain.*

The definition of blue and red will be useful even if e is certain, or if the uncertainty matroid has no uniformly optimal basis. The following lemma, whose proof is in the full version, highlights the utility of this definition.

▶ **Lemma 11.** *Let $(\mathcal{M}, \mathcal{A})$ be an uncertainty matroid such that an $\mathcal{A}$-basis exists.*

(i) *If e is blue (resp. red) then there exists an $\mathcal{A}$-basis T such that $e \in T$ (resp. $e \notin T$).*

(ii) *Let e be an uncertain element. Then e is blue (resp. red) if and only if e is inside (resp. outside) every $\mathcal{A}$-basis.*

The previous lemma shows that if the set of uniformly optimal bases is nonempty then all uncertain elements are colored either red or blue. Furthermore the uncertain elements contained in every $\mathcal{A}$-basis are exactly the blue uncertain elements. The next theorem, which is the main result of this section, shows that a converse also holds.

▶ **Theorem 12.** *An $\mathcal{A}$-basis exists if and only if every uncertain element is colored.*

In order to prove this theorem we need the following simple lemmas, whose proofs are deferred to the full version. Basically, they show that contracting blue elements and/or deleting red elements preserves structure and colors.

▶ **Lemma 13.** *Let $e \in E$ be a colored element (certain or uncertain).*

(i) *If e is blue: T is an $(\mathcal{M}/e, \mathcal{A}|_{E-e})$-basis if and only if $T + e$ is an $(\mathcal{M}, \mathcal{A})$-basis.*

(ii) *If e is red: T is an $(\mathcal{M} \setminus e, \mathcal{A}|_{E-e})$-basis if and only if T is an $(\mathcal{M}, \mathcal{A})$-basis.*

▶ **Lemma 14.** *Let $e \in E$ be a colored uncertain element, and $f \in E - e$.*

(i) *Suppose e is blue. If f is blue (resp. red) in $(\mathcal{M}, \mathcal{A})$, then f is blue (resp. red) in $(\mathcal{M}/e, \mathcal{A}|_{E-e})$.*

(ii) *Suppose e is red. If f is blue (resp. red) in $(\mathcal{M}, \mathcal{A})$, then f is blue (resp. red) in $(\mathcal{M} \setminus e, \mathcal{A}|_{E-e})$.*

Proof of Theorem 12. We only need to prove the converse and we proceed by induction on the number of uncertain elements k. If $k = 0$ an $\mathcal{A}$-basis is simply a basis of minimum weight, which clearly exists. Suppose that $k > 0$, and let $e \in E$ be any uncertain element. If e is blue, we have that every uncertain element of $E - e$ is colored in $(\mathcal{M}/e, \mathcal{A}|_{E-e})$, as colors were preserved. By inductive hypothesis, we have an $(\mathcal{M}/e, \mathcal{A}|_{E-e})$-basis T and by Lemma 13 we have that $T + e$ is an $(\mathcal{M}, \mathcal{A})$-basis. If e is red, one can proceed similarly but deleting instead. ◀

▶ Remark 15. The previous theorem gives an algorithmic way to test if $(\mathcal{M}, \mathcal{A})$ admits an $\mathcal{A}$-basis: we simply check if every element is colored, using Lemma 8. Let us now consider the problem of finding one such base. It is worth noting that algorithms for this task are available for closed interval and open interval uncertainty areas. For closed interval uncertainty areas, one can find an $\mathcal{A}$-basis by using Kaspersky and Zielinsky's approach [10] for finding a zero maximal regret basis. For open intervals (or singletons), one can simply run the 2-competitive U-RED algorithm by Erlebach, Hoffmann and Kammer [4] for the online adaptive variant: if this algorithm does not perform any query, then it outputs a uniformly optimal basis. Otherwise, the algorithm finds a witness set, i.e., a set for which at least one element must be queried in order to find a solution. In what follows we provide a new algorithm that finds $\mathcal{A}$-bases for arbitrary uncertainty areas (not just intervals).

If uniformly optimal bases exist, then the elements are partitioned into blue uncertain, red uncertain and certain elements. After contraction of the set B of all blue uncertain elements and deletion of the set R of all red uncertain elements, we are left with a matroid that only has certain elements, we call such weighted matroid the *certain weighted matroid* $(\mathcal{M}^c, w^c)$, where $\mathcal{M}^c = \mathcal{M}/B \setminus R$, and $w^c = \mathcal{A}|_{E\setminus(R\cup B)}$. The following theorem shows that every uniformly optimal basis arises by extending some optimal basis on the certain weighted matroid.

▶ **Theorem 16.** *Let $(\mathcal{M}, \mathcal{A})$ be an uncertainty matroid for which an $\mathcal{A}$-basis exists and $(\mathcal{M}^c, w^c)$ its certain weighted matroid. Then T is an $\mathcal{A}$-basis if and only if:*

(i) *T contains every blue uncertain element,*
(ii) *T avoids each red uncertain element, and*
(iii) *The certain elements of T form a minimum weight basis of $(\mathcal{M}^c, w^c)$.*

Proof. $\mathcal{A}$-bases always contain every blue uncertain element and avoid each red uncertain element by Lemma 11. By Lemma 14, we can delete each red uncertain element while preserving colors. More so, from Lemma 13 we conclude that T is uniformly optimal after these deletions. A similar argument allows us to now contract each blue uncertain element while preserving colors in each contraction. We are only left with the certain elements of T and by Lemma 13 we conclude they form a minimum weight basis of $(\mathcal{M}^c, w^c)$.

We show the converse by induction on the number of uncertain elements k of E. If $k = 0$, using (iii) we get that T is a minimum weight basis of $(\mathcal{M}^c, w^c)$. Noting that $\mathcal{M} = \mathcal{M}^c$ and $\mathcal{A} = w^c$ we conclude that T is an $(\mathcal{M}, \mathcal{A})$-basis.

If $k > 0$ select any uncertain element $e \in E$. If e is blue, we have from (i) that $e \in T$. As colors are preserved when contracting e, it follows by inductive hypothesis that $T - e$ is an $(\mathcal{M}/e, \mathcal{A}|_{E-e})$-basis, and using Lemma 13 we conclude that T is an $(\mathcal{M}, \mathcal{A})$-basis. If e is red, then $e \notin T$ by (ii). We now proceed as before but deleting e instead. ◀

Theorems 12 and 16 allow for algorithmic implementation. We can decide if an $\mathcal{A}$-basis exists by checking if all elements are colored. If every element is colored, we contract every blue uncertain element, delete each red uncertain element, compute a minimum weight basis of the certain weighted matroid and output the optimal certain basis along with every blue uncertain element. We summarize this result and discuss it in more detail in the full version. We also use the previous theorem to characterize the matroid $\mathtt{mat}(\mathcal{M}, \mathcal{A})$.

▶ **Corollary 17.** *There is an algorithm that finds an $\mathcal{A}$-basis or decides that none exists in polynomial time.*

▶ **Corollary 18.** *If $(\mathcal{M}, \mathcal{A})$ admits an $\mathcal{A}$-basis, then the matroid $\mathtt{mat}(\mathcal{M}, \mathcal{A})$ of all $\mathcal{A}$-bases is a sum of minors of $\mathcal{M}$. In particular, if $\mathcal{M}$ belongs to some minor closed class of matroids (e.g., graphic, linear, gammoid) then so does $\mathtt{mat}(\mathcal{M}, \mathcal{A})$.*

4 Feasible Queries

▶ **Definition 19.** *A set $F \subseteq E$ is a feasible query (or simply feasible) if no matter its revelation it guarantees the existence of a uniformly optimal basis. That is, $\forall \mathcal{B} \in \mathcal{R}(F, \mathcal{A})$ there exists some $\mathcal{B}$-basis.*

Any superset of a feasible query is also feasible. Using this, one can show that feasible sets for a given uncertainty area function are also feasible for any revelation of a subset.

▶ **Lemma 20.** *Let $F \subseteq E$ be feasible in $(\mathcal{M}, \mathcal{A})$ and $X \subseteq E$. If $\mathcal{B} \in \mathcal{R}(X, \mathcal{A})$, then F is feasible for $(\mathcal{M}, \mathcal{B})$.*

Proof. Since F is feasible in $(\mathcal{M}, \mathcal{A})$, so is $X \cup F$. Consider any revelation $\mathcal{B}' \in \mathcal{R}(X, \mathcal{B})$. Since $\mathcal{B}' \in \mathcal{R}(X \cup F, \mathcal{A})$ and $X \cup F$ is feasible, we conclude that there exists a $\mathcal{B}'$-basis. ◀

Since revealing elements that are certain does not yield extra information, we also get that all minimal (for inclusion) queries only contain uncertain elements. A simple, yet strong result is that it never pays off to query a colored element. Due to space consideration, we defer the proof of the next lemma to the full version.

▶ **Lemma 21.** *Let $X \subseteq E$ a feasible query. If $e \in X$ is colored, then $X - e$ is a feasible query. In particular, if X is a feasible query minimal for inclusion then X consists only of uncertain uncolored elements.*

An exciting application of this lemma is that the set of all uncolored uncertain elements is always a feasible query set. To see this, start with all the uncertain elements (which are a feasible query) and repeatedly remove colored elements while applying Lemma 21.

By Theorem 12, a set F is feasible only if after its revelation all uncertain elements are colored. So, consider any uncertain element e before any revelation. Intuitively, its color depends on the possible relative position between its real weight w_e and the real weight of elements that could potentially span it (or cospan it). In particular, it is not hard too see that the *color* of e is unaffected if we reveal an element f whose uncertainty area is too low (say $U_f \leq L_e$), because the real value of f will be in every case at most that of e. A similar situation happens if the uncertainty area is too high (say $U_e \leq L_f$). A complicated thing occurs if $\mathcal{A}(f)$ intersects (L_e, U_e), because after revealing f we may still don't know the relative positions of w_e and w_f until we reveal e. Finally, if f is in none of the previous situation, then after revealing it we will know for sure the relative position of w_e, w_f even without revealing e. The previous discussion motivates the following definitions.

▶ **Definition 22.** *For each $e \in E$ define the sets $\mathtt{low}(e)$, $\mathtt{mid}(e)$, $\mathtt{high}(e)$ and $\mathtt{both}(e)$ by:*

$$\mathtt{low}(e) = \{f \in E - e : U_f \leq L_e\}, \qquad \mathtt{high}(e) = \{f \in E - e : U_e \leq L_f\},$$
$$\mathtt{mid}(e) = \{f \in E - e : \mathcal{A}(f) \cap (L_e, U_e) \neq \emptyset\},$$
$$\mathtt{both}(e) = \{f \in E \setminus \mathtt{mid}(e) - e : \mathcal{A}(f) \cap (-\infty, L_e] \neq \emptyset \ \wedge \ \mathcal{A}(f) \cap [U_e, \infty) \neq \emptyset\}.$$

Note that that for $e \in E$, $F(e) = (E - e) \setminus \mathtt{high}(e)$ and $F^*(e) = (E - e) \setminus \mathtt{low}(e)$. Furthermore if e is uncertain (i.e., $L_e < U_e$) then $E - e$ is partitioned into the sets $\mathtt{low}(e), \mathtt{high}(e), \mathtt{mid}(e)$ and $\mathtt{both}(e)$.

▶ **Definition 23.** *For each $e \in E$ denote $\mathcal{M}/\mathtt{low}(e) \setminus \mathtt{high}(e)$ by $\mathcal{M}'_e$*

▶ Remark 24. In this section we talk about different revelations simultaneously (for instance, $\mathcal{A}$ and $\mathcal{B}$). We differentiate the objects that arise this way by using superscript denoting these dependencies. For example $F^{\mathcal{A}}(e)$ denotes $F(e)$ with respect to the areas given by $\mathcal{A}$.

The next technical lemma formalizes the idea that the elements that influence the color of an uncertain element e are those in $\mathtt{mid}(e)$ and those in $\mathtt{both}(e)$ that are not queried.

▶ **Lemma 25.** *Let $X \subseteq E$ and $\mathcal{B} \in \mathcal{R}(E \setminus X, \mathcal{A})$ a revelation of its complement. If $e \in X$ is uncertain and uncolored in $\mathcal{B}$, then there exists a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $(C - e) \cap [\mathtt{mid}^{\mathcal{A}}(e) \cup (X \cap \mathtt{both}^{\mathcal{A}}(e))] \neq \emptyset$.*

Proof. Consider the revelation $\widetilde{\mathcal{B}} \in \mathcal{R}(\texttt{both}(e) \setminus X, \mathcal{A})$ such that $\widetilde{\mathcal{B}}(f) = \mathcal{B}(f) (= \{B_f\})$ if $f \in \texttt{both}(e) \setminus X$ and $\widetilde{\mathcal{B}}(f) = \mathcal{A}(f)$ otherwise and note that $\mathcal{B} \in \mathcal{R}(E \setminus X, \widetilde{\mathcal{B}})$. By Lemma 7, since e is uncolored in $(\mathcal{M}, \mathcal{B})$, we get that e is also uncolored in $(\mathcal{M}, \widetilde{\mathcal{B}})$. Define the auxiliary sets $Y = \{f \in \texttt{both}^{\mathcal{A}}(e) \setminus X : B_f \leq L_e\}$ and $\overline{Y} = \{f \in \texttt{both}^{\mathcal{A}}(e) \setminus X : B_f > L_e\}$. Note that $\texttt{low}^{\widetilde{\mathcal{B}}}(e) = \texttt{low}^{\mathcal{A}}(e) \cup Y; \texttt{high}^{\widetilde{\mathcal{B}}}(e) = \texttt{high}^{\mathcal{A}}(e) \cup \overline{Y}; \texttt{mid}^{\widetilde{\mathcal{B}}}(e) = \texttt{mid}^{\mathcal{A}}(e)$; and $\texttt{both}^{\widetilde{\mathcal{B}}}(e) = X \cap \texttt{both}^{\mathcal{A}}(e)$. Since e is uncertain and it is not blue nor red in $(\mathcal{M}, \widetilde{B})$ we get: $e \in \text{span}[\texttt{low}^{\widetilde{\mathcal{B}}}(e) \cup \texttt{mid}^{\widetilde{\mathcal{B}}}(e) \cup \texttt{both}^{\widetilde{\mathcal{B}}}(e)] = \text{span}[\texttt{low}^{\mathcal{A}}(e) \cup \texttt{mid}^{\mathcal{A}}(e) \cup Y \cup (X \cap \texttt{both}^{\mathcal{A}}(e))]$, and $e \in \text{cospan}[\texttt{high}^{\widetilde{\mathcal{B}}}(e) \cup \texttt{mid}^{\widetilde{\mathcal{B}}}(e) \cup \texttt{both}^{\widetilde{\mathcal{B}}}(e)] = \text{cospan}[\texttt{high}^{\mathcal{A}}(e) \cup \texttt{mid}^{\mathcal{A}}(e) \cup \overline{Y} \cup (X \cap \texttt{both}^{\mathcal{A}}(e))]$. Using that $e \in \text{cospan}[Q]$ implies $e \notin \text{span}[(E - e) \setminus Q]$ for any $Q \subseteq E$, we conclude:

$$e \in \text{span}[\texttt{low}^{\mathcal{A}}(e) \cup \texttt{mid}^{\mathcal{A}}(e) \cup Y \cup (X \cap \texttt{both}^{\mathcal{A}}(e))] \setminus \text{span}[\texttt{low}^{\mathcal{A}}(e) \cup Y]. \tag{1}$$

From (1), $e \in \text{span}[\texttt{low}^{\mathcal{A}}(e) \cup \texttt{mid}^{\mathcal{A}}(e) \cup Y \cup (X \cap \texttt{both}^{\mathcal{A}}(e))] \setminus \texttt{low}^{\mathcal{A}}(e) = \text{span}_{M'_e}[\texttt{mid}^{\mathcal{A}}(e) \cup Y \cup (X \cap \texttt{both}^{\mathcal{A}}(e))]$, where the equality follows from properties of contraction and deletion. Therefore there is a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $C - e \subseteq \texttt{mid}^{\mathcal{A}}(e) \cup Y \cup X \cap \texttt{both}^{\mathcal{A}}(e)$. If $(C - e) \cap [\texttt{mid}^{\mathcal{A}}(e) \cup (X \cap \texttt{both}^{\mathcal{A}}(e))] = \emptyset$, we would have that $C - e \subseteq Y$, implying that $e \in \text{span}_{\mathcal{M}'_e} Y = \text{span}[\texttt{low}^{\mathcal{A}}(e) \cup Y] \setminus \texttt{low}^{\mathcal{A}}(e)$ which contradicts (1). ◀

The previous lemma is useful to characterize the sets that intersect every feasible set.

▶ **Definition 26.** *A set $X \subseteq E$ is a witness set if it intersects every feasible set.*

Witness sets have been studied before in the context of online adaptive algorithms for MST and matroids. Since the definition of feasible is slightly different in that settings (they are feasible for the verification problem, in which one knows the real values a priori), these witness sets are also different from ours.

▶ **Lemma 27.** *Let $X \subseteq E$. The following statements are equivalent:*

(i) *X is a witness set.*

(ii) *There exists an uncertain element $e \in X$ and a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $C \cap [\texttt{mid}(e) \cup (X \cap \texttt{both}(e))] \neq \emptyset$.*

Proof. Let X be a witness set. Since $E \setminus X$ isn't feasible there is a revelation $\mathcal{B} \in \mathcal{R}(E \setminus X, \mathcal{A})$ such that there is no $(\mathcal{M}, \mathcal{B})$-basis and by Theorem 12 we must have an element e that is uncertain and uncolored in $(\mathcal{M}, \mathcal{B})$. Note that $e \in X$ as every element in $E \setminus X$ is certain in $(\mathcal{M}, \mathcal{B})$. We conclude by using Lemma 25 on e.

For the converse, set $Y = [\texttt{both}(e) \setminus X] \cap C$, $\overline{Y} = [\texttt{both}(e) \setminus X] \setminus C$ and note that $e \in \text{span}_{\mathcal{M}'_e}(C - e) = \text{span}_{\mathcal{M}'_e}[(C \cap \texttt{mid}(e)) \cup (C \cap (\texttt{both}(e) \setminus X)) \cup (C \cap \texttt{both}(e) \cap X)] \subseteq \text{span}_{\mathcal{M}'_e}[\texttt{mid}(e) \cup Y \cup (X \cap \texttt{both}(e))]$.

If $e \in \text{span}_{\mathcal{M}'_e}(Y)$ there would be a circuit D in $\mathcal{M}'_e$ such that $D - e \subseteq Y \subseteq C$, but since $C \cap [\texttt{mid}(e) \cup (X \cap \texttt{both}(e))] \neq \emptyset$ we get $D \subsetneq C$ which contradicts the minimality of C as circuit. Then, $e \in \text{span}_{\mathcal{M}'_e}[\texttt{mid}(e) \cup Y \cup (X \cap \texttt{both}(e))] \setminus \text{span}_{\mathcal{M}'_e} Y$, which is included in $\text{span}[\texttt{low}(e) \cup \texttt{mid}(e) \cup Y \cup (X \cap \texttt{both}(e))] \setminus \text{span}[\texttt{low}(e) \cup Y]$.

As $e \notin \texttt{high}(e) \cup \texttt{mid}(e) \cup \overline{Y} \cup (X \cap \texttt{both}(e))$ we conclude that $e \in \text{span}[\texttt{low}(e) \cup \texttt{mid}(e) \cup Y \cup (X \cap \texttt{both}(e))]$ and $e \in \text{cospan}[\texttt{high}(e) \cup \texttt{mid}(e) \cup \overline{Y} \cup (X \cap \texttt{both}(e))]$.

Choose two revelations $w^+, w^- \in \mathcal{R}(E, \mathcal{A})$ as follows:

$$w_f^+ \in \begin{cases} (L_e, U_e) \cap \mathcal{A}(f) & \text{if } f \in \texttt{mid}(e), \\ (-\infty, L_e] \cap \mathcal{A}(f) & \text{if } f \in Y \text{ or} \\ & f \in X \cap \texttt{both}(e), \\ [U_e, \infty) \cap \mathcal{A}(f) & \text{if } f \in \overline{Y}, \\ \mathcal{A}(e) \cap (L_e, U_e] & \text{if } f = e. \end{cases} \qquad w_f^- \in \begin{cases} [U_e, \infty) \cap \mathcal{A}(f) & \text{if } f \in X \cap \texttt{both}(e), \\ \mathcal{A}(e) \cap [L_e, U_e) & \text{if } f = e, \\ \{w_f^+\} & \text{otherwise.} \end{cases}$$

Note that w^+ and w^- only differ on $X \cap \texttt{both}(e)$ and e. As $e \in \text{span}[\texttt{low}(e) \cup \texttt{mid}(e) \cup Y \cup (X \cap \texttt{both}(e))]$ it is the unique heaviest element in a circuit in $(\mathcal{M}, w^+)$, therefore it is in no $(\mathcal{M}, w^+)$-basis. Similarly, since $e \in \text{cospan}[\texttt{high}(e) \cup \texttt{mid}(e) \cup \overline{Y} \cup (X \cap \texttt{both}(e))]$ it is the unique lightest element in a cocircuit in $(\mathcal{M}, w^-)$, hence it is in every $(\mathcal{M}, w^-)$-basis. To conclude suppose that there is a feasible query set F such that $X \cap F = \emptyset$, we then pick the revelation $\mathcal{B} \in \mathcal{R}(F, \mathcal{A})$ such that $\mathcal{B}(f) = \{w^+_f\} = \{w^-_f\}$ if $f \in F$, and $\mathcal{B}(f) = \mathcal{A}(f)$ otherwise.

Select any $\mathcal{B}$-basis T. As $w^+, w^- \in \mathcal{R}(E, \mathcal{B})$, T is both a w^+-basis and a w^--basis. By the previous paragraph, this implies that $e \notin T$ and $e \in T$ which is a contradiction. ◀

▶ **Lemma 28.** *The minimal feasible queries are the sets intersecting every witness set.*

Proof. Recall that a *clutter* is a family of sets such that no one is contained in another. The *blocker* of a clutter is the clutter of all minimal sets that intersect the first one. Thus, the minimal witness sets are the blocker of the minimal feasible queries. A basic result in packing and covering theory (see e.g., [15, Theorem 77.1]) states that the blocker of the blocker of a clutter is again the original clutter. The lemma follows from this fact. ◀

As we see below, minimal witness sets cannot be large: they can have at most 2 elements.

▶ **Corollary 29.** *Let X be a witness set such that $|X| \geq 2$. Then, there exists distinct $e, f \in X$ such that $\{e, f\}$ is a witness set.*

Proof. If $X \cap F \neq \emptyset$ for every feasible query set F then, by Lemma 27, there exists an uncertain $e \in X$, a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $C \cap [\texttt{mid}(e) \cup (X \cap \texttt{both}(e))] \neq \emptyset$.

If $C \cap (X \cap \texttt{both}(e)) = \emptyset$, then $C \cap \texttt{mid}(e) \neq \emptyset$ and by Lemma 27 we have that $\{e\} \cap F \neq \emptyset$ for every F feasible query set. Picking any $f \in X - e$ we conclude that $\{e, f\} \cap F \neq \emptyset$ for every feasible query set F. If $C \cap (X \cap \texttt{both}(e)) \neq \emptyset$, select any $g \in C \cap (X \cap \texttt{both}(e))$. Once again, Lemma 27 lets us conclude that $\{e, g\} \cap F \neq \emptyset$ for every F feasible query set. ◀

▶ **Definition 30.** *Let $\texttt{core} = \{e \in E \colon \{e\}$ is a witness set$\}$ and $\overline{\texttt{core}} = E \setminus \texttt{core}$. Define the graph $G^{wit} = (\overline{\texttt{core}}, E^{wit})$ where $ef \in E^{wit}$ if $\{e, f\}$ is a witness set.*

By Lemma 28, minimal feasible sets are exactly those sets containing all elements in `core` together with a vertex cover of G^{wit}. The following clean characterization of `core` follows directly from Lemma 27.

▶ **Lemma 31.** *Let e be an uncertain element. $e \in \texttt{core}$ if and only if there is a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $C \cap \texttt{mid}(e) \neq \emptyset$.*

We can turn the previous lemma into an algorithm that computes `core`. In order to do this we compute the connected component[4] of $\mathcal{M}'_e$ that contains e and check if it has non-empty intersection with $\texttt{mid}(e)$. We compute connected components with an algorithm due to Krogdhal [12] that takes polynomial time. Therefore, the previous procedure also takes polynomial time. In what follows we show that G^{wit} has a very nice structure.

▶ **Lemma 32.**

(i) *Let $e, f \in \overline{\texttt{core}}$ distinct. $ef \in E^{wit}$ if and only if $\mathcal{A}(e) = \mathcal{A}(f) = \{L_e, U_e\}$ with $L_e < U_e$ and there is a circuit C of $\mathcal{M}'_e$ such that $e, f \in C$.*

(ii) *The connected components of the graph G^{wit} are cliques.*

[4] Recall that e is connected to f in a matroid if and only if there is a circuit that contains e and f. A connected component is an equivalence class of this equivalence relation (see, eg. [14, Section 4.1]).

Proof.

(i) Suppose $ef \in E^{\text{wit}}$. Since $\{e, f\}$ is a witness set, $E \setminus \{e, f\}$ is not feasible. Let $\mathcal{B} \in \mathcal{R}(E \setminus \{e, f\}, \mathcal{A})$ be a revelation without $\mathcal{B}$-basis. Since $f \notin \texttt{core}$, we have that $E - f$ is feasible in $(\mathcal{M}, \mathcal{A})$ and by Lemma 20 it is also feasible in $(\mathcal{M}, \mathcal{B})$. If e was colored in $(\mathcal{M}, \mathcal{B})$ then, by Lemma 21 we would conclude that $(E - f) - e = E \setminus \{e, f\}$ is feasible in $(\mathcal{M}, \mathcal{B})$. But all elements in $E \setminus \{e, f\}$ are already certain in $(\mathcal{M}, \mathcal{B})$, from which we deduce that $\emptyset$ is feasible in $(\mathcal{M}, \mathcal{B})$, which is a contradiction.
We conclude that e is uncolored in $(\mathcal{M}, \mathcal{B})$. From this, we can use Lemma 25 to obtain a circuit C in $\mathcal{M}'_e$ such that $e \in C$ and $C \cap [\texttt{mid}^{\mathcal{A}}(e) \cup (\{e, f\} \cap \texttt{both}^{\mathcal{A}}(e))] \neq \emptyset$. Since $e \notin \texttt{core}$, we have by Lemma 31 that $C \cap \texttt{mid}(e) = \emptyset$. Then $C \cap \{e, f\} \cap \texttt{both}(e) \neq \emptyset$, consequently $e, f \in C$ and $f \in \texttt{both}(e)$. We can now use the same argument for f, concluding that $e \in \texttt{both}(f)$. The only way for $e \in \texttt{both}(f)$ and $f \in \texttt{both}(e)$ to occur at the same time is that $\mathcal{A}(e) = \mathcal{A}(f) = \{L_e, U_e\}$. Finally, since witness sets do not contain elements that are certain (this follows since minimal feasible sets only have uncertain elements, hence by removing certain elements from a witness set it would still intersect every feasible set) we must have $L_e < U_e$.
We now prove the converse. As e is an uncertain element such that there is a circuit C in $\mathcal{M}'_e$ and $f \in C \cap \{e, f\} \cap \texttt{both}(e)$ by Lemma 27 we conclude that $ef \in E^{\text{wit}}$.

(ii) We only need to show that whenever $ef, fg \in E^{\text{wit}}$ we also have $eg \in E^{\text{wit}}$. Suppose that $ef, fg \in E^{\text{wit}}$. By the previous item we have $\mathcal{A}(e) = \mathcal{A}(f) = \mathcal{A}(g) = \{L_e, U_e\}$, in particular $\mathcal{M}'_e = \mathcal{M}'_f = \mathcal{M}'_g \doteq \mathcal{M}'$. The previous item also allows us to conclude that there are two circuits C^1, C^2 in $\mathcal{M}'$ such that $e, f \in C^1$ and $f, g \in C^2$. Then e, f and g are in the same matroid connected component in $\mathcal{M}'$. Therefore there is a circuit C^3 in $\mathcal{M}'$ such that $e, g \in C^3$ and using the previous item we conclude that $eg \in E^{\text{wit}}$. ◀

We can test if $ef \in E^{\text{wit}}$ similarly to how we computed $\texttt{core}$: we start by considering elements with areas of size two (by checking if $(L_e, U_e) \cap \mathcal{A}(e) = \emptyset$ for every element e). If e and f have the same two-element uncertainty area, we check if they belong to the same connected component in $\mathcal{M}'_e = \mathcal{M}'_f$ using Krogdhal's algorithm [12].

▶ **Theorem 33.** *$X \subseteq E$ is a minimal feasible query if and only if $\texttt{core} \subseteq X$ and X intersects all but one element in each connected component of G^{wit}.*

Proof. By Lemma 28 and the definition of G^{wit} the minimal feasible queries X satisfies that $\texttt{core} \subseteq X$ and $X \cap \overline{\texttt{core}}$ is a minimal vertex cover of G^{wit}. Since every connected component is a clique, the minimal vertex covers of G^{wit} are exactly those sets containing all but one element in each connected component. ◀

▶ **Corollary 34.** *Let $c : E \to \mathbb{R}$ be any cost function. We can compute a minimum-cost feasible query in polynomial time.*

Proof. Computing $\texttt{core}$ and G^{wit} can be done in polynomial time and polynomial number of calls to the independence oracle of $\mathcal{M}$ or to minors of $\mathcal{M}$ (for example, $\mathcal{M}'_e$), since the oracle of independence of any minor of $\mathcal{M}$ can also be implemented using a polynomial number of calls to the oracle of $\mathcal{M}$. One can compute a minimum-cost minimal size feasible query F by simply returning a set containing $\texttt{core}$ and all but the most expensive element from each connected component of G^{wit}. If we allow negative costs, then the minimum-cost feasible query is F together with all the negative cost elements outside F. An efficient implementation is discussed in the full version of this paper. ◀

We finish our study with two special cases of the last theorem.

▶ **Corollary 35.** *Suppose that $\mathcal{A}(e)$ is an interval (of any type: open, closed, semiopen, trivial) for every element $e \in E$. Then the set S of all uncolored uncertain elements is the only minimum-size feasible query.*

▶ **Corollary 36.** *Let G be a connected graph such that for every $e \in E(G)$, $\mathcal{A}(e) = \{0, 1\}$. A set $F \subseteq E(G)$ is a minimal feasible query for the MST problem if and only if F contains all but one edge from each 2-connected component of G.*

Abstract

We obtain a streamlined proof of an important result by Alekhnovich and Razborov [2], showing that it is hard to automatize both tree-like and general Resolution. Under a different assumption than [2], our simplified proof gives improved bounds: we show under ETH that these proof systems are not automatizable in time $n^{f(n)}$, whenever $f(n) = o(\log^{1/7-\epsilon} \log n)$ for any $\epsilon > 0$. Previously non-automatizability was only known for $f(n) = O(1)$. Our proof also extends fairly straightforwardly to prove similar hardness results for PCR and Res(r).

We also thank Yijia Chen for providing more details on the construction in [14], and Pasin Manurangsi for giving feedback on the parameters in [13].

1 Introduction

Proof complexity first and foremost aims to understand, for a given propositional formula τ, how long of a proof is needed to verify that τ is unsatisfiable. To understand the expressiveness of a proof system, we need to understand what formulas can and cannot be efficiently proven in that system. However, for algorithmic applications where formulas often have fairly short proofs, what is perhaps more important than knowing the worst-case proof length of a given τ is actually *finding* proofs of τ. In particular, even if we're promised that τ has proofs of small size, say polynomial in the size of τ, can we hope to find one that's not too much larger?

This question, of finding optimal proofs in a given system, is known as *automatizability*, introduced by Bonet, Pitassi, and Raz [11]. A proof system $\mathcal{Q}$ is automatizable if there exists an algorithm which, given an unsatisfiable formula τ on n variables, returns a $\mathcal{Q}$-refutation of

τ in time $\mathsf{poly}(n, |\tau|, S)$ where $S := S_{\mathcal{Q}}(\tau)$ is the size of the shortest $\mathcal{Q}$-refutation of τ. Twenty years later no reasonable proof systems are known to be polynomially automatizable, and little is known even for the more general notion of f-automatizability, where the algorithm can run in time $f(n, |\tau|, S)$.

Understanding the automatizability of various proof systems is a major tool in algorithm design; two well known examples are SAT solvers, where the best algorithms are highly optimized version of the Resolution (Res) proof system (see e.g. [32]) and celebrated algorithmic versions of the Sum-of-Squares (SoS) proof system for approximation [37] and learning (see e.g. [38] for a survey on recent developments in this very active field of research). We especially draw attention to the question of automatizing Res. Resolution is a simple and fairly weak proof system, and yet Res proofs are the objects at the heart of the best known SAT solvers, with a long line of research connecting Res size to notions such as conflict driven clause learning and restarts [29, 30, 35, 42]. Automatizing Res is also key to the best known automated theorem provers for propositional and first order logics [17, 16]. Therefore, the tractability of finding short Res proofs lies at the heart of understanding the frontiers and limitations of SAT solving algorithms and automated theorem proving.

Despite the importance of automatizability for Res and other proof systems, our understanding of this question is limited at best. In terms of upper bounds, the best automatizing algorithm for Res runs in slightly subexponential time. In terms of lower bounds, until recently the main hardness result was the landmark paper of Alekhnovich and Razborov [2], who prove that under the assumption $\mathsf{FPT} \neq \mathsf{W[P]}$,[1] Res (as well as tree-like Res, denoted TreeRes) is not polynomially-automatizable. Using similar ideas, Galesi and Lauria [20] adapted Alekhnovich and Razborov's proof in order to obtain the same result for the Polynomial Calculus (PC) system, an extension of Res which is the proof complexity model for the Groebner basis algorithm [15].[2]

For all other well-studied practical systems almost nothing is known. To give a short list of other well-known proof systems used in algorithm design, we have Cutting Planes (CP), widely used for optimization algorithms (see e.g. [28]); Sherali-Adams (SA), which underlies a general family of linear programming algorithms [41]; and the aforementioned Sum-of-Squares (SoS)-based semi-definite programming algorithms. For these systems we have no extension of the argument of [2], and therefore no notable lower bounds on automatizability.

1.1 Our Contributions

Our motivation for this work is to adapt the techniques of [2], first to move past polynomial automatizability lower bounds for Res (and PC), and second to hopefully shed light on the automatizability of proof systems such as CP, SA, and SoS. The starting point of our contribution is in switching to the exponential time hypothesis (ETH) as opposed to the $\mathsf{FPT} \neq \mathsf{W[P]}$ assumption in [2, 20]. A central limitation in starting from the assumption that some problem has no FPT algorithm is that FPT algorithms run in time $f(k)n^{O(1)}$, and so the best lower bound one can get from such an assumption, without a careful analysis of f and the range of k, is $n^{\omega(1)}$. In the past decade a line of work by Chen and Lin [14] showed how to obtain fixed parameter lower bounds beyond $f(k)n^{O(1)}$ for gap versions of NP-hard

[1] The original result of [2] uses FPR, a randomized version of FPT, in place of FPT in the assumption. This was improved to the stated assumption by [19].

[2] While the most well-studied and widely used SAT solvers are based on Res, there have been some implementations that use the Groebner basis algorithm to utilize the more expressive power of PC, see e.g. [12].

problems, such as dominating set and hitting set, by starting not from an assumption about FPT but from ETH. Analyzing these reductions we can derive a hardness result for a *fixed* f and k, which allows us to go beyond the $n^{\omega(1)}$ barrier in [2, 20], albeit starting from the slightly stronger ETH assumption. We state our main theorem precisely now.

▶ **Theorem 1** (Main Theorem). *Let $\mathcal{Q} \in \{$Res, TreeRes, Nullsatz, PC, PCR$\}$. Assuming ETH holds $\mathcal{Q}$ is not n^f-automatizable for any $f = o(\log^{1/7-\varepsilon} \log n)$ (where $\varepsilon > 0$ is any constant).*

Equally important as extending the results of [2, 20] is our second goal, namely simplifying the presentation of the construction and proofs. Moving to the stronger ETH assumption allows us to change the central formula in a way that, while still using the core machinery of [2], leads to a conceptually simpler formula and proof. The basis of the formula in [2] is the monotone minimum circuit satisfying assignment (MMCSA) problem, which takes as input a poly-size monotone circuit. The natural encoding of their formula as a CNF formula requires extra variables to represent the internal gates of the monotone circuit, leading to many technicalities involved in proving a Res width lower bound, namely an indirect and highly redundant encoding of the circuit. Our proof starts from the hitting set problem, which is a special case of MMCSA where the circuit is a CNF. Since the formula is already a CNF, the input can be encoded directly as the formula rather than indirectly having variables for each of the gates, and as a result the upper and lower bound proofs in our paper are highly streamlined.

While we do start from a stronger assumption than [2, 20], there are few additional advantages to our new formula beyond presentation. First, going beyond superpolynomial hardness for Res allows us to obtain hardness results on the automatizability of Res(r), a proof system generalizing Res by allowing lines to be disjunctions of size r conjunctions. Prior to our paper nothing was known for Res(r) for any $r \geq 2$, and the formula from [2] would not be able to go past Res(r) for constant r.

▶ **Theorem 2** (Main Theorem for Res(r)). *Let $\mathcal{Q} =$ Res(r). Assuming ETH holds then for any $\varepsilon > 0$, $\mathcal{Q}$ is not $n^{f/\exp(r^2)}$-automatizable for any $f = o(\log^{\frac{1}{7}-\varepsilon} \log n)$ if $r \in O(\sqrt{\log f})$.*

Second, our technique has a direct, and in our view achievable, path to further improvement: if the reduction of [14] were to be improved to allow a lower bound against gap hitting set for larger parameters, it would immediately translate to a stronger non-automatizability result. We discuss this idea in detail in Section 6. Third, our results are also immediately strengthened if, instead of using ETH, one uses a slightly stronger assumption known as the *gap exponential time hypothesis* (GapETH), as introduced in [18, 27]. We formally define GapETH along with ETH in Section 2, but these results require no change in our formula nor our proofs. As with starting from [14] for our ETH results, the work required to use GapETH is analyzing a reduction of Chalermsook et al. [13], so we defer the results and analysis to to the full version of the paper.

1.2 Related Work

Table 1 lists the known results for Res and PC. An early result [1] shows that it is NP-hard to find proofs whose size is a constant factor of optimal, and this holds for *all* standard proof systems.

For stronger proof systems we have more lower bounds, although these bounds still only rule out polynomial automatizability and require cryptographic assumptions. Krajíček and Pudlák showed non-automatizability of the Extended Frege system under the hardness of

Proof system	Assumption	Result	Reference
all systems	$\mathsf{P} \neq \mathsf{NP}$	$\omega(1) \cdot n$	[1]
Res, TreeRes	$\mathsf{W[P]} \neq \mathsf{FPT}$	$n^{\omega(1)}$	[2]
Nullsatz, PC, PCR	$\mathsf{W[P]} \neq \mathsf{FPT}$	$n^{\omega(1)}$	[20]
Res, TreeRes, Nullsatz, PC, PCR	ETH	$n^{\Omega(\log^{1/7} \log n)}$	this work
Res(r)	ETH	$n^{\Omega(\log^{1/7} \log n / \exp(r^2))}$	this work

Figure 1 Lower bounds on automatizabillity of weak proof systems.

discrete log [25], with subsequent works proving the same lower bounds for Frege and AC^0-Frege under similar assumptions [10, 11]. Conceptually these more expressive classes should be harder to automatize because there exist many more short proofs than for say Res, but a nice upshot of these results is that they hold for a much weaker notion of automatizability, aptly named *weak automatizability*. Weak automatizability of a proof system $\mathcal{Q}$ only requires that the automatizing algorithm return a proof of τ in *some* proof system, so long as it's close in length to the shortest $\mathcal{Q}$-proof of τ.[3] Clearly hardness of weak automatizability implies hardness of automatizability, and hardness of weak automatizability is closely related to feasible interpolation [36], which was the tool used in the results listed above.

Turning to upper bounds, there are a class of *width/degree* based automatizability algorithms for Res, PC, SA, and SoS. The width of a Res refutation is the maximal number of literals appearing in any line of the refutation, and the width of a CNF formula τ, denoted $w(\tau)$, is the minimum width of any Res refutation refuting τ. It is not hard to see that exhaustive search allows us to find a Res refutation for τ in time $n^{O(w(\tau))}$ [8]. A non-trivial fact is that the same upper bound holds for PC (due to the Groebner basis paper of Clegg, Impagliazzo, and Edmonds [15]), SA [40], and SoS [34, 26], where the degree of the polynomials appearing in the proofs is used in place of width. These algorithms are known to be tight for width/degree based automatizability, as there exist tautologies τ with proof size $S(\tau) = n^{\Omega(d)}$ for Res, PC, SA, and SoS[4] [6].

A groundbreaking work of Ben-Sasson and Wigderson [9] showed that $w(\tau) \leq \log S(\tau)$ for the special case of TreeRes and $w(\tau) \leq \sqrt{n \log S(\tau)}$ for general Res. Combined with the $n^{O(w(\tau))}$ upper bound for both systems gives automatizability for TreeRes and Res in time $n^{O(\log S(\tau))}$ and $n^{O(\sqrt{n \log S(\tau)})}$, respectively. Perhaps even more surprisingly, a result of [15] gives the same degree/size tradeoff for PC as [9] gave for Res; $d(\tau) \leq \sqrt{n \log S(\tau)}$ for the case of PC, and $d(\tau) \leq \log S(\tau)$ for a static version of PC called *Nullstellensatz* (Nullsatz).[5] Combining these degree bounds with the degree based algorithms gives automatizability for Nullsatz and PC in time $n^{O(\log S(\tau))}$ and $n^{O(\sqrt{n \log S(\tau)})}$, respectively. While these upper bounds are very strong for TreeRes and Nullsatz, for Res and PC they are still weakly exponential, and the results of [9, 15] are tight. Thus non-width/degree based techniques are needed to improve these upper bounds.

[3] This can be seen as analogous to the two notions of of learning, proper versus nonproper, where the former is required to produce a hypothesis from the original concept class, whereas the latter may produce any hypothesis.

[4] The degree-automatizability of SoS is not established definitely due to the bit-complexity of the underlying polynomials, which can be exponential [33].

[5] This result of [15] actually preceded [9].

1.2.1 Recent Developments

In a recent breakthrough paper, Atserias and Müller [4] resolve the automatizability of (general) Resolution. In particular they show that it is NP-hard to distinguish whether τ has Res refutations of size $n^{1+\epsilon}$ or none of size $2^{n^{1/(2+\epsilon)}}$ for any $\epsilon > 0$, which implies that assuming ETH, Res is not $2^{n^{\delta}}$ automatizable for any $\delta < \frac{1}{2}$. Because of the quasipolynomial upper bounds on automatizability for the other systems that we study here (tree-like Resolution, and the Polynomial Calculus) our results as well as [2] are incomparable with [4]. Thus our results (and technique) are still at the frontier for all other systems discussed.

2 Preliminaries

Let $\tau = \{C_1, C_2, \ldots, C_m\}$ be an unsatisfiable CNF formula over $X = \{x_1 \ldots x_n\}$. We denote by $|\tau|$ the *size* of τ, and likewise for a proof π refuting τ let $|\pi|$ denote the size of π. For a proof system $\mathcal{Q}$ let $S := S_{\mathcal{Q}}(\tau)$ be the size of the shortest $\mathcal{Q}$-proof refuting τ. A proof system $\mathcal{Q}$ is said to be $f(n, |\tau|, S)$-*automatizable* if there exists an algorithm A such that for every unsatisfiable τ A runs in time $f(n, |\tau|, S)$ and outputs a valid $\mathcal{Q}$-proof refuting τ. A proof system $\mathcal{Q}'$ *p-simulates* $\mathcal{Q}$ if for every $\mathcal{Q}$-proof π refuting τ there is a corresponding $\mathcal{Q}'$-proof π' refuting τ such that $|\pi'| = |\pi|^{O(1)}$.

A *Resolution* (Res) refutation of τ is a sequence of clauses $\pi = \{D_1, D_2, \ldots, D_S\}$ such that $D_S = \emptyset$, and each line D_i is either some initial clause $C_j \in \tau$ or is derived from two previous lines using the *resolution rule*: from $(E \vee x)$, $(F \vee \overline{x})$ we derive $(E \vee F)$, where $x \in X$, E and F are clauses, and $E \vee F$ is their disjunction with repeated literals removed. We can view a Res proof π as a directed acyclic graph with a unique clause D_i at every vertex, with initial clauses $C_j \in \tau$ at the leaves, $\emptyset$ at the root, and having an edge from D_i to D_j if D_i was used to derive D_j. With this view, a TreeRes refutation requires that all non-leaf vertices of the underlying graph have outdegree 1 (so the underlying graph of any TreeRes proof is tree-like).

Given a Res or TreeRes refutation $\pi = \{D_1, D_2, \ldots, D_S\}$, the size of π is the number of lines in π, in this case S. The *width* of a clause D_i is the number of literals in it, and the width of π is the maximum width of a clause in the proof. We denote the width of a clause D_i or proof π by $w(D_i)$ and $w(\pi)$, respectively. Clearly Res can p-simulate TreeRes with respect to size and width, as every TreeRes-proof is also a Res-proof.

An *r-Resolution* (Res(r)) refutation[6] is similar to a Res refutation, but each line D_i is an r-DNF instead of a clause, and the resolution rule is adapted as follows: from $(E \vee (\vee_{j \in J} x_j)), (F \vee (\wedge_{j \in J} \overline{x_j}))$ we derive $(E \vee F)$, where $J \subseteq [n]$ such that $|J| \leq r$, E and F are r-DNFs, and $E \vee F$ is their disjunction with repeated conjunctions removed (note that $\vee_{j \in J} x_j$ is a DNF with $|J|$ terms while $\wedge_{j \in J} \overline{x_j}$ is a single term). Note that Res(1) = Res. The size of a Res(r) proof is the number of r-disjunctions in it. (See [39] for more details.)

An *algebraic proof system* for refuting CNF $\tau = \{C_1 \ldots C_{m'}\}$ over variable set X is a proof system where each of the clauses C_i is converted into a polynomial equality or inequality P_i over X, such that any assignment of all x_j to $\{0,1\}^n$ satisfies C_i iff it satisfies P_i. For this paper the conversion is done is by sending every positive literal x_j to $(1 - x_j)$ and every negative literal $\overline{x_j}$ to x_j, and P_i is satisfied if the product of all converted literals in C_i is 0. For example, the clause $C_i = x_1 \vee \overline{x_2} \vee x_3$ is converted to $P_i = (1 - x_1)(x_2)(1 - x_3) = 0$.

[6] This class is more commonly called k-Resolution, or Res(k), in proof complexity literature, but the parameter k already plays a central role in our paper.

In addition, we add the equations $x_j^2 - x_j = 0$ for all $j \leq n$. Let the resulting $m = m' + n$ equations corresponding to τ be denoted by $\mathcal{P} = \{P_1, \ldots, P_m\}$. Since every P_i is of the form $p_i = 0$ we use P_i to refer to p_i.

The *Nullstellensatz* (Nullsatz) refutation system [7] is an algebraic proof system that uses Hilbert's Nullstellensatz as a certificate of unsatisfiablility. A Nullsatz proof (over a field $\mathbb{F}$) of τ is a set of polynomials $Q_1, \ldots, Q_m$ such that $\sum_i P_i Q_i$ is the formal polynomial "1". Note that this contradicts the statement that there exists an assignment such that $P_i = 0$ for all i. The size of a Nullsatz refutation π is the sum over all $i \in [m]$ of the number of monomials in the expansion of the term $P_i Q_i$, while the *degree* of the refutation is the maximum degree $\deg(P_i Q_i)$ over all $i \in [m]$. It is known that Nullsatz p-simulates TreeRes.

The *Polynomial Calculus* (PC) system is a dynamic version of Nullsatz [15], where the lines of a PC proof π are all polynomials $Q_1, Q_2, \ldots, Q_S$. The lines Q_i can be any of the initial polynomial equations $\mathcal{P}$ or can be derived from previous lines by the following rules: (1) from Q_i we can derive $x_j Q_i$ or $(1 - x_j)Q_i$ for any variable x_j; (2) from Q_i, Q_j we can derive $aQ_i + bQ_j$ for any $a, b \in \mathbb{R}$. As with Nullsatz the final line Q_S is the formal polynomial "1". Similarly to Nullsatz the degree of a PC proof π is the maximal degree of any line Q_i, and the size of π is the total number of monomials in the refutation, where multiple occurrences of the same monomial are counted for each occurrence. PC trivially p-simulates Nullsatz and the simulation is degree-preserving.

The PCR system is a simple modification to the PC proof system so that it can p-simulate Res proofs with respect to size. For PCR, polynomials are allowed to use additional variables $\overline{x}_1, \ldots, \overline{x}_n$ and axioms of the form $1 - \overline{x}_j - x_j = 0$ for all $j \in [n]$. Furthermore all terms $(1 - x_j)$ in the input polynomials in $\mathcal{P}$ are replaced by the variables $\overline{x_j}$. Intuitively although the variables x_j and $\overline{x_j}$ are distinct they stand for the negations of one another, which is enforced by the new axiom corresponding to x_j. It is not hard to see that PCR can now p-simulate Res with respect to size.

Let $\mathcal{S} = \{S_1, \ldots, S_n\}$ be a collection of non-empty sets S_j over $[n]$. A *hitting set* $H \subseteq [n]$ is a set of elements such that $H \cap S_j \neq \emptyset$ for all $j \in [n]$. Let $\gamma(\mathcal{S})$ be the size of the smallest hitting set for $\mathcal{S}$. The *gap hitting set problem* is the task of distinguishing, on input $(\mathcal{S}, k, hk)$, the following two cases: (1) $\gamma(\mathcal{S}) \leq k$; (2) $\gamma(\mathcal{S}) > hk$.

▶ **Definition 3.** *The Exponential Time Hypothesis (ETH) states [23] that for sufficiently large m and n, no algorithm running in time $2^{o(n)}$ can decide, for given CNF τ with m clauses and n variables, whether all m clauses of τ are satisfiable or not. The Gap Exponential Time Hypothesis (GapETH) states [18, 27] that for sufficiently large m and n, no algorithm running in time $2^{o(n)}$ can decide, for given CNF τ with m clauses and n variables and any constant $\epsilon \in (0, 1)$, whether all m clauses of τ are satisfiable or if at most $(1 - \epsilon)m$ of the clauses are satisfiable.*

We state the following hardness results for the hitting set problem under ETH, which can be deduced from a construction by Chen and Lin [14]. The actual lemma we prove is slightly more technical but actually slightly stronger than the one we state here. A full discussion and proof of the lemma is included in the full version of the paper[7].

▶ **Lemma 4** (ETH-Hardness of Hitting Set)**.** *Assuming ETH, for sufficiently large n and $k = O(\log^{1/7-\epsilon} \log n)$ no algorithm can solve the gap hitting set problem $(\mathcal{S}, k, k^2)$ in time $n^{o(k)}$.*

[7] A similar result holds for GapETH, which can be deduced from recent work of Chalermsook et al [13]. See the full version for more details.

Consider a set $A \subseteq \{0,1\}^m$ of m-bit strings such that $|A| = m$. We say that A is (m,k)-*universal* if for every subset $J \subseteq [m]$ of up to k distinct positions in $[m]$, the projection $A|_J$ (restricting the strings in A to these positions) contains all possible $2^{|J|}$ binary strings of length $|J|$. Observe that we can take the dual of the set A in the following sense: if $A = \{a_1, \ldots, a_m\}$, and let $B \subseteq \{0,1\}^m$ be the set of all strings b_j for $j \in [m]$ such that the ith bit of b_j is the jth bit of a_i. Another way to think about B is taking the strings of A to be the columns of an $m \times m$ matrix and letting B be the columns of that matrix's transpose. We say A is (m,k)-*dual-universal* if B is (m,k)-universal. Equivalently A is (m,k)-dual-universal if for every ordered subset $I \subseteq A$ of up to k distinct strings in A and for every string $s \in \{0,1\}^{|I|}$, there exists some position $j \in [m]$ such that s is the string formed by concatenating the jth bit of all strings in I in order. The existence of efficiently constructible $(m, \log m/4)$-universal sets is known. It is also known that there exist efficiently constructible sets that are both $(m, \log m/4)$-universal *and* $(m, \log m/4)$-dual-universal. For a concrete example, [2] uses the *Paley graph* G_m on m vertices [8] For the rest of the paper we will fix an arbitrary A that is efficiently computable and is both $(m, \log m/4)$-universal and $(m, \log m/4)$-dual-universal.

3 Main reduction

We first state our main lemma from which Theorem 1 is easily proven.

▶ **Lemma 5.** *Let $\mathcal{Q} \in \{$Res, TreeRes, Nullsatz, PC, PCR$\}$. For sufficiently large n and $k = O(\log^{1/3} n)$, let $(\mathcal{S}, k, k^2)$ be an instance of the gap hitting set problem over $[n]$. Then there exists an unsatisfiable CNF $\tau_{\mathcal{S}}$ which can be computed in time $n^{O(1)}$ such that the following two properties hold*

(i) *if $\gamma(\mathcal{S}) \leq k$ then $S_{\mathcal{Q}}(\tau_{\mathcal{S}}) \leq n^{O(1)}$;*
(ii) *if $\gamma(\mathcal{S}) > k^2$ then $S_{\mathcal{Q}}(\tau_{\mathcal{S}}) \geq n^{\Omega(k)}$.*

Proof of Theorem 1. Assuming that $\mathcal{Q}$ is n^f automatizable for some $f(n) = o(\log^{1/7-\epsilon} \log n)$ for $\epsilon > 0$, we describe an efficient algorithm for the gap hitting set problem. Given an instance $(\mathcal{S}, k, k^2)$ of the gap hitting set problem over $[n]$, with n sufficiently large and $k = O(\log^{1/7-\epsilon} \log n)$, we generate the CNF $\tau_{\mathcal{S}}$, and simulate the automatizing algorithm on $\tau_{\mathcal{S}}$ for $n^{O(f)}$ timesteps. If the automatizing algorithm outputs a legal $\mathcal{Q}$ refutation of $\tau_{\mathcal{S}}$ within the allotted time, then we output "$\gamma(\mathcal{S}) \leq k$" and otherwise output "$\gamma(\mathcal{S}) > k^2$". Because $f = o(k)$ the correctness is guaranteed by Lemma 5. Thus we can decide the gap hitting set problem in time $n^{O(f)} = n^{o(k)}$, which by Lemma 4, contradicts ETH. ◀

The rest of the paper is devoted to the proof of Lemma 5. In this section we give the reduction $\tau_{\mathcal{S}}$, and prove the upper and lower bounds needed for the case of Res in Sections 4 and 5. This also gives the upper bound for PC and Res(r); the lower bounds are deferred to the full paper. We briefly note that the strength of the result in Theorem 1 relies solely on the largest value we can set k to. We choose $k = O(\log^{1/7-\epsilon} \log n)$ because this is the largest value we can use and still get a contradiction with Lemma 4, but for Lemma 5 to hold we can tolerate up to $k = O(\log^{1/3} \log n)$, meaning that if the reduction in [14] were

[8] Many examples of universal sets (including the Paley graph construction) are discussed in [24], as well as [31, 3]. Alternate constructions use properties such as k-wise independent sample spaces and linear codes, and counting arguments for different parameter regimes exist. Notably the Paley construction fulfills our four essential properties of being small (of size m), polytime constructible, $(m, \log m/4)$-universal, and $(m, \log m/4)$-dual-universal.

improved, a stronger version of Theorem 1 would immediately follow. Likewise, starting from the GapETH assumption we could use a stronger version of Lemma 4 and immediately get the stronger result claimed in Section 1 (see the full version of the paper).

Hereafter, fix $k = O(\log^{1/7-\epsilon} \log n)$ and define $m := n^{1/k}$. Observe that $k \log m = \log n$ and $k^2 < \log m$ for large enough n. In what follows we will abuse notation and x_i, y_j will denote a tuple of Boolean variables (rather than a single Boolean variable). The tuple size of x_i, y_j will be clear from context, but generally x_i will be a $O(\log m)$-tuple and y_j will be a $O(\log n)$-tuple. Additionally $\vec{x} = x_1, \ldots, x_n$, $\vec{y} = y_1, \ldots, y_m$ will denote vectors of the tuples x_i and y_j. α_i and β_j will denote a 0/1 assignment to the tuples x_i and y_j respectively, and $\vec{\alpha}, \vec{\beta}$ will each denote a 0/1 assignment to the vector of tuples $\vec{x}, \vec{y}$ respectively.

3.1 The Formula $\psi_{\mathcal{S}}$

Given a hitting set instance $\mathcal{S}$ we will define an unsatisfiable formula $\psi_{\mathcal{S}}$. Recall that A is a set of m-bit strings such that $|A| = m$ and A is both $(m, (\log m)/4)$-universal and $(m, (\log m)/4)$-dual-universal. We also define the *characteristic vector* of a set $S \subseteq [n]$ to be the binary vector $s \in \{0,1\}^n$ such that $s_i = 0$ for all $i \notin S$ and $s_i = 1$ for all $i \in S$.

The formula $\psi_{\mathcal{S}}$ will have variables $\vec{x}$ and $\vec{y}$ that will respectively encode n-by-m matrices M and N. The variables of $\vec{x}$ will define M such that each of the n rows of M is some vector in A, and the variables $\vec{y}$ will define N such that each of the m columns of N is the characteristic vector for some set S from the hitting set instance $\mathcal{S}$. In particular, x_i will indicate a vector in A to serve as the ith row of M, while y_j will indicate a set in $\mathcal{S}$ whose characteristic vector will serve as the jth column of N, with each x_i and y_j being chosen separately. For the remainder of the section, we restrict our attention to matrices M and N defined this way. We say that M and N *intersect* if $M[i,j] = N[i,j] = 1$ for some pair (i,j). $\psi_{\mathcal{S}}$ will be defined so that it is falsified whenever M and N intersect and satisfied otherwise.

Notice that when some column of M is the characteristic vector of a hitting set, $\psi_{\mathcal{S}}$ is falsified because there is no way to pick the corresponding column in N so that the two columns do not intersect. Conversely, if none of the columns in M represent a hitting set, then there is always a way to pick N so that $\psi_{\mathcal{S}}$ is satisfied (for each column we simply pick the set that was not hit). Therefore proving that $\psi_{\mathcal{S}}$ is unsatisfiable boils down to proving that for any choice of M, some column of M represents a hitting set.

▷ Claim 6. $\psi_{\mathcal{S}}$ is unsatisfiable when $\gamma(\mathcal{S}) \leq \frac{\log m}{4}$.

Proof sketch. Let H be any hitting set of size at most $\frac{\log m}{4}$, which we interpret of as a set of row indices into M. By the $(m, (\log m)/4)$-dual-universality of A, any set I of at most $(\log m)/4$ strings from A has a location such that all the strings in I contain a 1 at that location.[9] Since rows of M are strings in A, taking $I = H$ there must exist a column j^* such that $M[i, j^*] = 1$ for every $i \in H$. Because H is a hitting set and the jth column of N is the indicator vector of a set $S \in \mathcal{S}$, there must be some $i^* \in H$ such that $N[i^*, j^*] = 1$, and so M and N intersect at (i^*, j^*). ◁

Next, we define the formula more formally. The variables of $\psi_{\mathcal{S}}$ are $\vec{x} = \{x_i \mid i \in [n]\}$ where x_i is a tuple of $\log m$ boolean variables, and $\vec{y} = \{y_j \mid j \in [m]\}$ where y_j is a tuple of $\log n$ boolean variables. Given an assignment $\vec{\alpha} = \{\alpha_i \mid i \in [n]\}$ to the $\vec{x}$-variables, $\vec{\alpha}$

[9] We do not require that the rows of M are *distinct* rows of A, but because we are only looking for a location with a 1 for every row this does not pose an issue. In fact we only ever use the universal and dual universal properties to search for a location with either all 0 or all 1, where repetition doesn't break the universal properties we need.

encodes an n-by-m matrix $M_{\vec{\alpha}}$ where the i-th row of $M_{\vec{\alpha}}$ equals $a_{\alpha_i} \in A$ (interpreting α_i as an index in $[m]$). Similarly given an assignment $\vec{\beta} = \{\beta_j \mid j \in [m]\}$ to the $\vec{y}$-variables, $\vec{\beta}$ encodes an n-by-m matrix $N_{\vec{\beta}}$, where column j is the characteristic vector of the set $S_{\beta_j} \in \mathcal{S}$ (interpreting β_j as an index in $[n]$). We will sometimes write $M_{\vec{\alpha}}[i,j]$ as $M_{\alpha_i}[i,j]$ to stress that the ith row of $M_{\vec{\alpha}}$ is determined by α_i. Similarly, we will sometimes write $N_{\vec{\beta}}[i,j]$ as $N_{\beta_j}[i,j]$.

Lastly, we formally define the clauses in $\psi_{\mathcal{S}}$ so that it is falsified whenever $M_{\vec{\alpha}}$ and $N_{\vec{\beta}}$ intersect and satisfied otherwise.

▶ **Definition 7.** *For every $i \in [n]$ and $j \in [m]$, and for every pair of values $\alpha_i \in \{0,1\}^{\log m}$, $\beta_j \in \{0,1\}^{\log n}$ such that $M_{\alpha_i}[i,j] = 1$ and $N_{\beta_j}[i,j] = 1$, we have the clause $\overline{x_i^{\alpha_i} \wedge y_j^{\beta_j}}$ where $x_i^{\alpha_i} = \wedge_{t \in [n]} (x_i)_t^{(\alpha_i)_t}$ is the conjunction of all variables in x_i, each of which occurs positively when the corresponding bit of α_i is 1 and negatively when the corresponding bit of α_i is 0 (we define $y_j^{\beta_j}$ in the same way). This axiom is falsified iff x_i is assigned value α_i and y_j is assigned value β_j.*

This formula has the property we want because if $M_{\vec{\alpha}}$ and $N_{\vec{\beta}}$ intersect at some location i,j, then the axiom $\overline{x_i^{\alpha_i} \wedge y_j^{\beta_j}}$ exists in $\psi_{\mathcal{S}}$ and would be falsified. Conversely, if $\psi_{\mathcal{S}}$ is falsified, then some axiom $\overline{x_i^{\alpha_i} \wedge y_j^{\beta_j}}$ is falsified, which means $M_{\vec{\alpha}}[i,j] = N_{\vec{\beta}}[i,j] = 1$.

It is easy to check that the number of variables in $\psi_{\mathcal{S}}$ is $n \log m + m \log n$. The number of clauses is at most $n^2 m^2$, since for each $i \in [n]$ and $j \in [m]$, each of the mn possible assignments to (x_i, y_j) adds at most one clause to $\psi_{\mathcal{S}}$.

3.2 Redundantly Encoding $\psi_{\mathcal{S}}$

In order to prove our result we will need a way of proving both upper and lower bounds on $S_{\mathcal{Q}}(\psi_{\mathcal{S}})$, but it turns out that the lower bounds are difficult to prove if we use $\psi_{\mathcal{S}}$ as is. Thus, we will employ a standard trick in proof complexity, which is to redundantly encode the variables in the formula; more specifically we follow [2] and redundantly code blocks of variables, namely each row and column, using error-correcting codes. It is interesting to note that for our formulas, we are unable to prove even width lower bounds without the redundant encoding. In contrast, most proof complexity applications use this trick solely for the purpose of reducing size lower bounds to width lower bounds.

▶ **Definition 8.** *For $q, r, s \in \mathbb{N}$, a (q,r,s)-code is a total function f from $\{0,1\}^q$ to $\{0,1\}^r$ with the property that for any $\rho \in \{0,1,*\}^q$ such that ρ fixes at most s values to $\{0,1\}$, $f|_\rho$ is surjective on $\{0,1\}^r$. Efficiently computable constructions using linear codes are known for any $r, q = 6r, s = 2r$ (see e.g. [2]). We say that f is r-surjective.*

Let $f_x : \{0,1\}^{6 \log m} \to [m]$ be a $(6 \log m, \log m, 2 \log m)$-code and let $f_y : \{0,1\}^{6 \log n} \to [n]$ be a $(6 \log n, \log n, 2 \log n)$-code. We will have a vector $x_i \in \{0,1\}^{6 \log m}$ for each $i \in [n]$ and a vector $y_j \in \{0,1\}^{6 \log n}$ for each $j \in [m]$. Given an assignment $\vec{\alpha}$ to all of the $\vec{x}$-variables, we will associate with $\vec{\alpha}$ an n-by-m matrix $M_{\vec{\alpha}}$, where the ith row of $M_{\vec{\alpha}}$ will be the vector $a_{f_x(\alpha_i)} \in A$. Similarly given an assignment $\vec{\beta}$ to all of the $\vec{y}$-variables, we will associate with $\vec{\beta}$ an n-by-m matrix $N_{\vec{\beta}}$, where column j is the characteristic vector corresponding to the set $S_{f_y(\beta_j)} \in \mathcal{S}$ In other words, $N_{\vec{\beta}}[i,j]$ is 1 if and only if set $S_{f_y(\beta_j)}$ contains element i.

We now define our unsatisfiable CNF $\tau_{\mathcal{S}}$ in the same way as $\psi_{\mathcal{S}}$ using these redundant encodings. Note that it is unsatisfiable for exactly the same reason as stated before.

▶ **Definition 9.** *The clauses of $\tau_{\mathcal{S}}$ are defined as follows. For every $i \in [n], j \in [m]$ and for every pair of assignments (α_i, β_j) to (x_i, y_j) such that $M_{\alpha_i}[i,j] = 1$ and $N_{\beta_j}[i,j] = 1$, we have the clause $\overline{x_i^{\alpha_i} \wedge y_j^{\beta_j}}$.*

In the redundant encoding we have $n \cdot 6 \log m$ x-variables and $m \cdot 6 \log n$ y-variables, for a total of $O(n \log m)$ variables when $m = n^{1/k} \ll n$. The number of clauses in $\tau_{\mathcal{S}}$ is at most $n^7 m^7$, since for each $i \in [n]$ and $j \in [m]$, each of the $m^6 n^6$ possible assignments to (x_i, y_j) adds at most one clause to $\tau_{\mathcal{S}}$.

The following two lemmas, which will be the focus of the rest of the paper, give tight upper and lower bounds on $S_{\mathcal{Q}}(\tau_{\mathcal{S}})$ as a function of $\gamma(\mathcal{S})$. Since we can clearly construct $\tau_{\mathcal{S}}$ in time polynomial in n, proving these two lemmas is all we need to finish Lemma 5.

▶ **Lemma 10.** *For sufficiently large n and $k = O(\log^{1/3} n)$, let $(\mathcal{S}, k, k^2)$ be an instance of the gap hitting set problem over $[n]$ such that $\gamma(\mathcal{S}) \leq k$. Then $S_{\mathcal{Q}}(\tau_{\mathcal{S}}) \leq n^{O(1)}$ for any $\mathcal{Q} \in \{$Res, TreeRes, Nullsatz, PC, PCR$\}$.*

▶ **Lemma 11.** *For sufficiently large n and $k = O(\log^{1/3} n)$, let $(\mathcal{S}, k, k^2)$ be an instance of the gap hitting set problem over $[n]$ such that $\gamma(\mathcal{S}) > k^2$. Then $S_{\mathcal{Q}}(\tau_{\mathcal{S}}) \geq n^{\Omega(k)}$ for any $\mathcal{Q} \in \{$Res, TreeRes, Nullsatz, PC, PCR$\}$.*

It may be instructive to note that both the upper and lower bounds are exactly $n^{\Theta(\gamma(\mathcal{S})/k)} = m^{\Theta(\gamma(\mathcal{S}))}$, which is polynomial in the number of distinct assignments to $\alpha_1 \ldots \alpha_{\gamma(\mathcal{S})}$, assuming without loss of generality that the minimum hitting set of $\mathcal{S}$ is the first $\gamma(\mathcal{S})$ elements $\{1 \ldots \gamma(\mathcal{S})\} \subseteq [n]$. In Sections 4 and 5 we show how these assignments exactly characterize the shortest proof of τ.

4 Upper bound in TreeRes

In this section we prove Lemma 10. Note that it suffices to give an upper bound in TreeRes since all of the other proof systems can p-simulate TreeRes.

Proof of Lemma 10. The proof is just a formalization of the argument given in the proof of Claim 6. Using the well-known equivalence between TreeRes proofs and decision trees, it suffices to give a decision tree solving the search problem for $\tau_{\mathcal{S}}$; that is, a decision tree (over the underlying variables of $\tau_{\mathcal{S}}$), where every leaf l is labelled with a clause of $\tau_{\mathcal{S}}$ that is falsified by the partial assignment that labels the path to l.

We will first show that if $\gamma(\mathcal{S}) \leq k$, then there is a height $2 \log n$ decision tree (and therefore size n^2) for the unencoded formula $\psi_{\mathcal{S}}$. Since $\gamma(\mathcal{S}) \leq k$, assume without loss of generality that $H = \{1, \ldots, k\}$ is a valid hitting set for $\mathcal{S}$. The decision tree for $\psi_{\mathcal{S}}$ consists of two phases. First, the decision tree will branch on all of the Boolean variables in $x_1, \ldots, x_k$. This will result in a full binary tree, call it T, of depth $k \log m$. In the second phase, at each leaf vertex of T we will query all of the variables of some y_j variable, where the choice of y_j will be a function of the path taken in T.

Consider some path in T leading to leaf $l_{\vec{\alpha}}$, corresponding to the assignment $\vec{\alpha} = \alpha_1, \ldots \alpha_k$ for $x_1, \ldots, x_k$. The assignment $\vec{\alpha}$ corresponds to an ordered set of strings $I \subseteq A$, where $|I| \leq k$. Since $k \in O(\log^{1/3} n)$ and $m = n^{1/k}$, $k \leq \frac{\log m}{4}$ for large n. By the $(m, \log m/4)$-dual-universal property of A there is some $j \in [m]$ such that I restricted to position j is all 1's, and thus $M_{\vec{\alpha}}[i,j] = 1$ for all $i \in [k]$. In the second phase, at this leaf vertex $l_{\vec{\alpha}}$ of T we will then query all of the Boolean variables in y_j. Let β_j be one partial assignment to

these variables and consider the path labelled by $\vec{\alpha}\beta_j$ leading to the leaf vertex $l_{\vec{\alpha}\beta_j}$. Since $\{1,\dots,k\}$ is a hitting set for $\mathcal{S}$ we are guaranteed that $N_{\vec{\beta}_j}[i,j]=1$ for at least one $i\in[k]$, and since $M_{\vec{\alpha}}[i,j]=1$ for all $i\in[k]$, one of the clauses in $\tau_{\mathcal{S}}$ must be violated by the partial assignment $\vec{\alpha},\beta_j$, so we label $l_{\vec{\alpha}\beta_j}$ with any such clause. The resulting decision tree thus solves the search problem associated with $\psi_{\mathcal{S}}$ and has height $k\log m+\log n=2\log n$.

The decision tree for the redundant version $\tau_{\mathcal{S}}$ is essentially the same but instead we query the redundant encodings of the variables. First, we query $x_1,\dots,x_k$, resulting in a full binary tree of height $k\cdot 6\log m$, and then, we query a particular y_j (depending on the path taken in T), which is $6\log n$ variables, and thus the height is $k\cdot 6\log m+6\log n=12\log n$. ◀

5 Nonautomatizability of Res and TreeRes

In this section we prove Lemma 11 for the case of $\mathcal{Q}=$ Res, which implies the result for TreeRes as well. We begin by proving a *wide clause lemma* for $\tau_{\mathcal{S}}$, which alone is enough to prove lower bounds for TreeRes (using the size-width relationship for TreeRes due to Ben-Sasson and Wigderson [9]); for general Res, we apply a standard application of random restrictions to reduce to width.

Our notion of "wide" will be a bit richer than the usual definition. For a clause D, let $I_0(D)$ be the set of all $i\in[n]$ for which there are at least $\log m$ literals in D that correspond to variables from x_i. Likewise let $J_0(D)$ be the set of all $j\in[m]$ for which there are at least $\log n$ literals in D that correspond to variables from y_j.

▶ **Lemma 12** (Wide Clause Lemma). *For sufficiently large n, if $\gamma(\mathcal{S})>k^2$ and f_x (f_y) is $\log m$-surjective ($\log n$-surjective, respectively), then for any Res refutation π refuting $\tau_{\mathcal{S}}$ there exists a clause $D\in\pi$ such that $|I_0(D)|\geq k^2$ or $|J_0(D)|\geq k$.*

Proof. We follow the *prover-delayer game* of [36, 5] in the style of [6]. The width-w game on an unsatisfiable formula τ is played between a Delayer, who is asserting that she has a satisfying assignment for τ, and a Prover, who is trying to force the Delayer into a contradiction by asking her values of the underlying variables. However, the Prover has limited memory and can only remember the values of up to w of the variables at a time.

Both players know τ and the contents of the Prover's memory, which is initially empty. At the start of each round there are at most $w-1$ values in memory. The Prover asks the Delayer the value of some variable whose value is not currently in memory. The Delayer responds with an answer (either 0 or 1), and upon receiving the answer, the Prover adds this assignment to his memory (increasing the number of stored values by 1). He can then erase (forget) any existing values from memory, possibly decreasing the number of stored values. The Prover declares victory if at some point, the partial assignment written in his memory falsifies one of the clauses of τ. The Delayer has a winning strategy for the width-w game on τ if no matter how the Prover plays the game, he cannot win. It was shown [36, 5] that the Delayer has a winning strategy for the width-w game if and only if the Res width of τ is at least $w-1$.

For our formula $\tau_{\mathcal{S}}$, the game proceeds as above, but now let D be the set of literals in the Prover's memory, and we demand instead of only holding w variables total in memory that $|I_0(D)|\leq k^2$ and $|J_0(D)|\leq k$. By the transformation from [36], the Prover has a winning strategy for this game if there is a Res refutation such that $|I_0(D)|\leq k^2-1$ and $|J_0(D)|\leq k-1$ for every clause D. Therefore the Delayer has a winning strategy for this game if and only if the lemma holds. The Delayer's winning strategy is as follows.

- If the Prover asks about a variable in x_i:
  - If $i \notin I_0(D)$ and after adding this bit there are still less than $\log m$ variables from x_i in memory, the Delayer can answer with either 0 or 1 arbitrarily.
  - If $i \notin I_0(D)$ but after adding this bit to memory there are now $\log m$ variables from x_i in memory, the Delayer uses the fact that $|J_0(D)| \leq k \leq \log m/4$ and the $(m, \log m/4)$-universal property of A to find a string $a_0 \in A$ such that $a_0|_{J_0(D)}$ is the all-zeros string, and uses the surjective property of f_x to find an assignment α_i consistent with the assignment to the x_i variables in memory such that $f_x(\alpha_i) = a_0$. The Delayer will remember the assignment α_i for x_i from now on, and note that $I_0(D)$ now contains i.
  - Finally if $i \in I_0(D)$ then the Delayer is maintaining an assignment α_i for x_i, so she answers according to α_i.
- If the Prover asks about a variable in y_j:
  - If $j \notin J_0(D)$ and after adding this bit there are still less than $\log n$ variables from y_j in memory, the Delayer can answer with either 0 or 1 arbitrarily.
  - If $j \notin J_0(D)$ but there are now $\log n$ variables from y_j in memory, the Delayer uses the fact that $|I_0(D)| \leq k^2 < \gamma(\mathcal{S})$ and finds a set S_0 that doesn't contain any element $i \in I_0(D)$, and uses the surjective property of f_y to find an assignment β_j consistent with the assignment to the y_j variables in memory such that $f_y(\beta_j) = S_0$. The Delayer will remember the assignment β_j for x_j, and note that $J_0(D)$ now contains j.
  - Finally if $j \in J_0(D)$ then the Delayer is already maintaining an assignment β_j for y_j, so she answers according to β_j.
- Whenever the Prover erases a variable from x_i from his memory, if $i \in I_0$ and now there are less than $\log m$ variables from x_i in memory, the Delayer forgets α_i. (note that i is no longer in I_0) Similarly, whenever the Prover erases a variable from y_j from his memory, if $j \in J_0$ and now there are less than $\log n$ variables from y_j in memory, the Delayer removes β_j from J_0. (note that j is no longer in J_0)

Assume for contradiction the game ends with the Prover winning. Consider when the game ends, and say the Prover claims the axiom $\overline{x_i^{\alpha_i} \wedge y_j^{\beta_j}}$ was falsified, and thus that $M_{\vec{\alpha}}[i,j] = N_{\vec{\beta}}[i,j] = 1$. First, consider the case when either $i \notin I_0$ or $j \notin J_0$. In either case there are is at least one variable in the axiom that is not in memory, which means that it has not been falsified, which is a contradiction. So assume that $i \in I_0$ and $j \in J_0$, and consider the last time that i was added to I_0 and the last time that j was added to J_0. Assume that i was added after j. Since j was in J_0 at the time we defined α_i, $M_{\alpha_i}[i,j] = 0$ by our choice of α_i, which is a contradiction. Finally assume that j was added after i. Then since i was in I_0 at the time we defined β_j, $f_y(\beta_j)$ does not contain i, and so $N_{\beta_j}[i,j] = 0$, which is also a contradiction. ◀

Before proceeding on to the proof of Lemma 11, we need to change Lemma 12 slightly, in order to be able to apply a restriction argument to turn width lower bounds into size lower bounds for $\tau_{\mathcal{S}}$. We use the notation $f|_\rho$ to denote the *restriction* of the function f over $x_1 \dots x_s$ by $\rho \in \{0,1,*\}^s$, which is the function f over the variables x_i for all $i \in \rho^{-1}(*)$ obtained by setting all other variables x_j to $\rho(j)$. Likewise we use the notation $\tau|_\rho$ to denote the restriction of the tautology τ by ρ.

▶ **Definition 13.** *Let $\rho_{x_i} \in \{0,1,*\}^{x_i}$ and let $\rho_{y_j} \in \{0,1,*\}^{y_j}$. Furthermore, let $\mathcal{R}$ be the set of all $\vec{\rho} = \{\rho_{x_1} \dots \rho_{x_n}, \rho_{y_1} \dots \rho_{y_m}\}$, such that for all $i \in [n]$ and $j \in [m]$, $|\rho_{x_i}^{-1}(*)| = 5 \log m$ and $|\rho_{y_j}^{-1}(*)| = 5 \log n$. Let f_x^i be the function f_x on the variables $\rho_{x_i}^{-1}(*)$ after restricting all other inputs to ρ_{x_i}, and likewise for f_y^j.*

▶ **Lemma 14** (Wide Clause Lemma under restrictions). *For sufficiently large n and $\rho \in \mathcal{R}$, if $\gamma(\mathcal{S}) > k^2$ then for any Res refutation π refuting $\tau_{\mathcal{S}}|_{\vec{\rho}}$ there exists a clause $D \in \pi$ such that $|I_0(D)| \geq k^2$ or $|J_0(D)| \geq k$.*

We omit the proof of Lemma 14, as it is essentially identical to Lemma 12. The only difference is that in each row i the Delayer chooses α_i based on f_x^i instead of f_x, and likewise for the columns. Note that f_x was $2 \log m$ surjective before the restriction, and since only $\log m$ variables are fixed in every row f_x^i is still $\log m$ surjective (and similarly for f_y^j).

Proof of Lemma 11. Let π be a Res refutation of $\tau_{\mathcal{S}}$ and assume for contradiction that $|\pi| < n^{k/16}$. First, consider a clause $D \in \pi$ such that $|I_0(D)| \geq k^2$. For each $i \in I_0(D)$, the chance that a randomly chosen $\vec{\rho} \in \mathcal{R}$ doesn't set one of the x_i literals in D to 1 is less than $(1 - (\frac{1}{6} \cdot \frac{1}{2}))^{\log m}$. Thus the probability that no $i \in I_0(D)$ sets D to 1 is at most $(\frac{11}{12})^{k^2 \log m} = (\frac{11}{12})^{k \log n} < \frac{1}{n^{k/8}}$. By a union bound the probability that some clause D in π satisfying $|I_0(D)| \geq k^2$ is not set to 1 is less than $\frac{n^{k/16}}{n^{k/8}} = \frac{1}{n^{k/16}}$, using the fact that $|\pi| < n^{k/16}$.

Similarly the probability that some clause $D \in \pi$ satisfying $|J_0(D)| \geq k$ is not set to 1 is at most $\frac{1}{n^{k/16}}$. Thus with probability at least $1 - \frac{2}{n^{k/16}}$, all clauses D satisfying $|I_0(D)| \geq k^2$ or $|J_0(D)| \geq k$ are set to 1 by a random restriction, and thus there exists a restriction $\vec{\rho} = \{\rho_{x_1} \dots \rho_{x_n}, \rho_{y_1} \dots \rho_{y_m}\}$ setting all such clauses to 1. However, this contradicts Lemma 14, as $\tau_{\mathcal{S}}|_{\vec{\rho}}$ must still have at least one such clause. Thus $S_{\mathcal{Q}}(\tau_{\mathcal{S}}) \geq n^{c_l k}$ for $c_l = \frac{1}{16}$. ◀

6 Conclusions

In terms of optimality of our results, the constructions in [14, 13] are not known to be optimal, and any hardness results against approximating the gap hitting set problem in time $n^{o(k)}$ for a larger value of k immediately gives a lower bound of $n^{o(k)}$ against automatizability. While their results are "optimal" in terms of fixed-parameter tractability guarantees, there is nothing limiting a different reduction from getting the same (or even a weaker) result that works for larger values of the fixed parameter.[10]

On the flip side, all of our hardness results also work for TreeRes and Nullsatz, and therefore this reduction is limited to quasipolynomial hardness. This is in line with the details of the reduction; by the crucial fact that $k^2 \leq \frac{\log m}{4} = \frac{\log n}{4k}$, this technique can't be strengthened past the $k = o(\log^{1/3} n)$ threshold.[11] Thus, the upper limit of improving the reductions of [14, 13] coincides almost exactly with the upper limit of our argument, and by extension any argument using the machinery of [2].

A central motivation of this work was to make the techniques clear and simple in hopes that they can be made to work for stronger systems such as SA and SoS, where no lower bounds are known. A degree lower bound matching our results for Res and PC would shed light on the limitations of our current approximation algorithms. Similarly it's possible

[10] Classically the hitting set problem has no $o(\log n)$ approximations; the obstacle to using this classical hardness is that it only rules out algorithms that get $o(\log n)$ approximation for *all* hitting set sizes, whereas [14] rules out algorithms for any *fixed* hitting set size. Nevertheless it's believed that $\Omega(\log n)$ hardness holds even for fixed hitting set sizes, and getting a reduction that achieves this result would strengthen our argument.

[11] If we allow the formula to be satisfiable in the case where $\gamma(\mathcal{S}) > k^2$ we only need $k \leq \frac{\log m}{4}$ since we only ever allow the proof to query k columns. This can also be made to work in the base setting where the formula must always be unsatisfiable by standard tricks. However this still yields a barrier of $k = o(\log^{1/2} n)$.

that this proof can be made to work for the case of TreeCP or CP, where instead of arguing lower bounds directly we can hope to leverage the power of lifting theorems [22, 21]; in particular a constant-sized lifting gadget would immediately give results for TreeCP matching our other results.

Abstract

Motivated by applications in machine learning, such as subset selection and data summarization, we consider the problem of maximizing a monotone submodular function subject to mixed packing and covering constraints. We present a tight approximation algorithm that for any constant $\varepsilon > 0$ achieves a guarantee of $1 - 1/e - \varepsilon$ while violating only the covering constraints by a multiplicative factor of $1 - \varepsilon$. Our algorithm is based on a novel enumeration method, which unlike previously known enumeration techniques, can handle both packing and covering constraints. We extend the above main result by additionally handling a matroid independence constraint as well as finding (approximate) pareto set optimal solutions when multiple submodular objectives are present. Finally, we propose a novel and purely combinatorial dynamic programming approach. While this approach does not give tight bounds it yields *deterministic* and in some special cases also considerably faster algorithms. For example, for the well-studied special case of only packing constraints (Kulik et al. [Math. Oper. Res. '13] and Chekuri et al. [FOCS '10]), we are able to present the first deterministic non-trivial approximation algorithm. We believe our new combinatorial approach might be of independent interest.

1 Introduction

The study of combinatorial optimization problems with a submodular objective has attracted much attention in the last decade. A set function $f : 2^{\mathcal{N}} \to \mathbb{R}_+$ over a ground set $\mathcal{N}$ is called *submodular* if it has the *diminishing returns* property: $f(A \cup \{i\}) - f(A) \geq f(B \cup \{i\}) - f(B)$ for every $A \subseteq B \subseteq \mathcal{N}$ and $i \in \mathcal{N} \setminus B$.[1] Submodular functions capture the principle of economy of scale, prevalent in both theory and real world applications. Thus, it is no surprise that combinatorial optimization problems with a submodular objective arise in numerous disciplines, *e.g.*, machine learning and data mining [4, 5], algorithmic game theory and social networks [13, 22, 25, 27, 39], and economics [2]. Additionally, many classical problems in combinatorial optimization are in fact submodular in nature, *e.g.*, maximum cut and maximum directed cut [20, 21, 24, 26, 28], maximum coverage [15, 29], generalized assignment problem [8, 10, 14, 16], maximum bisection [3, 17], and facility location [1, 11, 12].

In this paper we consider the problem of maximizing a monotone[2] submodular function given mixed packing and covering constraints. In addition to being a natural problem in its own right, it has further real world applications.

As a motivating example consider the subset selection task in machine learning [18, 19, 30] (also refer to Kulesza and Taskar [31] for a thorough survey). In the subset selection task the goal is to select a diverse subset of elements from a given collection. One of the prototypical applications of this task is the document summarization problem [30, 34, 35]: given textual units the objective is to construct a short summary by selecting a subset of the textual units that is both representative and diverse. The former requirement, representativeness, is commonly achieved by maximizing a submodular objective function, *e.g.*, graph based [34, 35] or log subdeterminant [30]. The latter requirement, diversity, is typically tackled by penalizing the submodular objective for choosing similar textual units (this is the case for both of the above two mentioned submodular objectives). However, such an approach results in a submodular objective which is not necessarily non-negative thus making it extremely hard to cope with. As opposed to penalizing the objective, a remarkably simple and natural approach to tackle the diversity requirement is by the introduction of covering constraints. For example, one can require that for each topic that needs to appear in the summary, a sufficient number of textual units that refer to it are chosen. Unfortunately, to the best of our knowledge there is no previous work in the area of submodular maximization that incorporates general covering constraints.[3]

Let us now formally define the main problem considered in this paper. We are given a monotone submodular function $f : 2^{\mathcal{N}} \to \mathbb{R}_+$ over a ground set $\mathcal{N} = \{1, 2, \ldots, n\}$. Additionally, there are p packing constraints given by $\mathbf{P} \in \mathbb{R}_+^{p \times n}$, and c covering constraints given by $\mathbf{C} \in \mathbb{R}_+^{c \times n}$ (all entries of $\mathbf{P}$ and $\mathbf{C}$ are non-negative). Our goal is to find a subset $S \subseteq \mathcal{N}$ that satisfies all packing and covering constraints that maximizes the value of f:

$$\max \{f(S) : S \subseteq \mathcal{N}, \mathbf{P}\mathbf{1}_S \leq \mathbf{1}_p, \mathbf{C}\mathbf{1}_S \geq \mathbf{1}_c\}. \tag{1}$$

In the above $\mathbf{1}_S \in \mathbb{R}^n$ is the indicator vector for $S \subseteq \mathcal{N}$ and $\mathbf{1}_k \in \mathbb{R}^k$ is a vector of dimension k whose coordinates are all 1. We denote this problem as Packing-Covering Submodular Maximization (PCSM). It is assumed we are given a feasible instance, *i.e.*, there exists $S \subseteq \mathcal{N}$ such that $\mathbf{P}\mathbf{1}_S \leq \mathbf{1}_p$ and $\mathbf{C}\mathbf{1}_S \geq \mathbf{1}_c$.

---

[1] An equivalent definition is: $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for every $A, B \in \mathcal{N}$.
[2] f is monotone if $f(S) \leq f(T)$ for every $S \subseteq T \subseteq \mathcal{N}$.
[3] There are works on exact cardinality constraints for non-monotone submodular functions, which implies a special, uniform covering constraint [6, 33, 41].

As previously mentioned, (PCSM) captures several well known problems as a special case when only a single packing constraint is present ($p = 1$ and $c = 0$): maximum coverage [29], and maximization of a monotone submodular function given a knapsack constraint [40, 42] or a cardinality constraint [37]. For all of these special cases an approximation of $(1 - 1/e)$ is achievable and known to be tight [38] (even for the special case of a coverage function [15]). When a constant number of knapsack constraints is given ($p = O(1)$ and $c = 0$) Kulik et al. [32] presented a tight $(1 - 1/e - \varepsilon)$-approximation for any constant $\varepsilon > 0$. An alternative algorithm with the same guarantee was given by Chekuri et al. [9].

Our Results. We present a tight approximation guarantee for (PCSM) when the number of constraints is constant. Recall that we assume we are given a feasible instance, *i.e.*, there exists $S \subseteq \mathcal{N}$ such that $\mathbf{P1}_S \leq \mathbf{1}_p$ and $\mathbf{C1}_S \geq \mathbf{1}_c$. The following theorem summarizes our main result. From this point onwards we denote by O some fixed optimal solution to the problem at hand.

▶ **Theorem 1.** *For every constant $\varepsilon > 0$, assuming p and c are constants, there exists a randomized polynomial time algorithm for* (PCSM) *running in time $n^{poly(1/\varepsilon)}$ that outputs a solution $S \subseteq \mathcal{N}$ that satisfies:* (1) $f(S) \geq (1 - 1/e - \varepsilon)\, f(O)$*; and* (2) $\mathbf{P1}_S \leq \mathbf{1}_p$ *and* $\mathbf{C1}_S \geq (1 - \varepsilon)\mathbf{1}_c$.

We note four important remarks regarding the tightness of Theorem 1:

1. The loss of $1-1/e$ in the approximation cannot be avoided, implying that our approximation guarantee is (virtually) tight. The reason is that no approximation better than $1 - 1/e$ can be achieved even for the case where only a single packing constraint is present [38].
2. The assumption that the number of constraints is constant is unavoidable. The reason is that if the number of constraints is not assumed to be constant, then even with a linear objective (PCSM) captures the maximum independent set problem. Hence, no approximation better than $n^{-(1-\varepsilon)}$, for any constant $\varepsilon > 0$, is possible [23].[4]
3. No *true* approximation with a finite approximation guarantee is possible, *i.e.*, finding a solution $S \subseteq \mathcal{N}$ such that $\mathbf{P1}_S \leq \mathbf{1}_p$ and $\mathbf{C1}_S \geq \mathbf{1}_c$ with no violation of the constraints. The reason is that one can easily encode the subset sum problem using a single packing and a single covering constraint. Thus, just deciding whether a feasible solution exists, regardless of its cost, is already NP-hard.
4. Guaranteeing one-sided feasibility, *i.e.*, finding a solution which does not violate the packing constraints and a violates the covering constraint only by a factor of $1 - \varepsilon$, cannot be achieved in time $n^{o(1/\varepsilon)}$ unless the exponential time hypothesis fails (see [36] for details).

Therefore, we can conclude that our main result (Theorem 1) provides the best possible guarantee for the (PCSM) problem. We also note that all previous work on the special case of only packing constraints [9, 32] have the same running time of $n^{\text{poly}(1/\varepsilon)}$.

We present additional extensions of the above main result. The first extension deals with (PCSM) where we are also required that the output is an independent set in a given matroid $\mathcal{M} = (\mathcal{N}, \mathcal{I})$. We denote this problem by Matroid Packing-Covering Submodular Maximization (MatroidPCSM), and it is defined as follows:

[4] If the number of packing constraints p is super-constant then approximations are known only for special cases with "loose" packing constraints, *i.e.*, $P_{i,\ell} \leq O(\varepsilon^2 / \ln p)$ (see, *e.g.*, [9]).

$\max\{f(S) : S \subseteq \mathcal{N}, \mathbf{P1}_S \leq \mathbf{1}_p, \mathbf{C1}_S \geq \mathbf{1}_c, S \in \mathcal{I}\}$. As in (PCSM), we assume we are given a feasible instance, *i.e.*, there exists $S \subseteq \mathcal{N}$ such that $\mathbf{P1}_S \leq \mathbf{1}_p$, $\mathbf{C1}_S \geq \mathbf{1}_c$, and $S \in \mathcal{I}$. Our result is summarized in the following theorem.

▶ **Theorem 2.** *For every constant $\varepsilon > 0$, assuming p and c are constants, there exists a randomized polynomial time algorithm for* (MatroidPCSM) *that outputs a solution $S \in \mathcal{I}$ that satisfies:* (1) $f(S) \geq (1 - 1/e - \varepsilon)\, f(O)$*; and* (2) $\mathbf{P1}_S \leq \mathbf{1}_p$ *and* $\mathbf{C1}_S \geq (1-\varepsilon)\mathbf{1}_c$.

The second extension deals with the multi-objective variant of (PCSM) where we wish to optimize over several monotone submodular objectives. We denote this problem by Packing-Covering Multiple Submodular Maximization (MultiPCSM). Its input is identical to that of (PCSM) except that instead of a single objective f we are given t monotone submodular functions $f_1, \ldots, f_t : 2^{\mathcal{N}} \to \mathbb{R}_+$. As before, we assume we are given a feasible instance, *i.e.*, there exists $S \subseteq \mathcal{N}$ such that $\mathbf{P1}_S \leq \mathbf{1}_p$ and $\mathbf{C1}_S \geq \mathbf{1}_c$. Our goal is to find pareto set solutions considering the t objectives. To this end we prove the following theorem.

▶ **Theorem 3.** *For every constant $\varepsilon > 0$, assuming p, c and t are constants, there exists a randomized polynomial time algorithm for* (MultiPCSM) *that for every target values $v_1, \ldots, v_t$ either:* (1) *finds a solution $S \subseteq \mathcal{N}$ where $\mathbf{P1}_S \leq \mathbf{1}_p$ and $\mathbf{C1}_S \geq (1-\varepsilon)\mathbf{1}_c$ such that for every $1 \leq i \leq t$: $f_i(S) \geq (1 - 1/e - \varepsilon)\, v_i$; or* (2) *returns a certificate that there is no solution $S \subseteq \mathcal{N}$, where $\mathbf{P1}_S \leq \mathbf{1}_p$ and $\mathbf{C1}_S \geq \mathbf{1}_c$ such that for every $1 \leq i \leq t$: $f_i(S) \geq v_i$.*

We also note that Theorems 2 and 3 can be combined such that we can handle (MultiPCSM) where a matroid independence constraint is present, in addition to the given packing and covering constraints, achieving the same guarantees as in Theorem 3.

All our previously mentioned results employ a continuous approach and are based on the multilinear relaxation, and thus are inherently *randomized*.[5] We present a new combinatorial greedy-based dynamic programming approach for submodular maximization that enables us, for several well studied special cases of (PCSM), to obtain deterministic and considerably faster algorithms. Perhaps the most notable result is the first deterministic non-trivial algorithm for maximizing a monotone submodular function subject to a constant number of packing constraints (previous works [9, 32] are randomized).

▶ **Theorem 4.** *For every constants $\varepsilon > 0$ and $p \in \mathbb{N}$, there exists a deterministic algorithm for maximizing a monotone submodular function subject to p packing constraints, that runs in time $O(n^{\mathrm{poly}(1/\varepsilon)})$ and achieves an approximation of $1/e - \varepsilon$.*

The interesting special case of (PCSM) is when a single packing and a single covering constraints are present ($p = c = 1$) is summarized in the following theorem.

▶ **Theorem 5.** *For every constant $\varepsilon > 0$ and $p = c = 1$, there exists a deterministic algorithm for* (PCSM) *running in time $O(n^{1/\varepsilon})$ that outputs a solution $S \subseteq \mathcal{N}$ that satisfies:* (1) $f(S) \geq 0.353 f(O)$*; and* (2) $\mathbf{P1}_S \leq (1+\varepsilon)\mathbf{1}_p$ *and* $\mathbf{C1}_S \geq (1-\varepsilon)\mathbf{1}_c$*. For the case when the packing constraint is a cardinality constraint,* i.e.*, $\mathbf{P} = \mathbf{1}_n^\intercal/k$, we can further guarantee that $\mathbf{P1}_S \leq \mathbf{1}_p$ and a running time of $O(n^4/\varepsilon)$.*

Our Techniques. Our main result is based on a continuous approach: first a continuous relaxation is formulated, second it is (approximately) solved, and finally the fractional solution is rounded into an integral solution. Similarly to the previous works of [9, 32], which

[5] Known techniques to efficiently evaluate the multilinear extension are randomized, *e.g.*, [7].

focus on the special case of only packing constraints, the heart of the algorithm lies in an enumeration preprocessing phase that chooses and discards some of the elements prior to formulating the relaxation. The enumeration preprocessing step of [9, 32] is remarkably simple and elegant. It enumerates over all possible collections of large elements the optimal solution chooses, *i.e.*, elements whose size exceeds some fixed constant in at least one of the packing constraints and are chosen by the optimal solution.[6] All remaining large elements not in the guessed collection are discarded. This enumeration terminates in polynomial time and ensures that no large elements are left in any of the packing constraints. Thus, once no large elements remain concentration bounds can be applied. For the correct guess, any of the several known randomized rounding techniques can be employed (alongside a simple rescaling) to obtain an approximation of $1 - 1/e - \varepsilon$ (here $\varepsilon > 0$ is a constant that is used to determine which elements are considered large). Unfortunately, this approach fails in the presence of covering constraints since an optimal solution can choose *many* large elements in any given covering constraint. One can naturally adapt the above known preprocessing by enumerating over all possible collections of covering constraints that the optimal solution O covers using only large elements. However, this leads to an approximation of $1 - 1/e - \varepsilon$ while *both* packing and covering constraints are violated by a multiplicative factor of $1 \pm \varepsilon$. We aim to obtain one sided violation of the constraints, *i.e.*, only the covering constraints are violated by a factor of $1 - \varepsilon$ whereas the packing constraints are fully satisfied.

Avoiding constraint violation is possible in the presence of pure packing constraints [9, 32]. Known approaches for the latter are crucially based on *removing* elements in a pre-processing and post-processing step in order to guarantee that concentration bounds hold. For mixed constraints, these known removal operations may, however, arbitrarily violate the covering constraints. Our approach aims at pre-processing the input instance via partial enumeration so as to avoid discarding elements by ensuring that the remaining elements are "locally" small relatively to the *residual* constraints. If this property would hold scaling down the solution by a factor $1/(1+\varepsilon)$ would be sufficient to avoid violation of the packing constraints. Unfortunately, we cannot guarantee this to hold for all constraints. Rather, for some *critical* constraints locally large elements may still be present. We introduce a novel enumeration process that detects these critical constraints, *i.e.*, constraints that are prone to violation. Such constraints are given special attention as the randomized rounding might cause them to significantly deviate from the target value. Unlike the previously known preprocessing method, our enumeration process handles covering constraints with much care and it takes into account the *actual* coverage of the optimal solution O of each of the covering constraints. Combining the above, alongside a postprocessing phase that discards large elements from critical packing constraints, suffices to yield the desired result.

We also independently present a novel purely combinatorial greedy-based dynamic programming approach that yields deterministic and in some special cases considerably faster algorithms. Previously, greedy algorithms were known for one cardinality constraint [37] and one packing constraint [40]. But in the presence multiple constraints, it is not clear how to design a rule to greedily pick the next element. In fact, we tried several natural greedy strategies but all of them failed. This holds even when some oracle gives us the set of vectors of packing and covering values from an optimum solution and the algorithm follows any *fixed* sequence of these values.

[6] An additional part of the preprocessing involves enumerating over collections of elements whose marginal value is large with respect to the objective f, however this part of the enumeration is not affected by the presence of covering constraints and thus is ignored in the current discussion.

In our approach we maintain a table that contains greedy approximate solutions for all possible packing and covering values. Using this table we extend the simple greedy process by populating each table entry with the most profitable extension of the previous table entries. In this way we are able to simulate (in a certain sense) *all* possible sequences of packing and covering values for the greedy algorithm, ultimately leading to a good feasible solution. Our result implies that there exists one sequence (depending on the instance) where greedy performs well. To estimate the approximation factor we employ a factor-revealing linear program. To the best of our knowledge, this is the first time a dynamic programming based approach is used for submodular optimization. We believe our new combinatorial dynamic programming approach is of independent interest.

2 Preliminaries

In this paper we assume the standard *value oracle* model, where the algorithm can only access the given submodular function f with queries of the form: what is $f(S)$ for a given S? The running time of the algorithm is measured by the total number of value oracle queries and arithmetic operations it performs. Additionally, let us define $f_A(S) \triangleq f(A \cup S) - f(A)$ for any subsets $A, S \subseteq \mathcal{N}$. Furthermore, let $f_A(\ell) \triangleq f_A(\{\ell\})$.

The multiliear extension $F : [0,1]^{\mathcal{N}} \to \mathbb{R}_+$ of a given set function $f : 2^{\mathcal{N}} \to \mathbb{R}_+$ is:

$$F(\mathbf{x}) \triangleq \sum_{R \subseteq \mathcal{N}} f(R) \prod_{\ell \in R} x_\ell \prod_{\ell \notin R} (1 - x_\ell) \qquad \forall \mathbf{x} \in [0,1]^{\mathcal{N}}.$$

Additionally, we make use of the following theorem that provides the guarantees of the continuous greedy algorithm of [7].[7]

▶ **Theorem 6** (Chekuri et al. [7]). *We are given a ground set $\mathcal{N}$, a monotone submodular function $f : 2^{\mathcal{N}} \to \mathbb{R}_+$, and a polytope $\mathcal{P} \subseteq [0,1]^{\mathcal{N}}$. If $\mathcal{P} \neq \emptyset$ and one can solve in polynomial time $\operatorname{argmax}\{\mathbf{w}^T\mathbf{x} : \mathbf{x} \in \mathcal{P}\}$ for any $\mathbf{w} \in \mathbb{R}^{\mathcal{N}}$, then there exists a polynomial time algorithm that finds $\mathbf{x} \in \mathcal{P}$ where $F(\mathbf{x}) \geq (1 - 1/e)\, F(\mathbf{x}^*)$. Here $\mathbf{x}^*$ is an optimal solution to the problem:* $\max\{F(\mathbf{y}) : \mathbf{y} \in \mathcal{P}\}$.

3 Algorithms for the (PCSM) Problem

Preprocessing – Enumeration with Mixed Constraints. We define a *guess* D to be a triplet $(E_0, E_1, \mathbf{c}')$, where $E_0 \subseteq \mathcal{N}$ denotes elements that are discarded, $E_1 \subseteq \mathcal{N}$ denotes elements that are chosen, and $\mathbf{c}' \in \mathbb{R}_+^c$ represents a rough estimate (up to a factor of $1 + \varepsilon$) of how much an optimal solution O covers each of the covering constraints, *i.e.*, $\mathbf{C}\mathbf{1}_O$. Let us denote by $\tilde{\mathcal{N}} \triangleq \mathcal{N} \setminus (E_0 \cup E_1)$ the remaining undetermined elements with respect to guess D.

We would like to define when a given fixed guess $D = (E_0, E_1, \mathbf{c}')$ is *consistent*, and to this end we introduce the notion of *critical* constraints. For the i^{th} packing constraint the residual value that can still be packed is: $(\mathbf{r}_D)_i \triangleq 1 - \sum_{\ell \in E_1} \mathbf{P}_{i,\ell}$, where $\mathbf{r}_D \in \mathbb{R}^p$. For the j^{th} covering constraint the residual value that still needs to be covered is: $(\mathbf{s}_D)_j \triangleq \max\left\{0, \mathbf{c}'_j - \sum_{\ell \in E_1} \mathbf{C}_{j,\ell}\right\}$, where $\mathbf{s}_D \in \mathbb{R}^c$. A packing constraint i is called *critical* if $(\mathbf{r}_D)_i \leq \delta$, and a covering constraint j is called *critical* if $(\mathbf{s}_D)_j \leq \delta \mathbf{c}'_j$ ($\delta \in (0,1)$ is

[7] We note that the actual guarantee of the continuous greedy algorithm is $(1 - 1/e - o(1))$. However, for simplicity of presentation, we can ignore the $o(1)$ term due to the existence of a loss of ε (for any constant ε) in all of our theorems.

a parameter to be chosen later). Thus, the collections of critical packing and covering constraints, for a given guess D, are given by: $Y_D \triangleq \{i = 1, \ldots, p : (\mathbf{r}_D)_i \leq \delta\}$ and $Z_D \triangleq \{j = 1, \ldots, c : (\mathbf{s}_D)_j \leq \delta \mathbf{c}'_j\}$. Moreover, elements are considered *large* if their size is at least some factor α of the residual value of some non-critical constraint ($\alpha \in (0, 1)$ is a parameter to be chosen later). Formally, the collection of large elements with respect to the packing constraints is defined as $P_D \triangleq \{\ell \in \tilde{\mathcal{N}} : \exists i \notin Y_D \text{ s.t. } \mathbf{P}_{i,\ell} \geq \alpha(\mathbf{r}_D)_i\}$, and the collection of large elements with respect to the covering constraints is defined as $C_D = \{\ell \in \tilde{\mathcal{N}} : \exists j \notin Z_D \text{ s.t. } \mathbf{C}_{j,\ell} \geq \alpha(\mathbf{s}_D)_j\}$. It is important to note, as previously mentioned, that the notion of a large element is with respect to the residual constraint, as opposed to previous works [9, 32] where the definition is with respect to the original constraint. Let us now formally define when a guess D is called *consistent*.

▶ **Definition 1.** *A guess $D = (E_0, E_1, \mathbf{c}')$ is* consistent *if:* (1) $E_0 \cap E_1 = \emptyset$; (2) $\mathbf{c}' \geq \mathbf{1}_c$; (3) $\mathbf{P}\mathbf{1}_{E_1} \leq \mathbf{1}_p$; *and* (4) $P_D = C_D = \emptyset$.

Intuitively, requirement (1) states that a variable cannot be both chosen and discarded, (2) states that the each covering constraint is satisfied by an optimal solution O, (3) states the chosen elements E_1 do not violate the packing constraints, and (4) states that no large elements remain in any non-critical constraint.

Finally, we need to define when a consistent guess is *correct*. Assume without loss of generality that $O = \{o_1, \ldots, o_k\}$ and the elements of O are ordered greedily: $f_{\{o_1,\ldots,o_i\}}(o_{i+1}) \leq f_{\{o_1,\ldots,o_{i-1}\}}(o_i)$ for every $i = 1, \ldots, k-1$. In the following definition γ is a parameter to be chosen later.

▶ **Definition 2.** *A consistent guess $D = (E_0, E_1, \mathbf{c}')$ is called* correct *with respect to O if:* (1) $E_1 \subseteq O$; (2) $E_0 \subseteq \bar{O}$; (3) $\{o_1, \ldots, o_\gamma\} \subseteq E_1$; *and* (4) $\mathbf{c}' \leq \mathbf{C}\mathbf{1}_O \leq (1+\delta)\mathbf{c}'$.

Intuitively, requirement (1) states that the chosen elements E_1 are indeed elements of O, (2) states that no element of O is discarded, (3) states that the γ elements of largest marginal value are all chosen, and (4) states that $\mathbf{c}'$ represents (up to a factor of $1+\delta$) how much O actually covers each of the covering constraints.

We are now ready to present our preprocessing algorithm (Algorithm 1), which produces a list $\mathcal{L}$ of consistent guesses that is guaranteed to contain at least one guess that is also correct with respect to O. Lemma 7 summarizes this, its proof appears in [36].

Algorithm 1: Preprocessing.

```
L ← ∅
foreach j_1, ..., j_c ∈ {0, 1, ..., ⌈log_{1+δ} n⌉} do
    Let c' = ((1+δ)^{j_1}, ..., (1+δ)^{j_c})
    foreach E_1 ⊆ N such that |E_1| ≤ γ + (p+c)/(αδ) do
        Let H = (∅, E_1, c')
        Let E_0 = {ℓ ∈ N \ E_1 : f_{E_1}(ℓ) > (γ^{-1}) f(E_1)} ∪ P_H ∪ C_H
        Set D = (E_0, E_1, c')
        If D is consistent according to Definition 1 add it to L.
Output L.
```

▶ **Lemma 7.** *The output $\mathcal{L}$ of Algorithm 1 contains at least one guess D that is correct with respect to some optimal solution O.*

Proof. Fix any optimal solution O. At least one of the vectors $\mathbf{c}'$ enumerated by Algorithm 1 satisfies property (4) in Definition 2 with respect to O. Let us fix an iteration in which such a $\mathbf{c}'$ is enumerated. Define the "large" elements O has with respect to this $\mathbf{c}'$:

$$O_L \triangleq \{\ell \in O : \exists i \text{ s.t. } \mathbf{P}_{i,\ell} \geq \alpha\delta\} \cup \left\{\ell \in O : \exists j \text{ s.t. } \mathbf{C}_{j,\ell} \geq \alpha\delta\mathbf{c}'_j\right\}. \tag{2}$$

Denote by $O_\gamma \triangleq \{o_1, \ldots, o_\gamma\}$ the γ elements of O with the largest marginal (recall the ordering of O satisfies: $f_{\{o_1,\ldots,o_i\}}(o_{i+1}) \leq f_{\{o_1,\ldots,o_{i-1}\}}(o_i)$). Let us fix $E_1 \triangleq O_\gamma \cup O_L$ and choose $H \triangleq (\emptyset, E_1, \mathbf{c}')$. Clearly, $|E_1| \leq \gamma + {}^{(p+c)}/_{(\alpha\delta)}$ since $|O_\gamma| = \gamma$ and $|O_L| \leq {}^{(p+c)}/_{(\alpha\delta)}$. Hence, we can conclude that H is considered by Algorithm 1.

We fix the iteration in which the above H is considered and show that the resulting $D = (E_0, E_1, \mathbf{c}')$ of this iteration is correct and consistent (recall that Algorithm 1 chooses $E_0 = \{\ell \in \mathcal{N} \setminus E_1 : f_{E_1}(\ell) > (\gamma^{-1})f(E_1)\} \cup P_H \cup C_H$). The following two observations suffice to complete the proof:

Observation 1: $\forall \ell \in O \cup (\mathcal{N} \setminus E_0)$: $f_{E_1}(\ell) \leq \gamma^{-1} f(E_1)$.

Observation 2: $O \cap P_H = \emptyset$ and $O \cap C_H = \emptyset$.

Clearly properties (1) and (3) of Definition 2 are satisfied by construction of E_1, H, and subsequently D. Property (2) of Definition 2 requires the above two observations, which together imply that no element of O is added to E_0 by Algorithm 1. Thus, all four properties of Definition 2 are satisfied, and we focus on showing that the above D is consistent according to Definition 1. Property (1) of Definition 1 follows from properties (1) and (2) of Definition 2. Property (2) of Definition 1 follows from the choice of $\mathbf{c}'$. Property (3) of Definition 1 follows from the feasibility of O and property (1) of Definition 2. Lastly, property (4) of Definition 1 follows from the fact that $P_D \subseteq P_H$ and that $P_H \subseteq E_0$, implying that $P_D = \emptyset$ (the same argument applies to C_D). We are left with proving the above two observations.

We start with proving the first observation. Let $\ell \in O \cup (\mathcal{N} \setminus E_0)$. If $\ell \in \mathcal{N} \setminus E_0$ then the observation follows by the construction of E_0 in Algorithm 1. Otherwise, $\ell \in O$. If $\ell \in O_\gamma$ then we have that $f_{E_1}(\ell) = 0$ since $O_\gamma \subseteq E_1$. Otherwise $\ell \in O \setminus O_\gamma$. Note:

$$f_{E_1}(\ell) \leq f_{O_\gamma}(\ell) \leq \gamma^{-1} f(O_\gamma) \leq \gamma^{-1} f(E_1).$$

The first inequality follows from diminishing returns and $O_\gamma \subseteq E_1$. The third and last inequality follows from the monotonicity of f and $O_\gamma \subseteq E_1$. Let us focus on the second inequality, and denote $O = \{o_1, \ldots, o_k\}$ and the sequence $a_i \triangleq f_{\{o_1,\ldots,o_{i-1}\}}(o_i)$. The sequence of a_is is monotone non-increasing by the ordering of O and the monotonicity of f implies that all a_is are non-negative. Note that $a_1 + \ldots + a_\gamma = f(O_\gamma)$, thus implying that $f_{O_\gamma}(\ell) \leq \gamma^{-1} f(O_\gamma)$ for every $\ell \in \{o_{\gamma+1}, \ldots, o_k\}$ (otherwise $a_1 + \ldots + a_\gamma > f(O_\gamma)$). The second inequality above, *i.e.*, $f_{O_\gamma}(\ell) \leq \gamma^{-1} f(O_\gamma)$, now follows since $\ell \in O \setminus O_\gamma = \{o_{\gamma+1}, \ldots, o_k\}$.

Let us now focus on proving the second observation. Let us assume on the contrary that there is an element ℓ such that $\ell \in O \cap P_H$. Recall that $P_H = \{\ell \in \mathcal{N} \setminus E_1 : \exists i \notin Y_H \text{ s.t. } \mathbf{P}_{i,\ell} \geq \alpha(\mathbf{r}_H)_i\}$ where $Y_H = \{i : (\mathbf{r}_H)_i \leq \delta\}$. This implies that $\ell \in O \setminus E_1$, namely that $\ell \notin O_L$, from which we derive that for *all* packing constraint i we have that $\mathbf{P}_{i,\ell} < \alpha\delta$. Since $\ell \in P_H$ we conclude that there exists a packing constraint i for which $(\mathbf{r}_H)_i \leq \mathbf{P}_{i,\ell}/\alpha$. Combining the last two bounds we conclude that $(\mathbf{r}_H)_i < \delta$, which implies that the i^{th} packing constraint is critical, *i.e.*, $i \in Y_H$. This is a contradiction, and hence $O \cap P_H = \emptyset$. A similar proof applies to C_H and the covering constraints. □ ◀

Randomized Rounding. Before presenting our main rounding algorithm, let us define the residual problem we are required to solve given a consistent guess D. First, the residual objective $g : 2^{\tilde{\mathcal{N}}} \to \mathbb{R}_+$ is defined as: $g(S) \triangleq f(S \cup E_1) - f(E_1)$ for every $S \subseteq \tilde{\mathcal{N}}$. Clearly, g

is submodular, non-negative, and monotone. Second, let us focus on the feasible domain and denote by $\tilde{\mathbf{P}}$ ($\tilde{\mathbf{C}}$) the submatrix of $\mathbf{P}$ ($\mathbf{C}$) obtained by choosing all the columns in $\tilde{\mathcal{N}}$. Hence, given $D = (E_0, E_1, \mathbf{c}')$ the residual problem is:

$$\max\{g(S) + f(E_1) : S \subseteq \tilde{\mathcal{N}}, \tilde{\mathbf{P}}\mathbf{1}_S \leq \mathbf{r}_D, \tilde{\mathbf{C}}\mathbf{1}_S \geq \mathbf{s}_D\}. \tag{3}$$

In order to formulate the multilinear relaxation of (3), consider the following two polytopes: $\mathcal{P} \triangleq \{\mathbf{x} \in [0,1]^{\tilde{\mathcal{N}}} : \tilde{\mathbf{P}}\mathbf{x} \leq \mathbf{r}_D\}$ and $\mathcal{C} \triangleq \{\mathbf{x} \in [0,1]^{\tilde{\mathcal{N}}} : \tilde{\mathbf{P}}\mathbf{x} \geq \mathbf{s}_D\}$. Let $G : [0,1]^{\tilde{\mathcal{N}}} \to \mathbb{R}_+$ be the multilinear extension of g. Thus, the continuous multilinear relaxation of (3) is:

$$\max\left\{f(E_1) + G(\mathbf{x}) : \mathbf{x} \in [0,1]^{\tilde{\mathcal{N}}}, \mathbf{x} \in \mathcal{P} \cap \mathcal{C}\right\}. \tag{4}$$

Our algorithm performs randomized rounding of a fractional solution to the above relaxation (4). However, this is not enough to obtain our main result and an additional post-processing step is required in which additional elements are discarded. Since covering constraints are present, one needs to perform the post-processing step in great care. To this end we denote by L_D the collection of large elements with respect to some critical packing constraint: $L_D \triangleq \{\ell \in \tilde{\mathcal{N}} : \exists i \in Y_D \text{ s.t. } \mathbf{P}_{i,\ell} \geq \beta \mathbf{r}_D\}$ ($\beta \in (0,1)$ is a parameter to be chosen later). Intuitively, we would like to discard elements in L_D since choosing any one of those will incur a violation of a packing constraint. We are now ready to present our rounding algorithm (Algorithm 2).

Algorithm 2: $(f, \mathcal{N}, \mathbf{P}, \mathbf{C})$.

1 Use Algorithm 1 to obtain a list of guesses $\mathcal{L}$.
2 **foreach** $D = (E_0, E_1, \mathbf{c}') \in \mathcal{L}$ **do**
3 Use Theorem 6 to compute an approximate solution $\mathbf{x}^*$ to problem (4).
4 Scale down $\mathbf{x}^*$ to $\bar{\mathbf{x}} = \mathbf{x}^*/(1+\delta)$
5 Let R_D be such that for every $\ell \in \tilde{\mathcal{N}}$ independently: $\Pr[\ell \in R_D] = \bar{\mathbf{x}}_\ell$.
6 Let $R'_D = R_D \setminus L_D$.
7 $S_D \leftarrow E_1 \cup R'_D$.
8 $S_{alg} \leftarrow \operatorname{argmax}\{f(S_D) : D \in \mathcal{L}, \mathbf{P} \cdot \mathbf{1}_{S_D} \leq \mathbf{1}_p, \mathbf{C} \cdot \mathbf{1}_{S_D} \geq (1-\varepsilon)\mathbf{1}_c\}$

We note that Line 6 of Algorithm 2 is the post-processing step where all elements of L_D are discarded. Our analysis of Algorithm 2 shows that in an iteration a correct guess D is examined, with a constant probability, S_D satisfies the packing constraints, violates the covering constraint by only a fraction of ε, and $f(S_D)$ is sufficiently high.

The following lemma gives a lower bound on the value of the fractional solution $\bar{\mathbf{x}}$ computed by Algorithm 2 (for a full proof refer [36]).

▶ **Lemma 8.** *If $D \in \mathcal{L}$ is correct then in the iteration of Algorithm 2 it is examined the resulting $\bar{\mathbf{x}}$ satisfies: $G(\bar{\mathbf{x}}) \geq (1 - 1/e - \delta)f(O) - f(E_1)$.*

Let us now fix an iteration of Algorithm 2 for which D is not only consistent but also correct (the existence of such an iteration is guaranteed by Lemma 7). Intuitively, Algorithm 2 performs a straightforward randomized rounding where each element $\ell \in \tilde{\mathcal{N}}$ is independently chosen with a probability that corresponds to its fractional value in the solution of the multilinear relaxation (4). However, two key ingredients in Algorithm 2 are required in order to achieve an ε violation of the covering constraints and no violation of the packing constraints: (1) *scaling*: prior to the randomized rounding $\mathbf{x}^*$ is scaled down by a factor $(1+\delta)$ (line 4 in Algorithm 2); and (2) *post-processing*: after the randomized rounding all chosen large elements in a critical packing constraint are discarded (line 6 in Algorithm 2).

The first ingredient above (scaling of $\mathbf{x}^*$) allows us to prove using standard concentration bounds that with good probability all non-critical packing constraints are not violated. However, when considering critical packing constraints this does not suffice and the second ingredient above (discarding L_D) is required to show that with good probability even the critical packing constraints are not violated. While discarding L_D is beneficial when considering packing constraints, it might have a destructive effect on both the covering constraints and the value of the objective. To remedy this we argue that with high probability only few elements in L_D are actually discarded, *i.e.*, $|R_D \cap L_D|$ is sufficiently small. Combining the latter fact with the assumption that the current guess D is not only consistent but also correct, according to Definition 2, allows us to prove the following lemma (for a full proof refer to [36]).

▶ **Lemma 9.** *For any constant $\varepsilon > 0$, choose constants $\alpha = \delta^3$, $\beta = \delta^2/(3b)$, $\gamma = 1/\delta^3$, and $\delta < \min\{1/(15(p+c)), \varepsilon/(2+30(p+c)^2)\}$. With a probability of at least $1/2$ Algorithm 2 outputs a solution S_{alg} satisfying: (1) $\mathbf{P}\mathbf{1}_{S_{alg}} \leq \mathbf{1}_p$; (2) $\mathbf{C}\mathbf{1}_{S_{alg}} \geq (1-\varepsilon)\mathbf{1}_c$; and (3) $f(S_{alg}) \geq (1 - 1/e - \varepsilon)f(O)$.*

The above lemma suffices to prove Theorem 1, as it immediately implies it.

4 Greedy Dynamic Programming

In this section, we present a novel algorithmic approach for submodular maximization that leads to *deterministic* and considerably faster approximation algorithms in several settings. Perhaps the most notable application of our approach is Theorem 4. To the best of our knowledge, it provides the first *deterministic* non-trivial approximation algorithm for maximizing a monotone submodular function subject to packing constraints. To highlight the core idea of our approach, we first present a vanilla version of the greedy dynamic programming approach applied to (PCSM) that gives a constant-factor approximation and satisfies the packing constraints, but violates the covering constraints by a factor of 2 and works in pseudo-polynomial time.

Vanilla Greedy Dynamic Programming. Let us start with a sketch of the algorithm's definition and analysis. For simplicity of presentation, we assume in the current discussion relating to pseudo-polynomial time algorithms that $\mathbf{C} \in \mathbb{N}_+^{c \times n}$ and $\mathbf{P} \in \mathbb{N}_+^{p \times n}$. Let $\mathbf{p} \in \mathbb{N}_+^p$ and $\mathbf{c} \in \mathbb{N}_+^c$ be the packing and covering requirements, respectively. A solution $S \subseteq \mathcal{N}$ is feasible if and only if $\mathbf{C} \cdot \mathbf{1}_S \geq \mathbf{c}$ and $\mathbf{P} \cdot \mathbf{1}_S \leq \mathbf{p}$. We also use the following notations: $c_{\max} = \|\mathbf{c}\|_\infty$, $p_{\max} = \|\mathbf{p}\|_\infty$, and $[s]_0 = \{0, \ldots, s\}$ for every integer s.

We define our dynamic programming as follows: for every $q \in [n]_0$, $\mathbf{c}' \in [n \cdot c_{\max}]_0^c$, and $\mathbf{p}' \in [p_{\max}]_0^p$ a table entry $T[q, \mathbf{c}', \mathbf{p}']$ is defined and it stores an approximate solution S of cardinality q with $\mathbf{C} \cdot \mathbf{1}_S = \mathbf{c}'$ and $\mathbf{P} \cdot \mathbf{1}_S = \mathbf{p}'$. [8] For the base case, we set $T[0, \mathbf{0}_c, \mathbf{0}_p] \leftarrow \varnothing$. For populating $T[q, \mathbf{c}', \mathbf{p}']$ when $q > 0$, we examine every set of the form $T[q-1, \mathbf{c}' - \mathbf{C}_\ell, \mathbf{p}' - \mathbf{P}_\ell] \cup \{\ell\}$, where ℓ satisfies $\ell \in \mathcal{N} \setminus T[q-1, \mathbf{c}' - \mathbf{C}_\ell, \mathbf{p}' - \mathbf{P}_\ell]$, $\mathbf{c}' - \mathbf{C}_\ell \geq 0$, and $\mathbf{p}' - \mathbf{P}_\ell \geq 0$. Out of all these sets, we assign the most valuable one to $T[q, \mathbf{c}', \mathbf{p}']$. Note that this operation stores a *greedy approximate* solution in the table entry $T[q, \mathbf{c}', \mathbf{p}']$. The output of our algorithm is the best of the solutions $T[q, \mathbf{c}', \mathbf{p}']$, for $1 \leq q \leq n$, $\mathbf{c}' \geq \mathbf{c}/2$ and $\mathbf{p}' \leq \mathbf{p}$. See Algorithm 3 for pseudo code.

[8] We introduce a dummy solution $\perp$ for denoting undefined table entries, and initialize the entire table with $\perp$. For the exact details we refer to [36].

Algorithm 3: Vanilla Greedy Dynamic Program.

create a table $T\colon [n]_0 \times [n \cdot c_{\max}]_0^c \times [p_{\max}]_0^p \to 2^{\mathcal{N}}$ initialized with entries $\perp$
$T[0, \mathbf{0}_c, \mathbf{0}_p] \leftarrow \varnothing$
for $q = 0$ **to** n **do**
  foreach $\mathbf{c}' \in [n \cdot c_{\max}]_0^c$ *and* $\mathbf{p}' \in [p_{\max}]_0^p$ **do**
    foreach $\ell \in \mathcal{N} \setminus T[q, \mathbf{c}', \mathbf{p}']$ **do**
      $\mathbf{c}'' \leftarrow \mathbf{c}' + \mathbf{C}_\ell$, $\mathbf{p}'' \leftarrow \mathbf{p}' + \mathbf{P}_\ell$
      $T[q+1, \mathbf{c}'', \mathbf{p}''] \leftarrow \arg\max\{f(T[q+1, \mathbf{c}'', \mathbf{p}'']), f(T[q, \mathbf{c}', \mathbf{p}'] \cup \{\ell\})\}$
Output $\operatorname{argmax}_{q, \mathbf{c}' \geq \mathbf{c}/2, \mathbf{p}' \leq \mathbf{p}} f(T[q, \mathbf{c}', \mathbf{p}'])$.

Let us now sketch the analysis of the above algorithm. Let O be an optimal set solution. We consider an arbitrary permutation of O, say $\{o^1, o^2, \ldots, o^k\}$. Let $O^i = \{o^1, \ldots, o^i\}$ be the set of the first i elements in this permutation and let $O^0 = \emptyset$. We introduce the function $g\colon O \to \mathbb{R}_+$ for denoting the *marginal* value of the elements in O. More precisely, let $g(o^i) = f_{O^{i-1}}(o^i)$. Note that $f(O) = \sum_{\ell \in O} g(\ell)$. Let for any subset $S \subseteq O$, $g(S) = \sum_{\ell \in S} g(\ell)$. We then inductively construct an order $o_1, \ldots, o_k$ of O with the intention of upper bounding for every prefix $O_q = \{o_1, \ldots, o_q\}$ the value $g(O_q)$ in terms of the value $f(S_q)$ of the table entry $S_q := T[q, \mathbf{C1}_{O_q}, \mathbf{P1}_{O_q}]$ *corresponding to* O_q. The construction of the sequence $o_1, \ldots, o_k$ divides $[k]$ into m phases where m is a positive integer parameter. A (possibly empty) phase $i \in [m]$ is characterized by the following property. Consider a prefix O_q and its corresponding table entry S_q. If q is in phase i then there exists an element $o_{q+1} \in O \setminus O_q$ such that adding o_{q+1} to S_q increases f by at least an amount of $(1 - i/m)g(o_{q+1})$. We set $O_{q+1} = O_q \cup \{o_{q+1}\}$. Thus, in earlier phases we make more progress in the corresponding dynamic programming solution S_q relative to $g(O_q)$ than in later phases. Additionally, we can prove a complementing inequality. At the end of phase $i \in [m]$ all elements in $O \setminus O_q$ increase f by no more than $(1 - i/m)g(o_{q+1})$. We prove that this implies that $f(S_q)$ is at least $i/m \cdot g(O \setminus O_q)$ and thus large relatively to the *complement* of O_q. We set up a factor-revealing linear program that constructs the worst distribution of the marginal values over the phases that satisfy the above inequalities. For the purpose of analysis, by scaling, we assume that $f(O) = \sum_{o \in O} g(o) = 1$. The following lemma formalizes the above sketch. It is also the basis for the *factor-revealing* LP below (for its proof refer to [36]).

▶ **Lemma 10.** *Let $m \geq 1$ be an integral parameter. We can pick for each $i \in [m]$ a set $O_i = \{o_1^i, o_2^i, \ldots, o_{q_i}^i\} \subseteq O$ (possibly empty) such that the following holds. For $i \neq j$, we have that $O_i \cap O_j = \varnothing$. Let $L_i = \sum_{j=1}^i q_j$, $Q_i = \cup_{j=1}^i O_j$, $\mathbf{c}_i = \mathbf{C1}_{Q_i}$, $\mathbf{p}_i = \mathbf{P1}_{Q_i}$ and let $A_i := T[L_i, \mathbf{c}_i, \mathbf{p}_i]$ be the corresponding DP cell. Then $\mathbf{C1}_{A_m} \geq \mathbf{c}/2$ and the following inequalities hold.*

1. $f(A_0) = g(O_0)$ *where* $A_0 = O_0 = \varnothing$,
2. $f(A_i) \geq f(A_{i-1}) + (1 - i/m)g(O_i)$ $\forall i \in [m]$ *and*
3. $f(A_i) \geq \frac{i}{m}\left(1 - \sum_{j \leq i} g(O_j)\right)$ $\forall i \in \{0\} \cup [m]$.

Below we describe a *factor-revealing* LP that captures the above-described multi-phase analysis for the greedy DP algorithm. The idea is to introduce variables for the quantities in the inequalities in the previous lemma and determining the minimum ratio that can be

guaranteed by these inequalities.

$$\begin{aligned}
&\min\ a_m && \text{s.t.} && && \text{(LP)}\\
&\quad a_1 \geq \left(1-\tfrac{1}{m}\right) o_1; && && && (5)\\
&\quad a_i \geq a_{i-1} + \left(1-\tfrac{i}{m}\right) o_i && \forall i \in [m]\setminus\{1\}; && (6)\\
&\quad a_i \geq \tfrac{i}{m}\left(1-\textstyle\sum_{j\leq i} o_j\right) && \forall i \in [m]; && (7)\\
&\quad a_i \geq 0,\ o_i \geq 0 && \forall i \in [m]. && (8)
\end{aligned}$$

The variable o_i corresponds to the marginal value $g(O_i)$ for the set O_i in our analysis. Variables a_i correspond to the quantities $f(A_i)$ for the approximate solution A_i for each phase $i = 1, 2, \ldots, m$. We add all the inequalities we proved in Lemma 10 as the constraints for this LP. Note that since $f(O) = 1$, the minimum possible value of a_m will correspond to a lower bound on the approximation ratio of our algorithm.

The following is the dual for the above LP.

$$\begin{aligned}
&\max\ \textstyle\sum_{i=1}^{m} \frac{i}{m} y_i && \text{s.t.} && && \text{(DP)}\\
&\quad x_i + y_i - x_{i+1} \leq 0 && && \forall i \in [m-1]; && (9)\\
&\quad x_m + y_m \leq 1; && && && (10)\\
&\quad \textstyle\sum_{j\geq i} \frac{j}{m} y_j - (1-\frac{i}{m}) x_i \leq 0 && \forall i \in [m]; && (11)\\
&\quad x_i \geq 0,\ y_i \geq 0 && \forall i \in [m]. && (12)
\end{aligned}$$

This linear program gives for every m a lower bound on the approximation ratio. Analytically, we can show that if m tends to infinity the optimum value of the LP converges to $1/e$. This leads to the following lemma (for its proof refer to [36]).

▶ **Lemma 11.** *Assuming p and c are constants, the vanilla greedy dynamic programming algorithm for* (PCSM) *runs in pseudo-polynomial time $O(n^2 p_{\max} c_{\max})$ and outputs a solution $S \subseteq \mathcal{N}$ that satisfies:* (1) $f(S) \geq (1/e) \cdot f(O)$, (2) $\mathbf{P1}_S \leq \mathbf{p}$ *and* $\mathbf{C1}_S \geq 1/2 \cdot \mathbf{c}$.

Applications and Extensions of Greedy Dynamic Programming Approach

We briefly explain the applications of the approach to the various specific settings and the required tailored algorithmic extensions to the vanilla version of the algorithm.

Scaling, guessing and post-processing for packing constraints. An immediate consequence of Lemma 11 is a *deterministic* $(1/e)$-approximation for the case of constantly many packing constraints that runs in pseudo-polynomial time. We can apply standard scaling techniques to achieve truly polynomial time. This may, however, introduce a violation of the constraints within a factor of $(1 + \varepsilon)$. To avoid this violation, we can apply a pre-processing and post-processing by Kulik et al. [32] to achieve Theorem 4.

Forbidden sets for a single packing and a single covering constraints. In this setting we are able to ensure a $(1 - \varepsilon)$-violation of the covering constraints by using the concept of *forbidden sets*. Intuitively, we exclude the elements of these set from being included to the dynamic programming table in order to be able to complete the table entries to solutions with only small violation.

Fix some $\varepsilon > 0$. By guessing we assume that we know the set G of all, at most $1/\varepsilon$ elements ℓ from the optimum solution with $\mathbf{P}_\ell > \varepsilon \cdot \mathbf{p}$. We can guess G using brute force in $n^{O(1/\varepsilon)}$ time. This allows us to remove all elements with $\mathbf{P}_\ell \geq \varepsilon \cdot \mathbf{p}$ from the instance. Let $\mathcal{N}'$ be the rest of the elements. (For consistency reasons, we use bold-face vector notation here also for dimension one.)

Fix an order of $\mathcal{N}'$ in which the elements are sorted in a non-increasing order of $\mathbf{C}_\ell/\mathbf{P}_\ell$ values, breaking ties arbitrarily. Let $\mathcal{N}_i$ be the set of the first i elements in this order. For any $\mathbf{p}' \leq \mathbf{p}$, let $F_{\mathbf{p}'}$ be the smallest set $\mathcal{N}_i$ with $\mathbf{P}\mathbf{1}_{\mathcal{N}_i} \geq \mathbf{p} - \mathbf{p}'$. Note that the profit of $F_{\mathbf{p}'}$ is at least the profit of any subset of $\mathcal{N}'$ with packing value at most $\mathbf{p} - \mathbf{p}'$ and that the packing value of $F_{\mathbf{p}'}$ is no larger than $(1+\varepsilon)\mathbf{p} - \mathbf{p}'$. Also note that for any $0 \leq \mathbf{p}' \leq \mathbf{p}'' \leq \mathbf{p}$, it holds that $F_{\mathbf{p}''} \subseteq F_{\mathbf{p}'}$.

Now we explain the modified Greedy-DP that incorporates the guessing and the forbidden sets ideas. Let G be the set of the guessed big elements as described above. For the base case, we set $T[\mathbf{C}\mathbf{1}_G, \mathbf{P}\mathbf{1}_G] = G$ and $T[\mathbf{c}', \mathbf{p}'] = \perp$ for all table entries with $\mathbf{c}' \neq \mathbf{C}\mathbf{1}_G$ or $\mathbf{p}' \neq \mathbf{P}\mathbf{1}_G$.

In order to compute $T[\mathbf{c}', \mathbf{p}']$, we look at every set of the form $T[\mathbf{c}' - \mathbf{C}_\ell, \mathbf{p}' - \mathbf{P}_\ell] \cup \{\ell\}$, where $\ell \in \mathcal{N} \setminus (T[\mathbf{c}' - \mathbf{C}_\ell, \mathbf{p}' - \mathbf{P}_\ell] \cup F_{\mathbf{p}'})$, $\mathbf{c}' - \mathbf{C}_\ell \geq 0$, and $\mathbf{p}' - \mathbf{P}_\ell \geq 0$. Notice that we forbid elements belonging to $F_{\mathbf{p}'}$ to be included in any table entry of the form $T[\mathbf{c}', \mathbf{p}']$. Now out of all these sets, we assign the most valuable set to $T[\mathbf{c}', \mathbf{p}']$. The output of our algorithm is the best of the solutions $T[\mathbf{c}', \mathbf{p}'] \cup F_{\mathbf{p}'}$, such that $\mathbf{c}' + \mathbf{C}\mathbf{1}_{F_{\mathbf{p}'}} \geq \mathbf{c}$.

By means of a more sophisticated factor-revealing LP, we obtain Theorem 5. Finally, if the packing constraint is actually a cardinality constraint we can assume that $\varepsilon < 1/\mathbf{p}$. Hence, there will be no violation of the cardinality constraint and also guessing can be avoided.

5 Extensions: Matroid Independence and Multi-Objective

Refer to [36] for the extensions that deal with a matroid independence constraint and with multiple objectives.

Scheduling to Approximate Minimization Objectives on Identical Machines

Abstract

This paper considers scheduling on identical machines. The scheduling objective considered in this paper generalizes most scheduling minimization problems. In the problem, there are n jobs and each job j is associated with a monotonically increasing function g_j. The goal is to design a schedule that minimizes $\sum_{j\in[n]} g_j(C_j)$ where C_j is the completion time of job j in the schedule. An $O(1)$-approximation is known for the single machine case. On multiple machines, this paper shows that if the scheduler is required to be either non-migratory or non-preemptive then any algorithm has an unbounded approximation ratio. Using preemption and migration, this paper gives a $O(\log\log nP)$-approximation on multiple machines, the *first* result on multiple machines. These results imply the first non-trivial positive results for several special cases of the problem considered, such as throughput minimization and tardiness.

Natural linear programs known for the problem have a poor integrality gap. The results are obtained by strengthening a natural linear program for the problem with a set of covering inequalities we call *job cover inequalities*. This linear program is rounded to an integral solution by building on quasi-uniform sampling and rounding techniques.

1 Introduction

A common optimization challenge is scheduling a set of n jobs on m identical machines to optimize the quality of service delivered to the jobs. The quality of service objective could be: a delay based objective, such as minimizing the average waiting time; a fairness objective ensuring resources are shared fairly between jobs, such as the ℓ_2-norm of the waiting time; or a real-time objective such as ensuring a small number of jobs are not completed by their deadline.

Scheduling Model. This paper develops an algorithm that has strong guarantees for most reasonable objectives. This work considers the *identical* machines setting where all jobs are available at the same time. Each job j has a processing time p_j. The job can be processed on m identical machines where the processing time of the job is the same on all machines. This work assumes that *preemption* and *migration* are allowed. That is jobs can be stopped and resumed at a later time, possibly on a different machine.

This paper initiates the study of the general scheduling problem (GSP) on identical machines. In this problem, each job j has a function $g_j(t) : \mathbb{R}^+ \to \mathbb{R}^+$. The value of $g_j(t)$ specifies the cost of completing job j at time t. The goal is to design an algorithm that completes each job j at time C_j to minimize $\sum_{j\in[n]} g_j(C_j)$. No assumptions on the functions are made except that they are positive and non-decreasing, so there never is an incentive to have a job wait longer to be completed. Note that each job has its own, *individual*, cost function. In several systems, it is the case that jobs can be associated with distinct cost functions [15, 16, 17].

The problem generalizes many scheduling objectives. Examples include the following. In the following descriptions, each job j has a positive weight w_j denoting its priority.

- **Weighted Completion Time:** A job's cost is its weight multiplied by its completion time. The completion time is how long the job waits in the system and this objective focuses on minimizing the priority scaled average waiting time. This objective is captured by setting $g_j(t) = w_j \cdot t$.
- **Weighted kth Norm of Completion Time:** This objective focuses on minimizing $\sqrt[k]{\sum_{j\in[n]} w_j C_j^k}$ or, by removing the outer kth root, $\sum_{j\in[n]} w_j C_j^k$. This objective is captured by setting $g_j(t) = w_j \cdot t^k$. This is used to enforce fairness in the schedule and typically $k \in \{2, 3\}$.
- **Weighted Throughput Minimization:** The goal is to minimize the weighted number of jobs that miss their deadline. Each job j has a deadline d_j. Setting $g_j(t) = 0$ for $t \leq d_j$ and w_j otherwise gives this objective.
- **Weighted Tardiness:** Each job has no cost if completed before its deadline and otherwise the job pays its weighted waiting time after is deadline. Each job has a deadline d_j and weight w_j. This objective is obtained by setting $g_j(t) = 0$ for $t \leq d_j$ and $w_j(t - d_j)$ otherwise.
- **Exponential Completion Time:** In this objective a job's cost grows exponentially with its completion time. The objective is captured by setting $g_j(t) = w_j \cdot \exp(t)$.

These problems have been challenging to understand. The problem considered is NP-Hard, even on a single machine and the cost functions are piecewise linear [10]. It is known that Smith's rule is optimal for minimizing the total weighted completion time [21]. Bansal and Pruhs in a breakthrough result introduced a $O(1)$-approximation algorithm for the general scheduling problem on a single machine [2]. Cheung et al. improved this to show a $(4 + \epsilon)$ approximation [6, 7, 18]. Antoniadis et al. gave a quasi-polynomial time approximation scheme on a single machine [1, 11].

The next step in this line of work is to generalize these techniques to multiple machine environments, but there is a clear barrier when generalizing past approaches to multiple machines. Prior work introduced a strong linear program that uses a polynomial number of knapsack cover inequalities. See [3] for details on knapsack cover inequalities. The inequalities in [2, 7, 18] are weak in multiple machine environments and result in linear programs with an unbounded integrality gap.

An open question is if there exists a linear program with a small integrality gap for multiple machines. Further, are there good approximation algorithms for the GSP on multiple machines.

Results. This paper studies the GSP in the identical machine environment. The paper shows the following theorem. The technical contributions that result in this theorem are the derivation of valid strong linear program inequalities that are used to strengthen a natural linear program relaxation of the problem and an iterative rounding technique that builds on quasi-uniform sampling [22].

▶ **Theorem 1.** *There is a randomized algorithm that achieves a $O(\log \log nP)$ approximation in expectation and runs in expected polynomial time for the GSP on multiple identical machines with preemption and migration where P is the ratio of the maximum to minimum job size.*

A natural question is if preemption and migration are necessary for an algorithm to have a good approximation ratio. This paper shows that they are by establishing that any scheduler required to be non-preemptive or non-migratory has an unbounded approximation ratio unless $P = NP$. The proof is omitted

▶ **Theorem 2.** *The approximation ratio of any algorithm for GSP is unbounded unless P=NP if either the algorithm is required to be non-migratory or non-preemptive on m identical machines.*

Overview of Technical Contributions. The main result is enabled by a set of strengthening inequalities added to a natural linear program (LP) for the problem. The paper calls these inequalities, **job cover inequalities**. See Section 4. These inequalities are needed because without them the LP introduced in this paper has an unbounded integrality gap even if all jobs arrive at the same time on a single machine[1]. Other natural LP relaxations, such as a time indexed LP, also have an unbounded gap even on a single machine [2, 7].

Prior work on a single machine also used a set of covering inequalities to strengthen a linear program. These inequalities consider every interval I and the set of jobs that arrive during the interval S_I. A constraint states that the total processing time of jobs in S_I that are completed after I ends must be greater than the total processing time of jobs in S_I minus the length of I [2, 7]. This is a covering constraint ensuring that the jobs arriving during I that complete during I have total size at most the length of I. These covering constraints are strengthened using knapsack cover inequalities. If such constraints are satisfied integrally then the Earliest-Deadline-First algorithm can be used to construct a schedule of the same cost as the LP.

A natural idea to extend this to identical machines is to use the same constraint, but the total work completed after I ends must be greater than the size of jobs in S_I minus m times the length of I. This generalization takes into account that each machine can be busy during I. Then the natural next step is to use knapsack cover inequalities to strengthen this new set of constraints. Unfortunately, it is easy to show such inequalities are insufficient and result in an LP with a large integrality gap. There are several issues and they are all rooted in the fact that this does not take into account that a job can only be processed on one machine at any point in time. To overcome this shortcoming, this paper considers covering constraints used to strengthen a minimum cut constraint arises from a natural bipartite flow problem.

This paper proceeds by first reducing the scheduling problem to the problem of finding completion times for each of the jobs, without committing to a schedule. Once a feasible set of completion times is discovered, the scheduling of jobs can easily be obtained by solving a bipartite flow problem. See Section 3 for details. Feasible solutions to the bipartite flow problem have a one-to-one correspondence to the original scheduling problem. We note that the reduction to this flow problem is a well-known scheduling technique.

The bipartite graph in the flow problem is used to derive the job cover inequalities. First an LP is written based on the flow problem. To ensure a feasible flow is possible, a set of constraints is added that ensure the minimum cut in the graph is sufficiently large. Then this

[1] Without strengthening inequalities and when jobs arrive at the same time on a single machine the LP introduced in this paper can be reduced to an LP used in prior work where the gap is known [2, 7]

set of covering constraints are strengthened. While these inequalities are used to strengthen constraints that arise from a flow graph, they are different than previously studied flow cover inequalities [19, 20, 14]. The key to defining the improved constraints is leveraging the structure of the minimum cuts in the bipartite graph resulting from the scheduling problem.

The algorithm solves the strong LP and rounds the solution. The idea is to use iterative randomized rounding, but this results in a large approximation ratio. We remark that standard randomized rounding techniques can be used to obtain a $O(\log n)$ approximation by over sampling variables by a $O(\log n)$ factor and then union bounding over constraints to show they are satisfied with high probability. However, there are issues with reducing the approximation ratio below this factor; the most challenging is showing that the constraints are satisfied if variables are sampled by a smaller factor, which is what would be needed to reduce the approximation ratio.

Instead, the algorithm uses an iterative scheme to round the solution. In each iteration, the algorithm over samples variables by a small factor and modifies the linear program. The modification ensures that (1) in expectation no variable, over all iterations, is sampled by more than a $O(\log \log nP)$ factor than how much it is selected by the optimal LP solution and (2) the relaxation remains feasible. The scheme builds on techniques of quasi-uniform sampling [4, 22] and quasi-uniform iterative rounding [12].

Other Related Work

Single Machine. It is known the Smith's rule is optimal for minimizing the total weighted completion time [21]. The tardiness problem has been challenging to understand. Lawer [13] gave a polynomial approximation scheme if jobs have unit size. Before the work on the GSP in the single machine environment, the previously best known approximation for arbitrary sized jobs was a $(n-1)$-approximation [5]. For the GSP a $(4+\epsilon)$-approximation is known [6] and a quasi-polynomial time approximation scheme has been established [1].

Identical Machines. Smith's rule is optimal for minimizing the total weighted completion time [21]. It is not difficult to see that there is an optimal algorithm for makespan[2] if jobs can be preempted and migrated across machines. An PTAS is known if migration is disallowed [9]. As far as the author is aware, there are no non-trivial results known for exponential completion time and tardiness on multiple machines.

2 Preliminaries

In the general scheduling problem (GSP), there is a set J of n jobs. Each job i has integer processing time p_i. Let P denote the maximum job size and assume the minumum job size is one. The jobs are to be scheduled on a set M of m identical machines that can schedule one job at any point in time. It is assumed that time is slotted and job i must be scheduled for p_i time units over all machines. Jobs can be preempted and migrated across machines. Jobs cannot be scheduled on more than one machine simultaneously. Every job i is associated with a function $g_i : \mathbb{R}^+ \to \mathbb{R}^+$ where $g_i(t)$ specifies the cost of completing job i at time t. Without loss of generality, assume that $g_i(0) = 0$ for all jobs i. The only assumption on $g_i(t)$ is that it is a non-negative non-decreasing function. Under a given schedule, job i is completed at time C_i. The goal is for the scheduler to minimize $\sum_{i \in J} g_i(C_i)$. Note that it can be assumed that all jobs are completed by time nP.

[2] Makespan is equivalent to minimizing the maximum completion.

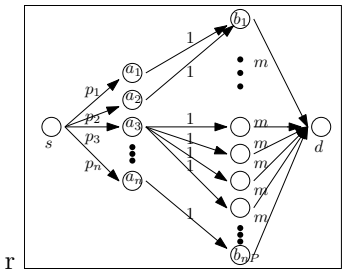

Figure 1 The graph G. A job i needs to assign p_i units of flow (processing time) to machines before C_i. Machines can process up to m units at each time.

3 Scheduling Jobs with Deadlines

This section shows that if the completion times of the jobs are fixed then there is a method to determine how to schedule the jobs at or before their completion times or determine if such a schedule is not possible. Notice that if such a schedule is feasible then this ensures the objective is either the same or smaller in the computed schedule than if all jobs are completed at exactly their given completion times. Let job i have a given completion time C_i. The completion time C_i is interpreted as job i's deadline.

The method to construct a schedule for the jobs is to setup a flow problem. Setting up a flow graph to determine if a set of jobs can be feasibly scheduled is a standard scheduling technique (e.g. [8]), but is presented here so that later this graph can be used in a linear program formulation. Consider creating a bipartite flow graph $G = (\{s, d\} \cup A \cup B, E)$ where A contains a node a_i for every job i and B contains a node b_t for every time step t. There is additionally a source s with an outgoing edge to each node a_i in A with capacity p_i. There is a sink node d that has an incoming edge from each node in B with capacity m. Finally there is an edge from $a_i \in A$ to $b_t \in B$ of capacity 1 if and only if $t \leq C_i$. See Figure 1.

A set of completion times are feasible if and only if there is a feasible flow in this network of value $\sum_{i \in [n]} p_i$. This is because a job can be scheduled for a unit at each time during $[0, C_i]$ and must be scheduled for p_i units total. Further, every time step can schedule up to m jobs.

There are two messages to takeaway from this. One is that the problem can be solved by only knowing completion times for the jobs. The other is that this flow graph can be used to determine if a set of completion times can be associated with a valid schedule. A set of completion times are said to be **valid** if there is a schedule that completes each job only earlier than the given completion time.

The following theorem follows from the construction of G.

▶ **Theorem 3.** *A set of completion times is valid if and only if there is a feasible maximum flow of value $\sum_{i=1}^{n} p_i$ in the flow graph G.*

Given a set of valid completion times, one can construct a feasible schedule using the flow graph. That is, an assignment of jobs to machine at each time step. Unfortunately, the graph has size $\Omega(nP)$ and could be exponential in size. Recall that P is the ratio of the maximum to minimum job size. There is a polynomial time algorithm that constructs a feasible schedule in time polynomial in n and $\log W$ given a set of valid completion times. Here W denotes the maximum value of $g_j(t)$ for $t \leq nP$. This algorithm is omitted due to space. It can be obtained by rounding possible completion times to geometrically increasing times.

4 Strengthened Linear Program with Job Cover Inequalities

Consider the following natural integer program. The constraints in the program come from the flow graph of the prior section. Let $x_{j,t}$ be 1 if job j is not completed at time t and 0 otherwise.[3] This implies that $x_{j,t}$ is continuously 1 for t less than j's completion time and then 0 for times t thereafter in an integer solution. Let T be the set of all time slots and J the set of all jobs. By assuming $g_j(0) = 0$ for all j, the objective function is a telescoping summation for each job j whose value will be $g_j(t)$ if t is the last time j is not fully processed. The first set of constraints says that if job j is completed at time $t-1$ then it is also completed at time t. The second set of constraints are more involved. One can think of the latest time t that $x_{j,t} = 1$ as being the completion time of j. Given this, the constraint says that every cut in the flow network from Section 3 has value at least $\sum_{i \in J} p_i$. This is a valid constraint by Theorem 3 and the maximum-flow minimum-cut theorem. Note that J' corresponds to jobs whose nodes are on the side of the cut with the source s. Similarly, T' corresponds to time steps whose nodes are on the side of the cut with the sink d.

$$\min \sum_{j \in J} \sum_{t \in T} x_{j,t}(g_j(t) - g_j(t-1)) \tag{1}$$

$$\text{s.t.} \quad x_{j,t} \leq x_{j,t-1} \qquad \forall j \in J, t \in T \tag{2}$$

$$\sum_{j \in J \setminus J'} p_j + \sum_{j \in J'} \sum_{t \in T'} x_{j,t} + \sum_{t \in T \setminus T'} m \geq \sum_{j \in J} p_j \qquad \forall J' \subseteq J, T' \subseteq T \tag{3}$$

$$x_{j,t} \in \{0,1\} \qquad \forall j \in J, t \in T$$

The goal is to derive a set of valid strengthening inequalities for the IP (1). These inequalities are used to strengthen the minimum cut constraints. These inequalities are needed because without them the LP has an unbounded integrality gap even if all jobs arrive at the same time on a single machine [7]. Other natural LP relaxations, such as a time indexed LP also have an unbounded gap even on a single machine.

We can derive a set of strengthening inequalities for this linear program that replace the set of constraints (3). The proof establishing validity of the following constraints is omitted due to space. The strengthening focuses on the constraints in (3) for $J' = J$. In the end, the derived constraints are strictly stronger than the above and one need not consider the other sets J'.

Fix $J' = J$ and consider the constraints $\sum_{j \in J} \sum_{t \in T'} x_{j,t} + \sum_{t \in T \setminus T'} m \geq \sum_{j \in J} p_j$ for all $T' \subseteq T$. For a job j and a collection of time steps T' let $E(T', j)$ be the set of up to $\min\{p_j, \sum_{i \in J} p_i - m|T \setminus T'|\}$ **earliest** time steps in T'. The full analysis first shows that we can strengthen this to

$$\sum_{j \in J} \sum_{t \in E(j,T')} x_{j,t} + \sum_{t \in T \setminus T'} m \geq \sum_{j \in J} p_j \text{ for all } T' \subseteq T.$$

Notice the first summation now only considers time steps in $E(T', j)$ for each job j.

The proof further improves these inequalities by taking inspiration from knapsack cover inequalities. Let D be a **vector** where D_j is a time corresponding to job j. Intuitively, D_j is a lower bound on the completion time for job j. The constraints below say that even if all jobs j are set to have completion times **at least** D_j then the constraints should still be satisfied.

[3] Note that this is *not* the standard time indexed LP where the variables represent the amount j is processed at time t.

Fix $T' \subseteq T$ and a vector D of completion times for every job. Consider the constraint for T' in the above set of inequalities. If job j is given a completion time of at least D_j then j will contribute at least $\sum_{t \in [0,D_j] \cap E(T',j)} 1$ to the left side of the inequality. Let $V(T',D) = \sum_{i \in J} p_i - \sum_{t \in T \setminus T'} m - \sum_{j \in J} \sum_{t \in [0,D_j] \cap E(T',j)} 1$. Let $E(T',D,j)$ be the **earliest** $V(T',D)$ time steps in $E(T',j)$ later than D_j. The new constraints are as follows. These are the **job cover inequalities**.

$$\sum_{j \in J} \sum_{t \in E(T',D,j)} x_{j,t} \geq V(T',D) \quad \forall T' \subseteq T, \forall D, V(T',D) > 0 \tag{4}$$

The validity of these inequalities is not difficult to show, but technical. Notice that the number of inequalities is large. We can somewhat reduce the number of constraints as follows. It can be established that any *integer* solution satisfies all the constraints in (4) if and only if the following are satisfied. The proof is omitted.

$$\sum_{j \in J} \sum_{t \in E(T',D,j)} x_{j,t} \geq V(T',D) \quad \forall b \in [0,\infty], T' = [b,\infty], \forall D, V(T',D) > 0 \tag{5}$$

These constraints state that if the subset of constraints in (4) are satisfied for any D and all sets T' that consist of a continuous set of time steps from some time b to time ∞ then all of the constraints in (4) are satisfied (for any T'). Due to this, we will only need to use the constraints in (5) that restricts the sets T'.

The constraints (3) in the IP are replaced by the constraints in (5). Throughout the paper these constraints are discussed and it is said that a fixed constraint is defined by the set $T' = [b,\infty]$ and a vector D.

Note on Solving the LP. The IP is relaxed to a LP. The LP is solved and then subsequently rounded to an integer solution. There are an exponential number of constraints. To solve the LP, the ellipsoid method is used. The author does not know of an efficient separation oracle for the set of constraints in (4). The reduced set of constraints in (5) are the only constraints needed for the analysis. For this set of constraints, an efficient dynamic programming algorithm can be used as a separation oracle. The separation oracle has been omitted due to space constraints.

5 The Rounding Algorithm

In this section the algorithm for rounding a fractional LP solution to an integral solution is described. Recall in Section 3 it was shown how to assign jobs to machines and time slots if a valid set of completion times have been established. The remaining goal is to design an algorithm that rounds a fractional LP solution to an integral solution, giving the completion times for the jobs.

The algorithm takes as input a fractional solution to the LP x'. The input solution is for the LP given in the previous section with constraints (3) replaced with the derived constraints (5). The algorithm rounds the x' solution to an *integral* solution x^*. If this solution is feasible, then the algorithm terminates. Otherwise x^* is modified to obtain a new feasible fractional solution $\tilde{x}^*$ that the algorithm recurses on.

Informal Algorithm Description and Intuition. The algorithm runs in phases. During a phase the algorithm finds a completion time for each job. The completion times are pushed back to later times in each phase. In a fixed phase the algorithm runs a randomized rounding

procedure to sample completion times for the jobs. Roughly, each completion time will be over sampled by a $\Theta(\log \log nP)$ factor over the fractional part of the LP. After sampling an integer solution x^* is created and variables are set corresponding to the sampled completion times of the jobs. Some of the constraints in the LP will be satisfied. These constraints will always remain satisfied because each job's completion time is only pushed back to a later time in subsequent iterations. The algorithm needs to satisfy the remaining constraints, which it does by recursing on a fractional LP solution $\tilde{x}^*$ to make completion times later. The fractional solution $\tilde{x}^*$ is constructed by increasing variables in the integral solution x^*.

In each iteration, the cost of the sampling is bounded by a $\Theta(\log \log nP)$ factor more than the *fractional* portion of the linear program objective in expectation. Ideally, one can use standard iterative rounding for the recursion. However, naive approaches could have large cost as it is difficult to bound the number of times the algorithm recurses and therefore difficult to bound how many times a variable in the LP is sampled. A standard approach will result in a $\Theta(\log nP)$ approximation.

The idea is to only include some fractional variables in the linear program solution that the algorithm recurses on. The variables that are included can be slightly larger than their original value. The essential properties are that (1) the linear program is feasible and (2) each fractional variable is set to 0 with constant probability. Using (2) it will be shown that the expected value of each variable drops by a constant (e.g. $\frac{1}{2}$) factor of its value at the beginning of the iteration. If this is established, then the probability a completion time is sampled decreases geometrically over the phases and we can bound the algorithm's objective by the cost of the sampling in the first phase, a $\Theta(\log \log nP)$ factor within the original LP object in expectation.

The recursion will determine fractional variables to set to satisfy all constraints. One can think of the fractional variables as **fractional completion times** for the jobs. The idea is to associate each constraint with a set of fractional completion times that are *critical* for satisfying the constraint in the solution x'. This will not be all completion times used to satisfy the constraint, but an essential subset of them. By slightly increasing the linear program variables in the integral solution x^* to get a solution $\tilde{x}^*$ it is the case that only the critical completion times are needed to satisfy their corresponding unsatisfied constraints.

If a constraint is unsatisfied, then the solution $\tilde{x}^*$ will set positive fractional values for all completion times critical for this constraint to satisfy it. The analysis will show that each fractional completion time is 0 (not increased) in $\tilde{x}^*$ with constant probability. For a completion time to be 0 in the recursion we need to ensure all constraints are satisfied where the completion time is critical by the integer solution x^*. Unfortunately, a completion time could be critical for many constraints. Due to this, it is insufficient to show each constraint is satisfied with good probability and then union bound over all constraints.

Fix a fractional completion time. The proof establishes that with good probability *every* constraint that the completion time is critical for is satisfied in x^*. This ensures that the the completion is 0 with constant probability. This will be used to show that the expected value of a fractional variable in the LP decreases geometrically over the iterations. A completion time is over-sampled by at most a $\Theta(\log \log nP)$ factor as compared to the original LP solution in expectation over all iterations. The cost is as if only one iteration of uniform sampling occurred. This is similar to the analysis approach used in quasi-uniform sampling [22] and rounding [12].

5.1 Formal Algorithm Description

The ith phase of the algorithm is the following. The algorithm recurses on the following until all constraints are satisfied. Let the input to the first phase be x, the optimal fractional solution to the LP. The algorithm utilizes randomized rounding parameterized by $c \leq 1$. The value of c will be set to be $\frac{1}{\Theta(\log\log nP)}$.

Phase i of the Algorithm. The algorithm first uses **randomized rounding**. Let x' be a feasible fractional solution to the LP at ith phase of the algorithm. For each job j, the algorithm chooses a value $\alpha_j \in [0,1]$ uniformly at random and independently. Let $C_{j,\alpha}$ be the latest time t where $x'_{j,t} \geq c\alpha_j$. Let β'_j be the latest time t where $x'_{j,t} = 1$. Let $\text{LP}'_{\text{int}} = \sum_j g_j(\beta'_j)$ be the total **integral cost** of the LP solution x' and let $\text{LP}'_{\text{frac}} = \sum_{j\in J}\sum_{t>\beta'_j} x'_{j,t}(g_j(t) - g_j(t-1))$ be the total **fractional cost** of the LP solution x'.

The algorithm modifies the LP solution x' to get a new (possibly infeasible) solution x^*. This is further modified to get a feasible solution $\tilde{x}^*$ that the algorithm recurses on. The algorithm sets $x^*_{j,t} = 1$ for all j and t where $t \leq C_{j,\alpha}$ and 0 otherwise. If all constraints are satisfied in the LP, then the algorithm sets $C^*_j = C_{j,\alpha}$ and returns this set of completion times as the final solution. If not, then the algorithm further modifies x^* as described below and recurses on phase $i+1$. Let x^* denote the current integral solution and $\tilde{x}^*$ a fractional solution resulting from the following modification to x^*.

Consider any constraint in (5) defined by a set of time steps T' and a vector of completion times D' that is not satisfied by x^*. Assume D' is chosen so that $D'_j \geq C_{j,\alpha}$ for all j. We only need to consider these constraints because $x_{j,t} = 1$ for $t \leq C_{j,\alpha}$. Recall that we may assume T' contains a continuous set of time steps beginning with some time $t_{T'}$ and going to ∞. The algorithm identifies a set of pairs of jobs and completion times that are fractionally chosen in x' that are "critical" for satisfying this constraint. Intuitively, we will need to include these same fractional completion times in $\tilde{x}^*$.

Let $J_{T',D'}$ be the set of jobs j where $\sum_{t\in E(T',D',j)} x'_{j,t} > 0$. These are jobs used to satisfy the constraint in x'. The following two sets of jobs can be thought of as *not* critical for the constraint.

1. Order the jobs j in $J_{T',D'}$ as $1,2,3,\ldots|J_{T',D'}|$ in decreasing order of D'_j. Let $M_{T',D'} \subseteq J_{T',D'}$ be the smallest prefix of jobs $1,2,\ldots k$ from this order such that $\sum_{j=1}^{k}\sum_{t\in E(T',D',j)} x'_{j,t} \geq \frac{1}{10}V(T',D')$.
2. Order the jobs j in $J_{T',D'}$ as $1,2,3,\ldots,|J_{T',D'}|$ in increasing order of D'_j. Let $L_{T',D'} \subseteq J_{T',D'}$ be the smallest prefix of jobs $1,2,\ldots k$ in this order such that $\sum_{j=1}^{k}\sum_{t\in E(T',D',j)} x'_{j,t} \geq \frac{1}{10}V(T',D')$.

We will say that the jobs in $\mathcal{J}_{T',D'} = J_{T',D'} \setminus (L_{T',D'} \cup M_{T',D'})$ are **critical** for satisfying the constraint T', D'. Let $\mathcal{J}^* = \{j \mid \exists T'D' \text{ s.t. the constraint for } T' \text{ and } D' \text{ is unsatisfied in } x^* \text{ and } j \in \mathcal{J}_{T',D'}\}$. This is the set of all critical jobs for constraints that are not satisfied by x^*.

For each job $j \in \mathcal{J}^*$ set $\tilde{x}^*_{j,t'}$ to be $10x'_{j,t'}$ for all $t' \geq C_{j,\alpha}$. Note that if $c < \frac{1}{10}$ and $C_{j,\alpha} \leq t'$ it is the case that $\tilde{x}^*_{j,t'} \leq c \leq 1/10$, so $\tilde{x}^*$ is in $[0,1]$ as desired. After performing all updates, recurse.

Terminating Condition. The above description states that the algorithm terminates when all constraints are satisfied by the integer solution x^*. The analysis will show that this occurs in polynomial time in expectation.

6 Bounding the Cost and Feasibility of the Algorithm

In this section, the correctness of the algorithm is established and the total cost of the algorithm is bounded as well as the running time. The analysis has several intermediate goals. One is to show that the resulting solution $\tilde{x}^*$ is feasible. Another is to show that the increase in cost of the randomized rounding is bounded by the cost of the fractional part of the LP in one iteration. The final goal is showing that the expected value of the objective for the fractional part of the LP solution decreases significantly in each iteration. After establishing these facts Theorem 3 will prove the main theorem.

Feasibility of the Algorithm. We now establish that $\tilde{x}^*$ is feasible for the LP. This ensures the algorithm constructs a feasible solution. The proof is omitted due to space. The proof follows by the fact that each unsatisfied constraint is associated with variables in the solution x' which are within a constraint multiplicative factor of satisfying the constraint. In the recursion, these variables are included in $\tilde{x}^*$ with their fractional valuesincreased by a factor 10 over x' ensuring their corresponding constraint is satisfied.

▶ **Lemma 4.** *In any iteration of the algorithm, if x' is a feasible LP solution then the algorithm constructs a feasible solution $\tilde{x}^*$ at the end of the iteration for any $c \leq 1/10$.*

Bounding the Cost and Running Time of the Algorithm. This section bounds the cost of the LP solution $\tilde{x}^*$ and the running time of the algorithm. First the cost of the randomized rounding is bounded. This bounds the cost of the *intermediate* integral solution x^*. The following lemma shows that the expected cost *increase* of the LP solution x^* over x' is bounded by $\frac{1}{c}\mathrm{LP}'_{\mathrm{frac}}$. Recall that x^* is the solution obtained by only the randomized rounding part of the algorithm and it is a possibly infeasible integer solution. After this lemma, the cost of the solution $\tilde{x}^*$ is bounded. This is the solution the algorithm recurses on. Combining the cost over the entire algorithm is bounded.

The following lemma bounds the cost of the solution x^*. The proof is omitted. The proof follows by a standard analysis of randomized rounding.

▶ **Lemma 5.** *The total expected different in cost of x^* and x' is at most $\frac{1}{c}\mathrm{LP}'_{\mathrm{frac}}$. That is, $\mathrm{E}[\sum_{j\in J}\sum_t (x^*_{j,t} - x'_{j,t})(g_j(t) - g_j(t-1))] \leq \frac{1}{c}\sum_{j\in J}\sum_t \mathrm{LP}'_{\mathrm{frac}}$.*

Let $\mathrm{LP}^*_{\mathrm{frac}} := \sum_{j\in J}\sum_{t>C_{j,\alpha}} \tilde{x}^*_{j,t}(g_j(t) - g_j(t-1))$ be the fractional cost of $\tilde{x}^*$ and $\mathrm{LP}^*_{\mathrm{int}} = \sum_{j\in J} g(C_{j,\alpha})$ be the integral cost. Note that $\mathrm{LP}^*_{\mathrm{int}}$ is precisely the objective of the integral solution x^*. The key to bounding the cost of the algorithm is to show that the fractional cost of the LP solution decreases by a constant factor in each iteration. This is stated in the following lemma. The proof is deferred due to space. This lemma is the most interesting part of the analysis and the proof is presented in Section 6.1.

▶ **Lemma 6.** *In any iteration of the algorithm, $\mathrm{E}[\mathrm{LP}^*_{\mathrm{frac}}] \leq \frac{1}{4}\mathrm{LP}'_{\mathrm{frac}}$.*

Using this lemma, the total cost of the algorithm can be bounded.

▶ **Lemma 7.** *Let OPT be the optimal feasible objective to the LP. It is the case that the algorithm's total cost is at most $\frac{2}{c}$OPT in expectation.*

Proof. Let $\mathrm{LP}^{\mathrm{i}}_{\mathrm{frac}}$ denote the fractional part of the objective in the LP solution at the beginning of the ith iteration of the algorithm. Note that $\mathrm{LP}^1_{\mathrm{frac}} \leq \mathrm{OPT}$. Inductively, Lemma 6 gives that $\mathrm{E}[\mathrm{LP}^{\mathrm{i}}_{\mathrm{frac}}] \leq \frac{1}{4^i}\mathrm{OPT}$.

Lemma 5 ensures that the integral portion of the LP objective increases by at most $\frac{1}{c}\mathrm{LP}^{\mathrm{i}}_{\mathrm{frac}}$ in each iteration. Thus the total cost can be bounded by $\frac{1}{c}\sum_{i=1}^{\infty}\frac{1}{4^i}\mathrm{OPT} \leq \frac{2}{c}\mathrm{OPT}$. ◀

The following proposition bounds the run time of the algorithm and the proof is omitted. This follows because the previous lemma will ensure the variables in the LP converge to 0 after $O(\log nP)$ iterations.

▶ **Proposition 8.** *The algorithm runs in polynomial time in expectation.*

Lemma 7 bounds the objective of the algorithm. Lemma 4 ensures that the algorithm constructs a feasible solution. Finally, Propostion 8 shows the algorithm runs in polynomial time. Together, this proves the main result, Theorem 1.

6.1 Proof of Lemma 6: Expected Decrease in the Fractional Objective

This section proves Lemma 6 for a fixed iteration of the algorithm. Fix a job j and the fractional solution x' that is input to the rounding algorithm in this iteration. The goal is to show that the probability that j is in $\mathcal{J}^*$ is small and therefore the algorithm only includes integral variables $\tilde{x}^*_{j,t}$ for job j when it recurses. In particular, the goal is to show the following lemma. In the following, n and P are assumed to be sufficiently large.

▶ **Lemma 9.** *Fix any job j^*. With probability at most $\frac{2}{\log^2 nP} \leq 1/40$ it is the case that there is a constraint T', D' unsatisfied by x^* and $j^* \in \mathcal{J}_{T',D'}$ when $c \leq \frac{1}{1000 \log\log nP}$.*

This lemma implies Lemma 6.

Proof of Lemma 6. Fix any job j and an iteration of the algorithm. If there is a constraint T', D' unsatisfied, $j \in \mathcal{J}_{T',D'}$, $x'_{j,t}$ is fractional, $t \geq C_{j,\alpha}$ and $t \in E(T', D', j)$ then the algorithm sets $\tilde{x}^*_{j,t}$ to be $10x'_{j,t}$.

This event increases the cost of $\tilde{x}^*$ by at most $10\sum_{t>C_{j,\alpha}} x'_{j,t}(g_j(t) - g_j(t-1))$ and it happens for some T', D' with probability at most $1/40$. The total expected cost $\mathrm{LP}^*_{\mathrm{frac}}$ is at most the following.

$$10\sum_{j\in J}\sum_{t>C_{j,\alpha}} x'_{j,t}(g_j(t) - g_j(t-1))\Pr[\exists T', D' |\, j \in \mathcal{J}_{T',D'} \text{ and constraint } T', D' \text{ unsatisfied by } x^*]$$

$$\leq 10\sum_{j\in J}\sum_{t>C_{j,\alpha}} x'_{j,t}(g_j(t) - g_j(t-1))\frac{1}{40} \leq \frac{1}{4}\sum_{j\in J}\sum_{t>C_{j,\alpha}} x'_{j,t}(g_j(t) - g_j(t-1)) \quad \text{[Lemma 9]}$$

Thus, the expected cost of $\mathrm{LP}^*_{\mathrm{frac}}$ decreases by a factor $1/4$ over $\mathrm{LP}'_{\mathrm{frac}}$. ◀

The remaining goal of this section is to prove Lemma 9. The proof begins by observing that since the solution x^* is integral if a constraint T' and D' is satisfied for a particular set D' then the constraints for T' and all sets D'' are satisfied. This will allow us to focus on constraints for one special set D'. The proof is omitted.

▶ **Proposition 10.** *Let $t_{T'}$ be some time step and $T' = [t_{T'}, \infty]$. Let D' be set such that D'_j is the latest time t where $x'_{j,t} \geq c$ for all jobs j. If the constraint for T' and D' is satisfied in the solution x^* then all constraints for T' and any set D'' are satisfied in the soultion x^*.*

For the remainder of the proof, fix D' to be as described in the prior lemma. Now we establish some basic propositions on which jobs contribute to a constraint. This will be useful for identifying critical jobs. Note that the two propositions below are different depending on the ordering of the times considered. The proofs are omitted.

▶ **Proposition 11.** *Fix any job j and two sets $T = [t_T, \infty]$ and $T' = [t_{T'}, \infty]$ where $D'_j \leq t_T < t_{T'}$. For any fractional LP solution x satisfying constraints (2) if $V(T, D') \geq \frac{1}{2}V(T', D')$ then it is the case that $\sum_{t \in E(T', D', j)} x_{j,t} \leq 2 \sum_{t \in E(T, D', j)} x_{j,t}$.*

▶ **Proposition 12.** *Fix any job j and two sets $T = [t_T, \infty]$ and $T' = [t_{T'}, \infty]$ and $D'_j > t_T > t_{T'}$. For any fractional LP solution x satisfying constraints (2) if $V(T, D') \geq \frac{1}{2}V(T', D')$ then $\sum_{t \in E(T', D', j)} x_{j,t} \leq 2 \sum_{t \in E(T, D', j)} x_{j,t}$.*

The next lemma establishes that for any fixed constraint T' and D', it is the case that the constraint is satisfied with good probability in the integral solution x^*. Further, the constraint is satisfied if only the jobs in $M_{T', D'}$ (or $L_{T', D'}$) are considered in the summation in the left hand side of the constraint. Due to space, the proof is ommited.

▶ **Lemma 13.** *Fix any $T' = [t_{T'}, \infty]$ and let the vector D' contain the time D'_j that is the latest time t where $x'_{j,t} \geq c$ for all jobs j. With probability at least $1 - \frac{1}{\log^{10} nP}$ it is the case that $\sum_{j \in L_{T', D''}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 10V(T', D')$ and $\sum_{j \in M_{T', D'}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 10V(T', D')$ when $c \leq \frac{1}{1000 \log \log nP}$.*

Fix any job j^*. Group constraints into two classes for job j^*. The first class are those constraints $T' = [t_{T'}, \infty]$ where $t_{T'} > D'_{j^*}$ and the second class are the remaining constraints. It will be shown separately for both groups of constraints that they are all unsatisfied with small probability.

In the following lemma, the first class of constraints are considered. This lemma heavily relies on Proposition 11.

▶ **Lemma 14.** *Fix any job j^*. With probability at most $1/\log^2 nP$ it is the case that there exists a constraint T', D'' unsatisfied by x^*, $j^* \in \mathcal{J}_{T', D''}$ and $t_{T'} > D'_{j^*}$ when $c \leq \frac{1}{1000 \log \log nP}$.*

Proof. Fix any job j^*. Let D' be set such that D'_j is the latest time t where $x'_{j,t} \geq c$ for all jobs j. The proof will establish that with probability greater $1 - \frac{1}{\log^2 nP}$ it is the case that the constraints for D' and any $T' = [t_{T'}, \infty]$ with $t_{T'} > D'_{j^*}$ are satisfied by x^*. Applying Proposition 10 this implies that x^* satisfies the same allowing for any constraint D'', proving the lemma.

Geometrically group constraints based on the value of $V(T', D')$. Let $\mathcal{C}_k$ contain the set $T' = [t_{T'}, \infty]$ if $j^* \in \mathcal{J}_{T', D'}$, $2^k \leq V(T', D') < 2^{k+1}$ and $t_{T'} > D'_{j^*}$ for any integer $0 \leq k \leq \log nP$.

Fix k and the set $T' \in \mathcal{C}_k$ such that $t_{T'}$ is as late as possible. Let $L_{T', D'}$ be as described in the algorithm definition. We will establish that if $\sum_{j \in L_{T', D'}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 10V(T', D')$ then all constraints $V(T'', D')$ for any $T'' \in \mathcal{C}_k$ are satisfied. Once this is established, this will complete the proof as follows. We apply Lemma 13 stating that $\sum_{j \in L_{T', D'}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 10V(T', D')$ occurs with probability at least $1 - \frac{1}{\log^{10} nP}$. By union bounding for all $\log nP$ values for k the lemma follows.

Say that $\sum_{j \in L_{T', D'}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 10V(T', D')$. Consider any set $T'' \in \mathcal{C}_k$. By definition of the set $L_{T', D'}$ it is the case that $D'_j \leq D'_{j^*}$ for all $j \in L_{T', D'}$. Hence, $D'_j \leq D'_{j^*} \leq t_{T''} \leq t_{T'}$. Thus, Proposition 11 and the geometric grouping of constraints gives that $\sum_{j \in L_{T', D'}} \sum_{t \in E(T'', D', j)} x^*_{j,t} \geq \frac{1}{2} \sum_{j \in L_{T', D'}} \sum_{t \in E(T', D', j)} x^*_{j,t} \geq 5V(T', D') \geq V(T'', D')$. Thus the constraint for T'' and D' is satisfied, proving the lemma. ◀

Similar to the previous lemma, in the following lemma it is shown that all of the second class of constraints are satisfied with good probability. This lemma heavily relies on Proposition 12. This proof is similar to the prior lemma and is omitted.

▶ **Lemma 15.** *Fix any job j^*. With probability at most $1/\log^2 nP$ it is the case that there exists a constraint T', D'' unsatisfied by x^*, $j^* \in \mathcal{J}_{T',D'}$ and $t_{T'} < D'_{j^*}$ when $c \leq \frac{1}{1000 \log\log nP}$.*

For sufficiently large n and P, a union bound and Lemmas 14 and 15 prove Lemma 9.

7 Conclusion

This paper introduced a new set of strong inequalities for scheduling problems on multiple identical machines. Using these inequalities, the paper showed an iterative algorithm that rounds a fractional LP solution to an integral solution which achieves an $O(\log\log nP)$ approximation for most reasonable scheduling minimization problems.

An open question is if there are algorithms with an $O(1)$ approximation ratio for GSP on identical machines. It is also of interest to determine if the inequalities introduced can be extended to other bipartite assignment problems. Can these inequalities be extended to more general environments, such as the related machines or restricted assignment settings? Could a similar analysis be used when jobs arrive over time? These cases introduce new technical hurdles, but $O(1)$ approximation algorithms could be possible by leveraging the given constraints and assuming preemption and migration are allowed.[4] For example, if jobs arrive over time then a generalization of the LP with the strengthened constraints can be derived. However, the rounding becomes challenging because there appears to be no reduction showing only a polynomial number of time sets T' need to be considered in the set of constraints, like was established in this paper. Due to this, it is challenging to show all exponential number of constraints based on sets of times are satisfied by the rounding algorithm.

Computing Optimal Epsilon-Nets Is as Easy as Finding an Unhit Set

mustafan@esiee.fr

Abstract

Given a set system $(X, \mathcal{R})$ with VC-dimension d, the celebrated result of Haussler and Welzl (1987) showed that there exists an ϵ-net for $(X, \mathcal{R})$ of size $O\left(\frac{d}{\epsilon} \log \frac{1}{\epsilon}\right)$. Furthermore, the algorithm is simple: just take a uniform random sample from X! However, for many geometric set systems this bound is sub-optimal and since then, there has been much work presenting improved bounds and algorithms tailored to specific geometric set systems.

In this paper, we consider the following natural algorithm to compute an ϵ-net: start with an initial random sample N. Iteratively, as long as N is not an ϵ-net for $\mathcal{R}$, pick *any* unhit set $S \in \mathcal{R}$ (say, given by an Oracle), and add $O(1)$ randomly chosen points from S to N.

We prove that the above algorithm computes, in expectation, ϵ-nets of asymptotically optimal size for all known cases of geometric set systems. Furthermore, it makes $O\left(\frac{1}{\epsilon}\right)$ calls to the Oracle. In particular, this implies that computing optimal-sized ϵ-nets are as easy as computing an unhit set in the given set system.

1 Introduction

Let X be a set of n base elements, and $\mathcal{R}$ a collection of m sets over X. Given a parameter $\epsilon > 0$, an ϵ-net for $(X, \mathcal{R})$ is a set $N \subseteq X$ such that for all $S \in \mathcal{R}$ with $|S| \geq \epsilon n$, we have $N \cap S \neq \emptyset$.

The notion of ϵ-nets has been heavily studied across several disciplines, including discrete and computational geometry, machine learning, statistics, convex geometry and randomized algorithms. We refer the reader to the books [3, 7, 14, 16, 20] as well as recent surveys [19, 21].

For general set systems $(X, \mathcal{R})$, it is easy to see that there exists an ϵ-net of size $O\left(\frac{1}{\epsilon} \log |\mathcal{R}|\right)$. For more constrained set systems – for example, those arising in geometric configurations – one can show the existence of ϵ-nets of considerably smaller size. This was realized in the 1980s with the seminal work of Clarkson [8] and Haussler-Welzl [11]. In particular, when the VC-dimension of $(X, \mathcal{R})$, denoted by VC-dim$(\mathcal{R})$, is at most d, then there exist ϵ-nets of size $O\left(\frac{d}{\epsilon} \log \frac{1}{\epsilon}\right)$ – of size *independent* of $|X|$ or $|\mathcal{R}|$. Furthermore, to construct a net of this expected size, the algorithm is simple: just take a uniform random sample.

Haussler-Welzl Net-Finder Algorithm.

Input: base elements X, a set system $\mathcal{R}$ on X, a parameter $\epsilon > 0$.

N: pick each $x \in X$ independently with probability $\Theta\left(\frac{d}{\epsilon|X|}\log\frac{1}{\epsilon}\right)$.

return N.

It has been observed over the past 30 years that improvements to the Clarkson and Haussler-Welzl bounds are possible for a variety of geometric set systems – e.g., $O(\frac{1}{\epsilon})$-sized nets exist for subsets induced by disks in the plane, half-spaces in $\mathbb{R}^2$ and $\mathbb{R}^3$, subsets induced by pseudo-disks, dual set systems of linear union complexity and so on. More recently, the work of Varadarajan [23], Aronov et al. [4] and Chan et al. [6] has settled the question on sizes of ϵ-nets for many basic geometric set systems precisely in terms of their so-called shallow-cell complexity – in particular, there exist ϵ-nets of size $O\left(\frac{1}{\epsilon}\log\varphi_{\mathcal{R}}\left(O\left(\frac{1}{\epsilon}\right), O\left(1\right)\right)\right)$. A set system $(X, \mathcal{R})$ has shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$ if for any $Y \subseteq X$, the number of subsets in $\mathcal{R}|_Y$ of size at most l is $|Y| \cdot \varphi_{\mathcal{R}}\left(|Y|, l\right)$ (here $\mathcal{R}|_Y = \{S \cap Y : S \in \mathcal{R}\}$ is the projection of the set system $\mathcal{R}$ on Y). Bounds for $\varphi_{\mathcal{R}}\left(\cdot,\cdot\right)$ has been well-studied and by now we know asymptotically optimal bounds for the basic geometric set systems (see [19]).

However, all the above algorithms for constructing ϵ-nets either have efficient implementations but then only work for very specific set systems (e.g., near-linear time algorithm for disks in $\mathbb{R}^2$ [5], half-spaces in $\mathbb{R}^3$ [15]), or are inefficient if they work for general set systems. Consider these algorithms from recent work:

1. Chan et al. [6] construction gives optimal-sized nets as a function of the shallow-cell complexity of the set system; however the algorithm is inefficient. It has to enumerate over each set of $\mathcal{R}$ – there can be $\Omega(n^d)$ such sets for some constant d – to compute a representative of each set of $\mathcal{R}$. Furthermore, it needs to have access to all the sets of $\mathcal{R}$ at the beginning to be able to compute these representatives.
2. Aronov et al. [4] and Varadarajan [23] algorithms can be implemented to work efficiently, but they work for special cases of set systems (so-called dual set systems induced by geometric objects in the plane) and further also need certain spatial decompositions (for the complement of the union) which are specific to the types of geometric objects.
3. Mustafa et al. [18] also give general bounds in terms of the shallow-cell complexity of a set system. However, the algorithm needs to first select a special maximal subset of $\mathcal{R}$ called a packing. This packing can have large size, and furthermore, computing this packing is inefficient, taking $\Omega(n^2)$ time.

2 Our Result

Our main insight is that the cause of inefficiency – the careful construction of sets needed for the "alterations" – can be avoided altogether. By extending the ideas present in the work in 1. and 3. above, we present a simple algorithm that

a) computes an ϵ-net of expected size matching the current-best bounds for known geometric set systems, and

b) avoids any pre-computation, hierarchical subdivisions, representation-computation, or partitioning.

Here is our algorithm – as it turns out, a slight addition of the **Haussler-Welzl Net-Finder Algorithm**.

General Net-Finder Algorithm.

Input: base elements X, a set system $\mathcal{R}$ on X, a parameter $\epsilon > 0$.

N: pick each $x \in X$ independently with probability p to be fixed later (Section 3).

while *there exists a set* $S \in \mathcal{R}$, $|S| \geq \epsilon|X|$, *not hit by* N **do**
    update N by adding $O(1)$ uniformly chosen elements of S to N.

return N

Oracle. In order to separate the set system-specific implementation details from the net algorithm, we will assume the existence of an Oracle that can return an unhit set in our set system with respect to the current candidate net N. We refer the reader to Chazelle [7] for details on oracle-based bounds for sampling in geometric set systems. For geometric set systems, the existence of efficient implementation of such oracles follow from the extensive work on range searching, reporting and emptiness data-structures (see [1]). For example, for the case where X is a set of points in $\mathbb{R}^2$ and the sets are induced by disks, the oracle can be implemented to run in overall time $O(n \cdot \text{polylog}(n))$ using standard techniques (e.g., see [5]).

We refer the reader to Agarwal-Pan [2] for details on data-structures for several other geometric set systems.

Our main theorem:

▶ **Theorem 1.** ***General Net-Finder Algorithm*** *computes an ϵ-net of expected optimal size for ϵ-nets for the following set systems:*

1. $O\left(\frac{1}{\epsilon}\log\varphi_{\mathcal{R}}\left(O\left(\frac{d}{\epsilon}\right), O(d)\right) + \frac{d}{\epsilon}\right)$*: abstract set systems as a function of their shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$ (we will assume that $\varphi_{\mathcal{R}}(\cdot,\cdot)$ is non-decreasing in both arguments) and VC-dimension d,*
2. $O\left(\frac{1}{\epsilon}\right)$*: half-spaces in $\mathbb{R}^2$, half-spaces in $\mathbb{R}^3$, pseudo-disks and disks in $\mathbb{R}^2$, dual systems of linear union complexity,*
3. $O\left(\frac{1}{\epsilon}\log\log\frac{1}{\epsilon}\right)$*: axis-parallel rectangles in $\mathbb{R}^2$,*
4. $O\left(\frac{\log(\epsilon\cdot\kappa_{\mathcal{R}}(1/\epsilon))}{\epsilon}\right)$*: dual set systems as a function of their union complexity $\kappa_{\mathcal{R}}(\cdot)$,*
5. $O\left(\frac{d}{\epsilon}\log\frac{1}{\epsilon}\right)$*: set systems of VC-dimension at most d, half-spaces in $\mathbb{R}^d$.*

See [19, Table 47.4.1] for the complete list of known bounds, all of which are produced by our algorithm.

Furthermore, it makes expected $O(\frac{1}{\epsilon})$ calls to the Oracle.

▶ Remark 1. For example, all the bounds presented in the work of Varadarajan [23], Clarkson and Varadarajan [10], Pyrga-Ray [22], Chan et al. [6], Aronov et al. [4], Mustafa et al. [18] are achieved by our **General Net-Finder Algorithm**.

▶ Remark 2. We note here that the unhit set S returned by the Oracle at each step need not be random – it can be any unhit set. The expectation is over the choice of the initial random sample as well as the $O(1)$ random points picked from S. The specific choice of S is irrelevant.

▶ Remark 3. In particular, Theorem 1 shows that computing an ϵ-net of optimal size is as easy/hard – within a multiplicative factor of $\frac{1}{\epsilon}$ – as computing one set unhit by $N \subseteq X$ in a set system $(X, \mathcal{R})$.

▶ Remark 4. This work is an example of the phenomenon where the "complexity" is moved from the algorithm to its analysis. Thus while our analysis uses specific combinatorial and geometric structures, the algorithm itself becomes very simple and oblivious to these structures (e.g., see [24]).

Lastly, we observe that for the case of set systems with linear-sized ϵ-nets, it is not even necessary to take an initial random sample. The algorithm simplifies even further to:

Special Net-Finder Algorithm.

Input: base elements X, a set system $\mathcal{R}$ on X, a parameter $\epsilon > 0$.

$N = \emptyset$.
while *there exists a set* $S \in \mathcal{R}$, $|S| \geq \epsilon|X|$, *not hit by* N **do**
    update N by adding $O(1)$ uniformly chosen elements of S to N.

return N.

Our second theorem is the following.

▶ **Theorem 2.** *If the shallow-cell complexity of* $\mathcal{R}$ *satisfies* $\varphi_{\mathcal{R}}(n,k) = O\left(k^c\right)$, *then* ***Special Net-Finder Algorithm*** *computes an* ϵ*-net of expected size* $O\left(\frac{1}{\epsilon}\right)$. *In particular, it computes a* $O\left(\frac{1}{\epsilon}\right)$*-sized net for the set systems induced by half-spaces in* $\mathbb{R}^2$, *half-spaces in* $\mathbb{R}^3$, *pseudo-disks and disks in* $\mathbb{R}^2$, *and dual systems of linear union complexity.*

Furthermore it makes expected $O(\frac{1}{\epsilon})$ *calls to the Oracle.*

Organization. In Section 3 we prove some key structural lemmas about the random process common to both the above algorithms. Then in Section 4 we give the proof of Theorem 1, and in Section 5 the proof of Theorem 2.

3 Key Lemmas

We first re-state our main method, **General Net-Finder Algorithm**, more precisely by filling in the exact constant values and probabilities that will be then used in the proofs.

Let $(X, \mathcal{R})$ be the given set system with VC-dim$(\mathcal{R}) \leq d$, and shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$.

General Net-Finder Algorithm.

Input: $(X, \mathcal{R})$ with VC-dim$(\mathcal{R}) \leq d$ and shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$, parameter $\epsilon > 0$.

β, γ, c_a are absolute constants (explicitly fixed later).

N_0: pick $x \in X$ i.i.d. with prob. $c_a \cdot \left(\frac{1}{\left(\frac{3}{4} - \frac{\beta}{2}\right)\epsilon|X|} \log\left(d^3 \varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon}, \frac{24d}{\beta}\right)^2 \right) + \frac{d}{\left(\frac{3}{4} - \frac{\beta}{2}\right)\epsilon|X|} \log \frac{1}{\left(\frac{3}{4} - \frac{\beta}{2}\right)} \right)$

$N = N_0$.
while *there exists a set* $S \in \mathcal{R}$, $|S| \geq \epsilon|X|$, *not hit by* N **do**
    N_S: pick each $x \in S$ independently with probability $c_a \cdot \left(\frac{1}{\gamma|S|} \log 2 \; + \; \frac{d}{\gamma|S|} \log \frac{1}{\gamma} \right)$.
    $N = N \cup N_S$.

return N.

For the **Special Net-Finder Algorithm**, simply omit the initial random sample, and start with $N = N_0 = \emptyset$.

The proof of our main result builds on the technique in [18]. There the packing lemma was used to construct a maximal packing. The new insight in this paper is that through the use of *two-level* packings, it is not necessary to even know or construct maximal packings (the computational bottleneck earlier). The algorithm is blind to the specific packing; however the analysis amortizes the cost of adding new points to a second-level packing constructed from the sets of the first packing. This is the key new idea, enabling us to bound the total number of points added after the initial random sample.

For the proof of our two main theorems, we will need the following results.

▶ **Theorem A** (Epsilon-net Theorem [11, 12]). *Let $(X, \mathcal{R})$ be a set system, $d \in \mathbb{N}^+$ a positive integer such that* VC-dim$(\mathcal{R}) \leq d$*, and $\epsilon \in [0, 1]$ a given real parameter. Then there exists an absolute constant $c_a > 0$ such that a random sample N constructed by picking each point of X independently with probability*

$$c_a \cdot \left(\frac{1}{\epsilon |X|} \log \frac{1}{\gamma} \; + \; \frac{d}{\epsilon |X|} \log \frac{1}{\epsilon} \right).$$

is an ϵ-net for $\mathcal{R}$ with probability at least $1 - \gamma$.

Given $(X, \mathcal{R})$, a (k, δ)-packing of $\mathcal{R}$ is a subset $\mathcal{P} \subseteq \mathcal{R}$ such that $i)$ for all $S \in \mathcal{P}$ we have $|S| \leq k$, and $ii)$ for all $S, S' \in \mathcal{P}$ we have $|\Delta(S, S')| \geq \delta$. Here $\Delta(A, B) = (A \setminus B) \cup (B \setminus A)$ is the symmetric difference of A and B.

▶ **Theorem B** (Shallow Packing Lemma [17]). *Let $(X, \mathcal{P})$ be a (k, δ)-packing on n elements, for integers $k, \delta > 0$. If* VC-dim$(\mathcal{P}) \leq d$ *and $\mathcal{P}$ has shallow-cell complexity $\varphi(\cdot, \cdot)$, then $|\mathcal{P}| \leq \frac{24dn}{\delta} \cdot \varphi\big(\frac{4dn}{\delta}, \frac{12dk}{\delta}\big)$.*

In the proof below, we assume that each set S considered by the algorithm has size $[\epsilon n, 2\epsilon n]$. Then we will show that, in expectation, $O(\frac{1}{\epsilon})$ additional points are added after the initial random sample N_0. The general case – where the sets S considered by the algorithm can have any size greater than ϵn – follows directly: we group the sets considered by the algorithm by their sizes – all sets of size $[2^i \epsilon n, 2^{i+1} \epsilon n]$ go into the same group i. So the algorithm can be seen as constructing different nets, a ϵ'-net where $\epsilon' = 2^i \epsilon$, for group i, simultaneously. The proof below shows that for each group i, the expected number of elements added is $O\left(\frac{1}{\epsilon'}\right) = O\left(\frac{1}{2^i \epsilon}\right)$. Then summing up gives a geometric series, with the overall bound of $O\left(\frac{1}{\epsilon}\right)$ points added over all groups. The initial random sample N_0 can be thought of as a different sample for each group, with the total size over all groups again forming a geometric series which sums up to the stated bound.

Let β, γ be two positive reals whose value will be fixed later, with the property that $\gamma \leq \frac{1}{4}$ and $0 \leq \beta + \gamma \leq 1$.

Fix any *maximal* $(2\epsilon n, \beta \epsilon n)$-packing $\mathcal{P}$ of $\mathcal{R}$ consisting of sets of size at least ϵn; say the packing consists of the sets

$$\mathcal{P} = \left\{P^1, \ldots, P^m\right\}, \text{ where } m \leq \frac{24dn}{\beta \epsilon n} \varphi_{\mathcal{R}} \left(\frac{4dn}{\beta \epsilon n}, \frac{24d\epsilon n}{\beta \epsilon n} \right)$$
$$= O\left(\frac{d}{\beta \epsilon} \cdot \varphi_{\mathcal{R}} \left(\frac{4d}{\beta \epsilon}, \frac{24d}{\beta} \right) \right) \text{ (by Theorem B).}$$

Say the **Net-Finder Algorithm** (both general and special) continues for t steps, and adds additional points of X to N for each of the sets $S_1, \ldots, S_t$, namely the points $N_{S_1}, \ldots, N_{S_t}$.

As $\mathcal{P}$ is a maximal $(2\epsilon n, \beta\epsilon n)$-packing of $\mathcal{R}$ and $\epsilon n \leq |S_i| \leq 2\epsilon n$ for each $i = 1, \ldots, t$, it must be that for each S_i, there exists an index $j \in [m]$ with $|\Delta(S_i, P^j)| < \beta\epsilon n$ (note that it is possible that $P^j = S_i$). Assign S_i to the set P^j (pick an arbitrary one if there are several such possibilities).

For each $j \in [m]$, let n_j be the number of sets of $\{S_1, \ldots, S_t\}$ assigned to $P^j \in \mathcal{P}$, and denote them by

$$\mathcal{S}^j = \langle S^j_1, \ldots, S^j_{n_j} \rangle, \quad \text{listed } \textit{in the order} \text{ considered by the } \textbf{Net-Finder Algorithm}.$$

Note that $\sum_{j=1}^{m} n_j = t$, and furthermore,

$$\text{for every } j \in [m], \;\; i \in [n_j], \quad \text{we have} \quad |\Delta(S^j_i, P^j)| < \beta\epsilon n. \tag{1}$$

▷ Claim 3. For each $j \in [m]$ and $i \in [n_j]$, we have

$$|P^j \cap S^j_i| > \frac{|P^j| + |S^j_i| - \beta\epsilon n}{2}.$$

Proof. For each $i \in [n_j]$, we have

$$|P^j| + |S^j_i| = |P^j \setminus S^j_i| + |S^j_i \setminus P^j| + 2|P^j \cap S^j_i| < \beta\epsilon n + 2|P^j \cap S^j_i|, \tag{2}$$

where the last inequality follows from (1). Re-arranging the terms above gives the required statement. ◁

For each $j \in [m]$, define

$$\mathcal{S}'^j = \left\{ S \in \mathcal{S}^j : N_S \text{ turns out to be a } \gamma\text{-net for the set system } (S, \mathcal{R}|_S) \right\}.$$

▷ Claim 4. For any $j \in [m]$,

$$|\mathcal{S}'^j| = \begin{cases} O\left(\frac{d}{\frac{3}{2}-\beta-\gamma} \cdot \varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2}-\beta-\gamma}, \frac{12d}{\frac{3}{2}-\beta-\gamma}\right)\right) & \text{if } \beta + \gamma \geq \frac{1}{2}, \\ O(1) & \text{otherwise.} \end{cases}$$

Proof. Let $n'_j = |\mathcal{S}'^j|$. By re-labeling the sets of $\mathcal{S}^j$, we can assume that $\mathcal{S}'^j = \langle S^j_1, \ldots, S^j_{n'_j} \rangle$, again listed here in the order that they were considered by the **Net-Finder Algorithm**.

Consider the set system $\mathcal{T}'^j = \langle T^j_1, \ldots, T^j_{n'_j} \rangle$ over the base set P^j, where $T^j_i = S^j_i \cap P^j$. Consider two distinct indices $k, l \in [n'_j]$ with $k < l$. The set $N_{S^j_k}$ was added to N in the algorithm *before* the set S^j_l was considered. In particular, as $N_{S^j_k}$ is a γ-net for $\left(S^j_k, \mathcal{R}|_{S^j_k}\right)$ (by the definition of $\mathcal{S}'^j$), it must be that the set S^j_l was not hit by the γ-net for $\left(S^j_k, \mathcal{R}|_{S^j_k}\right)$ and so $|S^j_k \cap S^j_l| < \gamma \cdot |S^j_k|$. In particular, this implies that

$$|T^j_k \cap T^j_l| = |S^j_k \cap S^j_l \cap P^j| \leq |S^j_k \cap S^j_l| < \gamma \cdot |S^j_k|. \tag{3}$$

Thus we have

$$\begin{aligned}
|\Delta(T_k^j, T_l^j)| &= |T_k^j| + |T_l^j| - 2|T_k^j \cap T_l^j| \qquad (4)\\
&= |S_k^j \cap P^j| + |S_l^j \cap P^j| - 2|T_k^j \cap T_l^j|\\
&> \frac{|P^j| + |S_k^j| - \beta\epsilon n}{2} + \frac{|P^j| + |S_l^j| - \beta\epsilon n}{2} - 2|T_k^j \cap T_l^j| \quad \text{(by Claim 3)}\\
&> \frac{|P^j| + |S_k^j| - \beta\epsilon n}{2} + \frac{|P^j| + |S_l^j| - \beta\epsilon n}{2} - 2\cdot\gamma\cdot|S_k^j| \qquad \text{(by Inequality (3))}\\
&= |P^j| - \beta\epsilon n + \frac{|S_l^j|}{2} + \left(\frac{1}{2} - 2\gamma\right)|S_k^j|\\
&\geq |P^j| - \beta|P^j| + \frac{|P^j|/2}{2} + \left(\frac{1}{2} - 2\gamma\right)\frac{|P^j|}{2} \quad (\text{as } \epsilon n \leq |P^j|, |S_k^j|, |S_l^j| \leq 2\epsilon n,\ \gamma \leq \tfrac{1}{4})\\
&= \left(\frac{3}{2} - \beta - \gamma\right)\cdot|P^j|. \qquad (5)
\end{aligned}$$

There are two cases to consider here:

- $\beta + \gamma < \frac{1}{2}$. In this case, Inequality (5) implies that $|\Delta(T_k^j, T_l^j)| > |P^j|$, which cannot happen as both T_k^j and T_l^j are subsets of P^j. Thus $\mathcal{S}'^j$ must consist of at most one set, and we're done.
- $\beta + \gamma \geq \frac{1}{2}$. In this case, the sets of $\mathcal{T}'^j$ form a $\left(|P^j|, \left(\frac{3}{2} - \beta - \gamma\right)\cdot|P^j|\right)$-packing over the elements of P^j. Thus by Theorem B, we have

$$|\mathcal{S}'^j| = |\mathcal{T}'^j| = O\left(\frac{d}{\frac{3}{2} - \beta - \gamma}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2} - \beta - \gamma}, \frac{12d}{\frac{3}{2} - \beta - \gamma}\right)\right).$$ ◁

▶ **Lemma 5.**

$$\mathbf{E}\left[|\mathcal{S}^j|\right] = \begin{cases} O\left(\frac{d}{\frac{3}{2}-\beta-\gamma}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2}-\beta-\gamma}, \frac{12d}{\frac{3}{2}-\beta-\gamma}\right)\right) & \text{if } \beta+\gamma \geq \frac{1}{2},\\ O(1) & \text{otherwise.}\end{cases}$$

Further, the above bound holds for any choice of N_0.

Proof. We prove this bound for any choice of N_0, relying, in the following analysis, only on the sets N_S that were added iteratively. Note that there may be complicated dependencies among the sets of $\mathcal{S}^j$. For example, a set S_l^j may only exist in $\mathcal{S}^j$ because of the choice of the random sample for some earlier set S_k^j, $k < l$. However, for a fixed $S \in \mathcal{R}$, the probability of the random sample N_S being a γ-net for the set system $(S, \mathcal{R}|_S)$ is independent of earlier iterations, and occurs with probability at least $\frac{1}{2}$ by Theorem A. Recalling that $|\mathcal{S}'^j|$ is the number of sets of $\mathcal{S}^j$ for which the random sample succeeds to be a γ-net, we have

$$\mathbf{E}\left[|\mathcal{S}'^j|\right] = \sum_{S\in\mathcal{S}^j}\Pr\left[N_S \text{ is a } \gamma\text{-net for } (S, \mathcal{R}|_S)\right] \geq \frac{|\mathcal{S}^j|}{2}.$$

On the other hand, Claim 4 upper-bounds $|\mathcal{S}'^j|$ and thus $\mathbf{E}[|\mathcal{S}'^j|]$. Putting them together implies the lemma. ◀

4 Proof of Theorem 1

We first give the key theorem from which we will then derive all the bounds promised in Theorem 1. We continue to use the notations and definitions defined earlier.

▶ **Theorem 6.** *Let $(X, \mathcal{R})$ be a set system with shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$ and VC-dimension at most d. Then the* ***General Net-Finder Algorithm*** *returns an ϵ-net of expected size $O\left(\frac{1}{\epsilon}\log\varphi_{\mathcal{R}}\left(O\left(\frac{d}{\epsilon}\right), O(d)\right) + \frac{d}{\epsilon}\right)$. Furthermore, it makes expected $O\left(\frac{1}{\epsilon}\right)$ calls to the Oracle.*

Proof. Clearly the algorithm only stops when N is an ϵ-net. Thus it remains to bound the expected size and the expected running time.

Consider an index $j \in [m]$. By Claim 3, we have that for any $i \in [n_j]$,

$$|P^j \cap S_i^j| > \frac{|P^j| + |S_i^j| - \beta\epsilon n}{2} \geq \frac{|P^j| + |P^j|/2 - \beta|P^j|}{2} = \left(\frac{3}{4} - \frac{\beta}{2}\right)\cdot|P^j|,$$

recalling that $\beta \leq 1$. Thus if N_0 is a $\left(\frac{3}{4}-\frac{\beta}{2}\right)$-net for $\left(P^j, \mathcal{R}|_{P^j}\right)$, then any $S \in \mathcal{S}^j$ would be hit by N_0 and so it must be that $\mathcal{S}^j = \emptyset$. By Theorem A, for a fixed index j, N_0 fails to be a $\left(\frac{3}{4}-\frac{\beta}{2}\right)$-net for $\left(P^j, \mathcal{R}|_{P^j}\right)$ with probability $O\left(\frac{1}{d^3\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon}, \frac{24d}{\beta}\right)^2}\right)$.

At each iteration, for a set $S \in \mathcal{R}$ not hit by N, we add

$$\mathbf{E}\left[|N_S|\right] = |S|\cdot c_a \cdot \left(\frac{1}{\gamma|S|}\log 2 \;+\; \frac{d}{\gamma|S|}\log\frac{1}{\gamma}\right) = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)$$

new points to N. Thus the points added to N over all iterations are

$$\begin{aligned}
&\mathbf{E}\left[\sum_{i=1}^{t}|N_{S_i}|\right] = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot\mathbf{E}[t] = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot\mathbf{E}\left[\sum_{j=1}^{m}|\mathcal{S}^j|\right]\\
&= O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot\sum_{j=1}^{m}\Pr\left[N_0 \text{ is not a } \left(\frac{3}{4}-\frac{\beta}{2}\right)\text{-net for } (P^j,\mathcal{R}|_{P^j})\right]\cdot\\
&\qquad\qquad\mathbf{E}\left[|\mathcal{S}^j|\,\middle|\,N_0 \text{ is not a } \left(\frac{3}{4}-\frac{\beta}{2}\right)\text{-net for } (P^j,\mathcal{R}|_{P^j})\right]\\
&= O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot m\cdot O\left(\frac{1}{d^3\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{12d}{\beta/2}\right)^2}\right)\cdot O\left(\frac{d}{\frac{3}{2}-\beta-\gamma}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2}-\beta-\gamma},\frac{12d}{\frac{3}{2}-\beta-\gamma}\right)\right).
\end{aligned}$$

As $\frac{3}{2}-\beta-\gamma \geq \frac{1}{2} \geq \max\left\{\beta\epsilon, \frac{\beta}{2}\right\}$ for $\epsilon \leq 0.5$ and by the assumption that $\varphi_{\mathcal{R}}(\cdot,\cdot)$ is non-decreasing in the first and second arguments,

$$\begin{aligned}
&\leq O\left(\frac{1}{\gamma\left(\frac{3}{2}-\beta-\gamma\right)}\log\frac{1}{\gamma}\right)\cdot m\cdot O\left(\frac{1}{d\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)}\right)\\
&= O\left(\frac{1}{\gamma\left(\frac{3}{2}-\beta-\gamma\right)}\log\frac{1}{\gamma}\right)\cdot O\left(\frac{d}{\beta\epsilon}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)\right)\cdot O\left(\frac{1}{d\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)}\right)\\
&= O\left(\frac{1}{\gamma\left(\frac{3}{2}-\beta-\gamma\right)}\log\frac{1}{\gamma}\right)\cdot O\left(\frac{1}{\beta\epsilon}\right).
\end{aligned}$$

For the initial set N_0, we have

$$\mathbf{E}\left[|N_0|\right] = O\left(\frac{1}{\left(\frac{3}{4}-\frac{\beta}{2}\right)\epsilon}\log\left(d\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)\right) + \frac{d}{\left(\frac{3}{4}-\frac{\beta}{2}\right)\epsilon}\log\frac{1}{\left(\frac{3}{4}-\frac{\beta}{2}\right)}\right)$$

Putting everything together, we get

$$\begin{aligned}\mathbf{E}\left[|N|\right] &= \mathbf{E}\left[|N_0|\right] + \mathbf{E}\left[\sum_{i=1}^{t} |N_{S_t}|\right] \\ &= O\left(\frac{1}{\left(\frac{3}{4}-\frac{\beta}{2}\right)\epsilon}\log\left(d\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)\right) + \frac{d}{\left(\frac{3}{4}-\frac{\beta}{2}\right)\epsilon}\log\frac{1}{\left(\frac{3}{4}-\frac{\beta}{2}\right)}\right) \\ &\quad + O\left(\frac{1}{\gamma\left(\frac{3}{2}-\beta-\gamma\right)}\log\frac{1}{\gamma}\right)\cdot O\left(\frac{1}{\beta\epsilon}\right).\end{aligned}$$

We can set γ to be any small-enough constant, say $\gamma = \frac{1}{100}$, and set $\beta = \frac{3}{4}$. Thus we get

$$\mathbf{E}\left[|N|\right] = O\left(\frac{1}{\epsilon}\log\left(d\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)\right) + \frac{d}{\epsilon}\right) = O\left(\frac{1}{\epsilon}\log\varphi_{\mathcal{R}}\left(O\left(\frac{d}{\epsilon}\right), O\left(d\right)\right) + \frac{d}{\epsilon}\right). \blacktriangleleft$$

▶ **Theorem 1.** ***General Net-Finder Algorithm*** *computes an ϵ-net of expected optimal size for ϵ-nets for the following set systems:*

1. $O\left(\frac{1}{\epsilon}\log\varphi_{\mathcal{R}}\left(O\left(\frac{d}{\epsilon}\right), O(d)\right) + \frac{d}{\epsilon}\right)$*: abstract set systems as a function of their shallow-cell complexity $\varphi_{\mathcal{R}}(\cdot,\cdot)$ (we will assume that $\varphi_{\mathcal{R}}(\cdot,\cdot)$ is non-decreasing in both arguments) and VC-dimension d,*
2. $O\left(\frac{1}{\epsilon}\right)$*: half-spaces in $\mathbb{R}^2$, half-spaces in $\mathbb{R}^3$, pseudo-disks and disks in $\mathbb{R}^2$, dual systems of linear union complexity,*
3. $O\left(\frac{1}{\epsilon}\log\log\frac{1}{\epsilon}\right)$*: axis-parallel rectangles in $\mathbb{R}^2$,*
4. $O\left(\frac{\log(\epsilon\cdot\kappa_{\mathcal{R}}(1/\epsilon))}{\epsilon}\right)$*: dual set systems as a function of their union complexity $\kappa_{\mathcal{R}}(\cdot)$,*
5. $O\left(\frac{d}{\epsilon}\log\frac{1}{\epsilon}\right)$*: set systems of VC-dimension at most d, half-spaces in $\mathbb{R}^d$.*

See [19, Table 47.4.1] for the complete list of known bounds, all of which are produced by our algorithm.

Furthermore, it makes expected $O(\frac{1}{\epsilon})$ calls to the Oracle.

Proof. All except one required bound follows directly from Theorem 6; we refer the reader to the survey [19]. Briefly, for the case of halfspaces in $\mathbb{R}^2$, $\mathbb{R}^3$, disks and pseudo-disks in $\mathbb{R}^2$, we have $\varphi(n,k) = O(k^c)$, for a constant c (by the bound on $(\leq k)$-sets [9]) and so the algorithm returns ϵ-nets of size $O(\frac{1}{\epsilon})$. For the case of half-spaces in $\mathbb{R}^d$ and balls in $\mathbb{R}^{d-1}$, $d \geq 4$, we have $\varphi(n,k) = n^{\lfloor d/2\rfloor - 1}k^{\lceil d/2\rceil}$ and so the algorithm returns ϵ-nets of size $O\left(\frac{d}{\epsilon}\log\frac{1}{\epsilon}\right)$. Similarly the bounds follow for the dual set systems as a function of their union complexity.

The exception is the bound of $O\left(\frac{1}{\epsilon}\log\log\frac{1}{\epsilon}\right)$ for the primal system induced by axis-parallel rectangles in the plane. Here we use a result of Aronov et al. [4] which shows that given a set X of n points in the plane, and $\mathcal{R}$ the set system induced on X by all axis-parallel rectangles, there exists another set system $\mathcal{R}'$ on X with the following property:

1) For each set $R \in \mathcal{R}$ of size at least ϵn induced by an axis-parallel rectangle in the plane, there exists a set $f(R) \in \mathcal{R}'$ also induced by an axis-parallel rectangle in the plane, with $f(R) \subseteq R$ and further $|f(R)| \geq \frac{|R|}{2}$.

2) The shallow-cell complexity of $\mathcal{R}'$ is small – $\varphi_{\mathcal{R}'}(n,k) = O\left(\log n \cdot k^3\right)$.

Now **General Net-Finder Algorithm** takes a $O(1)$-sized uniform random sample from a currently unhit set of $\mathcal{R}$, say R. But then by property 1) above, it takes a $O(1)/2$-sized uniform random sample from $f(R)$. From property 2) above, we have $\varphi_{\mathcal{R}'}(n,k) = O\left(\log n \cdot k^3\right)$ and so Theorem 6 implies a bound of $O\left(\frac{1}{\epsilon}\log\log\frac{1}{\epsilon}\right)$. ◀

5 Proof of Theorem 2

All the known bounds of $O\left(\frac{1}{\epsilon}\right)$ for set systems follow because for such a system $\mathcal{R}$, we have $\varphi_{\mathcal{R}}(n,k) = k^c$ for some constant c. Thus Theorem 2 can be deduced from the following theorem.

▶ **Theorem 7.** *Let $(X,\mathcal{R})$ be a set system with shallow-cell complexity $\varphi(n,k) = O(k^c)$ for some absolute constant c. Then the **Special Net-Finder Algorithm** returns an ϵ-net of expected size $O\left(\frac{1}{\epsilon}\right)$.*

Proof. Clearly the algorithm only stops when N is an ϵ-net. Thus it remains to bound the expected size and the expected running time.

At each iteration, for a set $S \in \mathcal{R}$ not hit by N, we add

$$\mathbf{E}[|N_S|] = |S| \cdot c_a \cdot \left(\frac{1}{\gamma|S|}\log 2 \;+\; \frac{d}{\gamma|S|}\log\frac{1}{\gamma}\right) = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)$$

new points to N. Thus the points added to N over all iterations are

$$\begin{aligned}
&\mathbf{E}\left[\sum_{i=1}^{t}|N_{S_i}|\right] = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot\mathbf{E}[t] = O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot\mathbf{E}\left[\sum_{j=1}^{m}|\mathcal{S}^j|\right]\\
&= O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot m\cdot O\left(\frac{d}{\frac{3}{2}-\beta-\gamma}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2}-\beta-\gamma},\frac{12d}{\frac{3}{2}-\beta-\gamma}\right)\right)\\
&= O\left(\frac{d}{\gamma}\log\frac{1}{\gamma}\right)\cdot O\left(\frac{d}{\beta\epsilon}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\beta\epsilon},\frac{24d}{\beta}\right)\right)\cdot O\left(\frac{d}{\frac{3}{2}-\beta-\gamma}\cdot\varphi_{\mathcal{R}}\left(\frac{4d}{\frac{3}{2}-\beta-\gamma},\frac{12d}{\frac{3}{2}-\beta-\gamma}\right)\right)
\end{aligned}$$

Using $\gamma = \frac{1}{100}$, $\beta = \frac{3}{4}$, c is an absolute constant, and $d = O(c)$ since $\varphi_{\mathcal{R}}(n,k) = O(k^c)$,

$$= O(d)\cdot O\left(\frac{d}{\epsilon}\cdot d^c\right)\cdot O(d\cdot d^c) = O\left(\frac{1}{\epsilon}\right). \qquad \blacktriangleleft$$

▶ **Theorem 2.** *If the shallow-cell complexity of $\mathcal{R}$ satisfies $\varphi_{\mathcal{R}}(n,k) = O(k^c)$, then **Special Net-Finder Algorithm** computes an ϵ-net of expected size $O\left(\frac{1}{\epsilon}\right)$. In particular, it computes a $O\left(\frac{1}{\epsilon}\right)$-sized net for the set systems induced by half-spaces in $\mathbb{R}^2$, half-spaces in $\mathbb{R}^3$, pseudo-disks and disks in $\mathbb{R}^2$, and dual systems of linear union complexity.*

Furthermore it makes expected $O(\frac{1}{\epsilon})$ calls to the Oracle.

Proof. For each of these specific cases, we have $\varphi_{\mathcal{R}}(n,k) = O(k^c)$ for some constant c, and thus Theorem 7 implies the bounds. ◀

6 Conclusion

Some final remarks:

- The algorithms, as they are stated, need the bound on the shallow-cell complexity (in fact, in the case of rectangles, even a finer decomposition bound) to set the initial sample size. However, by a standard exponential search trick, one can start with an initial guess of $O(1)$ for N_0, run the algorithm for $O\left(\frac{1}{\epsilon}\right)$ iterations and if the resulting set is not an ϵ-net, re-run the algorithm with a doubled initial sample size. This incurs an additional $O\left(\log\frac{1}{\epsilon}\right)$ penalty in the running time.

- Our algorithm, unlike earlier work, is adaptive: after the initial random sample, further additional points are added incrementally, and each additional set of $O(1)$ points that are added takes into account the previously added points.
- There has been recent work towards new algorithmic approaches for sketches and samples that work well in practice [13]. We leave for future work the experimental evaluation of our algorithm and comparison with earlier approaches, both in efficiency and whether the adaptive nature of our algorithm leads to improved size bounds in practice.

Abstract

The Weighted Tree Augmentation problem (WTAP) is a fundamental problem in network design. In this paper, we consider this problem in the online setting. We are given an n-vertex spanning tree T and an additional set L of edges (called links) with costs. Then, terminal pairs arrive one-by-one and our task is to maintain a low-cost subset of links F such that every terminal pair that has arrived so far is 2-edge-connected in $T \cup F$. This online problem was first studied by Gupta, Krishnaswamy and Ravi (SICOMP 2012) who used it as a subroutine for the online survivable network design problem. They gave a deterministic $O(\log^2 n)$-competitive algorithm and showed an $\Omega(\log n)$ lower bound on the competitive ratio of randomized algorithms. The case when T is a path is also interesting: it is exactly the online interval set cover problem, which also captures as a special case the parking permit problem studied by Meyerson (FOCS 2005). The contribution of this paper is to give tight results for online weighted tree and path augmentation problems. The main result of this work is a deterministic $O(\log n)$-competitive algorithm for online WTAP, which is tight up to constant factors.

1 Introduction

In the *weighted tree augmentation problem* (WTAP), we are given an n-vertex spanning tree $T = (V, E)$ together with an additional set of edges L called *links*, where $L \subseteq \binom{V}{2}$. Each link $\ell \in L$ has a cost $c(\ell) \geq 0$. Terminal pairs (s_i, t_i), $i = \{1, \ldots, k\}$, are given and the goal is to compute a minimum cost subset of links $F \subseteq L$ such that each terminal pair is (edge) 2-connected in $T \cup F$. In the unweighted version, the links have unit costs and the problem

is known as the *tree augmentation problem* (TAP). If the spanning tree T is a path, then the unweighted problem is called the *path augmentation problem* (PAP), while the weighted version is called *weighted path augmentation* (WPAP).

TAP and WTAP are considered to be fundamental connectivity augmentation problems, and have been studied extensively. TAP is already known to be APX-hard and the best approximation algorithms for WTAP and TAP achieve approximation factors of 2 and 1.458 respectively [6, 7]. Improving these bounds is an important open problem.

We consider these problems in the online setting. In online WTAP, we are initially given a spanning tree $T = (V, E)$, and the set of links L together with their costs. The terminal pairs (s_i, t_i) arrive online one by one. Our goal is to maintain a low-cost subset of links $F \subseteq L$ such that each terminal pair seen so far is (edge) 2-connected in $T \cup F$.

Online WTAP occurs as a subproblem in the online survivable network design algorithm of Gupta, Krishnaswamy and Ravi [8]. They observed that the online tree augmentation problem can be cast as an instance of the online set cover problem[1] in which the elements are the fundamental cuts defined by the terminal pairs and the sets are the links. Since there are only n elements and $O(n^2)$ sets, applying the results of Alon et al. [1] yields a fractional $O(\log n)$-competitive algorithm. But, then, how does one round the fractional solution online? Randomized rounding seems to be the only rounding technique we have for this problem, and it yields a randomized $O(\log^2 n)$-competitive algorithm, as observed by [1]. This competitive factor can even be achieved deterministically at no further cost [1]. We note that the loss of a logarithmic factor in the rounding step seems inherent. Interestingly, Gupta, Krishnaswamy and Ravi [8] also showed for the rooted setting ($s_i = r$ for some root r) a lower bound of $\Omega(\log n)$ against randomized algorithms. It is easy to observe that this lower bound also holds against fractional online algorithms.

There has been a long line of work on maintaining connectivity online, starting in the seminal paper of Imase and Waxman [11]. A $\Theta(\log n)$-competitive algorithm is given there for the online Steiner problem in undirected graphs. In this problem the graph with a fixed root vertex is known in advance and the terminals are given one by one, and one must ensure that all terminals that have arrived so far are connected to the root. Other polylogarithmic (in n) competitive algorithms have been given for more complex models of connectivity, including those with node costs rather than edge costs and penalties for violating connectivity constraints; see [2, 3, 13, 9, 10, 16, 14]. Gupta, Krishnaswamy, and Ravi [8] consider the online survivable network design problem, which generalizes WTAP. In this problem, a graph is fixed in advance and terminal pairs (s_i, t_i) arrive with connectivity requirements r_i; one must ensure that there are at least r_i edge-disjoint paths between s_i and t_i for all pairs that have arrived thus far. They give a randomized $\tilde{O}(r_{\max} \log^3 n)$-competitive algorithm for the problem, where $r_{\max} = \max_i r_i$. Note that this problem with uniform requirements $r_i = 2$ already generalizes WTAP.

The online WPAP, when T is a path, is an interesting problem in its own right. This problem is equivalent to online interval set cover. It captures as a special case the parking permit problem introduced by Meyerson [12]. In this problem, there is a sequence of days; each day it is either sunny or it rains, and if it rains we must purchase a parking permit. Permits have various durations and costs. We can model the parking permit problem by online path augmentation by letting the edges of the path correspond to the sequence of days, the links to the permits, and the rainy days to a terminal pair request for the

[1] In the online set cover problem, elements arrive online and need to be covered upon arrival by sets from a set system known in advance. (Note that not necessarily all elements will appear.)

corresponding day. Meyerson [12] gives a deterministic $O(\log n)$-competitive algorithm for the problem and a randomized $O(\log \log n)$-competitive algorithm, and shows lower bounds on the competitive ratio of $\Omega(\log n / \log \log n)$ for deterministic algorithms and $\Omega(\log \log n)$ for randomized algorithms. Note that online WPAP is a strict generalization of the parking permit problem because the parking permit problem assumes that permits of the same duration have the same cost, whereas no such assumption is made of the links in WPAP.

1.1 Our Results

The contribution of this paper is to give tight results (within constant factors) for online tree and path augmentation problems. Our main result is that weighted online tree augmentation has a competitive ratio of $\Theta(\log n)$.

▶ **Theorem 1.** *There is a deterministic algorithm for online WTAP with competitive ratio* $O(\log n)$.

This result is tight up to constant factors because of the $\Omega(\log n)$ lower bound on randomized algorithms for WTAP given by [8]. As we mention above, [8] gives a randomized $\tilde{O}(r_{\max} \log^3 n)$-competitive algorithm for the online survivable network design problem. An intriguing open question is whether this competitive ratio can be improved, say to $O(r_{\max} \log n)$ or even $O(\log n)$. In fact, we are unaware of lower bounds that rule out the latter bound. We view our main result as a necessary stepping stone towards obtaining an $O(r_{\max} \log n)$ or $O(\log n)$ bound. Indeed, for $r_{\max} = 2$, plugging in our algorithm for online WTAP into the algorithm of [8] improves their competitive ratio from $\tilde{O}(\log^3 n)$ to $\tilde{O}(\log^2 n)$.

▶ **Corollary 2.** *For online survivable network design with* $r_{\max} = 2$*, there is a randomized algorithm with competitive ratio* $\tilde{O}(\log^2 n)$.

Our second result shows that the competitive ratio for deterministic algorithms for online path augmentation is also $\Theta(\log n)$. Meyerson [12] gives a lower bound of $\Omega(\log n / \log \log n)$ for deterministic algorithms for the parking permit problem, and hence for online path augmentation. We improve the analysis of his lower bound instance to show the following.

▶ **Theorem 3.** *Every deterministic algorithm for online WPAP has competitive ratio* $\Omega(\log n)$.

Since we use a parking permit instance to show the lower bound, we have the same lower bound for the parking permit problem.

Finally, we show that the fractional version of online path augmentation has competitive ratio $\Theta(\log \log n)$ for deterministic algorithms. Meyerson [12] gives a lower bound of $\Omega(\log \log n)$ for randomized algorithms for the parking permit problem, and hence for online fractional path augmentation. Our algorithm implies an exponential gap between the competitive ratios of fractional path augmentation and fractional tree augmentation. We show the following.

▶ **Theorem 4.** *There is a deterministic algorithm for online fractional WPAP with competitive ratio* $O(\log \log n)$.

Recall that online WPAP is equivalent to online interval set cover. Thus, Theorems 1 and 4 imply that restricting online set cover to interval sets allows for improved competitive ratios. Also, even though interval set cover and interval hitting set are equivalent in the offline case, the latter turns out to be exponentially more difficult than the former in the online case; in contrast to Theorem 4, Even and Smorodinsky [5] gave a lower bound of $\Omega(\log n)$ for online fractional hitting set.

1.2 Our Techniques

We now outline some of the ideas behind our algorithms.

Online WTAP

As mentioned before, there is an online *fractional* $O(\log n)$-competitive algorithm for WTAP that follows from the work of [1] on the online set cover problem. However, it is unclear how to exploit the special structure of the set system in hand in WTAP (as defined by the links) to avoid the loss of another factor of $O(\log n)$ when rounding the fractional solution into an integral one (either randomized or deterministic). Thus, our approach to proving Theorem 1 takes a completely different route. There are two key ingredients in our proof:

1. **Low-width path decomposition.** The first ingredient is a path decomposition of low "width": in particular, there is a decomposition of the tree into edge-disjoint paths such that any path in the tree intersects at most $O(\log n)$ paths of the decomposition. Such a decomposition can be obtained using the heavy-path decomposition of Sleator and Tarjan [15]. This immediately implies an $O(\log n)$-approximate black-box reduction from online tree augmentation to online path augmentation. Unfortunately, Theorem 3 gives a lower bound of $\Omega(\log n)$ for the latter problem. Since a tree may have width $\Omega(\log n)$ in the worst case (e.g., a binary tree), the best we can achieve for WTAP using a black-box reduction is a competitive ratio of $O(\log^2 n)$.
2. **Refined guarantee for path augmentation.** The second ingredient is our main technical contribution. We define a notion of *projection* for links onto paths in the path decomposition, and call the projected link *rooted* if it has, as its endpoint, the node of the path closest to the root of the tree. The key insight is that the path decomposition has a special structure: for each link, its projection is rooted for all but at most one of the paths in the decomposition. We then give a version of the path algorithm that treats rooted links differently from non-rooted links; in particular, an online path augmentation algorithm that finds a solution whose cost is within a constant factor of the rooted links of the optimal solution plus an $O(\log n)$ factor of the cost of the non-rooted links. Intuitively, then, summing the cost over all the paths in the decomposition, each link appears as a rooted link in at most $O(\log n)$ paths in the decomposition and as a non-rooted link in at most one path in the decomposition, yielding the $O(\log n)$ factor overall.

Online Fractional WPAP

Directly applying the online fractional set cover algorithm of [1] to online fractional WPAP only yields a competitive ratio of $O(\log n)$. However, for online set cover instances in which each element is covered by at most d sets, the algorithm of [1] is $O(\log d)$-competitive. Thus, to get a competitive ratio of $O(\log \log n)$, the basic idea is to reduce to a restricted instance in which each request can only be covered by $O(\log n)$ links. For such restricted instances, applying the algorithm of [1] gives a competitive ratio of $O(\log \log n)$.

1.3 Other Related Work

Recently, Dehghani et al. [4] studied online survivable network design, giving a bicriteria approximation algorithm, and considering several stochastic settings.

1.4 Organization of the Paper

We start with the preliminaries and describe the low-width path decomposition in Section 2. In Section 3, we present the refined guarantee needed for online path augmentation. Then, we show how to achieve the required refined guarantee in Section 4. Due to lack of space, we defer the proofs of Theorems 3 and 4 to the full version.

2 Preliminaries

We restate the formal definition of the problem. In the online weighted tree augmentation problem, we are initially given a spanning tree $T = (V, E)$, and an additional set of edges called *links* $L \subseteq \binom{V}{2}$ with costs $c(\ell) \geq 0$. Then, terminal pairs (s_i, t_i) arrive one by one. Our goal is to maintain a low-cost subset of links $F \subseteq L$ such that each terminal pair seen so far is 2-connected in $T \cup F$.

Notation

Denote by $P(u, v)$ the path between u and v in T. For a link $\ell = (u, v)$, we write $P(\ell) = P(u, v)$ and for a set S of links, we write $P(S) = \bigcup_{\ell \in S} P(\ell)$. We say that a link $\ell \in L$ *covers* an edge $e \in E$ if $e \in P(\ell)$. Define $\text{cov}(e) = \{\ell \in L : e \in P(\ell)\}$ to be the set of links covering e. Note that $\text{cov}(e)$ is exactly the set of links crossing the cut induced by the tree edge e. Let $R \subseteq E$ be a set of requests. Then, a solution F is feasible if and only if for every edge $e \in R$, we have $F \cap \text{cov}(e) \neq \emptyset$; or equivalently, if $P(F) \supseteq R$.

Simplifying assumptions

In the rest of this paper, we assume that link costs are powers of 2; this assumption is without loss of generality since we can round up all edge costs and lose only a factor of 2 in the competitive ratio. Given that link costs are powers of 2, we say that the *class* of a link ℓ is j if $c(\ell) = 2^j$ and we write $\text{class}(\ell) = j$.

Given an instance in which link costs are powers of 2, we also assume that requests are *elementary*: each request (s_i, t_i) is a tree edge $e \in E$. This is without loss of generality because an adversary can simulate a non-elementary request (s_i, t_i) by a sequence of requests, where each request is an edge along the path between s_i and t_i in T.

Path decomposition

We next define a rooted path decomposition, see Figure 1 for an example.

▶ **Definition 5** (Rooted Path Decomposition). *Let T be a tree. A* path decomposition *of T is a partition $\mathcal{P}$ of its edge set into edge-disjoint paths. We say $\mathcal{P}$ is* rooted *if there is a vertex $r \in T$ such that if we root T at r, then for each path $p \in \mathcal{P}$, the least common ancestor of the vertices on p is an endpoint of the path (we call this endpoint the* root *of p). The* width *of $\mathcal{P}$ is* $\text{width}(\mathcal{P}) = \max_{u,v \in V(T)} |\{p \in \mathcal{P} : P(u, v) \cap p \neq \emptyset\}|$*, the maximum number of paths $p \in \mathcal{P}$ that any path in T intersects.*

▶ **Lemma 6** (Existence of Low Width Rooted Path Decompositions). *Every tree on n vertices admits a rooted path decomposition of width $O(\log n)$.*

An $O(\log n)$-width rooted path decomposition can be obtained using the so-called *heavy path decomposition* of Sleator and Tarjan [15]. For the sake of completeness, we give a proof here. The following notion of a caterpillar decomposition will be convenient.

Figure 1 Example of a graph and its rooted path decomposition. The edge colors reflect the partition of the edges. The root of each path is the highest vertex of the path.

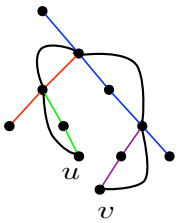

Figure 2 Illustration of the projections of the link (u, v) onto the paths of the decompositon. Only the projection onto the blue path is non-rooted.

▶ **Definition 7** (Caterpillar Decomposition)**.** *Let T be a rooted tree on n vertices. A* caterpillar decomposition *of T is a vertex-disjoint decomposition of T into a root-to-leaf path B (called the* backbone*) and subtrees T_i that are connected to B. The decomposition is* balanced *if for each subtree T_i, we have $|V(T_i)| \leq n/2$.*

▶ **Lemma 8.** *Every tree admits a balanced caterpillar decomposition.*

Proof. The existence of a balanced caterpillar decomposition is an easy consequence of the fact that every tree T has a balanced vertex separator v, i.e. after removing v from T, each of the remaining connected components has at most $n/2$ vertices. The following is a balanced caterpillar decomposition of T: pick an arbitrary root-to-leaf path containing v to be the backbone B, and the subtrees T_i to be the connected components of T after removing B. ◀

Proof of Lemma 6. The lemma easily follows by choosing an arbitrary root vertex of T and recursively applying Lemma 8. ◀

3 Refined Guarantee for Online Path Augmentation

As already mentioned, Lemma 6 implies an $O(\log n)$-approximate black-box reduction to online path augmentation: given an α-competitive algorithm for online path augmentation, we have an $O(\alpha \log n)$-competitive algorithm for online tree augmentation. However, Theorem 3 says that $\alpha = \Omega(\log n)$ for deterministic algorithms. To get around this lower bound, a more refined guarantee for online path augmentation is needed.

We need some notation to describe this refined guarantee. Suppose $\mathcal{P}$ is a rooted path decomposition of T and ℓ a link. For $Q \in \mathcal{P}$, let $\pi_Q(\ell)$ be the link whose endpoints are endpoints of the path $P(\ell) \cap Q$; we call $\pi_Q(\ell)$ the *projection* of ℓ onto Q. We say that ℓ is *Q-rooted* if one of the endpoints of $\pi_Q(\ell)$ is the root of Q, and *Q-non-rooted* otherwise. (See Fig. 2 for an illustration.) The main ingredient for the refined guarantee is the next lemma.

▶ **Lemma 9.** *Consider a tree T and link $\ell = (u, v)$. Suppose $\mathcal{P}$ is a rooted path decomposition of T. Then, there is at most one path $Q \in \mathcal{P}$ for which ℓ is Q-non-rooted.*

Proof. We claim that for any path $Q \in \mathcal{P}$ such that ℓ is a non-rooted link, the least common ancestor a of u and v must lie in Q but is not an endpoint of Q, i.e. it lies strictly in the middle of Q. Since $\mathcal{P}$ is an edge-disjoint decomposition of T, there can be at most one such path and thus the claim implies the lemma.

We proceed to prove the claim. Let u', v' be the endpoints of $\pi_Q(\ell)$. Since $\mathcal{P}$ is a rooted path decomposition, either u' is an ancestor of v' or vice versa; suppose the former. We now argue that u' is the least common ancestor of u and v. There are two cases: (1) either u' is an endpoint of ℓ; (2) or there is a vertex z of $P(u, v)$ adjacent to u' but is not on Q. In case (1), we are done. Consider case (2). Since u' is not an endpoint of Q, its parent must be on Q, and thus z is a child of u'. Therefore, u' is the least common ancestor of u and v. ◀

Motivated by Lemma 9, we define the online rooted path augmentation problem. An instance of online rooted path augmentation consists of a rooted path Q where the root r is an endpoint of Q. For such an instance, we say that a link is rooted if one of its endpoints is r. Lemma 9 suggests that we should devise an algorithm for online rooted path augmentation with the following refined guarantee.

▶ **Definition 10** (Nice Solution). *A solution F for an instance of online rooted path augmentation is* nice *if for any feasible solution F^*, we have $c(F) \leq O(1)c(R^*) + O(\log n)c(S^*)$ where R^* is the set of rooted links and S^* is the set of non-rooted links of F^*, respectively. An algorithm is nice if it always produces a nice solution.*

▶ **Lemma 11.** *Suppose that there exists a deterministic nice algorithm Path-ALG for online rooted path augmentation. Then, there exists an $O(\log n)$-competitive deterministic algorithm for online tree augmentation.*

Proof. Here is our algorithm for general instances. Consider a general instance of online weighted tree augmentation with tree $T = (V, E)$, requests $e_1, \ldots, e_k \subseteq E$ and links $L = \binom{V}{2}$ with costs $c(\ell)$. Our algorithm works as follows. By Lemma 6, there exists a rooted path decomposition $\mathcal{P}$ of T with width $w = O(\log n)$. Now, each rooted path $Q \in \mathcal{P}$ defines an instance of online rooted path augmentation: the links are $L_Q = \{\pi_Q(\ell) : \ell \in L\}$ where $\pi_Q(\ell)$ has cost $c(\ell)$, and the sequence of requests is exactly the subsequence of requests that lie on Q. So, our algorithm runs in parallel $|\mathcal{P}|$ instantiations of Path-ALG, one per rooted path $Q \in \mathcal{P}$. When request e_i arrives, if $e_i \in Q$ (since e_i is an elementary request, it must lie on some path of $\mathcal{P}$), then our algorithm uses the instantiation of Path-ALG on Q to handle that request; in particular, if Path-ALG buys the projected link $\pi_Q(\ell)$, then our algorithm buys the link ℓ.

Let us now analyze the competitive ratio of this algorithm. Let F^* be a feasible solution. For $Q \in \mathcal{P}$, we denote by R^*_Q, and S^*_Q the subset of F^* which is Q-rooted, and Q-non-rooted, respectively. Since Path-ALG is nice, we have that our algorithm's solution F has cost

$$c(F) \leq \sum_{Q \in \mathcal{P}} \left[O(1)c(R^*_Q) + O(\log n)c(S^*_Q) \right] \leq O(\log n)c(F^*),$$

where the last inequality is because Lemma 9 implies that each link of F^* is in S^*_Q for at most one $Q \in \mathcal{P}$ and is in R^*_Q for at most $w = O(\log n)$ paths $Q \in \mathcal{P}$. ◀

In the next section, we construct a nice deterministic algorithm. Together with Lemma 11 this gives a deterministic $O(\log n)$-competitive algorithm for online tree augmentation, thus proving Theorem 1.

4 A Nice Algorithm for Online Path Augmentation

In this section, we devise a nice algorithm for online rooted path augmentation. In the following, we use the convention that the root of the path is the left endpoint of the path.

We begin by showing in Section 4.1 that it suffices to consider simpler instances that we call *minimal instances*. Then, we describe in Section 4.2 how to prove niceness using an LP for the problem. Finally, we describe and analyze the algorithm in Sections 4.3 and 4.4.

4.1 Minimal Instances

The first step is a preprocessing step that simplifies the structure of the link set. In particular, we prune the instance so that it is of the following type.

▶ **Definition 12** (Minimal Instances). *A set of links L and its costs c are* minimal *if they satisfy the following properties:*

1. *for each class j, there is at most one rooted link and for every edge e, there are at most two links ℓ with $e \in P(\ell)$;*
2. *for any two rooted links ℓ and ℓ', if $\text{class}(\ell) > \text{class}(\ell')$, then $P(\ell) \supsetneq P(\ell')$.*

An instance is minimal if its links and costs are minimal.

Given a set of links L and its costs c, we prune L to get a minimal subset of links $L' \subseteq L$ as follows. We begin by pruning the rooted links: while there exists a rooted link ℓ and a rooted link ℓ' of the same or lower class such that $P(\ell') \supseteq P(\ell)$, remove ℓ. Then we prune the non-rooted links for each class j: let L_j be the set of class j links and L'_j be a minimum-size subset of L_j that covers L_j, i.e. $P(L'_j) \supseteq P(L_j)$; then, remove the links $L_j \setminus L'_j$. Such a minimum cover may be computed efficiently using an algorithm for minimum interval cover. By minimality, we have that for any edge e, there are at most two links $\ell, \ell' \in L'_j$ such that $e \in P(\ell) \cap P(\ell')$. The following claim shows that any link $\ell \in L_j$ that was pruned away can be replaced with at most three links of L'_j and so restricting to L' only causes the value of the optimal solution to increase by at most a factor of 3. We defer the proof to the full version.

▷ Claim 13. For every link $\ell \in L_j \setminus L'_j$, there exists (at most) three links $\ell_1, \ell_2, \ell_3 \in L'_j$ with $P(\ell) \subseteq P(\ell_1) \cup P(\ell_2) \cup P(\ell_3)$.

Given a subset of links $L' \subseteq L$, we say that a solution $F \subseteq L'$ is *nice for* L' if for any feasible solution $F' \subseteq L'$, we have $c(F) \leq O(1)c(R') + O(\log n)c(S')$ where R' is the set of rooted links and S' is the set of non-rooted links of F', respectively. The following lemma says that it suffices to have a solution that is nice for a pruning of L and thus it suffices to devise a nice algorithm for minimal instances. We defer the proof of the lemma to the full version.

▶ **Lemma 14.** *Let $L' \subseteq L$ be a pruning of L. Then, a solution that is nice for L' is also nice for L.*

Henceforth, we will focus on devising a nice algorithm for minimal instances.

4.2 Proving Niceness via the Dual LP

Our algorithm uses the standard LP formulation of the problem. Let $\mathcal{R}$ be the set of requests. The following are the primal and dual LPs, respectively.

$$\begin{aligned} &\text{minimize} && \sum_{\ell \in L} x(\ell) c(\ell) \\ &\text{subject to} && \sum_{\ell \in \text{cov}(e)} x(\ell) \geq 1 \qquad \forall e \in \mathcal{R} \end{aligned} \tag{1}$$

$$\begin{aligned} &\text{maximize} && \sum_{e \in \mathcal{R}} y(e) \\ &\text{subject to} && \sum_{e \in P(\ell)} y(e) \leq c(\ell) \qquad \forall \ell \in L \end{aligned} \tag{2}$$

We say that a link ℓ is *tight* with respect to a dual solution y if $\sum_{e \in P(\ell)} y(e) = c(\ell)$.

The following lemma tells us how to use the dual to prove niceness.

▶ **Lemma 15.** *Let F be a solution. Suppose y is a dual solution such that*

1. $c(F) \leq O(1) \sum_e y(e)$,
2. $\sum_{e \in P(\ell)} y(e) \leq O(\log n) c(\ell)$ *for every non-rooted link ℓ, and*
3. $\sum_{e \in P(\ell)} y(e) \leq O(1) c(\ell)$ *for every rooted link ℓ.*

Then, F is a nice solution.

Proof. Let F^* be a feasible solution, R^* be the subset of F^* that is rooted and S^* the subset that is non-rooted. We now show that $\sum_e y(e) \leq O(1) c(R^*) + O(\log n) c(S^*)$, which then implies that $c(F) \leq O(1) c(R^*) + O(\log n) c(S^*)$. Since we have a dual variable $y(e)$ for each request e and F^* is feasible, we have that

$$\sum_e y(e) \leq \sum_{e \in P(R^*)} y(e) + \sum_{e \in P(S^*)} y(e).$$

Using the fact that $\sum_{e \in P(\ell)} y(e) \leq O(1) c(\ell)$ for every rooted link ℓ, we also have

$$\sum_{e \in P(R^*)} y(e) \leq \sum_{\ell \in R^*} \sum_{e \in P(\ell)} y(e) \leq O(1) c(R^*).$$

Similarly, we get that $\sum_{e \in P(S^*)} y(e) \leq O(\log n) c(S^*)$. Putting all of these together, we conclude that $\sum_e y(e) \leq O(1) c(R^*) + O(\log n) c(S^*)$, as desired. ◀

4.3 Algorithm

We now give some of the ideas behind our algorithm.

An $O(\log n)$-competitive algorithm

First, we describe a simple algorithm that constructs a solution F and a dual solution y that satisfies $c(F) \leq O(1) \sum_e y(e)$ and $\sum_{e \in P(\ell)} y(e) \leq O(\log n) c(\ell)$ for *every* link ℓ. The algorithm maintains a maximal feasible dual solution y and is as follows: when a request e_i arrives, raise its dual variable $y(e_i)$ until some link ℓ with $e_i \in P(\ell)$ goes tight; add this link to F. There are two parts to the analysis. First, let $\widehat{F}$ be the set of links in F that

cost at least $\max_{\ell \in F} c(\ell)/n^2$. Since $|F| \leq n^2$, we get that $c(F) \leq 2c(\widehat{F})$ so it suffices to bound $c(\widehat{F})$. The second part of the analysis uses the following charging argument to bound $c(\widehat{F})$: whenever we add a tight link ℓ to $\widehat{F}$, we charge its cost to the dual variables $y(e)$ for $e \in P(\ell)$. Let $\lambda(e)$ be the total number of links charged to $y(e)$ and $\widehat{y}$ be the dual solution where $\widehat{y}(e) = \lambda(e)y(e)$. We have $c(\widehat{F}) \leq O(1)\sum_e \lambda(e)y(e)$. Now observe that $\lambda(e) \leq O(\log n)$ because Property 1 of minimal instance implies that there can be at most 2 links $\ell \in \widehat{F}$ with $e \in P(\ell)$ for a single cost class, and, by definition, $\widehat{F}$ can have at most $O(\log n)$ cost classes. So, for each link ℓ, we have

$$\sum_{e \in P(\ell)} \lambda(e)y(e) \leq O(\log n) \sum_{e \in P(\ell)} y(e) \leq O(\log n)c(\ell)$$

where the last inequality follows from the fact that y is feasible.

Saving the rooted links

A natural idea to ensure that $\sum_{e \in P(\ell)} \lambda(e)y(e) \leq O(1)c(\ell)$ for each rooted link ℓ is to modify the above algorithm to explicitly take into account the charging method as follows: after buying the tight link (we call this a type-1 link), if there is a rooted link ℓ' such that $\sum_{e \in P(\ell')} \lambda(e)y(e) > c(\ell')$, buy the one of highest class among such links (we call this a type-2 link). Moreover, we also modify the charging method to only charge each type-1 link ℓ to the dual variables $y(e)$ for $e \notin P(\ell')$ where ℓ' is the last type-2 link bought.

As we will see later, these modifications allow us to argue that $\sum_{e \in P(\ell)} \lambda(e)y(e) \leq O(1)c(\ell)$ for each rooted link ℓ. However, it also introduces a complication: it might be possible that for some type-1 link ℓ, most of the dual variables $y(e)$ paying towards its cost have $e \in P(\ell')$ where ℓ' is the last type-2 link bought. Since the charging method only charges to dual variables $y(e)$ for $e \notin P(\ell')$, this would mean that it might charge an amount that is much less than the cost of ℓ'.

Fixing the complication

To fix the above issue, whenever we buy a type-2 link ℓ', we also buy all links ℓ'' of class at most class(ℓ') that crosses ℓ', i.e. $\emptyset \subsetneq P(\ell'') \cap P(\ell') \subsetneq P(\ell')$. Property 1 implies that the total cost of these links is at most $O(1)c(\ell')$. We call these links type-3 links. This ensures that later on, when we buy a type-1 link ℓ, if $P(\ell) \cap P(\ell') \neq \emptyset$, then ℓ must be of higher class than ℓ' and thus most of its cost is paid for by dual variables $y(e)$ for $e \notin P(\ell')$.

We describe the complete algorithm formally in Algorithm 1. In Algorithm 1, we use Z to keep track of $P(\ell)$ where ℓ is the last type-2 link bought so far ($Z = \emptyset$ if no type-2 link is bought yet). The links bought in Step 4, 9, 11, are type-1, type-2, and type-3 links, respectively.

4.4 Analysis of Algorithm

We now prove that Algorithm 1 is nice. Let $F_1, F_2, F_3 \subseteq F$ be the sets of type-1, type-2 and type-3 links, respectively. The proof consists of three steps. First, we show that $c(F) \leq O(1)c(F_1)$ (Lemma 17) and thus it suffices to bound the cost of type-1 links. Then, we construct a dual solution $\widehat{y}$ that accounts for the cost of type-1 links (Lemma 18). This shows that $\widehat{y}$ satisfies the first condition of Lemma 15. Finally, Lemmas 20 and 19 show that $\widehat{y}$ satisfies the remaining conditions of Lemma 15.

For each type-1 link $\ell \in F_1$, define $C(\ell)$ to be the set of edges e such that $\lambda(e)$ was incremented during the iteration that ℓ was assigned to F_1, i.e. each dual variable $y(e)$ for $e \in C(\ell)$ contributes towards paying $c(\ell)$. Observe that $\lambda(e) = |\{\ell : e \in C(\ell)\}|$ and $C(\ell) \subseteq P(\ell)$.

Algorithm 1 Nice algorithm for online rooted path augmentation.

$F \leftarrow \emptyset; y \leftarrow 0; \lambda \leftarrow 0; Z \leftarrow \emptyset$
for each unsatisfied request e_i **do**
  Increase $y(e_i)$ until some link ℓ with $e_i \in P(\ell)$ goes tight
  Add such a link ℓ to F
  for each $e \in P(\ell) \setminus Z$ such that $y(e) > 0$ **do**
    $\lambda(e) \leftarrow \lambda(e) + 1$
  end for
  if there exists a rooted link $\ell \notin F$ such that $\sum_{e \in P(\ell)} \lambda(e) y(e) \geq c(\ell)$ **then**
    Among such links, add to F the link ℓ of highest class
    for $j \leq \text{class}(\ell)$ **do**
      Add to F all class-j links ℓ' that cross ℓ, i.e. $\emptyset \subsetneq P(\ell') \cap P(\ell) \subsetneq P(\ell)$
    end for
    $Z \leftarrow P(\ell)$
  end if
end for

▶ **Proposition 16.** *Algorithm 1 satisfies the following properties. Let Z_i and λ_i denote Z and λ at the end of the i-th iteration. Then, for every iteration i, we have*

1. $Z_i \supseteq Z_{i-1}$;
2. *if* $y(e_i) > 0$, *then* $\lambda_i(e_i) > 0$.

Proof. The first follows from Property 2 of minimal instances. The second follows from the fact that in the iteration that e_i arrives, since it is unsatisfied, it must not be contained in Z. Let ℓ be the link added to F in that iteration. Since $e_i \in P(\ell) \setminus Z$ and $y(e_i) > 0$, we have that $\lambda(e_i)$ is increased by 1 during the iteration and thus $\lambda_i(e_i) > 0$. ◀

▶ **Lemma 17.** $c(F) \leq O(1)c(F_1)$.

Proof. We will show that $c(F_3) \leq O(1)c(F_2)$, that $c(F_2) \leq O(1)\sum_e \lambda(e)y(e)$ and that $\sum_e \lambda(e)y(e) \leq c(F_1)$. Let ℓ_r be the last type-2 link bought. We have that $c(\ell_r) \leq \sum_{e \in P(\ell_r)} \lambda(e)y(e)$ by construction. Moreover, since $c(\ell_r) \geq c(\ell)$ for every $\ell \in F_2$ and there is at most one rooted link of each class, we get that $c(F_2) \leq 2c(\ell_r)$. Thus, we get that $c(F_2) \leq 2\sum_{e \in P(\ell_r)} \lambda(e)y(e)$. For each type-2 link ℓ bought, we buy at most two type-3 links per class $j \leq \text{class}(\ell)$ because of Property 1 of minimal instances. Therefore, we have $c(F_3) \leq 2c(F_2) \leq 4\sum_{e \in P(\ell_r)} \lambda(e)y(e)$.

Finally, we show that $\sum_e \lambda(e)y(e) \leq c(F_1)$. Since $\lambda(e) = |\{\ell : e \in C(\ell)\}|$, we have $\sum_e \lambda(e)y(e) = \sum_{\ell \in F_1} \left(\sum_{e \in C(\ell)} y(e)\right)$. Now, since $C(\ell) \subseteq P(\ell)$ and y is feasible, we get $\sum_{e \in C(\ell)} y(e) \leq \sum_{e \in P(\ell)} y(e) \leq c(\ell)$. Combining the previous two inequalities gives us that $\sum_e \lambda(e)y(e) \leq c(F_1)$. ◀

Let $c_{\max} = \max_{\ell \in F_1} c(\ell)$. Define $\widehat{F}_1 = \{\ell \in F_1 : c(\ell) \geq c_{\max}/n^2\}$ and $\widehat{\lambda}(e) = |\{\ell \in \widehat{F}_1 : e \in C(\ell)\}|$. We now show that F and the dual solution $\widehat{y}$ where $\widehat{y}(e) = \widehat{\lambda}(e)y(e)$ satisfies the conditions of Lemma 15.

▶ **Lemma 18.** $c(F_1) \leq O(1)\sum_e \widehat{\lambda}(e)y(e)$.

Proof. Observe that $c(F_1) \leq 2c(\widehat{F}_1)$ so it suffices to prove that

$$c(\widehat{F}_1) \leq O(1)\sum_e \widehat{\lambda}(e)y(e). \tag{3}$$

We now show that this inequality holds at the end of each iteration of the algorithm. Consider an iteration in which the current request e_i is not already covered and suppose $\ell \in \widehat{F}_1$ is the type-1 link bought in this iteration. The LHS of Inequality (3) increases by $c(\ell)$ in this iteration. We now show that $\sum_e \widehat{\lambda}(e)y(e)$ increases by at least $c(\ell)/2$. In this iteration, $\widehat{\lambda}(e)$ increases by 1 for every $e \in P(\ell) \setminus Z$ and $y(e) > 0$, and so $\sum_e \widehat{\lambda}(e)y(e)$ increases by exactly $\sum_{e \in P(\ell)\setminus Z} y(e)$.

In the remainder of the proof, we show that $\sum_{e \in P(\ell)\setminus Z} y(e) \geq c(\ell)/2$. If $P(\ell) \cap Z = \emptyset$, then $\sum_{e \in P(\ell)\setminus Z} y(e) = \sum_{e \in P(\ell)} y(e) = c(\ell)$ since ℓ is tight. Now suppose $P(\ell) \cap Z \neq \emptyset$. Let ℓ' be the type-2 link such that $Z = P(\ell')$. Since $P(\ell) \cap P(\ell') \neq \emptyset$, it must be the case that ℓ is of type higher than class(ℓ'). This is because otherwise, ℓ would have been bought earlier as a type-3 link in the same iteration as ℓ'. But then since $e_i \in P(\ell)$, it would contradict the assumption that e_i is not already covered at the start of the current iteration. Thus, class$(\ell) >$ class(ℓ') and so $c(\ell) \geq 2c(\ell')$. So, we now have

$$\sum_{e \in P(\ell)\setminus Z} y(e) \geq \sum_{e \in P(\ell)} y(e) - \sum_{e \in P(\ell')} y(e) \geq c(\ell) - c(\ell') \geq c(\ell)/2,$$

where the second last inequality follows from the fact that y is a feasible dual and ℓ is tight. Therefore, Inequality (3) holds at the end of each iteration, as desired. ◀

Lemmas 17 and 18 imply that $c(F) \leq O(1) \sum_e \widehat{y}(e)$.

▶ **Lemma 19.** *For each non-rooted link ℓ, we have $\sum_{e \in P(\ell)} \widehat{\lambda}(e)y(e) \leq O(\log n)c(\ell)$.*

Proof. Property 1 of minimal instances implies that for each j, there are at most two links $\ell' \in \widehat{F}_1$ of class j with $e \in C(\ell')$. Since each link in $\widehat{F}_1$ has cost between $c_{\max}/n^2$ and $c_{\max}$ and link costs are powers of 2, we have that $\widehat{\lambda}(e) \leq O(\log n)$. Thus we get that $\sum_{e \in P(\ell)} \widehat{\lambda}(e)y(e) \leq O(\log n) \sum_{e \in P(\ell)} y(e) \leq O(\log n)c(\ell)$, where the last inequality follows from the fact that y is a feasible dual. ◀

▶ **Lemma 20.** *For each rooted link ℓ, we have $\sum_{e \in P(\ell)} \widehat{\lambda}(e)y(e) \leq O(1)c(\ell)$.*

Proof. We will in fact show that $\sum_{e \in P(\ell)} \lambda(e)y(e) \leq O(1)c(\ell)$. Suppose, at the end of some iteration, that we have $\sum_{e \in P(\ell)} \lambda(e)y(e) > c(\ell)$. Consider the earliest iteration that this happens. We now show that $\sum_{e \in P(\ell)} \lambda(e)y(e) \leq O(1)c(\ell)$ at the end of the iteration and later show that the LHS cannot increase in future iterations.

Let $\lambda^{\text{old}}(e)$ and $y^{\text{old}}(e)$ denote the values of $\lambda(e)$ and $y(e)$ at the start of the iteration and $\lambda^{\text{new}}(e)$ and $y^{\text{new}}(e)$ denote their values at the end. We have that $\sum_{e \in P(\ell)} \lambda^{\text{old}}(e)y^{\text{old}}(e) < c(\ell)$. We now show that $\sum_{e \in P(\ell)} \lambda^{\text{new}}(e)y^{\text{new}}(e) \leq 3c(\ell)$. Let e_i be the request of the current iteration. During this iteration, we only increase $y(e)$ for $e = e_i$ and we set $\lambda(e_i) = 1$ so $\lambda^{\text{new}}(e_i)y^{\text{new}}(e_i) = y(e_i)$. So, we have

$$\sum_{e \in P(\ell)} \lambda^{\text{new}}(e)y^{\text{new}}(e) = \sum_{e \in P(\ell)\setminus\{e_i\}} \lambda^{\text{new}}(e)y^{\text{old}}(e) + y(e_i).$$

Since y is a feasible dual, we have that $y(e_i) \leq c(\ell)$. Now, Proposition 16 implies that $\lambda^{\text{old}}(e) \geq 1$ if $y^{\text{old}}(e) > 0$. Together with the fact that $\lambda^{\text{new}}(e) \leq \lambda^{\text{old}}(e) + 1$, we get that $\lambda^{\text{new}}(e)y^{\text{old}}(e) \leq 2\lambda^{\text{old}}(e)y^{\text{old}}(e)$ and so

$$\sum_{e \in P(\ell)\setminus\{e_i\}} \lambda^{\text{new}}(e)y^{\text{new}}(e) \leq 2 \sum_{e \in P(\ell)\setminus\{e_i\}} \lambda^{\text{old}}(e)y^{\text{old}}(e) < 2c(\ell).$$

Thus, $\sum_{e \in P(\ell)} \lambda^{\text{new}}(e)y^{\text{new}}(e) \leq 3c(\ell)$ at the end of the current iteration.

Finally, we show that $\sum_{e \in P(\ell)} \lambda(e) y(e)$ does not increase in future iterations. At the end of the current iteration, ℓ is a candidate to be added to F. Among all candidates, the one with highest class is added, so either ℓ is added to F or a rooted link ℓ' of higher class is added to F. In the second case, by Proposition 16, we have $P(\ell') \supseteq P(\ell)$. Thus, in either case, we have that $Z \supseteq P(\ell)$ at the end of the current iteration. Moreover, in future iterations, we still have $Z \supseteq P(\ell)$ by Proposition 16. Therefore, $\sum_{e \in P(\ell)} \lambda(e) y(e)$ does not increase in future iterations. Thus, we conclude that $\sum_{e \in P(\ell)} \lambda(e) y(e) \leq 3c(\ell)$ at the end of the algorithm. ◀

Therefore, we conclude that Algorithm 1 is nice. Together with Lemma 11, we get Theorem 1.

Abstract

Short cycle decomposition is an edge partitioning of an unweighted graph into edge-disjoint short cycles, plus a small number of extra edges not in any cycle. This notion was introduced by Chu et al. [FOCS'18] as a fundamental tool for graph sparsification and sketching. Clearly, it is most desirable to have a *fast* algorithm for partitioning the edges into as *short* as possible cycles, while omitting *few* edges.

The most naïve procedure for such decomposition runs in time $O(m \cdot n)$ and partitions the edges into $O(\log n)$-length edge-disjoint cycles plus at most $2n$ edges. Chu et al. improved the running time considerably to $m^{1+o(1)}$, while increasing both the length of the cycles and the number of omitted edges by a factor of $n^{o(1)}$. Even more recently, Liu-Sachdeva-Yu [SODA'19] showed that for every constant $\delta \in (0, 1]$ there is an $O(m \cdot n^{\delta})$-time algorithm that provides, w.h.p., cycles of length $O(\log n)^{1/\delta}$ and $O(n)$ extra edges.

In this paper, we significantly improve upon these bounds. We first show an $m^{1+o(1)}$-time *deterministic* algorithm for computing nearly optimal cycle decomposition, i.e., with cycle length $O(\log^2 n)$ and an extra subset of $O(n \log n)$ edges not in any cycle. This algorithm is based on a reduction to *low-congestion cycle covers*, introduced by the authors in [SODA'19].

We also provide a simple deterministic algorithm that computes edge-disjoint cycles of length $2^{1/\epsilon}$ with $n^{1+\epsilon} \cdot 2^{1/\epsilon}$ extra edges, for every $\epsilon \in (0, 1]$. Combining this with Liu-Sachdeva-Yu [SODA'19] gives a *linear* time randomized algorithm for computing cycles of length $\mathsf{poly}(\log n)$ and $O(n)$ extra edges, for every n-vertex graphs with $n^{1+1/\delta}$ edges for some constant δ.

These decomposition algorithms lead to improvements in all the algorithmic applications of Chu et al. as well as to new distributed constructions.

1 Introduction

Short cycle decomposition introduced by Chu et al. [3] is a partitioning of the graph edges into edge-disjoint short cycles and a small subset of extra edges that are not in any cycle.

▶ **Definition 1** (Short Cycle Decomposition). *An $(\widehat{m}, L)$-short cycle decomposition of an unweighted undirected graph G is a collection of edge-disjoint cycles in G, each of length at most L, such that at most $\widehat{m}$ edges of G are not covered by these cycles.*

In their recent paper, Chu et al. [3] demonstrated the power of short cycle decomposition as a fundamental tool for a number of problems in graph sparsification. This includes the construction of degree preserving sparsifiers, resistance sparsifiers, graphical spectral sketches, approximation of the Laplacian's determinant and more. Chu et al. [3] showed that the efficiency of this long list of problems is determined by the time complexity, the cycle length, and the number of uncovered edges of the short cycle decomposition routine in hand. Clearly, it is most desirable to compute fast a decomposition into the shortest possible edge-disjoint cycles, while omitting as few as possible edges.

As they have observed, there is a naïve short cycle decomposition which runs in time $O(mn)$ (where n is the number of vertices in the graph, and m is the number of edges), and outputs an optimal[1] decomposition: cycle length of $O(\log n)$ and $O(n)$ extra edges. In their key algorithmic result, [3] significantly improved this time complexity by presenting an almost-linear time algorithm[2] which decomposes G into edge-disjoint cycles of length $n^{o(1)}$, and an extra number of $n^{1+o(1)}$ edges. Thus, the improvement in the time complexity came with the cost of increasing both the cycle length as well as the number of left-over edges by a multiplicative factor of $n^{o(1)}$. Improving the efficiency of the short cycle decomposition was stated in [3] as a highly motivated target, as it immediately leads to a large sequence of algorithmic consequences:

> *"Critically, any improvement to our short-cycle decomposition algorithm will achieve an improvement in all of our results."*

Very recently, Liu, Sachdeva and Yu [8] provided the first improvement for the problem, by presenting an $O(m \cdot n^{\delta})$-time algorithm that decomposes G into edge-disjoint cycles of length $O(\log n)^{1/\delta}$ and an extra subset of $O(n)$ edges, for any *constant* $\delta \in (0, 1]$. This simplifies and improves the decomposition algorithm of [3] in terms of all parameters, but still leaves the following fundamental question open:

Is there an ***optimal*** *cycle decompositios in almost* ***linear*** *time?*

In this paper, we answer this question in the affirmative and present an $m^{1+o(1)}$-time algorithm for decomposing the graph into edge-disjoint cycles of length $O(\log^2 n)$, and an extra number of $O(n \log n)$ edges.

▶ **Theorem 2** (Nearly Optimal Decomposition in Almost-Linear Time). *There is an almost-linear time algorithm for computing a cycle decomposition with cycle length of $O(\log^2 n)$, and $O(n \log n)$ extra edges.*

We also have a much simpler algorithm that achieves the same quality of cycle decomposition[3] as by [3], only in $\widetilde{O}(m)$ time. An additional benefit of this algorithm is that it is deterministic.

▶ **Theorem 3** (Longer Cycles in Linear Time). *For every n-vertex graph $G = (V, E)$ with m edges, one can compute in $\widetilde{O}(m)$ time, a decomposition with cycle length $n^{o(1)}$ and $n^{1+o(1)}$ extra edges.*

---

[1] Optimality in this context is up to poly-logarithmic terms.

[2] A graph algorithm is almost-linear if runs in time $m^{1+o(1)}$.

[3] In fact, the quality here is slightly better, as the $n^{o(1)}$ factor (in the cycle length and number of uncovered edges) is $2^{\sqrt{\log n}}$ and in [3] et al. it is $2^{(\log n)^{3/4}}$.

The latter provides an improvement for approximating the determinant of the Laplacian. We can also combine with the algorithm of [8] to obtain a randomized decomposition that is optimal (up to log-n factors) in all three complexity measures: time, length and number of leftover edges provided that the graph is sufficiently dense.

▶ **Theorem 4** (Optimal Decomposition for Dense Graphs). *For every constant $\delta \in (0,1]$, there exists a randomized algorithm that computes in time $\widetilde{O}(m) + n^{1+1.1\delta}$ a collection of edges disjoint cycles of length $O(\log n)^{1/\delta}$ and at most $O(n)$ leftover edges.*

Table 1 provides a summary of our results in comparison to [3, 8]. Our algorithms are based on independent ideas compared to [3, 8], which are related to the concept of *low-congestion cycle covers*.

Table 1 Summary of our results.

	Cycle Length	#Uncovered Edges	Time	Type
Chu et al. [3]	$n^{o(1)}$	$n^{1+o(1)}$	$m^{1+o(1)}$	Randomized
Liu-Sachdeva-Yu [8]	$O(\log n)^{1/\delta-1}$ for constant $\delta \leq 1$	$O(n)$	$O(mn^{\delta})$	Randomized
This Work	$O(\log^2 n)$	$O(n \log n)$	$m^{1+o(1)}$	Deterministic
This Work	$O(\log n)^{1/\delta}$ for constant $\delta \leq 1$	$O(n)$	$m + n^{1+1.1\delta}$	Randomized
This Work	$n^{o(1)}$	$n^{1+o(1)}$	$m + n^{1+o(1)}$	Deterministic

1.1 Low-Congestion Cycle Covers

A cycle cover of a graph G is a collection of cycles such that each edge of G appears in at least one of the cycles. Cycle covers were introduced by Itai and Rodeh [6] in 1978 with the objective to cover all edges of a bridgeless[4] graph with cycles of minimum *total* length. Motivated by applications to distributed computation, [11] recently introduced[5] the notion of *low-congestion* cycle covers: a collection of cycles that are both *short*, nearly *edge-disjoint* and covering all edges.

▶ **Definition 5** (Low-Congestion Cycle Cover). *A $(\mathtt{d}, \mathtt{c})$-cycle cover of a graph G is a cycle collection that covers all edges in G. Each cycle has length at most $\mathtt{d}$, and each edge participates in at least one cycle and at most $\mathtt{c}$ cycles.*

Low-congestion cycle covers provide the basic communication backbone in different settings of resilient distributed computation such as Byzantine fault model and secure computation [11, 10]. Whereas a-priori it is not clear that cycles of short length and small overlap exist, our main result in [11] shows that one can enjoy a dilation of $O(D \log n)$ while incurring only a poly-logarithmic congestion, where D is the diameter of the graph.

Comparison to Short Cycle Decomposition. Low-congestion covers bare some similarity to short cycle decomposition but differs from it in two main aspects. The first aspect follows from the definition: Low-congestion covers allow a small *overlap* between the cycles,

[4] A graph G is bridgeless, if any single edge removal keeps the graph connected.
[5] In an independent manner to the notion of short cycle decomposition.

but require covering *all* edges. On the other hand, short cycle decomposition insists on edge-disjoint cycles, i.e., with no-overlap, but allows omitting a subset of leftover edges that are not in any cycle. The second difference concerns the algorithmic focus. In low-congestion covers, the main goal was in showing that optimal covers which are both short and with small overlap *exist*. Computation time was not the primary concern, and in fact, the first step in the construction in [11] used the naïve decomposition algorithm (that runs in time $O(m \cdot n)$) to reduce the number of uncovered edges into $2n$. In contrast, for short cycle decomposition, it is easy to obtain the optimal decomposition in $O(m \cdot n)$ time, and hence the primary algorithmic focus is computation time.

1.2 Improved Graph Sparsification Algorithms via Short Cycles

Spectral sparsifiers introduced by Spielman and Teng [13] are sparse (weighted) subgraphs that approximately preserve the Laplacian quadratic form of the graph. Recall that the *Laplacian*, $\mathbf{L}_G$, of an undirected weighted graph $G = (V, E_G, w_G)$ is the unique symmetric $V \times V$ matrix such that for all $x \in \mathbb{R}^{|V|}$, it holds that

$$x^T \mathbf{L}_G x = \sum_{(u,v)\in E_G} w_G(u,v) \cdot (x_u - x_v)^2 \ .$$

For $\epsilon < 1$, a graph $H = (V, E_H, w_H)$ is an *ϵ-sparsifier* for G if

$$\forall x \in \mathbb{R}^n,\ x^T \mathbf{L}_G x \in (1 \pm \epsilon) x^T \mathbf{L}_H x \ .$$

Batson, Spielman and Srivastava [2] presented a construction of spectral sparsifiers with $O(n/\epsilon^2)$ edges, which is tight. In the last years, related graph structures have been defined, which are weaker than spectral sparsifiers, and thus potentially sparser. The recent work of Chu et al. [3] used short cycle decomposition to derive new existential results on the sparsity of sparsifiers and spectral sketches. As the time complexity and the quality of their algorithms depend on the efficiency of the decomposition, our decomposition algorithm leads to immediate improvements for all the algorithmic results from [3].

Graphic ϵ-Spectral Sketch and Resistance Sparsifiers. A spectral sketch [1] is a data structure for a graph G that given a query vector $x \in \mathbb{R}^n$ returns w.h.p. a $(1+\epsilon)$ approximation for the quadratic form $x^T \mathbf{L}_G x$. A data structure that works w.h.p. for *all* $x \in \{\pm 1\}^n$ requires n/ϵ^2 space. However, Jambulapati and Sidford [7] showed that when requiring the high probability guarantee for a *fixed* unknown vector, the size of the data structure can be made $\widetilde{O}(n/\epsilon)$. In the same manner, one can define the *graphic spectral sketch* of G to be a sparse graph H satisfying $x^T \mathbf{L}_G x \in (1 \pm \epsilon) x^T \mathbf{L}_H x$ for a fixed unknown vector x with high probability. Chu et al. showed that graphical spectral sketches with $\widetilde{O}(n/\epsilon)$ edges exist.

Resistance sparsifiers are sparse subgraphs that preserve the effective resistance[6] of all vertex pairs up to a multiplicative factor of $(1 + \epsilon)$. This notion was introduced by Dinitz-Krauthgamer-Wagner [4] who conjectured that resistance sparsifiers with $\widetilde{O}(n/\epsilon)$ edges always exist. The conjecture was indeed resolved by [3] using the tool of short cycle decomposition. By combining Theorem 2 with [3, Theorem 6.1] we get:

[6] The effective resistance between a pair u, v is the difference in the voltage between u, v when the graph is an electrical network, with every edge e of weight w_e has a resistor of resistance $1/w_e$ and 1 unit of current is sent from u to v.

▶ **Theorem 6** (Graphic Spectral Sketches and Resistance Sparsifiers). *One can compute an ϵ-resistance sparsifier H and a graphical spectral sketch H' with $\widetilde{O}(n/\epsilon)$ edges in time $m^{1+o(1)}$. Alternatively, these algorithms can be tuned to run in $\widetilde{O}(m)$ time while producing such graphs H, H' with $n^{1+o(1)}/\epsilon$ edges.*

These two results should be compared with (i) the $O(m \cdot n^{\Theta(1)})$-time algorithm of [8] that gives sparsifiers with $\widetilde{O}(n/\epsilon)$ edges; and (ii) the $m^{1+o(1)}$-time algorithms of [3, 8] that give sparsifiers with $n^{1+o(1)}/\epsilon$ edges. Hence, we provide the first almost-linear time algorithm for optimal size sparsifiers with $\widetilde{O}(n/\epsilon)$ edges, and the first near linear time algorithm[7] for almost-linear size sparsifiers with $\widetilde{O}(n^{1+o(1)}/\epsilon)$ edges.

Degree Preserving Sparsifiers and Sparsifiers for Eulerian Directed Graphs. Short cycle decompositions are useful for providing spectral sparsifiers that preserve additional key properties in the original graphs. *Degree preserving sparsifier* is a spectral sparsifier H for a graph G which preserves (exactly) the *weighted degree* of each vertex $v \in V$. To get an intuition for the usefulness of edge-disjoint cycles in this context, imagine G to be an unweighted union of edge-disjoint cycles of even length. A degree preserving sparsifier H that contains half of the edges in G, can be obtained by the following correlated sampling: For each cycle, with probability $1/2$ add to H the odd edges with weight 2, and with probability $1/2$ add to H the even edges with weight 2. It is easy to see that every vertex v has exactly the same weighted degree in H as in G, and the number of edges in G was cut by half. By combining Theorem 3.3 of Chu et al. [3] with Theorem 2, we get:

▶ **Theorem 7** (Optimal Degree Preserving Sparsifiers in Almost Linear Time). *There exists an algorithm that runs in time $m^{1+o(1)}$ and constructs a degree-preserving ϵ-sparsifier of G with $\widetilde{O}(n/\epsilon^2)$ edges, with high probability. Alternatively, an $n^{1+o(1)}/\epsilon^2$-size degree-preserving sparsifier can be computed in $\widetilde{O}(m)$ time.*

A similar approach has been taken in Chu et al. [3] to construct a sparsification of Eulerian directed graphs. By plugging Theorem 2 in Theorem 5.1 of [3], we get:

▶ **Theorem 8** (Sparsification of Eulerian Directed Graphs). *There exists an algorithm $\mathcal{A}$ that given an Eulerian directed graph $\overrightarrow{G}$ with polynomial bounded edge weights returns an Eulerian directed graph $\overrightarrow{H}$ such that either: (i) $\overrightarrow{H}$ has $\widetilde{O}(n/\epsilon^2)$ edges and $\mathcal{A}$ has time complexity $m^{1+o(1)}$, or (ii) $\overrightarrow{H}$ has $n^{1+o(1)}/\epsilon^2$ edges and $\mathcal{A}$ has time complexity $\widetilde{O}(m)$.*

Estimation of the Effective Resistance and the Determinant of the Laplacian. Finally, we show how incorporating our improved construction of resistance sparsifiers can yield a faster approximation of the determinant of the graph Laplacian with the last row and column removed. In particular, this yields the first linear time algorithm for sufficiently dense graphs. Recall that by Theorem 6, given a graph G with m edges, we can compute in time $\widetilde{O}(m)$, a resistance sparsifier H with $n^{1+o(1)}/\epsilon$ edges, with high probability. By applying [3, Thm. 3.8] on H, we get:

▶ **Theorem 9** (Faster Approximation of Effective Resistance). *Given an undirected graph G with m edges, one can compute with high probability an ϵ-approximations to the effective resistances between a given set of t vertex pairs in time $\widetilde{O}(m) + (n+t)n^{o(1)}\epsilon^{-1.5}$.*

[7] A graph algorithm is *near linear* if it runs in $O(m \cdot \mathsf{poly}(\log n))$ time.

Hence, for $t = o(m^{1-o(1)} \cdot \epsilon^{1.5})$, we obtain a linear time algorithm for approximating the effective resistance. As observed in [3], the running time bottleneck of the determinant estimation algorithm for Laplacians by Durfee et al. [5] is the estimation of the effective resistance of $O(n^{1.5})$ pairs with an error of $\epsilon = n^{-0.25}$. Plugging our improved Theorem 9 in Lemma B.1 of [3] yields:

▶ **Corollary 10** (Faster Approx. of Laplacian's Determinant). *Given a graph Laplacian* $\mathbf{L}$ *and any error* $0 < \epsilon < 1/2$*, one can compute an* $1 \pm \epsilon$ *estimate to* $\det(\mathbf{L}_{-n})$[8] *in time* $\widetilde{O}(m) + n^{15/8+o(1)} \cdot \epsilon^{-7/4}$*, thus in linear time for sufficiently dense graphs.*

1.3 Distributed Implementation

Our centralized construction has the benefit of naturally being implemented in the standard CONGEST model of distributed computing. As in the centralized setting, the decomposition is based on constructing low-congestion cycle covers. We show:

▶ **Lemma 11** (Distributed Low-Congestion Covers). *There exists a distributed algorithm that given n-vertex graph* $G = (V, E)$ *constructs a* $(\mathtt{d}, \mathtt{c})$ *cycle cover within* $O(\mathtt{d} \cdot \mathtt{c})$ *rounds for* $\mathtt{d}, \mathtt{c} = 2^{O(\sqrt{\log n})}$.

The proof appears in the full version of the paper. This improves upon the linear time algorithm of [11, 10]. By combining this algorithm with Luby-MIS algorithm [9], we get:

▶ **Theorem 12** (Distributed Short Cycle Decomposition). *There exists an* $2^{O(\sqrt{\log n})}$*-round distributed algorithm that given n-vertex graph* $G = (V, E)$ *decomposes* G *into edge-disjoint cycles of length* $2^{O(\sqrt{\log n})}$ *plus* $O(n \log n)$ *extra edges.*

One might hope that using this distributed construction of cycle decomposition we would get a distributed algorithm for all the above application. Unfortunately, in the distributed setting, to this point, we do not have an efficient algorithm that approximates (even up to a constant factor) the effective resistance of all edges[9] in G. This is the only missing piece for obtaining the above mentioned algorithmic applications of the short cycle decomposition in a distributed setting.

Comparison to the work of Chu et al. [3] and Liu-Sachdeva-Yu [8]. We first observe that in [8], the number of leftover edges is $O(n)$, whereas in our case it is $O(n \log n)$. By applying the algorithm of [8] on these last $O(n \log n)$ edges, for any constant $\delta \in (0, 1)$, we can compute an $O(n, (\log n)^{1/\delta-1})$-decomposition in time $O(n^{1+\delta} \log n + m^{1+1/\log\log n})$, which considerably improves upon the time complexity of $O(m \cdot n^{\delta})$ of [8]. Since we consider log-n factors to be negligible in this work (i.e., the size of the sparsifiers is $\Omega(n \log n)$ in any case), we omit this step.

Fixing the number of leftover edges to $\widetilde{O}(n)$, then [8] computes cycles of length $O(\log n)^{1/\delta-1}$ in time $2^{O(1/\delta)} \cdot n^{\delta} \cdot m$. In comparison, our algorithm computes cycles of length $2^{1/\delta} \cdot O(\log n)$ in roughly the same time $2^{O(1/\delta)} \cdot n^{\delta} \cdot m$. For example, when taking $\delta = 1/\log\log n$, both algorithms have roughly the same time complexity, but our algorithm produces cycles of length $O(\mathsf{poly}\log n)$ and their algorithm has cycle length $O(\log n)^{\log\log n}$.

From an algorithmic point of view, both our algorithm and the algorithm of [8] use low-diameter decomposition[10]. This allows one to restrict attention to $O(\log n)$-diameter graphs.

---

[8] the determinant of $\mathbf{L}$ with the last row and column removed

[9] In the output of such an algorithm we want each edge (u, v) to obtain a constant approximation for the effective resistance between u and v in G.

[10] We use a neighborhood covers which are close variant of low-diameter decomposition.

The approach of [8] contracts each of the components of the low-diameter decomposition and recursively computes vertex-disjoint short cycles on the contracted graph. The diameter of each super-node is $O(\log n)$, when lifting the contracted cycles back to edges in G the length of the cycles increases exponentially with the number of recursive layers. In particular, halving within $1/\delta$ recursive calls the length of the cycles becomes $O(\log n)^{1/\delta-1}$. Our approach is quite different. We also decompose trees into smaller components, but instead of contracting these components we use their internal edges carefully in our cycles. By enjoying the internal edges inside each cycle, the length of the cycles increases by a factor of at most 2 in each level of the recursion, thus after $1/\delta$ recursion levels, the length of the cycle is $2^{1/\delta}$.

2 Longer Edge-Disjoint Cycles in Nearly Linear Time

We begin by describing a deterministic algorithm for computing cycle decomposition of the same quality as that of Chu et al. [3], but in nearly linear time $\widetilde{O}(m)$. In particular, the cycle length will be bounded by $2^{\sqrt{\log n}}$ and at most $2^{\sqrt{\log n}} \cdot n$ edges will be left uncovered. Note that the recent randomized algorithm of [8] achieves such cycles in almost linear time $m \cdot n^{O(\log\log n/\sqrt{\log n})} \cdot 2^{\sqrt{\log n}/\log\log n}$. We can also reduce the number of leftover edges to $O(n)$, by running the algorithm of [8] on the remaining subset of $n^{1+o(1)}$ leftover edges. However, note that in any case, the efficiency of the algorithmic applications for these cycles depends on $\widehat{m} + nL$ where $\widehat{m}$ is the number of leftover edges and L is the largest cycle length.

▶ **Theorem 13.** *For every $\epsilon \in (0,1]$, there exists an $\widetilde{O}(m)$-time algorithm that computes an $(\widehat{m}, L)$ short cycle decomposition with $\widehat{m} = 1/\epsilon \cdot 2^{1/\epsilon} \cdot n^{1+O(\epsilon)}$ and $L = 2^{O(1/\epsilon)}$. Setting $\epsilon = 1/\sqrt{\log n}$, gives $\widehat{m} = 2^{O(\sqrt{\log n})} \cdot n$ and $L = 2^{O(\sqrt{\log n})}$.*

Thm. 4 follows immediately: Set $\epsilon = 1/\log\log n$ in Theorem 13, yeilding cycles of length $O(\log n)$ and $n^{1+o(1)}$ leftover edges. Then, using the randomized algorithm of [8] on this remaining subgraph with some constant $\delta \in (0,1]$, covers the remaining edges with cycles of length $O(\log n)^{1/\delta}$ with time complexity of $n^{1+1.1\delta}$. In addition, Thm. 3 follows by plugging $\epsilon = 1/\sqrt{\log n}$ in Theorem 13.

Throughout, a *block* is a subset of vertices with a bounded size. The algorithm is recursive and has $\ell = \lceil 1/\epsilon \rceil$ levels of recursion. During each recursion level, some virtual edges $\widetilde{E}$ will be added to the set of edges E' that we wish to cover by cycles (initially $E' = E$). Informally speaking, whenever the algorithm adds a virtual edge between two nodes u and v, it implies that the algorithm has already computed a u-v walk denoted by $W((u,v))$, and the virtual edge (u,v) indicates the need for computing another u-v walk so that we will end up with a cycle. In other words, adding a virtual edge means that we defer the closure of the cycle to future iterations. We also maintain a leftover subgraph H, and in certain cases, we give up on completing the cycles of the virtual edges, and add their walk edges to this subgraph.

We now describe Alg. FasterLongerCycles. The algorithm is recursive and has $O(1/\epsilon)$ levels of recursion. Initially, let $E' = E(G)$. The preliminary walk collection is $\mathcal{W} = \{e \mid e \in G\}$, the cycle collection $\mathcal{C}'$ is empty. In addition, we have a subgraph $H \leftarrow \emptyset$ that will contain the edges that are not covered by cycles.

In each independent level $i \geq 1$ of the recursion, we are given a block B, and a subset of edges E' with both endpoints in B. In addition, we are given a set of current walks $\mathcal{W}$ for the edges in E', a current cycle collection $\mathcal{C}'$, and a leftover subgraph H.

Block Partitioning. First the algorithm partitions B into $k = n^{\epsilon}$ balanced blocks $B_1, \ldots, B_k$ each with $\Theta(|B|/n^{\epsilon})$ vertices.

Taking care of edges between blocks. Our goal is to replace edges between blocks, to edges inside blocks. For block B_a, we do as follows for every $v \in B_a$ and every $b \in \{a+1, \ldots, k\}$. Define by $N_{a,b}(v) = \{u \in B_b \mid (u,v) \in E'\}$ to be the E'-neighbors of v in B_b. If $N_{a,b}(v)$ is odd, we will omit from it at most one vertex u, in order to make it even. The edge (u,v) of the omitted vertex u is omitted from E', and its walk $W((u,v))$ is added to the leftover subgraph H.

From now on, we can assume that the set $N_{a,b}(v)$ is even. We then (arbitrarily) match the vertices in $N_{a,b}(v)$ into pairs $\langle x,y \rangle$. Each matched pair $\langle x,y \rangle$ is handled as follows:

Case (1): The set E' already contains an (x,y) edge. If E' already contains an edge (x,y) (this edge might be virtual), we define a cycle $C = W((v,x)) \circ W((x,y)) \circ W((y,v))$ and add it to the cycle collection $\mathcal{C}'$. In addition, we omit the edges $(v,x),(x,y)$ and (y,v) from E', and omit their walks from $\mathcal{W}$.

Case (2): The set E' does not contain an (x,y) edge. In this case, we add a virtual edge (x,y) to E', as well as a walk $W((x,y)) = W((x,v)) \circ W((v,y))$ to $\mathcal{W}$. This completes the description of the i^{th} recursion level. The algorithm then recurses on each of the blocks $B_1, \ldots, B_k$. See Fig. 1 for pseudocode. Finally, as in Alg. PartialCycleCover, the cycles of $\mathcal{C}'$ might re-visit the same vertex, and hence in the final cleanup phase, the algorithm traverses each of the cycles in $\mathcal{C}'$ and simplify them.

Algorithm FasterLongerCycles$(B, E', \mathcal{W}, \mathcal{C}', H)$**.**
Level i of the Recursion (for non-singleton block B):

1. Decompose B into $k = n^{\epsilon}$ blocks $B_1, \ldots, B_k$ each with $|B|/k$ vertices.
2. For every block B_a and every vertex $v \in B_a$, do the following for every $b > a$:
   - **a.** Let $N_{a,b}(v) = \{u \in B_b \mid (u,v) \in E'\}$
   - **b.** If $|N_{a,b}(v)|$ is odd:
     - Omit an arbitrary u from $N_{a,b}(v)$.
     - Omit the walk $W((u,v))$ from $\mathcal{W}$ and the edge (u,v) from E'.
     - Add $W((u,v))$ to H.
   - **c.** Match the vertices in $N_{a,b}(v)$ into pairs $\langle x,y \rangle$ (in an arbitrary manner).
   - **d.** For each matched pair $\langle x,y \rangle$ do:
     - If $(x,y) \in E'$:
       - Add the cycle $W((v,x)) \circ W((x,y)) \circ W((y,v))$ to $\mathcal{C}'$.
       - Remove the edges $(v,x),(x,y),(y,v)$ from E', and their walks from $\mathcal{W}$.
     - Otherwise:
       - Add a virtual edge (x,y) to E', and add to $\mathcal{W}$ the x-y walk:

$$W((x,y)) = W((x,v)) \circ W((v,y)).$$

3. For every $a \in \{1, \ldots, k\}$ do:
   - Let E'_a be the edges in E' with both endpoints in B_a.
   - Let $\mathcal{W}_a = \{W(e) \in \mathcal{W} \mid e \in E'_a\}$.
   - Apply FasterLongerCycles$(B_a, E'_a, \mathcal{W}_a, \mathcal{C}', H)$.

Figure 1 Description of $n^{o(1)}$-length cycle decomposition in $\widetilde{O}(m)$ time.

Analysis. Let $E_i, \mathcal{W}_i$ be the union of the $E', \mathcal{W}$ sets over all the recursion calls in level i.

▷ Claim 14 (Cycle Length). (a) All walks added in level i have length $\leq 2^i$; (b) All cycles added in level i have length $\leq 2^{i+1}$.

Proof. Consider the first level for the base of the induction. Let $B_1, \ldots, B_k$ be the first level blocks. Fix a pair of blocks B_a, B_b for $a < b$, and $v \in B_a$. Let $\langle x, y \rangle$ be a matched pair in $N_{a,b}(v)$. First, assume that when considering $\langle x, y \rangle$, the current edge set E' does not contain (x, y). In such a case, we add an x-y walk $W((x, y)) = (x, v) \circ (v, x)$ of length 2 as required. Otherwise, E' already contains the edge (x, y) and by the explanation above, $|W((x, y))| \leq 2$. In such a case, we add a cycle $C = (v, x) \circ W((x, y)) \circ (y, v)$ which has length at most 4 as required.

Assume that the claim holds up to level $i-1$, and consider level i. Using the induction assumption, we can apply the same argument for the induction base and get that either: (1) we add an x-y walk $W((x, y)) = W((x, v)) \circ W((v, y))$. Note that by definition (x, v) and (y, v) are edges between blocks in level $i+1$. Thus if these edges are virtual, they must have been added in level $i-1$ (since all virtual edges added in level i connect vertices in the same $(i+1)$-level blocks). We have by induction assumption that $|W((x, v))|, |W((v, y))| \leq 2^{i-1}$. Thus $|(W((x, y))| \leq 2^i$. (2) Otherwise, if E' already contained the edge (x, y) when considering this matched pair, the algorithm adds a cycle $C = W((v, x)) \circ W((x, y)) \circ W((y, v))$. Note that the edge (x, y) could potentially be added in level-i (since it is inside an $(i+1)$-level block). Thus $|W((x, y))| \leq 2^i$ (by the previous case), and $|W((x, v))|, |W((v, y))| \leq 2^{i-1}$. Overall, $|C| \leq 2^{i+1}$. The claim follows. ◁

Since the algorithm has $\ell = O(1/\epsilon)$ levels, overall all cycles have length $2^{O(1/\epsilon)}$ as required.

Missing proofs appear in the full version of the paper.

▷ Claim 15. [Number of Uncovered Edges] $|E(H)| = 1/\epsilon \cdot 2^{1/\epsilon} \cdot n^{1+O(\epsilon)}$.

Proof. We bound the number of edges added to the leftover subgraph H due to a fixed vertex v. Since the blocks are vertex-disjoint at every recursion level, a vertex belongs to at most $O(1/\epsilon)$ blocks: at most one block, in each level in the recursion tree (once a vertex becomes a singleton block, we stop sub-dividing it). Consider level i, and let B_v be the unique block containing v. Recall that in this level, the input edge set E_i contains only edges whose both endpoints are in the same i-level block.

Now, the algorithm subdivides B_v into n^ϵ disjoint blocks: $B_1, \ldots, B_k$. W.l.o.g., let B_1 be the block containing the vertex v. For every other block B_j for $j \in \{2, \ldots, k\}$, we omit at most one edge $e_j \in E_i$ and add a walk $W(e_j)$ to H. By Claim 14, every walk $W(e_j)$ is of length at most $2^{O(1/\epsilon)}$. Therefore, there is a total of $k \cdot 2^{O(1/\epsilon)}$ edges on the walks $W(e_1), \ldots, W(e_k)$ that are added to H when considering v. Summing over all the vertices, and over all $O(1/\epsilon)$ recursion levels, we get that $|H| = 1/\epsilon \cdot 2^{1/\epsilon} \cdot n^{1+O(\epsilon)}$. ◁

Finally, we show that all the edges that are not in H are covered by the cycles in $\mathcal{C}$.

▷ Claim 16 (Cover). Every edge is either in H or covered by the cycles in $\mathcal{C}$.

Proof. We claim by induction on i, that every edge $e \in G \setminus H$, either has a walk $W(e')$ such that $e' \in E_i$ and $e \in W(e')$, or that e is covered by a cycle in $\mathcal{C}$. The base of the induction holds vacuously. Assume it holds for $i-1$ and consider level i. It remains to take care for edges $e \in G$ such that (i) there exists $e' \in E_{i-1}$ satisfying that $e \in W(e')$ and (ii) $e' \notin E_i$. To see this observe that if (i) does not hold, then the statement holds by induction assumption. If (i) holds but (ii) does not hold, then $e \in W(e')$ for an $e' \in E_i$ and the statement holds.

Consider then such an edge e that satisfies the above two conditions. Since e' was omitted from E_i in phase $i-1$, it implies that $e' = (u, v)$ was an edge between two i-level (brother) blocks B_a and B_b. W.l.o.g., $u \in B_a$ and $v \in B_b$. We first observe that if u has an odd

number of edges in E_i with a second endpoint of B_b, then the unique edges e'' omitted from consideration cannot be e'. This holds since when omitting e'', we add $W(e'')$ to H. Since $e \in W(e')$ but $e \notin H$, it must hold that $e' \neq e''$. From now on, we know that e' was matched to another u-edge (u, v'). In this case either an v-v' walk $W(\widehat{e})$ for $\widehat{e} = (v, v')$ is added to the walk collection, or that a cycle containing $W(e')$ is added to $\mathcal{C}$. In either case, since $e \in W(e')$, it is indeed covered by either the walks or the cycles in level-i. ◁

Setting $\epsilon = 1/\sqrt{\log n}$, yields cycles of length $2^{\sqrt{\log n}}$ and at most $|H| = 2^{O(\sqrt{\log n})} \cdot n$ edges. All other edges not in H are covered by a cycle.

Edge-Disjoint Cycles. We prove (1) every edge belongs to at most one walk in $\mathcal{W}_i$ for every i, and (2) cycles are made by gluing a disjoint set of walks. Claim (1) can be shown by induction on the set of walks $\mathcal{W}_i$. The base of the induction holds vacuously. Assume that it holds up to i and consider the walks added in level i. The walks are formed one by one, where walks of level i formed by gluing together walks in $\mathcal{W}_i$. Whenever a walk $W(e) = W(e') \circ W(e'')$ is formed, the walks $W(e'), W(e'')$ are omitted from the walk collection and would not be considered again. The claim follows by combining with the induction assumption. To see (2) observe that whenever we form a cycle, all its walks are omitted from the walk collection. The proof follows from the fact that all walks are edge-disjoint.

Time Complexity. We claim that each all recursion calls of level i can be implemented in $O(m)$ time, for every $i = 1, \ldots, \ell$. We claim that all operations are linear in m. We keep the block ID of each vertex v (the maximum vertex ID in its block) in each level $i \geq 1$. Then by traversing over the edges in E_i, we can compute the edges $E_{a,b}$ between each pair of bothering blocks B_a, B_b in level i. We traverse the edges in $E_{a,b}$ for each vertex v in B_a. All operations of gluing walks due to an addition of virtual edges are linear in the length of the walks. Since all walks are edge-disjoint, we touch each edge $e \in E$ at most $O(1)$ many times in each phase.

3 Shorter Cycles in Almost Linear Time

We next turn to consider the high-level idea of our main algorithm which computes a decomposition with almost optimal quality in almost-linear time. Thus establishing Theorem 2. Specifically, here the cycle length will be bounded by $O(\log^2 n)$, and we will omit at most $O(n \log n)$ edges. Note that the simple algorithm described above omits $2^{1/\epsilon} \cdot n^{1+\epsilon}$ edges which is at least $2^{\sqrt{\log n}} n$ for any value of ϵ.

One option to improve this bound is by setting $\epsilon = 1/\log\log n$ to get cycles of length $O(\log n)$, while omitting $n^{1+o(1)}$ edges. Then by applying the algorithm of [8] on the remaining edges with $\delta = 1/c$ for some constant c we get an algorithm for covering all but $O(n)$ edges with $\mathsf{polylog}(n)$ length cycles in total time $m + n^{1+\delta}$. Since δ is constant, this algorithm is not an almost linear algorithm for graphs with $m = n^{1+o(1)}$ edges. Therefore, in order to obtain a truely almost linear algorithm that that omits $\widetilde{O}(n)$ edges, runs in time $m^{1+o(1)}$ and produces cycles of length $\mathsf{polylog}(n)$, we must come up with some new ideas.

Our alternative algorithm is recursive and has $O(1/\epsilon)$ recursion levels. It is also based on a balanced partitioning into blocks, only that the blocks in this context are more involved. Instead of computing edge-disjoint cycles directly, we compute short cycles that have a small amount of overlap. This notion is captured by low-congestion cycle cover defined as follows.

Key Task:

- **Input:** Parameter $\epsilon \in (0,1)$, an n-vertex graph G of diameter $O(\log n)$ with m edges, and a BFS tree $T \subseteq G$.
- **Goal:** Cover *all* non-tree edges with cycles of length at most $\mathtt{d} = O(2^{1/\epsilon} \cdot \log n)$, such that each edge appears on at most $\mathtt{c} = 1/\epsilon \cdot n^{O(\epsilon)}$ cycles. That is, compute a $(\mathtt{d}, \mathtt{c})$ cycle cover for the non tree edges.

Figure 2 The key sub-problem for short cycle decomposition.

For a bridgeless graph $G = (V, E)$, a $(\mathtt{d}, \mathtt{c})$ cycle cover is a collection of cycles of length at most $\mathtt{d}$, such that each edge in G appears on at least one cycle and on at most $\mathtt{c}$ cycles[11]. Intuitively, if each edge appears on few cycles, then one can greedily pick a subset of edge-disjoint cycles which covers a large enough fraction of the edges, and then repeat again (after removing all edges that are currently covered). Moreover, we also show that computing the decomposition boils down into an even easier variant of the low-congestion cycle cover problem.

Note that the key task considers all graphs of diameter $O(\log n)$, whereas in our case the input graph G might have a large diameter. To add more insult to the injury, the low-congestion cover computation is computed repeatedly on the subset of yet uncovered edges (i.e., by the current subset of edge-disjoint cycles). Thus, even if the original input graph has a small diameter, already in its second application, the input graph to the algorithm might not be even connected. In the full version, we show how to settle down this mystery using the notion of neighborhood covers. From now on, we focus on the key task.

Solving the Key Task. Given a tree T and an $\epsilon \in (0,1]$, our goal now is to cover all non-tree edges $E \setminus T$ with cycles of length at most $\mathtt{d} = 2^{1/\epsilon} \cdot O(\log n)$, such that each edge appears on at most $\mathtt{c} = 1/\epsilon \cdot n^{\epsilon}$ cycles.

The algorithm is recursive with $\ell = O(1/\epsilon)$ recursion levels. In each independent level $i \in \{1, \ldots, \ell\}$ of the recursion, we are given a subtree T' and a collection of at most $m/n^{\epsilon \cdot (i-1)}$ edges E' with both endpoints in T' that should be covered. Some of the edges in E' (in level $i \geq 2$) might be virtual, and in such a case it implies that the algorithm has already computed a partial cycle (i.e., a walk) that covers them. We are also given a set of walks $\mathcal{W}$ that contains a walk $W(e)$ for each $e \in E'$. Initially, T' is simply T, E' contains all edges in $E(G) \setminus T$ that we want to cover, and $\mathcal{W} = \{e : e \in G\}$ contains the trivial walks for each edge.

Step (1): Balanced Block Partitioning. The first step of the algorithm is to partition T' into $k = \Theta(n^{\epsilon})$ edge-disjoint subtrees $T_1, \ldots, T_k$ that are *balanced* with respect to their degrees in E'. We call such balanced subtrees *blocks*. Any vertex whose degree in E' is too high defines a singleton block.

As in the previous algorithm, we will distinguish between two types of E'-edges: edges inside a block and edges between blocks. We next describe how to replace edges between blocks with virtual edges that are *inside a block*, in a way that covering the virtual edges by

[11] Our constructions do not require the graph to be bridgeless, it covers edges by cycles provided that such a cycle exists.

cycles will, later on, be translated back to a covering of the original inter-block edges. Unlike the previous algorithm, here we do not have the privilege to throw away edges to leftover subgraphs. Thus, we will have to make sure that all virtual edges are eventually completed into a cycle.

Step (2): Handling Edges Between Blocks. Let $E_{a,b}$ be all the edges in E' with one endpoint in T_a and the other in T_b. Our goal now is the following: we want to find a matching of the edges in $E_{a,b}$ in a way such that if $e = (x, y)$ and $e' = (x', y')$ where $x, x' \in T_a$ and $y, y' \in T_b$ are matched then there is a path $\pi(x, x')$ in T_a such that these paths for all pairs are edge disjoint. Then, we add the virtual edge $(y, y') \in T_b \times T_b$ and remove e and e'. Furthermore, we maintain the set of walks $\mathcal{W}$ connecting the endpoints of each virtual edge $\widehat{e} = (y, y')$ where $W(\widehat{e}) = e \circ \pi(x, x') \circ e'$.

Intuitively, the addition of a virtual edge (y, y') indicates to the algorithm that a cycle covering the edges e and e' is "under construction": there is currently an y-y' walk which will become a cycle when covering the virtual edge (y, y'). Importantly, all the virtual edges are internal to T_b and thus will be covered recursively by a path inside T_b. This path, along with $W(e)$ will complete the cycle. This procedure is applied for each pair of subtrees T_a, T_b separately, eventually converting all inter-block edges to internal block edges. Then, we apply the algorithm recursively on each block.

Notice that when the algorithm is applied recursively, then the inter-block edges e, e' might be virtual. Thus, we define the walks as follows. Initially, we set $W(e) = e$ for all edges of the graph and let $\mathcal{W} = \{W(e), e \in E'\}$. Then, we update $W(\widehat{e}) = W(e) \circ \pi(x, x') \circ W(e')$. That is, if e is a virtual edge then instead of adding it to the path we added its path $W(e)$ that contain "real" edges of the graph. This, of course, makes the walk longer and we bound their length later on.

We are left to describe how the matching is performed. As long as there is a vertex x in either T_a or T_b that is adjacent to at least two edges $E_{a,b}$, then we can match these two edges. That is, in this case, we have that $x = x'$ and thus the path $\pi(x, x') = x$ is the trivial path and is, of course, edge-disjoint from any other path. Thus, we can now assume that each vertex in T_a and T_b is adjacent to at most one edge in $E_{a,b}$. Note in the previous algorithm, when we got to a point that a vertex in a block is incident to one vertex in another block, we simply got rid of this edge by adding it to the leftover subgraph H. Here, we do not have this option, as we really need to cover *all* non-tree edges. This is exactly the point where congestion kicks in: covering all edges will come with the cost of producing cycles with some overlap, rather than edge-disjoint cycles as in the previous algorithm.

Let $M_{a,b} \subset T_a$ be all the vertices in T_i that are adjacent to an endpoint of an edge in $E_{a,b}$. If $|M_{a,b}|$ is odd, then we omit a single vertex y from this set, and cover the edge (x, y) by adding the "fundamental" cycle $C = W((x, y)) \circ \pi(x, y, T)$ to the cycle collection[12].

From now on, we assume that $M_{a,b}$ is even, and each $y \in M_{a,b}$ is incident to a unique edge in $E_{a,b}$ to be covered. The key tool used in this context is the following lemma:

▷ Fact 17. [12] Given a tree T and an even subset of marked vertices $M \subseteq V(T)$, one can compute a matching the vertices of M into pairs such that the collection of tree paths $\pi(x, y, T)$ over all the matched pairs are edge-disjoint.

We apply Algorithm DisjointMatching to the instance $T_a, M_{a,b}$. The output of this algorithm is a matching of the marked vertices $M_{a,b}$ into pairs $\langle x_i, y_i \rangle$, along with a collection of edge-disjoint paths in T_a connecting the matched pairs. The matched vertices naturally

[12] If e is an edge in G it is indeed a fundamental cycle.

define the matching between the remaining edges, along with edge-disjoint paths. This completes the high-level description of level i, while omitting some minor technical subtleties.

Why It Works. We give an overview of the analysis of this algorithm.

1. **Cycle lengths:** Let d_i be the maximum length of all walks at the beginning of level i of the recursion. In level i, the walks $W(\widehat{e}) = W(e) \circ \pi(x, x') \circ W(e')$ contain two $(i-1)$-level walks and a tree segment. Since the depth of the tree is $O(\log n)$, we get $d_{i+1} \leq 2d_i + O(\log n)$. Solving for $i = O(1/\epsilon)$, gives the desired cycle length of $2^{O(1/\epsilon)} \cdot \log n$.
2. **Congestion:** We first consider the congestion added when creating walks via the routing edge-disjoint matching algorithm. We claim that in every recursion level, the congestion on the tree edges is increased by (at most) an additive term of n^ϵ. The non-tree edges, in contrast, will belong to exactly one cycle (using a similar argument to the previous algorithm).
   The congestion argument works by induction as well. Assume by induction that every tree edge e appears at most c_{i-1} many times on all walks computed up to level i. In level i, every walk is of the form: $W(\widehat{e}) = W(e) \circ \pi(x, x') \circ W(e')$. That is, it has a tree segment $\pi(x, x')$ and two segments of an $(i-1)$-level walks. Since each $(i-1)$-level walk is added to at most one i-level walk (due to the matching step), the total congestion on the non-tree part of the i-level walks is kept the same. The increase in the congestion is then due to the tree segment $\pi(x, x')$. Recall that this tree segment is the outcome of applying the routing disjoint algorithm in some block T_a. For each application of this algorithm in T_a w.r.t to the edges of a fixed block T_b, the tree segments are disjoint. However, since the algorithm is applied in T_a for n^ϵ many times – per other block T_b, the total congestion on its tree edges is n^ϵ. Overall, we get that $c_i \leq c_{i-1} + n^\epsilon$. Solving for $i = O(1/\epsilon)$, gives the desired bound.
   Finally, we bound the congestion due to the fundamental cycles. Recall that whenever the number of edges between blocks T_a and T_b is odd, we cover a single edge with its fundamental cycle. Let T' be an i-level block and $T_1, \ldots, T_k$ be its children. The tree segment of the fundamental cycle of each edge between T_a and T_b is contained in T'. Since T' has $k = O(n^\epsilon)$ children, the tree edge appears on $n^{2\epsilon}$ cycles. Next, observe that since the blocks of each level are edge-disjoint, an edge appears on $O(1/\epsilon)$ many blocks over all, thus the total congestion added due to the fundamental cycles of the child components is $1/\epsilon n^{2\epsilon}$.
3. **Time Complexity:** In each phase, for each of the blocks T_a we have $k = O(n^\epsilon)$ applications of the routing disjoint matching algorithm. This algorithm can be implemented in linear time. Since the blocks are edge-disjoint, overall it takes $k \cdot \sum_a O(|T_a|) = m \cdot n^\epsilon$. Computing the walks defined by these matching outcome can be done in linear time in the total length of all i-level walks. Since each tree edge appears at most n^ϵ times on this walks (in each recursion level), the total length of the walks is $O(m + n^\epsilon \cdot n)$. Summing overall $O(1/\epsilon)$ recursion levels gives the desired bound. The pseudocode of the algorithm appears, illustrations, the complete analysis and the distributed implementation all appear in the full version of the paper.

Abstract

In the last two decades the study of random instances of constraint satisfaction problems (CSPs) has flourished across several disciplines, including computer science, mathematics and physics. The diversity of the developed methods, on the rigorous and non-rigorous side, has led to major advances regarding both the theoretical as well as the applied viewpoints. The two most popular types of such CSPs are the Erdős-Rényi and the random regular CSPs.

Based on a ceteris paribus approach in terms of the density evolution equations known from statistical physics, we focus on a specific prominent class of problems of the latter type, the so-called *occupation problems*. The regular r-in-k occupation problems resemble a basis of this class. By now, out of these CSPs only the satisfiability threshold – the largest degree for which the problem admits asymptotically a solution – for the 1-in-k occupation problem has been rigorously established. In the present work we take a general approach towards a systematic analysis of occupation problems. In particular, we discover a surprising and explicit connection between the 2-in-k occupation problem satisfiability threshold and the determination of *contraction coefficients*, an important quantity in information theory measuring the loss of information that occurs when communicating through a noisy channel. We present methods to facilitate the computation of these coefficients and use them to establish explicitly the threshold for the 2-in-k occupation problem for $k = 4$. Based on this result, for general $k \geq 5$ we formulate a conjecture that pins down the exact value of the corresponding coefficient, which, if true, is shown to determine the threshold in all these cases.

1 Introduction

Inspired by the pioneering work [22] of Erdős and Rényi in 1960, random discrete structures have been systematically studied in literally thousands of contributions. The initial motivation of this research was to study open problems in graph theory and combinatorics. In the following decades, however, the application of such models proved useful as a unified approach

to treat a variety of problems in several fields. To mention just a few, random graphs turned out to be valuable in solving fundametal theoretical and practical problems, such as the development of error correcting codes [34], the study of statistical inference through the stochastic block model [1], and the establishment of lower bounds in complexity theory [27, 24].

The results of the past years of research suggest the existence of *phase transitions* in many classes of random discrete structures, i.e. a specific value of a given model parameter at which the properties of the system in question change dramatically. Constraint satisfaction problems are one specific type of such structures that tend to exhibit this remarkable property and that are of particular interest in too many areas to mention, covering complexity theory, combinatorics, statistical mechanics, artificial intelligence, biology, engineering and economics. An instance of a CSP is defined by a set of variables that take values in – typically finite – domains and a set of constraints, where each constraint is satisfied for specific assignments of the subset of variables it involves. A major computational challenge is to determine whether such an instance is satisfiable, i.e. to determine if there is an assignment of all variables that satisfies all constraints.

Since the 1980s non-rigorous methods have been introduced in statistical physics that are targeted at the analysis of phase transitions in *random* CSPs [37, 36, 33]. Within this line of research, a variety of exciting and unexpected phenomena were discovered, as for example the existence of multiple phase transitions with respect to the structure of the solution space in random CSPs; these transitions may have a significant impact on the hardness of the underlying instances. Since then these methods and the description of the conjectured regimes have been heavily supported by several findings, including the astounding empirical success of randomized algorithms like *belief* and *survey propagation* [9], as well as rigorous verifications, most prominently the phase transition in k-SAT [19] (for sufficiently large k) and the condensation phase transition in many important models [14]. However, a complete rigorous study is still a big challenge for computer science and mathematics.

Usually, the relevant model parameter of a random CSP is a certain problem specific *density* as illustrated below. The main focus of research is to study the occurrence of phase transitions in the solution space structure and in particular the existence of *(sharp) satisfiability thresholds*, i.e. critical values of the density such that the probability that a random CSP admits a solution tends to one as the number of variables tends to infinity for densities below the threshold, while this limiting probability tends to zero for densities above the threshold.

Random CSPs. The two most popular types of random CSPs are Erdős Rényi (ER) type CSPs and random regular CSPs. In both cases the number $n = |V|$ of variables and the number k of variables involved in each constraint is fixed. In ER type CSPs we further fix the number $m = |F|$ of constraints and thereby the *density* $\alpha = m/n$, i.e. the average number of constraints that a variable is involved in. In random regular CSPs we only consider instances where each variable is involved in the same number d of constraints, which fixes the *density* d as well as the number $m = dn/k$ of constraints. In a second step we randomly choose the sets of satisfying assignments for each constraint depending on the problem. For example, in the prominent k-SAT one forbidden assignment is chosen uniformly at random from all possible assignments of the involved binary variables for each constraint independently. Another famous example is the coloring of hypergraphs, where the constraints are attached to the hyperedges and the variables to the vertices of the hypergraph, i.e. the variables involved in a constraint correspond to the vertices incident to a hyperedge. In this case the satisfying assignments are determined since each constraint is violated iff all involved vertices take the same color.

In our work we focus on the class of random regular CSPs where the choice of satisfying assignments per constraint is determined, i.e. a class that covers the regular occupation problems and the coloring of (d-regular k-uniform) hypergraphs amongst others, sparing problems with random constraints like k-SAT and XORSAT. A unique feature of this class is, intuitively speaking, that the local structure of almost all instances is fixed almost everywhere for sufficiently large n. The lack of randomness makes this class particularly accessible for an analysis of the asymptotic solution space structure and significantly simplifies simulations based on the well-known *population dynamics*. Using such simulations, non-rigorous results for this class have been mostly established for the case where the variables are binary valued, so called occupation problems, or restricted to variants of hypergraph coloring for non-binary variables. Besides the extensive studies on the coloring of simple graphs, i.e. $k = 2$, the only rigorous results derived so far consider the arguably most simple type of occupation problems where each constraint is satisfied if exactly one involved variable evaluates to true, which we refer to as d-regular 1-in-k occupation problem. In our current work we strive to extend these results to general d-regular r-in-k occupation problems, i.e. problems where each constraint is satisfied if r out of the k involved variables evaluate to true.

1.1 Occupation Problems

We continue with the formal definition of the class of problems we consider. Let $k, d \in \mathbb{Z}_{>1}$ and $r \in [k-1] := \{1, \dots, k-1\}$ be fixed. Additionally, we are given non-empty sets V of variables and constraints F. We will use the convention to index elements of V with the letter i and elements of F with the letter a (and subsequent letters) in the remainder. Then an instance o of the d-regular r-in-k occupation problem is specified by a sequence $o = (v(a))_{a \in F}$ of $m = |F|$ subsets $v(a) \subseteq V$ of size k such that each of the $n = |V|$ variables is contained in d of the subsets. In graph theory the instance o has a natural interpretation as a (d, k)-biregular graph (or d-regular k-factor graph) with node sets $V \dot\cup F$ and edges $\{i, a\} \in E$ if $i \in v(a)$.

Given an instance o as just described, we say that an assignment $x \in \{0,1\}^V$ *satisfies* a constraint $a \in F$ if $\sum_{i \in v(a)} x_i = r$, otherwise x *violates* a. If x satisfies all constraints $a \in F$, then x is a *solution* of o. We write $z(o)$ for the number of solutions of o. An example of a 4-regular 2-in-3 occupation problem is shown in Figure 1a.

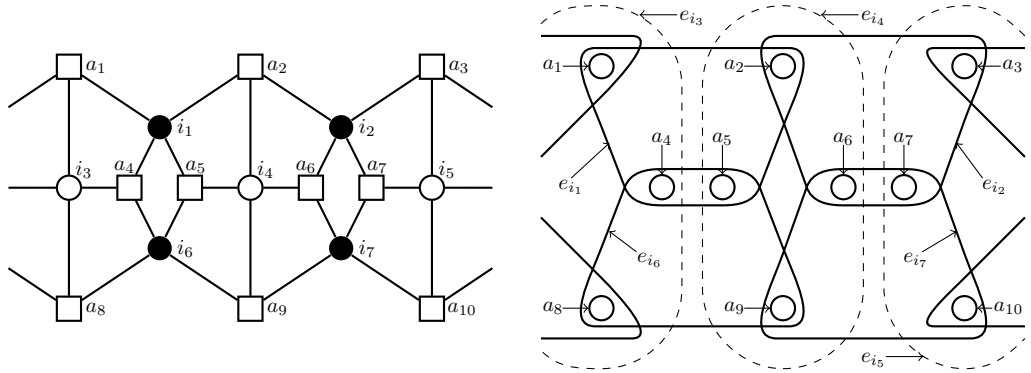
Further, for given $m, n \in \mathbb{Z}_{>0}$ let $\mathcal{O} = \mathcal{O}(k, d, n, m)$ denote the set of all instances o with variables $V = [n]$ and constraints $F = [m]$. If $\mathcal{O}$ is not empty, then the random d-regular r-in-k occupation problem O is the random variable O equipped with the uniform distribution $P = P_{\mathcal{O}}$ on $\mathcal{O}$ and $Z = z(O)$ the number of solutions of O.

1.2 Examples and Related Problems

A problem that is closely related and can be reduced to the d-regular r-in-k occupation problem is the d-regular positive r-in-k SAT problem, a variant of k-SAT introduced above. In this case, we consider a boolean formula

$$f = \bigwedge_{a \in F} c_a, \quad c_a = \bigvee_{i \in v(a)} i,\ a \in F,$$

in conjunctive normal form with m clauses over n variables $i \in V$, such that no literal appears negated (hence *positive* r-in-k SAT), and where each clause c_a is the disjunction of k literals and each variable appears in exactly d clauses (hence d-regular). The decision problem is to determine if there exists an assignment x such that exactly r literals in each



(a) Solution of the 2-occupation problem. **(b)** A 2-factor in a hypergraph.

Figure 1 On the left we see a solution of the 4-regular 2-in-3 occupation problem on a 4-regular 3-factor graph, where the rectangles and circles depict the constraints (factors) and variables (filled if they take the value one in the solution). The figure on the right shows a 2-factor in a 3-regular 4-uniform hypergraph, where the circles, solid and dashed shapes represent the vertices, hyperedges in the 2-factor and the other hyperedges respectively.

clause evaluate to true (hence r-in-k SAT). In [39] the satisfiability threshold for this problem was determined for $r = 1$, i.e. the case where exactly one literal in each clause evaluates to true. One of our main results, Theorem 1.1, solves this problem when $r = 2$ and $k = 4$.

Our second example deals with a prominent problem related to graph theory. A k-regular d-uniform hypergraph h is a pair $h = (F, E)$ with $m = |F|$ vertices and $n = |E|$ (hyper-)edges such that each edge contains d vertices and the degree of each vertex is k. An *r-factor* E' is a subset of the hyperedges such that each vertex $a \in F$ is incident to r hyperedges $e_i \in E'$. In this case the problem is to determine if h has an r-factor. For example, the case $r = 1$ is the well-known perfect matching problem and the threshold was determined in [16]. An example of a 2-factor in a hypergraph is shown in Figure 1b. Theorem 1.1 solves also this problem for $r = 2$ and $k = 4$.

There are several other problems in complexity and graph theory that are closely related to the examples above. The satisfiability threshold in Theorem 1.1 also applies to a variant of the vertex cover problem (or hitting set problem from set theory perspective), where we choose a subset of the vertices (variables with value one) in a d-regular 4-uniform hypergraph such that each hyperedge is incident to exactly two vertices in the subset. Analogously, Theorem 1.1 also establishes the threshold for a variant of the set cover problem in set theory corresponding to 2-factors in hypergraphs, i.e. given a family of d-subsets (hyperedges) and a universe (vertices) with each element contained in four subsets, the problem is to find a subfamily of the subsets such that each element of the universe is contained in exactly two subsets of the subfamily. Further, Theorem 1.1 can e.g. also be used to give sufficient conditions for the (asymptotic) existence of Euler families in regular uniform hypergraphs as discussed in [6].

1.3 Main Results

The d-regular 1-in-k occupation problem has been completely solved in [39, 16], which also covers the d-regular 2-in-3 occupation problem due to color symmetry. Our first result addresses the next non-trivial case, namely the location of the satisfiability threshold of the

random d-regular 2-in-4 occupation problem. For $k \in \mathbb{Z}_{>3}$ let

$$w_1^* = w_1^*(k) = \frac{2}{k},\ w_2^* = w_2^*(k) = \binom{k}{2}^{-1} \text{ and } d^* = d^*(k) = \frac{kH(w_1^*)}{kH(w_1^*) + \ln(w_2^*)}, \tag{1}$$

where $H(p) = -p\ln(p) - (1-p)\ln(1-p)$ is the binary entropy of $p \in [0,1]$. The following theorem establishes the location of the threshold at $d^*(4) \approx 2.83$ for $k = 4$.

▶ **Theorem 1.1** (2-in-4 Occupation Satisfiability Threshold). *Let $k = 4$, $d \in \mathbb{Z}_{>1}$, and $\mathcal{O} = \mathcal{O}(k,d,n,m)$, $Z = Z_{k,d,n,m}$ be as in Section 1.1.*

(a) *The set $\mathcal{O}$ is non-empty iff $m = m(n) = \frac{dn}{k}$. Then, the number Z of solutions is zero almost surely if k does not divide $2n$, i.e. $\mathbb{P}[Z = 0] = 1$. Further, the threshold d^* is not an integer.*

(b) *There exists a sharp satisfiability threshold at d^*, i.e. for any increasing sequence $(n_i)_{i\in\mathbb{Z}_{>0}} \subseteq \mathcal{N} = \{n : dk^{-1}n,\ 2k^{-1}n \in \mathbb{Z}_{>0},\}$ and $m_i = m(n_i)$ we have*

$$\lim_{i\to\infty} \mathbb{P}[Z > 0] = \begin{cases} 1 & , d < d^* \\ 0 & , d > d^* \end{cases}.$$

We prove Theorem 1.1 using the second moment method for Z and the small subgraph conditioning method to boost the probability asymptotically to one below the threshold d^*. However, an important question remains at this point, namely what happens when $k > 4$ or $r > 2$.

Our second main result in this paper addresses the behavior for $k > 4$, which can be directly extended to $r > 2$. In particular, a main technical contribution in proving Theorem 1.1 is the optimization of a certain multivariate function that appears in the computation of the second moment, which encodes the interplay between the "similarity" of various assignments and the change in the corresponding probability of being satisfying that they induce. A similar but more complex function appears in the computation of the second moment for $k > 4$, but there we are unfortunately not able to pin down the maximizer. However, apart from that, we discover a surprising connection between this optimization problem and a seemingly unrelated fundamental problem in information theory. In particular, we find that the optimization problem is equivalent to developing a so-called *strong data processing inequality (SDPI)*, which, roughly speaking, encodes the minimum amount of loss in the process of communication through a noisy channel. Such inequalities are of particular importance in the analysis of noisy channels.

We postpone the formal definitions and more relevant background to the next section. Further, we show that our anticipated forms of the corresponding SDPIs directly yield the locations of the global extrema required for our satisfiability threshold proof and thereby imply the following theorem based on Conjecture 1.3.

▶ **Theorem 1.2** (2-in-k Occupation Satisfiability Threshold). *Assume that Conjecture 1.3 is true. Then Theorem 1.1 holds for any $k \in \mathbb{Z}_{>3}$.*

We are confident that this surprising connection does not only apply to 2-in-k occupation problems, but to all r-in-k occupation problems and we believe that it also extends to other classes of random CSPs. Hence, this bridge facilitates the combination of the methods that have been devised in information theory and the study of random graphs, ultimately relating the second moment method to the hypercontractivity ribbon.

1.4 Contraction Coefficients

One central concept in information theory [28, 17] is the notion of a communication channel. Let us assume for concreteness that we have sets $[m]$ and $[n]$ of input and output symbols respectively. We consider the communication through a noisy channel, that is, for a given input $x \in [m]$ the output is $y \in [n]$ with a certain fixed probability $W_{y,x}$. Thus, the channel is completely characterized by its column stochastic transition probability matrix $W = (W_{y,x})_{y\in[n],x\in[m]} \in [0,1]^{n\times m}$.

In a second step, let us consider a distribution P on $[m]$ with probability mass function (pmf) $p \in [0,1]^m$, i.e. a distribution on the inputs. Then the corresponding distribution Q on the received outputs is given by the pmf $q = Wp \in [0,1]^n$. The study of the properties of such channels involves the quantification of the communicated information and further a channel capacity, i.e. the maximum amount of transmittable information. The *data processing inequality (DPI)* is a fundamental result stating that information can only *decrease* when communicated through a noisy channel.

The version of the DPI, see e.g. Lemma 3.11 in [17], relevant here is as follows. Fix a reference input distribution P^* with pmf $p^* \in \mathbb{R}^m$, i.e. the reference output distribution Q^* has the pmf $q^* = Wp^* \in \mathbb{R}^n$. If we then consider an input distribution P with pmf p and the corresponding output distribution Q with pmf $q = Wp$, it is easier to distinguish the distributions P and P^* *before* the transmission. This suggests a loss of information in the process of communication; formally, this means that

$$D_{\mathrm{KL}}(P \parallel P^*) \geq D_{\mathrm{KL}}(Q \parallel Q^*), \quad \text{where} \quad D_{\mathrm{KL}}(P \parallel P^*) = \sum_{x\in[m]} p_x \ln\left(\frac{p_x}{p_x^*}\right).$$

The quantity $D_{\mathrm{KL}}(\cdot \parallel \cdot)$ is the well-known K(ullback)–L(eibler) divergence and one of the most important means of measuring the similarity between given distributions.

This fundamental DPI can be further improved by introducing the optimal ratio $d_* = d_*(P^*, W)$ of $D_{\mathrm{KL}}(Q \parallel Q^*)$ and $D_{\mathrm{KL}}(P \parallel P^*)$ and deriving the tight bound

$$d_* D_{\mathrm{KL}}(P \parallel P^*) \geq D_{\mathrm{KL}}(Q \parallel Q^*) \quad \text{with} \quad d_* = \sup_{P\neq P^*} \frac{D_{\mathrm{KL}}(Q \parallel Q^*)}{D_{\mathrm{KL}}(P \parallel P^*)}.$$

In particular d_* is independent of the input distribution P and the output distribution $Q = Q(P)$. A data processing inequality of this type is referred to as a strong data processing inequality (SDPI) with *contraction coefficient* d_* [2, 4, 3]. In this sense the contraction coefficient $d^*(P^*, W) = d^*(X;Y)$ can be regarded as an alternative measure for the mutual information $I(X;Y)$, i.e. the KL divergence of the distribution of (X,Y) with respect to the distribution of X and Y assuming independence, where the distribution of (X,Y) has the pmf $(W_{yx}p_x^*)_{x,y} \in \mathbb{R}^{n\times m}$. This quantity is of great importance in the analysis of noisy channels and hence not only of interest in theory building, but also in many applications covering image and audio processing, biology, economics and engineering.

1.5 The Conjecture

Let $k \in \mathbb{Z}_{>3}$, $w_1^* = \frac{2}{k}$, $w_2^* = \binom{k}{2}^{-1}$ as defined in (1),

$$W = (W_{(s-1),(t-1)})_{s,t\in[3]} = \begin{pmatrix} 1-2w_1^* & 1-\frac{3}{2}w_1^* & 1-w_1^* \\ 2w_1^* & w_1^* & 0 \\ 0 & \frac{1}{2}w_1^* & w_1^* \end{pmatrix}, \tag{2}$$

and for $w \in \mathcal{W} = \{w \in [0,1]^2 : 2w_1 - 1 \leq w_2 \leq w_1\}$ let

$$p = (p_{s-1})_{s\in[3]} = \begin{pmatrix} 1 - 2w_1 + w_2 \\ 2(w_1 - w_2) \\ w_2 \end{pmatrix}, \quad q = Wp = (q_{s-1})_{s\in[3]} = \begin{pmatrix} 1 - 2w_1^* + w_1^* w_1 \\ 2w_1^*(1 - w_1) \\ w_1^* w_1 \end{pmatrix}. \quad (3)$$

Notice that W is the transition probability matrix of a (fixed) channel for fixed k, that p, q are pmfs for all $w \in \mathcal{W}$ and further any pmf on $\{0,1,2\}$ can be attained by p. As discussed in Section 1.3, $w \in \mathcal{W}$, p and q quantify the similarity of two random satisfying assignments in the following sense. Intuitively and due to symmetry, a given variable i involved in any given constraint takes the value one with probability $w_1^* = \mathbb{P}[X_i = 1]$, while two given variables i, j involved in the constraint both take the value one with probability $w_2^* = \mathbb{P}[X_i + X_j = 2]$ under a random satisfying assignment X. The parameter $w_1 = \mathbb{P}[Y_i = 1 | X_i = 1]$ gives the conditional probability that i takes the value one under a second satisfying assignment Y given that i takes the value one under X, while $w_2 = \mathbb{P}[Y_i + Y_j = 2 | X_i + X_j = 2]$ gives the conditional probability that both i, j take the value one under Y assuming that they both take the value one under X. Further, p is the pmf of $(Y_i + Y_j)|(X_i + X_j) = 2$, i.e. of the distribution of the number $(Y_i + Y_j)$ of ones taken by i and j under Y given that i, j take one under X, while q is the pmf of the distribution of the number $(X_i + Y_i)$ of ones taken by i under X and Y. In this sense, w_1 and w_2 quantify the similarity of two satisfying assignments X and Y. For example, the choice $w_1 = w_2 = 1$ of parameters implies that Y is determined by X and hence, intuitively, corresponds to a minimum loss of information.

Let P^* be the reference input distribution with pmf $p^* = p(w^*)$, then by the discussion above and in Section 1.4 we can employ the contraction coefficient $d_* = d_*(k) = d_*(P^*, W)$ to quantify the loss of information in a communication through the channel W, and further expect that d_* is attained at $w = (1,1)$.

▶ **Conjecture 1.3** (Contraction Coefficient Conjecture). *The contraction coefficient d_* is attained for the degenerate input pmf p at two, that is,*

$$w_1 = w_2 = 1 \quad \textit{and} \quad d_* = \frac{H(w_1^*)}{-\ln(w_2^*)}.$$

In our contribution, we do not only show that the computation of d_* is equivalent to the optimization problem in the second moment method, but that Conjecture 1.3 is actually equivalent to the applicability of the second moment method.

1.6 Related Work

The regular version of the random 1-in-k occupation problem (and related problems) has been completely solved in [16, 39] using the first and second moment method with small subgraph conditioning. The paper [41] shows that $d^*(k) \geq 2$ for $k \in \mathbb{Z}_{>1}$ in the d-regular 2-in-k occupation problem, i.e. the existence of 2-factors in k-regular simple graphs. A recent discussion of 2-factors (and the related Euler families) that does not rely on the probabilistic method is presented in [6]. Further, randomized polynomial time algorithms for the generation and approximate counting of 2-factors in random regular simple graphs have been introduced in [25].

The study of Erdős Rényi (hyper-)graphs was initiated by the ground breaking publication [22] in 1960 and turned into a fruitful field of research with many applications, including early results on 1-factors in simple graphs [23]. On the contrary, results for the random d-regular k-uniform (hyper-)graph ensemble were rare before the introduction of the configuration

(or pairing) model by Bollobás [8] and the development of the small subgraph conditioning method [30, 31] thereafter, see also [44]. While the derived proof scheme facilitated rigorous arguments to establish the existence and location of satisfiability thresholds of random regular CSPs [38, 7, 32, 12, 15, 20, 21, 5], the problems are treated on a case by case basis, while results on entire classes of random regular CSPs are still outstanding.

One of the main reasons responsible for the complexity of a rigorous analysis of random (regular) CSPs seems to be a conjectured structural change of the solution space for increasing densities. This hypothesis has been put forward by physicists, verified in parts and mostly for ER ensembles, further led to new rigorous proof techniques [19, 15, 13] and to randomized algorithms [9, 35] for NP-hard problems that are not only of great value in practice, but can also be employed for precise numerical (though non-rigorous) estimates of satisfiability thresholds An excellent introduction to this *replica theory* can be found in [36, 33, 43]. Specifically, numerical results indicating the satisfiability thresholds for d-regular r-in-k occupation problems (more general variants, and for ER type hypergraphs) based on this conjecture were discussed in various publications [10, 18, 42, 26, 29, 46, 45], where *occupation problems* were introduced for the first time in [40].

Another fundamental obstacle in the rigorous analysis is of a very technical nature and directly related to the second moment method as discussed in detail in our current presentation. In the case of regular r-in-k occupation problems (amongst others) this optimization problem is closely related to the computation of the *contraction coefficient* (for fixed channels and reference distributions) known from information theory. For a general introduction to information theory we recommend [17], while profound discussions and applications of contraction coefficients can be found in [3, 4] and references therein.

1.7 Open Problems

As mentioned in Section 1.2, we focus on the analysis of random regular CSPs with determined constraints. The starting point for this systematic study are r-in-k occupation problems, where we rigorously established the threshold for $r = 2$ and $k = 4$. However, apart from the optimization step in the second moment calculation our proof canonically extends to the general case. A rigorous proof of this step for general r and k is involved, but further assumptions may significantly simplify the analysis. For example, as an extension of the current work one may focus on r-in-$2r$ occupation problems, where the constraints are symmetric in the colors. As can be seen from our proof, this yields useful symmetry properties of the objective function $\frac{D_{\mathrm{KL}}(Q \parallel Q^*)}{D_{\mathrm{KL}}(P \parallel P^*)}$. Further, as suggested by the literature [11, 13, 14] such *balanced* problems [45, 46] are usually more accessible to a rigorous study. On the other hand, the optimization usually also significantly simplifies if only carried out for $k \geq k_0(r)$ for some large $k_0(r)$, as this pushes the minimum to the boundary of the function domain.

Apart from the generalizations discussed above, results for the r-in-k occupation problems are also still outstanding for Erdős-Rényi type CSPs. An analysis of this related problem might allow to tackle the crucial optimization step from a different perspective and thereby also help to establish the thresholds for the regular version.

From the algorithmic perspective, although some methods have been developed for simple graphs [25], we are not aware of algorithms designed specifically to identify solutions of the regular occupation problems (like WalkSAT for the k-SAT problem), only general methods like belief propagation based decimiation. However, problem specific obstacles for the design of such algorithms were discussed in [46].

2 Proof Techniques

In this section we give a high-level overview of our proof, in particular we present the major steps that lead to the main results. We make heavy use of the so-called *configuration model* for the generation of random instances in the form used by Moore [39].

2.1 The Configuration Model

Working with the uniform distribution on d-regular k-uniform hypergraphs directly is challenging. Instead, we show Theorems 1.2 and 1.1 for occupation problems on configurations. A d-regular k-configuration is simply a bijection $g : [n] \times [d] \to [m] \times [k]$, where the v-edges $(i, h) \in \mathrm{dom}(g)$ represent pairs of variables $i \in [n]$ and i-edges, i.e. half-edge indices $h \in [d]$. The image $(a, h') = g(i, h)$ is an f-edge, i.e. a pair of a constraint (factor) $a \in [m]$ and an a-edge (or half-edge) $h' \in [k]$, indicating that the i-edge h of the variable i is wired to the a-edge h' of a and thereby suggesting that i is connected to a in the corresponding d-regular k-factor graph. The number of such d-regular k-configurations on n variables can be easily determined and is given by $(dn)! = (km)!$, hence the uniform distribution on configurations is suitable for combinatorial arguments. Further, the occupation problem on factor graphs directly translates to configurations, which allows to introduce the number Z of solutions of the occupation problem on the random configuration G. In the following we discuss the proof of the analogues to Theorems 1.2 and 1.1 for configurations and further the translation of these results back to factor graphs and hypergraphs.

2.2 The First Moment Method

In the first step we apply the first moment method to the occupation problem on configurations, yielding the following result.

▶ **Lemma 2.1** (First Moment Method). *Let $k \in \mathbb{Z}_{>3}$, $d \in \mathbb{Z}_{>1}$. For $n \in \mathcal{N}$ tending to infinity we have*

$$\mathbb{E}[Z] \sim \sqrt{d} e^{n\phi_1}, \text{ where } \phi_1 = \frac{d}{k}(-\ln(w_2^*)) - (d-1)H(w_1^*).$$

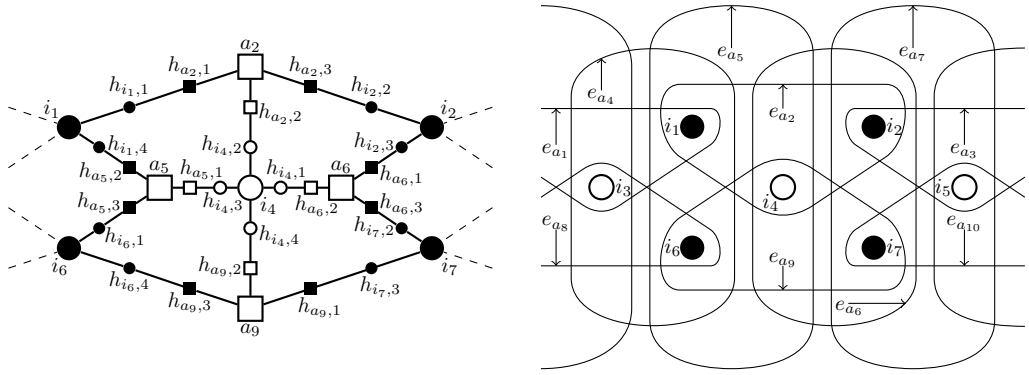
In particular this implies that $\mathbb{E}[Z] \to \infty$ for $d < d^*$ and $\mathbb{E}[Z] \to 0$ for $d > d^*$ with d^* as defined in (1). With an application of Markov's inequality we see that $\mathbb{P}[Z > 0] \to 0$ for $d > d^*$. The map ϕ_1 is known as annealed free entropy density. While the domain of ϕ_1 is trivial in this case (and further in any r-in-k occupation problem), it is non-trivial for the vast majority of CSPs, also covering the general occupation problem.

2.3 The Second Moment Method

Let $k \in \mathbb{Z}_{>3}$, $d \in \mathbb{Z}_{>1}$, further let p, q and $\mathcal{W}$ be the notions from Section 1.5, the distributions P, Q be given by the pmfs p, q and let $\phi_2 : \mathcal{W} \to \mathbb{R}$ be given by

$$\phi_2(w) = \frac{d}{k} D_{\mathrm{KL}}(P \parallel P^*) - (d-1) D_{\mathrm{KL}}(Q \parallel Q^*) \text{ for } w \in \mathcal{W}. \tag{4}$$

Conjecture 1.3 can be used to show that ϕ_2 attains its global minimum at zero iff $w = w^*$ and $d < d^*$. The proof for the specific case $k = 4$ will be presented later in this work. This conclusion then allows to derive the following result using Laplace's method for sums.



(a) occupation problem on configurations. **(b)** 4-regular 2-in-3 vertex cover.

Figure 2 The figure on the left shows the solution on a configuration corresponding to the solution in Figure 1. We only denoted a-edges (small boxes, filled if they the a-edge takes the value one) and i-edges (small circles, filled if the i-edge takes the value one) instead of f-edges and v-edges for brevity (e.g. $h_{a_1,1}$ instead of $(a_1, h_{a_1,1})$). The figure on the right illustrates the corresponding 2-in-3 vertex cover (given by the filled circles).

▶ **Lemma 2.2** (Second Moment Method). *Assume that Conjecture 1.3 holds. Then we have*

$$\frac{\mathbb{E}[Z^2]}{\mathbb{E}[Z]^2} \sim \sqrt{\frac{2}{(2\pi)^2 \prod_{i=0}^{2} p_i(w^*)}} \sqrt{\frac{(2\pi)^2}{\det\left(\frac{k}{\sqrt{2d}} H\right)}} = \sqrt{\frac{k-1}{k-d}},$$

for $n \in \mathcal{N}$ tending to infinity and where H denotes the Hessian of ϕ_2 at $w = w^*$.

Using Lemma 2.2 and Chebyshev's inequality we see that $\mathbb{P}[Z = 0] \leq \sqrt{\frac{k-1}{k-d}} - 1$. While this bound suggests a threshold exists, we need to show that the threshold at d^* is *sharp*.

2.4 Small Subgraph Conditioning

We conclude the proof of the theorem (for configurations) by applying the small subgraph conditioning method to establish that the satisfiability threshold d^* is *sharp*.

▶ **Theorem 2.3** (Small Subgraph Conditioning). *Let Z and $X_1, X_2, \ldots$ be non-negative integer-valued random variables. Suppose that $\mathbb{E}[Z] > 0$ and that for each $\ell \in \mathbb{Z}_{>0}$ there are constants $\lambda_\ell \in \mathbb{R}_{>0}$, $\delta_\ell \in \mathbb{R}_{>-1}$ such that*

(a) *for any $\bar{\ell}$ the variables $X_\ell, \ldots, X_{\bar{\ell}}$ are asymptotically independent and Poisson distributed with $\mathbb{E}[X_\ell] \sim \lambda_\ell$,*

(b) *for any sequence $r_1, \ldots, r_{\bar{\ell}}$ of non-negative integers,*

$$\frac{\mathbb{E}\left[Z \prod_{\ell=1}^{\bar{\ell}} (X_\ell)_{r_\ell}\right]}{\mathbb{E}[Z]} \sim \prod_{\ell=1}^{\bar{\ell}} \mu_\ell^{r_\ell},\ \mu_\ell = \lambda_\ell(1+\delta_\ell),$$

(c) *we explain the variance, i.e.*

$$\frac{\mathbb{E}[Z^2]}{\mathbb{E}[Z]^2} \sim \exp\left(\sum_{\ell=1}^{\infty} \lambda_\ell \delta_\ell^2\right),\ \left|\sum_{\ell=1}^{\infty} \lambda_\ell \delta_\ell^2\right| < \infty.$$

Then we have $\lim_{n\to\infty} \mathbb{P}[Z > 0] = 1$.

The discussion of the factorial moments in Theorem 2.3 (b) is performed in detail, which requires additional concepts and complex combinatorial arguments. To facilitate the presentation we also give a self-contained proof of the following well-known theorem on the expected number of small cycles (the variables X_ℓ in Theorem 2.3), which can then be extended to a proof of Theorem 2.3 (b). In order to understand what a cycle in a configuration is, we notice that we can represent a configuration g by an equivalent graph with (disjoint) vertex sets given by the variables $V = [n]$, constraints (factors) $F = [m]$, v-edges $H_1 = [n] \times [d]$ and f-edges $H_2 = [m] \times [k]$, where each variable $i \in [n]$ connects to all its v-edges $(i, h_1) \in H_1$, each constraint $a \in [m]$ to all its f-edges $(a, h_2) \in H_2$ and a v-edge (i, h_1) connects to an f-edge (a, h_2) if $g(i, h_1) = (a, h_2)$. Since we are mostly interested in the factor graph associated with a configuration we divide lengths of paths by three, e.g. a cycle of length four in a configuration is actually a cycle of length twelve in its equivalent graph representation. Figures 1a and 2a show an example of a factor graph and the corresponding configuration in its graph representation.

▶ **Theorem 2.4** (Number of Small Cycles). *For $\ell \in \mathbb{Z}_{>0}$ let X_ℓ be the number of 2ℓ-cycles in G, further*

$$\lambda_\ell = \frac{[(k-1)(d-1)]^\ell}{2\ell},$$

and $Z_\ell \sim \mathrm{Po}(\lambda_\ell)$ be independent Poisson distributed random variables. Then the random variables X_ℓ converge in distribution to Z_ℓ for $n \to \infty$, jointly for all $\ell \in \mathbb{Z}_{>0}$.

Using Theorem 2.4 we determine μ_ℓ, δ_ℓ for $\ell \in \mathbb{Z}_{>0}$ and use these results to establish the remaining parts of Theorem 2.3.

▶ **Lemma 2.5.** *The constants μ_ℓ and δ_ℓ for $\ell \in \mathbb{Z}_{>0}$ in Theorem 2.3 are given by*

$$\delta_\ell = \left(-\frac{1}{k-1}\right)^\ell.$$

2.5 Translation of the Results

We first translate the results for configurations to factor graphs using Theorem 2.4, i.e. the contiguity of the factor graph model with respect to the configuration model. For completeness we then also provide self-contained proofs to establish the application to hypergraphs with labeled and unlabeled hyperedges (where the constraints may be attached to either the vertices or to the hyperedges). This establishes our claims in Sections 1.2 and 1.3 except for the verification of Conjecture 1.3 for $k = 4$.

2.6 Contraction Coefficient for $k = 4$

Finally, we prove Conjecture 1.3 for $k = 4$, i.e. we derive Theorem 1.1 from Theorem 1.2. Using a slightly different parametrization and simplifying the KL divergence in the nominator yields

$$\begin{aligned}
d_*(4) &= \sup_{w \in \mathcal{W} \setminus \{w^*\}} R(w),\ R(w) = \frac{D_2(w_1)}{D_1(w)},\\
D_1(w) &= (w_1 - w_2)\ln(6(w_1 - w_2)) + 2w_2\ln(3w_2) + (1 - w_1 - w_2)\ln(6(1 - w_1 - w_2)),\\
D_2(w_1) &= w_1\ln(2w_1) + (1 - w_1)\ln(2(1 - w_1)),\\
\mathcal{W} &= \{w \in [0,1]^2 : w_2 \le w_1,\ w_2 \le 1 - w_1\}.
\end{aligned}$$

We focus on suitable lower bounds for D_1, therefore we minimize D_1 with respect to w_2, yielding

$$D_{\min}(w_1) = w_1 \ln(6(w_1 - w_2)) + (1 - w_1) \ln(6(1 - w_1 - w_2)),$$
$$w_2 = w_2(w_1) = \frac{1}{3}\left(2 - \sqrt{12\left(w_1 - \frac{1}{2}\right)^2 + 1}\right),\ w_1 \in [0, 1].$$

Since R is symmetric to $w_1 = \frac{1}{2}$, it is sufficient to show that $R \leq d_*$ for $w_1 \leq \frac{1}{2}$. On this interval we lower bound $D_{\min}$ using the functions

$$D_-(w_1) = 2w_1 \ln\left(\frac{12}{5}w_1\right) + (1 - 2w_1)\ln(6(1 - 2w_1)),\ w_1 \in [0, \bar{w}_1],\ \text{and}$$
$$D_+(w_1) = 6\left(\frac{1}{2} - w_1\right)^2,\ w_1 \in [\bar{w}_1, 0.5],$$

where $\bar{w}_1 \approx 0.10831$ is an intersection point of D_- and D_+ that we determined numerically. Finally, we use monotonicity arguments for the corresponding upper bounds of R to derive $R \leq d^*$.

Abstract

Given two (di)graphs G, H and a cost function $c : V(G) \times V(H) \to \mathbb{Q}_{\geq 0} \cup \{+\infty\}$, in the minimum cost homomorphism problem, MinHOM(H), we are interested in finding a homomorphism $f : V(G) \to V(H)$ (a.k.a H-coloring) that minimizes $\sum_{v \in V(G)} c(v, f(v))$. The complexity of *exact minimization* of this problem is well understood [35], and the class of digraphs H, for which the MinHOM(H) is polynomial time solvable is a small subset of all digraphs.

In this paper, we consider the approximation of MinHOM within a constant factor. In terms of digraphs, MinHOM(H) is not approximable if H contains a *digraph asteroidal triple (DAT)*. We take a major step toward a dichotomy classification of approximable cases. We give a dichotomy classification for approximating the MinHOM(H) when H is a graph (i.e. symmetric digraph). For digraphs, we provide constant factor approximation algorithms for two important classes of digraphs, namely bi-arc digraphs (digraphs with a *conservative semi-lattice polymorphism* or *min-ordering*), and k-arc digraphs (digraphs with an *extended min-ordering*). Specifically, we show that:

- **Dichotomy for Graphs:** MinHOM(H) has a $2|V(H)|$-approximation algorithm if graph H admits a *conservative majority polymorphims* (i.e. H is a *bi-arc graph*), otherwise, it is inapproximable;
- MinHOM(H) has a $|V(H)|^2$-approximation algorithm if H is a bi-arc digraph;
- MinHOM(H) has a $|V(H)|^2$-approximation algorithm if H is a k-arc digraph.

In conclusion, we show the importance of these results and provide insights for achieving a dichotomy classification of approximable cases. Our constant factors depend on the size of H. However, the implementation of our algorithms provides a much better approximation ratio. It leaves open to investigate a classification of digraphs H, where MinHOM(H) admits a constant factor approximation algorithm that is independent of $|V(H)|$.

1 Introduction

For a digraph D, let $V(D)$ denote the vertex set of D, and let $A(D)$ denote the arcs of D. We denote the number of vertices of D by $|D|$. Instead of $(u,v) \in A(D)$, we use the shorthand $uv \in A(D)$ or simply $uv \in D$. A graph G is a symmetric digraph, that is, $xy \in A(G)$ if and only if (iff) $yx \in A(G)$. An edge is just a symmetric arc.

A *homomorphism* of a digraph D to a digraph H (a.k.a H-COLORING) is a mapping $f : V(D) \to V(H)$ such that for each arc xy of D, $f(x)f(y)$ is an arc of H. We say mapping f does not satisfy arc xy, if $f(x)f(y)$ is not an arc of H. The homomorphism problem for a fixed target digraph H, HOM(H), takes a digraph D as input and asks whether there is a homomorphism from D to H. Therefore, by fixing the digraph H we obtain a class of problems, one problem for each digraph D. For example, HOM(H), when H is an edge, is exactly the problem of determining whether the input graph G is bipartite (i.e., the 2-COLORING problem). Similarly, if $V(H) = \{u,v,x\}, A(H) = \{uv, vu, vx, xv, ux, xu\}$, then HOM($H$) is exactly the classical 3-COLORING problem. More generally, if H is a clique on k vertices, then HOM(H) is the k-COLORING problem. The H-COLORING problem can be considered within a more general framework, the constraint satisfaction problem (CSP). In the CSP associated with a finite relational structure $\mathbb{H}$, CSP($\mathbb{H}$), the question is whether there exists a homomorphism of a given finite relational structure to $\mathbb{H}$. Thus, the H-COLORING problem is a particular case of the CSP in which the involved relational structures are digraphs. A celebrated result due to Hell and Nesetril [31], states that, for graph H, HOM(H) is in P if H is bipartite or contains a looped vertex, and that it is NP-complete for all other graphs H. See [9] for an algebraic proof of the same result, and [12, 55] for a dichotomy for CSP($\mathbb{H}$).

There are several natural optimization versions of the HOM(H) problem. One is to find a mapping $f : V(D) \to V(H)$ that maximizes (minimizes) number of satisfied (unsatisfied) arcs in D. This problem is known under the name of MAX 2-CSP (MIN 2-CSP). For example, the most basic BOOLEAN MAX 2-CSP problem is MAX CUT where the target graph H is an edge. This line of research has received a lot of attention in the literature and there are very strong results concerning various aspects of approximability MAX 2-CSP and MIN 2-CSP [2, 22, 28, 41, 45]. See [47] for a recent survey on this and approximation of MAX k-CSP and MIN k-CSP. We consider another natural optimization version of the HOM(H) problem, i.e., we are not only interested in the existence of a homomorphism, but want to find the "best homomorphism". The *minimum cost homomorphism problem* to H, denoted by MinHOM(H), for a given input digraph D, and a cost function $c(x,i), x \in V(D), i \in V(H)$, seeks a homomorphism f of D to H that minimizes the total cost $\sum_{x \in V(D)} c(x, f(x))$. The cost function c can take non-negative rational values and positive infinity, that is $c : V(D) \times V(H) \to \mathbb{Q}_{\geq 0} \cup \{+\infty\}$. The MinHOM was introduced in [25], where it was motivated by a real-world problem in defence logistics. The MinHOM problem offers a natural and practical way to model and generalizes many optimization problems.

▶ **Example 1** ((WEIGHTED) MINIMUM VERTEX COVER)**.** This problem can be seen as MinHOM(H) where $V(H) = \{0,1\}, E(H) = \{11, 01\}$ and $c(u,0) = 0$, $c(u,1) > 0$ for every $u \in V(G)$. Note that G and H are graphs.

▶ **Example 2** (LIST HOMOMORPHISM (LHOM))**.** LHOM(H), seeks, for a given input digraph D and lists $L(x) \subseteq V(H), x \in V(D)$, a homomorphism f from D to H such that $f(x) \in L(x)$ for all $x \in V(D)$. This is equivalent to MinHOM(H) with $c(u,i) = 0$ if $i \in L(u)$, otherwise $c(u,i) = +\infty$. This problem is also known as LIST H-COLORING and its complexity is fully understood due to series of results [5, 8, 10, 11, 18, 33].

The MinHOM problem generalizes many other problems such as (Weighted) Min Ones [1, 15, 40], Min Sol [39, 53], a large class of bounded integer linear programs, retraction problems [19], Minimum Sum Coloring [4, 21, 44], and various optimum cost chromatic partition problems [27, 37, 38, 43].

A special case of MinHOM problem is where the cost function c is choosen from a fixed set Δ. This problem is denoted by MinHOM(H, Δ) [14, 53, 54]. The Valued Constrained Satisfaction Problems (VCSPs) is a generalization of this special case of the MinHOM problem. An instance of the VCSP is given by a collection of variables that must be assigned labels from a given domain with the goal to minimize the objective function that is given by the sum of cost functions, each depending on some subset of the variables [13]. Interestingly, a recent work by Cohen *et al.* [14] proved that VCSPs over a fixed valued constraint language are polynomial-time equivalent to MinHOM(H, Δ) over a fixed digraph and a proper choice of Δ.

Exact Minimization. The complexity of *exact minimization* of MinHOM(H) was studied in a series of papers, and complete complexity classifications were given in [23] for undirected graphs, in [35] for digraphs, and in [51] for more general structures. Certain minimum cost homomorphism problems have polynomial time algorithms [23, 24, 25, 35], but most are NP-hard. We remark that, the complexity of *exact minimization* of VCSPs is well understood [42, 52].

Approximation. For a minimization problem, an *α-approximation* algorithm is a (randomized) polynomial-time algorithm that finds an approximate solution of cost at most α times the minimum cost. A constant ratio approximation algorithm is an α-approximation algorithm for some constant α. We say a problem is not approximable if there is no polynomial time approximation algorithm with a multiplicative guarantee unless P = NP. The approximability of MinHOM is fairly understood when we restrict the cost function to a fixed set Δ, and further, we restrict it to take only finite values (not ∞). This setting is a special case of finite VCSPs, and there are strong approximation results on finite VCSPs. For finite VCSPs, Raghavendra [50] showed how to use the basic SDP relaxation to obtain a constant approximation. Moreover, he proved that the approximation ratio cannot be improved under Unique Game Conjecture (UGC). This constant is not explicit, but there is an algorithm that can compute it with any given accuracy in doubly exponential time. In another line of research, the power of so-called *basic linear program (BLP)* concerning constant factor approximation of finite VCSPs has been recently studied in [16, 17]. However, the approximability of VCSPs for constraint languages that are not finite-valued remains poorly understood, and [30, 39] are the only results on approximation of VCSP for languages that have cost functions that can take infinite values.

Hell *et al.,* [30] proved a dichotomy for approximating MinHOM(H) when H is a bipartite graph by transforming the MinHOM(H) to a linear program, and rounding the fractional values to get a homomorphism to H.

▶ **Theorem 3** (Dichotomy for bipartite graphs [30]). *For a fixed bipartite graph H, MinHOM(H) admits a constant factor approximation algorithm if H admits a* min-ordering *(complement of H is a* circular arc *graph), otherwise MinHOM(H) is not approximable unless $P = NP$.*

Beyond this, there is no result concerning the approximation of MinHOM(H). We go beyond bipartite case and present a constant factor approximation algorithm for *bi-arc* graphs (graphs with a *conservative majority* polymorphism). Designing an approximation

algorithm for MinHOM(H) when H is a digraph is much more complex than when H is a graph. We improve state-of-the-art by providing constant factor approximation algorithms for MinHOM(H) where H belongs to these two important cases of digraphs, namely *bi-arc* digraphs (digraphs with a *conservative semi-lattice* polymorphism a.k.a min-ordering), and *k-arc* digraphs (digraphs with a k-min-ordering). To do so, we introduce new LPs that reflect the structural properties of the target (di)graph H as well as new methods to round the fractional solutions and obtain homomorphisms to H. We will show our randomized rounding procedure can be de-randomized, and hence, we get a deterministic polynomial algorithm. Furthermore, we argue that our techniques can be used towards finding a dichotomy for the approximation of MinHOM(H).

1.1 Our Contributions

Most of the minimum cost homomorphism problems are NP-hard, therefore we investigate the approximation of MinHoM(H).

Approximating Minimum Cost Homomorphism to Digraph H.
Input: A digraph D and a vertex-mapping costs $c(x,u), x \in V(D), u \in V(H)$,
Output: A homomorphism f of D to H with the total cost of $\sum_{x \in V(D)} c(x, f(x)) \leq \alpha \cdot OPT$, where α is a constant.

Here, OPT denotes the cost of a minimum cost homomorphism of D to H. Moreover, we assume size of H is constant. Recall that we approximate the cost over real homomorphisms, rather than approximating the maximum weight of satisfied constraints, as in, say, Max Csp. One can show that if LHOM(H) is not polynomial time solvable then there is no approximation algorithm for MinHOM(H) [30, 48].

▶ **Observation 4.** *If LHOM(H) is not polynomial time solvable, then there is no approximation algorithm for MinHOM(H).*

The complexity of the LHOM problems for graphs, digraphs, and relational structures (with arity two and higher) have been classified in [18, 33, 10] respectively. LHOM(H) is polynomial time solvable if the digraph H does not contain a *digraph asteroidal triple (DAT)*[1] as an induced sub-digraph, and NP-complete when H contains a DAT [33].

MinHOM(H) is polynomial time solvable when digraph H admits a k-min-max-ordering, a subclass of DAT-free digraphs, and otherwise, NP-complete [35, 34]. Here, in this paper, we take an important step towards closing the gap between DAT-free digraphs and the one that admit a k-min-max-ordering. First, we consider digraphs that admit a min-ordering. Digraphs that admit a min-ordering have been studied under the name of *bi-arc* digraphs [36] and *signed interval* digraphs [29]. Deciding if digraph H has a min-ordering and finding a min-ordering of H is in P [36]. We provide a constant factor approximation algorithm for MinHOM(H) where H admits a min-ordering.

▶ **Theorem 5** (Digraphs with a min-ordering)**.** *If digraph H admits a min-ordering, then MinHOM(H) has a constant factor approximation algorithm.*

Sections 4,5 are dedicated to the proof of Theorem 5. In section 6, we turn our attention to digraphs with k-min-orderings, for integer $k > 1$. They are also called digraphs with *extended X-underbar* [3, 26, 46]. It was shown in [26] that if H has the X-underbar property,

[1] The definition of DAT is rather technical and it is not necessary to fully understand it in this paper.

then the HOM(H) problem is polynomial time solvable. In Lemma 21, we show that if H admits a k-min-ordering, then H is a DAT-free digraph, and provide a simple proof that LHOM(H) is polynomial time solvable. Finally, we have the following theorem.

▶ **Theorem 6** (Digraphs with a k-min-ordering)**.** *If digraph H admits a k-min-ordering for some integer $k > 1$, then MinHOM(H) has a constant factor approximation algorithm.*

Considering graphs, Feder *et al.,* [18] proved that LHOM(H) is polynomial time solvable if H is a *bi-arc* graph, and is NP-complete otherwise. In the same paper, they showed graph H is a bi-arc graph iff it admits a conservative majority polymorphism. In Section 7, we show that the same dichotomy classification holds in terms of approximation.

▶ **Theorem 7** (Dichotomy for graphs)**.** *There exists a constant factor approximation algorithm for MinHOM(H) if H is a bi-arc graph, otherwise MinHOM(H) is inapproximable.*

In section 8, we give a concrete plan of how to solve the general case. By combining the approach for obtaining the dichotomy in the graph case, together with the idea of getting an approximation algorithm for digraphs admitting a min-ordering, we might be able to achieve a constant factor approximation algorithm for MinHOM(H) when H is DAT-free.

Our constant factors depend on the size of H. However, the implementation of the LP and the ILP would yield a small integrality gap (details in the full version [49]). This indicates perhaps a better analysis of the performance of our algorithm is possible.

▶ **Open Problem 8.** *For which digraphs MinHOM(H) is approximable within a constant factor independent of size of H?*

2 Preliminaries and Definitions

Complexity and approximation of the minimum cost homomorphism problems, and in general the constraint satisfaction problems, are often studied under the existence of *polymorphisms* [6]. A polymorphism of H of arity k is a mapping f from the set of k-tuples over $V(H)$ to $V(H)$ such that if $x_iy_i \in A(H)$ for $i = 1, 2, \ldots, k$, then $f(x_1, x_2, \ldots, x_k)f(y_1, y_2, \ldots, y_k) \in A(H)$. If f is a polymorphism of H we also say that H admits f. A polymorphism f is *idempotent* if it satisfies $f(x, x, \ldots, x) = x$ for all $x \in V(H)$, and is *conservative* if $f(x_1, x_2, \ldots, x_k) \in \{x_1, x_2, \ldots, x_k\}$. A conservative *semi-lattice* polymorphism is a conservative binary polymorphism that is associative, idempotent, commutative. A conservative *majority* polymorphism μ of H is a conservative ternary polymorphism such that $\mu(x, x, y) = \mu(x, y, x) = \mu(y, x, x) = x$ for all $x, y \in V(H)$.

A conservative semi-lattice polymorphism of H naturally defines a binary relation $x \leq y$ on the vertices of H by $x \leq y$ iff $f(x, y) = x$; by associative, the relation $\leq$ is a linear order on $V(H)$, which we call a *min-ordering* of H.

▶ **Definition 9.** *The ordering $v_1 < v_2 < \cdots < v_n$ of $V(H)$ is a*

- min-ordering *iff $uv \in A(H), u'v' \in A(H)$ and $u < u', v' < v$ implies that $uv' \in A(H)$;*
- max-ordering *iff $uv \in A(H), u'v' \in A(H)$ and $u < u', v' < v$ implies that $u'v \in A(H)$;*
- min-max-ordering *iff $uv \in A(H), u'v' \in A(H)$ and $u < u', v' < v$ implies that $uv', u'v \in A(H)$.*

For bipartite graph $H = (B, W)$ let $\overrightarrow{H}$ be the digraph obtained by orienting all the edges of H from B to W. If $\overrightarrow{H}$ admits a min-ordering then we say H admits a min-ordering. It is worth mentioning that, a bipartite graph H admits a conservative majority, iff it admits a min-ordering [30]. Moreover, the complement of H is a circular arc graphs with clique cover two [18].

▶ **Definition 10.** *Let $H = (V, E)$ be a digraph that admits a homomorphism $f : V(H) \to \overrightarrow{C_k}$ (here $\overrightarrow{C_k}$ is the induced directed cycle on $\{0, 1, 2, \ldots, k-1\}$(i.e., arc set $\{(01, 12, 23, ..., (k-2)(k-1), (k-1)0\}$). Let $V_i = f^{-1}(i)$, $0 \leq i \leq k-1$.*

- *A* k-min-ordering *of H is a linear ordering $<$ of the vertices of H, so that $<$ is a min-ordering on the subgraph induced by any two circularly consecutive V_i, V_{i+1} (subscript addition modulo k).*
- *A* k-min-max-ordering *of H is a linear ordering $<$ of the vertices of H, so that $<$ is a min-max-ordering on the subgraph induced by any two circularly consecutive V_i, V_{i+1} (subscript addition modulo k).*

3 LP for Digraphs with a min-max-ordering

Before presenting the LP, we give a procedure to modify lists associated to the vertices of D. To each vertex $x \in D$, associate a list $L(x)$ that initially contains $V(H)$. Think of $L(x)$ as the set of possible images for x in a homomorphism from D to H. Apply the *arc consistency* procedure as follows. Take an arbitrary arc $xy \in A(D)$ ($yx \in A(D)$) and let $a \in L(x)$. If there is no out-neighbor (in-neighbor) of a in $L(y)$ then remove a from $L(x)$. Repeat this until a list becomes empty or no more changes can be made. Note that if we end up with an empty list after arc consistency then there is no homomorphism of D to H.

Let $a_1, a_2, a_3, \ldots, a_p$ be a min-max-ordering $<$ of the target digraph H. Define $\ell^+(i)$ to be the smallest subscript j such that a_j is an out-neighbor of a_i (and $\ell^-(i)$ to be the smallest subscript j such that a_j is an in-neighbor of a_i).

Consider the following linear program. For every vertex v of D and every vertex a_i of H define variable v_i. Moreover, define variable v_{p+1} for every $v \in D$ whose value is set to zero.

$$\begin{array}{rll}
\min & \sum_{v,i} c(v, a_i)(v_i - v_{i+1}) & \\
\text{subject to:} & v_i \geq 0 & \text{(C1)} \\
& v_1 = 1 & \text{(C2)} \\
& v_{p+1} = 0 & \text{(C3)} \\
& v_{i+1} \leq v_i & \text{(C4)} \\
& v_{i+1} = v_i \quad \text{if } a_i \notin L(v) & \text{(C5)} \\
& u_i \leq v_{l^+(i)} \quad \forall uv \in A(D) & \text{(C6)} \\
& v_i \leq u_{l^-(i)} \quad \forall uv \in A(D) & \text{(C7)}
\end{array}$$

Let $\mathcal{S}$ denote the set of constraints of the above LP, then:

▶ **Theorem 11.** *If digraph H admits a min-max-ordering, then there is a one-to-one correspondence between homomorphisms of D to H and integer solutions of $\mathcal{S}$.*

Proof. For homomorphism $f : D \to H$, if $f(v) = a_t$ we set $v_i = 1$ for all $i \leq t$, otherwise we set $v_i = 0$. We set $v_1 = 1$ and $v_{p+1} = 0$ for all $v \in V(D)$. Now all the variables are nonnegative and we have $v_{i+1} \leq v_i$. Note that if $a_i \notin L(v)$ then $f(v) \neq a_i$ and we have $v_i - v_{i+1} = 0$. It remains to show that $u_i \leq v_{l^+(i)}$ for every uv arc in D. Suppose for contradiction that $u_i = 1$ and $v_{l^+(i)} = 0$ and let $f(u) = a_r$ and $f(v) = a_s$. This implies that $u_r = 1$, whence $i \leq r$; and $v_s = 1$, whence $s < l^+(i)$. Since $a_i a_{l^+(i)}$ and $a_r a_s$ both are arcs of H with $i \leq r$ and $s < l^+(i)$, the fact that H has a min-ordering implies that $a_i a_s$ must also be an arc of H, contradicting the definition of $l^+(i)$. The proof for $v_i \leq u_{l^-(i)}$ is analogous.

Conversely, if there is an integer solution for $\mathcal{S}$, we define a homomorphism f as follows: we let $f(v) = a_i$ when i is the largest subscript with $v_i = 1$. We prove that this is indeed a homomorphism by showing that every arc of D is mapped to an arc of H. Let uv be an arc

of D and assume $f(u) = a_r$, $f(v) = a_s$. We show that $a_r a_s$ is an arc in H. Observe that $1 = u_r \leq v_{l^+(r)} \leq 1$ and $1 = v_s \leq u_{l^-(s)} \leq 1$, therefore we must have $v_{l^+(r)} = u_{l^-(s)} = 1$. Since r and s are the largest subscripts such that $u_r = v_s = 1$ then $l^+(r) \leq s$ and $l^-(s) \leq r$. Since $a_r a_{l^+(r)}$ and $a_{l^-(s)} a_s$ are arcs of H, we must have the arc $a_r a_s$, as H admits a max-ordering. Furthermore, $f(v) = a_i$ iff $v_i = 1$ and $v_{i+1} = 0$, so, $c(v, a_i)$ contributes to the sum iff $f(v) = a_i$. ◀

We have translated the minimum cost homomorphism problem to a linear program. In fact, this linear program corresponds to a minimum cut problem in an auxiliary network, and can be solved by network flow algorithms [23, 48]. In [30], a similar result to Theorem 11 was proved for the MinHOM(H) problem on undirected graphs when target graph H is bipartite and admits a min-max-ordering. We shall enhance the above system $\mathcal{S}$ to obtain an approximation algorithm for the case where H is only assumed to admit a min-ordering.

4 LP for Digraphs with a min-ordering

In the rest of the paper assume lists are not empty. Moreover, non-empty lists guarantee a homomorphism when H admits a min-ordering.

▶ **Lemma 12.** *[32] Let H be a digraph that admits a min-ordering. If all the lists are non-empty after arc consistency, then there exists a homomorphism from D to H.*

Suppose $a_1, a_2, \ldots, a_p$ is a min-ordering of H. Let E' denote the set of all the pairs (a_i, a_j) such that $a_i a_j$ is not an arc of H, but there is an arc $a_i a_{j'}$ of H with $j' < j$ and an arc $a_{i'} a_j$ of H with $i' < i$. Let $E = A(H)$ and define H' to be the digraph with vertex set $V(H)$ and arc set $E \cup E'$. Note that E and E' are disjoint sets.

▶ **Observation 13.** *The ordering $a_1, a_2, \cdots, a_p$ is a min-max-ordering of H'.*

▶ **Observation 14.** *Let $e = a_i a_j \in E'$. Then a_i does not have any out-neighbor in H after a_j, or a_j does not have any in-neighbor in H after a_i.*

Observation 14 easily follows from the fact that H has a min-ordering. Since H' has a min-max-ordering, we can form system of linear inequalities $\mathcal{S}$, for H' as described in Section 3. Homomorphisms of D to H' are in a one-to-one correspondence with integer solutions of $\mathcal{S}$, by Theorem 11. However, we are interested in homomorphisms of D to H, not H'. Therefore, we shall add further inequalities to $\mathcal{S}$ to ensure that we only admit homomorphisms from D to H, i.e., avoid mapping arcs of D to the arcs in E'.

For every arc $e = a_i a_j \in E'$ and every arc $uv \in A(D)$, by Observation 14, two of the following set of inequalities will be added to $\mathcal{S}$ (i.e. either (C8), (C11) or (C9), (C10) or (C9), (C11)).

$$v_j \leq u_s + \sum_{t<i, a_t a_j \in E, a_t \in L(u)} (u_t - u_{t+1}) \quad \text{if } a_s \in L(u) \text{ is the first in-neighbour of } a_j \text{ after } a_i \qquad \text{(C8)}$$

$$v_j \leq v_{j+1} + \sum_{t<i, a_t a_j \in E, a_t \in L(u)} (u_t - u_{t+1}) \quad \text{if } a_j \text{ has no in-neighbour after } a_i \qquad \text{(C9)}$$

$$u_i \leq v_s + \sum_{t<j, a_i a_t \in E, a_t \in L(v)} (v_t - v_{t+1}) \quad \text{if } a_s \in L(v) \text{ is the first out-neighbour of } a_i \text{ after } a_j \qquad \text{(C10)}$$

$$u_i \leq u_{i+1} + \sum_{t<j, a_i a_t \in E, a_t \in L(v)} (v_t - v_{t+1}) \quad \text{if } a_i \text{ has no out-neighbour after } a_j \qquad \text{(C11)}$$

Additionally, for every pair $(x, y) \in V(D) \times V(D)$ consider a list $L(x, y)$ of possible pairs (a, b), $a \in L(x)$ and $b \in L(y)$. Perform *pair consistency* procedure as follows. Consider three vertices $x, y, z \in V(D)$. For $(a, b) \in L(x, y)$ if there is no $c \in L(z)$ such that $(a, c) \in L(x, z)$

and $(c, b) \in L(z, y)$ then remove (a, b) from $L(x, y)$. Repeat this until a pair list becomes empty or no more changes can be made. Here, we assume that after pair consistency procedure no pair list is empty, as otherwise there is no homomorphism of D to H. Therefore, by pair consistency, add the following constraints for every u, v in $V(D)$ and $a_i \in L(u)$:

$$u_i - u_{i+1} \quad \leq \quad \sum_{\substack{j: \\ (a_i, a_j) \in L(u,v)}} (v_j - v_{j+1}) \qquad \text{(C12)}$$

▶ **Lemma 15.** *If H admits a min-ordering, then there is a one-to-one correspondence between homomorphisms of D to H and integer solutions of the extended system $\mathcal{S}$.*

5 Approximation for Digraphs with a min-ordering

In what follows, we describe an overview of our approximation algorithm for MinHOM(H) where the fixed digraph H has a min-ordering. We encourage the reader to see Algorithm 1 while reading this section. An overview of the proofs of the correctness and approximation bound are postponed for the later subsections (further details in the full version [49]).

Let D be the input digraph together with a cost function c. Let $a_1, \ldots, a_p$ be a min ordering of the vertices of H. The algorithm, first constructs digraph H' from H as in Section 4. By Observation 13, $a_1, \ldots, a_p$ is a min-max-ordering for H'. By Lemma 15, the integral solutions of the extended LP are in one-to-one correspondence to homomorphisms from D to H. At this point, our algorithm will minimize the cost function over extended $\mathcal{S}$ in polynomial time using a linear programming algorithm. This will generally result in a fractional solution (Even though the original system $\mathcal{S}$ is known to be totally unimodular [23, 48] and hence have integral optima, we have added inequalities, and hence lost this advantage). We will obtain an integer solution by a randomized procedure called *rounding*. Choose, uniformly at random, a random variable $X \in [0, 1]$, and define the rounded values $u'_i = 1$ when $u_i \geq X$ (u_i is the returned value by the LP), and $u'_i = 0$ otherwise. It is easy to check that the rounded values satisfy the original inequalities, i.e., correspond to a homomorphism f of D to H'.

Now the algorithm will once more modify the solution f to become a homomorphism from D to H, i.e., to avoid mapping the arcs of D to the arcs in E'. This will be accomplished by another randomized procedure, which we call Shift. We choose, uniformly at random, another random variable $Y \in [0, 1]$, which will guide the shifting. Let F denote the set of all arcs in E' to which some arcs of D are mapped by f. If F is empty, we need no shifting. Otherwise, let $a_i a_j$ be an arc of F. Since $F \subseteq E'$, Observation 14 implies that either a_j has no in-neighbor after a_i or a_i has no out-neighbor after a_j. Suppose the first case happens (the shifting process is similar in the other case).

Consider a vertex v in D such that $f(v) = a_j$ (i.e. $v'_j = 1$ and $v'_{j+1} = 0$) and v has an in-neighbor u in D with $f(u) = a_i$ (i.e. $u'_i = 1$ and $u'_{i+1} = 0$). For such a vertex v, let $S_v = \{a_{t_1}, a_{t_2}, \ldots, a_{t_k}\}$ be the set of all vertices a_t with $t < j$ such that $a_i a_t \in E$ and $a_t \in L(v)$. Suppose S_v consists of a_t with subscripts t ordered as $t_1 < t_2 < \cdots < t_k$.

▶ **Lemma 16.** *During procedure Shift, the set of indices $t_1 < \cdots < t_k$ considered in Line 6 of the Algorithm 1 is non-empty.*

By Lemma 16, S_v is not empty. The algorithm now selects one vertex from this set as follows. Let $P_{v,t} = \frac{v_t - v_{t+1}}{P_v}$, where $P_v = \sum_{\substack{t<j \\ a_i a_t \in E, a_t \in L(v)}} (v_t - v_{t+1})$.

Note that $P_v > 0$ because of constraints (C9) and (C10). Then a_{t_q} is selected if $\sum_{p=1}^{q} P_{v,t_p} < Y \leq \sum_{p=1}^{q+1} P_{v,t_p}$. Thus a concrete a_t is selected with probability $P_{v,t}$, which is

proportional to the difference of the fractional values $v_t - v_{t+1}$. When the selected vertex is a_t, we shift the image of the vertex v from a_j to a_t, and set $v'_r = 1$ if $r \leq t$, else set $v'_r = 0$. Note that a_t is before a_j in the min-ordering. Now we might need to shift images of the neighbors of v. In this case, repeat the shifting procedure for neighbors of v. This processes continues in a Breadth-first search (BFS) like manner, until no more shift is required (Figure 1 gives an illustration). Note that a vertex might be visited multiple times in procedure shift while a pair $(v, a_i) \in V(D) \times V(H)$ is considered at most one time.

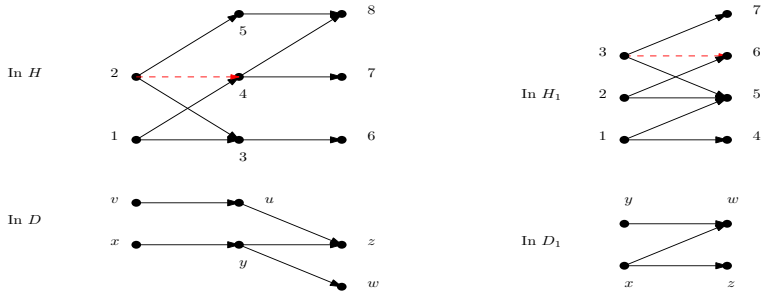

Figure 1 Two examples. In the right example, the target digraph is H_1 and input is D_1. Digraphs D_1 and H_1 both can be view as bipartite graphs and $1, 2, 3, 4, 5, 6, 7$ is a min-ordering of H. When x, y are mapped to 3 and w is mapped to 6 then the algorithm should shift the image of w from 6 to 5 and since 35 is an arc there is no need to shift the image of y. In the left example, the target digraph is H and the input is D. $1, 2, 3, 4, 5, 6, 7, 8$ is a min-ordering of H and 24 is a missing arc. Suppose x is mapped to 2, y to 4, w to 7, z to 8, u to 5 and v to 2. Then we should shift the image of y to 3 and then w to 6 and z to 6 and then u to 3 and v to one of the $1, 2$.

We remark that the images of vertices in D are always shifted towards smaller elements in their lists. Lemma 17 shows that this shifting modifies the homomorphism f, and hence, the corresponding values of the variables. Namely, $v'_{t+1}, \ldots, v'_j$ are reset to 0, keeping all other values the same. Note that these modified values still satisfy the original set of constraints $\mathcal{S}$, i.e., the modified mapping is still a homomorphism.

▶ **Lemma 17.** *Procedure* SHIFT*, in polynomial time, returns a homomorphism of D to H'.*

We repeat the same process for the next v with these properties, until no edge of D is mapped to an edge in E'. Each iteration involves at most $|V(H)| \cdot |V(D)|$ shifts. After at most $|E'|$ iterations, no edge of D is mapped to an edge in F and we no longer need to shift. Next theorem follows from Lemma 16 and 17.

▶ **Theorem 18.** *Our algorithm, in polynomial time, returns a homomorphism of D to H.*

5.1 Analyzing the Approximation Ratio

We now claim that the cost of this homomorphism is at most $|V(H)|^2$ times the minimum cost of a homomorphism. Let w denote the value of the objective function with the fractional optimum u_i, v_j, and w' denote the value of the objective function with the final values u'_i, v'_j, after the rounding and all the shifting. Also, let w^* be the minimum cost of a homomorphism of D to H. Obviously, $w \leq w^* \leq w'$.

We now show that the expected value of w' is at most a constant times w. Let us focus on the contribution of one summand, say $v'_t - v'_{t+1}$, to the calculation of the cost. In any integer solution, $v'_t - v'_{t+1}$ is either 0 or 1. The probability that $v'_t - v'_{t+1}$ contributes to w' is the probability of the event that $v'_t = 1$ and $v'_{t+1} = 0$. This can happen in the following:

Algorithm 1 Approximation MinHOM(H).

procedure Approx–MinHOM(D, H)
  Construct H' from H (as in Section 3)
  Let u_is be the (fractional) values returned by the extended LP
  Choose a random variable $X \in [0,1]$, and $\forall u_i$s : if $X \leq u_i$ let $u'_i = 1$, else let $u'_i = 0$
  Let $f(u) = a_i$ where i is the largest subscript with $u'_i = 1$ ▷ f is a homomorphism from D to H'
  Choose a random variable $Y \in [0,1]$
  while $\exists uv \in A(D)$ such that $f(u)f(v) \in A(H') \setminus A(H)$ **do**
    if $f(v)$ does not have an in-neighbor after $f(u)$ **then** Shift(f, v)
    else if $f(u)$ does not have an out-neighbor after $f(v)$ **then** Shift(f, u)
  return f ▷ f is a homomorphism from D to H

Algorithm 2 The Shifting Procedure.

procedure Shift(f, x)
  Let Q be a Queue, $Q.enqueue(x)$
  while Q is not empty **do**
    $v \leftarrow Q.dequeue()$
    for $uv \in A(D)$ with $f(u)f(v) \notin A(H)$ **or** $vu \in A(D)$ with $f(v)f(u) \notin A(H)$ **do**
      ▷ Here we assume the first condition holds, the other case is similar
      ▷ Further, we assume $f(v)$ does not have an in-neighbor after $f(u)$
      Let $t_1 < \cdots < t_k$ be indices so that $a_{t_j} < f(v), a_{t_j} \in L(v), f(u)a_{t_j} \in A(H)$
      Let $P_v \leftarrow \sum_{j=1}^{j=k} (v_{t_j} - v_{t_j+1})$ and $P_{v,t} \leftarrow (v_t - v_{t+1}) \,/\, P_v$
      if $\sum_{p=1}^{q} P_{v,t_p} < Y \leq \sum_{p=1}^{q+1} P_{v,t_p}$ **then**
        $f(v) \leftarrow a_{t_q}$, set $v'_i = 1$ for $1 \leq i \leq t_q$, and set $v'_i = 0$ for $t_p < i$
      for $vz \in A(D)$ $(zv \in A(D))$ with $f(v)f(z) \notin A(H)$ $(f(z)f(v) \notin A(H))$ **do**
        $Q.enqueue(z)$
  return f ▷ f is a homomorphism from D to H'

1. v is mapped to a_t by rounding, and is not shifted away. In other words, we have $v'_t = 1$ and $v'_{t+1} = 0$ after rounding, and these values don't change by procedure Shift.
2. v is first mapped to some $a_j, j > t$, by rounding, and then re-mapped to a_t by procedure Shift.

▶ **Lemma 19.** *The expected contribution of one summand, say $v'_t - v'_{t+1}$, to the expected cost of w' is at most $|V(H)|^2 c(v, a_t)(v_t - v_{t+1})$.*

▶ **Theorem 20.** *Algorithm 1 returns a homomorphism with expected cost $|V(H)|^2 \cdot OPT$. The algorithm can be de-randomized to obtain a deterministic $|V(H)|^2$-approximation algorithm.*

6 Approximation for Digraphs with a k-min-ordering

Digraphs admitting k-min-ordering ($k > 1$) do not admit a min-ordering or a conservative majority polymorphism. However, this does not rule out the possibility of a constant factor approximation algorithm. We show that they are in fact DAT-free digraphs, and they admit a nice geometric representation (see the full version [49]).

▶ **Lemma 21.** *Let H be a digraph that admits a k-min-ordering. Then H is DAT-free, and LHOM(H) is polynomial time solvable.*

Let H be a digraph with a k-min-ordering ($k > 1$) and partition $V_0, V_1, \ldots, V_{k-1}$ of its vertices, and let $<$ be a k-min-ordering of $V(H)$. It is easy to argue that the input digraph D must be homomorphic to $\overrightarrow{C_k}$ otherwise there is no homomorphism from D to H. Therefore, we assume (for some $0 \leq \ell \leq k-1$), $L(u) \subseteq V_i$ for every $u \in U_{i+\ell}$, $0 \leq i \leq k-1$. Now the LP is designed according to the lists L. Since $<$ is a min-ordering of $V_i \cup V_{i+1}$, the constraints are very similar to the ones in Section 3. The conclusion of this section is the following:

▶ **Theorem 22.** *There is a (deterministic) $|V(H)|^2$-approximation algorithm for MinHOM(H) when the target digraph H admits a k-min-ordering, $k > 1$.*

7 A Dichotomy for Graphs

Feder and Vardi [20] proved that if a graph H admits a conservative majority polymorphism, then LHOM(H) is polynomial time solvable. Later, Feder *et al.,* [18] showed that LHOM(H) is polynomial time solvable iff H is a *bi-arc* graph. Hence, by Observation 4, the problem is inapproximable beyond bi-arc graphs. A bi-arc graph is represented by a pair of families of arcs on a circle with specific conditions (exact definition is given in the full version [49]). Note that in a bi-arc graph a vertex may have a self-loop.

▶ **Theorem 23** ([7, 18])**.** *A graph admits a conservative majority polymorphism iff it is a bi-arc graph.*

▶ **Definition 24** (G^*)**.** *Let $G = (V, E)$ be a graph. Let G^* be a bipartite graph with partite sets V, V' where V' is a copy of V. Two vertices $u \in V$, and $v' \in V'$ of G^* are adjacent in G^* iff uv is an edge of G.*

A *circular arc* graph is a graph that is the intersection graph of a family of arcs on a circle. A bipartite graph whose complement is a circular arc graph, is called a *co-circular arc* graph. Note that co-circular arc graphs are irreflexive, meaning no vertex has a loop.

▶ **Lemma 25.** *Let H^* be the bipartite graph constructed from a bi-arc graph H. Then H^* is a co-circular arc graph and H^* admits a min-ordering.*

Let H be a bi-arc graph, with vertex set I, and let $H^* = (I, I')$ be the bipartite graph constructed from H. Let $a_1, a_2, \ldots, a_p$ be an ordering of the vertices in I and $b_1, b_2, \ldots, b_p$ be an ordering of the vertices of I'. Note that each a_i has a copy $b_{\pi(i)}$ in $\{b_1, b_2, \ldots, b_n\}$ where π is a permutation on $\{1, 2, 3, \ldots, p\}$. By Lemma 25, let us assume $a_1, a_2, \ldots, a_p, b_1, b_2, \ldots, b_p$ is a min-ordering for H^*.

Let G be the input graph with vertex set V and a cost function c. Construct G^* from G with vertex set $V \cup V'$ as in Definition 24. Now construct an instance of the MinHOM(H^*) for the input graph G^* and set $c(v', b_{\pi(i)}) = c(v, a_i)$ for $v \in V$ and $v' \in V'$. Further, make H^* a digraph by orienting all its edges from I to I', and similarly make G^* a digraph by

orienting all its edges from V to V'. Note that, by construction of H^* and G^*, there exists a homomorphism $f : G \to H$ with cost $\mathfrak{C}$ iff there exists homomorphism $f^* : G^* \to H^*$ with cost $2\mathfrak{C}$ such that, if $f^*(v) = a_i$ then $f^*(v') = b_j$ with $j = \pi(i)$.

We first perform the arc consistency and pair consistency procedures for the vertices in G^*. Note that if $L(u)$ contains element a_i then $L(u')$ contains $b_{\pi(i)}$ and when $L(u')$ contains some b_j then $L(u)$ contains $a_{\pi^{-1}(j)}$. Next, we define the system of linear equations $\widehat{S^*}$ with the same construction as in Sections 3, 4. Further, we add the following constraint to $\widehat{S^*}$. The full set of constraints in $\widehat{S^*}$ is presented in the extended version.

$$u_i - u_{i+1} = u'_{\pi(i)} - u'_{\pi(i)+1} \qquad \forall u, u' \in G^*, \forall a_i, b_{\pi(i)} \in H^*$$

▶ **Lemma 26.** *If H is a bi-arc graph, then there is a one-to-one correspondence between homomorphisms from G to H and integer solutions of $\widehat{S^*}$.*

Once again we round an optimal fractional solution of $\widehat{S^*}$, using random variable $X \in [0, 1]$. Let $\mathcal{F}$ be a mapping form $V(G^*)$ to $V(H^*)$ obtained after rounding using X. We give an algorithm that modifies $\mathcal{F}$ and achieves a homomorphism $f : G \to H$ (i.e. an integral solution that satisfies $\widehat{S^*}$). The algorithm deploys a shifting procedure that first uses a random variable Y to shift the images of some of the vertices of $V(G^*)$ to obtain a homomorphism f from G^* to H^*. Second, it applies a breadth-first search function to make f consistent on V and V'; meaning that $f(u) = a_i$, $u \in V$ iff $f(u') = b_{\pi(i)}$, $u' \in V'$. The proof of the following theorems and de-randomization of the algorithm appear in the full version [49].

▶ **Theorem 27.** *There exists a randomized algorithm that modifies $\mathcal{F}$ and obtain a homomorphism $f : G \to H$. Moreover, the expected cost of the homomorphism returned by this algorithm is at most $2|V(H)| \cdot OPT$.*

▶ **Theorem 28.** *If H admits a conservative majority polymorphism, then MinHOM(H) has a (deterministic) $2|V(H)|$-approximation algorithm, otherwise it is inapproximable.*

8 Beyond majority and min-ordering (DAT-free cases)

This section offers a view of moving forward to get a dichotomy classification for constant approximability of MinHOM(H). We believe the class of DAT-free digraphs is the right boundary between the approximable cases, and the ones that do not admit any approximation.

▶ **Conjecture 29.** *MinHOM(H) admits a constant approximation polynomial time algorithm when H is a DAT-free digraph, otherwise, MinHOM(H) is not approximable.*

For digraph $D = (V, A)$, let D^* be a bipartite digraph with partite sets V, V' where V' is a copy of V. There is an arc in D^* from $u \in V$ to $v' \in V'$ iff uv is an arc of D. In what follows, we give a road map for solving the conjecture. Let us start off by making a connection between homomorphisms from D to a DAT-free target digraph H, and the homomorphisms from D^* to H^*.

▶ **Proposition 30.** *Let D, H be two digraphs and let D, H, L (here L are the lists) be an instance of the LHOM(H). Suppose H is DAT-free. Then H^* admits a min-ordering, and LHOM(H^*) is polynomial time solvable for instance D^*, H^* where $L^*(v') = \{a' | a \in L(v)\}$ and $L^*(v) = L(v)$ for every $v \in V(D)$.*

Similar to Lemmas 15 and 26, we can obtain set of constraints $\widehat{S^*}$ such that there is a one-to-one correspondence between homomorphisms from D to H and integer solutions of $\widehat{S^*}$ (details in the full version [49]). Our primary challenge would be finding a rounding

procedure to obtain a homomorphism from D to H. We believe there is a need to deploy the shift procedure in min-ordering case (Section 3), as well as, the shifting procedure in the majority case (Section 7). This essentially means obtaining a new way of solving a list homomorphism from D to H when H is a DAT-free, using the bi-partition method. The calculation should work out; yielding a constant bound between the fractional value of the LP and the integral value obtained by rounding. Notice that in the majority case the symmetry of the arcs is heavily used in our argument, whereas in the digraph case we no longer have this property in hand.

Abstract

We say a subset $C \subseteq \{1, 2, \ldots, k\}^n$ is a k-hash code (also called k-separated) if for every subset of k codewords from C, there exists a coordinate where all these codewords have distinct values. Understanding the largest possible rate (in bits), defined as $(\log_2 |C|)/n$, of a k-hash code is a classical problem. It arises in two equivalent contexts: (i) the smallest size possible for a perfect hash family that maps a universe of N elements into $\{1, 2, \ldots, k\}$, and (ii) the zero-error capacity for decoding with lists of size less than k for a certain combinatorial channel.

A general upper bound of $k!/k^{k-1}$ on the rate of a k-hash code (in the limit of large n) was obtained by Fredman and Komlós in 1984 for any $k \geq 4$. While better bounds have been obtained for $k = 4$, their original bound has remained the best known for each $k \geq 5$. In this work, we present a method to obtain the first improvement to the Fredman-Komlós bound for every $k \geq 5$, and we apply this method to give explicit numerical bounds for $k = 5, 6$.

1 Introduction

A code of length n over an alphabet of size k is a subset $C \subseteq \{1, 2, \ldots, k\}^n$. We say such a code C is a *k-hash code* (also called k-separated in the literature), if for every subset of k distinct codewords $\{c^{(1)}, c^{(2)}, \ldots, c^{(k)}\}$ from C, there exists a coordinate j such that all these codewords differ in this coordinate, i.e. $\{c_j^{(1)}, c_j^{(2)}, \ldots, c_j^{(k)}\} = \{1, 2, \ldots, k\}$. The rate (in bits) of the code is defined as $R = \frac{\log_2 |C|}{n}$. Then for each fixed integer k, let R_k be the limit superior ($\limsup$), as $n \to \infty$, of the rate of the largest k-hash code of length n.

The study of the quantity R_k is a fundamental problem in combinatorics, information theory, and computer science. As the name suggests, k-hash codes have strong connections to the hashing problem. A family of functions mapping a universe of size N to the set

$\{1, 2, \ldots, k\}$ is called a perfect k-hash family if any k elements of the universe are mapped in one-to-one fashion by at least one hash function from this family. If C is a k-hash code, then a perfect k-hash family for universe C with n functions is just the family of coordinate projections. Therefore, R_k gives the growth rate of the size of universes for which perfect k-hash families of a given size exist. Equivalently, an upper bound on R_k is equivalent to a lower bound on the size of a perfect k-hash family as a function of the universe size.

An equivalent information-theoretic context in which k-hash codes arise concerns zero-error list decoding on certain channels. A channel can be thought of as a bipartite graph (V, W, E), where V is the set of channel inputs, W is the set of channel outputs, and $(v, w) \in E$ if on input v the channel can output w. The $k/(k-1)$ channel then is the channel with $V = W = \{1, 2, \ldots, k\}$, and $(v, w) \in E$ iff $v \neq w$. In this context, R_k is the largest asymptotic rate at which one can communicate using n repeated uses of the channel (as n grows), if we want to ensure that the receiver can identify a subset of at most $k-1$ sequences that is guaranteed to contain the transmitted sequence. See [4, 3] for more details.

Studying the rates of the codes and hashing family sizes in the above settings is a longstanding problem. A probabilistic argument shows the existence of k-hash codes with rate at least $\frac{1}{k-1} \log \frac{1}{1-k!/k^k} - o(1)$ [5, 10], and better bounds are known for some small values of k. Our focus here is on *upper bounds* on R_k, that is limitations on the size of k-hash codes. Here the best-known general upper bound on the rate R_k dates all the way back to the 1984 paper of Fredman and Komlós [5]:

$$R_k \leq \frac{k!}{k^{k-1}} =: \alpha_k \ . \tag{1}$$

For large k the multiplicative discrepancy between the probabilistic lower bound on R_k and the above Fredman-Komlós upper bound (1) grows approximately as k^2, so the current bounds on the rate require tightening to obtain better estimations of R_k. There is another trivial upper bound, $R_k \leq \log_2 \left(\frac{k}{k-1}\right)$, that follows from a simple double-counting or first moment method. The above bound (1) is much better than this bound for $k \geq 4$. For $k = 3$ (which is called the trifference problem by Körner), however, $R_3 \leq \log_2(3/2) \approx 0.585$ remains the best upper bound, and improving it (or showing it can be achieved!) is a major combinatorial challenge. For the case $k = 4$, the bound (1) which states $R_4 \leq 0.375$ has been improved, first by Arikan to 0.3512 [1], and recently by Dalai, Guruswami, and Radhakrishnan [3] to $6/19 \leq 0.3158$.

However, the above quantity α_k remained the best known upper bound on R_k for each $k > 4$. Our main result gives the first improvement to the Fredman-Komlós bound (1) for $k \geq 5$, proving that R_k is strictly smaller than α_k for every k.

▶ **Theorem 1.** *For all $k \geq 4$ there exists β_k such that $R_k \leq \beta_k < \alpha_k$. For $k = 5, 6$, we have the explicit upper bounds $R_5 < \beta_5 = 0.190826 < 0.192 = \alpha_5$, and $R_6 < \beta_6 = 0.0922789 < 0.0\overline{925} = \frac{5}{54} = \alpha_6$.*

Our approach provides a method to compute the explicit bound β_k for any $k \geq 5$ by finding a root of a degree-$O(k)$ polynomial, which lies within a specific interval. Moreover, we present a technical conjecture on the optimum values of certain polynomial optimization problems over the simplex, assuming which even stronger upper bounds on R_k can be obtained. Using the tools of numerical optimization in *Mathematica*, we verify this conjecture for the cases $k = 5, 6$, which gives us better values of β_5 and β_6, claimed in the Theorem above.

Our approach is also applicable to the (b, k)-hashing problem for $b \geq k$, where one considers codes $C \subseteq \{1, 2, \ldots, b\}^n$ with the property that for any k distinct codewords $\{c^{(1)}, c^{(2)}, \ldots, c^{(k)}\}$ from C there exists a coordinate j such that all these codewords differ

in this coordinate. Using exactly the same arguments, we obtain an improvement on the Körner-Marton upper bound [9] on the rate of such codes. When $b = k$, this latter bound is identical to the Fredman-Komlós bound, but can be better than the corresponding bound in [5] when $b > k$. For some small pairs of values (b, k) with $b > k$, the Körner-Marton bound was further improved by Arikan [1]. In those cases, the bounds we get are probably weaker than Arikan's. For this reason and for the sake of simplicity, in this paper we analyze only the case $b = k$, which corresponds to k-hashing, but all our proofs generalize in a straightforward way for (b, k)-hashing as well.

2 Background and approach

The previous general upper bounds on the rates of k-hash codes by Fredman and Komlós [5], Körner and Marton [9], and Arikan [1] are all based on information-theoretic inequalities for graph covering, related to the Hansel lemma [6]. Körner [10] cast the Fredman-Komlós proof in the language of graph entropy, which he had introduced in [8] (see [12] for a nice survey on graph entropy). Körner and Marton [9] generalized this approach to the hypergraph case, which led to improvements to the Fredman-Komlós bound for the (b, k)-hashing problem in certain cases when $b > k$, but not for R_k. In this paper we use the following version of the Hansel lemma, which is also proved in [11] via a simple probabilistic argument:

▶ **Lemma 2** (Hansel). *Let K_m be a complete graph on m vertices. Let also $G_1, G_2, \ldots, G_t$ be bipartite graphs, such that $E(K_m) = \bigcup_{i=1}^{t} E(G_i)$. Denote by $\tau(G_i)$ the fraction of non-isolated vertices in G_i. Then the following holds:*

$$\log m \leq \sum_{i=1}^{t} \tau(G_i). \tag{2}$$

To relate this lemma to the context of the paper, consider a k-hash code $C \subseteq [k]^n$. Take a subset of this code $\{x_1, x_2, \ldots, x_{k-2}\} \subseteq C$, and define bipartite graphs $G_i^{x_1,\ldots,x_{k-2}}$, for $i \in [n]$, as follows:

$$V(G_i^{x_1,\ldots,x_{k-2}}) = C \setminus \{x_1, x_2, \ldots, x_{k-2}\},$$
$$E(G_i^{x_1,\ldots,x_{k-2}}) = \left\{ \{y_1, y_2\} \ : \ (y_1)_i, (y_2)_i, (x_1)_i, (x_2)_i, \ldots, (x_{k-2})_i \text{ are distinct} \right\}.$$

Note that since C is a k-hash code, for any pair $\{y_1, y_2\} \subseteq C \setminus \{x_1, x_2, \ldots, x_{k-2}\}$, there exists some coordinate i, such that all the k codewords $y_1, y_2, x_1, x_2, \ldots, x_{k-2}$ differ in the i^{th} coordinate. In other words, $\{y_1, y_2\} \in E(G_i^{x_1,\ldots,x_{k-2}})$ for this i. Therefore, $E\left(K_{|C|-(k-2)}\right) = \bigcup_{i=1}^{n} E(G_i^{x_1,\ldots,x_{k-2}})$. Then Hansel lemma 2 applies directly, and denoting $\tau_i(x_1, x_2, \ldots, x_{k-2}) = \tau\left(G_i^{x_1,\ldots,x_{k-2}}\right)$, we obtain

$$\log\left(|C| - k + 2\right) \leq \sum_{i=1}^{n} \tau_i(x_1, x_2, \ldots, x_{k-2}). \tag{3}$$

Taking the expectation over the choice of $x_1, x_2, \ldots, x_{k-2}$, we get

$$\log\left(|C| - k + 2\right) \leq \sum_{i=1}^{n} \mathbb{E}[\tau_i(x_1, x_2, \ldots, x_{k-2})]. \tag{4}$$

By bounding the RHS of the above inequality one might obtain an upper bound on $\log |C|$, and thus on the rate of this code. Different strategies to pick the codewords $\{x_1, x_2, \ldots, x_{k-2}\}$ from C lead to different approaches to bound the RHS of (4). Here we briefly present the ideas underlying the previous works and then outline our approach.

In the original bound by Fredman and Komlós [5] the codewords $x_1, x_2, \ldots, x_{k-2}$ are picked independently at random from the code C. Then one can use symmetry arguments (or Muirhead's inequality) to bound the RHS of (4), which leads to the inequality

$$R_k \leq \frac{k!}{k^{k-1}}. \tag{5}$$

Due to the symmetry arguments involved, this bound is actually tight only in the case when the frequencies of the symbols of the code C in each coordinate are exactly uniform.

Arikan [1, 2] used rate versus distance results (the Plotkin bound) from coding theory to ensure that it is possible to pick $x_1, x_2, \ldots, x_{k-2}$ which agree on many coordinates. Note that this already guarantees that many terms in the RHS of (3) equal 0. Together with an argument which allows to modify the code so that it doesn't have any coordinate where the symbols have an overly skewed (far from uniform) frequency, Arikan was able to improve the bound (5) for $k = 4$. However, no improvement was gained for larger k.

Dalai, Guruswami, and Radhakrishnan [3] combine aspects of the above two approaches for the case $k = 4$. As in Arikan's work, they pick x_1, x_2 to agree on the first several coordinates. However, instead of a fixed such choice, they pick such a pair at random from a rich subcode of C with a common prefix. Considering such subcodes with common prefixes is a standard approach that leads to the Plotkin bound. The technical crux of the argument in [3] is a concavity claim for some quadratic form which says that despite conditioning on a common prefix, which might greatly alter the frequency vector of symbols in any coordinate in the suffix, the Fredman-Komlós bound for completely random x_1, x_2 is still valid on those coordinates. (In some sense, only the average frequency vector over all prefixes matters, not the individual ones.) Actually this holds modulo a technical condition that there are no coordinates with very skewed symbol distribution, which can be ensured by some pre-processing of the code similar to [2]. Thus some terms in (4) are equal to 0 and the other are bounded by 3/8, and balancing these appropriately, a bound of $R_4 \leq \frac{6}{19}$ is obtained in [3].

In this work, we follow the strategy of [3] for general k by picking $x_1, x_2, \ldots, x_{k-2}$ randomly so that they all lie in a rich subcode of C. However, rather than taking Plotkin-type subcode with a common prefix, we consider a subcode C which takes at most $(k-3)$ values on each coordinate from some large set T. This again implies that the coordinates from T contribute 0 to the RHS of (4). In this case, however, the analogous concavity claim seems out of reach, as one has to argue about degree-$(k-2)$ polynomials rather than quadratics. We instead take a different approach that works directly with the arbitrary symbol frequencies that may arise upon conditioning within a subcode, avoiding the averaging or concavity step. (This leads to worse bounds, but still allows to beat the Fredman-Komlós bound for $k > 4$.) However, another problem arises in that the constraint on the code to have non-skewed frequencies in each coordinate cannot be dealt with using Arikan's argument for large k. To cope with this issue, we differentiate two separate cases: (i) where C has only a few coordinates with skewed distributions of symbols, and (ii) where there are a lot of such coordinates.

- In the first case, we pick the coordinates T (where $x_1, x_2, \ldots, x_{k-2}$ are chosen to collide) to include all these skewed coordinates. Note that this is unlike [1, 3] where any choice of T of prescribed size works. Our choice of T ensures that in the remaining coordinates the frequency vector is not too far from uniform, and we apply the approach of [3] to get an improvement upon the Fredman-Komlós bound.

- In the second case, we use the original random strategy of picking $x_1, x_2, \ldots, x_{k-2}$ as in [5]. The idea here is that the bound (5) is tight only when all the frequencies of symbols are exactly uniform. Then, in the case when there are a lot of far-from-uniform frequencies, it is possible to improve the bound (5).

By picking the correct way to differentiate between skewed and non-skewed distributions, we then obtain an improvement on the Fredman-Komlós bound (5) for every $k \geq 4$ in section 3.3. As mentioned earlier, this is the *first* such improvement for $k \geq 5$. For $k = 5$ and $k = 6$ we also use numerical optimization tools to provide slightly stronger explicit bounds on R_k.

3 Upper bound on the rate of k-hash codes

Let $\Sigma = \{1, 2, \ldots, k\} = [k]$, and let $C \subseteq \Sigma^n$ be a k-hash code with rate $R = \frac{\log |C|}{n}$ (all logarithm are to the base 2). Let $f_i \in \mathbb{R}^k$ be the frequency vector of symbols of the code for each coordinate $i \in [n]$, namely:

$$f_i[a] = \frac{1}{|C|}|\{x \in C : x_i = a\}|.$$

Throughout the analysis, we will be interested in two cases: when for most of the coordinates the distribution of codeword symbols is close to uniform (non-skewed), or when this doesn't hold. To define the term "close to uniform" formally, we consider a *threshold* γ, that satisfies $\frac{1}{2k-3} \leq \gamma \leq \frac{1}{k}$, and say that $f \in \mathbb{R}^k$ is close to uniform when $f[a] \geq \gamma$ for all $a \in [k]$. Denote then $P_\gamma = \{i \in [n] : \min\limits_{a \in \Sigma} f_i[a] \geq \gamma\}$ – the set of all the coordinates for which the distribution of codeword symbols is close to uniform. Denote also $\ell := \left\lfloor \frac{nR - \log n}{\log\left(\frac{k}{k-3}\right)} \right\rfloor$. We then consider two cases:

1. *Unbalanced:* $|P_\gamma| < n - \ell$, so there is a decent fraction of coordinates where the distribution of codeword symbols is skewed. For this case, we apply a random strategy to pick $x_1, x_2, \ldots, x_{k-2}$ in (4).
2. *Almost balanced:* $|P_\gamma| \geq n - \ell$, so for almost all coordinates, the distribution of codeword symbols is close to uniform. Then we follow the approach from [3] to pick $x_1, x_2, \ldots, x_{k-2}$ which collide on many coordinates.

For both of these cases, we will obtain some bounds on the rate of C, which depend on the threshold γ. It then will remain to choose γ in a manner ensuring that both these bounds beat (5). Then, since for any code C exactly one of the cases holds, we can obtain a general upper bound on the rate.

Before we continue with studying the two cases separately, let's look at how we can estimate $\tau_i(x_1, x_2, \ldots, x_{k-2})$. Clearly, the codeword $y \in C$ appears non-isolated in the graph $G_i^{x_1, x_2, \ldots, x_{k-2}}$ only if all the codewords $x_1, x_2, \ldots, x_{k-2}$ and y differ in the i^{th} coordinate. Therefore, the fraction of non-isolated vertices in $G_i^{x_1, x_2, \ldots, x_{k-2}}$ satisfies

$$\tau_i(x_1, \ldots, x_{k-2}) \leq \left(\frac{|C|}{|C| - (k-2)}\right)\left(1 - f_i[(x_1)_i] - f_i[(x_2)_i] - \cdots - f_i[(x_{k-2})_i]\right) \times \\ \times \mathbf{1}\Big[(x_1)_i, (x_2)_i, \ldots, (x_{k-2})_i \text{ distinct}\Big], \tag{6}$$

where $\mathbf{1}[E]$ is the indicator variable for an event/condition E.

3.1 Unbalanced case

We will pick $x_1, x_2, \ldots, x_{k-2}$ uniformly at random without replacement from C to obtain an upper bound on the rate of C from (4). Taking the expectations of the both sides in (6) gives

$$\begin{aligned}
&\mathbb{E}[\tau_i(x_1, \ldots, x_{k-2})] \\
&\quad \le \frac{|C|}{|C|-k+2} \sum_{\substack{a_1,\ldots,a_{k-2} \in \Sigma \\ \{a_s\} \text{ distinct}}} \left(1 - \sum_{s=1}^{k-2} f_i[a_s]\right) \cdot \mathbb{P}\big[(x_s)_i = a_s,\ s = 1, \ldots, (k-2)\big] \\
&\quad = \frac{|C|}{|C|-k+2} \prod_{j=0}^{k-3} \frac{|C|}{|C|-j} \sum_{\substack{a_1,a_2,\ldots,a_{k-2} \in \Sigma \\ \{a_s\} \text{ distinct}}} \left(1 - \sum_{s=1}^{k-2} f_i[a_s]\right) \cdot f_i[a_1] f_i[a_2] \ldots f_i[a_{k-2}],
\end{aligned} \tag{7}$$

where the coefficients $\frac{|C|}{|C|-j}$, $j = 0, 1, \ldots, k-3$ appear because we pick elements from C without replacement. Define the following function of two probability vectors $g, f \in \mathbb{R}^k$:

$$\phi_k(g, f) := \sum_{\substack{a_1,a_2,\ldots,a_{k-2} \in \Sigma \\ \{a_s\} \text{ distinct}}} \prod_{s=1}^{k-2} g[a_s] \Big(1 - \sum_{s=1}^{k-2} f[a_s]\Big). \tag{8}$$

Using this notation, we derive from (7):

$$\mathbb{E}[\tau_i(x_1, x_2, \ldots, x_{k-2})] \le \phi_k(f_i, f_i)\big(1 + o(1)\big). \tag{9}$$

Since $\sum_{a \in \Sigma} f_i[a] = 1$, it is easy to see that $\phi_k(f_i, f_i)$ is a symmetric expression in $f_i[a]$ for all $a \in \Sigma$. Denote by $S_h^t(g)$ the h-th elementary symmetric sum of the first t coordinates of the vector $g \in \mathbb{R}^k$, i.e. the sum of all products of h distinct elements from $\{g[1], g[2], \ldots, g[t]\}$. Then we can write

$$\phi_k(f_i, f_i) = (k-2)! \cdot \binom{k-1}{k-2} S_{k-1}^k(f_i) = (k-1)! \cdot S_{k-1}^k(f_i)$$

It is not hard to show that $S_h^k(g)$ for g being a probability vector in $\mathbb{R}^k$ is maximized when g is uniform. Indeed, if there are two non-equal coordinates $g[a] \ne g[b]$, then substituting the values in these coordinates by their arithmetic average strictly increases the value of $S_h^k(g)$. Then let us denote by u the uniform distribution on k elements, i.e. $u[a] = 1/k$ for all $a \in [k]$, and so $S_h^k(g) \le S_h^k(u)$. Then in (9)

$$\mathbb{E}[\tau_i(x_1, x_2, \ldots, x_{k-2})] \le (k-1)! \cdot S_{k-1}^k(f_i) \cdot \big(1 + o(1)\big) \le (k-1)! \cdot S_{k-1}^k(u) \cdot \big(1 + o(1)\big),$$

where we compute $S_{k-1}^k(u) = \binom{k}{k-1} \cdot \left(\frac{1}{k}\right)^{k-1} = \left(\frac{1}{k}\right)^{k-2}$. Therefore, we retrieve

$$\mathbb{E}[\tau_i(x_1, x_2, \ldots, x_{k-2})] \le \frac{(k-1)!}{k^{k-2}} \cdot \big(1 + o(1)\big) = \frac{k!}{k^{k-1}} \cdot \big(1 + o(1)\big). \tag{10}$$

Substituting this inequality into (4), notice that we derive exactly the Fredman-Komlós bound (5). Denote then

$$\alpha_k := \frac{k!}{k^{k-1}},$$

the Fredman-Komlós upper bound on the rate R_k.

Now recall that we are considering the unbalanced case, in which there are a lot of coordinates with frequencies of codeword symbols being far from uniform. Take i to be any of such coordinates, and let for convenience $f = f_i$, so $\min_{a\in\Sigma} f[a] < \gamma$. Without loss of generality, say $f[k] < \gamma$. Notice the following trivial property of symmetric sums:

$$\phi_k(f,f) = (k-1)!\cdot S^k_{k-1}(f) = (k-1)!\Big(S^{k-1}_{k-1}(f) + f[k]\cdot S^{k-1}_{k-2}(f)\Big).$$

The above expression is symmetric in the first $(k-1)$ coordinates of f. Let's then fix $f[k]$, and do the same averaging operations with all the remaining coordinates of f, making in the end $f'[1] = f'[2] = \cdots = f'[k-1] = \frac{1-f[k]}{k-1}$. The value of $\phi_k(f,f)$ only increases after such operations, so

$$\phi_k(f,f) \le (k-1)!\Big(f'[1]f'[2]\cdots f'[k-1] + f[k]\cdot S^{k-1}_{k-2}(f')\Big).$$

Let $y = \frac{1-f[k]}{k-1}$, so $f[k] = 1-(k-1)y$. Since $0 \le f[k] < \gamma$ by the assumption above, it holds $\frac{1-\gamma}{k-1} \le y \le \frac{1}{k-1}$. Recall that we took the threshold $\gamma \le \frac{1}{k}$, thus $y \ge \frac{1-\gamma}{k-1} \ge \frac{1}{k}$. Then

$$\phi_k(f,f) \le (k-1)!\Big(y^{k-1} + \big(1-(k-1)y\big)\cdot(k-1)y^{k-2}\Big) = (k-1)!y^{k-2}\Big((k-1)-(k^2-2k)y\Big).$$

Denote $G_k(y) = (k-1)!y^{k-2}\Big((k-1)-(k^2-2k)y\Big)$, so $\phi_k(f,f) \le G_k(y)$. We have

$$\big(G_k(y)\big)' = (k-1)!(k-1)(k-2)y^{k-3}\big(1-ky\big), \tag{11}$$

so the derivative of G_k is negative on the interval $\frac{1}{k} \le \frac{1-\gamma}{k-1} < y \le \frac{1}{k-1}$, and it is zero at $y = \frac{1}{k}$. Therefore, we finally obtain for any such f:

$$\phi_k(f,f) \le \max_{y\in\left[\frac{1-\gamma}{k-1},\frac{1}{k-1}\right]} G_k(y) = G_k\left(\frac{1-\gamma}{k-1}\right). \tag{12}$$

Note that $G_k\left(\frac{1-\gamma}{k-1}\right) \le G_k\left(\frac{1}{k}\right) = \alpha_k$ for any $\gamma \le \frac{1}{k}$, and the strict inequality $G_k\left(\frac{1-\gamma}{k-1}\right) < G_k\left(\frac{1}{k}\right) = \alpha_k$ holds when $\gamma < \frac{1}{k}$.

So if $\min_{a\in[k]} f_i[a] < \gamma$ for some coordinate i, we retrieved the bound

$$\mathbb{E}[\tau_i(x_1,x_2,\ldots,x_{k-2})] \le G_k\left(\frac{1-\gamma}{k-1}\right)\big(1+o(1)\big). \tag{13}$$

For now we obtained two bounds for the summands in the RHS of (4): (i) the bound (10) holds for all the coordinates, and (ii) the bound (13) holds for the coordinates with codeword symbol frequencies far from uniform. As we noted above, the second bound is strictly stronger than the first bound when we take the threshold $\gamma < \frac{1}{k}$. Also recall that in the unbalanced case which we now consider, there are a lot of coordinates of the second type, so essentially the bound (13) applies many times. Let's now formalize this argument to obtain an improvement on the Fredman-Komlós bound for the unbalanced case.

Denote $\xi_k(\gamma) = G_k\left(\frac{1-\gamma}{k-1}\right)$, then

$$\xi_k(\gamma) = (k-1)!\frac{(1-\gamma)^{k-2}}{(k-1)^{k-2}}\,\frac{(k-1)^2-(k^2-2k)(1-\gamma)}{k-1} = \frac{(k-2)!(1-\gamma)^{k-2}\big((k^2-2k)\gamma+1\big)}{(k-1)^{k-2}}, \tag{14}$$

and note that $\xi_k(\gamma) \le \alpha_k$ for $\gamma \le \frac{1}{k}$. Recall that we denoted by P_γ the set of coordinates i for which $\min_{a\in\Sigma} f_i[a] \ge \gamma$. For such $i \in P_\gamma$ we directly apply the bound (10). For all the other coordinates $i \in [n] \setminus P_\gamma$ we use the inequality (13). In the unbalanced case $|P_\gamma| < n - \ell$, thus $n - |P_\gamma| > \ell$. Applying all these arguments to (4), we obtain

$$\begin{aligned}\log(|C| - k + 2) &\le \Big(|P_\gamma|\alpha_k + \big(n - |P_\gamma|\big)\xi_k(\gamma)\Big)(1 + o(1)) \\ &< \Big(n\alpha_k - \ell\left(\alpha_k - \xi_k(\gamma)\right)\Big)(1 + o(1)) \\ &\le \left(n\alpha_k - \frac{nR}{\log\left(\frac{k}{k-3}\right)}\left(\alpha_k - \xi_k(\gamma)\right) + o(n)\right)(1 + o(1)),\end{aligned}$$

where $\ell = \left\lfloor \frac{nR - \log n}{\log\left(\frac{k}{k-3}\right)} \right\rfloor$. Since $|C| = 2^{Rn}$, the above implies for $n \to \infty$:

$$R \le \alpha_k - \frac{R\left(\alpha_k - \xi_k(\gamma)\right)}{\log\left(\frac{k}{k-3}\right)} + o(1),$$

$$\boxed{R_k^{\text{unbal}}(\gamma) \le \frac{\alpha_k}{1 + \frac{\alpha_k - \xi_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}}.} \tag{15}$$

Note that for $\gamma = \frac{1}{k}$ the above bound becomes equal to α_k, since $\xi_k(1/k) = G\left(\frac{1-1/k}{k-1}\right) = G\left(\frac{1}{k}\right) = \alpha_k$. Moreover, the previous analysis (11) of the function $G_k(\cdot)$ implies that the RHS of the above bound is strictly increasing as a function of γ. Thus the bound (15) is strictly better than the Fredman-Komlós bound for the unbalanced case for any threshold $\gamma < \dfrac{1}{k}$.

3.2 Almost balanced case

For this case we extend the approach used in [3] for 4-hashing. Namely, in [3] the authors considered a Plotkin-type subcode of C containing the words with the common prefix, and then picked x_1, x_2 from this subcode. For our purposes, we will consider a rich subcode of codewords which can take a restricted set of symbols on some fixed set of coordinates, and choose $x_1, x_2, \ldots, x_{k-2}$ randomly from the subcode. In the almost balanced case, we are able to ensure that the distributions of codeword symbols in all non-fixed coordinates are close to uniform, which will allow us to use some continuity argument to bound the RHS of (4).

In the almost balanced case we assume $|P_\gamma| \ge n - \ell$, so there are at most ℓ coordinates where the distribution of codeword symbols is skewed. The set of such coordinates is $\overline{P_\gamma} = [n] \setminus P_\gamma$, $|\overline{P_\gamma}| \le \ell$. Then take any subset $T \subset [n]$, such that $\overline{P_\gamma} \subseteq T$ and $|T| = \ell$, and denote $S = [n] \setminus T$.

Our goal is to find a subcode of C of sufficient size, such that any $(k-2)$ codewords $x_1, x_2, \ldots, x_{k-2}$ from this subcode collide in all the coordinates from T. In other words, for any coordinate $t \in T$ there should exist i, j such that $(x_i)_t = (x_j)_t$. This will ensure that the coordinates from T contribute 0 to the RHS of (4), which will allow us to prove a better bound on the rate of the code C. We will now define the subcodes which satisfy this property.

First, denote by $\binom{\Sigma}{p}$ the family of p-element subsets of the alphabet $\Sigma = \{1, 2, \ldots, k\}$. Then define $\Omega := \underbrace{\binom{\Sigma}{k-3} \times \binom{\Sigma}{k-3} \times \cdots \times \binom{\Sigma}{k-3}}_{\ell}$.

Now, for any $\omega \in \Omega$ and any string $s \in \Sigma^\ell$, denote $s \vdash \omega$ if $s_1 \in \omega_1, s_2 \in \omega_2, \ldots, s_\ell \in \omega_\ell$. Then, for any $\omega \in \Omega$, we define:

$$C_\omega := \{x \in C : x_{\{T\}} \vdash \omega\},$$

where $x_{\{T\}}$ is the projection of the codeword x on the set of coordinates T. Notice that C_ω has the property we discussed above. Indeed, for any pick $x_1, x_2, \ldots, x_{k-2} \in C_\omega$ and any $t \in T$, it holds $(x_1)_t, (x_2)_t, \ldots, (x_{k-2})_t \in \omega_t$, but $|\omega_t| = k-3$, and therefore $(x_1)_t, (x_2)_t, \ldots, (x_{k-2})_t$ are not all distinct.

Denote then $M_\omega = |C_\omega|$. Note that for each $x \in C$ there are exactly $\binom{k-1}{k-4}^\ell$ different elements $\omega \in \Omega$ such that $x_{\{T\}} \vdash \omega$. Therefore

$$\sum_{\omega \in \Omega} M_\omega = |C| \cdot \binom{k-1}{k-4}^\ell.$$

It suffices to prove that there exists at least one $\omega \in \Omega$ such that $M_\omega \geq n$ for our arguments further. For the sake of contradiction, suppose $M_\omega < n$ for all $\omega \in \Omega$. But then

$$2^{nR} = |C| = \sum_{\omega \in \Omega} M_\omega \frac{1}{\binom{k-1}{k-4}^\ell} < \frac{\binom{k}{k-3}^\ell}{\binom{k-1}{k-4}^\ell} \cdot n = \left(\frac{k}{k-3}\right)^\ell n = 2^{\ell \cdot \log \frac{k}{k-3} + \log n} \leq 2^{nR},$$

where $\ell = \left\lfloor \frac{nR - \log n}{\log\left(\frac{k}{k-3}\right)} \right\rfloor$. The above is a contradiction, so there exists such $\omega \in \Omega$ that $M_\omega \geq n$.

We are finally ready to describe the strategy to pick the codewords $x_1, x_2, \ldots, x_{k-2}$ in the almost balanced case. We do the following: first, deterministically choose some $\omega \in \Omega$ such that $M_\omega \geq n$, and then pick $x_1, x_2, \ldots, x_{k-2}$ uniformly at random (without replacement) from C_ω. Since all the codewords collide on the coordinates from the set T, we obtain in (4):

$$\log(|C| - k + 2) \leq \sum_{m \in [n]} \mathbb{E}[\tau_m(x_1, x_2, \ldots, x_{k-2})] = \sum_{m \in S} \mathbb{E}[\tau_m(x_1, x_2, \ldots, x_{k-2})]. \tag{16}$$

Now fix some $m \in S$, and let $f_{m|\omega}$ be the frequency vector of the m^{th} coordinate in the subcode C_ω. Taking expectation over the choice of $x_1, x_2, \ldots, x_{k-2}$ in (6) with respect to the the random strategy described above, we have

$$\begin{aligned}
&\mathbb{E}[\tau_m(x_1, x_2, \ldots, x_{k-2})] \\
&= \frac{|C|}{|C| - k + 2} \prod_{j=0}^{k-3} \frac{|C_\omega|}{|C_\omega| - j} \sum_{\substack{a_1, \ldots, a_{k-2} \in \Sigma \\ \{a_s\} \text{ distinct}}} \left(1 - \sum_{s=1}^{k-2} f_m[a_s]\right) \cdot f_{m|\omega}[a_1] f_{m|\omega}[a_2] \ldots f_{m|\omega}[a_{k-2}],
\end{aligned}$$

where the coefficients $\frac{|C_\omega|}{|C_\omega| - j}$, $j = 0, 1, \ldots, (k-3)$ appear because we pick $(k-2)$ elements from C_ω without replacement. Since we took ω such that $|C_\omega| \geq n$, it follows that $\frac{|C_\omega|}{|C_\omega| - j} \leq \frac{n}{n-j}$.

Using the function $\phi_k(g, f)$ which was defined in (8), we can rewrite the above as

$$\mathbb{E}[\tau_m(x_1, x_2, \ldots, x_{k-2})] \leq \prod_{j=0}^{k-2} \left(\frac{n}{n-j}\right) \phi_k(f_{m|\omega}, f_m) = \phi_k(f_{m|\omega}, f_m) \cdot \big(1 + o(1)\big). \tag{17}$$

Consider the following definition:

$$\boxed{\theta_k(\gamma) := \max_{g,f} \{\phi_k(g, f) : f, g \in \mathbb{R}^k \text{ are probability vectors, } \min_{a \in \Sigma} f[a] \geq \gamma\}.} \tag{18}$$

Let's first consider the bound we obtain using this definition, and then analyze $\theta_k(\gamma)$.

Since $\min_{a\in\Sigma} f_m[a] \geq \gamma$ by construction of the set S, we have $\phi_k(f_{m|\omega}, f_m) \leq \theta_k(\gamma)$ for any $m \in S$, so substituting it into (17) gives

$$\mathbb{E}[\tau_m(x_1, x_2, \ldots, x_{k-2})] \leq \theta_k(\gamma) \cdot \big(1 + o(1)\big).$$

Therefore, in (16) we derive

$$\begin{aligned}\log(|C| - k + 2) &\leq |S| \cdot \theta_k(\gamma)\big(1 + o(1)\big) = (n - \ell) \cdot \theta_k(\gamma)\big(1 + o(1)\big) \\ &\leq \left(n - \frac{nR}{\log\left(\frac{k}{k-3}\right)} + \frac{\log n}{\log\left(\frac{k}{k-3}\right)} + 1\right) \theta_k(\gamma)\big(1 + o(1)\big).\end{aligned}$$

Recall that $|C| = 2^{nR}$, thus for $n \to \infty$

$$R \leq \left(1 - \frac{R}{\log\left(\frac{k}{k-3}\right)}\right) \theta_k(\gamma) + o(1),$$

$$\boxed{R_k^{\mathrm{bal}}(\gamma) \leq \frac{\theta_k(\gamma)}{1 + \frac{\theta_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}}.} \tag{19}$$

It now remains to understand how $\theta_k(\gamma)$, defined in (18), behaves as a function of γ.

Upper bound for $\theta_k(\gamma)$

First, note that for $\gamma = \frac{1}{k}$ the only probability vector f with $\min_{a\in\Sigma} f[a] \geq \gamma$ is the uniform vector u. Then $\phi_k(g, u)$ is an elementary symmetric sum of all the coordinates of g, and therefore we obtain $\phi_k(g, u) \leq \phi_k(u, u) = \alpha_k$, and so $\theta_k(1/k) = \alpha_k$.

Now take any $\gamma \leq \frac{1}{k}$, and let g, f be probability vectors in $\mathbb{R}^k$ such that $f[a] \geq \gamma$ for $a \in \Sigma$. We will further use "f_a" to refer to the a^{th} coordinate of vector f rather than "$f[a]$".

Let $t = \binom{k}{2} = k(k-1)/2$ and let $P_1, P_2, \ldots, P_t$ be an enumeration of all $(k-2)$-element subsets of $\Sigma = \{1, 2, \ldots, k\}$. Then we have from (8)

$$\phi_k(g, f) = \sum_{\substack{a_1,\ldots,a_{k-2}\in\Sigma \\ \{a_i\} \text{ distinct}}} \prod_{i=1}^{k-2} g_{a_i}\left(1 - \sum_{i=1}^{k-2} f_{a_i}\right) = (k-2)! \sum_{j=1}^{t} \left[\prod_{a\in P_j} g_a \cdot \left(1 - \sum_{a\in P_j} f_a\right)\right]. \tag{20}$$

Denote $d_j := \prod_{a\in P_j} g_a$, and let $d_{(i)}$ be the i^{th} order statistic of the set $\{d_1, d_2, \ldots, d_t\}$, i.e. $\{d_{(1)}, d_{(2)}, \ldots, d_{(t)}\} = \{d_1, d_2, \ldots, d_t\}$ and $d_{(1)} \geq d_{(2)} \geq \cdots \geq d_{(t)}$. The proof of the following claim can be found in the full version of the paper.

▷ Claim 3.

$$\phi_k(g, f) \leq (k-2)!\left[(1 - k\gamma)\sum_{j=1}^{k-1} d_{(j)} + 2\gamma \sum_{j=1}^{t} d_{(j)}\right]. \tag{21}$$

Now, $\sum_{j=1}^{t} d_{(j)} = \sum_{j=1}^{t} d_j$ is just an elementary symmetric sum of degree $k-2$ for the probability vector g, so this expression is maximized for the uniform vector, and then we get $\sum_{j=1}^{t} d_{(j)} \leq \binom{k}{2}\left(\frac{1}{k}\right)^{k-2}$.

Finally, we use $d_{(j)} \le \left(\frac{1}{k-2}\right)^{k-2}$, because each $d_{(j)}$ is a product of $(k-2)$ coordinates of some probability vector. Thus we obtain

$$\phi_k(g,f) \le (k-2)!\left[(1-k\gamma)\frac{(k-1)}{(k-2)^{k-2}} + \gamma\frac{(k-1)}{k^{k-3}}\right] = (k-1)!\left[\frac{(1-k\gamma)}{(k-2)^{k-2}} + \frac{\gamma}{k^{k-3}}\right]. \quad (22)$$

Since this holds for any g and any f such that $\min_{a\in\Sigma} f[a] \ge \gamma$, we obtain an upper bound

$$\theta_k(\gamma) \le (k-1)!\left[\frac{(1-k\gamma)}{(k-2)^{k-2}} + \frac{\gamma}{k^{k-3}}\right] =: \rho_k(\gamma). \quad (23)$$

Note that $\rho_k(\gamma)$ is linear in γ for a fixed k, and that $\rho_k(1/k) = \alpha_k = \theta_k(1/k)$, so this upper bound is tight for $\gamma = \frac{1}{k}$.

3.2.1 Conjecture on the exact value of $\theta_k(\gamma)$

We now describe the conjecture we make on the exact value of $\theta_k(\gamma)$. Consider the upper bound (21) on $\phi_k(g,f)$. Even for some fixed ordering of the coordinates of g, say (without loss of generality) $g_1 \ge g_2 \ge \cdots \ge g_k \ge 0$, there might be different cases of orderings within the set $\{d_1, d_2, \ldots, d_t\}$. Say there are q_k different ways to take the first $(k-1)$ order statistics within the set $\{d_1, d_2, \ldots, d_t\}$ (with this fixed ordering), then there would be q_k different functionals of d_i's, and thus of g_i's, in the RHS of (21), call them $\Theta_k^{(1)}(g,\gamma), \Theta_k^{(2)}(g,\gamma), \ldots, \Theta_k^{(q_k)}(g,\gamma)$. Since exactly one ordering within $\{d_1, \ldots, d_t\}$ is correct for any particular vector g, we obtain

$$\phi_k(g,f) \le \max_{i=1,2,\ldots,q_k} \Theta_k^{(i)}(g,\gamma).$$

Then define

$$\theta_k^{(i)}(\gamma) := \max_x \left\{\Theta_k^{(i)}(x,\gamma) : \sum_{j=1}^{k} x_j = 1, x \ge 0\right\}, \qquad \text{for } i = 1,2,\ldots,q_k, \quad (24)$$

and so the quantity $\theta_k(\gamma)$ defined in (18) satisfies

$$\theta_k(\gamma) \le \max_{i=1,2,\ldots,q_k} \theta_k^{(i)}(\gamma).$$

So to find an upper bound on $\theta_k(\gamma)$ it suffices to find the maximum among $\theta_k^{(i)}(\gamma)$ for $i = 1,2,\ldots,q_k$. Unfortunately, q_k grows exponentially as k increases, so it is not clear how to do this efficiently. We introduce a conjecture below, which suggests that we can determine which of the values $\theta_k^{(i)}(\gamma)$, $i = 1,2,\ldots,q_k$, is the greatest for any k.

Specifically, the conjecture is stated as follows: we assume that the maximum among all the values $\theta_k^{(i)}(\gamma)$, $i = 1,2,\ldots,q_k$, is the greatest for the functional $\Theta_k^{(i)}(x,\gamma)$ corresponding to the case, when the first $(k-1)$ order statistics of the set $\{d_1, d_2, \ldots, d_t\}$ form the set $\left\{\frac{\prod_{i=1}^{k-1} g_i}{g_a}\right\}_{a\in[k-1]}$. In other words, $\{d_{(1)}, d_{(2)}, \ldots, d_{(k-1)}\}$ correspond to the sets P_j that contain all their $(k-2)$ elements from $\{1,2,\ldots,k-1\}$ (recall $d_j = \prod_{a\in P_j} g_j$). So the first $(k-1)$ order statistics are formed as the products of only the first $(k-1)$ coordinates of g, ignoring the coordinate g_k. Our intuition behind the assumption that this functional will have the greatest maximum is based on symmetry arguments.

Recall that we denote by $S_h^t(g)$ the h-th elementary symmetric sum of the first t coordinates of g. Then the above conjecture can be formalized as follows:

▶ **Conjecture 4.**

$$\theta_k(\gamma) = \max_x \left\{ (k-2)! \left[\Big(1-(k-2)\gamma\Big) S_{k-2}^{k-1}(x) + 2\gamma \cdot x_k \cdot S_{k-3}^{k-1}(x) \right] : \quad \sum_{i=1}^{k} x_i = 1, x \geq 0 \right\}. \quad (25)$$

Indeed, the function $\Theta_k^{\gamma}(g) = (k-2)! \left[\Big(1-(k-2)\gamma\Big) S_{k-2}^{k-1}(g) + 2\gamma \cdot g_k \cdot S_{k-3}^{k-1}(g) \right]$ just corresponds to the functional in the RHS of (21) in the case we discussed above.

Simple computation of the RHS of (25) gives us another formulation of this conjecture:

$$\theta_k(\gamma) = \frac{(k-1)!(k-3)^{k-3}\gamma^{k-2}}{\big((k^2-2k)\gamma - 1\big)^{k-3}}. \quad (26)$$

3.3 Improvement of the Fredman-Komlós bound

In this section we show that it is possible to choose such a threshold γ that both bounds (15) and (19) are stronger than the Fredman-Komlós bound.

Using (23) in the bound (19), we obtain

$$R_k^{\text{bal}}(\gamma) \leq \frac{\theta_k(\gamma)}{1 + \frac{\theta_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}} \leq \frac{\rho_k(\gamma)}{1 + \frac{\rho_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}}. \quad (27)$$

Since for any k-hash code C either the unbalanced or the almost balanced case holds, and we get to choose the threshold γ to differentiate between these cases, the above, combined with (15), gives us the following upper bound for the rate in the general case:

$$R_k \leq \min_{\gamma \in \left(\frac{1}{2k-3}, \frac{1}{k}\right)} \max \left\{ \frac{\rho_k(\gamma)}{1 + \frac{\rho_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}}, \ \frac{\alpha_k}{1 + \frac{\alpha_k - \xi_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}} \right\}. \quad (28)$$

The optimal threshold γ is such that the bounds (27) and (15) are equal, since the first bound becomes stronger as γ increases, while the second bound becomes weaker. Therefore, the optimal threshold is the solution of the following equation:

$$\frac{\rho_k(\gamma)}{1 + \frac{\rho_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}} = \frac{\alpha_k}{1 + \frac{\alpha_k - \xi_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}} \quad (29)$$

where $\alpha_k = \dfrac{k!}{k^{k-1}}$ is the Fredman-Komlós bound, $\rho_k(\gamma)$ can be found using expression (23), and $\xi_k(\gamma)$ is found via (14). Note that $\rho_k(\gamma)$ is a linear function and $\xi_k(\gamma)$ is a rational functions with degree $O(k)$, and therefore the above equation is equivalent to finding a root of a polynomial of degree $O(k)$ in variable γ, which lies in the interval $\left(\frac{1}{2k-3}, \frac{1}{k}\right)$. Such a solution certainly exists, because at $\gamma = \frac{1}{k}$ the LHS is less than α_k, while the RHS is equal to α_k, however at $\gamma = \frac{1}{2k-3}$ the LHS is greater than α_k while the RHS is less than α_k. Therefore, there exists a point $\gamma^* \in \left(\frac{1}{2k-3}, \frac{1}{k}\right)$ where these bounds are equal, since these functions are continuous. The values of the bounds for $\gamma = \frac{1}{k}$ guarantee that both bounds will be less than α_k when we take the optimal threshold γ^*. Therefore, for each k this optimal threshold γ^*, substituted into (28), gives a new upper bound on the rate of k-hash codes, which is stronger than the Fredman-Komlós bound (5).

Assuming the conjecture 4 holds, we obtain a stronger bound by using the exact value of $\theta_k(\gamma)$ instead of its upper bound $\rho_k(\gamma)$. The optimal threshold in this case is the solution of

$$\frac{\theta_k(\gamma)}{1+\frac{\theta_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}} = \frac{\alpha_k}{1+\frac{\alpha_k-\xi_k(\gamma)}{\log\left(\frac{k}{k-3}\right)}}, \tag{30}$$

where the value for $\theta_k(\gamma)$ is taken from (26). The value attained by the above expressions at the optimal threshold is the new upper bound on R_k.

New bounds for $k = 5$ and $k = 6$

Currently, the conjecture 4 is formulated in such a way that for any γ (from an appropriate range) one particular functional, parametrized with γ, has a maximum value on a simplex larger than some other set of functionals, also parametrized with γ. However, for our purposes of obtaining an upper bound on R_k, we only need the conjecture to hold specifically for the value of the optimal threshold $\gamma = \gamma^*$, found via (30). This is because if (26) holds for this γ^*, we then know that the upper bounds (15) and (19) for unbalanced and balanced cases are equal by the choice of γ^* and thus give a general upper bound on the rate R_k.

So to use the conjecture for a given k it just suffices to solve all optimization problems (24) for this value γ^*, and check if the conjecture indeed holds (namely, that the maximum of $\Theta_k^{(i)}(g,\gamma)$ is the greatest for the functional $\Theta_k^{\gamma}(g)$ described in the conjecture).

Applying (30) for $k = 5$ gives us the optimal threshold $\gamma_5^* \approx 0.136163$. We then use the numberical optimization tools in *Wolfram Mathematica* [7] to verify that the conjecture 4 indeed holds, which in this case reduces to optimizing two degree-3 multilinear polynomials with 5 variables over the simplex. After verifying the conjecture, we obtain the new general bound for 5-hashing:

$$R_5 < 0.190826 < 0.192 = \frac{24}{125} = \alpha_5.$$

For $k = 6$, the above approach gives us:

$$R_6 < 0.0922789 < 0.0\overline{925} = \frac{5}{54} = \alpha_6.$$

Abstract

We establish and generalise several bounds for various random walk quantities including the mixing time and the maximum hitting time. Unlike previous analyses, our derivations are based on rather intuitive notions of local expansion properties which allow us to capture the progress the random walk makes through t-step probabilities.

We apply our framework to dynamically changing graphs, where the set of vertices is fixed while the set of edges changes in each round. For random walks on dynamic connected graphs for which the stationary distribution does not change over time, we show that their behaviour is in a certain sense similar to static graphs. For example, we show that the mixing and hitting times of any sequence of d-regular connected graphs is $O(n^2)$, generalising a well-known result for static graphs. We also provide refined bounds depending on the isoperimetric dimension of the graph, matching again known results for static graphs. Finally, we investigate properties of random walks on dynamic graphs that are not always connected: we relate their convergence to stationarity to the spectral properties of an average of transition matrices and provide some examples that demonstrate strong discrepancies between static and dynamic graphs.

1 Introduction

Problem and Motivation. A random walk is a stochastic process on an undirected connected graph $G = (V, E)$. A particle starts on a specified vertex, and then at each time-step $t = 1, 2, \ldots$ it moves to a neighbouring vertex chosen uniformly at random. Random walks have proven to be extremely powerful in the design of various sampling schemes, exploration strategies, and distributed algorithms [26]. They provide a simple yet robust way to explore a large network. Most of the studies on random walks, however, assume the underlying graph to be fixed. In contrast, many prevalent networks today (such as the Internet, social networks, and wireless communication networks) are subject to dramatic changes in their topology over time. Therefore, understanding the theoretical power and limitations of dynamic graphs has been identified as one of the key challenges in computer science [28].

Recently, several works have considered this problem and investigated the behaviour of random walks [3, 4, 34, 12, 25, 32, 33] or similar processes [6, 9, 11, 18, 23] on such dynamic graphs, and their applications to distributed networks [3, 34, 23]. Moreover, rather than a property of the underlying network itself, dynamic graphs may naturally arise in distributed algorithms when communication is performed on a changing, possibly disconnected, subgraph like a spanning-tree or a matching (see, e.g., [7]).

One very popular model is that of an evolving graph, where we consider a sequence of graphs $G^{(1)}, G^{(2)}, \ldots$ over the same set of vertices but with a varying set of edges. This model has been the subject of the majority of previous studies of random walks on dynamic graphs and will be the object of our study as well. Another important feature of dynamic networks is that, with a changing set of edges, the resulting connectivity (i.e., expansion) changes. This might be very common in communication networks, where nodes change their location in space over time and can only communicate if they are within a certain distance of each other. For example, [23] highlights the need to study such evolving graphs with relatively poor connectivity and [28] emphasises the unpredictable nature of fast-changing dynamic networks. To incorporate these features into our model, we will consider evolving graphs with relatively mild assumptions on their connectivity and will not make any restriction on how fast they are changing. Our quantitative analysis is focused on the *mixing time*, the time to converge to the equilibrium distribution, and the *hitting time*, the expected number of steps required by a random walk that starts in a vertex u to reach a vertex v. Analysing the mixing time of dynamic graphs is also useful for load balancing applications, where the mixing time represents the time it takes for all nodes to have (roughly) a load that is proportional to their stationary distribution. Most theoretical studies of load balancing so far assumed the graph to be fixed.

Our Results. The main motivation for our work comes from the results by Avin et al. [4], which describe a remarkable dichotomy with respect to the behaviour of random walks in evolving graphs: while sequences of connected graphs that share the same stationary distribution are guaranteed to have mixing and hitting times polynomial in the size of the graphs, even small incremental changes to the stationary distribution can cause hitting times to become exponential in the worst case. We focus on the first case of this dichotomy and prove that, at least regarding mixing and hitting times, there is essentially no difference in the behaviour of random walks on static and evolving graphs with a time-independent stationary distribution.

Recall that, for static graphs, it is well-known that the worst-case hitting time is $O(n^2)$ for regular graphs and $O(n^3)$ for arbitrary graphs [14, 15]. Quite surprisingly, we can show that something very similar holds in the setting of evolving graphs: our theorem below proves an upper bound of $O(n^2)$ for the mixing and hitting times of regular evolving graphs, which is optimal even for static graphs, an upper bound of $O(n^3)$ for the mixing time of non-regular evolving graphs, which is again optimal even for static graphs, and an $O(n^3 \log n)$ upper bound for the maximum hitting time, which is only a factor of $O(\log n)$ short from the optimal bound on static graphs (simply consider the Barbell graph, i.e., two cliques of size $n/3$ connected by a path of length $n/3$, which has $O(n^3)$ mixing and maximum hitting time). Below, we use $p_{u,v}^{[0,t]}$ for the probability that a random walk started in u is in v after t steps.

▶ **Main Result 1** (restated, see Theorem 3.3 on page 9). *Let $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ be a sequence of connected graphs with n vertices, the same stationary distribution π with $\pi_* = \min_u \pi(u)$, and at most m^* edges. Then:*

1. $t_{mix}(\mathcal{G}) = O(n/\pi_*)$,
2. $\left|\frac{p_{u,v}^{[0,t]}}{\pi_v} - 1\right| \lesssim \frac{m^*}{t} + \frac{1}{\pi_* \sqrt{t}}$, *simplifying to* $\left|\frac{p_{u,v}^{[0,t]}}{\pi_v} - 1\right| \lesssim \frac{n}{\sqrt{t}}$ *if all graphs in $\mathcal{G}$ are d-regular,*
3. $t_{hit}(\mathcal{G}) = O(n \log n/\pi_*)$. *Furthermore, if the graphs in $\mathcal{G}$ are d-regular, $t_{hit}(\mathcal{G}) = O(n^2)$.*

We point out that the second statement in the above result is implied by [34, Lemma 4.6] for the class of regular and bounded-degree graphs.

▶ Remark 1.1. In this work, we never explicitly derive upper bounds on the cover time (i.e., the expected time for a random walk to visit all vertices). However, analogous to Matthew's Bound for static graphs [26, Chapter 11.2], all the *stated* upper bounds on hitting times can be converted into upper bounds on cover times at the cost of an additional $O(\log n)$-factor.

▶ Remark 1.2. Unlike static graphs where the gap between cover and hitting time is $O(\log n)$ (thanks to Matthew's Bound), for evolving graphs the gap could be $\Omega(n)$ even if the sequence consists of regular connected graphs. For example, for any $t \leqslant cn \ln n$, let $G^{(t)}$ be a complete graph with n vertices, while for any $t > cn \ln n$, let $G^{(t)}$ be a cycle with n vertices. We can choose the constant c so that, with probability $1 - \Theta(n^{-1})$, every fixed vertex is visited before $cn \ln n$ steps, but with constant nonzero probability, there is at least one unvisited vertex which is at distance $\Omega(n)$ from the location of the walk at step $cn \ln n$. This yields a $\Theta(n)$ maximum hitting time, but a $\Theta(n^2)$ cover time.

▶ Remark 1.3. Since the stationary distribution of a random walk depends only on the degrees of the vertices, having the same stationary distribution means that the degrees in each graph of the sequence are the same up to scaling.

A natural question is of course under which conditions the worst-case bound on the hitting time can be improved. For static graphs, it has been observed that for many regular networks, the hitting time is indeed optimal, i.e., $O(n)$. One very general and unifying condition is the conjecture of Aldous and Fill [1, Open Problem 6.20] stating that for any bounded-degree, d-regular graph, an isoperimetric dimension of $2 + \varepsilon$ is enough for hitting times to be linear (which is as good as possible). Since the isoperimetric dimension is equal to the dimension of grids, it follows that grids of dimension 3 or higher have a linear hitting time, while grids of dimension 2 have a hitting time of $O(n \log n)$.

For static graphs, a positive answer to the above conjecture by Aldous and Fill was first given by [5], and another proof was found by [2]. Both these proofs, however, exploit the connection between hitting times and electrical resistances [8], which is not known to exist for *general* evolving graphs (however, for a special class of *randomly* evolving graphs such a connection has been used in [4, Theorem 18]). Since our techniques for bounding hitting times are more probabilistic in nature and avoid arguments based on electrical networks, we are able to show that the conjecture by Aldous and Fill is true even in a dynamic setting.

▶ **Main Result 2** (restated, see Theorem 4.2 on page 9). *Let $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ be a sequence of n-vertex graphs such that each $G^{(t)}$ is regular, has bounded degree, and satisfies the following isoperimetric condition: there exists $\varepsilon \in [0, 1/4]$ such that, for any subset of vertices A with $1 \leqslant |A| \leqslant n/2$, $|E(A, V \setminus A)| = \Omega(|A|^{\frac{1}{2}+\varepsilon})$. Then,*

1. $t_{mix}(\mathcal{G}) = O(n^{1-2\varepsilon})$,
2. $\left|\frac{p_{u,v}^{[0,t]}}{n} - 1\right| = O\left(\frac{1}{t^{1+2\varepsilon}}\right)$,
3. $t_{hit}(\mathcal{G}) = O(n)$ *if* $\varepsilon > 0$, $t_{hit}(\mathcal{G}) = O(n \log n)$ *if* $\varepsilon = 0$.

Note that the isoperimetric condition essentially says that each graph in the sequence must be at least as well-connected as a $(2 + \varepsilon)$-dimensional grid. For $\varepsilon = 0$, we recover the $O(n \log n)$ hitting time for static two-dimensional grids. Both of these cases might be relevant in certain applications of moving wireless devices or robots performing terrain exploration.

The first two results apply to settings where there is a "stable connectivity", but each graph in the sequence may have a relatively poor expansion. The next result applies to scenarios where connectivity is more intermittent, in fact some of the vertices may even be

isolated at some time steps. However, "averaging" over a sufficiently long time window, the graph will not only be connected but might also satisfy some reasonably strong expansion guarantee. In this sense, this model is somewhat related to that of [22], which stipulates the existence of a spanning subgraph over any time-interval of a certain length. More formally, in the next theorem we assume that the random walk is on a sequence $\mathcal{G}$ of graphs with transition matrices $P^{(1)}, P^{(2)}, ...$ and there exists a time-independent distribution π which is stationary for any $P^{(i)}$. We remark that we do not assume connectivity and, therefore, any individual $P^{(i)}$ might have multiple stationary distributions. We assume, however, that there exists a large enough time window t such that, for any $i \geqslant 1$, $\overline{P}^{[i,i+t]} = \frac{1}{t}(P^{(i)} + P^{(i+1)} + \cdots + P^{(i+t)})$ is ergodic with a unique stationary distribution π and spectral gap $\lambda(\overline{P}^{[i,i+t]}) \geqslant \lambda > 0$. We then can show that the distribution of a lazy random walk on $\mathcal{G}$ converges to π at a rate that depends on t and the spectral gap λ. We refer to Section 5 for details on the set-up.

▶ **Main Result 3** (restated, see Corollary 5.3 on page 11)**.** *Consider a dynamically evolving sequence $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ of graphs with transition matrices $\{P^{(i)}\}_{i=1}^{\infty}$ such that (1) there exists π which is a stationary distribution for any $P^{(i)}$; and (2) there exists a time-window $t \geqslant 0$ such that, for any $i \geqslant 0$, $\overline{P}^{[i,i+t]} = \frac{1}{t}(P^{(i)} + P^{(i+1)} + \cdots + P^{(i+t)})$ is ergodic and has spectral gap $\lambda\big(\overline{P}^{[i,i+t]}\big) \geqslant \lambda > 0$. Then, $t_{mix}(\mathcal{G}) = O\left(t^2 \log(1/\pi_*)\lambda^{-1}\right)$, where $\pi_* = \min_u \pi(u)$.*

This result is not only significant in the context of dynamically evolving graphs, but also in settings of static graphs where communication is restricted to a bounded-degree subgraph which potentially changes in each round. One prominent example are matching-based communications, where in each round a random matching is generated and only those edges can be used for averaging or exchanging information, e.g., [7].

Even when the assumptions of Main Theorem 3 are satisfied for a *small* time-window t, we cannot always guarantee that hitting and mixing times will be polynomial in the size of the graphs. Indeed, we exhibit examples of dynamic evolving graphs of n vertices that satisfy such conditions but have mixing and/or hitting times that are exponential in n and t. We show in Proposition 5.5 that, since graphs in the sequences need not be connected, it is possible to construct examples where the stationary distribution π has exponentially small probability mass on some vertices. This could result in exponential mixing and hitting times, but somewhat surprisingly also possibly in polynomial mixing time and exponential maximum hitting time. Both of the constructed graph sequences rely on the idea of simulating a directed graph by a sequence of disconnected bipartite graphs. We note that the idea of simulating directed graphs with a sequence of evolving graphs was introduced in [4], where it is shown how to simulate a directed graph by a sequence of connected evolving graphs with *varying* stationary distribution. In contrast, our result rely on simulating dynamic graphs with a sequence of disconnected evolving graphs with the *same* stationary distribution.

A natural question is whether we can relax the assumptions on the regularity or existence of a time-invariant stationary distribution. Unfortunately, we show that this is not always possible. We exhibit in Proposition 5.4 a sequence of graphs which are connected, have bounded-degree and constant spectral gap, but for which t-step probabilities are very far from the uniform distribution even for a time t which is larger than the mixing time of a random walk on any (static) graph in the sequence.

Going back to Main Result 2, the essence behind the proof is that, to achieve an optimal $O(n)$ hitting time, we do not need large sets to have high expansion. What we only need is that small sets have a "sufficiently high" expansion. We derive another result in the same spirit by upper bounding a variational characterisation of the commute time in terms of

some version of the conductance profile [27]. However, since we need to exploit a variational characterisation of the commute time, as opposed to the earlier results, this bound only holds for static graphs. Let C_{st} be the commute time from s to t. Then, we have the following.

▶ **Main Result 4** (restated, see Lemma 6.1 on page 12)**.** *For any static graph $G = (V, E)$ and $s, t \in V$, there exists a labelling of the vertices from 1 to n such that $C_{st} \leqslant 2m \sum_{j=1}^{n-1} |\partial[j]|^{-1}$, where $\partial[j]$ is the set of edges with one endpoint in $\{1, \ldots, j\}$ and one in $\{j+1, \ldots, n\}$.*

Note the relation between Main Theorem 4 and the well-known Nash-Williams' inequality [26, Proposition 9.15] which states that, for every set $\{E_1, E_2, \ldots, E_k\}$ of edge-disjoint cut-sets separating s from t, $C_{st} \geqslant 2m \sum_{j=1}^{k} |E_j|^{-1}$. Our upper bound, however, differs from the Nash-Williams' inequality in two ways: (1) the cut-sets $\partial[j]$ are in general not edge-disjoint; (2) we prove the existence of a "good" labelling, while Nash-Williams holds for *any* labelling.

As an application of this result, we consider the hitting time on d-regular graphs in terms of the edge-connectivity (i.e., the smallest number of edges that would need to be removed to make the graph disconnected), which does not impose any condition on the expansion of large sets.

▶ **Main Result 5** (restated, see Theorem 6.3 on page 13)**.** *Let $G = (V, E)$ be any static d-regular graph with edge-connectivity ρ. Then $t_{hit}(\mathcal{G}) \leqslant O(n^2 \cdot (\frac{\log d}{d} + \frac{1}{\rho}))$. In particular, since $\rho \leqslant d$, we get the simpler (but potentially slightly weaker) upper bound $t_{hit}(\mathcal{G}) = O(n^2 \log d/\rho)$.*

We remark that in Aldous and Fill [1, Proposition 6.22], it was shown that for any d-regular graph G which is ρ-edge-connected, the maximum hitting time is $O(n^2 d \cdot \rho^{-3/2})$. They also mention that if the graph is $\Omega(d)$-edge-connected, they obtain a bound of $O(n^2 \cdot d^{-1/2})$. For this case of maximal edge-connectivity, $\rho = \Theta(d)$, our bound is considerably better than the one by Aldous and Fill, and, modulo the $\log d$-factor, gives also the right dependency on d. In particular, we demonstrate in Section 6 that the dependency on the edge-connectivity ρ is as good as possible (neglecting logarithmic factors) in the sense that for any pair of ρ and d, there exists a d-regular graph with edge-connectivity ρ which matches the upper bound in Main Result 5 (Theorem 6.3) up to constant factors.

Further Related Work. While in this work we focus on standard (lazy) random walks on graphs, we should point out that previous work has established an alternative in form of the so-called *max-degree walk* [4, 12]. In this random walk variant, a large loop probability depending on the degree of the current vertex and (an estimate of) the maximum degree Δ is added. With this modification, the stationary distribution of each graph is identical (and uniform), which makes the analysis of this walk easier. However, one downside of this approach is that it either requires a good estimate of Δ (or even n), or the random walk may potentially be slowed down significantly. Also, studying standard random walks seems more natural and, as we will see later, it also helps us to uncover some of the subtle boundaries between fast mixing and polynomial hitting, and slow mixing and exponential hitting.

One of the earliest appearances of dynamic graphs is in the context of load balancing [17], where the authors assumed a uniform (i.e., time-independent) lower bound on the edge and vertex expansion. A refinement is to instead relate the balancing (mixing) time to the geometric mean of the spectral gaps, which was used in [13]. A result of a similar flavour for both the conductance and the vertex expansion was shown in [18] in the context of randomised rumour spreading, and more recently a similar result was shown for the voter model [6]. In [22], the authors analyse a sequence of graphs satisfying a T-interval

connectivity property, which asserts that for every T consecutive rounds there exists a stable connected spanning subgraph. The authors present upper bounds for several distributed computational problems.

One specific graph model that has been very popular is the so-called Markovian evolving graph. In this model every edge is associated to the same but independent two-state birth and death chain which decides whether the edge is present or not in the next step. Many aspects of this network have been studied, most notably the (dynamic) diameter [10] and the time to spread a piece of information [11]. Recently, however, Lamprou et al. [25] also considered the cover time of these graphs. In particular, suppose there exists an underlying graph G with minimum degree δ such that at each time t the graph $G^{(t)}$ contains each edge in G independently with probability p (i.e., the presence of an edge does not depend on the past). They show the cover time of such dynamic graph is at most $t_{\mathsf{cov}}(G)/(1-(1-p)^{\delta})$, where $t_{\mathsf{cov}}(G)$ is the cover time of G. They also study *random walks with a delay*, where at each step a particle chooses a random neighbour of the current vertex according to the topology of the underlying graph G, and moves there if the corresponding edge is present, otherwise waits till it becomes available. For this perhaps slightly less natural process, they give bounds on the cover time also for the case where the probability of an edge being available at time t depends on whether that edge was available at time $t-1$. We also highlight dynamical percolation, a particular type of Markovian evolving graphs that has received recent attention (see, e.g., [20, 30, 36]). Here, an "open" edge becomes "close" with probability p, while a close edge becomes open with probability $1-p$. In contrast to the literature above, however, works on random walks on dynamical percolation usually refer to continuous-time random walks.

Another class of dynamic graph models involves agents that move in some bounded space and can interact only if they are close enough [24, 29, 31]. In contrast to these works, our bounds are less tight but hold under much weaker assumptions on the graph and therefore capture a more dynamic and less "regular" setting.

Finally, we mention that Saloff-Coste and Zuniga [32, 33] have generalised spectral and geometric techniques, such as Nash and log-Sobolev inequalities, to time-inhomogeneous Markov Chains (of which random walks on dynamic graphs are a subset). In particular, in contrast to our results, they study chains where the individual transition matrices might not have the same time-independent stationary distribution. For this reason, they focus on *merging* properties of these chains, i.e., the ability of the chain to "forget" the initial distribution. They obtain bounds on merging for chains that satisfy the c-stability property, which implies (but it is not equivalent) that the stationary distributions of the individual transition matrices do not change too much over time. Unfortunately, proving that a time-inhomogeneous chain is c-stable is itself very difficult, and they are able to obtain concrete bounds on merging only for very simple time-inhomogeneous Markov chains.

2 Notation and preliminaries

Let $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ be an infinite sequence of undirected and unweighted graphs defined on the same vertex set V, with $|V| = n$. We study (lazy) random walks on $\mathcal{G}$: suppose that at a time $t \geqslant 0$ a particle occupies a vertex $u \in V$. At step $t+1$ the particle will remain at the same vertex u with probability $1/2$, or will move to a random neighbour of u in $G^{(t)}$. In other words, it will perform a single random walk step according to a transition matrix $P^{(t)}$, which is the transition matrix of a lazy random walk on $G^{(t)}$: $P^{(t)}(u,u) = 1/2$, $P^{(t)}(u,v) = 1/(2d_u)$ if there is an edge between u and v in $G^{(t)}$ (and in this case we write

$u \sim_t v$), or $P^{(t)}(u,v) = 0$ otherwise. We denote with $p_{u,v}^{[t_1,t_2]}$ the probability that a random walk that visits vertex $u \in V$ at time t_1 will visit $v \in V$ at time $t_2 \geqslant t_1$. Notice that given an initial probability distribution $p^{(0)} : V \to [0,1]$, $p^{[0,t]} = p^{(0)}P^{[0,t]} = p^{(0)}P^{(1)}P^{(2)}\cdots P^{(t)}$ is the probability distribution after t steps.

Unless stated otherwise we assume that all the graphs in $\mathcal{G}$ are connected and have the same stationary distribution π, i.e., $\pi P^{(t)} = \pi$ for any $t \geqslant 0$. We denote the smallest value assumed by π as $\pi_* = \min_{x\in V} \pi(x)$. We define the $\ell_2(\pi)$-inner product as $\langle f, g\rangle_\pi = \sum_{u\in V} f(u)g(u)\pi(u)$ for any $f, g : V \to \mathbb{R}$. Analogously, we denote with $\|f\|_{2,\pi} = \sqrt{\langle f, f\rangle_\pi}$ the $\ell_2(\pi)$-norm of $f : V \to \mathbb{R}$. Notice that since all the graphs in $\mathcal{G}$ are undirected, for any $t \geqslant 0$, $P^{(t)}$ is reversible with respect to π, i.e., $\pi(x)P^{(t)}(x,y) = \pi(y)P^{(t)}(y,x)$ for any $x, y \in V$ (this is also called the detailed balance condition). Moreover, $P^{(t)}$ is self-adjoint for the $\ell_2(\pi)$-inner product: for any $f, g : V \to \mathbb{R}$,

$$\langle P^{(t)}f, g\rangle_\pi = \langle f, P^{(t)}g\rangle_\pi. \tag{1}$$

We will often work with the likelihood ratio $\rho_{u,\cdot}^{[0,t]} = p_{u,\cdot}^{[0,t]}/\pi(\cdot)$. When it is clear from the context, we will drop the starting point u and use the shorthands $p^{(t)}$ and $\rho^{(t)}$ to indicate (respectively) the probability distribution of the random walk at time t and its likelihood ratio. We define the ℓ_2 mixing time as

$$t_{\mathsf{mix}}(\mathcal{G}) = \min\{t\colon \|\rho_{u,\cdot}^{[0,t]} - 1\|_{2,\pi} \leqslant 1/3 \text{ for any } u \in V\}.$$

Observe that, since $\mathbb{E}_\pi \rho^{(t)} = 1$, we have that $\|\rho^{(t)} - 1\|_{2,\pi}^2 = \mathrm{Var}_\pi \rho^{(t)} = \mathbb{E}_\pi \left(\rho^{(t)}\right)^2 - 1$.

Let p be a probability distribution with likelihood ratio $\rho = p/\pi$. For a reversible P,

$$P\rho(u) = \sum_{v\in V} P(u,v)\rho(v) = \sum_{v\in V} P(u,v)\frac{p(v)}{\pi(v)} = \frac{1}{\pi(u)}\sum_{v\in V} P(v,u)p(v) = \frac{pP(u)}{\pi(u)},$$

from which it follows that $P^{(t)}\cdots P^{(1)}\rho^{(0)}(u) = \rho^{(t)}(u)$.

Given a transition matrix P with stationary distribution π and a function $f\colon V \to \mathbb{R}$, we define the Dirichlet form as

$$\mathcal{E}_P(f,f) = \frac{1}{2}\sum_{u,v\in V} (f(u) - f(v))^2\,\pi(u)P(u,v).$$

When P is a transition matrix of a lazy random walk on a graph $G = (V,E)$ with $|E| = m$, $\mathcal{E}_P(f,f) = \frac{1}{4m}\sum_{u\sim v}(f(u) - f(v))^2$, where $u \sim v$ stands for $\{u,v\} \in E$. As long as P is lazy (i.e., $P(u,u) \geqslant 1/2$ for any $u \in V$), we can relate the ℓ_2^2 distance of a distribution from stationary to its Dirichlet form [16, Proposition 2.5]:

$$\mathrm{Var}_\pi \rho^{(t)} \geqslant \mathrm{Var}_\pi \rho^{(t+1)} + \mathcal{E}_{P^{(t+1)}}(\rho^{(t)}, \rho^{(t)}). \tag{2}$$

The *spectral gap* of P is defined as

$$\lambda(P) = \inf_{\substack{f:V\to\mathbb{R}\\ \mathrm{Var}_\pi f\neq 0}} \frac{\mathcal{E}_P(f,f)}{\mathrm{Var}\, f}.$$

We denote with $\Phi_P(A)$ the *conductance* of a subset of vertices $A \subset V$:

$$\Phi_P(A) = \frac{\sum_{u\in A, v\notin A}\pi(u)P(u,v)}{\min\{\pi(A), \pi(V\setminus A)\}},$$

where $\pi(A) = \sum_{u \in A} \pi(u)$. The conductance of P is then defined as $\Phi(P) = \min_{A \subset V} \Phi_P(A)$. Cheeger's inequality [35] relates $\lambda(P)$ to the conductance $\Phi(P)$ of a reversible P: $2\Phi(P) \geqslant \lambda(P) \geqslant \Phi(P)^2/2$.

Given two vertices u and v, we denote with $\tau_{u,v}$ the *hitting time* of v from u, i.e., the expected time to reach v starting from u. The maximum hitting time is defined as $t_{\mathsf{hit}}(\mathcal{G}) = \max_{u,v} \tau_{u,v}$. The *commute time* between u and v, denoted by $C_{u,v}$, is defined as the expected time for a random walk starting from u, to reach v and then return to u.

Finally, we write $A \lesssim B$, respectively $A \gtrsim B$, to mean that there exists some absolute constant $C > 0$, independent of the parameters of the sequence of graphs $\mathcal{G}$, such that $A \leqslant C \cdot B$, respectively $A \geqslant C \cdot B$.

3 Worst-case bounds for mixing and hitting times

In this section we assume that a particle performs a random walk on a sequence of graphs $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ where all the $G^{(t)}$ share the same set of n vertices V, are connected, and have a time-independent stationary distribution π with $\pi_* = \min_u \pi(u)$. In general, graphs in the sequence might have a different number of edges, but the ratio degree of a node over total number of edges remains the same. We denote with $m^* \leqslant n^2$ the maximum number of edges a graph in the sequence can have.

Our goal is to bound mixing and maximum hitting times of a random walk on $\mathcal{G}$. We start by studying the rate of convergence to stationarity. By equation (2), our goal then becomes to study $\operatorname{Var} \rho^{(t)} \leqslant \operatorname{Var} \rho^{(0)} - \sum_{i=1}^{t-1} \mathcal{E}_{P^{(i)}}(\rho^{(i-1)}, \rho^{(i-1)})$. The next lemma provides a lower bound on the Dirichlet form of graphs in $\mathcal{G}$. The main insight of this lemma is that it shows a faster decrease of the ℓ_2-distance to stationarity when this distance is large, i.e., at the beginning of the walk. This is in the same vein as, for example, bounds on mixing based on the spectral profile [19].

▶ **Lemma 3.1.** *Let P be the transition matrix of a lazy random walk on a graph $G \in \mathcal{G}$. Given a probability distribution $\sigma : V \to [0,1]$ with likelihood ratio $f = \sigma/\pi$ such that $\operatorname{Var}_\pi f = \varepsilon > 0$,*

$$\mathcal{E}_P(f,f) \gtrsim \max\left\{\frac{\varepsilon^2}{m^* + 1/(\pi_*^2(1+\varepsilon))}, \frac{\pi_* \varepsilon^2}{n}\right\}.$$

While the previous lemma will be directly used to derive bounds on mixing, to obtain a bound on the hitting time we will need to study t-step probabilities. For this reason, we prove a technical lemma that relates $2t$-step probabilities to the variance of the likelihood ratio of a t-step probability distribution, generalising a well-known result for time-homogeneous reversible Markov chains (see, e.g., [1, Lemma 3.20]). We remark, however, that while in time-homogeneous Markov chains $2t$-step transition probabilities will be as small as the variance of their t-step likelihood ratio, in our case, since the order in which transition matrices are applied can matter significantly, this might not be necessarily true: we can only relate these probabilities to the variance of the t-step likelihood ratio of a related but slightly different Markov chain.

▶ **Lemma 3.2.** *Let $t_1 < t_2$. Then, for any $u, v \in V$, it holds that*

$$\left|\rho_{v,u}^{[t_1,t_2]} - 1\right| \leqslant \max\left\{\operatorname{Var}_\pi\left(P^{(\lfloor \frac{t_1+t_2}{2} \rfloor)} \cdots P^{(t_2)} \rho_{u,\cdot}^{[t_1,t_1]}\right), \operatorname{Var}_\pi\left(P^{(\lfloor \frac{t_1+t_2}{2} - 1 \rfloor)} \cdots P^{(1)} \rho_{v,\cdot}^{[t_1,t_1]}\right)\right\}.$$

Using Lemma 3.1 and Lemma 3.2 we can obtain almost optimal worst case bounds on mixing, hitting, and t-step probabilities of a random walk on $\mathcal{G}$. In particular, when $\mathcal{G}$ comprises only regular graphs, the next theorem implies a $O(n^2)$ bound on mixing and

hitting times, which matches the well-known results for a random walk on a static undirected graph. In the general non-regular case, we prove a $O(n^3)$ bound on mixing and a $O(n^3 \log n)$ bound on hitting, which almost matches the $O(n^3)$ bound for mixing and hitting in static graphs. This improves upon [4], which presents a bound of $O(n^3 \log n)$ for hitting on regular graphs and a bound of $O(n^5 \log n)$ for hitting in the general case.

▶ **Theorem 3.3.** *Let $\mathcal{G}$ be a sequence of connected graphs with n vertices, the same stationary distribution π, and at most m^* edges in each graph. Then, for a lazy random walk on $\mathcal{G}$:*

1. $t_{mix}(\mathcal{G}) = O(n/\pi_*)$,
2. $\left|\frac{p_{u,v}^{[0,t]}}{\pi_v} - 1\right| \lesssim \frac{m^*}{t} + \frac{1}{\pi_* \sqrt{t}}$, *simplifying to* $\left|\frac{p_{u,v}^{[0,t]}}{\pi_v} - 1\right| \lesssim \frac{n}{\sqrt{t}}$ *if all the graphs in $\mathcal{G}$ are d-regular,*
3. $t_{hit}(\mathcal{G}) = O(n \log n/\pi_*)$. *Furthermore, if the graphs in $\mathcal{G}$ are d-regular, $t_{hit}(\mathcal{G}) = O(n^2)$.*

The proof, which is omitted here, proceeds roughly as follows. First we establish the bound on the mixing time based on Lemma 3.1, which readily implies that starting from a distance to stationarity equal to ε, such distance is halved in $O(n/(\varepsilon\pi_*))$ steps. We then connect the distance to stationarity to t-step probabilities with Lemma 3.2, obtaining the second result of Theorem 3.3. Finally, to bound the hitting time, we employ a probabilistic argument already exploited in, e.g., [21], and which makes use of both our bounds on mixing time and on t-step probabilities.

4 Bounds on hitting times based on the isoperimetric dimension

Aldous and Fill conjectured in their book [1, Open Problem 6.20] that whenever a regular bounded-degree graph satisfies $|E(A, A^c)| = \Omega(|A|^{\frac{1}{2}+\varepsilon})$ for any small positive ε, the maximum hitting time should be $O(n)$. Observe that this isoperimetric condition is satisfied by the torus in 3 or higher dimensions, which has indeed $O(n)$ maximum hitting time. Furthermore, to have $O(n)$ maximum hitting time, ε needs to be strictly greater than zero: take for example the 2-dimensional torus: there is a set A for which $|E(A, A^c)| = \Theta(|A|^{1/2})$ and, indeed, the maximum hitting time is $\Theta(n \log n)$.

The conjecture was first proved in [5], with a proof based on the relation between commute times and effective resistances in a graph. Since a similar relation is not known for time-inhomogeneous Markov chains, such a proof cannot be generalised to random walks on dynamic graphs. In this section we present a new proof of this result based on the "conditional expectation trick" already used in the proof of Theorem 3.3. We start by obtaining a bound on the Dirichlet form of a graph satisfying the aforementioned isoperimetric condition.

▶ **Lemma 4.1.** *Let $G = (V, E)$ be a d-regular undirected graph with $|V| = n$ and $d = O(1)$ such that, for any $A \subset V$ with $1 \leqslant |A| \leqslant n/2$, $|E(A, V \setminus A)| = \Omega(|A|^{\frac{1}{2}+\varepsilon})$ for $1/4 \geqslant \varepsilon \geqslant 0$. Consider the transition matrix P of a lazy random walk in G. Let σ be any probability distribution and $f = \sigma/\pi$, where π is the uniform distribution. If $\mathbb{E}_\pi f^2 = \beta > C$ for a large enough constant C, then*

$$\mathcal{E}_P(f, f) \gtrsim \frac{\beta^{2-2\varepsilon}}{n^{1-2\varepsilon}}.$$

We now apply the previous lemma to prove the main result of this section in an analogous way to the proof of Theorem 3.3.

▶ **Theorem 4.2.** *Let $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ be a sequence of n-vertex graphs such that each $G^{(t)}$ is regular, has bounded degree, and satisfies the following isoperimetric condition: there exists $\varepsilon \in [0, 1/4]$ such that, for any subset of vertices A with $1 \leqslant |A| \leqslant n/2$, $|E(A, V \setminus A)| = \Omega(|A|^{\frac{1}{2}+\varepsilon})$. Then,*

1. $t_{mix}(\mathcal{G}) = O(n^{1-2\varepsilon})$,
2. $\left|\frac{p_{u,v}^{[0,t]}}{n} - 1\right| = O\left(\frac{1}{t^{1+2\varepsilon}}\right)$,
3. $t_{hit}(\mathcal{G}) = O(n)$ *if* $\varepsilon > 0$, $t_{hit}(\mathcal{G}) = O(n \log n)$ *if* $\varepsilon = 0$.

5 Bounds on mixing based on average transition probabilities

Unlike in the time-homogeneous case, eigenvalues of the individual transition matrices of a time-inhomogenous Markov chain are not necessarily indicative of its mixing time, even when there exists a unique time-independent stationary distribution. An emblematic example is the following: consider a sequence of graphs $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ defined over a vertex set $V = \{1, \ldots, 2n\}$ such that, at odd t, $G^{(t)}$ is the union of two expanders (graphs with constant spectral gap), one over $\{1, \ldots, n\}$, the other over $\{n+1, \ldots, 2n\}$, while at even t, $G^{(t)}$ is a perfect matching between $\{1, \ldots, n\}$ and $\{n+1, \ldots, 2n\}$. Since all the graphs are disconnected, each transition matrix has spectral gap equals to 0, and eigenvalue bounds are, in this case, useless to analyse convergence to stationarity. On the other hand, it is quite clear that a lazy random walk on $\mathcal{G}$ mixes in $\Theta(\log n)$ time.

A more precise way to study mixing in time-inhomogeneous random walks would be to consider the spectral gap of the product of the transition matrices $P^{(1)} \cdots P^{(t)}$. Unfortunately, spectral bounds for the product of matrices are notoriously hard to come by. What is significantly easier is to study the *average* transition matrix $\overline{P} = \frac{1}{t}\left(P^{(1)} + P^{(2)} + \cdots + P^{(t)}\right)$, which at least does not depend on the order in which the transition matrices appear. For this reason, in this section we give bounds on mixing on $\mathcal{G}$ that depend on the Dirichlet form of $\overline{P}$. In particular, consider the aforementioned example where $G^{(t)}$ is two disjoint expanders at odd times, and a perfect matching between the two sets at even times. Consider the average transition matrix $\overline{P} = \frac{1}{2}\left(P^{(\ell)} + P^{(\ell+1)}\right)$ for any two consecutive steps $\ell, \ell+1$: $\overline{P}$ is just the transition matrix of a random walk on an expander graph defined over the entire set of vertices. Our results, then, make us easily derive the correct bound $t_{\mathsf{mix}}(\mathcal{G}) = O(\log n)$.

Throughout this section we assume that $\mathcal{G} = \{G^{(t)}\}_{t=1}^{\infty}$ is a sequence of undirected graphs over a vertex set V with $|V| = n$. The graphs are not necessarily connected, which means they might have multiple stationary distributions. We require, however, that there exists a time-independent distribution π which is a stationary distribution for all the graphs in $\mathcal{G}$. Fixing a time interval $[t_1, t_2]$, we consider $\overline{P} = \frac{1}{t_2 - t_1}\left(P^{(t_1)} + \cdots + P^{(t_2)}\right)$. We consider time intervals for which $\overline{P}$ is irreducible. Note since the transition matrices $\{P^{(i)}\}_i$ are strongly aperiodic and reversible with respect to π, so is $\overline{P}$. Therefore, we can always assume that $\overline{P}$ is ergodic and has a unique stationary distribution π, unlike the individual matrices $P^{(i)}$.

For simplicity, we assume in our proofs that each graph in $\mathcal{G}$ has the same number of edges m. Our results, however, also hold for sequences of graphs with different edges densities.

Notice that, by the detailed balance condition, if $u \sim_i v$ for some step i, $\pi(u)/\pi(v) = d_u/d_v$, where d_u and d_v are, respectively, the (time-independent) degrees of u and v[1]. In particular, this means there exists some $\alpha_u \geqslant 0$, which is independent from t, such that $\pi(u) = \alpha_u d_u / 2m$ and $\pi(v) = \alpha_u d_v / 2m$.

[1] it may happen that u is isolated in some round i, leading to u having degree 0 in that round. However, in that case, u can be safely ignored when computing $\mathcal{E}_{P^{(i)}}$. Hence, because the stationary distribution is always the same and so is the number of edges, we may assume that the degree of u is always d_u

▶ **Lemma 5.1.** *Let $p^{(0)}$ be an arbitrary initial probability distribution, and $\rho^{(0)} = p^{(0)}/\pi$. Suppose that for some $t \geqslant 1$ and $u \in V$, $|\rho^{(t)}(u) - \rho^{(0)}(u)| \geqslant \varepsilon > 0$. Then,*

$$\operatorname{Var}_\pi \rho^{(0)} - \operatorname{Var}_\pi \rho^{(t)} \geqslant \frac{\alpha_u}{4m} \sum_{i=1}^{t} \sum_{v \sim_i u} \left(\rho^{(i-1)}(u) - \rho^{(i-1)}(v)\right)^2 \geqslant \frac{2\varepsilon^2 \pi(u)}{t}.$$

We are now able to relate $\operatorname{Var}_\pi \rho^{(0)} - \operatorname{Var}_\pi \rho^{(t)}$ to $\mathcal{E}_{\overline{P}}(\rho^{(0)}, \rho^{(0)})$. The proof of the next theorem works roughly as follows. We divide the vertices in two classes: U contains all the vertices for which there exists an $1 \leqslant i \leqslant t-1$ such that $\rho^{(i)}(u)$ differs *significantly* from $\rho^{(0)}(u)$, while $V \setminus U$ contains the rest. We then use Lemma 5.1 to lower bound the contribution given by vertices in U to $\operatorname{Var}_\pi \rho^{(0)} - \operatorname{Var}_\pi \rho^{(t)}$. Since for $u \notin U$, $\rho^{(i)}(u)$ has not changed much from $\rho^{(0)}(u)$, we can instead directly lower bound its contribution to $\operatorname{Var}_\pi \rho^{(0)} - \operatorname{Var}_\pi \rho^{(t)}$ just looking at its contribution to $\mathcal{E}_{\overline{P}}(\rho^{(0)}, \rho^{(0)})$.

▶ **Theorem 5.2.** *Given a time interval of length t labelled $[1, t]$, let $\overline{P} = \frac{1}{t}(P^{(1)} + P^{(2)} + \cdots + P^{(t)})$ with spectral gap $\lambda(\overline{P})$. Then, for any initial probability distribution $p^{(0)}$ with likelihood $\rho^{(0)} = p^{(0)}/\pi$, it holds that*

$$\operatorname{Var}_\pi \rho^{(0)} - \operatorname{Var}_\pi \rho^{(t)} \geqslant \frac{1}{15t} \mathcal{E}_{\overline{P}}(\rho^{(0)}, \rho^{(0)}) \geqslant \frac{\lambda(\overline{P})}{15t}.$$

We remark we do not know if the dependency of t in the bound of Theorem 5.2 (which appears as a result of an application of the Cauchy-Schwarz inequality) is tight, or even if any dependency on t is needed at all.

From Theorem 5.2 it is easy to derive the following corollary:

▶ **Corollary 5.3.** *Given a lazy random walk on a sequence $\mathcal{G}$ of graphs with transition matrices $\{P^{(i)}\}_{i=1}^{\infty}$ such that (1) there exists π which is a stationary distribution for any $P^{(i)}$; (2) a time-window $t \geqslant 0$ such that, for any $i \geqslant 0$, $\overline{P}^{[i,i+t]} = \frac{1}{t}(P^{(i)} + P^{(i+1)} + \cdots + P^{(i+t)})$ is ergodic and has spectral gap $\lambda\big(\overline{P}^{[i,i+t]}\big) \geqslant \lambda > 0$. Then, $t_{mix}(\mathcal{G}) = O\big(\frac{t^2 \log(1/\pi_*)}{\lambda}\big)$.*

To highlight the applicability of Corollary 5.3, consider a sequence of connected graphs $\mathcal{G}$ with time-independent stationary distribution π in which, for any interval of t consecutive steps and subset of vertices A, there exists a transition matrix $P^{(i)}$ of a graph in the interval such that $\Phi_{P^{(i)}}(A) \geqslant \phi$. Then, $\Phi\left(\overline{P}\right) \geqslant \phi/t$ and $\lambda\left(\overline{P}\right) \geqslant \phi^2/t^2$. Hence, Corollary 5.3 gives us that $t_{\mathsf{mix}}(\mathcal{G}) = O(t^3 \log n/\phi^2)$.

Another natural question is whether our condition on the stationary distribution being fixed could be relaxed. This question is answered negatively by the following result:

▶ **Proposition 5.4.** *For any $t = \omega(\log n)$, there is a sequence of connected n-vertex bounded-degree expander graphs $\mathcal{G} = \{G^{(i)}\}_{i=1}^{\infty}$ and a constant $c > 0$ so that $p_{u,v}^{(t)} \geqslant n^{-1+c}$ for some vertices u and v.*

In Section 3 and Section 4 we have shown that the behaviour of a lazy random walk on a sequence of *connected* graphs with the same stationary distribution is comparable to the behaviour of random walks on static graphs, at least regarding mixing and hitting times. When the graphs are disconnected, however, the behaviour of random walks on dynamic graphs becomes more complicated. Theorem 5.2 shows that, if every t steps the average of the transition matrices applied in those steps is irreducible and strongly aperiodic with stationary distribution π, then the random walk will converge to π. However, π can be highly imbalanced and, as a result, mixing and hitting can be exponential in t and the number of vertices n. The next proposition shows an example of this behaviour.

▶ **Proposition 5.5.** *There is a sequence of n-vertex bounded-degree graphs $\mathcal{G} = \{G^{(i)}\}_{i=1}^{\infty}$ with transition matrices $\{P^{(i)}\}_{i=1}^{\infty}$ and a probability distribution π such that (1) for any i, π is stationary for $P^{(i)}$; (2) the average transition matrix $\overline{P}$ of any $4n$ consecutive steps is ergodic; (3) for any $t \geqslant 0$ there are two vertices u, v such that $p_{u,v}^{[0,t]} \leqslant 2^{-(n/4)-2}$. Moreover, $t_{mix}(\mathcal{G}) = O(\text{poly}(n))$, while $t_{hit}(\mathcal{G}) = 2^{\Omega(n)}$. There is also a sequence $\mathcal{G}'$ satisfying (1), (2), and (3) such that $t_{mix}(\mathcal{G}) = 2^{\Omega(n)}$.*

6 Bounds in terms of average edge connectivity

Recall that in Section 4 we proved several bounds which hold for graphs with sufficient expansion for small sets of vertices. Following a different direction, we now derive bounds on commute times for random walks on d-regular *static* graphs based on *average* connectivity measures (see the end of Section 2 for some basic relations between the commute time and hitting time). We assume $G = (V, E)$ is a connected, undirected and static graph with vertex set $V = \{1, \ldots, n\}$ and m edges. We denote with P the transition matrix of a lazy random walk on G and π its stationary distribution. Given A, B, the probability flow between A and B is defined as $\sum_{u \in A} \sum_{v \in B} \pi(u)P(u, v)$. The edge boundary of A, denoted with ∂A, is the set of edges with one endpoint in A and one in $V \setminus A$. For ease of notation we define $[i] = \{1, \ldots, i\}$. Also recall that we denote with C_{st} the expected commute time between s and t. We will use the following variational characterisation of the average commute time (see Aldous and Fill, [1, Theorem 3.36]):

$$C_{st} = \max_{g\colon V \to \mathbb{R}} \{1/\mathcal{E}_P(g, g)\colon 0 \leqslant g \leqslant 1, g(s) = 0, g(t) = 1\}. \tag{3}$$

▶ **Lemma 6.1.** *For any graph $G = (V, E)$ and $s, t \in V$, there exists a labelling of the vertices from 1 to n such that*

$$C_{st} \leqslant 2m \sum_{j=1}^{n-1} \frac{1}{|\partial[j]|}.$$

Furthermore, by considering the reversal of the labelling, we can also conclude that $C_{st} \leqslant 4m \sum_{j=1}^{n/2} \frac{1}{|\partial[j]|}$.

Note that the well-known Nash-Williams's inequality [26, Proposition 9.15] gives a very similar lower bound: it states that for every set of edge-disjoint cutsets separating s from t, $\{E_1, E_2, \ldots, E_k\}$, $C_{st} \geqslant 2m \sum_{j=1}^{k} \frac{1}{|E_j|}$. Note that in our upper bound however, the cutsets $\partial[j]$ are in general not edge-disjoint.

Finally, it can be shown that the lemma above holds even for a labelling such that the subgraph induced by $[i]$ is connected for every $1 \leqslant i \leqslant n$.

6.1 Commute times and edge-connectivity

We now apply Lemma 6.1 to obtain a bound on commute times that depends on the edge-connectivity of the graph, improving a result by Aldous and Fill [1, Proposition 6.22].

▶ **Lemma 6.2.** *Let $G = (V, E)$ be any graph with minimum degree δ so that any subset $S \subseteq V$ with $1 \leqslant |S| \leqslant n - 1$ satisfies $|\partial S| \geqslant \rho$ (in other words, G has edge-connectivity at least ρ). Then we have*

$$\sum_{i=1}^{n-1} \frac{1}{|\partial[i]|} = O(n/\delta^2 \cdot \log \delta + n/(\rho\delta)).$$

▶ **Theorem 6.3.** *Let $G = (V, E)$ be any graph with minimum degree δ, average degree $\overline{d}$ and edge-connectivity ρ. Then any commute time is bounded by $O(n^2\overline{d} \cdot (\frac{\log \delta}{\delta^2} + \frac{1}{\delta\rho}))$.*

We remark that Aldous and Fill [16, Proposition 6.22] proved that for any graph G with average degree $\overline{d}$ which is ρ-edge-connected, the maximum commute time is $O(n^2\overline{d} \cdot \rho^{-3/2})$. They also mention that if the graph is $\Omega(d)$-edge-connected, they obtain a bound of $O(n^2 \cdot d^{-1/2})$. For this case of maximal edge-connectivity, $\rho = \Theta(d)$, our bound is considerably better than the one by Aldous and Fill, and, modulo the $\log d$-factor, gives also the correct dependency on d. Furthermore, since the edge-connectivity ρ satisfies $\rho \leqslant \delta \leqslant d$, it is easy to verify that our bound is never worse than the bound in Aldous and Fill. In fact, as soon as $\delta \to \infty$, our upper bound will be asymptotically smaller than the bound by Aldous and Fill.

▶ Remark 6.4. For any pair of ρ and d there is a graph matching the upper bound in Theorem 6.3 up to a factor of $O(\log d)$.

Abstract

We consider algorithms with access to an unknown matrix $\mathbf{M} \in \mathbb{F}^{n \times d}$ via *matrix-vector products*, namely, the algorithm chooses vectors $\mathbf{v}^1, \ldots, \mathbf{v}^q$, and observes $\mathbf{M}\mathbf{v}^1, \ldots, \mathbf{M}\mathbf{v}^q$. Here the $\mathbf{v}^i$ can be randomized as well as chosen adaptively as a function of $\mathbf{M}\mathbf{v}^1, \ldots, \mathbf{M}\mathbf{v}^{i-1}$. Motivated by applications of sketching in distributed computation, linear algebra, and streaming models, as well as connections to areas such as communication complexity and property testing, we initiate the study of the number q of queries needed to solve various fundamental problems. We study problems in three broad categories, including linear algebra, statistics problems, and graph problems. For example, we consider the number of queries required to approximate the rank, trace, maximum eigenvalue, and norms of a matrix $\mathbf{M}$; to compute the AND/OR/Parity of each column or row of $\mathbf{M}$, to decide whether there are identical columns or rows in $\mathbf{M}$ or whether $\mathbf{M}$ is symmetric, diagonal, or unitary; or to compute whether a graph defined by $\mathbf{M}$ is connected or triangle-free. We also show separations for algorithms that are allowed to obtain matrix-vector products only by querying vectors on the right, versus algorithms that can query vectors on both the left and the right. We also show separations depending on the underlying field the matrix-vector product occurs in. For graph problems, we show separations depending on the form of the matrix (bipartite adjacency versus signed edge-vertex incidence matrix) to represent the graph.

Surprisingly, this fundamental model does not appear to have been studied on its own, and we believe a thorough investigation of problems in this model would be beneficial to a number of different application areas.

1 Introduction

Suppose there is an unknown matrix $\mathbf{M} \in \mathbb{F}^{n\times d}$ that you can only access via a sequence of *matrix-vector products* $\mathbf{M}\cdot\mathbf{v}^1,\ldots,\mathbf{M}\cdot\mathbf{v}^q$, where we call the vectors $\mathbf{v}^1,\ldots,\mathbf{v}^q$ the *query vectors*, which can be chosen in a randomized, possibly adaptive way. By adaptive, we mean that $\mathbf{v}^i$ can depend on $\mathbf{v}^1,\ldots,\mathbf{v}^{i-1}$ as well as $\mathbf{M}\mathbf{v}^1,\ldots,\mathbf{M}\mathbf{v}^{i-1}$. Here $\mathbb{F}$ is a field, and we study different fields for different applications. Suppose our goal is to determine if $\mathbf{M}$ satisfies a specific property $\mathcal{P}$, such as having approximately full rank, or for example whether $\mathbf{M}$ has two identical columns. A natural question is the following:

Question 1: How many queries q are necessary to determine if $\mathbf{M}$ has property $\mathcal{P}$?

A number of well-studied problems are special cases of this question, i.e., compressed sensing or sparse recovery, for which $\mathbf{M} \in \mathbb{R}^{1\times d}$ is an approximately k-sparse vector, and one would like a number q of queries close to k. It is known that if the query sequence is non-adaptive, meaning $\mathbf{v}^1,\ldots,\mathbf{v}^q$ are chosen before making any queries, then $q = \Theta(k\log(n/k))$ is necessary and sufficient [10, 5] to recover an approximately k-sparse vector[1]. However, if the queries can be adaptive, then $q = O(k\log\log n)$ queries suffice [12], while there is a lower bound of $\Omega(k+\log\log n)$ [24] (see also recent work [23, 13]).

The above problem is representative of an emerging field called *linear sketching* which is the underlying technique behind a number of algorithmic advances the past two decades. In this model one queries $\mathbf{M}\cdot\mathbf{v}^1,\ldots,\mathbf{M}\cdot\mathbf{v}^r$ for non-adaptive queries $\mathbf{v}^1,\ldots,\mathbf{v}^r$. For brevity we write this as $\mathbf{M}\cdot\mathbf{V}$, where $\mathbf{V}\in\mathbb{F}^{d\times r}$ has i-th column equal to $\mathbf{v}^i$. Linear sketching has played a central role in the development of streaming algorithms [2]. Perhaps more surprisingly, linear sketches are also known to achieve the minimal space necessary *of any, possibly non-linear, algorithm* for processing dynamic data streams under certain general conditions [20, 1, 15], which is an essential result for proving a number of lower bounds for approximating matchings in a stream [18, 4]. Linear sketching has also led to the fastest known algorithms for problems in numerical linear algebra, such as least squares regression and low rank approximation; for a survey see [29]. Note that given $\mathbf{M}\cdot\mathbf{V}$ and $\mathbf{M}'\cdot\mathbf{V}$, by linearity one can compute $(\mathbf{M}+\mathbf{M}')\cdot\mathbf{V} = \mathbf{M}\cdot\mathbf{V}+\mathbf{M}'\cdot\mathbf{V}$. This basic versatility property allows for fast updates in a data stream and mergeability in environments such as MapReduce and other distributed models of computation.

Given the applications above, we consider Question 1 an important question to understand for many different properties $\mathcal{P}$ of interest, which we describe in more detail below. A central goal of this work is to answer Question 1 for such properties and to propose this be a natural model of study in its own right.

One notable difference with our model and a number of appications of linear sketching is that we will allow for adaptive query sequences. In fact, our upper bounds will be non-adaptive, and our nearly matching lower bounds for each problem we consider will hold even

[1] Here the goal is to output a vector $\mathbf{M}'$ for which $\|\mathbf{M}-\mathbf{M}'\|_2 \le (1+\epsilon)\|\mathbf{M}-\mathbf{M}_k\|_2$, where $\mathbf{M}_k$ is the best k-sparse approximation to $\mathbf{M}$, and ϵ is a constant.

for adaptive query sequences. Our model is also related to property testing, where one tries to infer properties of a large unknown object by (possibly adaptively) sampling a sublinear number of locations of that object. We argue that linear queries are a natural extension of sampling locations of an object, and that this is a natural "sampling model" not only because of the desired properties of the distributed, linear algebra, and streaming applications above, but sometimes also for physical constraints, e.g., in compressed sensing, where optical devices naturally capture linear measurements.

From a theoretical standpoint, any property testing algorithm, i.e., one that samples q entries of $\mathbf{M}$, can be implemented in our model with q linear queries. However, our model gives the algorithm much more flexibility. From a lower bound perspective, as in the case of property testing [8], some of our lower bounds will be derived from communication complexity. However, not all of our bounds can be proved this way. For example, one notable result we show is an optimal lower bound on the number of queries needed to approximate the rank of $\mathbf{M} \in \mathbb{R}^{n\times n}$ up to a factor t by randomized, possibly adaptive algorithms; we show that $\frac{n}{t} + 1$ queries are necessary and sufficient. A natural alternative way to prove this would be to give part of the matrix to Alice, part of to Bob, and have the players exchange the $\mathbf{M}^L\mathbf{v}^i$ and $\mathbf{M}^R\mathbf{v}^i$, where $\mathbf{M} = \mathbf{M}^L + \mathbf{M}^R$ and $\mathbf{M}^L$ is Alice's part and $\mathbf{M}^R$ is Bob's part. Then, if the 2-player randomized communication complexity of approximating the rank of $\mathbf{M}$ up to a factor of t were known to be $\Omega(n^2/t)$, we would obtain a nearly-matching query lower bound of $\Omega(n/(t(b + \log n)))$, where b is the number of bits needed to specify the entries of $\mathbf{M}$ and the queries. However, it is unknown what the 2-player communication complexity of approximating the rank of $\mathbf{M}$ up to a factor t is over $\mathbb{R}$! We are not aware of any lower bound better than $\Omega(1)$ for constant t for this problem for adaptive queries. We note that for non-adaptive queries, there is an $\Omega(n^2)$ sketching lower bound over the reals given in [19], and an $\Omega(n^2/\log p)$ lower bound for finite fields (of size p) in [3]. There is also a property testing lower bound in [6], though such a lower bound makes additional assumptions on the input. Thus, our model gives a new lens to study this problem from, from which we are able to derive strong lower bounds for adaptive queries. Our techniques could be helpful for proving lower bounds in existing models, such as two-party communication complexity.

Our model is also related to linear decision tree complexity, see, e.g., [7, 14], though such lower bounds typically involve just seeing a threshold applied to $\mathbf{M}\mathbf{v}^i$, and typically $\mathbf{M}$ is a vector. In our case, we observe the entire output vector $\mathbf{M}\mathbf{v}^i$.

An interesting twist in our model is that in our formulation above, we only allowed to query $\mathbf{M}$ via matrix-vector products *on the right*, i.e., of the form $\mathbf{M} \cdot \mathbf{v}^i$. One could ask if there are natural properties $\mathcal{P}$ of $\mathbf{M}$ for which the number q_L of queries one would need to make if querying $\mathbf{M}$ via queries of the form $(\mathbf{u}^1)^T\mathbf{M}, (\mathbf{u}^2)^T\mathbf{M}, \ldots, (\mathbf{u}^{q_L})^T\mathbf{M}$ can be significantly smaller than the number q_R of queries one would need to make if querying $\mathbf{M}$ via queries of the form $\mathbf{M}\mathbf{u}^1, \mathbf{M}\mathbf{u}^2, \ldots, \mathbf{M}\mathbf{u}^{q_R}$:

Question 2: Are there natural problems for which $q_L \ll q_R$?

We show that this is in fact the case, namely, if we can only multiply on the right, then it takes $\Omega(n/\log n)$ queries to determine if there is a *column* of a matrix $\mathbf{M} \in \{0,1\}^{n\times n}$ which is all 1s. However, if we can multiply on the left, then the single query $(1, 1, \ldots, 1)$ can determine this.

We study a few problems around Question 2, which is motivated from several perspectives. First, matrices might be stored on computers in a specific encoding, e.g., a sparse row format, from which it may be much easier to multiply on the right than on the left. Also, in compressed sensing, it may be natural for physical reasons to obtain linear combinations of columns rather than rows.

Another important question is how the query complexity depends on the *underlying field* for which matrix-vector products are performed. Might it be that for a natural problem the query complexity if the matrix-vector products are performed modulo 2 is much higher than if the matrix-vector products are performed over the reals?

Question 3: Is there a natural problem for which the query complexity in our model over $\mathbb{F}[2]$ is much larger than that over the reals?

Yet another important application of this model is to querying graphs. A natural question is which representation to use for the graph. For example, a natural representation of a graph on n vertices is through its adjacency matrix $\mathbf{A} \in \{0,1\}^{n \times n}$, where $\mathbf{A}_{i,j} = 1$ if and only if $\{i,j\}$ occurs as an edge. A natural representation for a bipartite graph with n vertices in each part could be an $n \times n$ matrix $\mathbf{A}$ where $\mathbf{A}_{i,j} = 1$ iff there is an edge from the i-th left vertex to the j-th right vertex. Yet another representation could be the $\binom{n}{2} \times n$ edge-vertex incidence matrix, where the $\{i,j\}$-th row is either 0, or has exactly two ones, one in location i and one in location j. One often considers a signed edge-vertex incidence matrix, where one first arbitrarily fixes an ordering on the vertices and then the $\{i,j\}$-th entry has a 1 in the i-th position and a -1 in the j-th position if $i > j$, otherwise positions i and j are swapped. Yet another possible representation of a graph is through its Laplacian.

Question 4: Do some natural representations of graphs admit much more efficient query algorithms for certain problems than other natural representations?

We note that in the data stream model, where one sees a long sequence of insertions and deletions to the edges of a graph, each of the matrix representations above can be simulated and so they lead to the same complexity. We will show, perhaps surprisingly, that in this model there can be an exponential difference in the query complexity for two different natural representations of a graph for the same problem.

We next get into the details of our results. We would like to stress that even basic problems in this model are not immediately obvious how to tackle. As a puzzle for the reader, what is the query complexity of determining if a matrix $\mathbf{M} \in \mathbb{F}^{n \times n}$ is symmetric if one can only query vectors on the right? We will answer this later in the paper.

1.1 Formal Model and Our Results

We now describe our model and results formally in terms of an oracle. The oracle has a matrix $\mathbf{M} \in \mathbb{F}^{m \times n}$, for some underlying field $\mathbb{F}$ that we specify in each application. We can only query this matrix via matrix-vector products, i.e., we pick an arbitrary vector $\mathbf{x}$ and send it to the oracle, and the oracle will respond with a vector $\mathbf{y} = \mathbf{M} \cdot \mathbf{x}$. We focus our attention when the queries only occur on the right. Our goal is to approximate or test a number of properties of $\mathbf{M}$ with a minimal number of queries, i.e., to answer Question 1 for a large number of different application areas.

We study a number of problems as summarized in the table. Due to the space limitation, we leave some proofs in the full version. We assume $\mathbf{M}$ is an $m \times n$ matrix and $\varepsilon > 0$ is a parameter of the problem. The bounds hold for constant probability algorithms. In some problems, such as testing whether the matrix is a diagonal matrix, we always assume $m = n$, and in the graph testing problems we explicitly describe how the graph is represented using $\mathbf{M}$. Interestingly, we are able to prove very strong lower bounds for approximating the rank, which as described above, are unknown to hold for randomized communication complexity.

Motivated be streaming and statistics questions, we next study the query complexity of approximating the norm of each row of $\mathbf{M}$. We also study the computation of the majority or parity of each column or row of $\mathbf{M}$, the AND/OR of each column or row of $\mathbf{M}$, or equivalently, whether $\mathbf{M}$ has an all ones column or row, whether $\mathbf{M}$ has two identical columns or rows, and whether $\mathbf{M}$ contains an unusually large-normed row, i.e., a "heavy hitter". Here we show there are natural problems, such as computing the parity of all columns, which can be solved with 1 query if sketching on the left, but require $\Omega(n)$ queries if sketching on the right, thus answering Question 2. We also answer Question 3, observing for the natural problem of testing if a row is all ones, a single deterministic query suffices over the reals but over $\mathbb{F}[2]$ this deterministically requires $\Omega(n)$ queries.

For graph problems, we first argue if the graph is presented as an $n \times n$ bipartite adjacency matrix $\mathbf{M}$, then it requires $\Omega(n/\log n)$ possibly adaptive queries to determine if the graph is connected. In contrast, if the graph is presented as an $n \times \binom{n}{2}$ signed vertex-edge incidence matrix, then $\mathsf{polylog}(n)$ non-adaptive queries suffices. This answers Question 4, showing that the type of representation of the graph is critical in this model. Motivated by a large body of recent work on triangle counting (see, e.g., [11] and the references therein), we also give strong negative results for this problem in our model, which as with all of our lower bounds unless explicitly stated otherwise, hold even for algorithms which perform adaptive queries.

Table 1 Our Results.

Problem	Query Complexity
Linear Algebra Problems	
Approximate Rank (for any $p' > p$ distinguishing Rank$\leq p$ from Rank p')	$p+1$ (Section 3.1)
Trace Estimation	$\Omega(n/\log n)$ (Section 3.2)
Symmetric Matrix / Diagonal Matrix	$O(1)$ (Section 3.3 and full version)
Unitary Matrix	1 (full version)
Approximate Maximum Eigenvalue	$\Theta(\varepsilon^{-0.5}\log n)$ for adaptive queries, $\Theta(n)$ for non-adaptive queries (full version)
Streaming and Statistics Problems	
All Ones Column	$\Theta(n)$ over $\mathbb{F}[2]$, $\Omega(n/\log n)$ over $\mathbb{R}$ (Section 4.1)
Two Identical Columns Two Identical Rows	$\Theta(n)$ $O(\log m)$ (Section 4.2)
Approximate Row Norms / Heavy Hitters	$O\left(\varepsilon^{-2}\log m\right)$ (full version)
Majority of Columns Majority of Rows	$\Omega(n/\log n)$ over $\mathbb{R}$ $O(1)$ over $\mathbb{R}$ (full version)
Parity of Columns Parity of Rows	$\Theta(n)$ $O(1)$ (full version)
Graph Problems	
Connectivity given Bipartite Adjacency Matrix Connectivity given Signed Edge-Vertex Matrix	$\Omega(n/\log n)$ (Section 5.1) $O(\mathsf{polylog}(n))$ ([16], noted in Section 5.1)
Triangle Detection	$\Omega(n/\log n)$ (Section 5.2)

2 Preliminaries

We use capital bold letters, e.g., $\mathbf{A}, \mathbf{B}, \mathbf{M}$, to denote matrices, and use lowercase bold letters, e.g., $\mathbf{x}, \mathbf{y}$, to denote column vectors. Sometimes we write a matrix as a list of column vectors in square brackets, e.g., $\mathbf{M} = [\mathbf{m}_1, \ldots, \mathbf{m}_n]$. We use calligraphic letters, e.g., $\mathcal{D}$, to denote probability distributions, and use $\mathbf{M} \leftarrow \mathcal{D}$ to denote that $\mathbf{M}$ is sampled from distribution $\mathcal{D}$. In particular, we use $\mathcal{G}$ to denote a Gaussian distribution and $\mathbf{G}$ for a matrix whose entries are sampled from an independently and identically distributed (denoted as i.i.d. in the following) Gaussian distribution.

We call a matrix $\mathbf{M}$ i.i.d. Gaussian if each element is i.i.d. Gaussian. It is easy to check that if matrix $\mathbf{G}$ is a $p \times n$ i.i.d. Gaussian matrix, and $\mathbf{R}$ is an $n \times n$ rotation matrix, then $\mathbf{G} \times \mathbf{R}$ is still i.i.d. Gaussian, and has the same probability distribution of $\mathbf{G}$.

The *total variation distance*, sometimes called the statistical distance, between two probability measures P and Q is defined as $\mathsf{D}_{\mathsf{TV}}(P, Q) \stackrel{\text{def}}{=} \sup_A |P(A) - Q(A)|$.

Let $\mathbf{X}$ be an $n \times m$ matrix with each row i.i.d. drawn from an m-variate normal distribution $N(0, \Sigma)$. Then the distribution of the $m \times m$ random matrix $\mathbf{A} = \mathbf{X}^T\mathbf{X}$ is called the *Wishart distribution* with n degrees of freedom and covariance matrix Σ, denoted by $W_m(n, \Sigma)$. The distribution of eigenvalues of $\mathbf{A}$ is characterized in the following lemma.

▶ **Lemma 1** (Corollary 3.2.19 in [17]). *If $\mathbf{A}$ is $W_m(n, \lambda I_m)$, with $n > m - 1$, the joint density function of the eigenvalues $\mathbf{\Lambda} = (\lambda_1, \ldots, \lambda_m)$ of $\mathbf{A}$ (in descending order) is*

$$f(\mathbf{\Lambda}) = \frac{\pi^{m^2/2}}{(2\lambda)^{mn/2}\Gamma_m(m/2)\Gamma_n(n/2)} \exp\left(-\frac{1}{2\lambda}\sum_{i=1}^{m}\lambda_i\right)\prod_{i=1}^{m}\lambda_i^{(n-m-1)/2}\prod_{1\le i<j\le m}(\lambda_i - \lambda_j)$$

In particular, for $\lambda = 1$ and $n = m$, $\exists$ a constant Z_m independent from $\lambda_1, \ldots, \lambda_m$, such that

$$f(\mathbf{\Lambda}) = \frac{1}{Z_m}\exp\left(-\frac{1}{2}\sum_{i=1}^{m}\lambda_i\right)\prod_{i=1}^{m}\lambda_i^{-1/2}\prod_{1\le i<j\le m}(\lambda_i - \lambda_j)$$

3 Linear Algebra Problems

In this section we present our lower bound for rank approximation in Section 3.1, trace estimation in Section 3.2, and testing whether a matrix is symmetric. The results for testing diagonal or unitary matrices, and approximating the maximum eigenvalue is contained in the full version of our paper.

3.1 Lower Bound for Rank Approximation

In this section, we discuss how to approximate the rank of a given matrix $\mathbf{M}$ over the reals when the queries consist of right multiplication by vectors. A naïve algorithm to learn the rank is to pick random Gaussian query vectors non-adaptively. In order to approximate the rank, that is, to distinguish whether $\mathsf{rank}(\mathbf{M}) \le p$ or $\mathsf{rank}(\mathbf{M}) \ge p + 1$, this algorithm needs at least $p + 1$ queries, and it is not hard to see that the algorithm succeeds with probability 1. Indeed, if $\mathbf{H} \in \mathbb{R}^{n\times(p+1)}$ is the random Gaussian query matrix, and $\mathbf{M}$ the unknown $n \times n$ matrix, then writing $\mathbf{M}$ in its thin singular value decomposition as $\mathbf{M} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, where $\mathbf{U}$ and $\mathbf{V}$ have orthonormal columns, and $\mathbf{\Sigma}$ has positive diagonal entries, we have that $\mathrm{rank}(\mathbf{M} \cdot \mathbf{H}) = \mathrm{rank}(\mathbf{V}^T\mathbf{H})$, which by rotational invariance of the Gaussian distribution is the the same as the rank of a random Gaussian matrix, which will be the minimum of $p + 1$ and the rank of $\mathbf{M}$ with probability 1.

In the following, we will show that we cannot expect anything better. We will first show for non-adaptive queries, at least $p+1$ queries are necessary to learn the approximate rank. Then we generalize our results to adaptive queries. Our results hold for randomized algorithms by applying Yao's minimax principle.

3.1.1 Non-Adaptive Query Protocols

▶ **Theorem 2.** *Let constant $\varepsilon > 0$ be the error tolerance and let $\mathbf{M}$ be an $n \times n$ oracle matrix and suppose to start that we make non-adaptive queries. For integer $p < p' \leq n$, at least $p+1$ queries are necessary to distinguish $\mathsf{rank}(\mathbf{M}) \leq p$ from $\mathsf{rank}(\mathbf{M}) \geq p'$ with advantage $\geq \varepsilon$.*

Proof. Given any algorithm distinguishing $\mathsf{rank}(\mathbf{M}) \leq p$ from $\mathsf{rank}(\mathbf{M}) \geq p'$ for some $p' < n$, we can determine whether a $p' \times p'$ matrix $\mathbf{M}'$ has full rank p' or $\mathsf{rank}(\mathbf{M}') \leq p$, by padding $\mathbf{M}'$ to an $n \times n$ matrix $\mathbf{M}$. Therefore in what follows it suffices to prove the lower bound for two $n \times n$ matrices $\mathbf{M}_1$ and $\mathbf{M}_2$ where $\mathsf{rank}(\mathbf{M}_1) \leq p$ and $\mathsf{rank}(\mathbf{M}_2) = n$:

1. $\mathbf{M}_1 = \mathbf{U} \times \mathbf{G}^T$;
2. $\mathbf{M}_2 = \mathbf{U} \times \mathbf{G}^T + \frac{1}{Z(n)} \cdot \mathbf{U}^\perp \times \mathbf{H}^T$.

Here $\mathbf{U}$ has p columns and $\mathbf{U}^\perp$ has $(n-p)$ columns such that $\left[\mathbf{U}, \mathbf{U}^\perp\right]$ forms an $n \times n$ random orthonormal basis, $\mathbf{G}^T$ and $\mathbf{H}^T$ are $p \times n$ and $(n-p) \times n$ matrices whose entries sampled i.i.d. from the standard Gaussian distribution, and $Z(n)$ is a function in n which will be specified later. It immediately follows that $\mathsf{rank}(\mathbf{M}_1) \leq p$ and $\mathsf{rank}(\mathbf{M}_2) = n$ with overwhelmingly high probability. Then we assume $\mathsf{rank}(\mathbf{M}_2) = n$ and discuss the query lower bound for distinguishing $\mathbf{M}_1$ from $\mathbf{M}_2$.

Given $\mathbf{M} \in \{\mathbf{M}_1, \mathbf{M}_2\}$, without loss of generality we denote the q non-adaptive queries with an $n \times q$ orthonormal[2] matrix $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_q]$, where $q \leq p$ and each $n \times 1$ column vector $\mathbf{v}_i$ is a query to the oracle of matrix $\mathbf{M}$ which gets response $\mathbf{M} \cdot \mathbf{v}_i$, for $i \in [q]$. Then, it suffices to show that the following two distributions are hard to distinguish:

1. $\mathbf{M}_1 \times \mathbf{V} \equiv \mathbf{U}\mathbf{W}$, where $\mathbf{W} = \mathbf{G}^T\mathbf{V}$;
2. $\mathbf{M}_2 \times \mathbf{V} \equiv \mathbf{U}\mathbf{W} + \frac{1}{Z(n)} \cdot \mathbf{U}^\perp\mathbf{W}'$, where $\mathbf{W}' = \mathbf{H}^T\mathbf{V}$.

Note that $\left[\mathbf{U}, \mathbf{U}^\perp\right]$ is orthonormal, and hence $\mathbf{U}^T\mathbf{U} = \mathbf{I}_p$, $\left(\mathbf{U}^\perp\right)^T\mathbf{U}^\perp = \mathbf{I}_{n-p}$, $\mathbf{U}^T\mathbf{U}^\perp = \mathbf{0}_{p\times(n-p)}$. We introduce Lemma 3 to eliminate $\mathbf{U}, \mathbf{U}^\perp$ in the representation of $\mathbf{M} \times \mathbf{V}$.

▶ **Lemma 3.** *For $\mathbf{M}_1, \mathbf{M}_2$ and $\mathbf{V}$ defined as above, there is*

$$\mathsf{D}_{\mathsf{TV}}(\mathbf{M}_1\mathbf{V}, \mathbf{M}_2\mathbf{V}) = \mathsf{D}_{\mathsf{TV}}\left((\mathbf{M}_1\mathbf{V})^T\mathbf{M}_1\mathbf{V}, (\mathbf{M}_2\mathbf{V})^T\mathbf{M}_2\mathbf{V}\right)$$

Proof. The direction $\mathsf{D}_{\mathsf{TV}}(\mathbf{M}_1\mathbf{V}, \mathbf{M}_2\mathbf{V}) \geq \mathsf{D}_{\mathsf{TV}}\left((\mathbf{M}_1\mathbf{V})^T\mathbf{M}_1\mathbf{V}, (\mathbf{M}_2\mathbf{V})^T\mathbf{M}_2\mathbf{V}\right)$ is trivial following data processing inequality (i.e. for every $\mathbf{X}, \mathbf{Y}$ and function f, $\mathsf{D}_{\mathsf{TV}}(\mathbf{X}, \mathbf{Y}) \geq \mathsf{D}_{\mathsf{TV}}(f(\mathbf{X}), f(\mathbf{Y}))$). In what follows we only prove the other direction.

First we notice that for every fixed $n \times n$ orthonormal matrix $\mathbf{R}$ and for a random matrix $\mathbf{M}$ sampled as $\mathbf{M}_1$ or $\mathbf{M}_2$, the product $\mathbf{N} \stackrel{\text{def}}{=} \mathbf{R}\mathbf{M}$ follows exactly the same distribution of $\mathbf{M}$. Thus $\mathbf{N}\mathbf{V}$ and $\mathbf{M}\mathbf{V}$ are identically distributed.

Then, from a random sample $\mathbf{V}^T\mathbf{M}^T\mathbf{M}\mathbf{V}$ we can find $\mathbf{M}'$ such that $\mathbf{V}^T\mathbf{M}^T\mathbf{M}\mathbf{V} = (\mathbf{M}')^T\mathbf{M}'$ and $\mathbf{M}' = \mathbf{S}\mathbf{M}\mathbf{V}$ for some orthonormal matrix $\mathbf{S}$ and orthonormal query matrix $\mathbf{V}$. Although $\mathbf{M}'$ is not necessarily the same as $\mathbf{M}\mathbf{V}$ because of $\mathbf{S}$, we have $\mathbf{R}\mathbf{M}' \sim$

[2] Any non-orthonormal queries can be made orthonormal using a change of basis in post-processing.

$\mathbf{NV} \sim \mathbf{MV}$ for a uniformly random orthonormal matrix $\mathbf{R}$. Thus we transform a random sample from $\mathbf{V}^T\mathbf{M}^T\mathbf{MV}$ into a sample from $\mathbf{MV}$ via $\mathbf{RM'}$, and hence $\mathsf{D}_{\mathsf{TV}}(\mathbf{M}_1\mathbf{V}, \mathbf{M}_2\mathbf{V}) \leq \mathsf{D}_{\mathsf{TV}}\left((\mathbf{M}_1\mathbf{V})^T \mathbf{M}_1\mathbf{V}, (\mathbf{M}_2\mathbf{V})^T \mathbf{M}_2\mathbf{V}\right)$. ◀

Using Lemma 3, it suffices to prove an upper bound for $\mathsf{D}_{\mathsf{TV}}(\mathbf{\Lambda}, \mathbf{\Lambda'})$ as follows:

$$\mathsf{D}_{\mathsf{TV}}\left(\mathbf{UW}, \mathbf{UW} + \frac{\mathbf{U}^\perp\mathbf{W'}}{Z(n)}\right) = \mathsf{D}_{\mathsf{TV}}\left((\mathbf{UW})^T(\mathbf{UW}), \left(\mathbf{UW} + \frac{\mathbf{U}^\perp\mathbf{W'}}{Z(n)}\right)^T(\mathbf{UW} + \frac{\mathbf{U}^\perp\mathbf{W'}}{Z(n)})\right)$$
$$= \mathsf{D}_{\mathsf{TV}}\left(\mathbf{W}^T\mathbf{W}, \mathbf{W}^T\mathbf{W} + \frac{(\mathbf{W'})^T\mathbf{W'}}{Z^2(n)}\right) \leq \mathsf{D}_{\mathsf{TV}}\left(\mathbf{\Lambda}, \mathbf{\Lambda'}\right)$$

where $\mathbf{\Lambda} = \mathsf{diag}(\lambda_1, \ldots, \lambda_q), \mathbf{\Lambda'} = \mathsf{diag}(\lambda'_1, \ldots, \lambda'_q)$ are diagonal matrices such that $\mathbf{W}^T\mathbf{W} = \mathbf{A}^T\mathbf{\Lambda}\mathbf{A}$ and $\mathbf{W}^T\mathbf{W} + \frac{(\mathbf{W'})^T\mathbf{W'}}{Z^2(n)} = \mathbf{B}^T\mathbf{\Lambda'}\mathbf{B}$ for orthonormal matrices $\mathbf{A}$ and $\mathbf{B}$. The inequality follows because any algorithm separating $\mathbf{W}^T\mathbf{W}$ from $\mathbf{W}^T\mathbf{W} + \frac{(\mathbf{W'})^T\mathbf{W'}}{Z^2(n)}$ implies a separation of $\mathbf{\Lambda}$ from $\mathbf{\Lambda'}$ with the same advantage, by multiplying by random orthonormal matrices.

By Weyl's inequality [28, 31], for every $i \in [q]$, $\lambda'_i \in [\lambda_i - \|\mathbf{\Lambda'} - \mathbf{\Lambda}\|_2, \lambda_i + \|\mathbf{\Lambda'} - \mathbf{\Lambda}\|_2]$, and hence $\lambda'_i \in \left[\lambda_i - O\left(\frac{\|\mathbf{W'}\|_2}{Z^2(n)}\right), \lambda_i + O\left(\frac{\|\mathbf{W'}\|_2}{Z^2(n)}\right)\right]$. Notice that $\mathbf{W'}$ is an $(n-p) \times q$ i.i.d. Gaussian matrix, and hence $\|\mathbf{W'}\|_2^2$ is a chi-squared variable with $(n-p)q$ degrees of freedom, which is bounded by $O((n-p)q)$ with high probability (c.f. Example 2.12 in [27]). Recalling that $q \leq p$, in what follows we condition on the event $\lambda'_i \in \left[\lambda_i - O\left(\frac{np}{Z^2(n)}\right), \lambda_i + O\left(\frac{np}{Z^2(n)}\right)\right]$.

We then show the gaps between eigenvalues λ_i are sufficiently large. Note that since $\mathbf{G}^T$ is i.i.d Gaussian and $\mathbf{V}$ is an orthonormal matrix, each row in $\mathbf{W} = \mathbf{G}^T\mathbf{V}$ is independently drawn from an q-variate normal distribution, thus the probability distribution of $\mathbf{W}^T\mathbf{W}$ is a Wishart distribution $W_q(p, I_q)$. Let $q = p$ and $\lambda_1, \ldots, \lambda_p$ be sorted in descending order. Then by Lemma 1 the density function of $\mathbf{\Lambda}$ is:

$$f(\mathbf{\Lambda}) = \frac{1}{Z_p}\exp\left(-\frac{1}{2}\sum_{i=1}^{p}\lambda_i\right)\prod_{i=1}^{p}\lambda_i^{-1/2}\prod_{1\leq i<j\leq p}(\lambda_i - \lambda_j) \tag{1}$$

Let $\mathcal{E}$ denote the event that $\lambda_p \geq \frac{0.01}{\sqrt{n}}$ and $\forall 1 \leq i < j \leq p, \lambda_i - \lambda_j \geq \gamma = 2^{-\Theta(p^2 \log p)}$.

▶ **Lemma 4.** *For $\mathbf{W}^T\mathbf{W}$ defined as above and sufficiently small $\gamma = 2^{-\Theta(p^2 \log n)}$, $\Pr[\mathcal{E}] > 0.9$.*

Proof. By equation (2) in [25] we know that $\Pr[\sqrt{n}\lambda_p \geq y] = \exp\left(-(y^2/2 + y)\right)$. Thus for $y = 0.01$ and $\mathcal{E}_0 \stackrel{\text{def}}{=} \{\lambda_p \geq 0.01/\sqrt{n}\}$ we get:

$$\Pr[\mathcal{E}_0] = \Pr\left[\lambda_p \geq \frac{0.01}{\sqrt{n}}\right] = \exp(-0.01005) > 0.99000033$$

Also, we note that for every i, $\Pr[|\lambda_i| \leq 100n] \geq 1 - 2\exp(-32n)$, by setting $t = 8\sqrt{n}$ in Corollary 5.35 of [26]. In what follows we conditioned on $\mathcal{E}'_0$ that $|\lambda_i| \leq 100n$ for every $i \in [p]$.

Then we consider the joint distribution μ of $\lambda_1, \ldots, \lambda_p$ in $\mathbf{\Lambda}$. Let the $\mathcal{E}_i \stackrel{\text{def}}{=} \{\lambda_i - \lambda_{i+1} < \gamma\}$ be the event that λ_i and λ_{i+1} has a gap smaller than γ. Thus $\mathcal{E} = \mathcal{E}_0 \wedge \left(\wedge_{i=1}^{p-1}\overline{\mathcal{E}_i}\right)$. To lower bound $\Pr[\mathcal{E}]$, we need to upper bound the probability of $\mathcal{E}_i$ for $1 \leq i \leq p-1$.

Let f be the density function of μ as in (1), and let $\mathsf{Leb}(\cdot)$ be the Lebesgue measure in n dimensions. Then for every i,

$$\Pr[\mathcal{E}_i \mid \mathcal{E}'_0] = \mu(\lambda_i - \lambda_{i+1} < \gamma) \leq \mathsf{Leb}(\lambda_i - \lambda_{i+1} < \gamma) \cdot |f|_\infty = O(\gamma/n) \cdot |f|_\infty$$

Note that conditioning on $\mathcal{E}_0$ such that $\lambda_p \geq 0.01/\sqrt{n}$, the density function f is bounded as:

$$|f|_\infty \leq O\left(\exp\left(-\frac{1}{2}\lambda_1\right)\left(100\sqrt{n}\right)^{p/2}\lambda_1^{p^2/2}\right) = 2^{O\left(p^2\log n\right)}$$

As a result, we get $\Pr\left[\mathcal{E}_i \wedge \mathcal{E}_0 \mid \mathcal{E}_0'\right] \leq \gamma \cdot 2^{O\left(p^2\log n\right)}$.

Therefore, the probability of $\mathcal{E}$ is lower bounded for sufficiently small $\gamma = 2^{-\Theta(p^2\log n)}$,

$$\begin{aligned}
\Pr\left[\mathcal{E}\right] &\geq \Pr\left[\mathcal{E}_0'\right] \cdot \Pr\left[\mathcal{E}_0 \wedge \left(\wedge_{i=1}^{p-1}\overline{\mathcal{E}_i}\right) \mid \mathcal{E}_0'\right] \\
&\geq \Pr\left[\mathcal{E}_0'\right] \cdot \left(\Pr\left[\mathcal{E}_0 \mid \mathcal{E}_0'\right] - \sum_{i=1}^{p-1}\Pr\left[\mathcal{E}_i \wedge \mathcal{E}_0 \mid \mathcal{E}_0'\right]\right) \\
&> (1-2p\exp(-32n)) \cdot \left(0.99000033 - (p-1)\gamma \cdot 2^{O\left(p^2\log n\right)}\right) > 0.9
\end{aligned}$$

◀

Conditioned on event $\mathcal{E}$ and recalling that $\lambda_i' \in \left[\lambda_i - O\left(\frac{np}{Z^2(n)}\right), \lambda_i + O\left(\frac{np}{Z^2(n)}\right)\right]$, the probability density of $\mathbf{\Lambda}'$ has only a negligible difference from that of $\mathbf{\Lambda}$, since the small disturbance of eigenvalues is dominated by the corresponding terms in $f(\mathbf{\Lambda})$.

$$\begin{aligned}
\frac{f(\mathbf{\Lambda}')}{f(\mathbf{\Lambda})} &= \frac{\exp\left(-\frac{1}{2}\sum_{i=1}^p \lambda_i'\right)\prod_{i=1}^p \lambda_i'^{-1/2}\prod_{1\leq i<j\leq p}(\lambda_i'-\lambda_j')}{\exp\left(-\frac{1}{2}\sum_{i=1}^p \lambda_i\right)\prod_{i=1}^p \lambda_i^{-1/2}\prod_{1\leq i<j\leq p}(\lambda_i-\lambda_j)} \\
&\leq \exp\left(\frac{p\cdot np}{Z^2(n)}\right)\left(\frac{\lambda_p - \frac{np}{Z^2(n)}}{\lambda_p}\right)^{-p/2}\prod_{1\leq i<j\leq p}\frac{\lambda_i-\lambda_j+\frac{2np}{Z^2(n)}}{\lambda_i-\lambda_j} \\
&\leq \exp\left(\frac{np^2}{Z^2(n)}\right)\cdot\left(1+\frac{np}{\lambda_p\cdot Z^2(n)}\right)^p\left(1+\frac{2np}{Z^2(n)\cdot\min_{i\neq j}|\lambda_i-\lambda_j|}\right)^{p(p-1)/2} \\
&\leq \exp\left(\frac{np^2}{Z^2(n)}\right)\cdot\left(1+\frac{100\sqrt{n}\cdot np}{Z^2(n)}\right)^p\left(1+\frac{2np}{Z^2(n)\cdot\gamma}\right)^{p(p-1)/2} = 1+O\left(\frac{np^3\gamma^{-1}}{Z^2(n)}\right)
\end{aligned}$$

Similarly we can prove $f(\mathbf{\Lambda}')/f(\mathbf{\Lambda}) \geq 1 - O\left(np^3\gamma^{-1}/Z^2(n)\right)$. Thus the total variation distance between $\mathbf{\Lambda}$ and $\mathbf{\Lambda}'$ conditioned on $\mathcal{E}$ is $\mathsf{D}_{\mathsf{TV}}\left(\mathbf{\Lambda}, \mathbf{\Lambda}' \mid \mathcal{E}\right) \leq O\left(np^3\gamma^{-1}/Z^2(n)\right) = O\left(1/n^2\right)$ for sufficiently large $Z(n) \geq (np)^{1.5}\gamma^{-0.5} = 2^{\Theta(p^2\log n)}$. Thus, for sufficiently large n, we have:

$$\mathsf{D}_{\mathsf{TV}}\left(\mathbf{\Lambda}, \mathbf{\Lambda}'\right) \leq \Pr[\overline{\mathcal{E}}] + \Pr[\mathcal{E}]\cdot\mathsf{D}_{\mathsf{TV}}\left(\mathbf{\Lambda}, \mathbf{\Lambda}' \mid \mathcal{E}\right) \leq 0.1 + O\left(1/n^2\right) < 0.11$$

Therefore, with as many as $q = p$ non-adaptive queries to the oracle matrix $\mathbf{M}$, the two distributions $\mathbf{M}_1$ and $\mathbf{M}_2$ cannot be distinguished with advantage greater than 0.11. At least $p+1$ queries are necessary to distinguish those two matrices $\mathbf{M}_1$ and $\mathbf{M}_2$ of rank $\leq p$ and rank n, respectively.

Indeed, the above argument holds for every constant advantage ε if $y = \varepsilon/3$, $t > \sqrt{12n/\varepsilon}$, and γ sufficiently small in the proof of Lemma 4, and let $Z(n)$ be sufficiently large. ◀

3.1.2 Equivalence Between Adaptive and Non-Adaptive Protocols

Now, we consider the adaptive query matrix $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_q]$ where $\mathbf{v}_i$ is the i-th query vector. Without loss of generality, we can assume that $\forall i, \mathbf{v}_i$ is a unit vector and it is orthogonal to query vectors $\mathbf{v}_1, \cdots, \mathbf{v}_{i-1}$. This gives us the following formal definition of an adaptive query protocol.

▶ **Definition 5.** *For a target matrix* $\mathbf{M}$*, an adaptive query protocol* P *will output a sequence of query vectors* $\mathbf{v}_1, \mathbf{v}_2, \cdots$*. It is called a normalized adaptive protocol if for any* i*, the query vector* $\mathbf{v}_i$ *output by* P *satisfies*

1. $\mathbf{v}_i$ *is a unit vector;*
2. $\mathbf{v}_i$ *is orthogonal to the vectors* $\mathbf{v}_1, \cdots, \mathbf{v}_{i-1}$*;*
3. $\mathbf{v}_i$ *is deterministically determined by* $\mathbf{M} \times [\mathbf{v}_1, \ldots, \mathbf{v}_{i-1}]$*.*

Let P^{std} be a standard protocol which outputs $\mathbf{e}_1, \mathbf{e}_2, \cdots$ where $\mathbf{e}_i$ is the i-th standard basis. We then show that adaptivity is unnecessary by proving that P^{std} has the same power as any normalized adaptive protocol.

More formally, we show the following lemma:

▶ **Lemma 6.** *Fix any* $n \times p$ *matrix* $\mathbf{U}$ *and any normalized adaptive protocol* P*. Let* $\mathbf{G}^T$ *be a* $p \times n$ *i.i.d Gaussian matrix. Fix* $q \leq n$ *to be the number of queries. Let matrix* $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_q]$ *and* $\mathbf{V}^{std} = [\mathbf{e}_1, \cdots, \mathbf{e}_q]$ *be the query matrix outputed by protocol* P *and* P^{std}*, correspondingly. Then, the probability distribution of* $\mathbf{UG}^T\mathbf{V}$ *is the same as the distribution of* $\mathbf{UG}^T\mathbf{V^{std}}$*.*

Proof. Since $\mathbf{G}^T\mathbf{V^{std}}$ is i.i.d Gaussian, it is enough to show $\mathbf{G}^T\mathbf{V}$ is also i.i.d Gaussian. We will show it column-by-column.

Denote $\mathbf{V}_i = [\mathbf{v}_1, \ldots, \mathbf{v}_i]$ and $\mathbf{V}_i^{std} = [\mathbf{e}_1, \cdots, \mathbf{e}_i]$. Note that $\mathbf{v}_1, \ldots, \mathbf{v}_q$ are unit vectors and orthogonal to each other. We first define unitary rotation matrices $R_1, R_2, \cdots$ recursively as follows. The matrix R_1 will take $\mathbf{v}_1$ to $\mathbf{e}_1$. The matrix R_i will take $\mathbf{e}_j$ to $\mathbf{e}_j$ for any $j < i$ and takes $R_{i-1} \cdots R_1 \mathbf{v}_i$ to $\mathbf{e}_i$. Note, R_i only depends on the first i query vectors. We have $R_i \cdots R_1 \mathbf{V}_i = \mathbf{V}_i^{std}$ for any $i \leq q$, and $\mathbf{G}^T\mathbf{V} = \mathbf{G}^T \cdot R_1^{-1} \cdots R_q^{-1} \cdot \mathbf{V}^{std}$. In the following, we use induction to show $\mathbf{G}^T \cdot R_1^{-1} \cdots R_i^{-1} \cdot \mathbf{V}_i^{std}$ is i.i.d Gaussian for any $i \leq q$.

For $i = 1$, since R_1 is determined by $\mathbf{v}_1$ which is independent of $\mathbf{G}^T$ and R_1 is a unitary matrix, $\mathbf{G}^T R_1^{-1}$ is i.i.d Gaussian. Thus, $\mathbf{G}^T R_1^{-1} \times \mathbf{V}_1^{std}$ is the first column which is also i.i.d Gaussian.

Now, suppose $\mathbf{G}^T \cdot R_1^{-1} \cdots R_i^{-1} \cdot \mathbf{V}_i^{std}$ is i.i.d Gaussian. We will prove $\mathbf{G}^T \cdot R_1^{-1} \cdots R_{i+1}^{-1} \cdot \mathbf{V}_{i+1}^{std}$ is also i.i.d Gaussian. Let $\mathbf{G'} = \mathbf{G}^T \cdot R_1^{-1} \cdots R_i^{-1}$ which is i.i.d Gaussian. Since R_{i+1} is determined by $\mathbf{v}_1, \cdots, \mathbf{v}_{i+1}$, it is determined by the response of the first i queries, that is, determined by $\mathbf{UG}^T\mathbf{V}_i = \mathbf{UG'V}_i^{std}$. It means R_{i+1} is determined by the first i columns of $\mathbf{UG'}$. Therefore, it is dependent on the first i columns of $\mathbf{G'}$. On the other hand, $R_{i+1}\mathbf{e}_j = \mathbf{e}_j$ for any $j \leq i$, and thus $R_{i+1}^{-1} = \begin{bmatrix} I_i & 0 \\ 0 & R' \end{bmatrix}$ where I_i is the $i \times i$ identity matrix, and R' depends on the first i columns of $\mathbf{G'}$. Consequently, in the multiplication of $\mathbf{G'} \times R_{i+1}^{-1}$, the first i columns are the same as those in $\mathbf{G'}$. In the $(i+1)$-th column, the a-th element is $\sum_{b \geq i+1} g'_{ab} r'_{b,i+1}$ where $g'_{ab}, r'_{b,i+1}$ are the elements in $\mathbf{G'}, R'$ correspondingly. Since $r'_{b,i+1}$ only depends on the first i columns of $\mathbf{G'}$, it is independent of g'_{ab} when $b \geq i+1$. Thus, the $(i+1)$-th column is also i.i.d Gaussian and independent of the first i columns. Therefore, we show $\mathbf{G}^T \cdot R_1^{-1} \cdots R_{i+1}^{-1} \cdot \mathbf{V}_{i+1}^{std}$ is still i.i.d Gaussian.

By induction $\mathbf{G}^T\mathbf{V}$ is i.i.d Gaussian. This finishes our proof. ◀

We then show for $\mathbf{M}_2 = \mathbf{U} \times \mathbf{G}^T + \frac{1}{\mathsf{poly}(n)} \cdot \mathbf{U}^\perp \times \mathbf{H}^T$, adaptivity is also unnecessary by a similar argument.

▶ **Corollary 7.** *Consider* $\mathbf{M}_2 = \mathbf{U} \times \mathbf{G}^T + \frac{1}{\mathsf{poly}(n)} \cdot \mathbf{U}^\perp \times \mathbf{H}^T$*. For any fixed* $\mathbf{U}, \mathbf{U}^\perp$*, and any fixed normalized adaptive protocol* P*,* $\mathbf{M}_2\mathbf{V}$ *has the same distribution as* $\mathbf{M}_2\mathbf{V}^{std}$*.*

Proof. It is enough to show both $\mathbf{G}^T \cdot \mathbf{V}$ and $\mathbf{H}^T \cdot \mathbf{V}$ are i.i.d Gaussian. ◀

Combining these results and Theorem 2, together with Yao's minimax principle [30],

▶ **Theorem 8.** *Let constant $\varepsilon > 0$ be the error tolerance and let $\mathbf{M}$ be an $n \times n$ oracle matrix with adaptive queries. For every integer $p < n$, at least $p+1$ queries are necessary for any randomized algorithm to distinguish whether $\mathsf{rank}(\mathbf{M}) \leq p$ or $\mathsf{rank}(\mathbf{M}) \geq p+1$ with advantage $\geq \varepsilon$.*

3.2 Lower Bound for Trace Estimation

We lower bound the number of queries needed to approximate the trace $\mathsf{tr}(\mathbf{M})$ of a matrix $\mathbf{M}$. In particular we reduce this problem to triangle detection as will be proved in Theorem 14.

▶ **Theorem 9.** *For any integer $C > 0$ and symmetric $n \times n$ matrix $\mathbf{M}$ with entries in $\{0, 1, 2, \ldots, n^3\}$, the number of possibly adaptively chosen query vectors, with entries in $\{0, 1, 2, \ldots, n^C\}$, needed to approximate $\mathsf{tr}(\mathbf{M})$ up to any relative error, is $\Omega(n/\log n)$.*

Proof. Suppose we had a possibly adaptive query algorithm making $q(n)$ queries which for a symmetric matrix $\mathbf{M}$, could approximate $\mathsf{tr}(\mathbf{M})$ up to any relative error. If $\mathbf{M} = \mathbf{A}^3$ for a symmetric matrix $\mathbf{A}$, we can run the trace esimation algorithm on $\mathbf{M}$ as follows: if $\mathbf{x}_1$ is the first query, we compute $\mathbf{A}\mathbf{x}_1$, then $\mathbf{A}(\mathbf{A}\mathbf{x}_1)$, then $\mathbf{A}(\mathbf{A}(\mathbf{A}\mathbf{x}_1)) = \mathbf{A}^3\mathbf{x}_1$. This then determines the second query $\mathbf{x}_2$, and we similarly compute $\mathbf{A}\mathbf{x}_2$, then $\mathbf{A}(\mathbf{A}\mathbf{x}_2)$, then $\mathbf{A}(\mathbf{A}(\mathbf{A}\mathbf{x}_2)) = \mathbf{A}^3\mathbf{x}_2$, etc. Thus, given only query access to $\mathbf{A}$, we can simulate the algorithm on $\mathbf{M} = \mathbf{A}^3$ with $3q(n)$ adaptive queries.

Now, it is well known that for an undirected graph G with adjacency matrix $\mathbf{A}$, the trace $\mathsf{tr}(\mathbf{A}^3)/6$ is the number of triangles in G. By the argument above, it follows that with $3q(n)$ queries to $\mathbf{A}$, we can determine if G has a triangle or has no triangles. On the other hand, by Theorem 14 below, at least $\Omega(n/\log n)$ queries to $\mathbf{A}$ are necessary for any adaptive algorithm to decide if there is a triangle in G. Therefore $3q(n) = \Omega(n/\log n)$ and hence we complete the proof with $q(n) = \Omega(n/\log n)$. ◀

3.3 Deciding if M is a Symmetric Matrix

▶ **Theorem 10.** *Given an $n \times n$ matrix $\mathbf{M}$ over any finite field or over fields $\mathbb{R}$ or $\mathbb{C}$, $O(\log(\frac{1}{\varepsilon}))$ queries are enough to test whether $\mathbf{M}$ is symmetric or not with probability $1-\varepsilon$.*

Proof. We choose two random vectors $\mathbf{u}$ and $\mathbf{v}$, where over a finite field we choose from a uniform distribution and over fields $\mathbb{R}$ or $\mathbb{C}$ we choose the Gaussian distribution. We then compute $\mathbf{M}\mathbf{u}$ and $\mathbf{M}\mathbf{v}$. We declare $\mathbf{M}$ to be symmetric if and only if $\mathbf{u}^T \cdot \mathbf{M}\mathbf{v} = \mathbf{v}^T \cdot \mathbf{M}\mathbf{u}$. It is easy to check that if $\mathbf{M}$ is symmetric, the test will succeed. We then show if $\mathbf{M}$ is not symmetric, $\mathbf{u}^T\mathbf{M}\mathbf{v} \neq \mathbf{v}^T\mathbf{M}\mathbf{u}$ with constant probability, so we obtain success probability $1-\varepsilon$ by repeating the test $O(\log(\frac{1}{\varepsilon}))$ times.

Let $\mathbf{A} = \mathbf{M} - \mathbf{M}^T$. When $\mathbf{M}$ is not symmetric, $\mathbf{A}$ is not 0. Thus, $\mathbf{u}^T\mathbf{M}\mathbf{v} = \mathbf{v}^T\mathbf{M}\mathbf{u}$ means $\mathbf{u}^T\mathbf{A}\mathbf{v} = 0$. We can treat this as a degree-2 polynomial in the entries of $\mathbf{v}^T$ and $\mathbf{u}$, i.e., this is $\sum_{i,j} u_i v_j \mathbf{A}_{i,j} = \sum_i u_i \sum_j v_j \mathbf{A}_{i,j}$. Thus, this is a non-zero polynomial and has at most constant probability of evaluating to 0 for any underlying field. To see this, for each i, let $t_i = \sum_j v_j \mathbf{A}_{i,j}$. Then there will be at least one t_i which is non-zero with probability at least $1/2$, for any underlying field. So now we get $\sum_i u_i t_i$. Fix all the u_i except u_i for a given t_i that is non-zero. Then we obtain $S + u_i t_i$. Then if u_i has at least two possible values, this is 0 in one case and non-zero in the other case. So we obtain a probability of at least $1/4$ of detection overall. ◀

4 Streaming and Statistics Problems

In this section we discuss testing an all ones column/row and identical columns/rows. Our results for row norms and majority/parity of columns/rows are in the full version.

4.1 Testing Existence of an All Ones Column/Row

Given a matrix $\mathbf{M} \in \{0,1\}^{m\times n}$, we want to test if $\mathbf{M}$ has a column (or row) with all 1 entries. It is trivial to test whether $\mathbf{M}$ has an all 1 column (or row) using n queries, *e.g.* $\mathbf{e}_1, \ldots, \mathbf{e}_n$. We consider this problem both over $\mathbb{F}[2]$ and $\mathbb{R}$. Note in the case over $\mathbb{R}$, if we allow an arbitrary query vector, we can set one query $\mathbf{v} = \{1, 2, 4, 8, ...2^n\}$, and then reconstruct $\mathbf{M}$ exactly. Thus, in order to avoid such trivial cases, we also restrict the entries in the query to be in $\{0, 1, 2, \ldots, n^C\}$.

For testing the existence of an all ones column, we reduce the problem to the communication complexity of Disjointness. Disjointness requires $\Omega(n)$ bits of communication to decide whether two sets with characteristic vectors $\mathbf{x}, \mathbf{y} \in \{0,1\}^n$ are disjoint with constant probability. Suppose the fist $m-1$ rows in $\mathbf{M}$ equal $\mathbf{x}^T$ while the last row equals $\mathbf{y}^T$. If we can decide whether $\mathbf{M}$ has an all ones column with q non-adaptive queries $\mathbf{v}_1, \ldots, \mathbf{v}_q$, then we obtain a protocol for Disjointness with communication q by letting Alice send a message $\left(\mathbf{x}^T\mathbf{v}_1, \ldots, \mathbf{x}^T\mathbf{v}_q\right)$. Thus from the communication complexity lower bound of Disjointness, $q = \Omega(n)$ queries over $\mathbb{F}[2]$ are necessary to test if there is an all ones column in $\mathbf{M}$, which shows that the naïve algorithm is already optimal. For queries over $\mathbb{R}$, note that each entry $\mathbf{x}^T\mathbf{v}_j$ in the message is represented with $\log n$ bits, and as a result $q \geq \Omega\left(n/\log n\right)$.

Testing the existence of an all ones row with queries over $\mathbb{R}$ is trivial deterministically by querying $\mathbf{v} = (1, 1, \ldots, 1)$. Next we study the query complexity of testing an all 1s row deterministically with queries over $\mathbb{F}[2]$. With any $q \leq n-1$ queries $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_q]$, there is a non-zero vector $\mathbf{z} \neq \mathbf{0}$ such that $\mathbf{z}^T\mathbf{V} = \mathbf{0}$. Therefore the query matrix $\mathbf{V}$ cannot distinguish whether a row is from $\mathbf{x}^T$ or $\mathbf{x}^T + \mathbf{z}^T$. However, $\mathbf{x}^T$ and $\mathbf{x}^T + \mathbf{z}^T$ cannot be both all 1 rows, and hence n queries are necessary. This result also shows that the query complexity of the same problem over different fields might be quite different. We note for randomized algorithms, $O(\log(1/\epsilon))$ queries suffice over $\mathbb{F}[2]$ since the inner product of a row which is not all 1s disagrees with the parity of the query with probability $1/2$.

Evaluating the OR/AND function of columns/rows of a Boolean matrix can be reduced to testing existence of an all 1 or all 0 column/row, and hence the same bounds follow.

4.2 Identical Columns/Rows

Given an $m \times n$ matrix $\mathbf{M}$, we want to test whether $\mathbf{M}$ has two identical columns or rows. The trivial solution naively retrieves all information with n queries (column vectors).

Testing identical columns can be reduced to Disjointness. Suppose Alice and Bob have $\mathbf{x}, \mathbf{y} \in \{0,1\}^n$. Let Alice expand her vector $\mathbf{x}$ to an $\frac{m}{2} \times n$ matrix $\mathbf{M}_1$ as follows: the first row is $(1, \mathbf{x}^T) = (1, x_1, \ldots, x_n)$; for $2 \leq i \leq \frac{m}{2}$ the i-th row is $(1, z_1^{(i)}, \ldots, z_n^{(i)})$ where $z_j^{(i)} = 1$ if $x_j = 1$, and $z_j^{(i)}$ is uniformly random over $\{0,1\}$ if $x_j = 0$, for $1 \leq j \leq n$. Bob expands his vector $\mathbf{y}$ to $\mathbf{M}_2$ similarly. Putting $\mathbf{M}_1, \mathbf{M}_2$ together, we let $\mathbf{M} \stackrel{\text{def}}{=} \begin{bmatrix}\mathbf{M}_1 \\ \mathbf{M}_2\end{bmatrix}$. Then $\mathbf{M}$ is an $m \times (n+1)$ matrix with the first column being all 1s. For $j \geq 2$, the j-th column is all 1s if and only if $x_j = y_j = 1$, in which case $\mathbf{M}$ has two identical rows of all 1 entries. For columns where x_j, y_j are not both equal to 1, without loss of generality we may assume the j-th and j'-th columns satisfy $x_j = x_{j'} = 0$ and $y_j = y_{j'}$. Then two columns are identical only

if $(z_j^{(2)}, \ldots, z_j^{(\frac{m}{2})}) = (z_{j'}^{(2)}, \ldots, z_{j'}^{(\frac{m}{2})})$, which happens with probability $\leq 1/2^{\frac{m}{2}-1}$. Therefore the overall probability of two not-all-ones columns in $\mathbf{M}$ being identical is bounded by $m^2/2^{m/2} = 2^{-\Omega(m)}$.

That is, except for an exponentially small error $2^{-\Omega(m)}$, two identical columns in $\mathbf{M}$ are both all ones columns, which turns out to be equivalent to the case that two vectors $\mathbf{x}, \mathbf{y}$ held by Alice and Bob are not disjoint. Then, because DISJOINTNESS requires $\Omega(n)$ bits of communication, at least $\Omega(n)$ oracle queries to $\mathbf{M}$ are necessary. To test identical rows with error ε, if suffices to make $q = O(\log(m/\varepsilon))$ random queries with each entry uniform random over $\{0, 1\}$. Since for every pair of distinct rows, a random query distinguishes them with probability $\frac{1}{2}$, with $\lceil \log(m^2/\varepsilon) \rceil$ queries each pair of distinct rows is miscounted as identical with probability $\leq \varepsilon/m^2$. By a union bound, the overall false-positive error is bounded by $\frac{\varepsilon}{m^2} \cdot \binom{m}{2} < \varepsilon$, while there is no false-negative error since for all queries, identical rows always lead to identical outputs.

5 Graph Problems

5.1 Connectivity

▶ **Theorem 11.** *Given the bipartite adjacency matrix $\mathbf{A} \in \{0, 1\}^{n \times n}$ of a graph, we need $\Omega(n/\log n)$ queries to decide whether the graph is connected with constant probability*

Proof. Consider two row vectors $\mathbf{u}, \mathbf{v} \in \{0, 1\}^{n-1}$ and construct matrix $\mathbf{A}$ as follows. Firstly, the first $n/2$ rows of $\mathbf{A}$ equals to $\mathbf{u}$ and the rest are equal to $\mathbf{v}$, then add an all 1s column to $\mathbf{A}$. Now, matrix $\mathbf{A}$ can be treated as a bipartite adjacency matrix of a graph G with n vertices in each part, where $\mathbf{A}_{i,j} = 1$ iff there is an edge from the i-th left vertex to the j-th right vertex. Then G is disconnected if and only if the two vectors $\mathbf{u}$ and $\mathbf{v}$ are 0 on the same position. Thus any algorithm that uses $q(n)$ non-adaptive queries on the right of $\mathbf{A}$ to decide the connectivity of G immediately implies a protocol for set disjointness, provided we replace 1s with 0s in the input characteristic vectors to the set disjointness problem. So the communication is at most $q(n) \log n$, thus $q(n) = \Omega(n/\log n)$. ◀

▶ **Theorem 12.** *Given the signed edge-vertex incidence matrix $\mathbf{M} \in \{0, \pm 1\}^{n \times \binom{n}{2}}$ of a graph G with n vertices, the connectivity of G can be decided with $\mathsf{polylog}(n)$ non-adaptive queries.*

This follows from the main theorem of [16]. By the following theorem, every cut of G is multiplicatively approximated and hence G is connected iff H is connected, since a graph is disconnected iff it has a zero cut.

▶ **Theorem 13** ([16])**.** *There is a distribution on $\binom{n}{2} \times \mathsf{polylog}(n)$ matrices $\mathbf{S}$ such that from $\mathbf{MS}$, one can construct a (1 ± 0.1)-sparsifier H of the graph G with constant probability. Here, $\mathbf{x}^T \mathbf{L}_G x = (1 \pm .1)\mathbf{x}^T \mathbf{L}_H x$ for all x, with constant probability, where $\mathbf{L}_G$ and $\mathbf{L}_H$ are the corresponding graph Laplacians.*

5.2 Triangle Detection

▶ **Theorem 14.** *If an $n \times n$ matrix $\mathbf{A}$ is the adjacency matrix of a graph G, then determining whether G contains a triangle or not requires $\Omega(n/\log n)$ queries, even for randomized algorithms succeeding with constant probability.*

See the full version for a proof using communication complexity.

6 Conclusions

We initiated the study of querying a matrix through matrix-vector products. We illustrated that for some quantities, if one can only query matrix-vector products on one side, the problem becomes harder. We also illustrated the importance of the underlying field defining the matrix-vector products, as well as the representation of the graph for graph problems. Given connections to sketching algorithms, streaming, and compressed sensing, we believe this area deserves its own study. Some interesting open questions are for computing matrix norms, such as Schatten-p norms, for which tight bounds in streaming and communication complexity models remain elusive; for recent work on this see [21, 22, 9]. Given the success of our model in proving lower bounds for approximate rank, which we also do not have streaming or communication lower bounds for, perhaps tight bounds in our query model are possible for matrix norms. Such bounds may give insight for other models.

Abstract

We consider word RAM data structures for maintaining ordered sets of integers whose SELECT and RANK operations are allowed to return *approximate* results, i.e., ranks, or items whose rank, differ by less than Δ from the exact answer, where $\Delta = \Delta(n)$ is an error parameter. Related to approximate SELECT and RANK is approximate (one-dimensional) NEAREST-NEIGHBOR. A special case of approximate SELECT queries are approximate MIN queries. Data structures that support approximate MIN operations are known as *approximate heaps* (priority queues). Related to approximate heaps are *soft heaps*, which are approximate heaps with a different notion of approximation.

We prove the optimality of all the data structures presented, either through matching cell-probe lower bounds, or through equivalences to well studied static problems. For approximate SELECT, RANK, and NEAREST-NEIGHBOR operations we get matching cell-probe lower bounds. We prove an equivalence between approximate MIN operations, i.e., approximate heaps, and the static *partitioning* problem. Finally, we prove an equivalence between soft heaps and the classical *sorting* problem, on a smaller number of items.

Our results have many interesting and unexpected consequences. It turns out that approximation greatly speeds up some of these operations, while others are almost unaffected. In particular, while SELECT and RANK have identical operation times, both in comparison-based and word RAM implementations, an interesting separation emerges between the approximate versions of these operations in the word RAM model. Approximate SELECT is much faster than approximate RANK. It also turns out that approximate MIN is *exponentially* faster than the more general approximate SELECT. Next, we show that implementing soft heaps is harder than implementing approximate heaps. The relation between them corresponds to the relation between sorting and partitioning.

Finally, as an interesting byproduct, we observe that a combination of known techniques yields a *deterministic* word RAM algorithm for (exactly) sorting n items in $O(n \log\log_w n)$ time, where w is the word length. Even for the easier problem of finding duplicates, the best previous deterministic bound was $O(\min\{n \log\log n, n \log_w n\})$. Our new unifying bound is an improvement when w is sufficiently large compared with n.

1 Introduction

A data structure for maintaining *dynamic ordered sets* supports the operations INSERT, DELETE, and either, or both, of the operations SELECT and RANK. INSERT inserts an item, with an associated key, into the set. We assume that the keys of all items are distinct. DELETE receives a reference to an item in the set and deletes it from the set. SELECT receives an index i and returns the i-th item in the sorted order of the items currently in the set. RANK receives an item, not necessarily in the set, and returns its *rank*, i.e., the number of items in the set whose keys are smaller than the key of the item. If both SELECT and RANK operations are implemented, then it is easy to use them to support other operations such as PREDECESSOR, SUCCESSOR and NEAREST-NEIGHBOR. More specifically, PREDECESSOR(x) = SELECT(RANK(x)), SUCCESSOR(x) = SELECT(RANK$(x)+1$), and NEAREST-NEIGHBOR(x) is the closer of these two to x. (We assume here that x is not in the set.)

In the comparison-based model, each operation can be implemented in $O(\log n)$ time, and this is optimal. In this paper, however, our main focus is the word RAM model. Assuming integer keys, it models what can be implemented in a programming language such as C [18] which has been used for efficient portable code since 1978. Word operations take constant time. The word size w, measured in bits, is a unifying parameter of the model. All integers considered are assumed to fit in a word. If $|S| = n$, where S is the set of items in the data structure, then we assume that $w \geq \log n$, so that we can at least index the items in S. Integers can not only be compared. We can use all the standard arithmetic and bit-wise operations. Moreover, the random access memory of the word RAM implies that we can allocate tables or arrays of words, accessing entries in constant time using indices that may be computed from keys. These word RAM features are used in many classic algorithms, e.g., radix sort from 1929 [7] and hash tables from 1956 [9]. We note that by handling integer keys, we immediately handle floating point keys since their standard bit-representation (sign,exponent,mantissa) is such that casting them as integers gives the right ordering.

In the word RAM model, a more diverse picture emerges than in the comparison-based model. Pătraşcu and Thorup [20] obtained a data structure that supports all the above operations in $O(\log n/\log w)$ time. For SELECT and RANK this matches a lower bound of Fredman and Saks [12] which holds even if we only want to support SELECT or only want to support RANK. However, if we only want to support PREDECESSOR, SUCCESSOR and/or NEAREST-NEIGHBOR (plus INSERT and DELETE), then Andersson and Thorup [2] have shown that this can done in $O\sqrt{\log n/\log\log n}$) time per operation. This is the best possible bound in terms of n, matching a static lower bound of Beame and Fich [3].

In this paper, we consider word RAM data structures for maintaining ordered sets of integers where SELECT and RANK are allowed to return *approximate* results, i.e., ranks, or items whose rank, differ by *less* than Δ from the exact answer, where $\Delta = \Delta(n)$ is an error parameter. (When $\Delta = 1$, the data structure has to return exact results.) We use Δ-SELECT as a shorthand for Δ-approximate SELECT, and similarly for the other operations.

A Δ-MIN operation is an operation that returns one of the Δ smallest items in the ordered set. This is clearly a special case of Δ-SELECT operations. A data structure that supports INSERT, DELETE and Δ-MIN operations is known as an *approximate heap*, or Δ-heap.

An EXTRACT-Δ-MIN operation finds one of the smallest Δ items, using a Δ-MIN operation, returns it, and deletes it from the Δ-heap, using a DELETE operation. Our Δ-heap data structure satisfies the following *fairness* condition: an item cannot be one of the Δ smallest items in the data structure for 2Δ consecutive EXTRACT-Δ-MIN operations without being returned, and deleted, by one of the these EXTRACT-Δ-MIN operations.

Related to approximate heaps are *soft heaps*, introduced by Chazelle [6], which are, in a sense, approximate heaps with a different notion of approximation. Soft heaps were used by Chazelle [5] to obtain the fastest deterministic algorithm for computing minimum spanning trees in the comparison model. The implementation of soft heaps was simplified by Kaplan et al. [17]. Soft heaps were also used recently by Kaplan et al. [16] to obtain simplified optimal algorithms for some selection problems.

A *soft heap* is a heap data structure which is allowed to *increase* the keys of some of the items stored in the heap. Each item has both an *original* key, and a *current* key, which might be larger than its original key. An item whose current key is larger than its original key is said to be *corrupt*. A MIN operation returns an item with the minimum current key. (Once an item becomes corrupt, it remains corrupt, as its current key can only be increased. The user can examine the original and current keys of all items, including those of the item returned by a MIN operation.) A q-soft heap is a soft heap such that after any sequence that includes n INSERT operations, at most n/q of the items *in* the heap are corrupt. Clearly, an (n/Δ)-soft heap is also a Δ-heap. We show, however, that implementing an (n/Δ)-soft heap in the word RAM model is, in general, harder than implementing a Δ-heap.

Motivation. In addition to being natural computational problems that lead to many interesting, and perhaps unexpected, theoretical results, the problems we consider are also well motivated in practice. In many real life applications, keys are obtained using inexact measurements, or may change over time. We may be interested in 'sampling' items of given ranks, e.g., for statistical purposes, but typically when we ask for an item of rank i, an item whose rank is between $i - \Delta$ and $i + \Delta$, for a small enough Δ, will serve just as well. It is thus interesting to know whether allowing approximation can speed up such operations.

We note that the direct motivation for approximate versions of SELECT, RANK and MIN, is very different from the motivation of soft heaps which at first may look a bit peculiar, but which have proven to be useful data structure inside some important algorithms.

Our results

We show, among other things, that if $\Delta = n^\varepsilon$, for any $\varepsilon > 0$, then INSERT, DELETE and Δ-SELECT can be implemented in *constant time*.

While SELECT and RANK operations have the same running times in the word RAM model when exact results are required, an interesting separation emerges between the approximate versions of these operations. Surprisingly, Δ-SELECT is *easier* than Δ-RANK. We also show that Δ-MIN is "exponentially" faster than Δ-SELECT. As mentioned, we also show that soft heaps are harder to implement than approximate heaps.

Our results follow from a full characterization of the time needed for each subset of dynamic operations via either a matching cell-probe lower bound, or via an equivalence to the well-studied exact static problems of *ordered partition* and *sorting*.

More specifically, we obtain the following four main results:

(1) A data structure that supports INSERT, DELETE and Δ-SELECT in $O(\log n/\log(w\Delta))$ time, where n is the number of items in the set. We also obtain a matching lower bound that shows that at least one of these operations must take $\Omega(\log n/\log(w\Delta))$ time. For $\Delta = n^\varepsilon$, for any $\varepsilon > 0$, we get $O(1)$ time for each operations.

(2) An augmentation of the previous data structure that also supports Δ-RANK operations. INSERT, DELETE and Δ-SELECT operations still take $t_u = O(\log n/\log(w\Delta))$ time, while Δ-RANK takes $O\left(\log n/\log(w\Delta) + pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$ time, where $pred(n, t, s, w)$ is the

time for dynamically answering exact *predecessor queries* on a set of n items when the update time is $O(t)$, the space of the data structure is $O(s)$, and the word length is w. (It is known, for example that $pred(n,t,n,w) = O\left(\sqrt{\frac{\log n}{\log\log n}}\right)$, for every $w \geq \log n$, where $t = O\left(\sqrt{\frac{\log n}{\log\log n}}\right)$, and that this is the optimal bound in terms of n.) We also provide a matching lower bound for the complexity of Δ-RANK operations that shows that the $pred(\frac{n}{\Delta}, t_u\Delta, n, w)$ term in the upper bound cannot be removed. For $\Delta = n^\varepsilon$, for any $\varepsilon > 0$, we get $O(1)$ time for Δ-SELECT, while Δ-RANK operations still cost $\Omega\left(\sqrt{\frac{\log n}{\log\log n}}\right)$. This exhibits a somewhat surprising separation between Δ-SELECT and Δ-RANK, given that the exact versions of these operations have the same running times.

(3) A three-way equivalence between (i) *approximate heaps*, (ii) *approximate sorting* and (iii) (exact) *ordered partition*: There is a Δ-heap with $O(P_\Delta(n,w))$ time per operation, where $P_\Delta(n,w)$ is *non-decreasing* in n, if and only if it is possible, for every n, to Δ-sort a set of n items in $O(nP_\Delta(n,w))$ time, if and only if it is possible, for every n, to partition n items into $\frac{n}{\Delta}$ sets of size roughly Δ in $O(nP_\Delta(n,w))$ time, such that the items in each set are smaller than the items in the next set. (A sequence is Δ-sorted if no item is at distance greater than Δ from its position in the sorted sequence.)

(4) A three-way equivalence between (i) *soft heaps*, (ii) *exact heaps* and (iii) exact sorting: There is q-soft heap with $O(t)$ time per operation, if and only if there is an *exact* heap holding up to q items with $O(t)$ time per operation, if and only if it is possible to sort up to q items in $O(t)$ time per item.

Han and Thorup [15] showed that n items can be ordered partitioned into $\sqrt{n}$ sets of size roughly $\sqrt{n}$ in $O(n)$ time. By iterating, if follows that n items can be partitioned into sets of size roughly $n^{2^{-k}}$ in $O(kn)$ time. Thus, n items can be partitioned into subsets of size Δ in $O(n\log(\frac{\log n}{\log\Delta}))$ time. If $\Delta < w$ we can do even better. We only do $\log\frac{\log n}{\log w}$ partitioning iterations after which we are left with sets of size roughly w. These sets can be completely sorted in linear time using the *dynamic fusion node* of Pătraşcu and Thorup [20]. Combining these two results, we get that partitioning into sets of size Δ can be done in $O(n\log(\frac{\log n}{\log(w\Delta)}))$ time. In particular, for $\Delta = 1$, we get exact sorting in $O(n\log\log_w n)$ time, a bound that has not been observed before. By (3), there is a Δ-heap with $O(\log(\frac{\log n}{\log(w\Delta)}))$ time per operation. By the lower bound in (1), Δ-SELECT requires $\Omega((\log n)/\log(w\Delta))$ time. It follows that $time(\Delta\text{-MIN}) = O(\log time(\Delta\text{-SELECT}))$, i.e., Δ-MIN is "exponentially" faster than Δ-SELECT. To get a constant time for Δ-MIN, we currently need $\Delta = n^\varepsilon$, for some $\varepsilon > 0$, as for Δ-SELECT. But, while the result for Δ-SELECT is optimal, and hence cannot be improved, improved partitioning algorithms could potentially yield $O(1)$ time of Δ-MIN for smaller values of Δ.

The bounds we give in this paper are amortized. However, all claimed time bounds can be made worst-case using the techniques of Andersson and Thorup [2]. All our data structures use linear space.

Dumitrescu [10] and Fredman [11] considered *comparison-based* data structures that support Δ-SELECT and Δ-MIN operations. The optimal time bounds for these operations are $\Theta(\log\frac{n}{\Delta})$. Δ-RANK operations can be easily supported within the same time bounds. Thus, there is no separation between Δ-SELECT and Δ-RANK in this model, and to get a constant time per operation, Δ has to be *linear* in n.

A summary of our results for Δ-SELECT, Δ-NEAREST-NEIGHBOR and Δ-RANK are given in Table 1. Update time refers to the time of INSERT and DELETE operations. The first row gives the result of a general value of Δ. The query times are optimal given the update times and assuming $O(n)$ space. (We have no proof that the same query times cannot be obtained with

Error	Update time	Δ-SELECT	Δ-NEAREST	Δ-RANK
Δ	$t_u = \Theta\left(\frac{\log n}{\log(w\Delta)}\right)$	$\Theta\left(\frac{\log n}{\log(w\Delta)}\right)$	$\Theta\left(pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$	$\Theta\left(\begin{array}{c}\Delta\text{-SELECT} + \\ \text{NEAREST}\end{array}\right)$
$\Delta = \log n$	$\Theta\left(\frac{\log n}{\log\log n}\right)$	$\Theta\left(\frac{\log n}{\log\log n}\right)$	$\Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$	$\Theta\left(\frac{\log n}{\log\log n}\right)$
$\Delta = \sqrt{n}$	$\Theta(1)$	$\Theta(1)$	$\Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$	$\Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$
$\Delta = \frac{n}{w}$	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$

Figure 1 Running times for Δ-RANK, and Δ-SELECT and Δ-NEAREST-NEIGHBOR queries.

smaller update times.) The second and third rows specialize the results for the representative cases $\Delta = \log n$ and $\Delta = \sqrt{n}$, giving bounds that hold for all values of $w \geq \log n$. With regard to the second row, we note that the time bounds obtained for $\Delta = \log n$ are identical to the exact case, i.e., $\Delta = 1$. We also note that if only Δ-NEAREST-NEIGHBOR queries are to be answered, then the same query time of $\Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$ can be obtained with a reduced update time of $\Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$. (See [2].) In the third row $\Delta = \sqrt{n}$ can be replaced by $\Delta = n^\varepsilon$, for every $\varepsilon > 0$. Finally, in the forth row, we consider the case $\Delta = \frac{n}{w}$ (or equivalently $\Delta = \frac{n}{w^k}$, for any $k \geq 1$), where all update and query time drop down to a constant.

Chazelle [6], and Kaplan et al. [17], obtained $(1/\varepsilon)$-soft heaps with $O(\log\frac{1}{\varepsilon})$ amortized time per operation, which is optimal in the comparison-based model. In the word-RAM, we obtain by (4) $(1/\varepsilon)$-soft heaps with $O(\log\log\frac{1}{\varepsilon})$ amortized time per operation, or even $O(\sqrt{\log\log\frac{1}{\varepsilon}})$ amortized expected time per operation. We also obtain a w-soft heap with $O(1)$ time per operation.

The rest of the paper is organized as follows. In Section 2 we give a high-level description of the data structures and the equivalences obtained in this paper. The full details are given in the full version of the paper. In Section 3 we present our matching cell-probe lower bounds. We end in Section 4 with some concluding remarks and open problems.

2 High-level description of data structures and equivalences

In this section we sketch the techniques we use and give high level descriptions of the data structures and equivalences obtained in the paper.

2.1 Dynamic sets with approximate SELECT

Our goal is to obtain a data structure that supports INSERT, DELETE and Δ-SELECT operations in $O(\log n/\log(w\Delta))$ time per operation, which we later show is optimal. As mentioned, Pătraşcu and Thorup [20] obtained a data structure that supports INSERT, DELETE and exact SELECT operations in $O(\log n/\log w)$ time. Thus, we may assume that, say, $\Delta > w^3$ and devise a data structure that supports each operation in $O(\log n/\log\Delta)$ time.

Our data structure is built around a B-tree (see, e.g., [8]). The degree DEGREE$[v]$ of each node v in the tree is in the range $[\frac{1}{4}D, 4D]$, where $D = \Delta^{1/3}$. As with standard B-trees, a node v of degree d contains an array CHILD$[v]$ of size d with pointers to its d children,

a pointer PARENT[v] to its parent, and an array SPLIT[v] of $d-1$ *splitters*, $s_1, s_2, \ldots, s_{d-1}$. We also let $s_0 = -\infty$ and $s_d = \infty$. The keys of all items in the subtree of the i-th child CHILD[v][i] of v are all in the range $[s_i, s_{i+1})$, for $i = 0, 1, \ldots, d-1$. A non-root node v also contains its *index* INDEX[v] such that $v =$ CHILD[PARENT[v]][INDEX[v]], i.e., v is the INDEX[v]-th child of its parent. The leaves of a B-tree are all at the same depth.

The B-tree used differs from a standard B-tree in several important ways. The first is that the leaves of the tree do not contain single items, but rather *buckets* that contain between Δ and 2Δ items. These buckets are referred to as *leaf buckets*. The items in each leaf bucket are not sorted, but they all lie between the appropriate splitters in the non-leaf nodes of the tree. Second, each internal node v of the tree has a *buffer* BUFFER[v] associated with it. The size of each such buffer is at most $B = \Delta^{2/3}$. The operations on the B-tree are done *lazily*. An inserted item is simply placed at the buffer of the root. When a buffer is full, its items are partitioned according to the splitters stored in the node, and sent to the appropriate children. We refer to this operation as *flushing* the buffer.

All the items in the data structure reside in leaf buckets and buffers. The splitters in the internal nodes of the tree are copies of keys of items that belonged to the data structure at some stage.

The partitioning of the items in a buffer is done using the fast partitioning algorithm of Han and Thorup [15]. Their algorithm partitions q items according to $O(\sqrt{q})$ splitters in $O(q)$ time. The choice $B = \Delta^{2/3}$ and $D = \Delta^{1/3}$ ensures that a buffer can be flushed in $O(B)$ time. The use of this fast partitioning algorithm is the *only* place in which the data structure relies on the power of the word RAM model.

Another difference between the B-tree used and a standard one is that we impose explicit conditions on the *size* of each subtree. The size of a subtree is the total number of items in the leaf buckets and the buffers that belong to the subtree. The size of a subtree of height i (where the leaves are at height 0), is required to be in the range $[\frac{1}{2}\Delta, 2\Delta]D^i$. To maintain this condition, we store at each node v a $size[v]$ field that holds its current size. (To achieve that, $size[v]$ is updated by relevant INSERT and DELETE operations.) A simple calculation shows that the size condition implies that the degree of each node is in the range $[\frac{D}{4}, 4D]$. It also implies that the height h of the tree is at most $h \leq \log_D \frac{2n}{\Delta} \leq \frac{3 \log n}{\log \Delta}$, as $D = \Delta^{1/3}$. We thus need to show that the (amortized) cost of each INSERT, DELETE and Δ-SELECT is of the order of the depth of the tree.

To support approximate SELECT operations, we augment the B-tree by several additional components. To each non-leaf node v we add a *(rough) locator* array LOCATE[v] of size $\lfloor size_0[v]/(\frac{1}{2}\Delta D^{i-1}) \rfloor \leq 4D$, where $size_0[v]$ is the size of v when it was last rebuilt (see below). If v is at height i, where $i > 0$, then the j-entry of the array, for $j = 0, 1, \ldots, 4D-1$, contains the index of the child of v that contained the item of rank $\frac{1}{2}\Delta D^{i-1} \cdot j$ in the subtree rooted at v, i.e., the $(\frac{1}{2}\Delta D^{i-1} \cdot j)$-th item in the sorted order of all items in the subtree of v, when this subtree was last rebuilt. INSERT and DELETE operations performed after the last rebuilding of the subtree of v make the information in LOCATE[v] slightly inaccurate, but to an extent that can be tolerated, as we are only aiming for approximate results.

Finally, we also store at each non-leaf node v of degree d an array SUM[v] of size $d+1$ such that SUM[v][i], for $i = 0, 1, \ldots, d$, is the sum of sizes of the subtrees rooted at the first i children of v at the time the subtree of v was last rebuilt.

Using this augmented B-tree we can implement INSERT, DELETE and Δ-SELECT operations in $O(\log n / \log \Delta)$ amortized time. The challenge is to time the flushing of buffers and the rebuilding of subtrees so that, on the one hand, we do not spend too much time, and, on the other hand, the information in the B-tree is always sufficiently accurate so that the rank error in each SELECT operation is at most Δ.

Essentially, to locate an item whose rank is close to k, we navigate the tree using the LOCATE and SUM arrays. We start with v being the root and i being the height of the root. To find the child we need to descend to, we let $j \leftarrow \text{LOCATE}[v][\lfloor k/(\frac{1}{2}\Delta D^{i-1})\rfloor]$. It is easy to see that the k-th item in the subtree of v, at the time of the last rebuilding, is either contained in the j-th child of v, if $\text{SUM}[v][j] \leq i < \text{SUM}[v][j+1]$, or otherwise in the $(j+1)$-st child of v. (This follows as $k \leq (\frac{1}{2}\Delta D^{i-1})\lceil k/(\frac{1}{2}\Delta D^{i-1})\rceil$.) In the latter case, we increment j. We now descend to the j-th child of v, letting $v \leftarrow \text{CHILD}[v][j]$, $i \leftarrow i-1$, $k \leftarrow k - \text{SUM}[r][j]$, and repeat the process from there until we get to a leaf. We then return an arbitrary item contained in the corresponding leaf bucket. In the full version of the paper we analyze this process and show that the rank of the returned item is close enough to k.

To satisfy the *fairness* condition mentioned above, two minor changes are needed: (1) the insertion buffer should be emptied once for every Δ updates (not just every Δ insertions); (2) the base sets are maintained as queues (FIFO).

It is possible to convert the amortized time bounds into worst-case time bounds using the techniques of Andersson and Thorup [2].

2.2 Dynamic sets with approximate SELECT and RANK

Pătraşcu and Thorup [20] devised a data structure that supports INSERT, DELETE and *exact* SELECT and RANK operations in $O(\log n/\log w)$ time. An interesting separation between SELECT and RANK operations emerges when approximate results are allowed. In this section we explain how the data structure of Section 2.1 can be extended to support Δ-RANK operations. While the time of INSERT, DELETE and Δ-SELECT operations remains unchanged, i.e., $O(\log n/\log(w\Delta))$, the time of Δ-RANK operations is $O\left(\log n/\log(w\Delta) + pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$ time, where $pred(n,t,s,w)$ is the time for dynamically answering *predecessor queries* on a set of n items when the update is $O(t)$, the space used by the data structure is $O(s)$, and the word length is w. We later give a lower bound that shows that appearance of the $pred(\frac{n}{\Delta}, t_u\Delta, n, w)$ term here cannot be avoided.

Quite a lot is known about $pred(n,t,s,w)$, the time for answering exact PREDECESSOR queries. Beame and Fich [3] gave $\Omega\left(\sqrt{\frac{\log n}{\log\log n}}\right)$ and $\Omega\left(\frac{\log w}{\log\log w}\right)$ lower bounds for the static version of the problem, where polynomial time preprocessing and polynomial space are allowed. (Static means no updates.) Pătraşcu and Thorup [19] obtained a complete query-space tradeoff, when again no updates are allowed, i.e., they determined $pred(n,\infty,s,w)$ asymptotically for all s and w. Pătraşcu and Thorup [19] showed that $pred\left(n, \frac{\log n}{\log w}, n, w\right) = \Theta\left(\frac{\log n}{\log w}\right)$ and that $pred(w,1,w,w) = O(1)$. Further complications arise when deterministic vs. randomized variants of the problem are considered. We refer the reader to [19, 20] for the exact details. The picture simplifies considerably when $pred(n,t,s) = \max_w pred(n,t,s,w)$ is considered. Here, it is known that $pred(n, \sqrt{\frac{\log n}{\log\log n}}, n, w) = pred(n, n^{O(1)}, n^{O(1)}) = \Theta\left(\sqrt{\frac{\log n}{\log\log n}}\right)$.

As in Section 2.1, we may assume that $\Delta > w^3$, as the case $\Delta \leq w^3$ is covered by the exact algorithm of Pătraşcu and Thorup [20], and aim for $t_u = O(\log n/\log\Delta)$ and $O\left(\log n/\log\Delta + pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$ bounds, respectively.

It is not difficult to see that the rank of an item appearing in a leaf bucket or as a splitter in the data structure of Section 2.1 can be easily approximated in $O(\log n/\log\Delta)$ time. A Δ-RANK operation, however, must also be able to return the (approximate) rank of an item that does not appear in the data structure. To achieve that, we maintain an exact dynamic predecessor data structure on the splitters. Given an item not in the data structure we

do a PREDECESSOR query on the key of the item, and return the approximate rank of the returned splitter. As there are only $O(\frac{n}{\Delta})$ splitters, the total time of a Δ-RANK operation is $O\left(\log n/\log\Delta + pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$, as required. As we need to update the predecessor data structure, on average, only once in every Δ operations, we can afford to spend $t_u\Delta$ time on updates to the predecessor data structure. In Section 3, we show that the use of a predecessor data structure is essential.

2.3 Equivalence between approximate heaps and partitioning

The MIN operation is a very special SELECT operation in which the smallest, i.e., the item of rank 0, is sought after. Thus, any data structure that supports approximate SELECT operations also support approximate MIN operations. However, MIN operations could potentially be faster than general SELECT operations. This is true, for example, for the exact versions of these problems on the word RAM.

A data structure that supports INSERT, DELETE and MIN operations is a *priority queue*. A Δ-heap is a data structure that supports Δ-MIN operations which return one of the smallest Δ items in the data structure. (For $\Delta = 1$ we get an exact priority queue.)

Thorup [21] obtained an equivalence between priority queues and sorting. Namely, there is an (exact) priority queue that supports each operation in $P(n)$ time, where $P(n)$ is non-decreasing in n, if and only if it is possible, for every n, to sort n items in $O(n\,P(n))$ time. Here we extend this result to obtain an equivalence between Δ-heaps and the *ordered* Δ*-partition* problem: Given n items, partition them into $k \approx \frac{n}{\Delta}$ sets $A_1, A_2, \ldots, A_k$, each of size about Δ, such that $A_i < A_{i+1}$, i.e., all items in A_i are smaller than all items in A_{i+1}, for $i = 0, 1, \ldots, k-1$. We show that there is a Δ-heap with $O(P_\Delta(n))$ time per operation, where $P_\Delta(n)$ is non-decreasing in n, if and only if it is possible to Δ-partition a set of n items in $O(nP_\Delta(n))$ time.

Han and Thorup [15] showed that the ordered Δ-partition problem is equivalent to the problem of partitioning a set A of size n according to $k \approx \frac{n}{\Delta}$ splitters $s_1 < s_2 < \ldots < s_k$, producing sets $A_0, A_1, \ldots, A_k$ such that $s_i \le A_i < s_{i+1}$, for $i = 0, 1, \ldots, k$, where $s_0 = -\infty$ and $s_{k+1} = +\infty$. Note that in this variant the sets $A_0, A_1, \ldots, A_k$ are *not* necessarily of (roughly) equal size. This is the version of the ordered Δ-partition problem that we use in this section.

We sketch here the construction of a $O(\Delta \log n)$-approximate heap using an algorithm for the ordered Δ-partition problem, which is the interesting direction of the equivalence. In the full version of the paper we complete the details of this construction, remove the $O(\log n)$ from the approximation factor, and prove the other direction of the equivalence.

Most of the items in the priority queue constructed are stored in *buckets* $A_0, A_1, \ldots, A_k$ separated by $k+2$ *base splitters* $-\infty = s_0 < s_1 < s_2 < \ldots < s_k < s_{k+1} = +\infty$. Thus, $s_0 \le A_0 < s_1 \le A_1 < \ldots < s_k \le A_k < s_{k+1}$. The splitters are copies of keys of items that belong or belonged to the priority queue at some stage. The items within each bucket are unsorted. We let $\Phi = \Delta \log n$ and require that $\frac{\Phi}{4} \le |A_i| \le \Phi$, for $i = 0, 1, \ldots, k-1$, and $|A_k| \le \Phi$.

A logarithmic number of splitters $t_0 < t_1 < \ldots < t_{\ell+1}$, where $\ell = \Theta(\log n)$, also serve as *level splitters*. We have $t_0 = s_0 = -\infty$ and $t_{\ell+1} = s_{k+1} = +\infty$. Each level splitter t_j has a *level buffer* B_j associated with it that can hold up to $4^j\Delta$ items. We also maintain a counter q_j that provides an upper bound of the size of B_j. Finally, there is also an *insertion buffer* $B = B_0$ that can hold up to Φ items. We maintain the following invariants, for $j = 1, 2, \ldots \ell$:

(i) There are more than $\frac{1}{2}4^j \cdot \Phi$ bucket items smaller than t_j, if $t_j < \infty$.
(ii) There are less than $\frac{7}{4}4^j \cdot \Phi$ items smaller than t_j.
(iii) The keys of all items in B_j are in $[t_j, t_{j+2})$. Here $t_{\ell+1} = t_{\ell+2} = \infty$.

To insert an item, we simply add it to the insertion buffer. If the insertion buffer is not full, this completes the operation. To delete an item, given a pointer to it, we simply delete it from its bucket or buffer, and update some counters. A MIN operation returns an arbitrary item from the bucket A_0, referred to as the *head*. The rank of the returned item is at most $2\Phi = 2\Delta \log n$, as only items in the head and the insertion buffer may be smaller than the returned item.

When the insertion buffer B is full, i.e., it contains $\Phi = \Delta \log n$ items, we use the ordered Δ-partition algorithm to split the items in B according to the $O(\log n)$ level splitters. The amortized cost per item is $O(P_\Delta(\Delta \log n)) = O(P_\Delta(n))$. Recall that $O(P_\Delta(n))$ is the time, per item, needed to order partition n items into sets of size roughly Δ, or equivalently, to Δ-sort n items. (We may assume that $\Delta \leq n^{1/2}$, as $\Delta = n^{1/2}$ already yields a constant time per operation, and hence $\Delta \log n \leq n$.) Let $B^1 < B^2 < \ldots < B^\ell$ be the resulting partition. The items in B^j are added, one by one, into the level buffer B_j.

When a level buffer B_j is full, or when we need to change the level splitter t_j, we split its items according to all base splitters that are smaller than t_{j+2}. As the number of items smaller than t_{j+2} is $O(4^j\Phi)$, and as each bucket is of size $\Theta(\Phi)$, the number of splitters smaller than t_{j+2} is $O(4^j)$. The number of items in the buffer is at most $4^j\Delta$. Thus, the splitting can be done in $O(4^j\Delta \cdot P_\Delta(n))$ time. The items in each set of the partition generated are added, one by one, to the appropriate buckets.

The above "idyllic" description ignored the fact that base buckets may get too large or too small, and that the three invariants imposed on the level splitters may be violated. However, as we allowed enough slack in the size of the base buckets and in the invariants, it is not too difficult to fix these problems by merging and splitting adjacent base buckets, and by periodically redefining the level splitters. The fairly technical details are given in the full version of the paper. The amortized time per operation remains $O(P_\Delta(n))$.

2.4 Equivalence between soft heaps and sorting

A q-soft heap is a heap which is allowed to corrupt, i.e., increase the keys, of a small fraction of its items. More specifically, after n INSERT operations, at most n/q of the items *in* the heap are allowed to be corrupt. The hope, of course, is that allowing corruptions leads to a more efficient implementation of the heap operations. (It is important to note that the number of corrupt items is related to the number of insertions, not to the number of items currently in the heap.)

It follows easily from the definition that as long as less than q items are inserted into a q-soft heap, the heap is not allowed to corrupt any item. Thus, a q-soft heap with $O(t)$ time per operation can be used to exactly sort $q-1$ items in $O(qt)$ time. By Thorup's [21] equivalence between sorting and priority queues, we get that if there is q-soft heap with $O(t)$ time per operation, then there is also an *exact* heap that can hold up to q items with $O(t)$ time per operation. It is also easy, to obtain this result directly. To implement an exact heap on at most q items, we use a $2q$-soft heap. After every $2q$ insertions we rebuild the $2q$-soft heap using at most q insertions. The amortized time per operation stays $O(t)$.

More surprising is that we also have the opposite implication. If there is an exact heap on at most q items with $O(t)$ time per operation, then there is also a q-soft heap with $O(t)$ time per operation. (Note that the number of items in the q-soft heap is not bounded.) To

prove this result we use the simplified construction of soft heaps by Kaplan et al. [17]. We observe that certain components in this comparison-based implementation of soft heaps can be replaced by exact heaps that hold up to q items. This also leads to a clearer understanding of how soft heaps work.

2.5 Faster exact sorting

Han and Thorup [15] obtained a deterministic linear time algorithm for partitioning n items into a sequence of $\sqrt{n}$ sets, each of size roughly $\sqrt{n}$, such that the items in each set are smaller than the items in the next set. This leads, by repeated partitioning, to a deterministic $O(n \log\log n)$-time algorithm. A different deterministic $O(n \log\log n)$-time sorting algorithm was earlier obtained by Han [14].

More recently, Pătraşcu and Thorup [20], improving results of Fredman and Willard [13], implemented *dynamic fusion trees*, supporting INSERT, DELETE, RANK and SELECT in $O(\log_w n)$ time per operation, where n is the size of the set and w is the word length. This leads immediately to an $O(n \log_w n)$-time sorting algorithm. This algorithm is faster than the $O(n \log\log n)$-time algorithm for sufficiently large w, e.g., $w = n^{\omega(1/\log\log n)}$.

A simple combination of these two algorithms gives rise to a deterministic $O(n \log\log_w n)$-time algorithm. This bound subsumes the two previous bounds. Perform $\log\log_w n$ partitioning steps of [15] that partition the n input items into sets of size w. These sets are then sorted in linear time using the dynamic fusion trees of [20]. The $O(n \log\log_w n)$-time algorithm is asymptotically faster than the $O(n \log\log n)$-time algorithm for much smaller values of w, namely $w = n^{1/\log^{o(1)} n}$.

Han and Thorup [15] obtain a faster randomized $O(n\sqrt{\log\log n})$-time sorting algorithm. Andersson et al. [1] and Belazzougui et al. [4] have shown that sorting can be done in linear expected time when $w = \Omega(\log^2 n \log\log n)$.

It is an open problem whether randomization can speed up partitioning algorithms and lead, in particular, to faster data structures for the various operations considered in this paper, such as Δ-SELECT.

3 Lower bounds

In this section we give cell-probe lower bounds that match the upper bounds obtained by the data structures for approximate SELECT and RANK given in Sections 2.1 and 2.2.

3.1 Lower bound for approximate SELECT

Pătraşcu and Thorup [20], relying on previous results of Fredman and Sacks [12], proved the following cell-probe lower bound.

▶ **Theorem 3.1.** *For any cell-probe data structure that supports* INSERT, DELETE *and (exact)* SELECT *(or* RANK*) operations, if both* INSERT *and* DELETE *require $t = t(n)$ time per operation, then* SELECT *(or* RANK*) operations must take $\Omega\left(\frac{\log n}{\log(w \cdot t(n))}\right)$ time.*

Relying on this result, using a simple reduction, we obtain our lower bound for Δ-SELECT.

▶ **Theorem 3.2.** *For any cell-probe data structure that supports* INSERT, DELETE *and* Δ-SELECT *(or* Δ-RANK*) operations, if both* INSERT *and* DELETE *require at most $O(\log n)$ time per operation, then* SELECT *(or* RANK*) operations must take $\Omega\left(\frac{\log n}{\log(w\Delta)}\right)$ time.*

Proof. Given a Δ-approximate data structure, we can construct an exact data structure by *duplicating* each item 2Δ times. More specifically, when an item is to be inserted into the exact data structure, we insert 2Δ copies of the item into the Δ-approximate data structure. When an item is to be deleted from the exact data structure, we delete its 2Δ copies from the Δ-approximate data structure. To select the item of rank i, we Δ-approximately select an item of rank $2\Delta i + \Delta$. As the rank of the item returned differs from $2\Delta i + \Delta$ by *less* than Δ, the item returned must be a copy of the item of rank i. To compute the rank of an item, not necessarily in the data structure, we do a Δ-RANK query on the approximate data structure, divide the returned rank by 2Δ and round down. It is again easy to see that this is the exact rank of the queried item.

If the times of INSERT and DELETE of the Δ-approximate data structures are $t(n)$, then the times of INSERT and DELETE in the exact data structure are $\Delta t(\Delta n)$. If $s(n)$ is the time of Δ-SELECT (or RANK), then the time for exact SELECT (or RANK) is $s(\Delta n)$. If follows from Theorem 3.1 that $s(\Delta n) = \Omega\left(\frac{\log n}{\log(w \cdot \Delta t(\Delta n))}\right)$, or equivalently $s(n) = \Omega\left(\frac{\log \frac{n}{\Delta}}{\log(w \cdot \Delta \cdot t(n))}\right)$. If $t(n) = O(\log n)$, then as $w \geq \log n$, we also get that $t(n) = O(w)$. We may also assume that $\Delta < n^{1/2}$, as otherwise, the lower bound is a constant. Thus, $s(n) = \Omega\left(\frac{\log n}{\log(w \cdot \Delta)}\right)$, as claimed. ◀

The lower bound for Δ-SELECT is tight, as it matches the upper bound of the data structure given in Section 2.2.

3.2 Lower bound for approximate RANK

The lower bound of Theorem 3.2 holds also for Δ-RANK, but it is not tight for all values of Δ. We provide here a tight lower bound that matches the performance of the data structure given in Section 2.2. The lower bound relies on the fact an exact PREDECESSOR operation can be performed using one SELECT and one RANK operations, namely, PREDECESSOR(k) = SELECT(RANK(k)).

▶ **Theorem 3.3.** *For any linear space cell-probe data structure that supports* INSERT, DELETE *and* Δ-RANK *operations, if* INSERT *and* DELETE *take at most* $t_u = O\left(\log n / \log(w\Delta)\right)$ *time per operation, then* Δ-RANK *operations must take* $\Omega\left(\log n / \log(w\Delta) + pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$ *time.*

Proof. Suppose that we are given a linear space data structure that supports INSERT and DELETE operations in $t_u = O((\log n / \log(w\Delta))$ time, and Δ-RANK operations in $r(n)$ time. We already known, by Theorem 3.2, that $r(n) = \Omega\left(\log n / \log(w\Delta)\right)$ time. Thus, we only need to show that $r(n) = \Omega\left(pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$. We show that we can use the approximate data structure given to obtain a data structure that supports exact PREDECESSOR operations in $O(r(\Delta n))$. It would then follow that $r(n) = \Omega(pred(\frac{n}{\Delta}, t_u\Delta, n, w))$.

We first add to the data structure given to us the ability to support Δ-SELECT operations. This is easily done by using *both* the given data structure *and* our Δ-SELECT data structure of Section 2.1 to hold the same set of items. INSERT and DELETE operations still take $t_u = O((\log n / \log(w\Delta))$ time, and Δ-SELECT and RANK operations still take $r(n)$ time, as we already know that $r(n) = \Omega\left(\log n / \log(w\Delta)\right)$.

We now use the duplication technique used in the proof of Theorem 3.2. We get an exact data structure in which INSERT and DELETE take $\Delta t(\Delta n)$ time, and exact SELECT and RANK, and hence exact PREDECESSOR, take $r(\Delta n)$ time. Thus, $r(n) = \Omega\left(pred(\frac{n}{\Delta}, t_u\Delta, n, w)\right)$, as claimed. ◀

4 Concluding remarks and open problems

Data structures for supporting dynamic ordered sets, i.e., data structures that support INSERT, DELETE, and either one or both of SELECT and RANK, and possibly some other operations, are among the most basic and natural data structures. Pătraşcu and Thorup [20] obtained essentially optimal implementation of such data structures in the word RAM model, the model that most closely represents what can be done on a real computer.

Surprisingly, not much attention was paid before to data structures that support *approximate* versions of these operations. There are many conceivable applications in which, for example, we do not insist on knowing the exact rank of an item in the set, a good enough approximation might be enough.

We show that allowing approximation greatly speeds up some of these operations, while the complexity of the other operations remains essentially unchanged. We obtain a full characterization of the time needed to implement approximate versions of these operations. A fairly interesting picture emerges. While the exact versions of SELECT and RANK have the same complexity, a separation emerges between the approximate versions of these problems.

We also considered approximate MIN operations that correspond to the implementation of approximate heaps (priority queues). It is known that exact MIN operations are easier than the more general SELECT operations. We show that the "exponential" gap between these operations persists when approximation is allowed. We obtained a equivalence between approximate heaps and approximate sorting, extending the equivalence of Thorup [21] for the exact versions of these problems.

Closely related to approximate heaps are Chazelle's [6] soft heaps that feature prominently in his deterministic minimum spanning tree algorithm [5]. The exact relation between approximate and soft heaps was not understood before. Looking at these two data structures using the "word RAM lens" reveals an essential difference between these two data structures. Approximate heaps correspond to approximate sorting, or partitioning, while q-soft heaps actually correspond to the *exact* sorting of sets of size q. This might explain the additional usefulness of soft heaps.

The closer look at ordered set data structures, partitioning algorithms and sorting algorithms also revealed, as a byproduct, a new deterministic sorting algorithm that runs in $O(n \log \log_w n)$ time. The new bound subsumes and improves on the two previously known bounds of $O(n \log \log n)$ and $O(n \log_w n)$.

We focused in this paper on deterministic algorithm. Studying the effect of randomization on the various problems considered is an interesting research topic. In particular, it would be interesting to know whether randomization can speed up (ordered) partitioning algorithms.

Amplification with One NP Oracle Query

Thomas Watson
University of Memphis, Memphis, TN, USA
Thomas.Watson@memphis.edu

Abstract

We provide a complete picture of the extent to which amplification of success probability is possible for randomized algorithms having access to one NP oracle query, in the settings of two-sided, one-sided, and zero-sided error. We generalize this picture to amplifying one-query algorithms with q-query algorithms, and we show our inclusions are tight for relativizing techniques.

1 Introduction

Amplification of the success probability of randomized *algorithms* is a ubiquitous tool in complexity theory. We investigate amplification for randomized *reductions* to NP-complete problems, which can be modeled as randomized algorithms with the ability to make queries to an NP oracle. The usual amplification strategy involves running multiple independent trials, which would also increase the number of NP oracle queries, so this does not generally work if we restrict the number of queries. We study, and essentially completely answer, the following question:

> *If a language is solvable with success probability p by a randomized polynomial-time algorithm with access to one* NP *oracle query, what is the highest success probability achievable with one query (or $q > 1$ many queries) to an* NP *oracle?*

The question makes sense for two-sided error ($\mathsf{BPP}^{\mathsf{NP}[1]}$), one-sided error ($\mathsf{RP}^{\mathsf{NP}[1]}$), and zero-sided error ($\mathsf{ZPP}^{\mathsf{NP}[1]}$), and it was mentioned in [2] as "an interesting problem worthy of further investigation." Partial results for zero-sided error were shown in [3]. The question is also relevant to the extensive literature on bounded NP queries (the boolean hierarchy); e.g., $\mathsf{ZPP}^{\mathsf{NP}[1]}$ shows up frequently in the context of the "two queries problem" [4], which was the main application area of the results from [3].

Our first contribution characterizes the best amplification achievable by relativizing techniques in the two-sided error setting. In general, the best strategy for amplifying plain randomized algorithms is to take the majority vote of q independent trials, which in our setting would naively involve q NP oracle queries. One may suspect this majority vote strategy is optimal for us. We show this intuition is a red herring; it is possible to do better by "combining" NP oracle queries across different trials. As an extreme example, consider the special case of randomized *mapping* reductions to NP problems. These are equivalent to Arthur–Merlin games (AM), for which amplification is possible by running independent

trials and simply having Merlin's message consist of certificates for a majority of the trials. However, if we allow one NP oracle query, but do not necessarily output the same bit the oracle returns, then combining queries is less straightforward, and it turns out amplification is only possible to a limited extent.

Our main take-home message is that starting with success probability greater than $\frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k+1}$, where k is an integer, we can get arbitrarily close to $\frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k}$ success probability while still using one NP query; using q nonadaptive queries, roughly a factor q improvement over this is possible.

We give precise definitions in Section 2, but we now clarify our notation before stating the theorem. For $\epsilon \in (0, 1]$ (the *advantage*), $\mathsf{BPP}_{\epsilon}^{\mathsf{NP}[1]}$ is the set of all languages solvable by a randomized polynomial-time algorithm that may make one query to an NP oracle and produces the correct output with probability $\geq \frac{1}{2} + \frac{1}{2}\epsilon$ on each input. For convenience, we define $\mathsf{BPP}_{>\epsilon}^{\mathsf{NP}[1]}$ by requiring that for some constant c there exists such an algorithm with advantage $\geq \epsilon + n^{-c}$, and we define $\mathsf{BPP}_{\epsilon>}^{\mathsf{NP}[1]}$ by requiring that for every constant d there exists such an algorithm with advantage $\geq \epsilon - 2^{-n^d}$; the reason for these conventions is just that they naturally arise in the proofs (e.g., standard majority amplification implies $\mathsf{BPP}_{>0} = \mathsf{BPP}_{1>}$). We make similar definitions for $\mathsf{BPP}^{\mathsf{NP}\|[q]}$ but allowing q nonadaptive NP oracle queries. Allowing q adaptive NP queries is equivalent to allowing $2^q - 1$ nonadaptive NP queries [1].

▶ **Theorem 1** (Two-sided error). *For integers $1 \leq q \leq k$:*

- *If q is odd:*

$$\mathsf{BPP}_{>1/(k+1)}^{\mathsf{NP}[1]} \subseteq \mathsf{BPP}_{q/k>}^{\mathsf{NP}\|[q]} \quad \textit{and} \quad \mathsf{BPP}_{1/k}^{\mathsf{NP}[1]} \not\subseteq \mathsf{BPP}_{>q/k}^{\mathsf{NP}\|[q]} \textit{ relative to an oracle.}$$

- *If q, k are even:*

$$\mathsf{BPP}_{>1/(k+1)}^{\mathsf{NP}[1]} \subseteq \mathsf{BPP}_{q/k>}^{\mathsf{NP}\|[q]} \quad \textit{and} \quad \mathsf{BPP}_{1/(k-1)}^{\mathsf{NP}[1]} \not\subseteq \mathsf{BPP}_{>q/k}^{\mathsf{NP}\|[q]} \textit{ relative to an oracle.}$$

The word "oracle" has two meanings here. Besides the bounded NP oracle queries of central interest, "relative to an oracle" means there exists a language such that the separation holds when all computations (the randomized algorithm and the NP verifier) can make polynomially many adaptive queries to an oracle for that language. In particular, in the context of our relativized separations, randomized algorithms have access to two oracles. The separations in Theorem 1 are tight since the inclusions relativize. This implies that using "black-box simulation" techniques, it is not possible to significantly improve any of our inclusions.

If we start with advantage $> \frac{1}{k+1}$ where k is an integer, Theorem 1 tells us the best advantage achievable with q nonadaptive NP queries using relativizing techniques: if k is even we can amplify to essentially $\frac{q}{k}$; if k is odd we can amplify to essentially $\frac{q}{k}$ if q is odd, and $\frac{q}{k+1}$ if q is even. (Theorem 1 does not explicitly mention the case where q is even and k is odd, but in this case the best inclusion and separation are obtained by applying the theorem to the even integer $k + 1$.)

A subtle issue is whether "$q/k>$" in the inclusion subscripts can be improved to "q/k"; e.g., it remains open to show that $\mathsf{BPP}_{>1/3}^{\mathsf{NP}[1]} \subseteq \mathsf{BPP}_{1/2}^{\mathsf{NP}[1]}$ or that $\mathsf{BPP}_{>1/3}^{\mathsf{NP}[1]} \not\subseteq \mathsf{BPP}_{1/2}^{\mathsf{NP}[1]}$ relative to an oracle.

The proof of Theorem 1 appears in Section 3. No such nontrivial inclusion was known before; for relativized separations, the case $q = 1$, $k = 2$ was shown in [7].

Zero-sided error algorithms must output the correct bit with probability at least some $\epsilon \in (0, 1]$ and output $\perp$ (plead ignorance) with the remaining probability. We define the advantage (the subscript of $\mathsf{ZPP}^{\mathsf{NP}\|[q]}$) to be this ϵ.

[3] proved that $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4}$ and $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/2} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{1>}$,[1] and left it unresolved what happens between advantages $\frac{1}{4}$ and $\frac{1}{2}$. We settle this decade-old open problem: amplification is possible between $\frac{1}{4}$ and $\frac{1}{3}$ and between $\frac{1}{3}$ and $\frac{1}{2}$.

▶ **Theorem 2** (Zero-sided error). *For integers $1 \leq q \leq k \leq 4$:*

- *If $k = 4$:* $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k>}$.
- *If $k \leq 3$:* $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k>}$.
- *If $q = 1$:* $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/k} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{>q/k}$ *relative to an oracle.*

Moreover, the "$q/k>$" in the inclusion subscripts can be improved to "q/k" if $q < k \geq 3$.

The proof of Theorem 2 appears in Section 4. The "moreover" part uses a trick described in [3] for getting a tiny boost in the advantage. Like the situation with $\mathsf{BPP}^{\mathsf{NP}[1]}$, it remains open to show that $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/3} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/2}$ or that $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/3} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/2}$ relative to an oracle. There is no reason to consider $k > 4$ in Theorem 2, since then $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/4>}$.

We conjecture that the third bullet in Theorem 2 also holds for $q > 1$ (i.e., the relativized separations $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}\|[2]}_{>2/4}$ and $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}\|[3]}_{>3/4}$ and $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/3} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}\|[2]}_{>2/3}$). This remains open, though we are aware of how to prove that $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}\|[2]}_{>3/4}$. Anyway, $q = 1$ is the most natural case, and we provide a complete proof for it.

One-sided error algorithms must always output 0 if the answer is 0, and must output 1 with probability at least some $\epsilon \in (0, 1]$ if the answer is 1. We define the advantage (the subscript of $\mathsf{RP}^{\mathsf{NP}\|[q]}$) to be this ϵ. The proof of Theorem 3 appears in the full version of this paper [6] and is relatively straightforward.

▶ **Theorem 3** (One-sided error).

- $\mathsf{RP}^{\mathsf{NP}[1]}_{>1/2} \subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{1>}$.
- $\mathsf{RP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{1/2} \cap \mathsf{RP}^{\mathsf{NP}\|[2]}_{1>}$ *and* $\mathsf{RP}^{\mathsf{NP}[1]}_{1/2} \not\subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{>1/2}$ *relative to an oracle.*

Finally, we point out that none of the inclusions in this paper can be strengthened to yield advantage exactly 1 via relativizing techniques, since $\mathsf{BPP} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/2}$ relativizes [2] but $\mathsf{BPP} \not\subseteq \mathsf{P}^{\mathsf{NP}}$ relative to an oracle [folklore].

2 Definitions

We formally define the relevant complexity classes in Section 2.1 and their decision tree analogues (which are used for relativized separations) in Section 2.2.

2.1 Time complexity

We think of a randomized algorithm M as taking a uniformly random string $s \in \{0,1\}^r$ (for some number of coins r that depends on the input length); we let $M_s(x)$ denote M running on input x with outcome s.

For $\epsilon \in (0, 1]$ (the *advantage*) and integer $q \geq 1$, language L is in $\mathsf{BPP}^{\mathsf{NP}\|[q]}_{\epsilon}$ iff there is a polynomial-time randomized algorithm M (taking input x and coin tosses $s \in \{0,1\}^r$) and a language $L' \in \mathsf{NP}$ such that the following hold.

[1] [7] gave an alternative proof of the latter but with only $1 - \frac{1}{\text{poly}}$, rather than $1 - \frac{1}{\exp}$, success probability.

Syntax: The computation of $M_s(x)$ produces a tuple of query strings $(z_1, \ldots, z_q)$ and a truth table $out\colon \{0,1\}^q \to \{0,1\}$; the output is then $out(L'(z_1), \ldots, L'(z_q))$.
Correctness: The output is $L(x)$ with probability $\geq \frac{1}{2} + \frac{1}{2}\epsilon$.

$\mathsf{RP}^{\mathsf{NP}\|[q]}_{\epsilon}$ is defined similarly except for correctness, we require the output is always 0 if $L(x) = 0$, and is 1 with probability $\geq \epsilon$ if $L(x) = 1$. $\mathsf{ZPP}^{\mathsf{NP}\|[q]}_{\epsilon}$ is defined similarly except $out\colon \{0,1\}^q \to \{0,1,\perp\}$ and for correctness, we require the output is always $L(x)$ or $\perp$, and is $L(x)$ with probability $\geq \epsilon$.

For $\mathcal{C} \in \left\{\mathsf{BPP}^{\mathsf{NP}\|[q]}, \mathsf{RP}^{\mathsf{NP}\|[q]}, \mathsf{ZPP}^{\mathsf{NP}\|[q]}\right\}$, we define

$$\mathcal{C}_{>\epsilon} = \bigcup_{\text{constants } c} \mathcal{C}_{\epsilon+n^{-c}} \quad \text{and} \quad \mathcal{C}_{\epsilon>} = \bigcap_{\text{constants } d} \mathcal{C}_{\epsilon-2^{-n^d}}.$$

When $q = 1$ we may drop the $\|$ from the superscripts.

2.2 Decision tree complexity

We think of a randomized decision tree T as the uniform distribution over a multiset of corresponding deterministic decision trees T_s indexed by $s \in \{0,1\}^r$; we denote this as $T \sim \left\{T_s : s \in \{0,1\}^r\right\}$. In this setting, "query" actually has two meanings for us: a decision tree makes queries to individual input bits, then it forms an NP-type (DNF) oracle query.

We define a $\mathsf{BPP}^{\mathsf{NP}\|[q]}_{\epsilon}$-type decision tree T for $f\colon \{0,1\}^n \to \{0,1\}$ on input x as follows.

Syntax: $T \sim \left\{T_s : s \in \{0,1\}^r\right\}$ where each T_s makes queries to the bits of x until it reaches a leaf, which is labeled with a tuple of DNFs $(\varphi_1, \ldots, \varphi_q)$ and a function $out\colon \{0,1\}^q \to \{0,1\}$; the output is then $out(\varphi_1(x), \ldots, \varphi_q(x))$.
Correctness: The output is $f(x)$ with probability $\geq \frac{1}{2} + \frac{1}{2}\epsilon$.
Cost: The maximum height of any T_s, plus the maximum width of any DNF appearing at a leaf.

An $\mathsf{RP}^{\mathsf{NP}\|[q]}_{\epsilon}$-type decision tree is defined similarly except for correctness we require the output is always 0 if $f(x) = 0$, and is 1 with probability $\geq \epsilon$ if $f(x) = 1$. A $\mathsf{ZPP}^{\mathsf{NP}\|[q]}_{\epsilon}$-type decision tree is defined similarly except $out\colon \{0,1\}^q \to \{0,1,\perp\}$ and for correctness, we require the output is always $f(x)$ or $\perp$, and is $f(x)$ with probability $\geq \epsilon$.

We follow the convention of overloading complexity class names as decision tree complexity measures: for $\mathcal{C} \in \left\{\mathsf{BPP}^{\mathsf{NP}\|[q]}, \mathsf{RP}^{\mathsf{NP}\|[q]}, \mathsf{ZPP}^{\mathsf{NP}\|[q]}\right\}$, $\mathcal{C}^{\mathsf{dt}}_{\epsilon}(f)$ denotes the minimum cost of any $\mathcal{C}_{\epsilon}$-type decision tree for a partial function f, and $\mathcal{C}^{\mathsf{dt}}_{\epsilon}$ also denotes the class of all families of f's with $\mathcal{C}^{\mathsf{dt}}_{\epsilon}(f) \leq \mathrm{polylog}(n)$, and we define

$$\mathcal{C}^{\mathsf{dt}}_{>\epsilon} = \bigcup_{\text{constants } c} \mathcal{C}^{\mathsf{dt}}_{\epsilon+\log^{-c} n} \quad \text{and} \quad \mathcal{C}^{\mathsf{dt}}_{\epsilon>} = \bigcap_{\text{constants } d} \mathcal{C}^{\mathsf{dt}}_{\epsilon-n^{-d}}.$$

3 Two-sided error

To prove Theorem 1, we first restate it in a more convenient form.

▶ **Theorem 1** (Two-sided error, restated). *For integers $1 \leq q \leq k$:*

(i) *If k, q are odd:* $\mathsf{BPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]}_{q/k>}$.

(ii) *If k is even:* $\mathsf{BPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]}_{q/k>}$.

(iii) *If q, k are even:* $\mathsf{BPP}^{\mathsf{NP}[1]}_{1/(k-1)} \not\subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]}_{>q/k}$ *relative to an oracle.*

(iv) *If q is odd:* $\mathsf{BPP}^{\mathsf{NP}[1]}_{1/k} \not\subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]}_{>q/k}$ *relative to an oracle.*

We prove the inclusions (i) and (ii) in Section 3.1 and the separations (iii) and (iv) in Section 3.2.

3.1 Inclusions

We prove the $q = 1$ case of (i) in Section 3.1.1 and the $q = 1$ case of (ii) in Section 3.1.2 (together these show that $\mathsf{BPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{BPP}^{\mathsf{NP}[1]}_{1/k>}$ for all integers $k \geq 1$), then we generalize to the $q > 1$ case of (i) in Section 3.1.3 and the $q > 1$ case of (ii) in the full version [6]. The techniques from [3] for the zero-sided error setting are not particularly helpful for the two-sided error setting, so we develop the ideas from scratch.

We now describe the common setup. For some constant c we have $L \in \mathsf{BPP}^{\mathsf{NP}[1]}_{1/(k+1)+n^{-c}}$, witnessed by a polynomial-time randomized algorithm M (taking input x and coin tosses $s \in \{0,1\}^r$) and a language $L' \in \mathsf{NP}$. For an arbitrary constant d, we wish to show $L \in \mathsf{BPP}^{\mathsf{NP}\|[q]}_{q/k-2^{-n^d}}$.

Fix an input x. The first step is to sample a sequence of $m = O(n^{2c+d})$ many independent strings $s^1, \ldots, s^m \in \{0,1\}^r$, so with probability $\geq 1 - 2^{-n^d-1}$, the sequence is *good* in the sense that on input x, M still has advantage strictly greater than $\frac{1}{k+1}$ when its coin tosses are chosen uniformly from the multiset $\{s^1, \ldots, s^m\}$. Then we design a polynomial-time randomized algorithm which, given a good sequence, outputs $L(x)$ with advantage $\geq \frac{q}{k}$ after making q nonadaptive NP oracle queries. Hence, over the random $s^1, \ldots, s^m$ and the other randomness of our algorithm,

$$\begin{aligned}\mathbb{P}[\text{output is } L(x)] &\geq \mathbb{P}\big[\text{output is } L(x) \,\big|\, s^1, \ldots, s^m \text{ is good}\big] - \mathbb{P}[s^1, \ldots, s^m \text{ is bad}] \\ &\geq \left(\tfrac{1}{2} + \tfrac{1}{2} \cdot \tfrac{q}{k}\right) - 2^{-n^d-1} \;=\; \tfrac{1}{2} + \tfrac{1}{2}\left(\tfrac{q}{k} - 2^{-n^d}\right).\end{aligned}$$

Henceforth fix a good sequence $s^1, \ldots, s^m$, and let z^h and $out^h \colon \{0,1\} \to \{0,1\}$ be the query string and truth table produced by $M_{s^h}(x)$ (so the output is $out^h(L'(z^h))$). We assume w.l.o.g. that each out^h is nonconstant, and is hence either identity or negation. Henceforth assume that identity is at least as common as negation among $out^1, \ldots, out^m$; the proof is completely analogous if negation is more common.

Taking probabilities over a uniformly random $h \in [m]$, we make the following definitions.

$$\begin{aligned}\alpha &= \tfrac{1}{2}\mathbb{P}[out^h = \mathrm{id}] & \beta &= \tfrac{1}{2}\mathbb{P}[out^h = \mathrm{neg}] \\ a &= \mathbb{P}\big[out^h = \mathrm{id},\ L'(z^h) = 1\big] - \alpha & b &= \mathbb{P}\big[out^h = \mathrm{neg},\ L'(z^h) = 1\big] - \beta\end{aligned}$$

The key observation is now

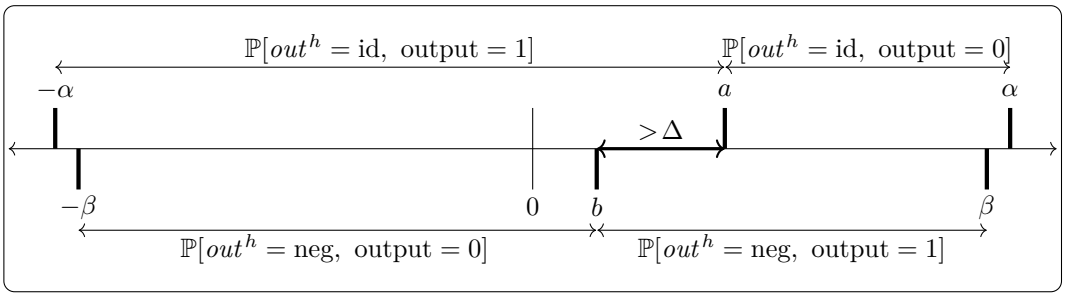
$$\begin{aligned}&(a + \alpha) + (\beta - b) \\ &= \mathbb{P}\big[out^h = \mathrm{id},\ \text{output} = 1\big] + \big(\mathbb{P}[out^h = \mathrm{neg}] - \mathbb{P}\big[out^h = \mathrm{neg},\ \text{output} = 0\big]\big) \\ &= \mathbb{P}\big[out^h = \mathrm{id},\ \text{output} = 1\big] + \mathbb{P}\big[out^h = \mathrm{neg},\ \text{output} = 1\big] \;=\; \mathbb{P}[\text{output} = 1]\end{aligned}$$

and thus, defining $\Delta = \frac{1}{2} \cdot \frac{1}{k+1}$, we have

$$a - b \;=\; (a + \alpha) + (\beta - b) - \tfrac{1}{2} \;=\; \mathbb{P}[\text{output} = 1] - \tfrac{1}{2} \begin{cases} > \Delta & \text{if } L(x) = 1 \\ < -\Delta & \text{if } L(x) = 0 \end{cases}$$

because of M's advantage w.r.t. a good sequence $s^1, \ldots, s^m$.

This figure shows an example of how these values may fall on the number line if $L(x) = 1$:



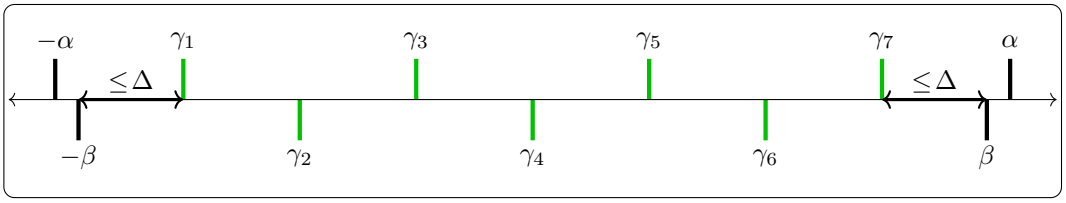
The following summarizes the key properties so far.

$$\alpha \geq \beta \qquad a \in [-\alpha, \alpha] \qquad a - b > \Delta \ \text{ if } L(x) = 1$$
$$\alpha + \beta = \tfrac{1}{2} \qquad b \in [-\beta, \beta] \qquad b - a > \Delta \ \text{ if } L(x) = 0$$

Also, for any real p, testing whether $a \geq p$ can be expressed as an NP oracle query: a witness consists of a list of witnesses for $L'(z^h) = 1$ for at least $(p + \alpha)m$ many h's with $out^h = \text{id}$. Similarly, testing whether $b \geq p$ can be expressed as an NP oracle query.

3.1.1 Proof of (i): $q = 1$

For $i \in [k]$ define $\gamma_i = (i - \frac{k+1}{2})\Delta$. We have $\beta - \gamma_k \leq \Delta$ and $\gamma_1 - (-\beta) \leq \Delta$ since $\beta \leq \frac{1}{4} = \big((k+1) - \frac{k+1}{2}\big)\Delta$. This figure shows an example with $k = 7$:



Our algorithm now picks one of these k possibilities uniformly at random:[2]

- for some odd $i \in [k]$: output 1 iff $a \geq \gamma_i$,
- for some even $i \in [k]$: output 0 iff $b \geq \gamma_i$.

First suppose $L(x) = 1$. We have $a > \gamma_1$ since $a - b > \Delta$ and $b \geq -\beta$ and $\gamma_1 - (-\beta) \leq \Delta$. Consider the greatest odd $j \in [k]$ such that $a \geq \gamma_j$; thus $a \geq \gamma_i$ for $\frac{j+1}{2}$ many odd i's $(1, 3, \ldots, j)$. If $j < k$ then $b < \gamma_{j+1}$ since $a - b > \Delta$ and $a < \gamma_{j+2}$; thus $b < \gamma_i$ for at least $\frac{k-j}{2}$ many even i's $(j+1, j+3, \ldots, k-1)$. Hence the probability of outputting 1 is at least $\frac{1}{k}\big(\frac{j+1}{2} + \frac{k-j}{2}\big) = \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k}$.

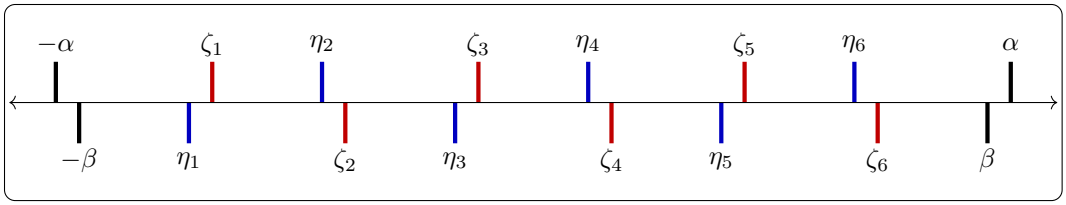
Now suppose $L(x) = 0$. We have $a < \gamma_k$ since $b - a > \Delta$ and $b \leq \beta$ and $\beta - \gamma_k \leq \Delta$. Consider the least odd $j \in [k]$ such that $a < \gamma_j$; thus $a < \gamma_i$ for $\frac{k-j+2}{2}$ many odd i's $(j, j+2, \ldots, k)$. If $j > 1$ then $b > \gamma_{j-1}$ since $b - a > \Delta$ and $a \geq \gamma_{j-2}$; thus $b \geq \gamma_i$ for at least $\frac{j-1}{2}$ many even i's $(2, 4, \ldots, j-1)$. Hence the probability of outputting 0 is at least $\frac{1}{k}\big(\frac{k-j+2}{2} + \frac{j-1}{2}\big) = \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k}$.

[2] Of course, if k is not a power of 2 and we insist on using uniform coin flips as our only source of randomness, then we must incur a tiny error since it is not possible to exactly sample $i \in [k]$ uniformly. We sweep this pedantic issue under the rug throughout the paper.

That concludes the formal proof, but here is an intuitive way to visualize what is happening: Call γ_i for odd i "upper marks," and call γ_i for even i "lower marks," and assume for convenience all lower marks are in $(-\beta, \beta)$. Suppose $L(x) = 1$ and $b = -\beta$ so $a > \gamma_1$; then at least one upper mark is left of a and all $\frac{k-1}{2}$ lower marks are right of b, resulting in $\frac{k+1}{2}$ of the algorithm's possibilities outputting 1. Now as we continuously sweep a and b to the right, keeping $a - b$ fixed, a passes each upper mark before b passes the preceding lower mark, so at all times at least $\frac{k+1}{2}$ of the possibilities output 1. Suppose $L(x) = 0$ and $b = \beta$ so $a < \gamma_k$; then at least one upper mark is right of a and all $\frac{k-1}{2}$ lower marks are left of b, resulting in $\frac{k+1}{2}$ of the algorithm's possibilities outputting 0. Now as we continuously sweep a and b to the left, keeping $b - a$ fixed, a passes each upper mark before b passes the succeeding lower mark, so at all times at least $\frac{k+1}{2}$ of the possibilities output 0.

3.1.2 Proof of (ii): $q = 1$

For $i \in [k]$ define $\zeta_i = -\beta + i\Delta$ and $\eta_i = -\alpha + i\Delta$. Note that $\alpha - \zeta_k = \Delta$ (so $\zeta_1, \ldots, \zeta_k$ divide the interval $[-\beta, \alpha]$ into $k+1$ subintervals each of length Δ) and $\beta - \eta_k = \Delta$ (so $\eta_1, \ldots, \eta_k$ divide the interval $[-\alpha, \beta]$ into $k+1$ subintervals each of length Δ). This figure shows an example with $k = 6$:



Our algorithm now picks one of these $2k$ possibilities uniformly at random:

- for some odd $i \in [k]$: output 1 iff $a \geq \zeta_i$,
- for some even $i \in [k]$: output 0 iff $b \geq \zeta_i$,
- for some even $i \in [k]$: output 1 iff $a \geq \eta_i$,
- for some odd $i \in [k]$: output 0 iff $b \geq \eta_i$.

First suppose $L(x) = 1$. We have $a > \zeta_1$ since $a - b > \Delta$ and $b \geq -\beta$. Consider the greatest odd $j \in [k]$ such that $a \geq \zeta_j$; thus $a \geq \zeta_i$ for $\frac{j+1}{2}$ many odd i's $(1, 3, \ldots, j)$. We have $b < \zeta_{j+1}$ since $a - b > \Delta$ and either $a < \zeta_{j+2}$ (if $j < k-1$) or $a \leq \alpha$ and $\alpha - \zeta_k = \Delta$ (if $j = k-1$); thus $b < \zeta_i$ for at least $\frac{k-j+1}{2}$ many even i's $(j+1, j+3, \ldots, k)$. Consider the greatest even $j' \in [k]$ such that $a \geq \eta_{j'}$, or let $j' = 0$ if it does not exist; thus $a \geq \eta_i$ for $\frac{j'}{2}$ many even i's $(2, 4, \ldots, j')$. If $j' < k$ then $b < \eta_{j'+1}$ since $a - b > \Delta$ and $a < \eta_{j'+2}$; thus $b < \eta_i$ for at least $\frac{k-j'}{2}$ many odd i's $(j'+1, j'+3, \ldots, k-1)$. Hence the probability of outputting 1 is at least $\frac{1}{2k}\left(\frac{j+1}{2} + \frac{k-j+1}{2} + \frac{j'}{2} + \frac{k-j'}{2}\right) = \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k}$.

Now suppose $L(x) = 0$. Consider the least odd $j \in [k]$ such that $a < \zeta_j$, or let $j = k+1$ if it does not exist; thus $a < \zeta_i$ for $\frac{k-j+1}{2}$ many odd i's $(j, j+2, \ldots, k-1)$. If $j > 1$ then $b > \zeta_{j-1}$ since $b - a > \Delta$ and $a \geq \zeta_{j-2}$; thus $b \geq \zeta_i$ for at least $\frac{j-1}{2}$ many even i's $(2, 4, \ldots, j-1)$. We have $a < \eta_k$ since $b - a > \Delta$ and $b \leq \beta$ and $\beta - \eta_k = \Delta$. Consider the least even $j' \in [k]$ such that $a < \eta_{j'}$; thus $a < \eta_i$ for $\frac{k-j'+2}{2}$ many even i's $(j', j'+2, \ldots, k)$. We have $b > \eta_{j'-1}$ since $b - a > \Delta$ and either $a \geq \eta_{j'-2}$ (if $j' > 2$) or $a \geq -\alpha$ (if $j' = 2$); thus $b \geq \eta_i$ for at least $\frac{j'}{2}$ many odd i's $(1, 3, \ldots, j'-1)$. Hence the probability of outputting 0 is at least $\frac{1}{2k}\left(\frac{k-j+1}{2} + \frac{j-1}{2} + \frac{k-j'+2}{2} + \frac{j'}{2}\right) = \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k}$.

That concludes the formal proof, but here is an intuitive way to visualize what is happening: Call ζ_i for odd i and η_i for even i "upper marks," and call ζ_i for even i and η_i for odd i "lower marks," and assume for convenience all lower marks are in $(-\beta, \beta)$. Suppose $L(x) = 1$ and $b = -\beta$ so $a > \zeta_1$; then at least one upper mark is left of a and all k lower marks are right of b, resulting in $k+1$ of the algorithm's possibilities outputting 1. Now as we continuously sweep a and b to the right, keeping $a - b$ fixed, a passes each upper mark (ζ_i or η_i) before b passes the corresponding preceding lower mark (ζ_{i-1} or η_{i-1} respectively), so at all times at least $k+1$ of the possibilities output 1. Suppose $L(x) = 0$ and $b = \beta$ so $a < \eta_k$; then at least one upper mark is right of a and all k lower marks are left of b, resulting in $k+1$ of the algorithm's possibilities outputting 0. Now as we continuously sweep a and b to the left, keeping $b - a$ fixed, a passes each upper mark (ζ_i or η_i) before b passes the corresponding succeeding lower mark (ζ_{i+1} or η_{i+1} respectively), so at all times at least $k+1$ of the possibilities output 0.

3.1.3 Proof of (i): $q > 1$

For $i \in [k]$ define I_i as the set of q successive integers starting with i and wrapping around to 1 when k is exceeded: $I_i = \{i, i+1, \ldots, i+q-1\}$ if $i \leq k-q+1$, and $I_i = \{i, i+1, \ldots, k, 1, 2, \ldots, i+q-1-k\}$ if $i > k-q+1$. Define $i^{\nwarrow} = \min(\text{odd } i' \in I_i) - k - 1$ and $i^{\swarrow} = \min(\text{even } i' \in I_i) - k - 1$; the $-k-1$ is a simple way to ensure $i^{\nwarrow}, i^{\swarrow} < \min(i' \in I_i)$. Since k, q are odd, the sorted order of $I_i \cup \{i^{\nwarrow}, i^{\swarrow}\}$ alternates between odd and even numbers.

Our algorithm picks $i \in [k]$ uniformly at random and for each $i' \in I_i$ does an oracle query to see whether $a \geq \gamma_{i'}$ if i' is odd, or whether $b \geq \gamma_{i'}$ if i' is even. Consider the greatest odd $i^\sharp \in I_i$ such that $a \geq \gamma_{i^\sharp}$, or let $i^\sharp = i^{\nwarrow}$ if it does not exist. Consider the greatest even $i^\flat \in I_i$ such that $b \geq \gamma_{i^\flat}$, or let $i^\flat = i^{\swarrow}$ if it does not exist. Our algorithm outputs 1 if $i^\sharp > i^\flat$, or 0 if $i^\flat > i^\sharp$.

First suppose $L(x) = 1$. Consider the greatest odd $j \in [k]$ such that $a \geq \gamma_j$ (which exists since $a > \gamma_1$). We have $i^\sharp > i^\flat$ if one of the following mutually exclusive events holds:

(1) $j \in I_i$, since then $i^\sharp = j$ and $i^\flat \leq j-1$ (since $b < \gamma_{j+1}$ if $j < k$);
(2) i is odd and $i \leq j-q-1$, since then $i^\sharp = i+q-1$ and trivially $i^\flat \leq i+q-2$;
(3) i is even and $j+1 \leq i \leq j-q-1+k$, since then either:
- $i \leq k-q$, in which case $i^\sharp = i^{\nwarrow} > i^{\swarrow} = i^\flat$, or
- $i = k-q+2$, in which case $i^\sharp = 1$ and $i^\flat = i^{\swarrow} < 1$, or
- $i \geq k-q+4$, in which case $i^\sharp = i+q-1-k$ and $i^\flat \leq i+q-2-k$.

There are q many type-(1) i's. If $j > q$ then there are $\frac{j-q}{2}$ many type-(2) i's $(1, 3, \ldots, j-q-1)$ and $\frac{k-j}{2}$ many type-(3) i's $(j+1, j+3, \ldots, k-1)$. If $j \leq q$ then there are $\frac{k-q}{2}$ many type-(3) i's $(j+1, j+3, \ldots, j-q-1+k)$. Either way, $i^\sharp > i^\flat$ holds for at least $q + \frac{k-q}{2} = \frac{k+q}{2}$ many i's, and hence the probability of outputting 1 is at least $\frac{1}{k} \cdot \frac{k+q}{2} = \frac{1}{2} + \frac{1}{2} \cdot \frac{q}{k}$.

Now suppose $L(x) = 0$. Consider the least odd $j \in [k]$ such that $a < \gamma_j$ (which exists since $a < \gamma_k$). As a special case, if $j = 1$ then $i^\sharp = i^{\nwarrow}$ and so $i^\flat > i^\sharp$ if $i^{\swarrow} > i^{\nwarrow}$, which happens for $\frac{k+q}{2}$ many i's $(1, 3, \ldots, k-q+1$ and $k-q+2, k-q+3, \ldots, k)$. Now assume $j > 1$. We have $i^\flat > i^\sharp$ if one of the following mutually exclusive events holds:

(1) $j-1 \in I_i$, since then $i^\sharp \leq j-2$ and $i^\flat \geq j-1$ (since $b > \gamma_{j-1}$ if $j > 1$);
(2) i is even and $i \leq j-q-2$, since then $i^\sharp = i+q-2$ and $i^\flat = i+q-1$;
(3) i is odd and $j \leq i \leq j-q-2+k$, since then either:
- $i \leq k-q+1$, in which case $i^\sharp = i^{\nwarrow} < i^{\swarrow} \leq i^\flat$, or
- $i \geq k-q+3$, in which case $i^\sharp = i+q-2-k$ and $i^\flat \geq i+q-1-k$.

There are q many type-(1) i's. If $j > q$ then there are $\frac{j-q-2}{2}$ many type-(2) i's $(2, 4, \ldots, j-q-2)$ and $\frac{k-j+2}{2}$ many type-(3) i's $(j, j+2, \ldots, k)$. If $j \leq q$ then there are $\frac{k-q}{2}$ many type-(3) i's $(j, j+2, \ldots, j-q-2+k)$. Either way, $i^\flat > i^\sharp$ holds for at least $q + \frac{k-q}{2} = \frac{k+q}{2}$ many i's, and hence the probability of outputting 0 is at least $\frac{1}{k} \cdot \frac{k+q}{2} = \frac{1}{2} + \frac{1}{2} \cdot \frac{q}{k}$.

3.2 Separations

The relativized separations follow routinely [5] from the corresponding decision tree complexity separations:

(iii) If q, k are even: $\mathsf{BPP}^{\mathsf{NP}[1]\mathsf{dt}}_{1/(k-1)} \not\subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]\mathsf{dt}}_{>q/k}$.

(iv) If q is odd: $\mathsf{BPP}^{\mathsf{NP}[1]\mathsf{dt}}_{1/k} \not\subseteq \mathsf{BPP}^{\mathsf{NP}\|[q]\mathsf{dt}}_{>q/k}$.

We prove (iii) in Section 3.2.1 and (iv) in the full version [6]; the arguments are similar in structure. Our proof of (iv) also works if q is even, but in that case the result is subsumed by (iii). The case $q = 1$, $k = 2$ of (iii) was proven in [7], but our proof is somewhat different even specialized to that case.

Let $\mathrm{wt}(\cdot)$ refer to Hamming weight. Henceforth fix the constants q and k, and assume $q < k$ since otherwise there is nothing to prove.

3.2.1 Proof of (iii)

Define the partial function $f\colon \{0,1\}^n \to \{0,1\}$ that interprets its input as $(x, y) \in \{0,1\}^{n/2} \times \{0,1\}^{n/2}$, such that

$$f(x,y) = \begin{cases} 1 & \text{if } \mathrm{wt}(x) = \mathrm{wt}(y) + 1 \leq \frac{k}{2} \\ 0 & \text{if } \mathrm{wt}(x) = \mathrm{wt}(y) \leq \frac{k}{2} - 1 \end{cases}.$$

▶ **Lemma 4.** $\mathsf{BPP}^{\mathsf{NP}[1]\mathsf{dt}}_{1/(k-1)}(f) \leq \frac{k}{2}$.

▶ **Lemma 5.** $\mathsf{BPP}^{\mathsf{NP}\|[q]\mathsf{dt}}_{q/k+\delta}(f) \geq \Omega(\delta n)$ *for every* $\delta(n)$.

The separation follows by taking $\delta = \log^{-c} n$ for any constant c.

Proof of Lemma 4. Given (x, y), pick one of these $k-1$ possibilities uniformly at random:

- for some $i \in [\frac{k}{2}]$: output 1 iff $\mathrm{wt}(x) \geq i$,
- for some $i \in [\frac{k}{2} - 1]$: output 0 iff $\mathrm{wt}(y) \geq i$.

The decision tree does not directly query any bits of (x, y), and the DNF has width $i \leq \frac{k}{2}$ (it is the OR over all i-subsets of either x's bits or y's bits, of the AND of those bits), so the cost is $\frac{k}{2}$. If $f(x, y) = 1$ with $\mathrm{wt}(x) = j$ and $\mathrm{wt}(y) = j - 1$, then the probability of outputting 1 is $\frac{j+((k/2-1)-(j-1))}{k-1} = \frac{1}{2} + \frac{1}{2} \cdot \frac{1}{k-1}$ since conditioned on picking x, the output is 1 iff $i \leq j$, and conditioned on picking y, the output is 1 iff $i \geq j$. Similarly, if $f(x, y) = 0$ with $\mathrm{wt}(x) = \mathrm{wt}(y) = j$, then the probability of outputting 1 is $\frac{j+((k/2-1)-j)}{k-1} = \frac{1}{2} - \frac{1}{2} \cdot \frac{1}{k-1}$. ◀

Proof of Lemma 5. It suffices to show that for some distribution on valid inputs (x, y) to f, every cost-$o(\delta n)$ $\mathsf{P}^{\mathsf{NP}\|[q]}$-type decision tree T has advantage $< \frac{q}{k} + \delta$ over a random input. Let $T(x, y)$ denote the output produced after T receives the answers to its DNF queries. Let u be the leaf reached after seeing only 0's, and say u is labeled with DNFs $(\varphi_1, \ldots, \varphi_q)$ and function $out\colon \{0,1\}^q \to \{0,1\}$ (so if (x, y) leads to u then $T(x, y) = out(\varphi_1(x, y), \ldots, \varphi_q(x, y))$).

We generate the distribution on valid inputs (x, y) as follows. Let $v^0 = w^0 \in \{0,1\}^{n/2}$ be the all-0 string, and for $i = 1, \ldots, \frac{k}{2}$ obtain v^i by flipping a uniformly random 0 of v^{i-1}

to a 1, and for $i = 1, \ldots, \frac{k}{2} - 1$ obtain w^i by flipping a uniformly random 0 of w^{i-1} to a 1. Pick a uniformly random $j \in [\frac{k}{2}]$, and then let (x, y) be either the 1-input (v^j, w^{j-1}) or the 0-input (v^{j-1}, w^{j-1}) with probability $\frac{1}{2}$ each.

Let v denote $(v^0, \ldots, v^{k/2})$ and w denote $(w^0, \ldots, w^{k/2-1})$, and call (v, w) *good* iff:

- for each $j \in [\frac{k}{2}]$: both inputs (v^j, w^{j-1}) and (v^{j-1}, w^{j-1}) lead to u, and
- for each $j \in [\frac{k}{2}]$ and each $i \in [q]$: $\varphi_i(v^j, w^{j-1}) \geq \varphi_i(v^{j-1}, w^{j-1}) \geq \varphi_i(v^{j-1}, w^{j-2})$ (the latter inequality is only required if $j > 1$).

We claim that

(1) $\mathbb{P}[(v, w) \text{ is bad}] < \frac{\delta}{2}$, and

(2) $\mathbb{P}\big[T(x, y) = f(x, y) \,\big|\, (v, w) \text{ is good}\big] \leq \frac{1}{2} + \frac{1}{2} \cdot \frac{q}{k}$,

from which it follows that

$$\mathbb{P}[T(x, y) = f(x, y)] \leq \mathbb{P}\big[T(x, y) = f(x, y) \,\big|\, (v, w) \text{ is good}\big] + \mathbb{P}[(v, w) \text{ is bad}] < \tfrac{1}{2} + \tfrac{1}{2}(\tfrac{q}{k} + \delta).$$

We argue claim (1). Since the path to u queries $o(\delta n)$ locations, with probability $\geq 1 - o(k\delta) > 1 - \frac{\delta}{4}$ each of the 1's placed throughout v and w avoids these locations, in which case the first bullet holds in the definition of good. Fixing j and i in the second bullet, if we condition on $\varphi_i(v^{j-1}, w^{j-1}) = 1$ and choose an arbitrary term of φ_i that accepts (v^{j-1}, w^{j-1}), then since the term has width $o(\delta n)$, with probability $\geq 1 - o(\delta)$ the 1 that is placed to obtain v^j from v^{j-1} avoids this term, in which case the term continues to accept (v^j, w^{j-1}) and so $\varphi_i(v^j, w^{j-1}) = 1$. Thus $\mathbb{P}\big[\varphi_i(v^j, w^{j-1}) \geq \varphi_i(v^{j-1}, w^{j-1})\big] \geq \mathbb{P}\big[\varphi_i(v^j, w^{j-1}) = 1 \,\big|\, \varphi_i(v^{j-1}, w^{j-1}) = 1\big] \geq 1 - o(\delta)$. Similarly, $\mathbb{P}\big[\varphi_i(v^{j-1}, w^{j-1}) \geq \varphi_i(v^{j-1}, w^{j-2})\big] \geq 1 - o(\delta)$. A union bound over j and i shows that the second bullet holds with probability $\geq 1 - o(kq\delta) > 1 - \frac{\delta}{4}$, so finally the two bullets hold simultaneously with probability $> 1 - \frac{\delta}{2}$.

We argue claim (2). Condition on any particular good (v, w). We abbreviate the q-tuple $(\varphi_1(x, y), \ldots, \varphi_q(x, y))$ as $\varphi(x, y) \in \{0, 1\}^q$. Consider the sequence of k inputs (v^0, w^0), $(v^1, w^0), (v^1, w^1), (v^2, w^1), \ldots$ (like climbing a ladder but placing both feet on each rung). Each of these possibilities for (x, y) leads to u and thus $T(x, y) = \mathit{out}(\varphi(x, y))$. Also, the corresponding sequence of $\varphi(x, y)$'s is monotonically nondecreasing in each of the q coordinates. Thus the sequence of inputs can be partitioned into segments of lengths say $\ell_0, \ell_1, \ldots, \ell_q$ (which sum to k) such that for the first ℓ_0 (x, y)'s in the sequence, $\varphi(x, y)$ has weight 0 (hence $T(x, y)$ is the same), and for the next ℓ_1 (x, y)'s in the sequence, $\varphi(x, y)$ is the same weight-1 string (hence $T(x, y)$ is the same), and so on. Since each segment alternates between 0-inputs and 1-inputs of f, we have $T(x, y) = f(x, y)$ for at most $\lceil \frac{\ell_i}{2} \rceil \leq \frac{\ell_i + 1}{2}$ inputs in the i^{th} segment.

Thus, out of the k possibilities for (x, y) given (v, w), at most $\sum_{i=0}^{q} \frac{\ell_i + 1}{2} = \frac{k}{2} + \frac{q+1}{2}$ are such that $T(x, y) = f(x, y)$. This implies that $\mathbb{P}\big[T(x, y) = f(x, y) \,\big|\, (v, w) \text{ is good}\big] \leq \frac{1}{2} + \frac{1}{2} \cdot \frac{q+1}{k}$, which is almost what we want. This issue can be fixed by observing that since k is even and $q + 1$ (the number of segments) is odd, at least one segment must have even length, in which case $\lceil \frac{\ell_i}{2} \rceil = \frac{\ell_i}{2}$. Thus, out of the k possibilities for (x, y) given (v, w), $T(x, y) = f(x, y)$ holds for at most $\frac{k}{2} + \frac{q}{2}$ of them, which gives (2). ◀

4 Zero-sided error

We now prove Theorem 2, restated here for convenience.

▶ **Theorem 2** (Zero-sided error, restated). *For integers $1 \leq q \leq k \leq 4$:*

(i) *If $k = 4$:* $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k>}$.

(ii) *If* $k \leq 3$*:* $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k>}$.

(iii) $\mathsf{ZPP}^{\mathsf{NP}[1]}_{1/k} \not\subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/k}$ *relative to an oracle.*

Moreover, the "$q/k>$*" in the inclusion subscripts can be improved to "*q/k*" if* $q < k \geq 3$.

We prove the inclusions (i) and (ii) in Section 4.1 and the separations (iii) in the full version [6].

4.1 Inclusions

Straightforwardly generalizing the proof of $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4}$ in [3] yields (i), but we take a different tack by showing in Section 4.1.1 that (i) follows directly from Theorem 3. We prove (ii) from first principles in Section 4.1.2; our proof for the case $k = 1$ is equivalent to the one in [3], but we include it for completeness.

4.1.1 Proof of (i)

Let $L \in \mathsf{ZPP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{>0}$. By Theorem 3 and closure of $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>0}$ under complement,

$$L \in \mathsf{RP}^{\mathsf{NP}[1]}_{1/2} \text{ by some algorithm } M^1, \qquad L \in \mathsf{RP}^{\mathsf{NP}\|[2]}_{1>} \text{ by some algorithm } M^2,$$
$$\overline{L} \in \mathsf{RP}^{\mathsf{NP}[1]}_{1/2} \text{ by some algorithm } \overline{M}^1, \qquad \overline{L} \in \mathsf{RP}^{\mathsf{NP}\|[2]}_{1>} \text{ by some algorithm } \overline{M}^2.$$

We let each of these four M-algorithms refer to the entire computation, including the NP oracle queries, which we elide for convenience. (Note that $\overline{M}^i$ does not mean "complement of M^i" – it is a different algorithm.) We assume M^2 and $\overline{M}^2$ have advantage $\geq 1 - 2^{-n^d}$ for an arbitrary constant d. Furthermore, we assume all four algorithms have been modified to output $\perp$ instead of 0, and $\overline{M}^1$ and $\overline{M}^2$ have been modified to output 0 instead of 1.

If $q = 1$: $L \in \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/4}$ by running M^1 or $\overline{M}^1$ with probability $\frac{1}{2}$ each.

If $q = 2$: $L \in \mathsf{ZPP}^{\mathsf{NP}\|[2]}_{1/2}$ by running M^1 and $\overline{M}^1$, and if one of them outputs a bit, outputting that bit or $\perp$ otherwise.

If $q = 4$: $L \in \mathsf{ZPP}^{\mathsf{NP}\|[4]}_{1>}$ by running M^2 and $\overline{M}^2$, and if one of them outputs a bit, outputting that bit or $\perp$ otherwise.

If $q = 3$: $L \in \mathsf{ZPP}^{\mathsf{NP}\|[3]}_{3/4>}$ by running M^1 and $\overline{M}^2$ with probability $\frac{1}{2}$, or M^2 and $\overline{M}^1$ with probability $\frac{1}{2}$, and if one of them outputs a bit, outputting that bit or $\perp$ otherwise. This falls slightly short of our promise of showing $L \in \mathsf{ZPP}^{\mathsf{NP}\|[3]}_{3/4}$, but that can be fixed by noting that the proof of Theorem 3 actually shows that M^1 and $\overline{M}^1$ can have advantage $\geq \frac{1}{2} + 2^{-n^e}$ for some constant e depending on L. Then taking $d \geq e$ ensures we get advantage $\geq \frac{1}{2}\left(\frac{1}{2} + 2^{-n^e}\right) + \frac{1}{2}\left(1 - 2^{-n^d}\right) \geq \frac{3}{4}$.

4.1.2 Proof of (ii)

We just prove $\mathsf{ZPP}^{\mathsf{NP}[1]}_{>1/(k+1)} \subseteq \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k>}$; the "moreover" part follows by exactly the same trick (due to [3]) for strengthening $\mathsf{RP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{1/2>}$ to $\mathsf{RP}^{\mathsf{NP}[1]}_{>0} \subseteq \mathsf{RP}^{\mathsf{NP}[1]}_{1/2}$, which we describe in the full version [6].

For some constant c we have $L \in \mathsf{ZPP}^{\mathsf{NP}[1]}_{1/(k+1)+n^{-c}}$, witnessed by a polynomial-time randomized algorithm M (taking input x and coin tosses $s \in \{0,1\}^r$) and a language $L' \in \mathsf{NP}$. For an arbitrary constant d, we wish to show $L \in \mathsf{ZPP}^{\mathsf{NP}\|[q]}_{q/k-2^{-n^d}}$.

Fix an input x. The first step is to sample a sequence of $m = O(n^{2c+d})$ many independent strings $s^1, \ldots, s^m \in \{0,1\}^r$, so with probability $\geq 1 - 2^{-n^d}$, the sequence is *good* in the sense that on input x, M still has advantage strictly greater than $\frac{1}{k+1}$ when its coin tosses are chosen uniformly from the multiset $\{s^1, \ldots, s^m\}$. Then we design a polynomial-time randomized algorithm which, given a good sequence, outputs $L(x)$ with probability $\geq \frac{q}{k}$ after making q nonadaptive NP oracle queries, and which has zero-sided error for all sequences (good and bad). Hence, over the random $s^1, \ldots, s^m$ and the other randomness of our algorithm,

$$\mathbb{P}[\text{output is } L(x)] \;\geq\; \mathbb{P}\big[\text{output is } L(x) \,\big|\, s^1, \ldots, s^m \text{ is good}\big] - \mathbb{P}[s^1, \ldots, s^m \text{ is bad}] \;\geq\; \tfrac{q}{k} - 2^{-n^d}.$$

Henceforth fix a good sequence $s^1, \ldots, s^m$, and let z^h and $out^h \colon \{0,1\} \to \{0,1\}$ be the query string and truth table produced by $M_{s^h}(x)$ (so the output is $out^h(L'(z^h))$). We assume w.l.o.g. that out^h is nonconstant. If there is an h such that $out^h \in \{\text{id}, \text{neg}\}$, then our algorithm simply uses the NP oracle to evaluate $L'(z^h)$ and then outputs $out^h(L'(z^h)) = L(x)$. Otherwise, each out^h is one of the four functions out_{ab} (for $ab \in \{0,1\}^2$) that maps a to b and $1-a$ to $\perp$:

	out_{00}	out_{01}	out_{10}	out_{11}
0	0	1	$\perp$	$\perp$
1	$\perp$	$\perp$	0	1

For each $ab \in \{0,1\}^2$ consider the "ab" query:

$\exists\, h :\ out^h = out_{ab}$ and $L'(z^h) = a$?

If $a = 1$ then the "ab" query can be expressed as an NP oracle query: a witness consists of an h with $out^h = out_{ab}$ and a witness for $L'(z^h) = 1$. If $a = 0$ then the "ab" query can be expressed as a coNP oracle query: a nonexistence witness consists of a witness for $L'(z^h) = 1$ for each h such that $out^h = out_{ab}$. We say the "ab" query returns yes iff it indicates the existence of such an h (i.e., the NP oracle returns the bit a). If the "ab" query returns yes, we can safely output b since there exists an h such that $out^h(L'(z^h)) = out_{ab}(a) = b = L(x)$.

Our algorithm is:

1. Identify a set $P \subseteq \{0,1\}^2$ of size k for which there is guaranteed to exist an $ab \in P$ such that the "ab" query would return yes.
2. Pick a uniformly random $Q \subseteq P$ of size q.
3. For each $ab \in Q$ do the "ab" query and output b if it returns yes.
4. Finally output $\perp$ if all queries returned no.

This outputs $L(x)$ with probability $\geq \frac{q}{k}$. We just need to prove that we can indeed find such a P in step 1. Let $H = \{h \in [m] : M_{s^h} \text{ outputs } L(x)\}$ (so by assumption, $|H| > \frac{m}{k+1}$) and $H_{ab} = \{h \in [m] : out^h = out_{ab}\}$. Note that the "$ab$" query would return yes iff $H \cap H_{ab} \neq \emptyset$, and that $H \subseteq H_{0b} \cup H_{1b}$ for $b = L(x)$.

If $k = 3$: Let P contain all ab's except the one with the smallest H_{ab} (which has size $\leq \frac{m}{4}$), breaking ties arbitrarily. Then $H \cap H_{ab} \neq \emptyset$ for at least one $ab \in P$ assuming $|H| > \frac{m}{4}$.

If $k = 2$: If $|H_{00} \cup H_{10}| \leq \frac{m}{3}$ then $L(x) = 1$ assuming $|H| > \frac{m}{3}$, so we can let $P = \{01, 11\}$. Similarly, if $|H_{01} \cup H_{11}| \leq \frac{m}{3}$ then we can let $P = \{00, 10\}$. Otherwise, the smaller of H_{00}, H_{10} has size $\leq \frac{m}{3}$, and the smaller of H_{01}, H_{11} has size $\leq \frac{m}{3}$, so we can let P contain the two ab's corresponding to the larger of H_{00}, H_{10} and the larger of H_{01}, H_{11}, breaking ties arbitrarily.

If $k = 1$: If $|H_{00} \cup H_{10}| \leq \frac{m}{2}$ then $L(x) = 1$ assuming $|H| > \frac{m}{2}$, and furthermore the smaller of H_{01}, H_{11} has size $\leq \frac{m}{2}$, so we can let P contain the ab corresponding to the larger of H_{01}, H_{11}. Similarly, if $|H_{01} \cup H_{11}| < \frac{m}{2}$ then we can let P contain the ab corresponding to the larger of H_{00}, H_{10}.

Abstract

In a k-party communication problem, the k players with inputs $x_1, x_2, \ldots, x_k$, respectively, want to evaluate a function $f(x_1, x_2, \ldots, x_k)$ using as little communication as possible. We consider the message-passing model, in which the inputs are partitioned in an arbitrary, possibly worst-case manner, among a smaller number t of players ($t < k$). The t-player communication cost of computing f can only be smaller than the k-player communication cost, since the t players can trivially simulate the k-player protocol. But how much smaller can it be? We study deterministic and randomized protocols in the one-way model, and provide separations for product input distributions, which are optimal for low error probability protocols. We also provide much stronger separations when the input distribution is non-product.

A key application of our results is in proving lower bounds for data stream algorithms. In particular, we give an optimal $\Omega(\varepsilon^{-2}\log(N)\log\log(mM))$ bits of space lower bound for the fundamental problem of $(1\pm\varepsilon)$-approximating the number $\|x\|_0$ of non-zero entries of an n-dimensional vector x after m updates each of magnitude M, and with success probability $\geq 2/3$, in a strict turnstile stream. Our result matches the best known upper bound when $\varepsilon \geq 1/\mathsf{polylog}(mM)$. It also improves on the prior $\Omega(\varepsilon^{-2}\log(mM))$ lower bound and separates the complexity of approximating L_0 from approximating the p-norm L_p for p bounded away from 0, since the latter has an $O(\varepsilon^{-2}\log(mM))$ bit upper bound.

1 Introduction

Consider a k-party communication problem, in which the players have inputs $x_1, x_2, \ldots, x_k$ respectively, and want to compute a function $f(x_1, x_2, \ldots, x_k)$ of their inputs using as little communication as possible. We consider the message-passing model, in which the inputs are partitioned in an arbitrary, possibly worst-case manner among a smaller number t of players. That is, we partition $\{1, 2, \ldots, k\}$ into t subsets $S_1, S_2, \ldots, S_t$ such that $\cup_{i=1}^{t} S_i = \{1, 2, \ldots, k\}$ and $S_i \cap S_j = \emptyset$ for every $1 \leq i < j \leq t$, and let the i-th player P_i hold the sequence of inputs $y_i := \left(x_{i_1}, x_{i_2}, \ldots, x_{i_{|S_i|}}\right)$. We are still interested in computing the original function f. The total communication required must be smaller than in the original k-player setting, since the t players can simulate the protocol involving the original k players. A natural question is: *how much smaller can the communication be?*

There are many communication models that are possible, but our main motivation for looking at this question comes from applications to data streams, see below, and so we are primarily interested in the *one-way number-in-hand* model. In this model, each of the t players can only see its own input. The first player composes a message m_1 based on its input y_1 and sends m_1 to the second player. The second player takes m_1 and its input y_2 to compute a message m_2 for the third player, and so on. The t-th (also the last) player, upon receiving the message m_{t-1} from the $(t-1)$-st player, computes the output of the protocol based on m_{t-1} and its own input y_t. We sometimes abuse notation and refer to the output as m_t. The total communication cost is the maximum of $\sum_{i=1}^{t} |m_i|$, where $|m_i|$ denotes the length of the i-th message and the maximum is taken over all possible inputs $y_1, \ldots, y_t$ (which is a partition of $\{x_1, \ldots, x_k\}$) and all random coin tosses of the players. For streaming applications we are especially interested in $\max_{i \in \{1,\ldots,t\}} |m_i|$.

To explain the connection to data streams, almost all known lower bound arguments on the memory required of a data stream algorithm are proven via communication complexity, or at least can be reformulated using communication complexity. The basic idea is to partition the elements of an input stream contiguously, consisting of say k elements, into a possibly smaller number t of players. Then one argues that if there is a data stream algorithm solving the problem, then the communication problem can be solved by passing the memory contents as messages from player to player. Note that this naturally gives rise to the one-way number-in-hand model. Since the total communication cost is $t \cdot S$, where S is the size of the memory of the streaming algorithm, if the randomized t-player communication complexity of the function f is CC_t, we must have $S \geq CC_t/t$. Many lower bounds in data streams are proven already with two players. However, it is known that for some functions more players are needed to obtain stronger lower bounds, such as for estimating the frequency moments in insertion only streams (see, e.g., [3, 17] and references therein).

One cannot help but ask *how powerful is communication complexity for proving data stream lower bounds*? Another natural question is: *for a given function f, which number t of players should one partition the stream into*? Yet another question is regarding the input distribution – should it be a product distribution for which the inputs to the players are chosen independently, or should the inputs be drawn from a non-product distribution to obtain the best space lower bounds? Since we are interested in the limits of using t players for establishing lower bounds for data stream algorithms, we allow the original k inputs (which correspond to the k elements in a stream) to be partitioned in the worst possible way for a t-player communication protocol, as this will give the strongest possible lower bound.

1.1 Our Results

In this paper we study these communication questions and their connections to data streams.

We first make the simple observation that for non-product input distributions, the communication complexity can be arbitrarily smaller if we partition the k inputs into $t < k$ players. Indeed, consider the k-player set disjointness problem in which the i-th player, $1 \leq i \leq k$, has a set $S_i \subseteq [n]$, where for notational simplicity we define $[n] := \{1, 2, \ldots, n\}$ for $n \in \mathbb{N}$. The input distribution satisfies the promise that either (1) $S_i \cap S_j = \emptyset$ for every $1 \leq i < j \leq k$, or (2) there is a unique item $a \in [n]$ such that $a \in S_i$ for all $i \in [k]$, and for any other $a' \neq a$, there is at most one $i \in [k]$ for which $a' \in S_i$. It is well-known that the randomized communication complexity of this problem is $\Omega(n/k)$ [3, 8, 10], and that the bound holds even for multiple rounds of communication and players share a common blackboard. However, if we look at $t < k$ players and an arbitrary, even if the worst-case mapping of the input sets $S_1, \ldots, S_k$ to the t players, then by the pigeonhole principle there exists a player who gets two input sets S_i, S_j with $i \neq j$. Now this player can locally determine the output of the function by checking if $S_i \cap S_j = \emptyset$. Thus with $t < k$ players the problem is solvable using $O(1)$ bits per player. This simple argument shows that for non-product distributions, there can be an arbitrarily large gap between the k-player and the t-player worst-case-partitioned randomized communication complexities. Note that this example applies to a symmetric problem, meaning that the k-player set disjointness problem is invariant under any one-to-one assignment of $x_1, \ldots, x_k$ to the k players.

Perhaps surprisingly, and this is one of the main messages of our work: for symmetric functions and product input distributions, we show that for any $t < k$, for deterministic one-way communication complexity or randomized one-way communication complexity with error probability $1/\mathsf{poly}(k)$, there *is no gap* in maximum message length between the k-player and t-player communication complexities. That is, the gap is at most a multiplicative $O(1)$ factor in message length and $O(k)$ in total communication. Further, this gap is tight, as there are problems for which the input distribution is a product distribution, and the t-player communication with $1/\mathsf{poly}(k)$ error probability is $O(\log k)$ for constant $t = O(1)$, while the k-player communication with $1/\mathsf{poly}(k)$ error probability is $\Omega(k \log k)$. Thus, the answer for product input distributions is significantly different than what we saw for non-product distributions, even for symmetric functions.

We also show that for constant error protocols and under product input distributions, the gap is at most a multiplicative $O(\log k)$ factor in message length and $O(k \log k)$ in total communication. Further, we show there exists a symmetric function and input distribution which is product on any $k-1$ out of k inputs, for which this gap is best possible. We leave open the question of the existence of a symmetric function and product input distribution (on all k inputs rather than $k-1$ out of k) which realizes this gap for constant error protocols.

One takeaway message from our results is that when showing space lower bounds for data stream algorithms computing symmetric functions on product distributions, by looking at 2-player communication complexity (which is by far the most common communication setup), there is only an $O(1)$ factor loss for error probability $1/\mathsf{poly}(k)$ protocols, and an $O(\log k)$ factor loss for constant error protocols.

Data Stream Lower Bounds: As a key application of our lower bound techniques, we provide a space lower bound for $(1 \pm \varepsilon)$-approximating the *Hamming norm* in the strict turnstile model. This problem, which is also known as the L_0 *norm estimation* and denoted by T_ε, requires estimating $\|\mathbf{x}\|_0 := |\{i \mid x_i \neq 0\}|$ of a vector $\mathbf{x} = (x_1, \ldots, x_N)$ and outputting an estimate $\widetilde{F}$ for which $(1-\varepsilon)\|\mathbf{x}\|_0 \leq \widetilde{F} \leq (1+\varepsilon)\|\mathbf{x}\|_0$ with constant probability. The vector $\mathbf{x}$ is initialized to all zeros and undergoes a sequence of m updates each of the

form $(i, v) \in [N] \times [\pm M]$, where $[\pm M] := \{0, \pm 1, \ldots, \pm M\}$ and each update (i, v) causes $x_i \leftarrow x_i + v$. In the strict turnstile model $x_i \geq 0$ holds for all i and at all points in the stream. We obtain an $\Omega\left(\varepsilon^{-2} \log(N) \log\log(mM)\right)$ bits of space lower bound for $(1 \pm \varepsilon)$-approximating the Hamming norm. This lower bound matches the best known upper bound $O\left(\varepsilon^{-2} \log(N) \left(\log(1/\varepsilon) + \log\log(mM)\right)\right)$ [12] for any $\varepsilon \geq 1/\mathsf{polylog}(mM)$. Note that $\varepsilon \geq 1/\mathsf{polylog}(mM)$ is required in order to obtain polylogarithmic space, and so is the most common setting of parameters. Perhaps surprisingly, there is an upper bound of $O\left(\varepsilon^{-2} \log(mM)\right)$ bits of space for $(1 \pm \varepsilon)$-approximating L_p for $p > 0$ [13] (improving an earlier $O\left(\log^2 N\right)$ bound of [9]; see also a time-efficient version in [11]), and thus we provide a strict separation in the complexities for $p = 0$ and $p > 0$. The Hamming norm has many applications, as it corresponds to estimating the number of distinct values, and can be used to estimate set union and intersection sizes (see [7] where it was introduced).

Technical Overview: We first illustrate the idea behind showing there is no gap between k-player and 2-player deterministic one-round communication complexity. The first player P_1 of the k-player protocol pretends to be Alice, the first player of the 2-player protocol, to create the message m_1 as Alice would do and sends it to the second player P_2 of the k-player protocol. Having received this message m_1, P_2 enumerates over all possible inputs of P_1 until finding one which would cause P_1 to send m_1. Since the protocol is deterministic and it evaluates a function defined on a product domain, meaning that it is a total function on a domain of the form $S_1 \times S_2 \times \cdots \times S_k$, the function value must be the same as long as P_1's input results in the same message m_1 to be sent. So P_2 can arbitrarily pick one of those inputs as his guess for P_1. Now P_2 has a guess x for P_1's input together with his own input y, and P_2 can simulate Alice in the 2-player protocol. This is feasible because the 2-player protocol works under any partitioning of the inputs. Then P_2 sends to the third player P_3 the message that Alice would send to Bob in the 2-player protocol, given that Alice had input (x, y). In case when every player P_i cannot figure out how many input items have been processed from his own input and the received message m_{i-1}, which is important for his simulation of the 2-player protocol, an additional logarithmic-many-bits index carrying this piece of information should be passed together with the simulated messages. In this way, the entire k-player protocol can be simulated and the per player communication equals to the communication of the 2-player protocol between Alice and Bob, sometimes plus the additional logarithmic many bits for the index. Moreover, both protocols are deterministic.

For the randomized case with a product input distribution, we first consider 2-player protocols with error probability $1/\mathsf{poly}(k)$. We would like to run the same simulation as for deterministic protocols, except now it is unclear how the second player P_2 can reconstruct a valid input x for the first player P_1 from the first message m_1. A natural thing would be for P_2 to choose the input x_1 to P_1 for which the probability of sending m_1, given that P_1's input is x_1, is greatest. This is not correct though, since the overall probability of P_1 holding x_1 and sending m_1 may be less than the $1/\mathsf{poly}(k)$ error bound and the protocol could afford to be always wrong on such a combination of x_1 and m_1. Thus we need some balancing between two probabilities: i) the first player P_1 sends m_1 on input x_1; and ii) the protocol output is correct given that P_1 has input x_1 and sends m_1.

The above naturally suggests that we should impose an input product distribution μ. Then it must be that for a good fraction of x, weighted according to μ, the k-player protocol is correct when the first player has input x_1 and sends message m_1. Thus we can sample x from the conditional distribution on μ given that message m_1 is sent. Here, for correctness, it is crucial that μ is a product distribution; this ensures for most settings of remaining player's inputs (weighted according to μ), for most choices of x_1 (weighted according to μ)

giving rise to m_1, the function evaluated on the inputs is the same, and x_1 can be sampled independently of remaining inputs. Once we have sampled x_1, and given that the second player has private input x_2 in the k-player protocol, we can then have the second player pretend to be Alice of a randomized 2-player protocol with input (x_1, x_2), similar to the deterministic case. Ultimately, we will show that under distribution μ we obtain a protocol with total communication at most $O(k)$ times that of the 2-player protocol with error probability $1/\mathsf{poly}(k)$ (and an $O(1)$ multiplicative blowup in maximum message length, times that of the 2-player protocol), where the factor k comes from the number of invocations of the 2-player protocol.

We illustrate the optimality of the randomized reduction above by looking at the Sum-Equal problem studied by Viola [16]: in this problem each of k players holds an input x_i mod p, where $p = \Theta\left(k^{1/4}\right)$ is a prime, and they wish to determine whether $\sum_i x_i = 0$ or $1 \mod p$. Viola shows this problem has randomized communication complexity $\Theta(k \log k)$, for both randomized protocols with constant error probability as well as deterministic protocols (and thus also randomized protocols with $1/\text{poly}(k)$ error probability). Moreover, for randomized protocols with $1/\text{poly}(k)$ error probability, Viola's $\Omega(k \log k)$ lower bound holds even for a product distribution on the inputs (where if $\sum_i x_i \mod p \notin \{0, 1\}$ the output can be arbitrary). We observe that under any partition of the inputs into 2-players Alice and Bob, the problem can be solved with $O(\log k)$ bits with probability $1 - 1/\text{poly}(k)$ just by running an equality test on the sum modulo p of Alice and the negated sum modulo p of Bob. Thus, this illustrates that the factor $O(k)$ gap for protocols for product input distributions with $1/\text{poly}(k)$ error probability is *optimal*.

On the other hand, for constant error protocols and a product input distribution, there is a 2-player $O(1)$ bit upper bound in the public coin model which comes from running an equality test with constant error probability (since we measure error with respect to an input distribution, equality has an $O(1)$ upper bound with constant error). We note that the k-player protocol has communication $\Omega(k \log k)$ for constant error protocols, which gives the $\Omega(k \log k)$ factor gap we claimed. The only downside is that the $\Omega(k \log k)$ lower bound holds for an input distribution which is product on $k - 1$ out of k players, rather than all k players. We leave it as an open question to give an optimal separation for product input distributions for constant error probability.

Given the importance of Viola's problem in showing separations, we next show a *direct sum theorem* for his problem, showing its communication complexity increases to $\Omega(kr \log k)$ for solving a constant fraction of r independent copies. To show the direct sum theorem for Viola's problem, one issue is that, unlike for two players where the technique of *information complexity* often provides direct sum theorems, for k-players the analogues are much weaker. A natural route would be to take Viola's *corruption bound*, argue it implies a high information bound, and then apply standard direct sum theorems for information. This approach does not give an information cost lower bound on private coin protocols, though one can fix it for two players using [5], which improves upon a bound in [6]. However, for k players similarly strong bounds are unknown. Another natural approach is to use the fact that if a problem has a corruption bound, then one immediately has a direct sum for it [4]. Again though, this is only for two players or the *number on forehead* model, and not for our setting.

Instead, our proof is inspired by Viola's rectangle argument for a single copy of the Sum-Equal problem, where each rectangle, restricted to the first $k - 1$ players, is a product distribution on which the protocol generates a message to the k-th player. We use a rectangle argument on multiple copies where the output is now a binary vector instead of a single bit. The main obstacle is that we must consider the Hamming distance between the protocol

output and the correct answer in a vector space, which is much more involved than studying the error probability for a single instance. The intuition of our proof is that for every large rectangle, there must be linearly many copies that appear (almost) uniformly random in the last player's view. The above argument is fairly intricate, and involves several levels of conversion: i) a large rectangle implies large conditional entropy in many players' inputs; ii) the large entropy of all copies implies we have min-entropy at least 1 on many copies; iii) a random variable of min-entropy at least 1 can always be decomposed into a convex combination of uniform distributions over two elements; iv) the summation of sufficiently many independent random variables that are each drawn from a uniform-over-two-element distribution turns out to be nearly uniform, and hence many Sum-Equal copies look uniform to the last player.

Thus, the last player can hardly outperform a random guess. Note that it is insufficient to prove uniformity for many copies individually (which is not too hard using the same idea as in Viola's proof), since such a situation could be simulated with a much smaller rectangle with very small error. We instead perform our rectangle argument inductively to show most copies appear almost uniform, even if conditioned on previous copies. For space considerations this induction is mostly deferred to the full version.

This direct sum technique has further applications. One application is to proving a lower bound for approximating the Hamming norm in a strict turnstile stream. Using a result of [2], to show lower bounds for streaming algorithms in the strict turnstile model, it suffices to show lower bounds in the simultaneous communication model, where each player simultaneously sends a message to a referee who outputs the answer. While our direct sum theorem holds in this more restrictive model, we also need to consider a composition of the gap-Hamming problem on top of the Sum-Equal instances as well as an augmented index version of the composed problem. In the augmented problem we additionally give a referee an index i and the answers to all copies j, with $j > i$. Similar augmentation has been studied for L_p-norms [13]. This allows us to reduce our communication problem to Hamming norm approximation, and ultimately prove our data stream lower bound.

2 Preliminaries

A function $f : \Sigma^k \to \Gamma$ is called a *k-party symmetric function* if for every $(x_1, x_2, \ldots, x_k) \in \Sigma^k$ and for every permutation σ over $\{1, 2, \ldots, k\}$, there is $f(x_1, \ldots, x_k) = f\left(x_{\sigma(1)}, \ldots, x_{\sigma(k)}\right)$. A k-dimensional vector space S is called a *product space* if it can be represented as $S = S_1 \times S_2 \times \cdots \times S_k$. A distribution μ is called a *product distribution* if it is obtained by taking the product of k independent distributions, i.e., $\mu = \mu_1 \times \mu_2 \times \cdots \times \mu_k$.

In the t-player communication complexity model, there are t computationally unbounded players, e.g., $P_1, \ldots, P_t$, required to compute a function $f : X_1 \times \cdots \times X_t \to Y$, where f is usually a t-party symmetric function. Each player P_i is given a private input $x_i \in X_i$ and follows a fixed protocol to exchange messages. For every input $(x_1, \ldots, x_t)$, the message transcript is denoted by $\Pi_t(x_1, \ldots, x_t)$ when all players follow the protocol Π_t (when Π_t is randomized, $\Pi_t(x_1, \ldots, x_t)$ is a random variable taking probabilities over players' random coins). A deterministic protocol Π_t computes f if there is a function Π_{out} such that $\Pi_{out}\left(\Pi_t^{(t)}(x_1, \ldots, x_t), x_t\right) \equiv f$, where $\Pi_t^{(t)}(x_1, \ldots, x_t)$ denotes P_t's view under the execution of Π_t on input $(x_1, \ldots, x_t)$ and for simplicity we let $\Pi_{out}(x_1, \ldots, x_t) := \Pi_{out}\left(\Pi_t^{(t)}(x_1, \ldots, x_t), x_t\right)$. A δ-error randomized protocol Π_t for f requires the existence of Π_{out} such that for all inputs $(x_1, \ldots, x_t)$, $\Pr\left[\Pi_{out}(x_1, \ldots, x_t) = f(x_1, \ldots, x_t)\right] \geq 1 - \delta$. The *communication cost* of Π_t is the maximum size of $\Pi_t(x_1, \ldots, x_t)$ over all $x_1, \ldots, x_t$ and all

random coins. The *t-player deterministic communication complexity* (resp. *t-player δ-error randomized communication complexity*), denoted by $\mathbf{DCC}_t(f)$ (resp. $\mathbf{RCC}_{t,\delta}(f)$), is the cost of the best t-player deterministic (resp. δ-error randomized) protocol Π_t for f.

Given a k-party function $f : X_1 \times \cdots \times X_k \to Y$ and $t < k$, we define $\mathbf{DCC}_t(f)$ and $\mathbf{RCC}_{t,\delta}(f)$ under a *worst-case partition* of inputs. That is, let $f_t(z_1, \ldots, z_t) = f(x_1, \ldots, x_k)$ be defined for every partition $i_0 = 0 \le i_1 \le \cdots \le i_t = k$ and $z_j := (x_{i_{j-1}+1}, \ldots, x_{i_j})$, and the t-player communication complexity of f is defined with respect to the worst choice of f_t, i.e., $\mathbf{DCC}_t(f) := \max_{f_t} \mathbf{DCC}_t(f_t)$ and $\mathbf{RCC}_{t,\delta}(f) := \max_{f_t} \mathbf{RCC}_{t,\delta}(f_t)$.

Given a t-party function f and its input distribution μ, we let $\mathbf{DCC}^{\mu}_{t,\delta}(f)$ denote the communication cost of the best t-player deterministic protocol Π_t computing f such that $\Pr_{x\sim\mu}[\Pi_{out}(x) \neq f(x)] \le \delta$. Similarly we define $\mathbf{RCC}^{\mu}_{t,\delta}(f)$ for randomized protocols.

In the restricted *one-way communication model* [15, 1, 14], the i-th player sends exactly one message to the $(i+1)$-st player for $i \in [t-1]$ following Π_t, and then P_t announces the output of Π_t as specified by Π_{out}. Note that in this setting there are only $k-1$ messages sent by $P_1, \ldots, P_{k-1}$, and we do not count the final output announced by P_t in the communication in order to best correspond to streaming algorithms. This is also known as a *sententious* protocol in previous work, e.g., [16]. We denote the *t-player one-way communication complexities of f* by $\overrightarrow{\mathbf{DCC}}_t(f)$ and $\overrightarrow{\mathbf{RCC}}_{t,\delta}(f)$, respectively.

In the *common reference string model* (aka *CRS model*), there is a sequence of public random coins, which is by default a uniformly random binary string, accessible to all players. The obvious advantage of communication in the CRS model is that players have access to the same random string and thus save the cost of synchronizing their private coins.

A streaming algorithm is an algorithm that scans the input $(x_1, \ldots, x_m) \in \Sigma^m$ as m stream input items in sequence, updates its internal memory of size $s = o(m \log |\Sigma|)$ (i.e., a streaming automaton with 2^s states, where the space cost of updating the internal memory is not accounted for), and finally outputs a function $f(x_1, \ldots, x_m)$ evaluated on all input items. If the best deterministic (resp. δ-error randomized) streaming algorithm computes f with s bits of memory and t passes over the data stream, then we say the *deterministic* (resp. *δ-error*) *streaming complexity* of f is st, denoted by $\mathbf{DSC}(f) = st$ (resp. $\mathbf{RSC}_\delta(f) = st$). In a popular and standard setting, a streaming algorithm scans the input stream in a *single pass* and only processes every input item once. The necessary amount of memory required by such single-pass algorithms is called the *single-pass deterministic/δ-error streaming complexity* and denoted by $\overrightarrow{\mathbf{DSC}}(f)$ and $\overrightarrow{\mathbf{RSC}}_\delta(f)$ respectively.

Note that every streaming algorithm can be naturally interpreted as a communication protocol where each party holds some (possibly an empty set of) input items on the stream and the messages capture the memory updates. The connection between streaming complexity and communication complexity trivially follows in the following lemma.

▶ **Lemma 1.** *For every function f and error tolerance δ, for every $k \in \mathbb{N}$, it holds that:*

$$\mathbf{DSC}(f) \ge \frac{1}{k} \cdot \mathbf{DCC}_k(f), \quad \mathbf{RSC}_\delta(f) \ge \frac{1}{k} \cdot \mathbf{RCC}_{k,\delta}(f)$$

Furthermore, similar relations hold for $\overrightarrow{\mathbf{DSC}}$, $\overrightarrow{\mathbf{RSC}}_\delta$ and $\overrightarrow{\mathbf{DCC}}_k$, $\overrightarrow{\mathbf{RCC}}_{k,\delta}$.

3 Communication Complexity for Functions on Non-Product Spaces

▶ **Theorem 2.** *For every $t \ge 2$, there is a t-party symmetric function f defined on $D \subseteq \{0,1\}^n = \left(\{0,1\}^{n/t}\right)^t$ such that for $\delta < 1/4$, $\overrightarrow{\mathbf{DCC}}_{t-1}(f) \le t-1$ but $\mathbf{RCC}_{t,\delta}(f) = \Omega(n/t)$. If $t = O(1)$, then $\overrightarrow{\mathbf{DCC}}_{t-1}(f) = O(1)$ and $\mathbf{RSC}_\delta(f) \ge \frac{1}{t} \cdot \mathbf{RCC}_{t,\delta}(f) = \Omega(n)$.*

Proof. Consider the t-party set disjointness problem $\textsc{Disj}_{n/t,t}$ defined as follows: there are t players $P_1, \ldots, P_t$ such that every player P_i holds a private indicator vector $\mathbf{x}_i \in \{0,1\}^{n/t}$ which represents a subset of $[n/t]$, i.e., $\textsc{Disj}_{n/t,t}(\mathbf{x}_1, \ldots, \mathbf{x}_t) = \vee_{j=1}^{n/t} (\wedge_{i=1}^{t} x_{i,j})$, where $x_{i,j}$ denotes the j-th coordinate of $\mathbf{x}_i$. We consider the domain D such that the vectors $\mathbf{x}_1, \ldots, \mathbf{x}_t \in \{0,1\}^{n/t}$ are either (1) pairwise disjoint, or (2) sharing a unique element $j \in [n/t]$. Let f be the function that computes $\textsc{Disj}_{n/t,t}$ on domain D.

On the one hand, it is easy to verify that $\overrightarrow{\mathbf{DCC}}_{t-1}(f) \leq t-1$. Indeed, at least one of the $t-1$ players obtains two distinct indicator vectors and hence can itself decide the output of f. The communication is 1 bit per player to pass the result, and hence the total communication is bounded by $t-1$ since there are $t-1$ players.

On the other hand, the $\Omega(n/t)$ lower bound for $\mathbf{RCC}_{t,\delta}(f)$ follows from the known lower bound for multi-player set disjointness (see [3], which was improved to optimal in [8, 10]). The lower bound for $\mathbf{RSC}_{\delta}(f)$ immediately follows by Lemma 1. ◀

4 Deterministic Communication and Streaming Complexity

We first show that 2-player one-way communication complexity is equivalent to the streaming complexity of single-pass streaming algorithms in the deterministic setting.

▶ **Theorem 3.** *For every symmetric function f, $\overrightarrow{\mathbf{DCC}}_2(f) \leq \overrightarrow{\mathbf{DSC}}(f) \leq \overrightarrow{\mathbf{DCC}}_2(f) + \log n$.*

Proof. Obviously, $\overrightarrow{\mathbf{DSC}}(f) \geq \overrightarrow{\mathbf{DCC}}_2(f)$ since a 2-player communication protocol simulates a streaming algorithm. It remains to prove $\overrightarrow{\mathbf{DSC}}(f) \leq \overrightarrow{\mathbf{DCC}}_2(f) + \log n$.

Suppose the input stream is $(x_1, \ldots, x_n) \in \Sigma^n$, and for every partition into $(x_1, \ldots, x_i)$ and $(x_{i+1}, \ldots, x_n)$ there is a deterministic 2-player one-way protocol Π_2^i computing f. We design the deterministic single-pass streaming algorithm A for f by simulating 2-player one-way communication protocols under different partitions. The memory usage of A is therefore bounded by the maximum communication cost of the simulated 2-player protocols plus an index in $[n]$ recording the number of processed items. Notice that when processing the item x_{i+1}, A has already processed $x_1, \ldots, x_i$ and has (m_i, i) in memory. A can thus reconstruct a compatible guess of $x_1'', \ldots, x_i''$ that would induce exactly the message m_i as in Π_2^i, and then sets the memory to be $(m_{i+1}, i+1)$ where m_{i+1} is the message sent in Π_2^{i+1} when P_1 has $(x_1'', \ldots, x_i'', x_{i+1})$ and P_2 has $(x_{i+2}, \ldots, x_n)$. A repeats this process for every $i = 1, \ldots, n-1$ and at the end it outputs $f(x_1, \ldots, x_n)$.

Therefore, we complete the proof with $\overrightarrow{\mathbf{DCC}}_2(f) \leq \overrightarrow{\mathbf{DSC}}(f) \leq \overrightarrow{\mathbf{DCC}}_2(f) + \log n$. ◀

▶ **Corollary 4.** *For every k-party symmetric function f,*

$$(k-1) \cdot \overrightarrow{\mathbf{DCC}}_2(f) \leq \overrightarrow{\mathbf{DCC}}_k(f) \leq (k-1) \cdot \left(\overrightarrow{\mathbf{DCC}}_2(f) + \log k \right)$$

Proof. Combining Lemma 1 and Theorem 3, it follows that

$$\overrightarrow{\mathbf{DCC}}_k(f) \leq (k-1) \cdot \overrightarrow{\mathbf{DSC}}(f) \leq (k-1) \cdot \left(\overrightarrow{\mathbf{DCC}}_2(f) + \log k \right)$$

The other direction $\overrightarrow{\mathbf{DCC}}_k(f) \geq (k-1) \cdot \overrightarrow{\mathbf{DCC}}_2(f)$ holds by giving $z_j = \emptyset$ to every player $j \in \{2, \ldots, k-1\}$ in the k-player case, when the problem degenerates to 2-player communication but the same message has to be passed $k-1$ times. ◀

Such a linear separation naturally extends to the communication complexity of t-player versus k-player protocols, as long as $2 \leq t < k$. Thus, the deterministic communication complexity grows *linearly* in the number of parties.

We remark that if every player must get a non-trivial input, i.e., at least one input element to the function, the linear growth remains for some but not all problems. For example, the communication complexity of the parity of k bits is linear in the number of players. However, to decide whether k elements in $[k]$ are distinct, the 2-player protocol requires communication $\log\binom{k}{k/2} \approx k - \log\sqrt{k}$, whereas the k-player worst-case communication grows sublinearly, i.e. for k players the communication is no more than $\sum_{i=1}^{k-1}\log\binom{k}{i} \ll (k-1)\cdot\log\binom{k}{k/2}$.

5 Communication Complexity for Functions on a Product Space

5.1 Separations for Randomized Communication Complexity

In this section, we consider the communication cost of randomized multi-player protocols defined on product input distributions and present a $k\log k$ versus $t\log t$ separation between k-player and t-player communication complexity.

First we introduce the Sum-Equal problem (as used in Viola's work [16]).

The *k-player* Sum-Equal *over integers*, denoted by Sum-Equal$_k$, requires deciding whether $\sum_{i=1}^{k} x_i = 0$, where each player P_i is given an integer x_i as well as k. In the CRS model, an additional public random string is also known to all players. The *k-player* Sum-Equal *over* $\mathbb{Z}_m$, denoted by Sum-Equal$_{k,m}$, is defined similarly as Sum-Equal$_k$, except that the input items are drawn from $\mathbb{Z}_m$ and the summation is over $\mathbb{Z}_m$, for a publicly known m.

▶ **Lemma 5** ([16], Theorem 15 and Theorem 29). *For every $k \in \mathbb{N}$, $0 \le \delta \le 1/3$, and in the CRS model, the k-player δ-error communication complexity of* Sum-Equal *satisfies:*

(a) *For every $m \in \mathbb{N}$, $\overrightarrow{\mathbf{RCC}}_{k,\delta}(\text{Sum-Equal}_{k,m}) = O(k\log(k/\delta))$.*

(b) *For every prime $p \in (k^{1/4}, 2k^{1/4})$, $\mathbf{RCC}_{k,\delta}(\text{Sum-Equal}_{k,p}) = \Omega(k\log k)$.*

In particular, $\mathbf{RCC}_{k,\delta}(\text{Sum-Equal}_{k,p}) = \Theta(k\log k)$ in the CRS model if $\delta = \Omega(1/\mathsf{poly}(k))$.

We remark that Viola's lower bound for Sum-Equal$_{k,p}$ is proved for a non-product distribution μ_H whose support covers exactly a $2/p$ fraction of the whole (product) input space. Thus if a k-player protocol solves Sum-Equal$_{k,p}$ with error $\delta \le 1/k$ on a uniform distribution μ over the whole input space, then its error with respect to μ_H is bounded by $\frac{1/k}{2/p} < k^{-3/4}$. By Lemma 5, the $\Omega(k)$ separation in Corollary 6 naturally follows.

▶ **Corollary 6.** *For prime $p \in (k^{1/4}, 2k^{1/4})$ and $\delta \le 1/\mathsf{poly}(k)$, there is a product distribution μ such that $\mathbf{RCC}^{\mu}_{k,\delta}(\text{Sum-Equal}_{k,p}) = \Omega(k\log k)$, $\overrightarrow{\mathbf{RCC}}_{2,\delta}(\text{Sum-Equal}_{k,p}) = O(\log k)$.*

For a larger error tolerance, say δ is a constant, we have a stronger separation between k-party communication and t-party communication. However, the hard distribution is slightly non-product, that is, it is a product distribution on any $k-1$ out of the k players.

▶ **Corollary 7.** *For every $k \in \mathbb{N}$, there is a k-party symmetric function f such that*

(a) *For any product distribution μ, for every $2 \le t \le k$ and $0 \le \delta \le 1/3$, $\overrightarrow{\mathbf{RCC}}^{\mu}_{t,\delta}(f) = O(t\log(t/\delta))$. In particular, $\overrightarrow{\mathbf{RCC}}^{\mu}_{2,\delta}(f) = O(\log(1/\delta))$.*

(b) *There exists a distribution μ_H, which is product on any $k-1$ out of k players, for which $\mathbf{RCC}^{\mu}_{k,\delta}(f) = \Omega(k\log k)$ as long as $\delta \le 1/3$.*

For $\delta \ge 1/\mathsf{poly}(t)$, the gap between $\mathbf{RCC}^{\mu}_{k,\delta}(f)$ and $\overrightarrow{\mathbf{RCC}}^{\mu}_{t,\delta}(f)$ is bounded as below:

$$\mathbf{RCC}^{\mu}_{k,\delta}(f) \,/\, \overrightarrow{\mathbf{RCC}}^{\mu}_{t,\delta}(f) = \Omega\left(\frac{k\log k}{t\log t}\right)$$

The outline of the proof of Corollary 7 was given in Section 1. That is, the upper bound in part (a) follows from applying $k = t$ in the first part of Lemma 5, while the lower bound in part (b) follows from the second part of Lemma 5. We defer the proofs to the full version.

5.2 Tightness of the Communication Complexity Separation

The following theorem and corollary show tightness of our separations.

▶ **Theorem 8.** *For every k-party function $f : \Sigma^k \to \Gamma$, product distribution μ over Σ^k, and error tolerance $\delta < 1/3$, if the optimal δ-error 2-player one-way protocol for f does not degenerate to the deterministic case, then the following holds:*

$$\overrightarrow{\mathbf{RCC}}^{\mu}_{k,\delta}(f) \,/\, \overrightarrow{\mathbf{RCC}}_{2,\delta}(f) \leq O\left(k \cdot \left(1 + \frac{\log k}{\log(1/\delta)}\right)\right) = \begin{cases} O(k \log k) & \text{if } \delta = \Omega(1) \\ O(k) & \text{if } \delta = 1/k^{\Omega(1)} \end{cases}$$

Proof sketch. We present the major steps and leave the complete proof to the full version.

First we let Π_0 be the optimal δ-error 2-player one-way protocol Π_0 that computes f with communication $C = \overrightarrow{\mathbf{RCC}}_{2,\delta}(f)$, and construct a new protocol Π_2 by taking $M = O\left(1 + \frac{\log k}{\log(1/\delta)}\right)$ repetitions of Π_0 such that the error probability of Π_2 is reduced to $\delta^2/(16k^2)$. Note that Π_2 is still a 2-player one-way protocol but has communication $O(CM)$.

Second we prove that for every product input distribution μ over Σ^k, the k-party function f can be evaluated by a randomized k-player one-way protocol Π_k with communication $O(k \cdot CM)$ and error $\delta/2$ with respect to μ. The idea is that given μ, each player P_i: 1) assumes that the received message m_{i-1} from P_{i-1} will lead to a correct answer with probability $\geq 1 - \frac{\delta}{4k}$; 2) samples a possible input $x'_1, \ldots, x'_{i-1}$ of previous players $P_1, \ldots, P_{i-1}$ on which with probability $\geq 1 - \frac{\delta}{4k}$ the protocol is correct conditioned on m_{i-1} being sent and $(x'_1 \ldots, x'_{i-1}, x_i, \ldots, x_k)$ being the actual input (here we use that μ is a product distribution); 3) and finally sends a message m_i of length $O(CM)$ as in Π_2 where Alice has input $(x'_1, \ldots, x'_{i-1}, x_i)$. By a union bound the error probability of Π_k is bounded by $\delta/2$ with respect to μ. The fact that μ is a product distribution is used in the second step where the sampling process relies on that previous players' inputs are independently distributed from that of future players.

Thus we finish the proof and conclude that $\overrightarrow{\mathbf{RCC}}^{\mu}_{k,\delta}(f) \leq O(kCM)$. ◀

Notice that in the proof of Theorem 8, every message in Π_k has the length bounded by $O(CM)$, which gives an upper bound for the single-pass streaming complexity.

▶ **Corollary 9.** *For every k-party function f and product input distribution μ, and for every $\delta < 1/3$, $\mathbf{RSC}^{\mu}_{\delta}(f) \leq \overrightarrow{\mathbf{RSC}}^{\mu}_{\delta}(f) \leq O\left(1 + \frac{\log k}{\log(1/\delta)}\right) \cdot \overrightarrow{\mathbf{RCC}}_{2,\delta}(f)$.*

6 A Direct Sum for Viola's Problem

We next turn to our direct sum theorem for Viola's problem, which is a crucial building block for our streaming application.

▶ **Theorem 10.** *Let $F : \left(\mathbb{Z}_p^m\right)^k \to \{0,1\}^m$ be the k-party function computing m independent copies of* Sum-Equal$_{k,p}$*, where p is a prime between $k^{1/4}$ and $2k^{1/4}$. For every error tolerance $\delta \in (0, 1/9)$, we say a protocol Π is* correct with probability $1 - \delta$ *if there is a reconstruction function G such that for every fixed $i \in [m]$ and input $x \in \left(\mathbb{Z}_p^m\right)^k$, $G\big(i, \Pi_{out}(x)\big)$ equals the output of the i-th instance of* Sum-Equal$_{k,p}$ *with probability at least $1 - \delta$, over the internal randomness of Π. Then the communication cost of any Π which is correct with probability $1 - \delta$, is $\Omega(mk \log k)$.*

We give a sketch of the proof of Theorem 10 here, and defer the full proof to the full version.

Proof sketch of Theorem 10. First we fix the randomness used in the protocol Π and convert it into a deterministic protocol Π' that has δ error with respect to a specific input distribution $\mathcal{H}$. Here $\mathcal{H} = (X_1, \ldots, X_{k-1}, X_k + v)$ for independent $X_1, \ldots, X_{k-1}$ uniformly distributing over $\mathbb{Z}_p^m$, $X_k = -\sum_{j=1}^{k-1} X_j$ and v uniformly sampled from $\{0,1\}^m$. Note that $\mathcal{H}_{-k} := (X_1, \ldots, X_{k-1})$ is uniform over $\left(\mathbb{Z}_p^m\right)^{k-1}$.

We next recall the intuition behind rectangle arguments in multi-player number-in-hand communication complexity: every k-player (number-in-hand) deterministic protocol with communication at most c partitions the inputs into $C = 2^c$ sets $R^1, R^2, \ldots, R^C$, where each R^i is a *rectangle* in the form of $R^i = R_1^i \times R_2^t \times \ldots \times R_k^i$ such that every input in R^i induces exactly the same transcript π_i. We will use the rectangle argument to show that Π' uses communication $c \geq \Omega(1) \cdot mk \log k$.

The main step is the following claim (with proof sketched later in this subsection):

▷ Claim 11. If $c < \frac{1-9\delta}{135} \cdot mk \log k$, then for every rectangle R satisfying $\Pr[\mathcal{H}_{-k} \in R_{-k}] \geq 1/(3C) = 1/(3 \times 2^c)$, there must be $L \subseteq [m]$ and $\ell := |L| \geq 9\delta m$ such that conditioned on $X_{-k} \in R_{-k}$, the distribution of $X_k^{(L)}$, which is X_k restricted on L, is ℓ/p-close to the uniform distribution over $\mathbb{Z}_p^\ell$.

Using Claim 11, it is easy to show $\Pr[\Pi'(\mathcal{H}) \text{ errs on } \leq 3\delta m \text{ coordinates}] \leq 2/3$, which contradicts that Π' has δ error with respect to $\mathcal{H}$ and $\delta < 1/9$. Therefore, the communication cost of Π', and hence of Π, must be $\geq \frac{1-9\delta}{135} \cdot mk \log k = \Omega(mk \log k)$. ◀

Proof sketch of Claim 11. This claim is proved using induction on the size of L. Suppose the claim is true for (w.l.o.g.) the first $\leq \ell - 1$ indices, we prove it for the next one. More specifically, we show that the last player P_k gets nearly no information about the ℓ-th copy when the input distribution follows $\mathcal{H}$ and X_{-k} falls into a sufficiently large rectangle $R_{-k} = R_1 \times \cdots \times R_{k-1}$. That is, for $X_{-k} \sim \left(\mathbb{Z}_p^m\right)^{k-1}$ and $X_k = -\sum_{j=1}^{k-1} X_j$, the marginal distribution $X_k^{(\ell)} \mid X_{-k} \in R_{-k}$ is statistically close to uniform.

The proof outline is as follows: first, let $\mathcal{E}_x$ denote the event that the first $k-1$ players have x on their first $\ell - 1$ coordinates, i.e. $X_{-k}^{[\ell-1]} = x$. Second, we consider frequently appearing x conditioned on $\mathcal{H}_{-k} \in R_{-k}$ such that $\Pr[\mathcal{E}_x \mid \mathcal{H}_{-k} \in R_{-k}] \geq \frac{1}{2p^{1+(\ell-1)(k-1)}}$ (the missed probability measure is at most $\frac{1}{2p}$ since there are $\leq p^{(\ell-1)(k-1)}$ different choices of x), and let $J_x \subseteq [k-1]$ be the set of players whose input falls into R_{-k} with "significant" probability conditioned on $\mathcal{E}_x$. Specifically, we prove that J_x must have size $|J_x| \geq 0.5k - 1$ for $J_x := \left\{ j \in [k-1] \;\middle|\; \Pr\left[X_j \in R_j \mid \mathcal{E}_x\right] \geq 2^{-1-2c/k} \right\}$. Third, for every player $j \in J_x$, we consider the set $I_{j,x}$ of coordinates such that for every $i \in I_{j,x}$, the conditional min-entropy of $X_j^{(i)}$ is large given that player j's input X_j is consistent with x and falls into R_j. In particular, for $I_{j,x} := \left\{ i \in [m] \mid \mathsf{H}_\infty\left[X_j^{(i)} \mid X_j \in R_j, \mathcal{E}_x\right] \geq 1 \right\}$, there is $|I_{j,x}| > m - \ell - \frac{2(1-9\delta)}{15} m + 1$.

Finally we apply Chebyshev's inequality and a Chernoff bound together with a standard averaging argument to conclude that there is a fixed coordinate, w.l.o.g. we call it ℓ, such that with probability $\geq 1 - e^{-\Omega(k)}$, the conditional min-entropy $\mathsf{H}_\infty\left[X_j^{(\ell)} \mid X_j \in R_j, \mathcal{E}_x\right] \geq 1$ for $\geq k/30$ players $j \in [k-1]$. As a result, the last player P_k's input $X_k^{(\ell)} = -\sum_{j=1}^{k-1} X_j^{(\ell)}$ is a convex combination of random variables where each of them is the summation of $\geq k/30$ uniform-over-two-elements variables. Repeating a very similar argument as in [16], we conclude that $X_k^{(\ell)}$ is $e^{-\Omega(\sqrt{k})}$ close to uniform.

The overall error probability of above arguments is bounded by $1/p$, which sums up to $\leq \ell/p$ for $X_k^{(L)}$ via a standard union bound. ◁

7 Lower bound for Hamming Norm Estimation

In this section we present a space lower bound for single-pass streaming algorithms for $(1\pm\varepsilon)$-approximating the Hamming norm L_0, which is denoted by T_ε as in Section 1.1. Recall that the underlying vector is N-dimensional and there are m updates each of magnitude $[\pm M]$.

▶ **Theorem 12.** *For error tolerance $\varepsilon < 1/3$ and $\varepsilon = \max\left\{\Omega\left(\sqrt{\frac{\log k}{k}}\right), \frac{1}{N^{0.49}}\right\}$, any single-pass streaming algorithm solving T_ε with probability $\geq 2/3$ in the strict turnstile model must use $\Omega\left(\varepsilon^{-2}\log(N)\log\log(mM)\right)$ bits of space.*

Proof sketch. We present a proof sketch here, with the detailed proof left to the full paper. First we introduce the $\mathrm{GHSE}_{n,k}$ problem, which is a composition of the n-dimensional gap Hamming weight problem $\textsc{Gap-Hamming}_n$ over the results of n copies of k-player $\textsc{Sum-Equal}_k$ instances, i.e., the result of $\mathrm{GHSE}_{n,k}$ is 1 if there are $\geq (1+\varepsilon)n/2$ underlying $\textsc{Sum-Equal}$ instances outputting 1, and 0 if $\leq (1-\varepsilon)n/2$ instances outputting 1.

The hard problem for our lower bound is the augmented index version of $\mathrm{GHSE}_{n,k}$, which we denote by $\textsc{Aug-Index-GHSE}^t_{n,k}$. In particular, $\textsc{Aug-Index-GHSE}^t_{n,k}$ has $t = \Theta(\log n)$ many $\mathrm{GHSE}_{n,k}$ instances embedded, where the last player P_k is given an index $i \in [t]$ together with the results of $\mathrm{GHSE}^{(i+1)}_{n,k}, \ldots, \mathrm{GHSE}^{(t)}_{n,k}$, and P_k is required to output the result of $\mathrm{GHSE}^{(i)}_{n,k}$. Following the reduction in Theorem 4.1 of [2] it suffices to prove our space lower bound in the simultaneous communication model, where each of $P_1, \ldots, P_{k-1}$ sends a single message to the referee P_k.

In the reduction from $\textsc{Aug-Index-GHSE}^t_{n,k}$ to T_ε, the input integers to underlying $\textsc{Sum-Equal}_k$ instances are processed as updates to distinct elements. Furthermore, every $\textsc{Sum-Equal}_k$ instance of $\mathrm{GHSE}^{(j)}_n$ embedded in the $\textsc{Aug-Index-GHSE}^t_{n,k}$ problem is given frequency 100^{j-1}, i.e., is counted as 100^{j-1} distinct elements. Thus the universe has $N := n + 100\cdot n + \cdots + 100^{t-1}\cdot n \leq 100^t n/99$ distinct elements in total, and the final Hamming norm is a weighted sum $F := \sum_{j=1}^t 100^{j-1} f_j$, where f_j is the Hamming weight of $\textsc{Sum-Equal}_k$ instances of $\mathrm{GHSE}^{(j)}_n$ for every $j \in [t]$. An algorithm solving T_ε will give a $(1\pm\varepsilon)$-estimate $\widetilde{F}$ of F, such that $(1-\varepsilon)F \leq \widetilde{F} \leq (1+\varepsilon)F$. From the estimate $\widetilde{F}$ we need to determine the result of $\mathrm{GHSE}^{(i)}_n$ for the given index i. Since the referee can precisely remove the influence of $\mathrm{GHSE}^{(i+1)}_{n,k}, \ldots, \mathrm{GHSE}^{(t)}_{n,k}$ using the auxiliary input before computing $\widetilde{F}$, it suffices to consider the case $i = t$ and the estimation of f_t. Indeed we prove that $\widetilde{F}$ is also a good approximation to $100^{t-1}f_t$ with high probability, as long as the additive error $\sum_{j=1}^{t-1} 100^{j-1} f_j$ is significantly less than the variance of $100^{t-1}f_t$. More specifically,

$$\mathbf{RCC}^{sim}_{k,1/3}(\mathrm{T}_\varepsilon) \geq \mathbf{RCC}^{sim}_{k,0.4}\left(\textsc{Aug-Index-GHSE}^t_{n,k}\right) \tag{1}$$

for our specified input distribution, which induces variance $O(n)$ on every f_j while our gap in advantage is $\Omega(n)$.

Then we prove that the communication cost of solving the augmented index version of t copies of $\mathrm{GHSE}_{n,k}$ is equal to simultaneously solving $\Omega(t)$ many copies.

$$\mathbf{RCC}^{sim}_{k,0.4}\left(\textsc{Aug-Index-GHSE}^t_{n,k}\right) \geq \Omega\left(t\cdot\mathbf{RCC}^{sim}_{k,0.01}(\mathrm{GHSE}_{n,k})\right) \tag{2}$$

The proof relies on the direct sum property of one-way communication for the GHSE problem. The intuition is that all necessary information for computing $\mathrm{GHSE}^{(1)}_{n,k}, \ldots, \mathrm{GHSE}^{(t)}_{n,k}$ must be included in the messages to the referee, since every instance $\mathrm{GHSE}^{(i)}_{n,k}$ can be determined at the referee's position by changing the referee's input alone (without tampering the messages).

Next we prove an $\Omega\left(\varepsilon^{-2}k\log\log k\right)$ lower bound for $\mathbf{RCC}^{sim}_{k,0.1}\left(\mathrm{GHSE}_{n,k}\right)$ and $mM = \mathsf{poly}(k)$. Consider the input $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_k)$ to the $\mathrm{GHSE}_{n,k}$ problem, where each player P_j gets $\mathbf{x}_j = \left(\mathbf{x}_j^{(1)}, \ldots, \mathbf{x}_j^{(n)}\right) \in \mathbb{Z}^n$, and for every $i \in [n]$, $Z^{(i)} := \textsc{Sum-Equal}_k\left(\mathbf{x}_1^{(i)}, \ldots, \mathbf{x}_k^{(i)}\right)$ denotes the result of the i-th Sum-Equal instance and the range is $\{\pm 1\}$. Let $\mathrm{HSE}(\mathbf{x}) := \sum_{i=1}^{k} Z^{(i)}$ denote the bias of the underlying vector for the $\textsc{Gap-Hamming}_n$ problem embedded in $\mathrm{GHSE}_{n,k}(\mathbf{x})$. Recall that $\mathrm{GHSE}_{n,k}$ distinguishes $\mathrm{HSE}(\mathbf{x}) \geq \varepsilon n$ and $\mathrm{HSE}(\mathbf{x}) \leq -\varepsilon n$, where the gap becomes $\sqrt{n'}$ for $\mathrm{GHSE}_{n',k}$ and $n' = 1/\varepsilon^2$. With random universal hash functions specified by the public randomness, we prove that

$$\mathbf{RCC}^{sim}_{k,0.01}\left(\mathrm{GHSE}_{n',k}\right) \geq \mathbf{RCC}^{sim}_{k,0.1}\left(\textsc{Aug-Index-Sum-Equal}_k^{n''}\right) \tag{3}$$

where $n'' = \Theta\left(n'\right)$ and $\textsc{Aug-Index-Sum-Equal}_k^{n''}$ is the augmented index version of n'' instances of the $\textsc{Sum-Equal}_k$ problem.

Furthermore, the lower bound holds for a distribution μ over $\mathbb{Z}^{n'\times k}$ such that for $\mathbf{x} \sim \mu$ the conditional expectation satisfies $\mathbf{Var}\left(\mathrm{HSE}(\mathbf{x})\right) \leq n'$, $\mathbf{E}\left[\mathrm{HSE}(\mathbf{x}) \mid \mathrm{GHSE}_{n',k}(\mathbf{x}) = 1\right] = 10\sqrt{n'}$ and $\mathbf{E}\left[\mathrm{HSE}(\mathbf{x}) \mid \mathrm{GHSE}_{n',k}(\mathbf{x}) = 0\right] = -10\sqrt{n'}$. More specifically, let each player specify independent hash functions for every $\textsc{Sum-Equal}_k$ instance, and send the majority of those hash values to the referee. The referee can guess the input and corresponding hash value of any specific $\textsc{Sum-Equal}_k$ instance, such that the conditional distribution of the majority of hash values has a $\Theta\left(1/\sqrt{n''}\right)$ bias under correct guesses. Therefore by taking $n' = \Theta\left(n''\right)$ independent instances of the majority of hash values and conditioned on the correctness of the guesses, the expected number of agreements of the majority and the guessed hash value has a gap of $\Theta\left(n'/\sqrt{n''}\right) = \Theta\left(\sqrt{n'}\right)$, while in both cases the variance is linear in n'. For convenience we shift $\mathrm{HSE}(\mathbf{x})$ to $\pm 10\sqrt{n'}$ by padding and hence the vector of majority instances becomes an input to $\textsc{Gap-Hamming}_{n'}$.

For $\mathbf{RCC}^{sim}_{k,0.1}\left(\textsc{Aug-Index-Sum-Equal}_k^{n''}\right)$, i.e., k-player 0.1-error simultaneous communication complexity of $\textsc{Aug-Index-Sum-Equal}_k^{n''}$, the lower bound follows Theorem 13.

▶ **Theorem 13.** *Let* Π *be an* δ*-error randomized simultaneous communication protocol for* $\textsc{Aug-Index-Sum-Equal}_k^{m'}$*, where* $m' \leq \frac{k\log\log k}{20\log k}$ *and the error tolerance* $\delta < 1/6$*. Then* Π *must have simultaneous communication cost* $\mathbf{RCC}^{sim}_{k,\delta}(\Pi) = \Omega\left(m'k\log\log k\right)$*. Furthermore, the lower bound holds when the inputs to the* $\textsc{Sum-Equal}_k$ *problems are drawn from* $\left([a]^{m'}\right)^{k-1} \times [\pm ka]^{m'}$ *and the sum of inputs to each copy of* $\textsc{Sum-Equal}_k$ *is promised to be* 0 *or* q*, where* $a = O\left(\log k\right)$ *and* $q = 2^{O(a)} \leq k^{1/8}$ *is a multiple of all integers in* $[a]$*.*

Here we present the proof intuition of Theorem 13, while the proof appears in the full paper. Suppose that in a simultaneous communication protocol, a player P_1 encodes multiple instances of $\textsc{Sum-Equal}_k$ independently in a message, say t_1 bits for $\textsc{Sum-Equal}_k^{(1)}$, t_2 bits for $\textsc{Sum-Equal}_k^{(2)}$, and so on. Then many $\textsc{Sum-Equal}_k$ instances will be irrecoverable if the message length $\sum_{i=1}^{m'} t_i$ is significantly less than necessary for handling m' instances in parallel, say $\sum_{i=1}^{m'} t_i \leq 0.1\cdot m'\cdot\mathbf{RCC}^{sim}_{k,\delta}\left(\textsc{Sum-Equal}_k\right)/k$, which means the $\textsc{Aug-Index-Sum-Equal}_k^{m'}$ cannot be solved with small error. Of course the full argument is much more involved, since the information in different Sum-Equal instances can be combined in the message, which we deal with via a dedicated rectangle argument for conditional distributions. Combining (1), (2), (3), and Theorem 13, we get $\mathbf{RCC}^{sim}_{k,1/3}\left(\mathrm{T}_\varepsilon\right) \geq \Omega\left(tn''k\log\log k\right)$. Recalling Theorem 4.1 of [2] and $t = \Theta\left(\log n\right) = \Omega\left(\log N\right)$, $n'' = \Theta\left(n'\right) = \Theta\left(\varepsilon^{-2}\right)$, $mM = \mathsf{poly}(k)$, we conclude that $\overrightarrow{\mathbf{RSC}}_{k,1/3}\left(\mathrm{T}_\varepsilon\right) = \Omega\left(\varepsilon^{-2}\log(N)\log\log(mM)\right)$. ◀

Abstract

Locally recoverable codes are a class of block codes with an additional property called locality. A locally recoverable code with locality r can recover a symbol by reading at most r other symbols. Recently, it was discovered by several authors that a q-ary optimal locally recoverable code, i.e., a locally recoverable code achieving the Singleton-type bound, can have length much bigger than $q+1$. In this paper, we present both the upper bound and the lower bound on the length of optimal locally recoverable codes. Our lower bound improves the best known result in [12] for all distance $d \geq 7$. This result is built on the observation of the parity-check matrix equipped with the Vandermonde structure. It turns out that a parity-check matrix with the Vandermonde structure produces an optimal locally recoverable code if it satisfies a certain expansion property for subsets of $\mathbb{F}_q$. To our surprise, this expansion property is then shown to be equivalent to a well-studied problem in extremal graph theory. Our upper bound is derived by an refined analysis of the arguments of Theorem 3.3 in [6].

1 Introduction

Motivated by applications in distributed and cloud storage systems, locally recoverable codes have been studied extensively in recent years. Informally speaking, a locally recoverable code (LRC for short) is a block code with an additional property called locality. For a locally recoverable code C of length n, dimension k and locality r, it was shown in [4] that the minimum distance $d(C)$ of C is upper bounded by

$$d(C) \leqslant n - k - \left\lceil \frac{k}{r} \right\rceil + 2. \tag{1}$$

The bound (1) is called the Singleton-type bound for locally recoverable codes. A code achieving the above bound is usually called optimal.

1.1 Known results

Construction of optimal locally recoverable codes, i.e., block codes achieving the bound (1) is of both theoretical interest and practical importance. This is a challenging task and has attracted great attention in the last few years. In the literature, there are a few constructions available and some classes of optimal locally recoverable codes are known. A class of codes constructed earlier and known as pyramid codes [8] are shown to be codes that are optimal. In [14], Silberstein *et al* proposed a two-level construction based on the Gabidulin codes combined with a single parity-check $(r+1, r)$ code. Another construction [16] used two layers of MDS codes, a Reed-Solomon code and a special $(r+1, r)$ MDS code. A common shortcoming of these constructions relates to the size of the code alphabet which in all the papers is an exponential function of the code length, complicating the implementation. There was an earlier construction of optimal locally recoverable codes given in [13] with alphabet size comparable to code length. However, the construction in [13] only produces a specific value of the length n, i.e., $n = \lceil \frac{k}{r} \rceil (r+1)$. Thus, the rate of the code is very close to 1. There are also some existence results given in [13] and [15] with less restrictions on the locality r. But both results require large alphabet which is an exponential function of the code length.

A recent breakthrough construction was given in [15]. This construction naturally generalizes Reed-Solomon construction which relies on the alphabet of cardinality comparable to the code length n. The idea behind the construction is very nice. The only shortcoming of this construction is restriction on the locality r. Namely, $r+1$ must be a divisor of either $q-1$ or q, or $r+1$ is equal to a product of a divisor of $q-1$ and a divisor of q for certain q, where q is the code alphabet. This construction was extended via automorphism group of rational function fields by Jin, Ma and Xing [10] and it turns out that there is more flexibility on the locality and the code length can be $q+1$. For some particular locality such as $r = 2, 3, 5, 7, 11$ or 23, it was shown that there exist q-ary optimal locally recoverable codes with length up to $q + 2\sqrt{q}$ via elliptic curves [11]. All these results are aimed at the optimal LRC with large distance.

Unlike classical MDS codes, it is surprising to discover that the optimal LRCs can have super-linear code length in alphabet size q. Barg et.al, [1] gave optimal LRCs by using algebraic surfaces of length $n \approx q^2$ when the distance $d = 3$ and $r \leqslant 4$. This inspired the construction of the optimal LRC with unbounded length and distance $d = 3, 4$ [12]. Furthermore, it was shown in [6] that an optimal LRC with $d \geq 5$ must have length upper bounded in terms of alphabet size q. More precisely, they showed that the length of an optimal q-ary linear LRC with distance $d \geqslant 5$ and locality r is upper bonded by $O\left(dq^{3+\frac{4}{d-4}}\right)$. As for the lower bound, they presented an explicit construction of optimal LRCs with code length $\Omega_r\left(q^{1+\frac{1}{\lfloor (d-3)/2 \rfloor}}\right)$ provided that $d \leq r+2$, where Ω_r means that the implied constant depends on r. One can see that there is still a huge gap between the lower bound and the upper bound. Following this discovery, there are several works dedicated to constructing the maximum length of optimal LRCs. The paper [9] aimed at the optimal LRC with small distance $d = 5$ or 6. In particular, for $d = 6$, the results given in [9] are obtained subject to the constraint that q is even.

1.2 Our results, comparisons and a conjecture

The main result of this paper can be summarized as follows.

▶ **Theorem 1.** *Suppose that $r \geqslant d-2$ and $(r+1)|n$. Then*

(i) *there exists an explicit construction of optimal locally recoverable codes with length $n = q^{2-o(1)}$, minimum distance d and locality r for $d = 7, 8$;*

(ii) *there exists an explicit construction of optimal locally recoverable codes with length* $n = q^{\frac{3}{2}-o(1)}$*, minimum distance* d *and locality* r *for* $d = 9, 10$*;*

(iii) *there exist optimal locally recoverable codes with length* $n = \Omega_{r,d}\left(q(q\log q)^{\frac{1}{\lfloor (d-3)/2 \rfloor}}\right)$*, minimum distance* d *and locality* r *for* $d \geq 11$*; and*

(iv) *there exists an explicit construction of optimal locally recoverable code with length* $n = \Omega_{r,d}\left(q^{1+\frac{1}{\lfloor (d-3)/2 \rfloor}}\right)$*, minimum distance* d *and locality* r *for a constant* $d \geq 11$*. Moreover, the complexity of this construction is upper bounded by* $O(n^d)$*.*

The first three results are derived from extremal graph theory (see Section 5). The last one is derived from the probabilistic arguments (see Section 4).

The first two results improve on the result in [6] which only achieves $n = \Omega(q^{3/2})$ for $d = 7, 8$ and $n = \Omega(q^{4/3})$ for $d = 9, 10$. The third one outperforms the result in [6] by a $(\log q)^{\frac{1}{\lfloor (d-3)/2 \rfloor}}$ multiplicative factor. In addition, for $d = 6$, we are able to remove the constraint required in [9] that q is even.

Although it was proved in [6] that the length of an optimal locally recoverable code is upper bounded by $q^{3+O\left(\frac{1}{d}\right)}$, both the constructions in [6] and this paper show from different angles that the length of an optimal locally recoverable code only achieve $q^{1+O\left(\frac{1}{d}\right)}$. Furthermore, via an upper bound from extremal graph theory, our construction in this paper can achieve at most $O\left(q^{1+\frac{2}{\lfloor (d-1)/2 \rfloor}}\right)$ (see Section 5). Thus, we make the following conjecture.

▶ **Conjecture 2.** *Every optimal locally recoverable code with minimum distance* d *and locality* r *has length upper bounded by* $q^{1+O\left(\frac{1}{d}\right)}$*.*

In addition to the above lower bound on length of optimal locally recoverable codes, we also provide an improved upper bound by refining the analysis of the arguments of Theorem 3.3 in [6].

▶ **Theorem 3** (Informal)**.** *Let* C *be an optimal* $[n, k, d]_q$*-linear locally repairable code with the locality* r*. If* $d \geqslant 5$*, then*

$$n \leq \begin{cases} O(q^3) & \text{if } d \bmod r+1 > 5 \text{ or } d \bmod r+1 < 2, \\ O(q^2) & \text{if } 2 \leq d \bmod r+1 \leq 5. \end{cases} \tag{2}$$

1.3 Our techniques

For minimum distance $d \geq 7$, the only optimal locally recoverable code with super-linear code length was given in [6]. In this paper, we present another construction for optimal LRCs for $d \geqslant 5$. Our idea comes from generalized Reed-Solomon codes where parity-check matrices have the Vandermonde structure. This idea was already employed in [9] for $d = 5, 6$. Similar to [9], we divide a parity-check matrix into disjoint blocks, each block with $r + 1$ columns. We require that each block of this matrix has a Vandermonde matrix structure. In order that the parity-check matrix with this structure produces an optimal locally recoverable code, elements in these blocks must satisfy certain expansion property. This property allows us to relate optimality of a locally recoverable code to a well-studied problem in extremal graph theory. With the help of extremal graph theory, we succeed to improve all of the best known results in [6] for $d \geq 7$.

Furthermore, by a random or probabilistic argument, we show an existence result. Moreover, for constant d the probabilistic method for the existence result can be converted into a deterministic algorithm via method of conditional probabilities. Thus, we obtain an algorithmic construction in polynomial time, i.e., Theorem 1(iv). The result of Theorem 1(iv) matches the result given in [6]. However, our parity-check matrix is more structured and this may lead to some other applications.

1.4 Organization

The paper is organized as follows. In Section 2, we briefly introduce locally recoverable codes and some basic notations on graph theory. Section 3 presents a necessary and sufficient condition for which a Vandermonde-type parity-check matrix produces an optimal locally recoverable code in terms of certain expansion property for subsets of $\mathbb{F}_q$. In Section 4, we first show an existence result via a probabilistic method. Then this probabilistic method is converted into an algorithmic construction in polynomial time. In Section 5, we show that the necessary and sufficient condition derived in Section 2 is equivalent to a central problem in extremal graph theory. By applying the known results from extremal graph theory, we obtain the desired results. Finally, in Section 6, we prove a general upper bound on the optimal LRC.

2 Preliminaries

2.1 Locally recoverable codes

Let q be a prime power and $\mathbb{F}_q$ be the finite field with q elements and denote by $[n]$ the set $\{1, 2, \ldots, n\}$. In this paper, we consider linear locally recoverable codes only. An $[n, k, d]$ linear code C is a k-dimensional subspace of $\mathbb{F}_q^n$ with minimum (Hamming) distance d. The (Euclidean) dual code of C, denoted by $C^\perp$, is defined by $C^\perp = \{\mathbf{b} \in \mathbb{F}_q^n : \ \mathbf{c} \cdot \mathbf{b} = 0 \text{ for all } \mathbf{c} \in C\}$, where $\mathbf{c} \cdot \mathbf{b}$ denotes the standard inner product of the two vectors $\mathbf{b}$ and $\mathbf{c}$.

Informally speaking, a block code is said to have locality r if every coordinate of a given codeword can be recovered by accessing at most r other coordinates of this codeword. There are several equivalent definitions of locally recoverable codes. A formal definition of a locally recoverable code with locality r is given as follows.

▶ **Definition 4.** A q-ary block code C of length n is called a locally recoverable code or locally repairable code (LRC for short) with locality r if for any $i \in [n]$, there exists a subset $R_i \subseteq [n] \setminus \{i\}$ of size r such that for any $\mathbf{c} = (c_1, \ldots, c_n) \in C$, c_i can be recovered by $\{c_j\}_{j \in R_i}$, i.e., for any $i \in [n]$, there exists a subset $R_i \subseteq [n] \setminus \{i\}$ of size r such that for any $\mathbf{u}, \mathbf{v} \in C$, $\mathbf{u}_{R_i \cup \{i\}} = \mathbf{v}_{R_i \cup \{i\}}$ if and only if $\mathbf{u}_{R_i} = \mathbf{v}_{R_i}$. The set R_i is called a recovering set of i.

In literature, there are various definitions for locally recoverable code and all of them are equivalent. For example, we have the following two definitions that are equivalent to Definition 4. For the sake of completeness, we give a proof.

▶ **Lemma 5.** *A q-ary code C of length n is a locally recoverable code if and only if one of the followings holds.*

- **(i)** *For any $i \in [n]$, there exists a subset $R_i \subseteq [n] \setminus \{i\}$ of size r such that position i of every codeword $\mathbf{c} \in C$ is determined by $\mathbf{c}_{R_i}$, i.e, there is a function $f_i(x_1, \ldots, x_r)$ (independent of $\mathbf{c}$ and only dependent on i) such that $c_i = f_i(\mathbf{c}_{R_i})$, where $\mathbf{c}_{R_i}$ stands for the projection of $\mathbf{c}$ at R_i.*
- **(ii)** *For any $i \in [n]$, there exists a subset $R_i \subseteq [n] \setminus \{i\}$ of size r such that*

$$C_{R_i}(i, \alpha) \cap C_{R_i}(i, \beta) = \emptyset$$

for any $\alpha \neq \beta \in \mathbb{F}_q$, where $C(i, \alpha) = \{\mathbf{c} \in C : \ c_i = \alpha\}$ and $C_{R_i}(i, \alpha)$ denotes the projection of $C(i, \alpha)$ on R_i.

The Singleton (upper) bound in (1) is given in terms of minimum distance d. We can also rewrite this bound in terms of dimension k.

▶ **Lemma 6.** *Let n, k, d, r be positive integers with $(r+1)|n$. If the Singleton-type bound* (1) *is achieved, then*

$$n - k = \frac{n}{r+1} + d - 2 - \left\lfloor \frac{d-2}{r+1} \right\rfloor. \tag{3}$$

Conversely, if $d - 2 \not\equiv r \pmod{r+1}$ and the equlity (3) *is satisfied, then the Singleton-type bound* (1) *is achieved.*

The proof is straightforward and can be found in [6].

▶ Remark 7. If $d - 2 \equiv r \pmod{r+1}$, one can verify that (3) implies that $r|k$. In this case, by [4, Corollary 10] one cannot achieve the Singleton-type bound (1) with equality and one must have $d \leqslant n - k - \left\lceil \frac{k}{r} \right\rceil + 1$. Therefore in this case we say an LRC attaining this latter bound as optimal.

▶ **Corollary 8.** *If $r \geqslant d-2$, then an $[n, k, d]$ locally recoverable code with locality r is optimal if*

$$n - k - \frac{n}{r+1} = d - 2. \tag{4}$$

Proof. As $r \geqslant d - 2$, $\left\lfloor \frac{d-2}{r+1} \right\rfloor = 0$. Hence, (3) and (4) are equivalent. ◀

The locality of a locally recoverable code C can be determined by a parity-check matrix of C as follows. Assume that $(r+1)|n$. Let $m = \frac{n}{r+1}$ and let D_i be $(n-k-m) \times (r+1)$ matrices. Put

$$H = \left(\begin{array}{c|c|c|c} \mathbf{1} & \mathbf{0} & \cdots & \mathbf{0} \\ \hline \mathbf{0} & \mathbf{1} & \cdots & \mathbf{0} \\ \hline \vdots & \vdots & \ddots & \vdots \\ \hline \mathbf{0} & \mathbf{0} & \cdots & \mathbf{1} \\ \hline D_1 & D_2 & \cdots & D_m \end{array} \right), \tag{5}$$

where $\mathbf{1}$ and $\mathbf{0}$ stand for the all-one row vector and the zero row vector of length $r+1$, respectively. Let C be the code with H as a parity-check matrix. Then it is clear that the dimension of C is at least k. Furthermore, we claim that the locality of C is r. Indeed, let $\mathbf{c} = (c_1, c_2, \ldots, c_n)$ be a codeword of C, then $\sum_{j=1+(r+1)i}^{(r+1)(i+1)} c_j = 0$ for $0 \leqslant i \leqslant m-1$ as $H\mathbf{c}^T = \mathbf{0}$. Hence, a coordinate c_j with $j \in \{1 + (r+1)i, \ldots, (r+1)(i+1)\}$ for some $0 \leqslant i \leqslant m-1$ can be repaired by $\mathbf{c}_{R_j}$ with $R_j = \{1 + (r+1)i, \ldots, (r+1)(i+1)\} \setminus \{j\}$.

In conclusion, to see if a linear code C with a parity-check matrix H of the form (5) is an optimal locally recoverable code, it is sufficient to check if the minimum distance of C satisfies (4) for $r \geqslant d - 2$.

2.2 Graphs

A undirected graph G is a pair $G = (V, E)$, where V is a finite set and E is a set consisting of some subsets of size 2 of V. An element of V is called a vertex and an element of E is called an edge. A subgraph G' of a graph G is a graph whose vertex set and edge set are subsets of those of G. We say that G has a cycle $(v_1, \ldots, v_m)$ if $\{v_i, v_{i+1}\} \in E$ for $i = 1, \ldots, m-1$ and $\{v_m, v_1\} \in E$. The following Lemma 9 provides a simple but useful way to determine if G contains a cycle. The proof can be found in any textbook about graph theory (see [3] for instance).

▶ **Lemma 9.** *An undirected graph G contains a cycle if $|E| \geq |V|$.*

Apart from the above usual definition of graphs, we also require some results on hypergraph in this paper. A hypergraph is a generalization of a graph in which an edge can join any number of vertices. Formally, a hypergraph H is a pair $H = (X, E)$ where X is a set of elements called vertices, and E is a set of non-empty subsets of X called hyperedges or edges. Therefore, E is a subset of $2^X \setminus \{\emptyset\}$, where 2^X stands for the power set of X.

▶ **Definition 10** (r-uniform Hypergraph (or r-graph for short))**.** *A hypergraph $H = (X, E)$ is called r-uniform if every hyperedge in E has size r. In other words, every hyperedge of an r-uniform hypergraph connects exactly r vertices.*

There are several ways to define cycles in a hypergraph that coincide with the definition of cycles in the usual graph. In this paper, we use the Berge cycle as the generalization of cycles in the usual graph.

▶ **Definition 11** (Berge cycle)**.** A r-uniform hypergraph $H = (X, E)$ contains a Berge k-cycle $(v_1, \ldots, v_k)$ if there exist k hyperedges $e_1, \ldots, e_k \in E$ such that $\{v_{i-1}, v_i\} \subseteq e_i$ for $i = 2, \ldots, k$ and $\{v_1, v_k\} \subseteq e_1$.

3 A criterion on minimum distance

It follows from Corollary 8 that for $d \leq r + 2$, a locally recoverable code with parity-check matrix H in (5) is optimal provided that any $d - 1$ columns of H are linearly independent and each D_i is a $(d - 2) \times (r + 1)$ matrix.

Let $\mathbb{F}_q$ be a finite field and put $m = \frac{n}{r+1}$. Assume that $A_1, \ldots, A_m$ are subsets of $\mathbb{F}_q$, each of size $r + 1$. Let $A_i = \{a_{i,1}, \ldots, a_{i,r+1}\}$ for $i = 1, \ldots, m$. Let $\mathbf{a}_{i,j} = (a_{i,j}, a_{i,j}^2, \ldots, a_{i,j}^{d-2})$ and put $D_i = (\mathbf{a}_{i,1}^T, \mathbf{a}_{i,2}^T, \ldots, \mathbf{a}_{i,r+1}^T)$. Thus, D_i is a Vandermonde-type matrix. Let $\mathbf{e}_1, \ldots, \mathbf{e}_m$ be the standard basis of vector space $\mathbb{F}_q^m$, i.e., all components of $\mathbf{e}_i$ are 0 except that the i-th component is 1. Then, we can rewrite H as follow.

$$H = \begin{pmatrix} \mathbf{e}_1^T & \cdots & \mathbf{e}_1^T & \cdots & \mathbf{e}_m^T & \cdots & \mathbf{e}_m^T \\ \mathbf{a}_{1,1}^T & \cdots & \mathbf{a}_{1,r+1}^T & \cdots & \mathbf{a}_{m,1}^T & \cdots & \mathbf{a}_{m,r+1}^T \end{pmatrix}. \tag{6}$$

We now present a sufficient and necessary condition under which any $d - 1$ columns of the matrix H in (6) are linearly independent.

▶ **Theorem 12.** *For $d \geqslant 5$, then any $d-1$ columns of H defined in* (6) *are linearly independent if and only if $|\bigcup_{i \in S} A_i| \geq r|S| + 1$ for any $S \subseteq [m]$ of size no more than $t = \lfloor \frac{d-1}{2} \rfloor$.*

Proof. We first prove the "if" direction. Let $\mathbf{h}_{i,j}$ be the (i, j)th column of H, i.e., $\mathbf{h}_{i,j} = (\mathbf{e}_i, \mathbf{a}_{i,j})^T$ for $1 \leqslant i \leqslant m$ and $1 \leqslant j \leqslant r+1$. Choose any $d-1$ columns $\{\mathbf{h}_{i,j}\}_{1 \leqslant i \leqslant m; j \in S_i}$ of H, where S_i are subsets of $[r+1]$ satisfying $\sum_{i=1}^m |S_i| = d-1$. Let $A_i' = \{a_{i,j} \in A_i : j \in S_i\}$, i.e., A_i' is the subset of A_i where each element is associated with one of the $d-1$ columns. Let H' be the $(n - k - m) \times (d - 1)$ matrix consisting of these $d - 1$ columns. We are going to show that H' has rank $d - 1$. We assume that S_i is either empty or of size at least 2. Otherwise, the unique column selected from D_i with $|S_i| = 1$ must be linearly independent from the rest $d - 2$ columns. We can consider the linear independence of the rest $d - 2$ columns instead. Now, we assume that there are at most t non-empty sets S_i. Let $A = \{a_{i,j}\}_{1 \leqslant i \leqslant m; j \in S_i}$.

Assume that $A = \{a_1, \ldots, a_s\}$ has s distinct elements. If $s = d-1$, then by elementary row operations, one can find a $(d-1) \times (d-1)$ Vandermonde submatrix of the form

$$\begin{pmatrix} 1 & 1 & \cdots & 1 \\ \mathbf{a}_1^T & \mathbf{a}_2^T & \cdots & \mathbf{a}_{d-1}^T \end{pmatrix}$$

of H', where $\mathbf{a}_i = (a_i, a_i^2, \ldots, a_i^{d-2})$. Thus, the rank of H' is $d-1$.

We proceed to the case where $s < d-1$. By permuting the columns of H', we obtain a matrix of the following form:

$$H_1 = \left(\begin{array}{cccc|ccc} \mathbf{e}_{i_1}^T & \mathbf{e}_{i_2}^T & \cdots & \mathbf{e}_{i_s}^T & \mathbf{e}_{i_{s+1}}^T & \cdots & \mathbf{e}_{i_{d-1}}^T \\ \mathbf{a}_1^T & \mathbf{a}_2^T & \cdots & \mathbf{a}_s^T & \mathbf{a}_{s+1}^T & \cdots & \mathbf{a}_{d-1}^T \end{array} \right),$$

where $1 \leqslant i_1 \leqslant i_2 \leqslant \cdots \leqslant i_{d-1} \leqslant m$ and $\{a_{s+1}, \ldots, a_{d-1}\}$ is a subset of A. Thus, a_j belongs to A_{i_j} for $1 \leqslant j \leqslant d-1$. By elementary column operations, we can erase $\mathbf{a}_{s+i}^T$ since it also appears in one of the first s columns. Hence, H_1 is equivalent to

$$H_2 = \left(\begin{array}{cccc|ccc} \mathbf{e}_{i_1}^T & \mathbf{e}_{i_2}^T & \cdots & \mathbf{e}_{i_s}^T & \mathbf{e}_{i_{s+1}}^T - \mathbf{e}_{k_{s+1}}^T & \cdots & \mathbf{e}_{i_{d-1}}^T - \mathbf{e}_{k_{d-1}}^T \\ \mathbf{a}_1^T & \mathbf{a}_2^T & \cdots & \mathbf{a}_s^T & \mathbf{0}^T & \cdots & \mathbf{0}^T \end{array} \right),$$

where $\{k_{s+1}, \ldots, k_{d-1}\}$ is a subset of $\{i_1, \ldots, i_s\}$. Since H_2 is an upper left triangular block matrix, showing that H_2 is a full-rank matrix is equivalent to showing both $(\mathbf{a}_1^T, \mathbf{a}_2^T, \ldots, \mathbf{a}_s^T)$ and $(\mathbf{e}_{i_{s+1}}^T - \mathbf{e}_{k_{s+1}}^T, \cdots, \mathbf{e}_{i_{d-1}}^T - \mathbf{e}_{k_{d-1}}^T)$ have full rank. Note that $(\mathbf{a}_1^T, \mathbf{a}_2^T, \ldots, \mathbf{a}_s^T)$ is a $(d-2) \times s$ Vandermonde matrix and hence it has full rank s. It remains to show that $\mathbf{e}_{i_{s+1}} - \mathbf{e}_{k_{s+1}}, \ldots, \mathbf{e}_{i_{d-1}} - \mathbf{e}_{k_{d-1}}$ are linearly independent. Suppose they were linearly dependent. Then there exist elements $\lambda_{s+1}, \ldots, \lambda_{d-1} \in \mathbb{F}_q$ which are not all zero such that

$$\sum_{j=s+1}^{d-1} \lambda_j (\mathbf{e}_{i_j} - \mathbf{e}_{k_j}) = 0.$$

Let P be the subset of $\{s+1, \ldots, d-1\}$ such that $\lambda_i \neq 0$ if and only if $i \in P$. It follows that

$$\sum_{i \in P} \lambda_i (\mathbf{e}_{j_i} - \mathbf{e}_{k_i}) = 0. \tag{7}$$

Let $U = \{j_i : i \in P\}$, $V = \{k_i : i \in P\}$ and $W = U \cup V$. As both U and V are subsets of $\{i \in [m] : |S_i| \geqslant 2\}$, we have $|W| \leqslant t = \lfloor \frac{d-1}{2} \rfloor$. Since λ_i is nonzero for all $i \in P$, every $\ell \in W$ must appear at least twice in the multiset consisting of elements of U and V. Otherwise, $\mathbf{e}_\ell$ could not be cancelled in (7). This implies $|W| \leq |P|$.

On the other hand, for each $a_i \in A$, there is exactly one subset A'_{k_i} containing a_i since the first s columns have s distinct $\mathbf{a}_i$. Furthermore, let $t_i = |\{\ell \in U : a_i \in A'_\ell\}|$. It follows that $\sum_{a_i \in A} t_i = |P|$ and a_i belongs to $t_i + 1$ subsets in $\{A'_\ell : \ell \in W\}$. This implies

$$\left| \bigcup_{\ell \in W} A_\ell \right| \leq \sum_{\ell \in W} |A_\ell| - \sum_{i=1}^{s} t_i = (r+1)|W| - |P|$$

since $A'_\ell \subseteq A_\ell$. Combining with the condition $|\bigcup_{\ell \in W} A_\ell| \geq r|W| + 1$ forces $|W| \geq |P| + 1$. A contradiction occurs and we complete the proof of the "if" direction.

We proceed to the "only if" direction. First, we claim that $|A_i \cap A_j| \leq 1$ for any $i \neq j$. Otherwise, we may assume that $A_i \cap A_j$ contains two distinct elements a_1 and a_2. Thus, H contains the four linearly dependent columns $(\mathbf{e}_i, \mathbf{a}_1)^T, (\mathbf{e}_i, \mathbf{a}_2)^T, (\mathbf{e}_j, \mathbf{a}_1)^T$ and $(\mathbf{e}_j, \mathbf{a}_2)^T$.

We prove the "only if" part by contradiction. Without loss of generality, we assume that the first s subsets $A_1, \ldots, A_s$ do not satisfy the condition, i.e. $|\bigcup_{i=1}^{s} A_i| \leq sr$, where s satisfies $s \leqslant t$. Define an undirected graph $G = ([s], E)$ such that $\{i, j\} \in E$ if and only if $A_i \cap A_j \neq \emptyset$. By inclusion-exclusion principle, we have

$$rs \geqslant \left|\bigcup_{i=1}^{s} A_i\right| \geq \sum_{i=1}^{s} |A_i| - \sum_{(i,j)\in E} 1 = s(r+1) - |E|.$$

This implies $|E| \geq s$. By Lemma 9, there exists a cycle in this undirected graph. Without loss of generality, we may assume that $(1, \ldots, \ell)$ is a cycle, i.e., $\{i, i+1\} \in E$ for $i = 1, \ldots, \ell - 1$ and $\{\ell, 1\} \in E$. By the definition of E, A_i and A_{i+1} contains a common element $\{a_{j_i}\}$. Then, we can pick two columns $(\mathbf{e}_i, \mathbf{a}_{j_{i-1}})^T$ [1] and $(\mathbf{e}_i, \mathbf{a}_{j_i})^T$ from the i-th block D_i for $i = 1, \ldots, \ell$. These 2ℓ columns are linearly dependent since

$$\sum_{i=1}^{\ell} \Big((\mathbf{e}_i, \mathbf{a}_{j_{i-1}}) - (\mathbf{e}_i, \mathbf{a}_{j_i}) \Big) = \sum_{i=1}^{\ell} (0, \mathbf{a}_{j_{i-1}} - \mathbf{a}_{j_i}) = \mathbf{0}.$$

The proof is completed. ◀

By Theorem 12, we immediately obtain the following result.

▶ **Theorem 13.** *If $t = \lfloor \frac{d-1}{2} \rfloor \geqslant 2$ and $(r+1)|n$, then there exists a q-ary optimal linear LRC with length n, minimum distance d and locality r provided that there are $m = \frac{n}{r+1}$ sets $A_1, \ldots, A_m \subseteq \mathbb{F}_q$ such that*

$$\begin{array}{ll} |A_i| = r+1 & \text{for } 1 \leq i \leq m, \\ |\bigcup_{i\in S} A_i| \geq |S|r + 1 & \text{for any } S \subseteq [m] \text{ of size at most } t. \end{array} \tag{8}$$

▶ Remark 14. We point out that there is another way to look at (8) as one reviewer suggests. Define an unbalanced bipartite expander graph where the vertex u_i on the left hand side are associated with sets A_i and the vertex v_j on the right hand side are associated with an element a_j in $\mathbb{F}_q$. u_i and v_j are adjacent if and only if a_j is contained in A_i. The expansion property (8) is now equivalent to the existence of good unbalanced bipartite graph [5]. However, the parameters discussed in this paper are not in the scope of explicit construction of good unbalanced bipartite graph, i.e., the expansion property in (8) is too strong for all known explicit constructions.

4 Random and algorithmic constructions

In the previous section, we converted the construction of optimal LRCs into a problem of finding subsets of $\mathbb{F}_q$ satisfying (8). In this section, we first present a probabilistic construction of subsets satisfying (8). In addition, we can derandomize this probabilistic construction into a deterministic construction in polynomial time if d is constant. The case $t = 2$, i.e., $d = 5$ and 6, is equivalent to the design of constant weight codes [9]. In this section, we assume $t \geq 3$. Since the algebraic structure is not important for the union of set, we replace $\mathbb{F}_q$ with $[q]$ from now on.

▶ **Theorem 15.** *There exist $m = \left\lceil \frac{q^{1+\frac{1}{t-1}}}{2t^2(r+1)^{2+\frac{2}{t-1}}} \right\rceil$ sets $A_1, \ldots, A_m$ satisfying (8) provided q is large enough.*

[1] Define $\mathbf{a}_{j_0} = \mathbf{a}_{j_\ell}$ for simplicity.

Proof. Let $X_i = \{x_{i,1}, \ldots, x_{i,r+1}\}, i = 1, \ldots, 2m$ be the set picked uniformly at random over all $(r+1)$-sized subsets of $[q]$. Define the binary random variable Y_S such that $Y_S = 1$ if $|\bigcup_{i \in S} X_i| \leq |S|r$ and 0 otherwise. Our goal is to bound the expectation $E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S\right]$. Without loss of generality, we may assume that $S = \{1, \ldots, a\}$ for some $1 < a \leq t$. We order the random variables in $X_i, i = 1, \ldots, a$, i.e., $x_{1,1}, \ldots, x_{1,r+1}, \ldots, x_{a,1}, \ldots, x_{a,r+1}$. We want to bound the probability of the event $Y_S = 1$, i.e., at least a elements repeated in this sequence. Given an element $x_{i,j}$, the probability that $x_{i,j} \neq x_{i',j'}$ for some $x_{i',j'}$ prior to $x_{i,j}$ is at least $1 - \frac{(i-1)(r+1)+j}{q} \geq 1 - \frac{a(r+1)}{q}$. Taking over all sets of size at least a in this sequence, the probability of $Y_S = 1$ is at most

$$\sum_{i=a}^{a(r+1)} \binom{a(r+1)}{i} \left(\frac{a(r+1)}{q}\right)^i \leq \sum_{i=a}^{a(r+1)} \frac{\left(a(r+1)\right)^i}{i!} \left(\frac{a(r+1)}{q}\right)^i \leq \frac{1.1}{a!} \left(\frac{a^2(r+1)^2}{q}\right)^a.$$

for $q \geq 10a^2(r+1)^2$. It follows that

$$\begin{aligned} E\left[\sum_{S \subset [2m], |S| \leq t} Y_S\right] &= \sum_{i=2}^{t} \sum_{S \subset [2m], |S|=i} \Pr[Y_S = 1] \leq \sum_{i=2}^{t} \binom{2m}{i} \frac{1.1}{i!} \left(\frac{i^2(r+1)^2}{q}\right)^i \\ &\leq \sum_{i=2}^{t} 1.1 (\frac{1}{i!})^2 \left(\frac{2mi^2(r+1)^2}{q}\right)^i \leq \sum_{i=2}^{t} 1.1 \left(\frac{1}{i!}\right)^2 \left(\frac{q}{(r+1)^2}\right)^{\frac{i}{t-1}} \\ &\leq 1.1 \times 1.5 \left(\frac{1}{t!}\right)^2 \left(\frac{q}{(r+1)^2}\right)^{\frac{t}{t-1}} \leq \frac{2}{4t^2} \left(\frac{q}{(r+1)^2}\right)^{\frac{t}{t-1}} \leq m. \end{aligned}$$

for $q \geq t^{2t} 3^t (r+1)$ and $t \geq 3$. The second inequality is due to $\binom{2m}{i} \leq \frac{(2m)^i}{i!}$ and the third inequality is due to

$$\left(\frac{1}{i!}\right)^2 \left(\frac{q}{(r+1)^2}\right)^{\frac{i}{t-1}} \geq 3 \left(\frac{1}{(i-1)!}\right)^2 \left(\frac{q}{(r+1)^2}\right)^{\frac{i-1}{t-1}}.$$

That means there exists $2m$ $(r+1)$-sized sets $A_1, \ldots, A_{2m}$ such that there are at most m subsets $S \subseteq [2m]$ with $|\bigcup_{i \in S} A_i| \leq |S|r$. For each of these m subsets S, remove one set from $A_i, i \in S$. The desired result follows as we remove at most m sets. ◀

Theorem 15 is an existence proof. However, if t is a constant, it is possible to turn this argument into an algorithm via the method of conditional probabilities.

▶ **Theorem 16.** *There exists a polynomial-time deterministic algorithm to find m sets in Theorem 15 provided that t is a constant.*

Proof. We follow the same notation in Theorem 15. Let $X_i = \{x_{i,1}, \ldots, x_{i,r+1}\}$ be a random set of size $r+1$. Our goal is to minimize $E[\sum_{S \subset [2m], |S| \leq t} Y_S]$ by fixing the set X_i one by one. Since

$$\begin{aligned} E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S\right] &= \sum_{A \subset [q], |A|=r+1} E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S | X_1 = A\right] \Pr[X_1 = A] \\ &= \frac{1}{\binom{q}{r+1}} \sum_{A \subset [q], |A|=r+1} E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S | X_1 = A\right], \end{aligned}$$

there exists a set A such that $E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S | X_1 = A\right] \leq E\left[\sum_{S \subseteq [2m], |S| \leq t} Y_S\right]$. If $r+1$ is a constant, we only need to enumerate all subsets of size $r+1$ in polynomial time. However, if $r+1$ is not a constant, we enumerate $x_{1,1} \in X_1$ instead of the whole set, i.e., minimizing

$E\left[\sum_{S\subseteq[2m],|S|\leq t} Y_S|x_{1,1}=a_{1,1}\right]$ for $a_{1,1}\in[q]$. Given a subset $S\subseteq[2m]$ of size t, let us show how to compute $E[Y_S|x_{1,1}=a_{1,1}]$. Without loss of generality, we assume $S=\{1,\ldots,t\}$. We list $t(r+1)$ random elements $x_{1,1}=a_{1,1},x_{1,2},\ldots,x_{1,r+1},\ldots,x_{t,1},\ldots,x_{t,r+1}$. For large enough q, it suffices to approximate $E[Y_S|x_{1,1}=a_{1,1}]$ by counting the number of sequences where there are exact t repetitions. There are $\binom{(r+1)t}{t}$ combinations of these t positions. Let $R\subseteq[t]\times[r+1]$ be any set of size t representing the t positions. we first remove these t positions from the sequence. The remaining tr positions in the sequence must have distinct elements and there are $\prod_{i=0}^{rt-1}(q-i)$ ways to pick these tr elements. Assume that we assign $1,\ldots,rt$ to these rt positions. To obtain our final result, we multiply it by $\prod_{i=0}^{rt-1}(q-i)$. It remains to fill our sequence by adding back the t positions in R. For each $(i,j)\in R$, we enumerate all possible choices of $x_{i,j},(i,j)\in R$ and find out the number of combinations that there are exact t repetitions in the resulting sequence. There are at most q^t ways to do the enumeration. Then, we obtain the exact value of $E[Y_S|x_{1,1}=a_{1,1}]$. Observe that there are at most $\sum_{i=2}^{t}\binom{n}{i}$ subsets S. Thus, this expectation can be computed in polynomial time as t is a constant. We do it $r+1$ times so as to fix all elements in X_1. Given $A_1,\ldots,A_k$, our goal is to find $X_{k+1}=A_{k+1}$ to minimize the expectation

$$E\left[\sum_{S\subseteq[2m],|S|\leq t} Y_S|X_1=A_1,\ldots,X_k=A_k\right]\leq E\left[\sum_{S\subseteq[2m],|S|\leq t} Y_S\right].$$

It can be done in the same way as $X_1,\ldots,X_{k-1}$ are already fixed. After we fix all these $2m$ sets, we will obtain $A_1,\ldots,A_{2m}$ with the same property as Theorem 15 claims. Then, we enumerate all t-sized subsets $S\subseteq[q]$ and do the same as Theorem 15 does. The resulting subsets are the output of our algorithm. The number of these subsets is at least m. Since t is constant, all this operation is done in polynomial time. The proof is completed. ◀

The following is a direct consequence of Theorem 12, Theorem 15 and Theorem 16.

▶ **Theorem 17.** *For $d\geqslant 5$, put $t=\left\lfloor\frac{d-1}{2}\right\rfloor$. If $r\geqslant d-2$, $(r+1)|n$ and q is sufficiently large, then there exists a q-ary $[n,k,d]$ optimal locally recoverable code with locality r and $n\geq\frac{q^{1+\frac{1}{t-1}}}{2t^2(r+1)^{1+\frac{2}{t-1}}}$. The parity check matrix of this code has the form of (6). Moreover, if d is a constant, there exists a deterministic algorithm running in polynomial time to construct this code.*

5 The connection with extremal graph theory

To our surprise, it turns out that finding a collection of sets satisfying (8) is equivalent to constructing an $(r+1)$-uniform hypergraph avoiding short Berge cycle. The latter is one of the central problems in extremal graph theory and this problem is extremely difficult.

▶ **Lemma 18.** *There exist m sets satisfying (8) if and only if there exists an $(r+1)$-hypergraph $H=([q],E)$ with $|E|=m$ that does not have any Berge ℓ-cycles for all $\ell\leq t$.*

Proof. To see the equivalence of these two problems, we define an $(r+1)$-hypergraph as follows: Let $H=(V,E)$ with $V=[q]$ and $E=\{A_1,\ldots,A_m\}$. It is clear that H is an $(r+1)$-hypergraph. Assume that there exists $k\leq t$ subsets $A_{i_1},\ldots,A_{i_k}$ does not satisfy the condition that $|\bigcup_{j=1}^{k}A_{i_j}|\geq rk+1$. The same argument in Theorem 12 implies that there exists a cycle $(1,2,\ldots,\ell)$ such that $j\in A_{i_j}\cap A_{i_{j+1}}$. That means $\{j-1,j\}\subseteq A_{i_j}$ for $j=2,\ldots,\ell$ and $\{1,\ell\}\subseteq A_{i_1}$. By the definition of Berge cycle, the $(r+1)$-hypergraph

H contains this Berge ℓ-cycle $(1, 2, \ldots, \ell)$. On the other hand, assume that there exists a Berge ℓ-cycle in H. Denote the ℓ edges of this cycle $A_{i_1}, \ldots, A_{i_\ell}$. The results follows since $|A_{i_j} \cap A_{i_{j+1}}| \geq 1$ for $i = 1, \ldots, \ell - 1$ and $|A_{i_1} \cap A_{i_\ell}| \geq 1$. ◀

The equivalence of both the problems allow us to make use of known results in this area. Let $\mathcal{F}$ be a family of $r+1$-graph. Denote by $ex_{r+1}(n, \mathcal{F})$ the maximum number of edges in an $(r+1)$-hypergraph that does not contain any subgraphs in $\mathcal{F}$. Denote by BC_k the set of k-cycles. Let $\mathcal{B}_k = \{BC_2, \ldots, BC_k\}$. One upper bound on $ex_{r+1}(n, \mathcal{B}_t)$ is obtained by reducing this problem to an $m \times n$ bipartite graph with girth more than $2t$ and apply the result in [7].

▶ **Proposition 19** ([19]). *$ex_{r+1}(n, \mathcal{B}_t)$ is upper bounded by*

(i) $\frac{n}{r}(\frac{n}{r+1})^{\frac{2}{t-1}} + \frac{n}{r+1}$ *if t is odd,*

(ii) $\frac{n}{r(r+1)}n^{\frac{2}{t}} + \frac{n}{r+1}$ *if t is even.*

Since these two problems are equivalent, Proposition 19 gives an upper bound on the number m of sets A_i. For $t = 3, 4$, the following two propositions show that this upper bound is asymptotically tight. However, constructing such hypergraph requires sophisticated knowledge in this area which is beyond the scope of this paper. We summarize the results as follows.

▶ **Proposition 20** ([18]). *There exists explicit construction of $(r+1)$-hypergraph $H = ([q], E)$ with $|E| = q^{2-o(1)}$ that contains no subgraph in $\mathcal{B}_3$.*

▶ **Proposition 21** ([17]). *There exists explicit construction of $(r+1)$-hypergraph $H = ([q], E)$ with $|E| = \Theta(q^{\frac{3}{2}-o(1)})$ that contains no subgraph in $\mathcal{B}_4$.*

Determining the exact value of $ex_{r+1}(n, \mathcal{B}_t)$ for $r \geq 2$ and $t \geq 3$ is extremely difficult. A major open problem in this area is whether $ex_{r+1}(n, \mathcal{B}_t) = \Omega(n^{1+\frac{2}{t}})$. A tighter lower bound for general t can be obtained from H-free random process [2]. The method in [2] can also be applied to hypergraph and add a log factor above the probabilistic method in Theorem 15. Again this technique is beyond our scope.

▶ **Proposition 22** ([18]). *$ex_{r+1}(n, \mathcal{B}_t) = \Omega_{r,t}(n(n \log n)^{\frac{1}{t-1}})$.*

Theorem 1 summarizes all above results in the language of codes.

6 An upper bound on the length of optimal LRC

In this section, we derive an upper bound on the length of optimal LRC. Our upper bound holds for all optimal LRC. The proof of our upper bound is a refined analysis of the argument of Theorem 3.3 in [6]. Recall the following Lemma in [6].

▶ **Lemma 23** (Lemma 3.1 [6]). *Let C be an $[n, k, d]_q$ linear optimal LRC with locality r. Then, there exist $\frac{n}{r+1}$ disjoint recovery sets, each of size $r+1$ provided that*

$$\frac{n}{r+1} \geq \left(d - 2 - \left\lfloor \frac{d-2}{r+1} \right\rfloor\right)(3r+2) + \left\lfloor \frac{d-2}{r+1} \right\rfloor + 1. \tag{9}$$

We use above lemma to force the optimal LRC to have disjoint recovery sets.

▶ **Theorem 24.** *Let C be an optimal $[n, k, d]_q$-linear locally repairable codes of locality r with $(r+1)|n$ and $n = \Omega(dr^2)$ satisfying (9) in Lemma 23. If $d \geqslant 5$, then*

$$n \leq \begin{cases} O(q^3) & \text{if } d \bmod r+1 > 5 \text{ or } d \bmod r+1 < 2, \\ O(q^2) & \text{if } 2 \leq d \bmod r+1 \leq 5. \end{cases} \tag{10}$$

Proof. Put $h = d - 2 - \lfloor \frac{d-2}{r+1} \rfloor$. Then $n - k = \frac{n}{r+1} + h$ and $h \leq d-2$. We first follow the same line of proof in Theorem 3.3, [6]. It allows us to assume that the parity-check matrix of optimal LRC C is as follows:

$$H = \left(\begin{array}{c|c|ccc|c} \mathbf{1} & \mathbf{0} & \cdots & \cdots & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{1} & \cdots & \cdots & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \cdots & \cdots & \mathbf{1} \\ \hline \multicolumn{6}{c}{A} \end{array} \right), \tag{11}$$

where A is an $h \times n$ matrix over $\mathbb{F}_q$. The submatrix consisting of the first ℓ rows of H is a block diagonal matrix. Let $\mathbf{h}_{i,j}$ be the $((i-1)(r+1)+j)$-th column of H, i.e.,

$$\mathbf{h}_{i,j} = (\underbrace{0, \ldots, 0}_{i-1}, 1, \underbrace{0, \ldots, 0}_{\ell - i}, \mathbf{v}_{i,j})^T \tag{12}$$

for some $\mathbf{v}_{i,j} \in \mathbb{F}_q^h$, where T stands for transpose. Define

$$\mathbf{h}'_{i,j} := \mathbf{h}_{i,j} - \mathbf{h}_{i,r+1} = (\underbrace{0, \ldots, 0}_{\ell}, \mathbf{v}_{i,j} - \mathbf{v}_{i,r+1})^T$$

for $i \in [\ell]$ and $j \in [r]$. It is clear that there are only $h = d - 2 - \lfloor \frac{d-2}{r+1} \rfloor$ nonzero components in $\mathbf{h}'_{i,j}$. Assume that $d - 6 = a(r+1) + b$ for some $0 \leq b \leq r$. Then, we claim that the first $ar + b$ columns $\mathbf{h}'_{i,j}$ are linearly independent. This is because the linear combination of these $ar + b$ columns leads to

$$\sum_{i=1}^{a} \sum_{j=1}^{r} \lambda_{i,j} (\mathbf{h}_{i,j} - \mathbf{h}_{i,r+1}) + \sum_{j=1}^{b} \lambda_{a+1,j} (\mathbf{h}_{a+1,j} - \mathbf{h}_{a+1,r+1}) \neq 0$$

as it is a linear combination of $ar + b + a + 1 = d - 5$ columns of H.

Since these $ar + b$ columns $\mathbf{h}'_{i,j}$ are linearly independent, there exist $ar + b$ indices where these $ar + b$ vectors $\mathbf{h}'_{i,j}$ span the whole space. Without loss of generality, we assume they are the last $ar + b$ indices. To simply our argument, we denote by S the index set of first $ar + b$ columns and $\bar{S}$ the index set of the rest columns. For each $(x, y) \in \bar{S}$, there exist $\lambda_{x_i, y_j} \in \mathbb{F}_q$ such that $\bar{\mathbf{h}}'_{x,y} = \mathbf{h}'_{x,y} - \sum_{(i,j) \in S} \lambda_{x_i, y_j} \mathbf{h}'_{i,j}$ gives a vector whose value on last $ar + b$ indices are all zero. The number of nonzero components of $\mathbf{h}'_{x,y}$ is at most

$$h - (ar + b) = d - 2 - \lfloor \frac{d-2}{r+1} \rfloor - (d-6) + \lfloor \frac{d-6}{r+1} \rfloor = 4 + \lfloor \frac{d-6}{r+1} \rfloor - \lfloor \frac{d-2}{r+1} \rfloor.$$

On the other hand, let $\bar{\mathbf{h}}'_{x_1,y_1}$ and $\bar{\mathbf{h}}'_{x_2,y_2}$ be any two vectors of $\bar{\mathbf{h}}'_{x,y}, (x, y) \in \bar{S}$. Observe that they lie in the space spanned by $ar + b$ columns $\mathbf{h}'_{i,j}$ and $\mathbf{h}'_{x_1,y_1}, \mathbf{h}'_{x_2,y_2}$ which in turn contained in the space spanned by the first $d - 5$ columns $\mathbf{h}_{i,j}$ together with $\mathbf{h}_{x_1,y_1}, \mathbf{h}_{x_1,r+1}, \mathbf{h}_{x_2,y_2}, \mathbf{h}_{x_2,r+1}$. This implies that $\bar{\mathbf{h}}'_{x_1,y_1}$ and $\bar{\mathbf{h}}'_{x_2,y_2}$ are linearly independent. Let H_1 be the matrix whose columns consist of $\bar{\mathbf{h}}'_{x,y}, (x, y) \in \bar{S}$. Remove all zero rows in H_1 and denote the resulting matrix H_2. It is clear that any two columns of H_2 are linearly independent and H_2 has at most $4 + \lfloor \frac{d-6}{r+1} \rfloor - \lfloor \frac{d-2}{r+1} \rfloor$ rows. Let C_1 be a linear code whose parity-check matrix is H_2. We divide our discussion into two cases.

1. $\lfloor \frac{d-6}{r+1} \rfloor - \lfloor \frac{d-2}{r+1} \rfloor = 0$, i.e., $d \bmod r + 1 > 5$ or $d \bmod r + 1 < 2$.
   Then, C_1 has length $N \geq \frac{rn}{r+1} - d$, dimension $k \geq N - 4$ and distance $d \geq 3$. In the worst scenario, we assume that $k = N - 4$ and $d = 3$. Applying the Hamming bound on code C_1 gives $q^{N-4} \leq \frac{q^N}{N(q-1)}$. This implies $N \leq q^3$, i.e., $n \leq \frac{r+1}{r}(d + q^3)$.

2. $\lfloor \frac{d-6}{r+1} \rfloor - \lfloor \frac{d-2}{r+1} \rfloor = -1$ i.e., $2 \leq d \bmod r+1 \leq 5$.
Then, C_1 has length $N \geq \frac{rn}{r+1} - d$, dimension $k \geq N-3$ and distance $d \geq 3$. In the worst scenario, we assume that $k = N-3$ and $d = 3$. Applying the Hamming bound on code C_1 gives $q^{N-3} \leq \frac{q^N}{N(q-1)}$. This implies $N \leq q^2$, i.e., $n \leq \frac{r+1}{r}(d+q^2)$.

The proof is completed. ◀

Abstract

Following the first paper on quantum algorithms for SDP-solving by Brandão and Svore [13] in 2016, rapid developments have been made on quantum optimization algorithms. In this paper we improve and generalize all prior quantum algorithms for SDP-solving and give a simpler and unified framework.

We take a new perspective on quantum SDP-solvers and introduce several new techniques. One of these is the quantum operator input model, which generalizes the different input models used in previous work, and essentially any other reasonable input model. This new model assumes that the input matrices are embedded in a block of a unitary operator. In this model we give a $\widetilde{\mathcal{O}}\left(\left(\sqrt{m}+\sqrt{n}\gamma\right)\alpha\gamma^4\right)$ algorithm, where n is the size of the matrices, m is the number of constraints, γ is the reciprocal of the scale-invariant relative precision parameter, and α is a normalization factor of the input matrices. In particular for the standard sparse-matrix access, the above result gives a quantum algorithm where $\alpha = s$. We also improve on recent results of Brandão et al. [12], who consider the special case when the input matrices are proportional to mixed quantum states that one can query. For this model Brandão et al. [12] showed that the dependence on n can be replaced by a polynomial dependence on both the rank and the trace of the input matrices. We remove the dependence on the rank and hence require only a dependence on the trace of the input matrices.

After we obtain these results we apply them to a few different problems. The most notable of which is the problem of shadow tomography, recently introduced by Aaronson [2]. Here we simultaneously improve both the sample and computational complexity of the previous best results. Finally we prove a new $\widetilde{\Omega}(\sqrt{m}\alpha\gamma)$ lower bound for solving LPs and SDPs in the quantum operator model, which also implies a lower bound for the model of Brandão et al. [12].

1 Semidefinite programs

In this paper we consider *semidefinite programs* (SDPs). SDPs have many applications in optimization, notable examples include approximation of NP-hard problems like MAXCUT [21] and polynomial optimization through the Sum-Of-Squares hierarchy [24, 29]. SDPs have also found applications in quantum information theory. Examples include POVM measurement design [18] and finding the winning probability of non-local games [16].

We consider the basic (primal) form of an SDP as follows:

$$\begin{aligned} \mathrm{OPT} = \max \quad & \mathrm{Tr}\left(CX\right) \\ \text{s.t.} \quad & \mathrm{Tr}\left(A_j X\right) \leq b_j \quad \text{for all } j \in [m], \\ & X \succeq 0, \end{aligned} \tag{1}$$

where $[m] := \{1, \ldots, m\}$. The input to the problem consists of $n \times n$ Hermitian constraint matrices $A_1, \ldots, A_m$, an objective matrix C, and reals $b_1, \ldots, b_m$. For normalization purposes we assume $\|C\|, \|A_j\| \leq 1$. The number of constraints is m (we do not count the standard $X \succeq 0$ constraint for this). The variable X of this SDP is an $n \times n$ positive semidefinite (psd) matrix. We assume that $A_1 = I$ and $b_1 = R$, giving a known bound on the trace of a solution: $\mathrm{Tr}\left(X\right) \leq R$. A primal SDP also has a *dual*. For a primal SDP of the above form (1) the dual SDP is

$$\begin{aligned} \mathrm{OPT} = \min \quad & b^T y \\ \text{s.t.} \quad & \sum_{j=1}^{m} y_j A_j - C \succeq 0, \\ & y \geq 0. \end{aligned} \tag{2}$$

We assume that the dual optimum is attained and that an explicit $r \geq 1$ is known such that at least one optimal dual solution y exists $\|y\|_1 \leq r$. These assumptions imply that strong duality holds, justifying the use of OPT for both optimal values. The parameters r and R correspond to the scale of the SDP, without these bounds we could scale the SDP such that a larger error can be allowed. In some cases $r \cdot R$ may be quite large, but there are natural problems, where it is constant, cf. zero-sum games [4]. Finally, note that linear programs (LPs) correspond to the case where all constraint matrices are diagonal.

In this paper we build on the observation that a normalized psd matrix can be naturally represented as a quantum state. Since operations on quantum states can sometimes be cheaper to perform on a quantum computer than operations on classical descriptions of matrices, this can give rise to faster algorithms for solving SDPs on a quantum computer [13].

We say an algorithm is an ε-approximate *quantum SDP-solver* if for all input numbers $g \in \mathbb{R}$ and $\zeta \in (0, 1)$, with success probability $1 - \zeta$, all of the following hold:

(i) The algorithm finds a vector $y' \in \mathbb{R}^{m+1}$ and a number $z \in \mathbb{R}$ defining its output

$$X := z \frac{e^{-\sum_{j=1}^{m} y'_j A_j + y'_0 C}}{\mathrm{Tr}\left(e^{-\sum_{j=1}^{m} y'_j A_j + y'_0 C}\right)}. \tag{3}$$

The output X is an *ε-feasible primal solution* with objective value at least $g - \varepsilon$, i.e.,

$$\forall j \in [m]\colon \mathrm{Tr}\left(XA_j\right) \leq b_j + \varepsilon,$$

and $\mathrm{Tr}\left(XC\right) \geq g - \varepsilon$. If the algorithm cannot find such an output X, then it correctly concludes that no feasible solution exist (if we set $\varepsilon = 0$).

(ii) The algorithm finds a $y \in \mathbb{R}^{m+1}$ that is an *ε-feasible solution* to the dual problem with objective value at most $g + \varepsilon$, i.e.,

$$\sum_{j=1}^{m} y_j A_j - C \succeq -\varepsilon I, \tag{4}$$

and $b^T y \leq g + \varepsilon$, or it correctly concludes that no feasible y exists (if we set $\varepsilon = 0$).

(iii) The algorithm determines whether $\mathrm{OPT} \leq g - \varepsilon$ or $\mathrm{OPT} \geq g + \varepsilon$. If $\mathrm{OPT} \in (g - \varepsilon, g + \varepsilon)$ then it may output either. (Note that this essentially follows from (i)-(ii).)

Notice that this solves a decision version of the problem. However, we can easily find an approximation of OPT using binary search on g if we have an ε-approximate SDP-solver. Since ε is scale depended we actually care about the dependence on the scale invariant parameter $\gamma := Rr/\varepsilon$. An algorithm that only satisfies (i) will be called an *ε-approximate SDP primal oracle*. For such an algorithm the relevant scale invariant parameter is $\gamma := R/\varepsilon$. Due to the form of the objective value constraint in the first point, and to simplify statements like (3), we write $A_0 := -C$ and $b_0 := -g$.

Notation

We use the following definition for $\tilde{\mathcal{O}}$:

$$\widetilde{\mathcal{O}}_{d,e}\left(f(a,b,c)\right) := \mathcal{O}\left(f(a,b,c) \cdot \mathrm{polylog}(f(a,b,c),d,e)\right).$$

We define $\tilde{\Omega}$ in a similar way and $\tilde{\Theta}$ as the intersection of the two. We write δ_{ij} for the Kronecker delta function and e_j for the jth basis vector in the standard basis when the dimension of the space is clear from context. For a Hermitian matrix H we write $\mathrm{Spec}(H)$ for its spectrum (set of eigenvalues). For a function $f : \mathbb{R} \to \mathbb{R}$ we write $f(H)$ for the matrix we get by applying f to the eigenvalues of H, i.e.,

$$f(H) = U \begin{bmatrix} f(\lambda_1) & & \\ & \ddots & \\ & & f(\lambda_n) \end{bmatrix} U^{-1} \text{ where } H = U \begin{bmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_n \end{bmatrix} U^{-1}.$$

2 SDP-solving frameworks

In this section we present two frameworks for SDP-solving, providing the basis of our quantum algorithms. First we present an algorithm to implement a primal oracle, and then the Arora-Kale framework, which is used for finding a good approximation of the optimal value and an almost feasible solution to the dual. These together implement a full SDP-solver.

Both frameworks have a very similar iterative structure, with iteration count $\widetilde{\mathcal{O}}_n\left(\gamma^2\right)$, where $1/\gamma$ is the relevant scale-invariant precision parameter (as we will see the value of γ differs by a factor r in the two cases). The main difference is that the iterative step of the primal oracle framework requires only a simple search, whereas in the Arora-Kale framework one needs to solve a slightly more complex task. Both algorithms start with $y = 0$, and in each step only a constant number of indices of y are incremented, thus in both cases we will work with a y vector that is non-negative and $\widetilde{\mathcal{O}}_n\left(1/\theta^2\right)$-sparse.

2.1 An SDP primal oracle

For the primal oracle we use the same algorithm as Brandão et al. [12] following the proof of Lemma 4.6 of Lee, Raghavendra and Steurer [25]. A few small reductions are required to apply this technique. To be able to work with density operators instead of X, the b_js in the constraints $1 \dots m$ are scaled down by a factor R, such that every solution X' to the new SDP has trace at most 1. Then, we add one new variable denoted by ω such that

$$\rho := \begin{bmatrix} X' & 0 \\ 0 & \omega \end{bmatrix}.$$

Now $\mathrm{Tr}(\rho) = 1$ and $\rho \succeq 0$ imply that $\mathrm{Tr}(X') \leq 1$, and we get a new SDP that is equivalent to the previous one. It can be shown that in our input models this reduction does not introduce more than a constant factor overhead in the complexity; note that this reduction also illustrates that for an SDP primal oracle $\frac{\varepsilon}{R}$ is the relevant scale-invariant precision parameter.

The following meta-algorithm for an SDP primal oracle assumes access to (some form of) a description of the SDP after the above-discussed reduction, and provides an output as in Eq. (3) of (i)

1. Let $y = 0 \in \mathbb{R}^{m+1}$ and $\theta = \frac{\varepsilon}{2R}$.
2. Repeat $\frac{\ln(n)}{\theta^2}$ times the following:
   a. Define $\rho := e^{-\sum_{j=0}^{m} y_j A_j} / \mathrm{Tr}\left(e^{-\sum_{j=0}^{m} y_j A_j}\right)$.
   b. Find an index j such that $\mathrm{Tr}(A_j \rho) \geq b_j$ or conclude correctly that for all j, $\mathrm{Tr}(A_j \rho) \leq b_j + \theta$.
   c. If no j is found, then we are done and output y and $z = R\mathrm{Tr}(X')$, where $\mathrm{Tr}(X')$ is the probability[1] of measuring ρ to be in the subspace corresponding to the variable X'.
   d. Otherwise update $y \leftarrow y + \theta e_j$.
3. Conclude that there is no solution for $\theta = 0$.

2.2 The Arora-Kale framework

Similarly to previous work [13] we build our results on the Arora-Kale framework. For a detailed description see the original paper by Arora and Kale [7]. For our application, the following broad overview suffices.[2]

Now we describe the Arora-Kale meta-algorithm. This algorithm assumes access to (some form of) a description of the SDP, such that the first constraint is $\mathrm{Tr}(X) \leq R$, i.e., $A_1 = I$ and $b_1 = R$. It provides an output as in Eq. (4) of (ii). (Remember that we set $A_0 = -C$ and $b_0 = -g$.)

1. Let $y = 0 \in \mathbb{R}^{m+1}$ and set $\theta = \frac{\varepsilon}{6Rr}$.
2. Repeat $\frac{\ln(n)}{\theta^2}$ times the following:
   (a) Define $\rho := e^{-\sum_{j=0}^{m} y_j A_j} / \mathrm{Tr}\left(e^{-\sum_{j=0}^{m} y_j A_j}\right)$.

[1] Note that a θ-approximation of $\mathrm{Tr}\left(X'\right)$ is easy to compute by means of amplitude estimation if ρ can be efficiently prepared as a quantum state – which is the case in our algorithms.

[2] For more discussion on general (quantum) SDP-solvers along this line, see [5].

(b) Find a $\tilde{y}$ in the polytope

$$\mathcal{P}_\delta(\rho) := \Big\{\tilde{y} \in \mathbb{R}^{m+1} : b^T\tilde{y} \leq 0, \sum_{j=0}^{m} \tilde{y}_j \mathrm{Tr}\left(A_j\rho\right) \geq -\delta, \tilde{y} \geq 0,\ \tilde{y}_0 = \frac{1}{2r},\ \|\tilde{y}\|_1 \leq 1\Big\}.$$

for $\delta = \theta$; if cannot find such a $\tilde{y}$ then conclude that none exists for $\delta = 0$.

(c) If no such $\tilde{y}$ exists, then conclude that OPT $> g$ and stop.

(d) If such a $\tilde{y}$ exists, then update $y \leftarrow y + \theta\tilde{y}$.

3. Conclude OPT $\leq g + \varepsilon$ and output $\frac{2r\theta}{\ln(n)}y + \frac{\varepsilon}{R}e_1 - e_0$ as a dual solution.

Note that in the above meta-algorithm, up to a constant factor, the θ parameter is essentially $\gamma^{-1} = \frac{\varepsilon}{rRs}$, illustrating that γ^{-1} is the relevant scale-invariant precision parameter for SDP-solving, for a more detailed discussion see [5].

Brandão and Svore [13] observed that $\rho := e^{-\sum_j y_j A_j}/\mathrm{Tr}\left(e^{-\sum_j y_j A_j}\right)$ is a quantum Gibbs state and this state can be prepared efficiently on a quantum computer, allowing fast trace estimation, in particular resulting in a quadratic speedup in n compared to classical methods.

A procedure that solves step (b) is called a *θ-oracle*, not to be confused with the input oracles. In the rest of this paper we will assume that the cost of updating the y vector is no more than the cost of a θ-oracle call. This is justified, because we use the geometric approach of Apeldoorn et al. [5, Lemma 16] for implementing a 3-sparse γ^{-1}-oracle. Their oracle returns a 3-sparse vector, and thus requires updating only 3 entries of y, which can be done efficiently using an efficient data structure.

3 Input models & Subroutines

We consider three input models: the *sparse matrix model*, the *quantum state model*, and the *quantum operator model*. The first two models were already studied in previous work. The quantum operator model is a common generalization of the other two models, and in fact any other reasonable model for SDPs, as we show.

In all models we assume quantum oracle access to the numbers b_j via the input oracle O_b satisfying[3] for all $j \in [m]$:

$$O_b|j\rangle|0\rangle = |j\rangle|b_j\rangle.$$

For all input oracles we assume we can apply both the oracle and its inverse[4] in a controlled fashion.

Sparse matrix model

In the *sparse matrix model* the input matrices are assumed to be s-row sparse for a known bound $s \in [n]$, meaning that there are at most s non-zero elements per row. The model is close to the classical model for sparse matrices. Access to the A_j matrices is provided by

[3] For simplicity we assume the bitstring representation has at most $\mathcal{O}\left(\log(nmRr/\varepsilon)\right)$ bits.

[4] When we talk about samples, e.g. in Section 4.1 of the full version of this paper [3], then we do not assume we can apply the inverse operation.

two oracles, similar to previous work on Hamiltonian simulation in [9]. The first of the two oracles is a unitary O_{sparse}, which serves the purpose of sparse access. This oracle calculates the **index** : $[m] \times [n] \times [s] \to [n]$ function, which for input (j, k, ℓ) gives the column index of the ℓth non-zero element in the kth row of A_j. We assume this oracle computes the index "in place":

$$O_{\text{sparse}}|j, k, \ell\rangle = |j, k, \mathbf{index}(j, k, \ell)\rangle. \tag{5}$$

(In the degenerate case where the kth row has fewer than ℓ non-zero entries, $\mathbf{index}(j, k, \ell)$ is defined to be ℓ together with some special symbol indicating this case.)

We also need another oracle O_A, returning a bitstring[3] representation of $(A_j)_{ki}$ for every $j \in [m]$ and $k, i \in [n]$:

$$O_A|j, k, i, z\rangle = |j, k, i, z \oplus (A_j)_{ki}\rangle. \tag{6}$$

This model corresponds directly to a classical way of accessing sparse matrices.

Quantum state model

In contrast to the sparse matrix model, the *quantum state model* is inherently quantum and has no classical counterpart for SDPs. In this model we assume that each A_j has a fixed decomposition of the form

$$A_j = \mu_j^+ \varrho_j^+ - \mu_j^- \varrho_j^- + \mu_j^I I$$

for (subnormalized) density operators $\varrho_j^\pm$, non-negative reals $\mu_j^\pm$ and real number $\mu_j^I \in \mathbb{R}$.

▶ **Definition 1** (Subnormalized density operators & Purification)**.** *A* subnormalized density operator ϱ *is a psd matrix of trace at most* 1*. A* purification *of a subnormalized density operator* ϱ *is a* 3*-register pure state such that tracing out the third register*[5] *and projecting on the subspace where the second register is* $|0\rangle$ *yields* ϱ*.*

We write "ϱ*" and "*ς*" for subnormalized density operators to distinguish them from normalized density operators, for which we write "*ρ*" and "*σ*".*

We assume access to an oracle O_μ that takes as input an index j and outputs binary representations[3] of μ_j^+, μ_j^- and μ_j^I.

Furthermore we assume access to a state-preparing oracle $O_{|\cdot\rangle}$ that prepares purifications[5] $|\psi_j^\pm\rangle$ of $\varrho_j^\pm$:

$$O_{|\cdot\rangle}|j\rangle|\pm\rangle|0\rangle = |j\rangle|\pm\rangle|\psi_j^\pm\rangle.$$

Finally we assume that a bound $B \in \mathbb{R}_+$ is known such that

$$\forall j : \mu_j^+ + \mu_j^- \leq B.$$

Note that a tight upper bound B can easily be found using $\mathcal{O}(\sqrt{m})$ quantum queries to O_μ by means of maximum finding [17].

[5] For simplicity we assume that for a d-dimensional density operator a purification has at most polylog(d) qubits.

Quantum operator model

Motivated by recent work [27, 20] we propose a new input model that we call the *quantum operator model*. In this model the input matrices are given by a unitary that implements a block-encoding:

▶ **Definition 2** (Block encoding). *Suppose that A is a w-qubit operator, $\alpha, \varepsilon \in \mathbb{R}_+$ and $k \in \mathbb{N}$, then we say that the $(a+w)$-qubit unitary U is an (α, a, ε)-block-encoding of A, if*

$$\left\| A - \alpha(\langle 0|^{\otimes a} \otimes I) U (|0\rangle^{\otimes a} \otimes I) \right\| \leq \varepsilon.$$

Roughly speaking this means that A is represented by a unitary

$$U \approx \begin{pmatrix} A/\alpha & . \\ . & . \end{pmatrix}.$$

In the quantum operator model we assume access to an oracle O_U that acts as follows:

$$O_U|j\rangle|\psi\rangle = |j\rangle(U_j|\psi\rangle).$$

Where U_j is an $(\alpha, a, 0)$-block-encoding[6] of A_j, for some fixed[7] $\alpha \in \mathbb{R}$ and for $a = \mathcal{O}(\log(nmRr/\varepsilon))$.

In Section 5 of the full version of this paper [3] we show that the sparse input model can be reduced to the quantum operator model with $\alpha = s$ and that the quantum state model can be reduced to it with $\alpha = B$. We also argue that if we can perform a measurement corresponding to $A_j \succeq 0$ using a ancilla qubits, i.e., accept a state ρ with probability $\mathrm{Tr}(A_j\rho)$, then we can implement a $(1, a+1, 0)$-block-encoding of A_j. In this way this input model is a common generalization of all reasonable input models for SDPs, since at the very least an input model should allow you to calculate $\mathrm{Tr}(A_j X)$.

Therefore if one can perform a POVM measurement on a quantum computer with a measurement operator M, one can also implement a block-encoding of M, and use it as an input matrix in our operator model. Similarly, being able to perform Hamiltonian simulation with a Hermitian matrix H gives access to H as a block-encoding, as shown by [28, 20]. Recent work [22] introduced QROM data structures that allow the efficient creation of a superposition over matrix elements of a matrix M. It turns out [15] that the corresponding block-encoding can be implemented with $\widetilde{\mathcal{O}}_{n,\gamma}(1)$ QROM calls, such that even for non-sparse matrices one has $\alpha \leq \sqrt{n}$.

Computational cost

We analyze the query complexity of algorithms and subroutines, i.e., the number of queries to controlled versions of the input oracles and their inverses. We denote the optimal quantum query complexity of an ε-approximate *quantum SDP-solver* with success probability $2/3$ by $T_{SDP}(\varepsilon)$ (this is a "meta quantity", which becomes concrete once the input model is specified). We only consider success probability $2/3$ to simplify the notation and proofs. However in all cases an ε-approximate SDP-solver with success probability $1-\zeta$ can easily be constructed using $\mathcal{O}(\log(1/\zeta)T_{SDP}(\varepsilon))$ queries.

[6] If n is not a power of 2, then we simply define A_j to be zero on the additional $2^w - n$ dimensions.

[7] Having a single normalization parameter α is not a serious restriction as it is easy to make a block-encoding more subnormalized so that every A_j gets the same normalization, cf. Lemma 14 of the full version of this paper [3].

In our algorithms we assume access to a quantum-read/classical-write RAM (known as QCRAM), and assume one read/write operation has a constant gate complexity[8]; the size of the QCRAM that we use is typically $\widetilde{\mathcal{O}}_{n,m}\left(\left(\frac{Rr}{\varepsilon}\right)^2\right)$ bits. Most often in our results the number of non-query elementary operations, i.e., two-qubit gates and QCRAM calls, matches the query complexity up to polylog factors. In particular, if not otherwise stated, in our results a T-query quantum algorithm uses at most $\widetilde{\mathcal{O}}_{n,m}(T)$ elementary operations.

Subroutines

We work with two major subroutines which need to be implemented according to the specific input model. First, the algorithms require an implementation of a Gibbs-sampler.

▶ **Definition 3** (Gibbs-sampler). *A θ-precise* Gibbs-sampler *on bounded input vectors $y \in \mathbb{R}^{m+1}_{\geq 0}$ is a quantum circuit that works under the promise that the support of y has size at most d, and $\|y\|_1 \leq K$. It takes as input a data structure storing the vector y, and for any input satisfying the promise, it creates as output a purification of a θ-approximation of the Gibbs state*

$$e^{-\sum_{j=0}^{m} y_j A_j} / \mathrm{Tr}\left(e^{-\sum_{j=0}^{m} y_j A_j}\right).$$

The minimum cost of such a circuit is denoted by $T_{Gibbs}(K, d, 4\theta)$ (this is again a "meta quantity", which becomes concrete once the input model is specified).

For technical reasons we also allow Gibbs-samplers that require a random classical input seed $S \in \{0,1\}^a$ for some $a = \mathcal{O}(\log(1/\theta))$. In this case the output should be a θ-approximation of the Gibbs state with high probability ($\geq 4/5$) over a uniformly random input seed S.

We use the approximate Gibbs states in order to estimate the quantity $\mathrm{Tr}(A_j\rho)$.

▶ **Definition 4** (Trace estimator). *A* (θ, σ)-trace estimator *is a quantum circuit that as input takes a quantum state ρ and index j. It outputs a sample from a random variable $Z_j \in \mathbb{R}$ which is an estimator of $\mathrm{Tr}(A_j\rho)$ with bias at most θ:*

$$|\mathrm{Tr}(A_j\rho) - \mathbb{E}[Z_j]| \leq \theta,$$

and the standard deviation of Z_j is at most σ. We write $T^{\sigma}_{Tr}(\theta)$ for the minimum cost of such a circuit (this is again a "meta quantity" as in the above definition).

4 Prior work

Classical SDP-solvers roughly fall into two categories: those with logarithmic dependence on R, r and $1/\varepsilon$, and those with polynomial dependence on these parameters but better dependence on m and n. In the first category the best known algorithm [26] at the time of writing has complexity

$$\widetilde{\mathcal{O}}_{Rr/\varepsilon}\left(m(m^2 + n^{\omega} + mns)\right).$$

where $\omega \in [2, 2.38]$ is the yet unknown exponent of matrix multiplication.

[8] Note that read/write operations of a QRAM or QCRAM of size S can be implemented using $\widetilde{\mathcal{O}}(S)$ two-qubit gates, so this assumption could hide a factor in the gate complexity which is at most $\widetilde{\mathcal{O}}(S)$.

In the second category Arora and Kale [7] gave an alternative framework for solving SDPs, using a matrix version of the "multiplicative weights update" method, see Section 2. Their framework can be tuned for specific types of SDPs, allowing for near linear-time algorithms in the case of for example the Goemans-Williamson SDP for the approximation of the maximum cut in a graph [21].

In 2016 Brandão and Svore [13] used the Arora-Kale framework to implement a general quantum SDP-solver in the sparse matrix model. They observed that the matrix

$$\rho := \frac{e^{-\sum_{j=0}^{m} y_j A_j}}{\operatorname{Tr}\left(e^{-\sum_{j=0}^{m} y_j A_j}\right)},$$

that is used for calculations in the Arora-Kale framework is in fact a $\log(n)$-qubit Gibbs state and can be efficiently prepared as a quantum state on a quantum computer. Using this they achieved a quantum speedup in terms of n. Combining this with a Grover-like speedup allowed for a speedup in terms of m as well, leading to an ε-approximate quantum SDP solver with complexity

$$\widetilde{\mathcal{O}}\left(\sqrt{mn}s^2\left(\frac{Rr}{\varepsilon}\right)^{32}\right).$$

They also showed an $\Omega(\sqrt{m}+\sqrt{n})$ quantum query lower bound for solving SDPs when all other parameters are constant. This left as open question whether a better lower bound, matching the $\sqrt{mn}$ upper bound, could be found. The upper bound for the sparse input model was subsequently improved by van Apeldoorn et al. [5] to

$$\widetilde{\mathcal{O}}\left(\sqrt{mn}s^2\left(\frac{Rr}{\varepsilon}\right)^{8}\right).$$

van Apeldoorn et al. also gave an $\Omega(\sqrt{\max(n,m)}\min(n,m)^{3/2})$ lower bound, albeit for non-constant parameters R and r. This bound implies that there is no general quantum SDP-solver that has a $o(nm)$ dependence on n and m and logarithmic dependence on R, r and $1/\varepsilon$. They also showed that every SDP-solver whose efficiency relies on outputting sparse dual solutions (including their algorithm and that of Brandão and Svore [13]) is limited, since problems with a lot of symmetry (like maxflow-mincut) in general require non-sparse dual solutions. Furthermore, they showed that for many combinatorial problems (like MAXCUT) R and r increase linearly with n and m.

Very recently Brandão et al. [11] gave an improved SDP-solver for the quantum state input model[9] that has a complexity bound with logarithmic dependence on n:

$$T_{SDP}(\varepsilon) = \widetilde{\mathcal{O}}_n\left(\sqrt{m}\ \operatorname{poly}\left(\frac{Rr}{\varepsilon}, B, \max_{j\in\{0,\dots,m\}}[\operatorname{rank}(A_j)]\right)\right).$$

Brandão et al. also applied their algorithm to the problem of *shadow tomography*, giving the first non-trivial application of a quantum SDP-solver.

Subsequently these results where further improved by the introduction of the Fast Quantum OR lemma by the same authors [12]. Approaches prior to [12] searched for a violated constraint in the SDP using Grover-like techniques, resulting in a multiplicative

[9] This model was already introduced in the first version of [13] together with a similar complexity statement, but there were some unresolved issues in the proof, that were only fixed by the contributions of [11].

complexity of Gibbs-sampling and searching. The Fast Quantum OR lemma can be used to separate the search phase from the initial Gibbs-state preparation phase. This led to the improved complexity bound [12] of

$$\widetilde{\mathcal{O}}_n\left(\left(\sqrt{m}+\mathrm{poly}(\max_{j\in\{0\ldots m\}}[\mathrm{rank}(A_j)])\right)\ \mathrm{poly}\left(\frac{Rr}{\varepsilon},B\right)\right).$$

We thank the authors of [12] for sending us an early draft of [12] introducing the Fast Quantum OR Lemma, which enabled us to work on these improvements. During the correspondence the application of the Fast OR lemma to the sparse matrix model was independently suggested by Brandão et al. [30] and by us.

5 Our results

In this paper we present multiple results. The main contribution consists of multiple improvements to the algorithms for SDP solving, based on combining various recent quantum algorithmic developments. Although some of these improvements require quite technical proofs, they come from simple new perspectives and ideas, often combining previous works in new ways. We also apply the resulting algorithms to a few problems in convex optimization. Finally, we prove a new lower bound that fits the novel input models that we work with.

5.1 Improvements to the quantum algorithms

In this paper we build on the Arora-Kale framework for SDP-solving in a similar fashion as [5, 13] and also use results from [11, 25] to construct a primal oracle. We improve on the previous results about quantum SDP-solving in three different ways:

Two-Phase Quantum Search and Minimum Finding

We give a computationally more efficient version of the Gentle Quantum Search Lemma [2] using the Fast Quantum OR Lemma from [12]. We also extend this to minimum finding to get our *Two-Phase Quantum Minimum Finding* (Lemma 7 of the full version of this paper [3]). As independently observed by the authors of [12] the Fast Quantum OR Lemma gives a speed-up for SDP primal oracles in general. Moreover, using Two-Phase Quantum Minimum Finding, we show how to improve the upper bound on the complexity of general SDP-solving from

$$T_{SDP}(\varepsilon)=\widetilde{\mathcal{O}}_n\left(\sqrt{m}T^{\sigma}_{Tr}((4\gamma)^{-1})T_{Gibbs}(\gamma,\gamma^2,\gamma^{-1})\gamma^3\sigma\right) \tag{7}$$

as implied in previous work [13, 5] to

$$T_{SDP}(\varepsilon)=\widetilde{\mathcal{O}}_n\left(\left(\sqrt{m}T^{\sigma}_{Tr}((4\gamma)^{-1})+T_{Gibbs}(\gamma,\gamma^2,\gamma^{-1})\right)\gamma^4\sigma^2\right), \tag{8}$$

where $\gamma=\Theta(Rr/\varepsilon)$. For the complexity of SDP primal oracles, the same upper bounds hold.

Quantum operator model and efficient data structures

We introduce the quantum operator input model unifying prior approaches. We show that both the sparse model and the quantum state model can be reduced to the quantum operator model with a constant overhead and with the choices of $\alpha=s$ and $\alpha=B$ respectively.

Moreover, we show that for $\sigma = \Theta(1)$, we have that

$$T^{\sigma}_{Tr}((4\gamma)^{-1}) = \widetilde{\mathcal{O}}_{\gamma}(\alpha),$$

in the quantum operator model.

The complexity of Gibbs-sampling in the sparse matrix input model previously was [5]:

$$T_{Gibbs}(K, d, \theta) = \widetilde{\mathcal{O}}_{\theta}\left(\sqrt{n}Ks^2d^2\right).$$

By considering the operator model, in which we can show how to simulate a linear combination of Hamiltonians efficiently, we can improve this to

$$T_{Gibbs}(K, d, \theta) = \widetilde{\mathcal{O}}_{\theta,d}\left(\sqrt{n}K\alpha\right).$$

This result is based on the idea of gradually building up an efficient data structure for state preparation, following ideas of [22]. This demonstrates that these data structures can be used efficiently even if one does not assume preprocessed data. Moreover, it shows that working in the operator model does not only unify prior approaches but also inspires more efficient quantum algorithms due to its conceptual clarity.

Table 1 Summary of the role of our various improvements, the theorem numbers refer to the numbers in the full version of the paper [3]. The main new results are on the bottom, the other complexity statements represent partial results following from only applying some of the improvements. We present the results for the sparse matrix and quantum state input models for comparison to prior work. However, note that our results presented for sparse input hold more generally for the quantum operator input model; to get the corresponding results one should just replace s by α in the table. Thereby similar bounds hold in the case of the quantum state input model too, after replacing s by B, which can be beneficial when $B^{2.5}\gamma^{2.5} \geq \sqrt{n}$. Notation: $\mathrm{rk} = \max_{j\in\{0,\dots,m\}} \mathrm{rank}(A_j)$ and $\gamma = \frac{Rr}{\varepsilon}$.

Gibbs sampling for the quantum state model

We develop a new method for Gibbs-sampling in the quantum state model. As noted in [12] this model has the nice property that it is relatively easy to find the important eigenspaces of the input matrices. We introduce a new technique for finding these important eigenspaces

that, in contrast to the approach in [12], does not introduce a dependence on the rank of the input matrices in the complexity. In particular we improve the complexity bound of [12]

$$T_{Gibbs}(K,d,\theta) = \mathcal{O}\left(\text{poly}(K,B,d,1/\theta,\max_{j\in\{0\ldots m\}}[\text{rank}(A_j)])\right),$$

to

$$T_{Gibbs}(K,d,\theta) = \widetilde{\mathcal{O}}_{d,\theta,n}\left((KB)^{3.5}\right),$$

both making the polynomial dependence explicit and improving it.

An important consequence of this improvement is that we do not get a dependence on the rank of the input matrices in the complexity of SDP solving, unlike Brandão et al. [12]. Since the most natural use for the quantum state model is when the A_j matrices naturally correspond to quantum states, B is often just 1. However, if the states are highly mixed, then the rank is about n, eliminating the speedup over the sparse input model when a rank dependence is present. Finally note that this Gibbs-sampling method is only beneficial if $\sqrt{n} \leq (KB)^{2.5}$, otherwise the reduction to the quantum operator model with $\alpha = B$ gives a better algorithm.

For the quantum operator input model the above improvements lead to the complexity bound

$$T_{SDP}(\varepsilon) = \widetilde{\mathcal{O}}\left(\left(\sqrt{m}+\sqrt{n}\gamma\right)\alpha\gamma^4\right), \tag{9}$$

where $\gamma := \frac{Rr}{\varepsilon}$. Note that the $\Omega(\sqrt{n}+\sqrt{m})$ lower bound of [13] also applies to the quantum operator model due to our reductions, matching the above upper bound (9) up to polylog factors in n and m when γ and α are constant. For the quantum state input model our improved Gibbs-sampler yields the complexity bound

$$T_{SDP}(\varepsilon) = \widetilde{\mathcal{O}}_n\left(\left(\sqrt{m}+B^{2.5}\gamma^{3.5}\right)B\gamma^4\right).$$

In both cases, the same bound holds for an SDP primal oracle but with $\gamma := R/\varepsilon$.

5.2 Applications

In Section 4 of the full version of this paper [3] we give some applications of quantum SDP-solvers. Due to the large error dependence the last two of these are not of practical interest. However they do show that a theoretical improvement in one of the parameters is possible over classical computers and more specified quantum algorithms might improve the error dependence.

Shadow tomography of quantum states

We extend the idea of applying SDP-solving to the problem of shadow tomography: given an unknown, n-dimensional quantum state ρ, find ε-additive approximations of the expectation values $\text{Tr}(E_1\rho),\ldots,\text{Tr}(E_m\rho)$ of several binary measurement operators. This problem was introduced by Aaronson in [2], he gave an efficient algorithm in terms of the number of samples from ρ. In particular he proved that $\widetilde{\mathcal{O}}\left(\log^4(m)\log(n)/\varepsilon^5\right)$ samples suffice. Brandão et al. [12] applied their SDP-solver to get a more efficient algorithm in terms of computation time when the measurements E_i are given in the quantum state model, while keeping the sample complexity as low as $\text{poly}(\log(m),\log(n),1/\varepsilon,B)$. We simultaneously improve on both results, giving a sample bound of $\widetilde{\mathcal{O}}\left(\log^4(m)\log(n)/\varepsilon^4\right)$ while also improving the best

known time complexity [2, 12] of the implementation for all input models. Finally we show that if we can efficiently implement the measurements $\mathrm{Tr}(E_1\rho), \ldots, \mathrm{Tr}(E_m\rho)$ on a quantum computer, then we can also efficiently represent $E_1, \ldots, E_m$ using the quantum operator input model, hence the computational complexity can be stated in terms of the number of measurements needed.

Quantum state discrimination

We apply the SDP-solvers to the problem of quantum state discrimination: given a set of quantum states, what is the best POVM for discriminating between the states? We consider the case of minimizing the total error in the measurements. In this case we get an algorithm with running time $\widetilde{\mathcal{O}}\left(\sqrt{k}\ \mathrm{poly}(d, 1/\varepsilon)\right)$ in the sparse input model, where k is the number of states and d is the dimension of the states. Due to the quantum state model for SDP-solving, we can also solve the problem when the states that need to be discriminated are actually given as quantum states, rather than classical descriptions of density operators.

Optimal design

We apply our sparse SDP-solver to the problem of E-optimal design: given a set of k experiments, find the optimal distribution of the experiments that minimizes the variance in our knowledge of a d-dimensional system. Our final bound is $\widetilde{\mathcal{O}}\left((\sqrt{k}+\sqrt{d})\mathrm{poly}(1/\varepsilon, P)\right)$, where P is a parameter that depends on the standard deviation of the experiments.

5.3 Lower bounds

We end the paper with proving new lower bounds. Lower bounds on the quantum query complexity of SDP-solving for the sparse input model were presented in previous works [13, 5]. We add to this by giving $\widetilde{\Omega}(\sqrt{m}B/\varepsilon)$ and $\widetilde{\Omega}(\sqrt{m}\alpha/\varepsilon)$ bounds for the quantum state model and quantum operator model respectively. These lower bounds show that the $\sqrt{m}$ factor and the polynomial dependence on the parameters B, α, and $1/\varepsilon$ are necessary.

Compared to problems with a discrete input, proving lower bounds on continuous-input quantum problems gives rise to extra challenges and often requires more involved techniques, see for example the work of Belovs [8] on generalizations of the adversary method. Due to these difficulties, fewer results are known in this regime. Examples of known continuous-input lower-bound results include phase-estimation related problems (cf. Bessen [10]) and the complexity-theoretic version of the no-cloning theorem due to Aaronson [1]. Recently, a new hybrid-method based approach was developed by Gilyén et al. [19] in order to handle continuous-input oracles, which they use for proving a lower bound for gradient computation. We use their techniques to prove our lower bounds, combined with efficient reductions between input models stemming from the smooth-functions of Hamitonians techniques developed in the work of van Apeldoorn et al. [5].

6 Subsequent work

A few months after the first version of our paper was posted on the arXiv, Kerenidis and Prakash [23] gave a quantum interior point algorithm for solving LPs and SDPs. They work in an input model where the input matrices are stored in QROM, which input model is also covered by our quantum operator input model. However, it is hard to compare their complexities to ours, because their final complexity statement depends polynomially on the condition number of the matrices that the interior point method encounters, and they do not

give explicit bounds for these condition numbers. Also they have two accuracy parameters, while one accuracy parameter only appears as a logarithmic factor, their complexity depends polynomially on the other.

Very recently Apeldoorn et al. [6] and Chakrabarti et al. [14] developed improved quantum algorithms for general black-box convex optimization. Since we work in a model where we are given access directly to the constraints defining the problem, our results are incomparable.

Abstract

While many applications of automata in formal methods can use nondeterministic automata, some applications, most notably synthesis, need deterministic or *good-for-games* automata. The latter are nondeterministic automata that can resolve their nondeterministic choices in a way that only depends on the past. The *minimization* problem for nondeterministic and deterministic Büchi and co-Büchi word automata are PSPACE-complete and NP-complete, respectively. We describe a polynomial minimization algorithm for good-for-games *co-Büchi* word automata with *transition-based* acceptance. Thus, a run is accepting if it traverses a set of designated transitions only finitely often. Our algorithm is based on a sequence of transformations we apply to the automaton, on top of which a minimal quotient automaton is defined.

1 Introduction

Automata theory is one of the longest established areas in Computer Science. A classical problem in automata theory is *minimization*: generation of an equivalent automaton with a minimal number of states. For automata on finite words, the picture is well understood: For nondeterministic automata, minimization is PSPACE-complete [16], whereas for deterministic automata, a minimization algorithm, based on the Myhill-Nerode right congruence [28, 29], generates in polynomial time a canonical minimal deterministic automaton [14]. Essentially, the canonical automaton, a.k.a. the *quotient automaton*, is obtained by merging equivalent states.

A prime application of automata theory is specification, verification, and synthesis of reactive systems [36, 8]. The automata-theoretic approach considers relationships between systems and their specifications as relationships between languages. Since we care about the on-going behavior of nonterminating systems, the automata run on infinite words. Acceptance in such automata is determined according to the set of states that are visited infinitely often along the run. In Büchi automata [5] (NBW and DBW, for nondeterministic and deterministic Büchi word automata, respectively), the acceptance condition is a subset α of states, and a run is accepting iff it visits α infinitely often. Dually, in co-Büchi automata (NCW and DCW), a run is accepting iff it visits α only finitely often. In spite of the extensive use of automata on infinite words in verification and synthesis algorithms and tools, some fundamental problems around their minimization are still open. For nondeterministic automata, minimization is PSPACE-complete, as it is for automata on finite words. Before

we describe the situation for deterministic automata, let us elaborate some more on the power of nondeterminism in the context of automata on infinite words, as this would be relevant to our contribution.

For automata on finite words, nondeterminism does not increase the expressive power, yet it leads to an exponential succinctness [31]. For automata on infinite words, nondeterminism may increase the expressive power and also leads to an exponential succinctness. For example, NBWs are strictly more expressive than DBWs [21]. In some applications of automata on infinite words, such as model checking, algorithms can proceed with nondeterministic automata, whereas in other applications, such as synthesis and control, they cannot. There, the advantages of nondeterminism are lost, and the algorithms involve complicated determinization constructions [32] or acrobatics for circumventing determinization [20]. Essentially, the inherent difficulty of using nondeterminism in synthesis lies in the fact that each guess of the nondeterministic automaton should accommodate all possible futures.

The study of nondeterministic automata that can resolve their nondeterministic choices in a way that only depends on the past and still accept all words in the language started already in 1996 [19], where the setting is modeled by means of tree automata for derived languages. It then continued by means of *good for games* (GFG) automata, introduced in [13].[1] Formally, a nondeterministic automaton $\mathcal{A}$ over an alphabet Σ is GFG if there is a strategy g that maps each finite word $u \in \Sigma^*$ to the transition to be taken after u is read; and following g results in accepting all the words in the language of $\mathcal{A}$. Note that a state q of $\mathcal{A}$ may be reachable via different words, and g may suggest different transitions from q after different words are read. Still, g depends only on the past, namely on the word read so far. Obviously, there exist GFG automata: deterministic ones, or nondeterministic ones that are *determinizable by pruning* (DBP); that is, ones that just add transitions on top of a deterministic automaton. In fact, the GFG automata constructed in [13] are DBP.[2]

In terms of expressive power, it is shown in [19, 30] that GFG automata with an acceptance condition γ (e.g., Büchi) are as expressive as deterministic γ automata. The picture in terms of succinctness is diverse. For automata on finite words, GFG automata are always DBP [19, 26]. For automata on infinite words, in particular NBWs and NCWs, GFG automata need not be DBP [3]. Moreover, the best known determinization construction for GFG-NBWs is quadratic, whereas determinization of GFG-NCWs has an exponential blow-up lower bound [17]. Thus, in terms of succinctness, GFG automata on infinite words are more succinct (possibly even exponentially) than deterministic ones. Further research studies characterization, typeness, complementation, and further constructions and decision procedures for GFG automata [17, 4, 2].

Back to the minimization problem. Recall that for finite words, an equivalent minimal deterministic automaton can be obtained by merging equivalent states. A similar algorithm is valid for determinisitic *weak* automata on infinite words: DBWs in which each strongly connected component is either contained in α or is disjoint form α [27, 23]. For general DBWs (and hence, also DCWs, as the two dualize each other), merging of equivalent states fails, and minimization is NP-complete [33].

The intractability of the minimization problem has led to a development of numerous heuristics. The heuristics either relax the minimality requirement, for example algorithms based on *fair bisimulation* [10], which reduce the state space but need not return a minimal

[1] GFGness is also used in [6] in the framework of cost functions under the name "history-determinism".

[2] As explained in [13], the fact that the GFG automata constructed there are DBP does not contradict their usefulness in practice, as their transition relation is simpler than the one of the embodied deterministic automaton and it can be defined symbolically.

automaton, or relax the equivalence requirement, for example algorithms based on *hyper-minimization* [1, 15] or *almost-equivalence* [33], which come with a guarantee about the difference between the language of the original automaton and the ones generated by the algorithm. In some cases, these algorithms do generate of a minimal equivalent automaton (in particular, applying relative minimization based on almost equivalence on a deterministic weak automaton results in an equivalent minimal weak automaton [33]), but in general, they are only heuristics. In an orthogonal line of work, researchers have studied minimization in richer settings of automata on finite words. One direction is to allow some nondeterminism. As it turns out, however, even the slightest extension of the deterministic model towards a nondeterministic one, for example by allowing at most one nondeterministic choice in every accepting computation or allowing just two initial states instead of one, results in NP-complete minimization problems [24]. Another direction is a study of quantitative settings. Here, the picture is diverse. For example, minimization of deterministic lattice automata [18] is polynomial for automata over linear lattices and is NP-complete for general lattices [11], and minimization of deterministic weighted automata over the tropical semiring is polynomial [25], yet the problem is open for general semirings.

Proving NP-hardness for DBW minimization, Schewe used a reduction from the vertex-cover problem [33]. Essentially[3], given a graph $G = \langle V, E\rangle$, we seek a minimal DBW for the language L_G of words of the form $v_{i_1}^+ \cdot v_{i_2}^+ \cdot v_{i_3}^+ \cdots \in V^\omega$, where for all $j \geq 1$, we have that $\langle v_{i_j}, v_{i_{j+1}}\rangle \in E$. We can recognize L_G by an automaton obtained from G by adding self loops to all vertices, labelling each edge by its destination, and requiring a run to traverse infinitely many original edges of G. Indeed, such runs correspond to words that traverse an infinite path in G, possibly looping at vertices, but not getting trapped in a self loop, as required by L_G. When, however, the acceptance condition is defined by a set of vertices, rather than edges, we need to duplicate some states, and a minimal duplication corresponds to a minimal vertex cover. Thus, a natural question arises: Is there a polynomial minimization algorithms for DBWs and DCWs whose acceptance condition is *transition based*? Beyond the theoretical interest, there is recently growing use of transition-based automata in practical applications, with evidences they offer a simpler translation of LTL formulas to automata and enable simpler constructions and decision procedures [9, 7, 34, 22].

In this paper we present a significant step towards a positive answer to this question and describe a polynomial-time algorithm for the minimization of GFG transition-based NCWs. Consider a GFG-NCW $\mathcal{A}$. Our algorithm is based on a chain of transformations we apply to $\mathcal{A}$. Some of the transformations are introduced in [17], in algorithms for deciding GFGness. We add two more transformations and prove that they guarantee minimality. Our reasoning is based on a careful analysis of the *safe components* of $\mathcal{A}$, namely the components obtained by removing transitions in α. We show that a minimal GFG-NCW equivalent to $\mathcal{A}$ can be obtained by defining an order on the safe components, and applying the quotient construction on a GFG-NCW obtained by restricting attention to states that belong to components that form a frontier in this order.

The paper is organized as follows. In Section 2, we define GFG-NCWs and some properties of GFG-NCWs that can be attained in polynomial time using existing results. In Section 3, we describe two additional properties and prove that they guarantee minimality. Then, in Sections 4 – 5, we show how the two properties can be attained in polynomial time, thus concluding our minimization procedure. In Section 6, we discuss how our results contribute to the quest for efficient DBW and DCW minimization.

[3] The exact reduction is more complicated and involves an additional letter that is required for cases in which vertices in the graph have similar neighbours.

2 Preliminaries

For a finite nonempty alphabet Σ, an infinite *word* $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$ is an infinite sequence of letters from Σ. A *language* $L \subseteq \Sigma^\omega$ is a set of words. We denote the empty word by ϵ, the set of finite words over Σ by Σ^*. For $i \geq 0$, we use $w[1, i]$ to denote the (possibly empty) prefix $\sigma_1 \cdot \sigma_2 \cdots \sigma_i$ of w and use $w[i+1, \infty]$ to denote its suffix $\sigma_{i+1} \cdot \sigma_{i+2} \cdots$.

A *nondeterministic automaton* over infinite words is $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, where Σ is an alphabet, Q is a finite set of *states*, $q_0 \in Q$ is an *initial state*, $\delta : Q \times \Sigma \to 2^Q \setminus \emptyset$ is a *transition function*, and α is an *acceptance condition*, to be defined below. For states q and s and a letter $\sigma \in \Sigma$, we say that s is a σ-successor of q if $s \in \delta(q, \sigma)$. The *size* of $\mathcal{A}$, denoted $|\mathcal{A}|$, is defined as its number of states, thus, $|\mathcal{A}| = |Q|$. Note that $\mathcal{A}$ is *total*, in the sense that it has at least one successor for each state and letter, and that $\mathcal{A}$ may be *nondeterministic*, as the transition function may specify several successors for each state and letter. If $|\delta(q, \sigma)| = 1$ for every state $q \in Q$ and letter $\sigma \in \Sigma$, then $\mathcal{A}$ is *deterministic*.

When $\mathcal{A}$ runs on an input word, it starts in the initial state and proceeds according to the transition function. Formally, a *run* of $\mathcal{A}$ on $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$ is an infinite sequence of states $r = r_0, r_1, r_2, \ldots \in Q^\omega$, such that $r_0 = q_0$, and for all $i \geq 0$, we have that $r_{i+1} \in \delta(r_i, \sigma_{i+1})$. We sometimes extend δ to sets of states and finite words. Then, $\delta : 2^Q \times \Sigma^* \to 2^Q$ is such that for every $S \in 2^Q$, finite word $u \in \Sigma^*$, and letter $\sigma \in \Sigma$, we have that $\delta(S, \epsilon) = S$, $\delta(S, \sigma) = \bigcup_{s \in S} \delta(s, \sigma)$, and $\delta(S, u \cdot \sigma) = \delta(\delta(S, u), \sigma)$. Thus, $\delta(S, u)$ is the set of states that $\mathcal{A}$ may reach when it reads u from some state in S.

The transition function δ induces a transition relation $\Delta \subseteq Q \times \Sigma \times Q$, where for every two states $q, s \in Q$ and letter $\sigma \in \Sigma$, we have that $\langle q, \sigma, s \rangle \in \Delta$ iff $s \in \delta(q, \sigma)$. We sometimes view the run $r = r_0, r_1, r_2, \ldots$ on $w = \sigma_1 \cdot \sigma_2 \cdots$ as an infinite sequence of successive transitions $\langle r_0, \sigma_1, r_1 \rangle, \langle r_1, \sigma_2, r_2 \rangle, \ldots \in \Delta^\omega$. The acceptance condition α determines which runs are "good". We consider here *transition-based* automata, in which α refers to the set of transitions that are traversed infinitely often during the run; specifically, $\alpha \subseteq \Delta$. We use the terms *α-transitions* and *$\bar{\alpha}$-transitions* to refer to transitions in α and in $\Delta \setminus \alpha$, respectively. We also refer to restrictions δ^α and $\delta^{\bar{\alpha}}$ of δ, where for all $q, s \in Q$ and $\sigma \in \Sigma$, we have that $s \in \delta^\alpha(q, \sigma)$ iff $\langle q, \sigma, s \rangle \in \alpha$, and $s \in \delta^{\bar{\alpha}}(q, \sigma)$ iff $\langle q, \sigma, s \rangle \in \Delta \setminus \alpha$. For a run $r \in \Delta^\omega$, let $inf(r) \subseteq \Delta$ be the set of transitions that r traverses infinitely often. Thus, $inf(r) = \{\langle q, \sigma, s \rangle \in \Delta : q = r_i, \sigma = \sigma_{i+1}$ and $s = r_{i+1}$ for infinitely many i's$\}$. In *co-Büchi* automata, a run r is *accepting* iff $inf(r) \cap \alpha = \emptyset$, thus if r traverses transitions in α only finitely often. A run that is not accepting is *rejecting*. A word w is accepted by $\mathcal{A}$ if there is an accepting run of $\mathcal{A}$ on w. The language of $\mathcal{A}$, denoted $L(\mathcal{A})$, is the set of words that $\mathcal{A}$ accepts. Two automata are *equivalent* if their languages are equivalent. We use tNCW and tDCW to abbreviate nondeterministic and deterministic transition-based co-Büchi automata over infinite words, respectively.

For a state $q \in Q$ of an automaton $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$, we define $\mathcal{A}^q$ to be the automaton obtained from $\mathcal{A}$ by setting the initial state to be q. Thus, $\mathcal{A}^q = \langle \Sigma, Q, q, \delta, \alpha \rangle$. We say that two states $q, s \in Q$ are *equivalent*, denoted $q \sim_{\mathcal{A}} s$, if $L(\mathcal{A}^q) = L(\mathcal{A}^s)$. The automaton $\mathcal{A}$ is *semantically deterministic* if different nondeterministic choices lead to equivalent states. Thus, for every state $q \in Q$ and letter $\sigma \in \Sigma$, all the σ-successors of q are equivalent: for every two states $s, s' \in Q$ such that $\langle q, \sigma, s \rangle$ and $\langle q, \sigma, s' \rangle$ are in Δ, we have that $s \sim_{\mathcal{A}} s'$. The following proposition follows immediately from the definitions.

▶ **Proposition 1.** *Consider a semantically deterministic automaton $\mathcal{A}$, states $q, s \in Q$, letter $\sigma \in \Sigma$, and transitions $\langle q, \sigma, q' \rangle, \langle s, \sigma, s' \rangle \in \Delta$. If $q \sim_{\mathcal{A}} s$, then $q' \sim_{\mathcal{A}} s'$.*

A tNCW $\mathcal{A}$ is *safe deterministic* if by removing its α-transitions, we get a (possibly not total) deterministic automaton. Thus, $\mathcal{A}$ is *safe deterministic* if for every state $q \in Q$ and letter $\sigma \in \Sigma$, it holds that $|\delta^{\bar{\alpha}}(q, \sigma)| \leq 1$. We refer to the components we get by removing $\mathcal{A}$'s α-transitions as the *safe components* of $\mathcal{A}$, and we denote the set of safe components of $\mathcal{A}$ by $S(\mathcal{A})$. For a safe component $S \in S(\mathcal{A})$, the *size* of S, denoted $|S|$, is the number of states in S. Note that an accepting run of $\mathcal{A}$ eventually gets trapped in one of $\mathcal{A}$'s safe components.

An automaton $\mathcal{A}$ is *good for games* (*GFG*, for short) if its nondeterminism can be resolved based on the past, thus on the prefix of the input word read so far. Formally, $\mathcal{A}$ is *GFG* if there exists a *strategy* $f : \Sigma^* \to Q$ such that the following holds:

1. The strategy f is consistent with the transition function. That is, for every finite word $u \in \Sigma^*$ and letter $\sigma \in \Sigma$, we have that $\langle f(u), \sigma, f(u \cdot \sigma) \rangle \in \Delta$.
2. Following f causes $\mathcal{A}$ to accept all the words in its language. That is, for every infinite word $w = \sigma_1 \cdot \sigma_2 \cdots \in \Sigma^\omega$, if $w \in L(\mathcal{A})$, then the run $f(w[1,0]), f(w[1,1]), f(w[1,2]), \ldots$, which we denote by $f(w)$, is accepting.

We say that the strategy f *witnesses* $\mathcal{A}$'s GFGness. For an automaton $\mathcal{A}$, we say that a state q of $\mathcal{A}$ is *GFG* if $\mathcal{A}^q$ is GFG. Finally, we say that a GFG-tNCW $\mathcal{A}$ is *minimal* if for every equivalent GFG-tNCW $\mathcal{B}$, it holds that $|\mathcal{A}| \leq |\mathcal{B}|$.

Consider a directed graph $G = \langle V, E \rangle$. A *strongly connected set* in G (SCS, for short) is a set $C \subseteq V$ such that for every two vertices $v, v' \in C$, there is a path from v to v'. A SCS is *maximal* if it is maximal w.r.t containment, that is, for every non-empty set $C' \subseteq V \setminus C$, it holds that $C \cup C'$ is not a SCS. The *maximal strongly connected sets* are also termed *strongly connected components* (SCCs, for short). The *SCC graph of* G is the graph defined over the SCCs of G, where there is an edge from a SCC C to another SCC C' iff there are two vertices $v \in C$ and $v' \in C'$ with $\langle v, v' \rangle \in E$. A SCC is *ergodic* iff it has no outgoing edges in the SCC graph. The SCC graph of G can be computed in linear time by standard SCC algorithms [35]. An automaton $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$ induces a directed graph $G_\mathcal{A} = \langle Q, E \rangle$, where $\langle q, q' \rangle \in E$ iff there is a letter $\sigma \in \Sigma$ such that $\langle q, \sigma, q' \rangle \in \Delta$. The SCSs and SCCs of $\mathcal{A}$ are those of $G_\mathcal{A}$. We say that a tNCW $\mathcal{A}$ is *normal* if all the safe components of $\mathcal{A}$ are SCSs. That is, for all states q and s of $\mathcal{A}$, if there is a path of $\bar{\alpha}$-transition from q to s, then there is also a path of $\bar{\alpha}$-transition from s to q.

We now combine several properties defined above and say that a GFG-tNCW $\mathcal{A}$ is *nice* if all the states in $\mathcal{A}$ are reachable and GFG, and $\mathcal{A}$ is normal, safe deterministic, and semantically deterministic. In the theorem below we combine arguments from [17] showing that each of these properties can be obtained in at most polynomial time, and without the properties being conflicting. For some properties, we give an alternative and simpler proof.

▶ **Theorem 2.** [17] *Every GFG-tNCW $\mathcal{A}$ can be turned, in polynomial time, into an equivalent nice GFG-tNCW $\mathcal{B}$ such that $|\mathcal{B}| \leq |\mathcal{A}|$.*

Proof. It is shown in [17] that one can decide the GFGness of a tNCW $\mathcal{A}$ in polynomial time. The proof goes through an intermediate step where the authors construct a two-players game such that if the first player does not win the game, then $\mathcal{A}$ is not GFG, and otherwise a winning strategy for him induces a safe-deterministic GFG-tNCW $\mathcal{B}$ equivalent to $\mathcal{A}$. As we start with a GFG-tNCW $\mathcal{A}$, such a winning strategy is guaranteed to exist, and we obtain an equivalent safe-deterministic GFG-tNCW $\mathcal{B}$ in polynomial time. In fact, it can be shown that $\mathcal{B}$ is also semantically deterministic. Yet, for completeness we give below a general procedure for semantic determinization.

For a tNCW $\mathcal{A}$, we say that a transition $\langle q, \sigma, s \rangle \in \Delta$ is *covering* if for every transition $\langle q, \sigma, s' \rangle$, it holds that $L(\mathcal{A}^{s'}) \subseteq L(\mathcal{A}^s)$. If $\mathcal{A}$ is GFG and f is a strategy witnessing its GFGness, we say that a state q of $\mathcal{A}$ is *used by* f if there is a finite word u with $f(u) = q$, and

we say that a transition $\langle q, \sigma, q' \rangle$ of $\mathcal{A}$ is *used by* f if there is a finite word u with $f(u) = q$ and $f(u\sigma) = q'$. Since states that are not GFG can be detected in polynomial time, and as all states that are used by a strategy that witnesses $\mathcal{B}$'s GFGness are GFG, the removal of non-GFG states does not affect $\mathcal{B}$'s language. Note that removing the non-GFG states may result in a non-total automaton, in which case we add a rejecting sink. Now, using the fact that language containment of GFG-tNCWs can be checked in polynomial time [12, 17], and transitions that are used by strategies are covering [17], one can semantically determinize $\mathcal{B}$ by removing non-covering transitions.

States that are not reachable are easy to detect, and their removal does not affect $\mathcal{B}$'s language. Normalization is also easy to obtain and involves adding some existing transitions to α [17]. Indeed, if the safe components of $\mathcal{B}$ are not SCSs, then every $\bar{\alpha}$-transition connecting different SCCs of $\mathcal{B}$'s safe components can be added to α without affecting the acceptance of runs in $\mathcal{B}$, as every accepting run traverses such transitions only finitely often. Thus, the language and GFGness of all states are not affected. Finally, it is not hard to verify that the properties, in the order we obtain them in the proof, are not conflicting, and thus the described sequence of transformations results in a nice GFG-tNCW. ◀

3 A Sufficient Condition for GFG-tNCW Minimality

In this section, we define two additional properties for nice GFG-tNCWs, namely *safe-centralized* and *safe-minimal*, and we prove that nice GFG-tNCWs that attain these properties are minimal. In Sections 4 – 5, we are going to show that the two properties can be attained in polynomial time. Before we start, let us note that a GFG-tNCW may be nice and still not be minimal. A simple example is a GFG-tNCW $\mathcal{A}_{\mathsf{fm}}$ for the language $(a+b)^* \cdot a^\omega$ that has two states, both with a $\bar{\alpha}$-self-loop labeled a and an α-transition labeled b to the other state. It is easy to see that $\mathcal{A}_{\mathsf{fm}}$ is nice but not minimal.

Consider a tNCW $\mathcal{A} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$. A run r of $\mathcal{A}$ is *safe* if it does not traverse α-transitions. The *safe language* of $\mathcal{A}$, denoted $L_{safe}(\mathcal{A})$, is the set of infinite words w, such that there is a safe run of $\mathcal{A}$ on w. Recall that two states $q, s \in Q$ are equivalent ($q \sim_{\mathcal{A}} s$) if $L(\mathcal{A}^q) = L(\mathcal{A}^s)$. Then, q and s are *strongly-equivalent*, denoted $q \approx_{\mathcal{A}} s$, if $q \sim_{\mathcal{A}} s$ and $L_{safe}(\mathcal{A}^q) = L_{safe}(\mathcal{A}^s)$. Finally, q is *subsafe-equivalent to* s, denoted $q \precsim_{\mathcal{A}} s$, if $q \sim_{\mathcal{A}} s$ and $L_{safe}(\mathcal{A}^q) \subseteq L_{safe}(\mathcal{A}^s)$. Note that the three relations are transitive. When $\mathcal{A}$ is clear from the context, we omit it from the notations, thus write $L_{safe}(q)$, $q \precsim s$, etc. The tNCW $\mathcal{A}$ is *safe-minimal* if it has no strongly-equivalent states. Then, $\mathcal{A}$ is *safe-centralized* if for every two states $q, s \in Q$, if $q \precsim s$, then q and s are in the same safe component of $\mathcal{A}$.

▶ **Example 3.** The nice GFG-tNCW $\mathcal{A}_{\mathsf{fm}}$ described above is neither safe-minimal (its two states are strongly-equivalent) nor safe-centralized (its two states are in different safe components). As another example, consider the tDCW $\mathcal{A}$ appearing in Figure 1. The dashed transitions are α-transitions. All the states of $\mathcal{A}$ are equivalent, yet they all differ in their safe language. Accordingly, $\mathcal{A}$ is safe-minimal. Since $a^\omega = L_{safe}(\mathcal{A}^{q_2}) \subseteq L_{safe}(\mathcal{A}^{q_0})$, we have that $q_2 \precsim q_0$. Hence, as q_0 and q_2 are in different safe components, the tDCW $\mathcal{A}$ is not safe-centralized.

▶ **Proposition 4.** *Consider a nice GFG-tNCW $\mathcal{A}$ and states q and s of $\mathcal{A}$ such that $q \approx s$ ($q \precsim s$). For every letter $\sigma \in \Sigma$ and $\bar{\alpha}$-transition $\langle q, \sigma, q' \rangle$, there is an $\bar{\alpha}$-transition $\langle s, \sigma, s' \rangle$ such that $q' \approx s'$ ($q' \precsim s'$, respectively).*

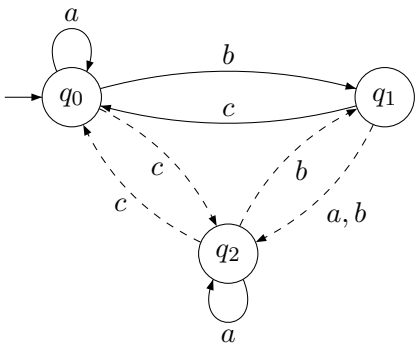

Figure 1 The tDCW $\mathcal{A}$.

Proof. We prove the proposition for the case $q \approx s$. The case $q \precsim s$ is similar. Since $\mathcal{A}$ is normal, the existence of the $\bar{\alpha}$-transition $\langle q, \sigma, q' \rangle$ implies that there is a safe run from q' back to q. Hence, there is a word $z \in L_{safe}(\mathcal{A}^{q'})$. Clearly, $\sigma \cdot z$ is in $L_{safe}(\mathcal{A}^q)$. Now, since $q \approx s$, we have that $L_{safe}(\mathcal{A}^q) = L_{safe}(\mathcal{A}^s)$. In particular, $\sigma \cdot z \in L_{safe}(\mathcal{A}^s)$, and thus there is a $\bar{\alpha}$-transition $\langle s, \sigma, s' \rangle$. We prove that $q' \approx s'$. Since $L(\mathcal{A}^q) = L(\mathcal{A}^s)$ and $\mathcal{A}$ is semantically deterministic, then, by Proposition 1, we have that $L(\mathcal{A}^{q'}) = L(\mathcal{A}^{s'})$. It is left to prove that $L_{safe}(\mathcal{A}^{q'}) = L_{safe}(\mathcal{A}^{s'})$. We prove that $L_{safe}(\mathcal{A}^{q'}) \subseteq L_{safe}(\mathcal{A}^{s'})$. The second direction is similar. Since $\mathcal{A}$ is safe deterministic, the transition $\langle s, \sigma, s' \rangle$ is the only σ-labeled $\bar{\alpha}$-transition from s. Hence, if by contradiction there is a word $z \in L_{safe}(\mathcal{A}^{q'}) \setminus L_{safe}(\mathcal{A}^{s'})$, we get that $\sigma \cdot z \in L_{safe}(\mathcal{A}^q) \setminus L_{safe}(\mathcal{A}^s)$, contradicting the fact that $L_{safe}(\mathcal{A}^q) = L_{safe}(\mathcal{A}^s)$. ◀

We continue with propositions that relate two automata, $\mathcal{A} = \langle \Sigma, Q_\mathcal{A}, q^0_\mathcal{A}, \delta_\mathcal{A}, \alpha_\mathcal{A} \rangle$ and $\mathcal{B} = \langle \Sigma, Q_\mathcal{B}, q^0_\mathcal{B}, \delta_\mathcal{B}, \alpha_\mathcal{B} \rangle$. We assume that $Q_\mathcal{A}$ and $Q_\mathcal{B}$ are disjoint, and extend the $\sim$, $\approx$, and $\precsim$ relations to states in $Q_\mathcal{A} \cup Q_\mathcal{B}$ in the expected way. For example, for $q \in Q_\mathcal{A}$ and $s \in Q_\mathcal{B}$, we use $q \sim s$ to indicate that $L(\mathcal{A}^q) = L(\mathcal{B}^s)$.

▶ **Proposition 5.** *Let $\mathcal{A}$ and $\mathcal{B}$ be equivalent nice GFG-tNCWs. For every state $q \in Q_\mathcal{A}$, there is a state $s \in Q_\mathcal{B}$ such that $q \precsim s$.*

Proof. Let g be a strategy witnessing $\mathcal{B}$'s GFGness. Consider a state $q \in Q_\mathcal{A}$. Let $u \in \Sigma^*$ be such that $q \in \delta_\mathcal{A}(q^0_\mathcal{A}, u)$. Since $\mathcal{A}$ and $\mathcal{B}$ are equivalent and semantically deterministic, an iterative application of Proposition 1 implies that for every state $q' \in \delta_\mathcal{B}(q^0_\mathcal{B}, u)$, we have $q \sim q'$. In particular, $q \sim g(u)$. If $L_{safe}(\mathcal{A}^q) = \emptyset$, then we are done, as $L_{safe}(\mathcal{A}^q) \subseteq L_{safe}(\mathcal{B}^{g(u)})$. If $L_{safe}(\mathcal{A}^q) \neq \emptyset$, then the proof proceeds as follows. Assume by way of contradiction that for every state $s \in Q_\mathcal{B}$ that is equivalent to q, it holds that $L_{safe}(\mathcal{A}^q) \not\subseteq L_{safe}(\mathcal{B}^s)$. We define an infinite word z such that $\mathcal{A}$ accepts $u \cdot z$, yet $g(u \cdot z)$ is a rejecting run of $\mathcal{B}$. Since $\mathcal{A}$ and $\mathcal{B}$ are equivalent, this contradicts the fact that g witnesses $\mathcal{B}$'s GFGness.

We define z as follows. Let $s_0 = g(u)$. Since $L_{safe}(\mathcal{A}^q) \not\subseteq L_{safe}(\mathcal{B}^{s_0})$, there is a finite nonempty word z_1 such that there is a safe run of $\mathcal{A}^q$ on z_1, but every run of $\mathcal{B}^{s_0}$ on z_1 is not safe. In particular, the run of $\mathcal{B}^{s_0}$ that is induced by g, namely $g(u), g(u \cdot z_1[1,1]), g(u \cdot z_1[1,2]), \ldots, g(u \cdot z_1)$, traverses an α-transition. Since $\mathcal{A}$ is normal, we can define z_1 so the safe run of $\mathcal{A}^q$ on z_1 ends in q. Let $s_1 = g(u \cdot z_1)$. We have so far two finite runs: $q \xrightarrow{z_1} q$ and $s_0 \xrightarrow{z_1} s_1$, where the first run is safe, and the second is not. Now, since $q \sim s_0$, then again by Proposition 1 we have that $q \sim s_1$, and by applying the same considerations, we can define a finite nonempty word z_2 and $s_2 = g(u \cdot z_1 \cdot z_2)$ such that $q \xrightarrow{z_2} q$ and $s_1 \xrightarrow{z_2} s_2$, where the first run is safe, and the second is not. After at most $|Q_\mathcal{B}|$ iterations, we get that there are

$0 \leq j_1 < j_2 \leq |Q_\mathcal{B}|$ such that $s_{j_1} = s_{j_2}$, and define $z = z_1 \cdots z_2 \cdots z_{j_1} \cdot (z_{j_1+1} \cdots z_{j_2})^\omega$. Since $j_1 < j_2$, the extension $z_{j_1+1} \cdots z_{j_2}$ is nonempty and thus z is infinite. On the one hand, since $q \in \delta_\mathcal{A}(q^0_\mathcal{A}, u)$ and there is a safe run of $\mathcal{A}^q$ on z, we have that $u \cdot z \in L(\mathcal{A})$. On the other hand, the run $g(u \cdot z)$ traverses an α-transitions infinitely often, and is thus rejecting. ◀

▶ **Proposition 6.** *Let $\mathcal{A}$ and $\mathcal{B}$ be equivalent nice GFG-tNCWs. For every state $p \in Q_\mathcal{A}$, there are states $q \in Q_\mathcal{A}$ and $s \in Q_\mathcal{B}$ such that $p \precsim q$ and $q \approx s$.*

Proof. The proposition follows from the combination of Proposition 5 with the transitivity of $\precsim$ and the fact $Q_\mathcal{A}$ and $Q_\mathcal{B}$ are finite. Formally, consider the directed bipartite graph $G = \langle Q_\mathcal{A} \cup Q_\mathcal{B}, E\rangle$, where $E \subseteq (Q_\mathcal{A} \times Q_\mathcal{B}) \cup (Q_\mathcal{B} \times Q_\mathcal{A})$ is such that $\langle p_1, p_2\rangle \in E$ iff $p_1 \precsim p_2$. Proposition 5 implies that E is total. That is, from every state in $Q_\mathcal{A}$ there is an edge to some state in $Q_\mathcal{B}$, and from every state in $Q_\mathcal{B}$ there is an edge to some state in $Q_\mathcal{A}$. Since $Q_\mathcal{A}$ and $Q_\mathcal{B}$ are finite, this implies that for every $p \in Q_\mathcal{A}$, there is a path in G that starts in p and reaches a state $q \in Q_\mathcal{A}$ (possibly $q = p$) that belongs to a nonempty cycle. We take s to be some state in $Q_\mathcal{B}$ in this cycle. By the transitivity of $\precsim$, we have that $p \precsim q$, $q \precsim s$, and $s \precsim q$. The last two imply that $q \approx s$, and we are done. ◀

▶ **Lemma 7.** *Consider a nice GFG-tNCW $\mathcal{A}$. If $\mathcal{A}$ is safe-centralized and safe-minimal, then for every nice GFG-tNCW $\mathcal{B}$ equivalent to $\mathcal{A}$, there is an injection $\eta : S(\mathcal{A}) \to S(\mathcal{B})$ such that for every safe component $T \in S(\mathcal{A})$, it holds that $|T| \leq |\eta(T)|$.*

Proof. We define η as follows. Consider a safe component $T \in S(\mathcal{A})$. Let p_T be some state in T. By Proposition 6, there are states $q_T \in Q_\mathcal{A}$ and $s_T \in Q_\mathcal{B}$ such that $p_T \precsim q_T$ and $q_T \approx s_T$. Since $\mathcal{A}$ is safe-centralized, the states p_T and q_T are in the same safe component, thus $q_T \in T$. We define $\eta(T)$ to be the safe component of s_T in $\mathcal{B}$. We show that η is an injection; that is, for every two safe components T_1 and T_2 in $S(\mathcal{A})$, it holds that $\eta(T_1) \neq \eta(T_2)$. Assume by way of contradiction that T_1 and T_2 are such that s_{T_1} and s_{T_2}, chosen as described above, are in the same safe component of $\mathcal{B}$. Then, there is a safe run from s_{T_1} to s_{T_2}. Since $s_{T_1} \approx q_{T_1}$, an iterative application of Proposition 4 implies that there is a safe run from q_{T_1} to some state q such that $q \approx s_{T_2}$. Since the run from q_{T_1} to q is safe, the states q_{T_1} and q are in the same safe component, and so $q \in T_1$. Since $q_{T_2} \approx s_{T_2}$, then $q \approx q_{T_2}$. Since $\mathcal{A}$ is safe-centralized, the latter implies that q and q_{T_2} are in the same safe component, and so $q \in T_2$, and we have reached a contradiction.

It is left to prove that for every safe component $T \in S(\mathcal{A})$, it holds that $|T| \leq |\eta(T)|$. Let $T \in S(\mathcal{A})$ be a safe component of $\mathcal{A}$. By the definition of η, there are $q_T \in T$ and $s_T \in \eta(T)$ such that $q_T \approx s_T$. Since $\mathcal{A}$ is normal, there is a safe run $q_0, q_1, \ldots q_m$ of $\mathcal{A}$ that starts in q_T and traverses all the states in T. Since $\mathcal{A}$ is safe-minimal, no two states in T are strongly equivalent. Therefore, there is a subset $I \subseteq \{0, 1, \ldots, m\}$ of indices, with $|I| = |T|$, such that for every two different indices $i_1, i_2 \in I$, it holds that $q_{i_1} \not\approx q_{i_2}$. By applying Proposition 4 iteratively, there is a safe run $s_0, s_1, \ldots s_m$ of $\mathcal{B}$ that starts in s_T and such that for every $0 \leq i \leq m$, it holds that $q_i \approx s_i$. Since the run is safe, it stays in $\eta(T)$. Then, however, for every two different indices $i_1, i_2 \in I$, we have that $s_{i_1} \not\approx s_{i_2}$, and so $s_{i_1} \neq s_{i_2}$. Hence, $|\eta(T)| \geq |I| = |T|$. ◀

We can now prove that the additional two properties imply the minimality of nice GFG-tNCWs.

▶ **Theorem 8.** *Consider a nice GFG-tNCW $\mathcal{A}$. If $\mathcal{A}$ is safe-centralized and safe-minimal, then $\mathcal{A}$ is a minimal GFG-tNCW for $L(\mathcal{A})$.*

Proof. Let $\mathcal{B}$ be a GFG-tNCW equivalent to $\mathcal{A}$. By Theorem 2, we can assume that $\mathcal{B}$ is nice. Indeed, otherwise we can make it nice without increasing its state space. Then, by Lemma 7, there is an injection $\eta : S(\mathcal{A}) \to S(\mathcal{B})$ such that for every safe component $T \in S(\mathcal{A})$, it holds that $|T| \leq |\eta(T)|$. Hence,

$$|\mathcal{A}| = \sum_{T \in S(\mathcal{A})} |T| \leq \sum_{T \in S(\mathcal{A})} |\eta(T)| \leq \sum_{T' \in S(\mathcal{B})} |T'| = |\mathcal{B}|.$$

Indeed, the first inequality follows from the fact $|T| \leq |\eta(T)|$, and the second inequality follows from the fact that η is injective. ◀

▶ Remark 9. Recall that we assume that the transition function of GFG-tNCWs is total. Clearly, a non-total GFG-tNCW can be made total by adding a rejecting sink. One may wonder whether the additional state that this process involves interferes with our minimality proof. The answer is negative: if $\mathcal{B}$ in Theorem 8 is not total, then, by Proposition 5, $\mathcal{A}$ has a state s such that $q_{rej} \precsim s$, where q_{rej} is a rejecting sink we need to add to $\mathcal{B}$ if we want to make it total. Thus, $L(\mathcal{A}^s) = \emptyset$, and we may not count it if we allow GFG-tNCWs without a total transition function.

4 Safe Centralization

Consider a nice GFG-tNCW $\mathcal{A} = \langle \Sigma, Q_{\mathcal{A}}, q^0_{\mathcal{A}}, \delta_{\mathcal{A}}, \alpha_{\mathcal{A}} \rangle$. Recall that $\mathcal{A}$ is safe-centralized if for every two states $q, s \in Q_{\mathcal{A}}$, if $q \precsim s$, then q and s are in the same safe component. In this section we describe how to turn a given nice GFG-tNCW into a nice safe-centralized GFG-tNCW. The resulted tNCW is also going to be *α-homogenous*: for every state $q \in Q_{\mathcal{A}}$ and letter $\sigma \in \Sigma$, either $\delta^{\alpha}_{\mathcal{A}}(q, \sigma) = \emptyset$ or $\delta^{\bar{\alpha}}_{\mathcal{A}}(q, \sigma) = \emptyset$.

Let $H \subseteq S(\mathcal{A}) \times S(\mathcal{A})$ be such that for all safe components $S, S' \in S(\mathcal{A})$, we have that $H(S, S')$ iff there exist states $q \in S$ and $q' \in S'$ such that $q \precsim q'$. That is, when $S \neq S'$, then the states q and q' witness that $\mathcal{A}$ is not safe-centralized. Recall that $q \precsim q'$ iff $L(\mathcal{A}^q) = L(\mathcal{A}^{q'})$ and $L_{safe}(\mathcal{A}^q) \subseteq L_{safe}(\mathcal{A}^{q'})$. Since language containment for GFG-tNCWs can be checked in polynomial time [12, 17], the first condition can be checked in polynomial time. Since $\mathcal{A}$ is safe deterministic, the second condition reduces to language containment between deterministic automata and can also be checked in polynomial time. Hence, the relation H can be computed in polynomial time.

▶ **Lemma 10.** *Consider safe components $S, S' \in S(\mathcal{A})$ such that $H(S, S')$. Then, for every $p \in S$ there is $p' \in S'$ such that $p \precsim p'$.*

Proof. Since $H(S, S')$, then, by definition, there are states $q \in S$ and $q' \in S'$ such that $q \precsim q'$. Let p be a state in S. Since $\mathcal{A}$ is normal, there is a safe run from q to p in S. Since $q \precsim q'$, an iterative application of Proposition 4 implies that there is a safe run from q' to some state p' in S' for which $p \precsim p'$, and we are done. ◀

▶ **Lemma 11.** *The relation H is transitive: for every safe components $S, S', S'' \in S(\mathcal{A})$, if $H(S, S')$ and $H(S', S'')$, then $H(S, S'')$.*

Proof. Let $S, S', S'' \in S(\mathcal{A})$ be safe components of $\mathcal{A}$ such that $H(S, S')$ and $H(S', S'')$. Since, $H(S, S')$, there are states $q \in S$ and $q' \in S'$ such that $q \precsim q'$. Now, since $H(S', S'')$, we get by Lemma 10 that that for all states in S', in particular for q', there is a state $q'' \in S''$ such that $q' \precsim q''$. The transitivity of $\precsim$ then implies that $q \precsim q''$, and so $H(S, S'')$. ◀

We say that a set $\mathcal{S} \subseteq S(\mathcal{A})$ is a *frontier of* $\mathcal{A}$ if for every safe component $S \in S(\mathcal{A})$, there is a safe component $S' \in \mathcal{S}$ with $H(S, S')$, and for all safe components $S, S' \in \mathcal{S}$ such that $S \neq S'$, we have that $\neg H(S, S')$ and $\neg H(S', S)$. Once H is calculated, a frontier of $\mathcal{A}$ can be found in linear time. For example, as H is transitive, we can take one vertex from each ergodic SCC in the graph $\langle S(\mathcal{A}), H\rangle$. Note that all frontiers of $\mathcal{A}$ are of the same size, namely the number of ergodic SCCs in this graph.

Given a frontier $\mathcal{S}$ of $\mathcal{A}$, we define the automaton $\mathcal{B}_\mathcal{S} = \langle \Sigma, Q_\mathcal{S}, q^0_\mathcal{S}, \delta_\mathcal{S}, \alpha_\mathcal{S}\rangle$, where $Q_\mathcal{S} = \{q \in Q_\mathcal{A} : q \in S \text{ for some } S \in \mathcal{S}\}$, and the other components are defined as follows. The initial state $q^0_\mathcal{S}$ is chosen such that $q^0_\mathcal{S} \sim_\mathcal{A} q^0_\mathcal{A}$. Specifically, if $q^0_\mathcal{A} \in Q_\mathcal{S}$, we take $q^0_\mathcal{S} = q^0_\mathcal{A}$. Otherwise, by Lemma 10 and the definition of $\mathcal{S}$, there is a state $q' \in Q_\mathcal{S}$ such that $q^0_\mathcal{A} \precsim q'$, and we take $q^0_\mathcal{S} = q'$. The transitions in $\mathcal{B}_\mathcal{S}$ are either $\bar{\alpha}$-transitions of $\mathcal{A}$, or α-transitions that we add among the safe components in $\mathcal{S}$ in a way that preserves language equivalence. Formally, consider a state $q \in Q_\mathcal{S}$ and a letter $\sigma \in \Sigma$. If $\delta^{\bar{\alpha}}_\mathcal{A}(q, \sigma) \neq \emptyset$, then $\delta^{\bar{\alpha}}_\mathcal{S}(q, \sigma) = \delta^{\bar{\alpha}}_\mathcal{A}(q, \sigma)$ and $\delta^{\alpha}_\mathcal{S}(q, \sigma) = \emptyset$. If $\delta^{\bar{\alpha}}_\mathcal{A}(q, \sigma) = \emptyset$, then $\delta^{\bar{\alpha}}_\mathcal{S}(q, \sigma) = \emptyset$ and $\delta^{\alpha}_\mathcal{S}(q, \sigma) = \{q' \in Q_\mathcal{S} :$ there is $q'' \in \delta^{\alpha}_\mathcal{A}(q, \sigma)$ such that $q' \sim_\mathcal{A} q''\}$. Note that $\mathcal{B}_\mathcal{S}$ is α-homogenous.

▶ **Example 12.** Consider the tDCW $\mathcal{A}$ appearing in Figure 1. Recall that the dashed transitions are α-transitions. Since $\mathcal{A}$ is normal and deterministic, it is nice. By removing the α-transitions of $\mathcal{A}$, we get the safe components described in in Figure 2. Since $q_2 \precsim q_0$, we have that $\mathcal{A}$ has a single frontier $\mathcal{S} = \{\{q_0, q_1\}\}$. The automaton $\mathcal{B}_\mathcal{S}$ appears in Figure 3. As all the states of $\mathcal{A}$ are equivalent, we direct a σ-labeled α-transition to q_0 and to q_1, for every state with no σ-labeled transition in $\mathcal{S}$.

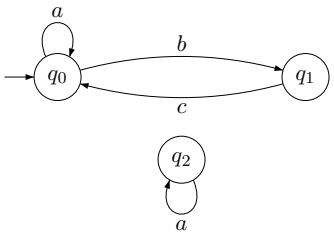

Figure 2 The safe components of $\mathcal{A}$.

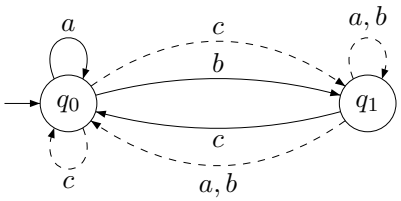

Figure 3 The tNCW $\mathcal{B}_{\{\{q_0,q_1\}\}}$.

We extend Proposition 1 to the setting of $\mathcal{A}$ and $\mathcal{B}_\mathcal{S}$:

▶ **Proposition 13.** *Consider states q and s of $\mathcal{A}$ and $\mathcal{B}_\mathcal{S}$, respectively, a letter $\sigma \in \Sigma$, and transitions $\langle q, \sigma, q'\rangle$ and $\langle s, \sigma, s'\rangle$ of $\mathcal{A}$ and $\mathcal{B}_\mathcal{S}$, respectively. If $q \sim_\mathcal{A} s$, then $q' \sim_\mathcal{A} s'$.*

Proof. If $\langle s, \sigma, s'\rangle$ is an $\bar{\alpha}$-transition of $\mathcal{B}_\mathcal{S}$, then, by the definition of $\Delta_\mathcal{S}$, it is also an $\bar{\alpha}$-transition of $\mathcal{A}$. Hence, since $q \sim_\mathcal{A} s$ and $\mathcal{A}$ is nice, in particular, semantically deterministic, we get by Proposition 1 that $q' \sim_\mathcal{A} s'$. If $\langle s, \sigma, s'\rangle$ is an α-transition of $\mathcal{B}_\mathcal{S}$, then, by the definition of $\Delta_\mathcal{S}$, there is some $s'' \in \delta_\mathcal{A}(s, \sigma)$ with $s' \sim_\mathcal{A} s''$. Again, since $q \sim_\mathcal{A} s$ and $\mathcal{A}$ is semantically deterministic, we have by Proposition 1 that $s'' \sim_\mathcal{A} q'$, and thus $s' \sim_\mathcal{A} q'$. ◀

▶ **Proposition 14.** *Let q and s be states of $\mathcal{A}$ and $\mathcal{B}_\mathcal{S}$, respectively, with $q \sim_\mathcal{A} s$. It holds that $\mathcal{B}^s_\mathcal{S}$ is a GFG-tNCW equivalent to $\mathcal{A}^q$.*

Proof. We first prove that $L(\mathcal{B}^s_\mathcal{S}) \subseteq L(\mathcal{A}^q)$. Consider a word $w = \sigma_1\sigma_2 \ldots \in L(\mathcal{B}^s_\mathcal{S})$. Let $s_0, s_1, s_2, \ldots$ be an accepting run of $\mathcal{B}^s_\mathcal{S}$ on w. Then, there is $i \geq 0$ such that $s_i, s_{i+1}, \ldots$ is a safe run of $\mathcal{B}^{s_i}_\mathcal{S}$ on the suffix $w[i+1, \infty]$. Let $q_0, q_1, \ldots q_i$ be a run of $\mathcal{A}^q$ on the prefix $w[1, i]$.

Since $q_0 \sim_{\mathcal{A}} s_0$, we get, by an iterative application of Proposition 13, that $q_i \sim_{\mathcal{A}} s_i$. In addition, as the run of $\mathcal{B}_{\mathcal{S}}^{s_i}$ on the suffix $w[i+1,\infty]$ is safe, it is also a safe run of $\mathcal{A}^{s_i}$. Hence, $w[i+1,\infty] \in L(\mathcal{A}^{q_i})$, and thus $q_0, q_1, \ldots, q_i$ can be extended to an accepting run of $\mathcal{A}^q$ on w.

Next, we prove that $L(\mathcal{A}^q) \subseteq L(\mathcal{B}_{\mathcal{S}}^s)$ and that $\mathcal{B}_{\mathcal{S}}^s$ is a GFG-tNCW. We do this by defining a strategy $g : \Sigma^* \to Q_{\mathcal{S}}$ such that for all words $w \in L(\mathcal{A}^q)$, we have that $g(w)$ is an accepting run of $\mathcal{B}_{\mathcal{S}}^s$ on w. First, $g(\epsilon) = s$. Then, for $u \in \Sigma^*$ and $\sigma \in \Sigma$, we define $g(u \cdot \sigma)$ as follows. Recall that $\mathcal{A}$ is nice. So, in particular, $\mathcal{A}^q$ is GFG. Let f be a strategy witnessing $\mathcal{A}^q$'s GFGness. If $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma) \neq \emptyset$, then $g(u \cdot \sigma) = q'$ for some $q' \in \delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma)$. If $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma) = \emptyset$, then $g(u \cdot \sigma) = q'$ for some state $q' \in Q_{\mathcal{S}}$ such that $f(u \cdot \sigma) \precsim_{\mathcal{A}} q'$. Note that since $\mathcal{S}$ is a frontier, such a state q' exists. We prove that g is consistent with $\Delta_{\mathcal{S}}$. In fact, we prove a stronger claim, namely for all $u \in \Sigma^*$ and $\sigma \in \Sigma$, we have that $f(u) \sim_{\mathcal{A}} g(u)$ and $\langle g(u), \sigma, g(u \cdot \sigma)\rangle \in \Delta_{\mathcal{S}}$.

The proof proceeds by an induction on $|u|$. For this induction base, as $f(\epsilon) = q$, $g(\epsilon) = s$, and $q \sim_{\mathcal{A}} s$, we are done. Given u and σ, consider a transition $\langle g(u), \sigma, s'\rangle \in \Delta_{\mathcal{S}}$. Since $\mathcal{B}_{\mathcal{S}}$ is total, such a transition exists. We distinguish between two cases. If $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma) \neq \emptyset$, then, as $\mathcal{B}_{\mathcal{S}}$ is α-homogenous and safe deterministic, the state s' is the only state in $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma)$. Hence, by the definition of g, we have that $g(u \cdot \sigma) = s'$ and so $\langle g(u), \sigma, g(u \cdot \sigma)\rangle \in \Delta_{\mathcal{S}}$. If $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma) = \emptyset$, we claim that $g(u \cdot \sigma) \sim_{\mathcal{A}} s'$ Then, as $s' \in \delta_{\mathcal{S}}^{\alpha}(g(u),\sigma)$, the definition of $\Delta_{\mathcal{S}}$ for the case $\delta_{\mathcal{S}}^{\bar{\alpha}}(g(u),\sigma) = \emptyset$ implies that $\langle g(u), \sigma, g(u \cdot \sigma)\rangle \in \Delta_{\mathcal{S}}$. By the induction hypothesis, we have that $f(u) \sim_{\mathcal{A}} g(u)$. Hence, as $\langle f(u), \sigma, f(u \cdot \sigma))\rangle \in \delta_{\mathcal{A}}$ and $\langle g(u), \sigma, s'\rangle \in \Delta_{\mathcal{S}}$, we have, by Proposition 13, that $f(u \cdot \sigma) \sim_{\mathcal{A}} s'$. Recall that g is defined so that $f(u \cdot \sigma) \precsim_{\mathcal{A}} g(u \cdot \sigma)$. In particular, $f(u \cdot \sigma) \sim_{\mathcal{A}} g(u \cdot \sigma)$. Hence, by transitivity of $\sim_{\mathcal{A}}$, we have that $g(u \cdot \sigma) \sim_{\mathcal{A}} s'$. In addition, by the induction hypothesis, we have that $f(u) \sim_{\mathcal{A}} g(u)$, and so, in both cases, Proposition 13 implies that $f(u \cdot \sigma) \sim_{\mathcal{A}} g(u \cdot \sigma)$.

It is left to prove that for every infinite word $w = \sigma_1\sigma_2 \ldots \in \Sigma^\omega$, if $w \in L(\mathcal{A}^q)$, then $g(w)$ is accepting. Assume that $w \in L(\mathcal{A}^q)$ and consider the run $f(w)$ of $\mathcal{A}^q$ on w. Since $f(w)$ is accepting, there is $i \geq 0$ such that $f(w[1,i]), f(w[1,i+1]) \ldots$ is a safe run of $\mathcal{A}^{f(w[1,i])}$ on the suffix $w[i+1,\infty]$. We prove that $g(w)$ may traverse at most one α-transition when it reads the suffix $w[i+1,\infty]$. Assume that there is some $j \geq i$ such that $\langle g(w[1,j]), \sigma_{j+1}, g(w[1,j+1])\rangle \in \alpha_{\mathcal{S}}$. Then, by g's definition, we have that $f(w[1,j+1]) \precsim_{\mathcal{A}} g(w[1,j+1])$. Therefore, as $\mathcal{B}_{\mathcal{S}}$ follows the safe components in $\mathcal{S}$, we have that $L_{safe}(\mathcal{A}^{f(w[1,j+1])}) \subseteq L_{safe}(\mathcal{A}^{g(w[1,j+1])}) = L_{safe}(\mathcal{B}_{\mathcal{S}}^{g(w[1,j+1])})$, and thus $w[j+2,\infty] \in L_{safe}(\mathcal{B}_{\mathcal{S}}^{g(w[1,j+1])})$. Since $\mathcal{B}_{\mathcal{S}}$ is α-homogenous and safe-deterministic, there is a single run of $\mathcal{B}_{\mathcal{S}}^{g(w[1,j+1])}$ on $w[j+2,\infty]$, and this is the run that g follows. Therefore, $g(w[1,j+1]), g(w[1,j+2]), \ldots$ is a safe run, and we are done. ◀

▶ **Proposition 15.** *For every frontier $\mathcal{S}$, the GFG-tNCW $\mathcal{B}_{\mathcal{S}}$ is nice, safe-centralized, and α-homogenous.*

Proof. It is easy to see that the fact $\mathcal{A}$ is nice implies that $\mathcal{B}_{\mathcal{S}}$ is normal and safe deterministic. It can be shown that all the states in $\mathcal{B}_{\mathcal{S}}$ are reachable, yet anyway states that are nonreachable are easy to detect and their removal affects neither $\mathcal{B}_{\mathcal{S}}$'s language nor its other properties. Finally, Proposition 14 implies that all its states are GFG. To conclude that $\mathcal{B}_{\mathcal{S}}$ is nice, we prove below that it is semantically deterministic. Consider transitions $\langle q, \sigma, s_1\rangle$ and $\langle q, \sigma, s_2\rangle$ in $\Delta_{\mathcal{S}}$. We need to show that $s_1 \sim_{\mathcal{B}_{\mathcal{S}}} s_2$. By the definition of $\Delta_{\mathcal{S}}$, there are transitions $\langle q, \sigma, s_1'\rangle$ and $\langle q, \sigma, s_2'\rangle$ in $\Delta_{\mathcal{A}}$ for states s_1' and s_2' such that $s_1 \sim_{\mathcal{A}} s_1'$ and $s_2 \sim_{\mathcal{A}} s_2'$. As $\mathcal{A}$ is semantically deterministic, we have that $s_1' \sim_{\mathcal{A}} s_2'$, thus by transitivity of $\sim_{\mathcal{A}}$, we get that $s_1 \sim_{\mathcal{A}} s_2$. Then, Proposition 14 implies that $L(\mathcal{A}^{s_1}) = L(\mathcal{B}_{\mathcal{S}}^{s_1})$ and $L(\mathcal{A}^{s_2}) = L(\mathcal{B}_{\mathcal{S}}^{s_2})$, and so we get that $s_1 \sim_{\mathcal{B}_{\mathcal{S}}} s_2$. Thus, $\mathcal{B}_{\mathcal{S}}$ is semantically deterministic.

As we noted in the definition of its transitions, $\mathcal{B}_\mathcal{S}$ is α-homogenous. It is thus left to prove that $\mathcal{B}_\mathcal{S}$ is safe-centralized. Let q and s be states of $\mathcal{B}_\mathcal{S}$ such that $q \preceq_{\mathcal{B}_\mathcal{S}} s$; that is, $L(\mathcal{B}^q_\mathcal{S}) = L(\mathcal{B}^s_\mathcal{S})$ and $L_{safe}(\mathcal{B}^q_\mathcal{S}) \subseteq L_{safe}(\mathcal{B}^s_\mathcal{S})$. Let $S, T \in \mathcal{S}$ be the safe components of q and s, respectively. We need to show that $S = T$. By Proposition 14, we have that $L(\mathcal{A}^q) = L(\mathcal{B}^q_\mathcal{S})$ and $L(\mathcal{A}^s) = L(\mathcal{B}^s_\mathcal{S})$. As $\mathcal{B}_\mathcal{S}$ follows the safe components in $\mathcal{S}$, we have that $L_{safe}(\mathcal{A}^q) = L_{safe}(\mathcal{B}^q_\mathcal{S})$ and $L_{safe}(\mathcal{A}^s) = L_{safe}(\mathcal{B}^s_\mathcal{S})$. Hence, $q \preceq_\mathcal{A} s$, implying $H(S, T)$. Since $\mathcal{S}$ is a frontier, this is possible only when $S = T$. ◀

▶ **Theorem 16.** *Every nice GFG-tNCW can be turned in polynomial time into an equivalent nice, safe-centralized, and α-homogenous GFG-tNCW.*

5 Safe Minimization

In the setting of finite words, a *quotient automaton* is obtained by merging equivalent states, and is guaranteed to be minimal. In the setting of co-Büchi automata, it may not be possible to define an equivalent language on top of the quotient automaton. For example, all the states in the GFG-tNCW $\mathcal{A}$ in Figure 1 are equivalent, and still it is impossible to define its language on top of a single-state tNCW. In this section we show that when we start with a nice, safe-centralized, and α-homogenous GFG-tNCW $\mathcal{B}$, the transition to a quotient automaton, namely merging of strongly-equivalent states, is well defined and results in a GFG-tNCW equivalent to $\mathcal{B}$ that attains all the helpful properties of $\mathcal{B}$, and is also safe minimal[4]. By Theorem 8, it is also minimal.

Consider a nice, safe-centralized, and α-homogenous GFG-tNCW $\mathcal{B} = \langle \Sigma, Q, q_0, \delta, \alpha \rangle$. For a state $q \in Q$, define $[q] = \{q' \in Q : q \approx_\mathcal{B} q'\}$. We define the tNCW $\mathcal{C} = \langle \Sigma, Q_\mathcal{C}, [q_0], \delta_\mathcal{C}, \alpha_\mathcal{C} \rangle$, where $Q_\mathcal{C} = \{[q] : q \in Q\}$, the transition function is such that $\langle [q], \sigma, [p] \rangle \in \Delta_\mathcal{C}$ iff there are $q' \in [q]$ and $p' \in [p]$ such that $\langle q', \sigma, p' \rangle \in \Delta$, and $\langle [q], \sigma, [p] \rangle \in \alpha_\mathcal{C}$ iff $\langle q', \sigma, p' \rangle \in \alpha$. Note that $\mathcal{B}$ being α-homogenous implies that $\alpha_\mathcal{C}$ is well defined; that is, independent of the choice of q' and p'. To see why, assume that $\langle q', \sigma, p' \rangle \in \bar{\alpha}$ and let q'' be a state in $[q]$. As $q' \approx_\mathcal{B} q''$, we have by Proposition 4 that there is $p'' \in [p]$ such that $\langle q'', \sigma, p'' \rangle \in \bar{\alpha}$. Thus, as $\mathcal{B}$ is α-homogenous, there is no σ-labeled α-transition from q'' to a state in $[p]$. Note that we have proved that if $\langle [q], \sigma, [p] \rangle$ is an $\bar{\alpha}$-transition of $\mathcal{C}$, then for every $q' \in [q]$, there is $p' \in [p]$ such that $\langle q', \sigma, p' \rangle$ is an $\bar{\alpha}$-transition of $\mathcal{B}$, and thus the $\supseteq$-direction of the following proposition, suggesting that a safe run in $\mathcal{C}$ induces a safe run in $\mathcal{B}$, follows by a simple induction. The $\subseteq$-direction follows immediately from the definition of $\mathcal{C}$.

▶ **Proposition 17.** *For every $[p] \in Q_\mathcal{C}$ and every $s \in [p]$, it holds that $L_{safe}(\mathcal{B}^s) = L_{safe}(\mathcal{C}^{[p]})$.*

We extend Propositions 1 and 13 to the setting of $\mathcal{B}$ and $\mathcal{C}$:

▶ **Proposition 18.** *Consider states $s \in Q$ and $[p] \in Q_\mathcal{C}$, a letter $\sigma \in \Sigma$, and transitions $\langle s, \sigma, s' \rangle$ and $\langle [p], \sigma, [p'] \rangle$ of $\mathcal{B}$ and $\mathcal{C}$, respectively. If $s \sim p$, then $s' \sim p'$.*

Proof. As $\langle [p], \sigma, [p'] \rangle$ is a transition of $\mathcal{C}$, there are states $t \in [p]$ and $t' \in [p']$, such that $\langle t, \sigma, t' \rangle \in \Delta$. If $s \sim p$, then $s \sim t$. Since $\mathcal{B}$ is nice, in particular, semantically deterministic, and $\langle s, \sigma, s' \rangle \in \Delta$, we get by Proposition 1 that $s' \sim t'$. Thus, as $t' \sim p'$, we are done. ◀

▶ **Proposition 19.** *For every $[p] \in Q_\mathcal{C}$ and $s \in [p]$, we have that $\mathcal{C}^{[p]}$ is a GFG-tNCW equivalent to $\mathcal{B}^s$.*

[4] In fact, α-homogeneity is not required, but as the GFG-tNCW $\mathcal{B}_\mathcal{S}$ obtained in Section 4 is α-homogenous, which simplifies the proof, we are going to rely on it.

Proof. We first prove that $L(\mathcal{C}^{[p]}) \subseteq L(\mathcal{B}^s)$. Consider a word $w = \sigma_1\sigma_2\ldots \in L(\mathcal{C}^{[p]})$. Let $[p_0], [p_1], [p_2], \ldots$ be an accepting run of $\mathcal{C}^{[p]}$ on w. Then, there is $i \geq 0$ such that $[p_i], [p_{i+1}], \ldots$ is a safe run of $\mathcal{C}^{[p_i]}$ on the suffix $w[i+1, \infty]$. Let $s_0, s_1, \ldots s_i$ be a run of $\mathcal{B}^s$ on the prefix $w[1, i]$. Note that $s_0 = s$. Since $s_0 \in [p_0]$, we have that $s_0 \sim p_0$, and thus an iterative application of Proposition 18 implies that $s_i \sim p_i$. In addition, as $w[i+1, \infty]$ is in $L_{safe}(\mathcal{C}^{[p_i]})$, we get, by Proposition 17, that $w[i+1, \infty] \in L_{safe}(\mathcal{B}^{p_i})$. Since $L_{safe}(\mathcal{B}^{p_i}) \subseteq L(\mathcal{B}^{p_i})$ and $s_i \sim p_i$, we have that $w[i+1, \infty] \in L(\mathcal{B}^{s_i})$. Hence, $s_0, s_1, \ldots s_i$ can be extended to an accepting run of $\mathcal{B}^s$ on w.

Next, we prove that $L(\mathcal{B}^s) \subseteq L(\mathcal{C}^{[p]})$ and that $\mathcal{C}^{[p]}$ is a GFG-tNCW. We do this by defining a strategy $h : \Sigma^* \to Q_{\mathcal{C}}$ such that for all words $w \in L(\mathcal{B}^s)$, we have that $h(w)$ is an accepting run of $\mathcal{C}^{[p]}$ on w. We define h as follows. Recall that $\mathcal{B}$ is nice. So, in particular, $\mathcal{B}^s$ is GFG. Let g be a strategy witnessing $\mathcal{B}^s$'s GFGness. We define $h(u) = [g(u)]$, for every finite word $u \in \Sigma^*$. Consider a word $w \in L(\mathcal{B}^s)$, and consider the accepting run $g(w) = g(w[1,0]), g(w[1,1]), g(w[1,2]), \ldots$ of $\mathcal{B}^s$ on w. Note that by the definition of $\mathcal{C}$, we have that $h(w) = [g(w[1,0])], [g(w[1,1])], [g(w[1,2])], \ldots$ is an accepting run of $\mathcal{C}^{[p]}$ on w, and so we are done. ◀

▶ **Proposition 20.** *The GFG-tNCW $\mathcal{C}$ is nice, safe-centralized, and safe-minimal.*

The proof of the proposition is in the full version. The considerations are similar to those in the proof of Proposition 15. In particular, for safe minimality, note that for states q and s of $\mathcal{B}$, we have that $[q] \approx [s]$ iff $[q] \precsim [s]$ and $[s] \precsim [q]$. Thus, it is sufficient to prove that if $[q] \precsim [s]$ then $q \precsim s$. Thus, we can now conclude the following:

▶ **Theorem 21.** *Every nice, safe-centralized, and α-homogenous GFG-tNCW can be turned in polynomial time into an equivalent nice, safe-centralized, and safe-minimal GFG-tNCW.*

6 Discussion

We presented a polynomial minimization algorithm for GFG-tNCWs. In contrast, minimization of DCWs is NP-complete [33]. This raises a natural question, as to whether both relaxations of the problem, namely the consideration of GFG automata, rather than deterministic ones, and the consideration of transition-based acceptance, rather than state-based one, are crucial for efficiency. Our conjecture is that minimization of transition-based DCWs (and hence, also transition-based DBWs) can be solved in polynomial time. Thus, the relaxation to GFG is not needed. Our conjecture is based on the understanding that the quotient construction fails for automata on infinite words as it does not capture traversal of transitions. Moreover, the study of GFG automata so far shows that their behavior is similar to that of deterministic automata. In particular, it is not hard to see that the NP-hardness proof of Schewe for DBWs minimization applies also to GFG-NBWs. The use of transition-based acceptance is related to another open problem in the context of DBW minimization: is there a 2-approximation polynomial algorithm for it, that is one that generates a DBW that is at most twice as big as a minimal one. Note that a tight minimization for the transition-based case would imply a positive answer here. Note also that the vertex-cover problem, used in Schewe's reduction has a polynomial 2-approximation. As described in Section 1, there is recently growing use of automata with transition-based acceptance. Our work here is another evidence to their usefulness.

We find the study of minimization of GFG automata of interest also beyond being an intermediate result in the quest for efficient transition-based DBW minimization. Indeed, GFG automata are important in practice, as they are used in synthesis and control, and in

the case of the co-Büchi acceptance condition, they may be exponentially more succinct than their deterministic equivalences. Another open problem, which is interesting from both the theoretical and practical points of view, is minimization of GFG-tNBW. Note that unlike the deterministic case, GFG-tNBW and GFG-tNCW are not dual. Also, experience shows that algorithms for GFG-tNBW and GFG-tNCW are quite different [3, 17, 4, 2].

Finally, recall that there may be different minimal tDCWs for a given language of infinite words. Our results show that the picture for minimal GFG-tNCWs is cleaner: Consider a language $L \subseteq \Sigma^\omega$, and let $\mathcal{A}$ be a minimal GFG-tNCW for L obtained by safe-centralizing and safe-minimizing a nice GFG-tNCW for it. Consider a nice minimal GFG-tNCW $\mathcal{B}$ for L. Then, the injection $\eta : S(\mathcal{A}) \to S(\mathcal{B})$ from Lemma 7 is actually a *bijection*; that is, η is one-to-one and onto. Indeed, for every safe component $T \in S(\mathcal{A})$ it holds that $|T| = |\eta(T)|$. Moreover, as both $\mathcal{A}$ and $\mathcal{B}$ are nice, related safe components are *isomorphic*, thus there is an bijection $\kappa : Q_\mathcal{A} \to Q_\mathcal{B}$ such that for every $q \in Q_\mathcal{A}$, we have that $q \approx \kappa(q)$, and for every $\bar{\alpha}$-transition $\langle q, \sigma, s\rangle$ of $\mathcal{A}$, we have that $\langle \kappa(q), \sigma, \kappa(s)\rangle$ is an $\bar{\alpha}$-transition of $\mathcal{B}$. Thus, all nice minimal GFG-tNCWs for L have the same set of safe components, and they differ only in α-transitions among these safe components. An interesting research direction is a study of these safe components and in particular a characterization of L by a congruence-based relation on finite words that is induced by them.

Abstract

In this paper we present the first JSON type system that provides the possibility of inferring a schema by adopting different levels of precision/succinctness for different parts of the dataset, under user control. This feature gives the data analyst the possibility to have detailed schemas for parts of the data of greater interest, while more succinct schema is provided for other parts, and the decision can be changed as many times as needed, in order to explore the schema in a gradual fashion, moving the focus to different parts of the collection, without the need of reprocessing data and by only performing type rewriting operations on the most precise schema.

1 Introduction

When a data analyst, or a programmer, accesses a JSON data collection for the first time, it is usually necessary to first have a look at its schema, as it is often the case that the data collection is badly documented and that it requires some visual data navigation in order to be fully understood. To this aim, some automated support can be quite useful, especially when the collection is massive and one is interested in a complete description of the structure.

The problem is that the structure of a data collection can be described at many different levels of abstraction: for example, when a semistructured collection of records is examined, one may either just list which fields are present in at least one element, or one may list every possible field combination. The choice of the abstraction level is extremely important, since an abstract description may hide too much information while, in other cases, a detailed description may be so big as to make the description unreadable. Unfortunately, there is

no objective and absolute definition of an "optimal" abstraction level, since it depends on the specific needs of the analyst, who may even need different abstraction levels in different phases of her/his work.

In [4] we proposed a first approach to this problem: a schema inference technique that is parametrized by an Equivalence Relation (ER); through this parameter, the user chooses one specific trade-off between succinctness and precision. This is much better than having no choice, but has important drawbacks. First of all, the choice of the value of the parameter is difficult. Secondly, and more importantly, one is typically very interested in some parts of the collection only, hence there is not a globally optimum trade-off: any intermediate choice between maximal detail and maximal compactness will typically be too compact for the interesting parts of the collection, but too detailed with respect to anywhere else. Hence, we built an interactive workbench, where the analyst can start from an abstract description of the collection, and then ask the system to selectively expand the structural description of some specific parts. Of course, the process can be iterated back and forth across the structural description of the data.

The analyst starts from an initial schema and interactively "expands" and "contracts" different parts of it. The main problem in the design of our workbench was that of understanding the exact meaning of these local "expansion" and "contraction" steps, as well as the lack of formal foundations for the optimization of these operations. In this paper we fill these gaps, by giving the formal foundations of interactive schema inference for massive JSON data. Our first contribution is a non-deterministic type system providing a formal characterisation of schemas featuring different precision levels for different parts of the typed dataset. We then define a deterministic version of this system, that is, a system where the user can choose a precision level through the choice of a *split criterion* parameter, that we will define. We then introduce an explicit representation of proof manipulations, in order to formalize the re-typing process, that is, the process of expanding/contracting a specific point of the schema. In principle, re-typing always involves to re-infer a schema from a portion of the data, which is not feasible in a big data setting. In our implementation, that we describe in [3], we exploit some properties of our *split criteria* in order to perform the re-typing without accessing data for a second time. Hence, we conclude our work by proving the soundness of this implementation technique, and studying the properties of our *split criteria* that allow this optimization.

2 Overview

Consider a massive collection of records, not perfectly homogeneous and sampled by the tiny collection below (left-hand side). The schema inference techniques described in [4] allows one to infer a type for each of the records, so as to obtain the collection of types below (right-hand side).

Data				*Types*			
$\{$	$a : \{j : 0, k : 0\},$	$b : \{bb : 0\}$	$\}$	$\{a : \{j : \texttt{Num}, k : \texttt{Num}\},$	$b : \{bb : \texttt{Num}\}$	$\}$
$\{$	$a : \{j : 0\},$	$c : \{cc : 0\}$	$\}$	$\{a : \{j : \texttt{Num}\},$	$c : \{cc : \texttt{Num}\}$	$\}$
$\{$	$a : \{y : 0, z : 0\}$	$c : \{cd : 0\}$	$\}$	$\{a : \{y : \texttt{Num}, z : \texttt{Num}\},$	$c : \{cd : \texttt{Num}\}$	$\}$
$\{$	$a : \{j : 0\},$	$b : 0$	$\}$	$\{a : \{j : \texttt{Num}\},$	$b : \texttt{Num}$	$\}$

The schema that is synthesized out of this collection of types depends on a parameter that is set by the analyst, which is an equivalence relation (ER) E: the inferred schema is obtained by merging any two types that are E-equivalent. For instance, we may use the

$\mathcal{K}$-equivalence, defined in [4] as the equivalence that equates all pairs of types of the same kind (record, array, or base type). In this way, all record types are merged, thus obtaining the following type, where a question mark indicates that the field is optional.

$$\{a : \{j : \texttt{Num}?, k : \texttt{Num}?, y : \texttt{Num}?, z : \texttt{Num}?\}, b : +_K(\{bb : \texttt{Num}\}, \texttt{Num})?, c : \{cc : \texttt{Num}?, cd : \texttt{Num}?\}?\}$$

Observe that all outer record types are merged, and, inside the record types, the types for the a and c keys are merged. The only two types that are kept distinct are those for the b key, since $\{bb : \texttt{Num}\}$ and $\texttt{Num}$ have two different kinds, hence b has a union type $+_K(\{bb : \texttt{Num}\}, \texttt{Num})$, where the $\mathcal{K}$ labels refers to the equivalence that guided the merging.

Before going on, we now rewrite this schema according to the syntax that we are using in this paper, which is more verbose but a bit more natural for our task. In this syntax, we have a union type in front of every record, array, or base type, so that the type above becomes:

$$\begin{array}{lll} +_K(& \{ & a : +_K(\{j : +_K(\texttt{Num})?, k : +_K(\texttt{Num})?, y : +_K(\texttt{Num})?, z : +_K(\texttt{Num})?\}), \\ & & b : +_K(\{bb : +_K(\texttt{Num})\}, \texttt{Num})?, \\ & & c : +_K(\{cc : +_K(\texttt{Num})?, cd : +_K(\texttt{Num})?\})?\}) \end{array}$$

The more types are merged, the smaller is the resulting schema, and the less precise it results. For example, the above schema is compact but is not very precise, since it does not specify how the different fields are mutually related: it only specifies that a and bb are mandatory, but, for the other fields, any combination is allowed. If the analyst wants more information about field correlation, she/he may move to the $\mathcal{L}$-equivalence, that specifies that two records are equivalent iff the respective sets of top-level field labels are the same, hence merging these equivalent types. In this way, we infer the following type (the $\mathcal{L}$-type):

$$\begin{array}{lll} +_L(& \{ & a : +_L(\quad \{j : +_L(\texttt{Num}), k : +_L(\texttt{Num})\}, \{j : +_L(\texttt{Num})\} \quad), \\ & & b : +_L(\quad \{bb : +_L(\texttt{Num})\}, \texttt{Num}) \\ & \}, & \\ & \{ & a : +_L(\quad \{j : +_L(\texttt{Num})\}, \{y : +_L(\texttt{Num}), z : +_L(\texttt{Num})\} \quad), \\ & & c : +_L(\quad \{cc : +_L(\texttt{Num})\}, \{cd : +_L(\texttt{Num})\} \quad) \\ & \}) & \end{array}$$

This type is much bigger, and it gives a lot of information about label correlation: it shows that b and c are mutually exclusive and one must always be present, and the same for cc and cd. It also shows that j and k are exclusive with y, z, that the presence of y, z inside a implies the presence of c, and so on.

The ability to start from a maximally compact type to get an overview of the schema, and then to move to a schema that is extremely detailed is already interesting but, in practice, the expanded schema may be overwhelming and may produce a lot of repetition. The analyst is often interested in just a subset of the input data and would like to be able to study the structure of that subset. For example, in this case the analyst may be mostly interested in the a field, and would like to be able to drill down on its structure only. Hence, she/he would like to start from the $\mathcal{K}$-type and to expand the a field only:

$$\begin{array}{lll} +_K(\{ & a : +_L(& \{j : +_L(\texttt{Num}), k : +_L(\texttt{Num})\}, \{j : +_L(\texttt{Num})\}, \{y : +_L(\texttt{Num}), z : +_L(\texttt{Num})\} \quad), \\ & b : +_K(& \{bb : +_K(\texttt{Num})\}, +_K(\texttt{Num}) \quad)?, \\ & c : +_K(& \{cc : +_K(\texttt{Num})?, cd : +_K(\texttt{Num})?\} \quad)? \ \} \quad) \end{array}$$

In this schema, we have full information about the type of the a field, while the outer structure and the c field are still represented in the compact style of the $\mathcal{K}$-types. Of course the analyst should be free now to also expand the c field, obtaining the following type.

$$+_K(\ \{\ a : +_L(\quad \{j : +_L(\texttt{Num}), k : +_L(\texttt{Num})\}, \{j : +_L(\texttt{Num})\}, \{y : +_L(\texttt{Num}), z : +_L(\texttt{Num})\}\quad),$$
$$\qquad b : +_K(\quad \{bb : +_K(\texttt{Num})\}, +_K(\texttt{Num})\quad)?,$$
$$\qquad c : +_L(\quad \{cc : +_L(\texttt{Num})\}, \{cd : +_L(\texttt{Num})\}\quad)?\ \}\quad)$$

Finally, we may collapse the a field, getting the following type.

$$+_K(\ \{\ a : +_K(\quad \{j : +_K(\texttt{Num})?, k : +_K(\texttt{Num})?, y : +_K(\texttt{Num})?, z : +_K(\texttt{Num})?\}\quad),$$
$$\qquad b : +_K(\quad \{bb : +_K(\texttt{Num})\}, +_K(\texttt{Num})\quad)?,$$
$$\qquad c : +_L(\quad \{cc : +_L(\texttt{Num})\}, \{cd : +_L(\texttt{Num})\}\quad)?\ \}\quad)$$

The formal definition of this operation of *local-equivalence-switch* is less obvious than it may appear. Essentially, the basic idea is that we apply different type-inference techniques to different parts of the data, but these parts are scattered in the dataset: in our example, the a fields are interleaved with the b and c fields. We would like to describe each step in the expand/collapse structure as a rewrite operation in the typing proof-tree, but this rewrite is non-local on the data, which is not trivial to formalize. Moreover, we would like that the relationship between a schema and the described data were fully described by the type, with its $\mathcal{K}$ and $\mathcal{L}$ annotations, and did not depend on the sequence of steps that has been used to arrive to that type. This property is very important for the analyst, who will usually not even remember the sequence of steps that she/he has used in order to arrive at the current schema, but still would like to have an interpretation of the meaning of that schema. The formalization of these properties is the theme of the paper.

3 Syntax and Semantics

We represent JSON values through the following grammar, that corresponds to actual JSON syntax, with the only exception that we do not put quotes around the keys (the labels) of the records. Following [6], we assume key uniqueness in records.

Syntax

$J ::=$	$B \mid R \mid A$		**JSON expressions**
$B ::=$	null $\mid$ true $\mid$ false $\mid n \mid s$	$n \in$ **Number**, $s \in$ **String**	**Basic values**
$R ::=$	$\{l_1 : J_1, \ldots, l_n : J_n\}$	$n \geq 0,\quad i \neq j \Rightarrow l_i \neq l_j$	**Records**
$A ::=$	$[J_1, \ldots, J_n]\quad n \geq 0$		**Arrays**

Basic values B include the null value, booleans, numbers n, and strings s. Records represent sets of fields, each field being a key-value pair (l, J), and arrays represent sequences of values. We will use J to range over JSON expressions and $\mathbb{J}$ to range over lists (or *collections*) of JSON expressions.

▶ **Notation 1.** *We use $L_1 \oplus L_2$ for list concatenation and $e.L$ to add e at the beginning of a list L. We use* collection *as a synonym for* list*, in situations where the order is there for technical reasons but is otherwise irrelevant.*

In the full paper [3] we define a semantic function $[\![\, J \,]\!]$ that maps each JSON term J to the corresponding mathematical entity, e.g. a number term into a number, a record into a set of pairs, an array into a list. That semantics is standard. As an example, the semantics of records is defined as $[\![\, \{l_1 : J_1, \ldots, l_n : J_n\} \,]\!] \triangleq \{\ (l_1, [\![\, J_1 \,]\!]), \ldots, (l_n, [\![\, J_n \,]\!])\ \}$

Our JSON types obey the following grammar. Every *union type* $\mathcal{T}$ is a union $+_{\mathcal{C}}(\mathcal{S}_1, \ldots, \mathcal{S}_n)$ of *structural types* $\mathcal{S}_1, \ldots, \mathcal{S}_n$, where the optional $\mathcal{C}$ subscript on non zero-ary union types can be ignored for the moment, and later will be used to indicate the "split criterion" that has been used in order to infer that part of the type. Every structural type

is either a base type $\mathcal{B}$, a record type $\mathcal{R}$ or an array type $\mathcal{A}$; record types and array types are defined in terms of union types. Each record field in a record type is labeled with a quantifier indicating whether the field is optional, noted as ?, or mandatory, noted as !. In our examples we will often omit the "!" symbol and only keep "?" for optional fields.

Syntax

$\mathcal{U}$	::=	$+(\mathcal{S}_1,\ldots,\mathcal{S}_n) \mid +_{\mathcal{C}}(\mathcal{S}_1,\ldots,\mathcal{S}_{n+1})$	$n \geq 0$	**Union Types**
$\mathcal{S}$	::=	$\mathcal{B} \mid \mathcal{R} \mid \mathcal{A}$		**Struct. types**
$\mathcal{B}$	::=	$\mathtt{Null} \mid \mathtt{Bool} \mid \mathtt{Num} \mid \mathtt{Str}$		**Basic types**
$\mathcal{R}$	::=	$\{l_1 : \mathcal{U}_1\mathtt{q}_1,\ldots,l_n : \mathcal{U}_n\mathtt{q}_n\}$	$n \geq 0\ , \mathtt{q}_i \in \{\ ?,!\ \}$	**Record types**
$\mathcal{A}$	::=	$[\mathcal{U}]$		**Array types**

The formal semantics of types is standard, and needs some explanation only in the records case. A record is a set of pairs, hence the empty record type { } denotes a singleton that only contains the empty record, that is, the empty set of pairs. A one-field record type is a set of singletons when the field is mandatory, and it also contains the empty record when the field is optional. Finally, a record that contains n fields is just a set that contains n pairs, hence a record that belongs to $\{l_1 : \mathcal{U}_1\mathtt{q}_1,\ldots,l_n : \mathcal{U}_n\mathtt{q}_n\}$ is just the union of one record for each field in the type. When a field $\mathcal{U}_i\mathtt{q}_i$ is optional, then the corresponding field in the value may be missing, which is captured by the presence of the empty set in the semantics of that field. In the semantics of $+(\mathcal{S}_1,\ldots,\mathcal{S}_n)$ we adopt the usual convention that $\cup_{i\in 1..0}\mathcal{S}_i$ is the empty set, hence $[\![+(\ )]\!] = \emptyset$. In this phase we just ignore the $\mathcal{C}$ annotation. The semantics of base types is standard, and we omit it in this extended abstract.

Semantics

$$
\begin{array}{lcl}
[\![\{\ \}]\!] & \triangleq & \{\ \emptyset\ \} \\
[\![\{l : \mathcal{U}!\}]\!] & \triangleq & \{\ \{\ (l, V)\ \} \mid V \in [\![\mathcal{U}]\!]\ \} \\
[\![\{l : \mathcal{U}?\}]\!] & \triangleq & [\![\{l : \mathcal{U}!\}]\!] \cup [\![\{\ \}]\!] \\
[\![\{l_1 : \mathcal{U}_1\mathtt{q}_1,\ldots,l_n : \mathcal{U}_n\mathtt{q}_n\}]\!] & \triangleq & \{\ R_1 \cup \ldots \cup R_n \mid R_i \in [\![\{l_i : \mathcal{U}_i\mathtt{q}_i\}]\!],\ i = 1,\ldots,n\ \}
\end{array}
$$

$$[\![[\mathcal{U}]]\!] \triangleq \{\ (V_1,\ldots,V_n) \mid n \geq 0,\ V_i \in [\![\mathcal{U}]\!]\ \}$$

$$[\![+_{[\mathcal{C}]}(\mathcal{S}_1,\ldots,\mathcal{S}_n)]\!] \triangleq \bigcup_{i\in 1..n} [\![\mathcal{S}_i]\!]$$

We partition the structural types into six kinds $\{\ \mathtt{Null}, \mathtt{Bool}, \mathtt{Num}, \mathtt{Str}, \{\ \}, [\ ]\ \}$ by using the following *kind*() function, that returns the *kind* of each structural type. $kind(K) = K$ for $K \in \{\ \mathtt{Null}, \mathtt{Bool}, \mathtt{Num}, \mathtt{Str}\ \}$ while $kind(\mathcal{A}) = [\ ]$ and $kind(\mathcal{R}) = \{\ \}$. We also define a *kind*() function that maps every JSON term to its kind – we omit the obvious definition. We say that a collection $\mathbb{J}$ of JSON terms is *kind-homogeneous* if it is not empty and all its elements have the same kind, in which case $kind(\mathbb{J})$ denotes that kind; $kind(\mathbb{J})$ is undefined when $\mathbb{J}$ is empty or when $\mathbb{J}$ is not kind-homogeneous.

4 Type System

4.1 The non-deterministic type system

In [4] we introduced a parametric deterministic type system, that is, a function that, given a JSON collection $\mathbb{J}$ and a parameter E, returns a type $\mathcal{U}$ for $\mathbb{J}$. The user could influence the type by choosing a specific equivalence relation for E: a finer equivalence results into a type that is more informative but bigger, while a coarser equivalence yields a type that is more compact but less informative. We focused our attention on two equivalence relations only, which we called $\mathcal{L}$ and $\mathcal{K}$, hence the analyst could choose, for each data collection, between two types, the $\mathcal{L}$-type, big and detailed, or the $\mathcal{K}$-type, smaller but less informative.

That approach is not flexible enough. The analyst may prefer to use a different size-precision trade-off for different parts of the data, depending on her/his interests. Hence, we need to formalize the notion that one term collection may have many different types, hence we need a type system that is much more flexible than the one in [4].

This inference system is based on two judgments that are mutually recursive: $\vdash \mathbb{J} :_u \mathcal{U}$ and $\vdash \mathbb{J} :_s \mathcal{S}$. Type inference rules are shown in Figure 1. The judgment $\vdash \mathbb{J} :_u \mathcal{U}$ specifies that the union type $\mathcal{U}$ describes the collection $\mathbb{J}$. Rule (EMPTY) specifies that the empty collection has the empty union type, while rule (+) splits $\mathbb{J}$, non-deterministically, into n kind-homogeneous subcollections $(\mathbb{J}_1, \ldots, \mathbb{J}_n)$. The *split criterion* $\mathcal{C}$ describes how $\mathbb{J}$ has been split. It is a partial function that describes how to split a collection of JSON terms. In this type system it is chosen non-deterministically, it may be different in any instance of the rule, can be optionally reported in the type, and it is only used to record how one specific collection has been split. In the deterministic variant of the system, presented in the next subsection, it will be chosen in a systematic way. The judgment $\vdash \mathbb{J} :_s \mathcal{S}$ assigns a structural type $\mathcal{S}$ to the kind-homogeneous collection $\mathbb{J}$, so that $kind(\mathbb{J}) = kind(\mathcal{S})$.

▶ **Definition 2** (*split*($\mathbb{J}$), split criterion $\mathcal{C}$). *For any non-empty collection of JSON terms, split*($\mathbb{J}$) *is the set of all partitionings of* $\mathbb{J}$ *into kind-homogeneous subcollections (abbreviated k-hom). A* split criterion $\mathcal{C}$ *is a partial function such that, for any non-empty collection of JSON terms* $\mathbb{J}$ *that belongs to its domain,* $\mathcal{C}(\mathbb{J}) \in split(\mathbb{J})$.

$$split(\mathbb{J}) = \{ (\mathbb{J}_1, \ldots, \mathbb{J}_n) \mid \mathbb{J}_1 \oplus \ldots \oplus \mathbb{J}_n = \mathbb{J}, \ \forall i, j.\ i \neq j \Rightarrow \mathbb{J}_i \cap \mathbb{J}_j = \emptyset, \forall i \in 1..n.\ \mathbb{J}_i \text{ is k-hom} \}$$

The three rules of Figure 1 for structural types can only be applied to kind-homogeneous collections. The notations used in the structural rules are introduced below.

$$\text{(EMPTY)}\ \frac{}{\vdash \emptyset :_u +()} \qquad \text{(+)}\ \frac{\mathcal{C} \text{ is a split criterion} \quad (\mathbb{J}_1, \ldots, \mathbb{J}_n) = \mathcal{C}(\mathbb{J}) \quad \forall i = 1, \ldots, n.\ \vdash \mathbb{J}_i :_s \mathcal{S}_i}{\vdash \mathbb{J} :_u +(\mathcal{S}_1, \ldots, \mathcal{S}_n) \text{ or } +_{\mathcal{C}}(\mathcal{S}_1, \ldots, \mathcal{S}_n)}$$

$$\text{(BASE)}\ \frac{kind(\mathbb{J}) = \mathcal{B}}{\vdash \mathbb{J} :_s \mathcal{B}} \qquad \text{(REC)}\ \frac{kind(\mathbb{J}) = \{\ \} \quad \text{Let } (a_1, \ldots, a_n) = keys(\mathbb{J}) \quad \forall i = 1, \ldots, n.\ \vdash \mathbb{J}/a_i :_u \mathcal{U}_i \quad q_i = Q(\frac{|\mathbb{J}/a_i|}{|\mathbb{J}|})}{\vdash \mathbb{J} :_s \{a_1 : \mathcal{U}_1 q_1, \ldots, a_n : \mathcal{U}_n q_n\}}$$

$$\text{(ARRAY)}\ \frac{kind(\mathbb{J}) = [\,] \quad \vdash \mathbb{J}/[*] :_u \mathcal{U}}{\vdash \mathbb{J} :_s [\mathcal{U}]}$$

Figure 1 Type inference rules.

Rule (+) is the key rule. Consider again the collection of Section 2.

$$\begin{array}{llllll} (& \{ & a : \{j : 0, k : 0\}, & b : \{bb : 0\} & \}, & \{ \quad a : \{j : 0\}, \quad c : \{cc : 0\} \quad \} \\ & \{ & a : \{y : 0, z : 0\} & c : \{cd : 0\} & \}, & \{ \quad a : \{j : 0\}, \quad b : 0 \qquad\quad \} \quad) \end{array}$$

If we split it into two different subsets, one for each different choice of the top-level labels, we will get a union type with two addends, similar to the $\mathcal{L}$-type presented in Section 2. However, if we consider the trivial split where all records are put together, we will have a type with only one top level addend, such as the three types whose root is labeled with $+_K$ in Section 2. We could also decide to split the collection in three subsets, in which case the resulting type will be the union of three types, one for each subset. A finer split will result into a union type that is bigger but where each addend is more precise. A coarser split will

yield a union type with less addends, and where each addend will be less precise. Every application of a union rule can use a different approach to splitting, and every application of a union rule corresponds to a different + in the resulting type. Hence, this rule gives us the flexibility that we need in order to model the process of interactive type modification.

For the rule (REC), we first introduce some notations.

▶ **Notation 3** ($J.a$, $\mathbb{J}/a, Q(x)$, $keys(\mathbb{J})$).

$$\begin{array}{llll} \{\ldots, a : J, \ldots\}.a = (\,J\,) & & Q(x) = \,! \;\; \textit{if } x = 1 \\ \{a_1 : J_1, \ldots, a_n : J_n\}.a = (\,) & \textit{if } \forall i \in 1..n.\ a_i \neq a & Q(x) = \,? \;\; \textit{if } 0 < x < 1 \\ \mathbb{J}/a = \bigoplus_{J \in \mathbb{J}} J.a & & keys(\mathbb{J}) = \bigcup_{J \in \mathbb{J}} (keys(J)) \end{array}$$

The rule (REC) specifies that, in order to analyze a kind-homogeneous collection of records, which may have different structures, we extract the collection of all keys that appear in any of them. For each key a_i, we collect the content of that key in all records and we infer a union type $\mathcal{U}_i$ for the collection $\mathbb{J}/a_i$. $\mathcal{U}_i$ will be the type for a_i in the result. Its qualifier will depend on the fraction of records where the a_i field is present, and will be ! if and only if the fraction is 1. In $Q(\,|\mathbb{J}/a_i| \,/\, |\mathbb{J}|\,)$, $|C|$ denotes the cardinality of a collection C.

The rule (ARRAY) is based on the $\mathbb{J}/[*]$ operator, that returns the content of all arrays in $\mathbb{J}$ as defined below; observe that both $(\,)/[*]$ and $(\,[\,], \ldots, [\,]\,)/[*]$ return the empty collection.

▶ **Notation 4** ($\mathbb{J}/[*]$). *For any collection of arrays, the operator $\mathbb{J}/[*]$ is defined as follows.*

$$(\,[J_1^1, \ldots, J_{n_1}^1], \ldots, [J_1^m, \ldots, J_{n_m}^m]\,)/[*] \triangleq (\,J_1^1, \ldots, J_{n_1}^1, \ldots, J_1^m, \ldots, J_{n_m}^m\,)$$

The use of the $\mathbb{J}/a$ and $\mathbb{J}/[*]$ operators in the typing rules is a technical contribution of this work and, in combination with the approach of typing a whole collection at the same time, is the fundamental tool that allows us to express the fact that the same criterion will be used for data that is not consecutive in the dataset but is related by the fact that it is reached through the same path.

This type system enjoys soundness, in the following sense.

▶ **Theorem 5** (Soundness). *For any JSON collection $\mathbb{J}$, union type $\mathcal{U}$, structural type $\mathcal{S}$:*

$$\vdash \mathbb{J} :_u \mathcal{U} \;\Rightarrow\; [\![\mathbb{J}]\!] \subseteq [\![\mathcal{U}]\!] \qquad \vdash \mathbb{J} :_s \mathcal{S} \;\Rightarrow\; [\![\mathbb{J}]\!] \subseteq [\![\mathcal{S}]\!]$$

▶ **Example 6.** Consider a collection $\mathbb{J} = (\,20, [1,3,5], [\,], [1, \text{true}], [2,4]\,)$. We want to find a union type $\mathcal{U}$ such that $\vdash \mathbb{J} :_u \mathcal{U}$. We start with the (+) rule, which divides $\mathbb{J}$ into kind-homogeneous subsets to be separately analyzed. For example, it may be divided into four homogeneous collections $(\,20\,), (\,[1,3,5], [2,4]\,), (\,[\,]\,), (\,[1, \text{true}]\,)$. The (BASE) rule assigns `Num` to $(\,20\,)$. The (ARRAY) rule reduces the problem $\vdash (\,[1,3,5], [2,4]\,) :_s \mathcal{S}_1$ to $\vdash (\,1,3,5,2,4\,) :_u \mathcal{U}_1$. If the split criterion keeps all the integers together, the (BASE) rule assigns `Num` to the integers, hence we have $\vdash (\,1,3,5,2,4\,) :_u +(\texttt{Num})$, hence $\vdash (\,[1,3,5], [2,4]\,) :_s [+(\texttt{Num})]$.

In this way, starting from a four-way split of the original collection, we prove the following judgment: $\vdash \mathbb{J} :_u +(\texttt{Num}, [+(\texttt{Num})], [+()], [+(\texttt{Num}, \texttt{Bool})])$.

By splitting $\mathbb{J}$ in different ways, we may prove the following judgments (among others), all of them correct, each exhibiting a different trade-off of size and precision. For example, the first type is the only one that fully describes all the possible different shapes of the arrays in the data. The second type indicates the existence of some "pure integers" array, while the third one indicates the presence of empty arrays. The fourth one is the less informative but is still sound, since every array in the collection meets that description.

i) $\vdash \mathbb{J} :_u +\,(\texttt{Num},\ [+(\texttt{Num})],\ [+()],\ [+(\texttt{Num}, \texttt{Bool})]\,)$
ii) $\vdash \mathbb{J} :_u +(\,\texttt{Num},\ [+(\texttt{Num})],\ [+(\texttt{Num}, \texttt{Bool})]\,)$
iii) $\vdash \mathbb{J} :_u +(\,\texttt{Num},\ [+()],\ [+(\texttt{Num}, \texttt{Bool})]\,)$
iv) $\vdash \mathbb{J} :_u +(\,\texttt{Num},\ [+(\texttt{Num}, \texttt{Bool})]\,)$

4.2 The deterministic type system

The non-deterministic type system is a general framework that will be used to prove that every judgment that is generated by the process of interactive typing is sound. We formalize now a deterministic subsystem, that models how the user guides the behaviour of the system.

While the non-deterministic type system takes a non-deterministic choice of a split criterion for each instance of the (+) rule, our type checker splits the $\mathbb{J}$ collection according to a criterion that is defined by the user, and this is modeled by the deterministic system.

Our split criteria will be based on equivalence relations defined on JSON terms, as follows.

▶ **Definition 7** ($\mathcal{C}(E)$)**.** *For a given equivalence relation E defined on JSON terms, the split criterion $\mathcal{C}(E)$ maps a collection $\mathbb{J}$ to a partition of $\mathbb{J}$ according to E.*

We can now define two important equivalence relations which will be used to define two split criteria. They are *kind equivalence* $\mathcal{K}(J_1, J_2)$ and *label equivalence* $\mathcal{L}(J_1, J_2)$, and correspond to the equivalences $\mathcal{K}(\mathcal{S}_1, \mathcal{S}_2)$ and $\mathcal{L}(\mathcal{S}_1, \mathcal{S}_2)$ defined in [4] for structural types. Kind equivalence is the coarsest equivalence that can be used to define a split criterion, since it keeps all kind-homogeneous terms together. Label equivalence is the same as kind equivalence for base values and for arrays but, when records are compared, it only groups those records that have exactly the same keys, hence it is much finer. The formal definition of the two equivalences is obvious, and reported in the full version [3].

The simplest way to "determinize" the non-deterministic type system would be to choose a split criterion to be adopted in every instance of the (+) rule. We need, however, some more freedom than this, hence we adopt the notion of *determinizer*, which is a function from integer sequences to split criteria (Definition 8), that we use to associate a split criterion to each instance of the (+) rule in a proof.

Formally, we define the deterministic type system by adding a $\mathcal{D}$ parameter (a determinizer) to the rules, and by specializing the (+) rule to the following (+D) rule, that specifies that $\mathcal{D}(\epsilon)$, where ϵ is the empty sequence, is used to split $\mathbb{J}$, while the determinizers $next(\mathcal{D}, i)$, as defined in Definition 8, will be used in the subproofs.

$$\frac{(\mathbb{J}_1, \ldots, \mathbb{J}_n) = \mathcal{D}(\epsilon)(\mathbb{J}) \qquad \vdash^{next(\mathcal{D},i)} \mathbb{J}_i :_s \mathcal{S}_i \quad i = 1, \ldots, n}{\vdash^{\mathcal{D}} \mathbb{J} :_u +_{\mathcal{D}(\epsilon)}(\mathcal{S}_1, \ldots, \mathcal{S}_n)} \text{(+D)}$$

▶ **Definition 8** (Determinizer, $next(\mathcal{D}, i)$)**.** *A* determinizer $\mathcal{D}$ *is a function that maps any sequence, possibly empty, of positive integers $\omega = (i_1, \ldots, i_n)$ to a split criterion $\mathcal{D}(\omega)$. For any determinizer $\mathcal{D}$, $next(\mathcal{D}, i)$ is the determinizer that maps ω to $\mathcal{D}(i.\omega)$.*

A determinizer is hence a function that determines the split criterion used at each node of the type proof. By construction, every proof in the deterministic type system is also a proof in the non-deterministic one. In the full paper we show that the converse also holds: for every proof in the non-deterministic system a determinizer exists that generates that proof.

A determinizer may map any sequence to any split criterion, but, in practice, we will focus on very simple split criteria and very simple determinizers. Our system currently supports only three determinizers, L, K, LK, all of them employing equivalence-based criteria and a constant or almost-constant function.

▶ **Definition 9** (L, K, LK)**.** *L is the constant determinizer that maps every sequence ω to the split criterion $\mathcal{C}(\mathcal{L})$. K maps every sequence to $\mathcal{C}(\mathcal{K})$. LK maps the empty sequence to $\mathcal{C}(\mathcal{L})$ and any other sequence to $\mathcal{C}(\mathcal{K})$.*

Hereafter, we use the terms $\mathcal{L}$-type and $\mathcal{K}$-type, for a collection $\mathbb{J}$, to refer to the type that is inferred using, respectively, the L or the K determinizer. By Definition 9, L and K use, respectively, $\mathcal{C}(\mathcal{L})$ and $\mathcal{C}(\mathcal{K})$ as split criteria, everywhere in the proof. LK uses $\mathcal{C}(\mathcal{L})$ at the top level but $\mathcal{C}(\mathcal{K})$ everywhere else, that is, it expands like the $\mathcal{L}$-type at the top level, but computes a $\mathcal{K}$-type everywhere else.

4.3 The proof validity system

The aim of this paper is to provide a formal specification of a system that dynamically recomputes a type for a subset of the input data. We believe that the most direct approach is to describe it as a system that manipulates typing proofs and, to this aim, we need a notation to explicitly describe proofs and their manipulations. To this aim, we extend our judgments with a proof term that describes the proof itself, so that, rather than judgments $\vdash \mathbb{J} : \mathcal{T}$, that specify that the collection $\mathbb{J}$ has type $\mathcal{T}$, we will have ternary judgments with the form $\pi \vdash \mathbb{J} : \mathcal{T}$, that specify that π is a proof tree that proves that $\mathbb{J}$ has type $\mathcal{T}$.

More precisely, we first define a language of proof terms as follows.

$$\begin{array}{lcll} \pi^u & ::= & \langle +(\pi^s_1, \ldots, \pi^s_n)\rangle & n \geq 0 \\ \pi^s & ::= & \langle \mathbb{J}, \mathcal{B}\rangle \mid \langle \mathbb{J}, \{l_1 : \pi^u_1 \mathtt{q}_1, \ldots, l_n : \pi^u_n \mathtt{q}_n\}\rangle \mid \langle \mathbb{J}, [\pi^u]\rangle & \end{array}$$

Then, we define an inference system, based on two judgments that are mutually recursive $\pi^u \vdash \mathbb{J} :_u \mathcal{U}$ and $\pi^s \vdash \mathbb{J} :_s \mathcal{S}$ that specify when a proof term π is a proof (and not just a proof term), and, in that case, the fact that π proves that $\mathbb{J}$ has type $\mathcal{U}$. In the sequel we will use the metavariable π to range over both structural type proofs π^s and union type proofs π^u. The type inference rules are shown in Figure 2.

$$\text{(EMPTY)}\ \frac{}{\langle +(\,)\rangle \vdash \emptyset :_u +(\,)} \qquad \text{(+)}\ \frac{\mathcal{C} \text{ is a split criterion} \quad (\mathbb{J}_1, \ldots, \mathbb{J}_n) = \mathcal{C}(\mathbb{J}) \quad \pi_i \vdash \mathbb{J}_i :_s \mathcal{S}_i \quad i = 1, \ldots, n}{\langle +(\pi_1, \ldots, \pi_n)\rangle \vdash \mathbb{J} :_u +_{[\mathcal{C}]}(\mathcal{S}_1, \ldots, \mathcal{S}_n)} \qquad \text{(BASE)}\ \frac{kind(\mathbb{J}) = \mathcal{B}}{\langle \mathbb{J}, \mathcal{B}\rangle \vdash \mathbb{J} :_s \mathcal{B}}$$

$$\text{(REC)}\ \frac{kind(\mathbb{J}) = \{\,\} \quad \text{Let } (a_1, \ldots, a_n) = keys(\mathbb{J}) \quad \forall i = 1, \ldots, n.\ \pi_i \vdash \mathbb{J}/a_i :_u \mathcal{U}_i \quad \forall i = 1, \ldots, n.\ q_i = Q(\frac{|\mathbb{J}/a_i|}{|\mathbb{J}|})}{\langle \mathbb{J}, \{a_1 : \pi_1 q_1, \ldots, a_n : \pi_n q_n\}\rangle \vdash \mathbb{J} :_s \{a_1 : \mathcal{U}_1 q_1, \ldots, a_n : \mathcal{U}_n q_n\}} \qquad \text{(ARRAY)}\ \frac{kind(\mathbb{J}) = [\,] \quad \pi \vdash \mathbb{J}/[*] :_u \mathcal{U}}{\langle \mathbb{J}, [\pi]\rangle \vdash \mathbb{J} :_s [\mathcal{U}]}$$

Figure 2 Proof validity rules.

Given a proof π, in the full paper we define $\mathtt{JJ}(\pi)$ and $\mathtt{U}(\pi)$ as the unique collection $\mathtt{JJ}(\pi)$ and type $\mathtt{U}(\pi)$ such that $\pi \vdash \mathtt{JJ}(\pi) : \mathtt{U}(\pi)$. We then define a notion of path inside a proof or a type, where the steps (i), $[*]$ and a traverse, respectively, the union, array, and record constructors:

$$p \quad ::= \quad \epsilon \mid (i)/p \mid [*]/p \mid a/p$$

We then define a notion of subproof along a path $\pi \downarrow p$, and a notion of substitution $\pi[p \leftarrow \pi_1]$, that is only well defined when $\mathtt{JJ}(\pi_1) = \mathtt{JJ}(\pi \downarrow p)$, that is, a substitution will change the type but not the term. In the full paper we prove the fundamental property of this operation: if π and π_1 are valid proofs, then $\pi[p \leftarrow \pi_1]$ is a valid proof as well, where *valid* is defined by the rules of Figure 2. This property is the foundation of the formalization that we are going to present.

5 The Local-Retype Operation

We are now ready to define the local-retype operation. In our tool, the analyst has a collection $\mathbb{J}$ and a type $\mathcal{T}$ for $\mathbb{J}$, she/he clicks on a union type $\mathcal{U}$ inside $\mathcal{T}$ and selects the new determinizer $\mathcal{D}$ to use in order to re-type the subforest of $\mathbb{J}$ that corresponds to the type $\mathcal{U}$.

In general, this subforest does not correspond to a subsequence of the JSON collection: when the analyst selects the type of the *authors* field of a record type, the objects that correspond to the *authors* key are scattered through all those records that actually contain an *authors* field. However, if we consider a proof tree π such that $\pi \vdash \mathbb{J} : \mathcal{T}$, then these objects are all collected in the only premise of the (REC) rule that infers a type for $\mathbb{J}/authors$. Hence, we may formalize this action as follows: the analyst chooses a path p inside the type $\mathcal{T}$ and a new determinizer $\mathcal{D}$, and the system computes a new proof π' for the collection that corresponds to $\pi \downarrow p$, substitutes π' to $\pi \downarrow p$, and visualizes the type that corresponds to the new proof. The analysts operate on types, but the system is manipulating the corresponding proofs. We formalize this through the *retype* operation, as follows.

▶ **Definition 10** (*retype*$(\pi, p, \mathcal{D})$)**.** *For any proof π such that $\pi \vdash \mathbb{J} : \mathcal{T}$, for any p such that $\mathcal{T} \downarrow p$ is defined, for any determinizer $\mathcal{D}$, retype$(\pi, p, \mathcal{D})$ is defined as follows , where $\pi_{\mathcal{D}}$ is uniquely determined by $\mathcal{D}$, π and p :*

$$(\exists \mathcal{T}'.\ \pi_{\mathcal{D}} \vdash^{\mathcal{D}} \mathit{JJ}(\pi \downarrow p) : \mathcal{T}') \ \Rightarrow\ \mathit{retype}(\pi, p, \mathcal{D}) \triangleq \pi[p \leftarrow \pi_{\mathcal{D}}]$$

In other terms, the analyst indicates a path p, the system retrieves the corresponding collection $\mathtt{JJ}(\pi \downarrow p)$ inside the current proof π, computes a $\mathcal{D}$-proof $\pi_{\mathcal{D}}$ for that collection, and substitutes $\pi \downarrow p$ with $\pi^{\mathcal{D}}$. From the analyst's viewpoint, the type at $\mathcal{T} \downarrow p$ has been substituted with a $\mathcal{D}$-type for the corresponding collection.

In the full paper, we extend this definition to a *retype*$^*(\pi, \sigma)$ operation that executes a sequence $\sigma = (\,(p_1, \mathcal{D}_1), \ldots, (p_n, \mathcal{D}_n)\,)$ of retyping steps, and we prove that, for any such sequence, the resulting type is always a correct description of the input collection and a tight description, where every path in the type actually corresponds to some piece of data. Moreover, we prove that the split criteria that are present in the type actually correspond to how the collections have been split in the proof. In other terms, we prove that the specific sequence of steps is irrelevant, hence the final type that is displayed to the analyst only depends on the terms in the collection. For space reason, we only present here the most important results, but leave the discussion and the proofs to the full paper.

▶ **Theorem 11** (Type soundness of *retype*$^*()$)**.** *For any proof π such that $\pi \vdash \mathit{JJ}(\pi) : \mathtt{U}(\pi)$, for any sequence σ of retyping steps, the proof retype$^*(\pi, \sigma)$ is still a proof for $\mathit{JJ}(\pi)$:*

$$\mathit{retype}^*(\pi, \sigma) = \pi_n \ \Rightarrow\ \pi_n \vdash \mathit{JJ}(\pi) : \mathtt{U}(\pi_n)$$

▶ **Corollary 12.** *For any π such that $\pi \vdash \mathit{JJ}(\pi) : \mathtt{U}(\pi)$, for any sequence σ of retyping steps such that retype$^*(\pi, \sigma) = \pi_r$, for any path p:*

1. $[\![\, \mathit{JJ}(\pi_r \downarrow p) \,]\!] \subseteq [\![\, \mathtt{U}(\pi_r \downarrow p) \,]\!]$ — *Soundness of retype$^*()$*
2. *if $\pi \downarrow p$ is not $+()$:* $[\![\, \mathit{JJ}(\pi_r \downarrow p) \,]\!] \neq \emptyset$ — *Tightness of retype$^*()$*
3. *if $\pi_r \downarrow p = +_{\mathcal{C}}(\pi_1, \ldots, \pi_m)$:* $(\,\mathit{JJ}(\pi_1), \ldots, \mathit{JJ}(\pi_m)\,) = \mathcal{C}(\mathit{JJ}(\pi_r \downarrow p))$ — *Soundness of the split criterion*

6 Implementation

According to our definition, any time the analyst expands or contracts a node in the type, all data associated to that node are type-checked again. Since we are dealing with massive data collections, and we aim for a very fast response, this approach is not acceptable.

In our implementation, we do a different thing. We currently support the three determinizers K, L, and LK of Definition 9, and the L-type contains enough information to rebuild the K-type and the LK-type. Hence, we first compute and store the L-type $\mathcal{U}_L$ of the dataset $\mathbb{J}$, and we compute the K-type $\mathcal{U}_K$, which is the first one to be visualized, starting from $\mathcal{U}_L$. Then, rather than keeping track of a proof $\pi \vdash \mathbb{J} : \mathcal{U}_K$, we store a type-level abstract proof $\pi_{LK} \vdash \mathcal{U}_L : \mathcal{U}_K$, formalized in a type-to-type inference system specified below. When we need to recompute the type of a subcollection $\texttt{JJ}(\pi \downarrow p)$, rather than type-checking the subcollection, which may be extremely big, we compute its type starting from the collection of types $\texttt{U}(\pi_{LK} \downarrow p)$, which is a subforest of $\mathcal{U}_L$, and is an abstract description of $\texttt{JJ}(\pi \downarrow p)$.

In the full paper, in this section we present this approach, which is crucial for the applicability of our tool, and prove its correctness. We recap here the contents of the section.

We want to specify a set of conditions that make it possible to compute an abstract type from a detailed type without accessing the data. We focus our attention to a specific class of determinizers, those whose split condition is defined in terms of an equivalence, and, for the detailed type, we also ask that the split condition is constant, as it happens for the L determinizer, which constantly uses the $\mathcal{C}(\mathcal{L})$ split criterion. We then define a judgment $\vdash^{\mathcal{D}} \mathbb{J} :: \mathbb{S}$ that specifies that a collection of terms $\mathbb{J}$ is "described" by a collection of structural types $\mathbb{S}$. We can now define a notion of *refinement*, that specifies a condition that is sufficient in order to compute an abstract type starting from the detailed type.

The notion is based on the existence of a *Type-level split criterion for $\mathcal{D}$ and $\mathcal{C}$* $tsplit^{\mathcal{C}}_{\mathcal{D}}(\mathbb{S})$, that is, a function that splits the collection $\mathbb{S}$ describing $\mathbb{J}$ in the "same way" as $\mathcal{C}$ would have split $\mathbb{J}$. If, for a determinizer $\mathcal{E}$, for any ω, we have a type-level split criterion $tsplit^{\mathcal{E}(\omega)}_{\mathcal{D}}(\mathbb{S})$, then $\mathcal{D}$ *refines* $\mathcal{E}$, and we prove that this is sufficient to compute the $\mathcal{E}$-type from the $\mathcal{D}$-type.

To this aim, we present a set of rules to compute an $\mathcal{E}$-type from a $\mathcal{D}$-type if $\mathcal{D}$ refines $\mathcal{E}$, and the corresponding proof of correctness. This set of rules, reported in Figure 3, defines a *type-to-type* system, where the type collections at the left hand side substitute the terms that they represent, and the operators $\mathbb{S}/a$, $qual(\mathbb{S}, a)$, $keys(\mathbb{S})$, $\mathbb{S}/[*]$ represent the type-level lifting of the corresponding term operators.

$$\frac{}{\vdash^{\mathcal{E}}_{\mathcal{D}} +_C(\,) :_u +_{\mathcal{E}(\epsilon)}(\,)} \text{(EMPTY)} \qquad \frac{kind(\mathbb{S}) = \mathcal{B}}{\vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_s \mathcal{B}} \text{(BASE)} \qquad \frac{kind(\mathbb{S}) = [\,] \quad \vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S}/[*] :_u \mathcal{U}}{\vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_s [\mathcal{U}]} \text{(ARRAY)}$$

$$\frac{(\mathbb{S}^1, \ldots, \mathbb{S}^n) = tsplit^{\mathcal{E}(\epsilon)}_{\mathcal{D}}(\mathbb{S}) \quad \vdash^{next(\mathcal{E},i)}_{\mathcal{D}} \mathbb{S}^i :_s \mathcal{S}'_i \quad i = 1, \ldots, n}{\vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_u +_{\mathcal{E}(\epsilon)}(\mathcal{S}'_1, \ldots, \mathcal{S}'_n)} \text{(+D)}$$

$$\frac{kind(\mathbb{S}) = \{\,\} \quad \text{Let } (a_1, \ldots, a_n) = keys(\mathbb{S}) \quad \forall i = 1, \ldots, n.\ \vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S}/a_i :_u \mathcal{U}_i \quad q_i = qual(\mathbb{S}, a_i)}{\vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_s \{a_1 : \mathcal{U}_1 q_1, \ldots, a_n : \mathcal{U}_n q_n\}} \text{(REC)}$$

Figure 3 The t2t system: rules to infer an $\mathcal{E}$-type from a $\mathcal{D}$-type.

We then prove that the type-to-type system can be used to correctly compute the $\mathcal{E}$-type of any collection starting from its $\mathcal{D}$-type.

▶ **Property 13** (Soundness and completeness of $\vdash^{\mathcal{E}}_{\mathcal{D}} \mathcal{U}_D :_u \mathcal{U}_E$)**.** *For any $\mathbb{J}$, $\mathbb{S}$, $\mathcal{D}$, $\mathcal{E}$, $\mathbb{J}_c$, $\mathcal{U}_E$, $\mathcal{S}_E$, where $\mathbb{J}_c$ is kind-homogeneous, if $\mathcal{D}$ refines $\mathcal{E}$, then:*

$$\vdash^{\mathcal{D}} \mathbb{J} :: \mathbb{S} \quad \Rightarrow \quad (\ \vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_u \mathcal{U}_E \quad \Leftrightarrow \quad \vdash^{\mathcal{E}} \mathbb{J} :_u \mathcal{U}_E\ )$$
$$\vdash^{\mathcal{D}} \mathbb{J}_c :: \mathbb{S} \quad \Rightarrow \quad (\ \vdash^{\mathcal{E}}_{\mathcal{D}} \mathbb{S} :_s \mathcal{S}_E \quad \Leftrightarrow \quad \vdash^{\mathcal{E}} \mathbb{J}_c :_s \mathcal{S}_E\ )$$

7 Related Work

While the problem of inferring structural information from JSON collections has recently gained a momentum [8, 1, 2, 13, 9, 14], we are not aware of any approach that is interactive. In the XML realm, among the plethora of schema inference approaches [5, 10, 7, 11, 15, 12], only the one presented [15] is interactive since it relies on user intervention for recognizing regular expressions that are similar enough to be merged and for guiding the system to derive sophisticated schema expressing inheritance and restrictions, two constructs that are difficult to infer in a purely automatic fashion. While this approach bears some resemblance with our work in that both give the user some form of freedom to decide when two types are similar, the interaction presented in [15] is only meant to guide the system during the schema inference and does not allow for exploring different parts of an already existing schema with different precision lenses. Another notable difference with our approach is the lack of a mechanism for reasoning about type "similarity" like an equivalence class.

8 Conclusions

When semistructured JSON data are retrieved from the web, the presence of an automatic tool that can infer a schema is very useful, but the same data can be described with schemas with different size-precision trade offs, and no trade-off is optimal in general. Moreover, it is often the case that one is mostly interested in a specific part of the data, hence we designed and implemented a system where the analyst can interactively decide which parts of the data should be described with a greater or lower level of detail.

In this paper we have studied the formal foundations of this approach. The main novelty of this formal study is the use of specific precision criteria on specific parts of the data, that are identified by acting on a node of the syntax tree of a type. This aspect has been formalized through the use of some technical tools such as the use of selectors such as $\mathbb{J}/a$ and $\mathbb{J}/[*]$ inside the type proofs, and the notion of proof terms. With these tools we have proved the soundness of the local retype operation that we implemented.

The basic ideas that we presented here admit many extensions. First of all, while we designed the foundations of an interactive tool for an elementary type system, all the extensions of that elementary type system that we briefly presented in [4] – such as type constraints, enumeration types, variant types, tuple types, keyset equivalence – can be easily added. In the same way, the approach that we defined here can be easily applied to the counting type system that we defined in [2], hence combining the interactivity that we presented here with the quantitative information that was presented in that paper. We are currently exploring these possibilities.

Finally, while in [4] and [2] we studied the use of equivalence relations in order to split collection, here we allow any criterion to be used. This opens the way to some new possibilities, such as a top-n split, where one separates and groups the n shapes that are most important and collapses the others, or even forms of value-based grouping, where different records are grouped in a way that depends on the values of the fields and not just on the types.

Abstract

Value iteration is a fundamental algorithm for solving Markov Decision Processes (MDPs). It computes the maximal n-step payoff by iterating n times a recurrence equation which is naturally associated to the MDP. At the same time, value iteration provides a policy for the MDP that is optimal on a given finite horizon n. In this paper, we settle the computational complexity of value iteration. We show that, given a horizon n in binary and an MDP, computing an optimal policy is **EXPTIME**-complete, thus resolving an open problem that goes back to the seminal 1987 paper on the complexity of MDPs by Papadimitriou and Tsitsiklis. To obtain this main result, we develop several stepping stones that yield results of an independent interest. For instance, we show that it is **EXPTIME**-complete to compute the n-fold iteration (with n in binary) of a function given by a straight-line program over the integers with max and + as operators. We also provide new complexity results for the bounded halting problem in linear-update counter machines.

1 Introduction

Markov decision processes (MDP) are a fundamental formalism of decision making under probabilistic uncertainty [29, 9]. As such, they play a prominent role in numerous domains, including artificial intelligence and machine learning [34, 33], control theory [10, 1], operations research and finance [11, 31], as well as formal verification [12, 5], to name a few. Informally, an MDP represents a system which is, at every time step, in one of the *states* from a finite set S. The system evolves in steps: in each step, we can perform an *action* (or *decision*) from a finite set A. When using an action $a \in A$ in state $s \in S$, we collect an immediate *reward* $R(s, a)$ and then transition stochastically to a successor state according to a rational-valued distribution $P(s, a)$, which is given as a part of the MDP. This interaction with an MDP proceeds over either a *finite* or *infinite* horizon. In the finite-horizon case, we are given a bound $H \in \mathbb{N}$ (a *horizon*) such that the interaction stops after H steps; in the infinite horizon case the process goes on forever. To *solve* an MDP means to find an optimal *policy*; that is, a blueprint for selecting actions that maximizes the expected reward accumulated over a finite or infinite horizon. The accumulated rewards are typically *discounted* by some factor $0 < \gamma \leq 1$; for infinite horizon, we need $\gamma < 1$ to ensure that the infinite sum is well defined.

Value iteration. Given the importance of MDPs, it is hardly surprising that they have attracted significant interest in the theory community. Past research on MDPs included the study of complexity issues [27] as well as the design and analysis of algorithms for solving MDPs [22, 24, 38, 39]. In this paper, we provide a fresh look on one of the most familiar algorithms for MDPs: *value iteration (VI)*. Introduced by Bellman in the 1950s [6], VI makes use of the optimality principle: the maximal n-step reward achievable from a state s, which we denote by $\vec{v}_n(s)$, satisfies the recurrence

$$\vec{v}_n(s) = \max_{a \in A} \left\{ R(s, a) + \gamma \cdot \sum_{s' \in S} P(s, a)(s') \cdot \vec{v}_{n-1}(s') \right\} , \tag{1}$$

with $\vec{v}_0(s) = 0$. Consequently, a finite-horizon policy is optimal if and only if it chooses, in a situation when the current state is s and n steps are remaining, an action maximizing the right-hand side (RHS) of (1). Thus, to solve an MDP with a finite horizon H, the VI algorithm computes the values $\vec{v}_n(s)$ for all $0 \leq n \leq H$ and all states s, by iterating the recurrence (1). Using these values, VI then outputs (using some tie-breaking rule) some policy satisfying the aforementioned optimality characterization. VI can be deployed also for infinite-horizon MDPs: one can effectively compute a horizon H such that action a is optimal in state s for an infinite horizon[1] if it maximizes the RHS of (1) for $n = H$ [8]. This H has a bit-size which is polynomial in the size of the original MDP, but the magnitude of H can be exponential in the size of the MDP if the discount factor is given in binary [22].

VI is one of the most popular MDP-solving algorithms due to its versatility (as shown above, it can be used for several MDP-related problems) and conceptual simplicity, which makes it easy to implement within different programming paradigms [30, 37], including implementation via neural nets [35]. Several variants of VI with improved performance were developed [36, 14]. For instance, the recent paper by Sidford et al. [32] presented a new class of randomized VI techniques with the best theoretical runtime bounds (for certain values

[1] In infinite-horizon MDPs, there is always an optimal *stationary* policy, which makes decisions based only on the current state. [29]

of parameters) among all known MDP solvers. The paper also expresses hope that their techniques "*will be useful in the development of even faster MDP algorithms.*" To get insight into the underlying structure of VI, which might enable or limit further such accelerations, we take a complexity-theoretic vantage point and study the theoretical complexity of computing an *outcome* of a VI execution. That is, we consider the following decision problem ValIt: given an MDP with a finite horizon H (encoded as a binary number), does a given action a maximize the RHS of (1) for $n = H$? This problem is inspired by the paper of Fearnley and Savani [16], where they show **PSPACE**-hardness (and thus also completeness) for the problem of determining an outcome of *policy iteration*, another well-known algorithm for MDP solving. To the best of our knowledge, VI has not yet been explicitly subjected to this type of analysis. However, questions about the complexity of ValIt were implicitly raised by previous work on the complexity of finite-horizon MDPs, as discussed in the next paragraph.

Finite-horizon MDPs. The complexity of finite-horizon MDPs is a long-standing open problem. Since "finding an optimal policy" is a function problem, we can instead consider the decision variant: "In a given finite-horizon MDP, is it optimal to use a given action in the first step?" As discussed above, this is exactly the ValIt problem in disguise.

In the seminal 1987 paper on the complexity of MDPs [27], Papadimitriou and Tsitsiklis showed **P**-completeness of a special case of finite-horizon optimization where the horizon H has magnitude polynomial in the size of the MDP. At the same time, they noted that in the general case of binary-encoded H, VI can be executed on an **EXPTIME**-bounded Turing machine (since H is represented using $\log(H)$ bits, the number of iterations is exponential in the size of the input). Hence ValIt is in **EXPTIME**. However, the exact complexity of the general finite-horizon optimization remained open ever since, with the best lower bound being the **P**-hardness inherited from the "polynomial H" sub-problem. Tseng [36] presented a more efficient (though still exponential) algorithm for finite-horizon MDPs satisfying a certain stability condition; in the same paper, he comments that *"in view of the stability assumptions needed to obtain an exact solution and the absence of negative results, we are still far from a complete complexity theory for this problem."*

In this paper, we address this issue, provide the missing negative results, and *provide tight bounds on the computational complexity* of ValIt and finite-horizon MDP optimization.

Our Results

The main result of the paper is that ValIt is **EXPTIME**-complete (Theorem 1). In the rest of this section, we first explain some challenges we needed to overcome to obtain the result. Then we sketch our main techniques and conclude with discussing the significance of our results, which extends beyond MDPs to several areas of independent interest.

Challenges

Bitsize of numbers. One might be tempted to believe that ValIt is in **PSPACE**, since the algorithm needs to store only polynomially many values at a time. However, the bitsize of these values may become exponentially large during the computation (e.g., the quantity $\vec{v}_n(s)$ may halve in every step). Hence, the algorithm *cannot* be directly implemented by a polynomial-space Turing machine (TM). One could try to adapt the method of Allender et al. [20, 2] based on an intricate use of the Chinese remainder representation (CRR) of integers. However, there is no known way of computing the max operation directly and efficiently on numbers in CRR.

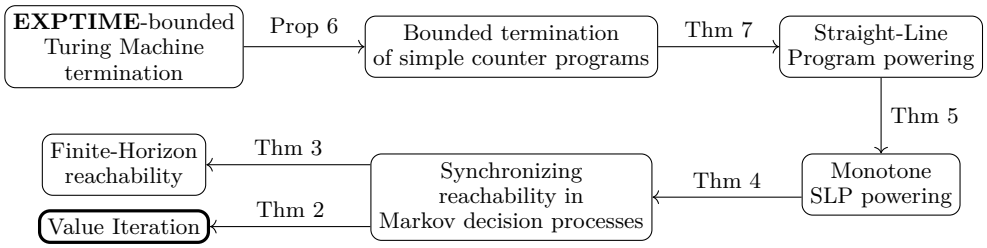

Figure 1 Chain of reductions.

Complex optimal policies. Another hope for **PSPACE** membership would be a possibly special structure of optimal policies. Fixing any concrete policy turns an MDP into a Markov chain, whose H-step behavior can be evaluated in polynomial space (using, e.g., the aforementioned CRR technique of Allender et al.). If we could prove that (A) an optimal policy can be represented in polynomial space and (B) that the Markov chain induced by such a policy is polynomially large in the size of the MDP, we would get the following **PSPACE** algorithm: cycle through all policies that satisfy (A) and (B), evaluate each of them, and keep track of the best one found so far. Tseng [36] commented that optimal policies in finite-horizon MDPs are "poorly understood". Hence, there was still hope that optimal Markovian deterministic policies may have a shape that satisfies both (A) and (B). Unless **PSPACE** = **EXPTIME**, our results put such hopes to rest.

No hardness by succinctness. One might try to prove **EXPTIME**-hardness using a *succinctness* argument. The results of [27] show that ValIt is **P**-hard when the horizon is written in unary, and many optimization problems over discrete structures incur an exponential blow-up in complexity when the discrete structure is encoded succinctly, e.g., by a circuit [28]. Giving a horizon H in binary amounts to a succinct encoding of an exponentially large MDP obtained by "unfolding" the original MDP into a DAG-like MDP of depth H. This unfolded MDP is "narrow" in the sense that it consists of many polynomial-sized layers, while standard **EXPTIME**-hardness-by-succinctness proofs, use succinct structures of an exponential "width" and "depth", accommodating the tape contents of an **EXPTIME**-bounded TM. Hence, straightforward succinctness proofs do not apply here; e.g., there does not seem to be a direct reduction from the succinct circuit value problem.

Our Techniques

To obtain **EXPTIME**-hardness of ValIt, we proceed by a sequence of non-trivial reductions. Below we outline these reductions in the order in which they appear in the sequence, see Figure 1. In the main text, we present the reductions in a different order (indicated by the numbering of propositions and theorems), so that we start with MDPs and gradually introduce more technical notions.

We start from a canonical **EXPTIME**-complete problem: the halting problem for an exponential-time TM. We then present a reduction to a halting problem for a class of counter programs (CPs; simple imperative programs with integer variables) that allow for linear variable updates. In this way, we encode the tape contents into numerical values (6). The crucial feature of this reduction is that the produced CP possesses a special *simplicity* property, which imposes certain restrictions on the use of tests during the computation.

Next, we introduce *straight-line programs (SLPs)* with max, +, and − operations. SLPs are a standard model of arithmetic computation [3] and they can be equivalently viewed

as arithmetic circuits consisting (in our case) of max, +, and − gates. We also consider a sub-class of SLPs with only max, + operations, so called *monotone SLPs*. We define the following *powering problem:* given a function $f\colon \mathbb{Q}^n \to \mathbb{Q}^n$ represented as an SLP, a horizon H, an initial argument $\vec{x} \in \{0,1\}^n$, and two indices $1 \leq i, j \leq n$, is it true that the i-component of $f^H(\vec{x})$, i.e. the image of $\vec{x}$ with respect to the H-fold composition of f, is greater than the j-component of $f^H(\vec{x})$? Although VI in MDPs does not necessarily involve integers, the powering problem for monotone SLPs captures the complexity inherent in iterating the recurrence (1). To obtain a reduction from CPs to SLP powering, we construct SLP gadgets with max, + and − (minus) operations to simulate the tests in CPs; the simplicity of the input CP is crucial for this reduction to work (Theorem 7). To get rid of the minus operation, we adapt a technique by Allender et al. [4], which introduces a new "offset" counter and models subtraction by increasing the value of the offset (Theorem 5).

A final step is to show a reduction from monotone SLP powering to ValIt. The reduction proceeds via an intermediate problem of *synchronizing reachability in MDPs* (maximize the probability of being in a target set of states T *after exactly* H steps [15]). This divides a rather technical reduction into more comprehensible parts. We present novel reductions from monotone SLP powering to synchronizing reachability (Theorem 4), and from the latter problem to ValIt (Theorem 2). As a by-product, we present a reduction proving **EXPTIME**-hardness of finite-horizon reachability in MDPs, arguably the conceptually simplest objective in probabilistic decision-making (Theorem 3).

Significance

As our main result, we characterize the complexity of computing an outcome of VI, one of the fundamental algorithms for solving both finite- and infinite-horizon MDPs. As a consequence, we resolve a long-standing complexity issue [27] of solving finite-horizon MDPs.

On our way to proving this result, we encounter non-trivial stepping stones which are of an independent interest. First, we shed light on the complexity of succinctly represented arithmetic circuits, showing that comparing two output wires of a given (max, +)-circuit incurs an exponential blow-up in complexity already when employing a very rudimental form of succinctness: composing a single (max, +)-circuit with H copies of itself, yielding a circuit of exponential "height" but only polynomial "width." Second, we obtain new hardness results for the bounded reachability problem in linear-update counter programs. CPs are related to several classical abstractions of computational machines, such as Minsky machines and Petri nets [25], see [13] for a recent breakthrough in this area. Our work establishes a novel connection between counter programs and MDPs.

Further Related Work

Our work is also related to a series of papers on finite-horizon planning [21, 17, 18, 23]. The survey paper [26] provides a comprehensive overview of these results. These papers consider either MDPs with a polynomially large horizon, or *succinctly* represented MDPs of possibly exponential "width" (the succinctness was achieved by circuit-encoding). The aforementioned hardness-by-succinctness proofs are often used here. The arbitrary horizon problem for standard MDPs, which we study, is left open in these papers, and our work employs substantially different techniques. The complexity of finite-horizon *decentralized* MDPs was studied in [7].

2 Markov Decision Processes and Finite-Horizon Problems

We start with some preliminaries. A *probability distribution* $d : S \to [0, 1]$ over a finite set S is a function such that $\sum_{s \in S} d(s) = 1$. We denote by $\mathcal{D}(S)$ the set of all (rational) probability distributions over S. The *Dirac* distribution on $s \in S$ assigns probability 1 to s.

A Markov decision process (MDP) $\mathcal{M} = (S, A, P, R, \gamma)$ consists of a finite set S of *states*, a finite set A of *actions*, a *transition function* $P \colon S \times A \to \mathcal{D}(S)$, a *reward function* $R : S \times A \to \mathbb{Q}$, and a *discount factor* $\gamma \in (0, 1]$. The transition function P assigns to each state s and action a a distribution over the successor states, while the reward function assigns to s and a a rational reward.

A *path* ϱ is an alternating sequence $s_0 a_1 s_1 \cdots a_n s_n$ of visited states and played actions in $\mathcal{M}$ (that starts and ends in a state); write $|\varrho| = n$ for the length of ϱ. We may use $s_0 \xrightarrow{\varrho} s_n$ to denote that path ϱ goes from s_0 to s_n. We extend the reward function R from single state-action pairs to paths by $R(\varrho) = \sum_{1 \leq i \leq n} R(s_{i-1}, a_i)\gamma^{i-1}$.

A *policy* for the controller is a function σ that assigns to each path a distribution over actions. Let $\mathbb{P}_{\mathcal{M},s,\sigma}(\varrho)$ denote the probability of a path ϱ starting in s when the controller follows the policy σ. This probability is defined inductively by setting $\mathbb{P}_{\mathcal{M},s,\sigma}(s_0) = 1$ if $s = s_0$, and $\mathbb{P}_{\mathcal{M},s,\sigma}(s_0) = 0$ otherwise. For a path $\varrho = s_0 a_1 s_1 \cdots s_{n-1} a_n s_n$, we set

$$\mathbb{P}_{\mathcal{M},s,\sigma}(\varrho) = \mathbb{P}_{\mathcal{M},s,\sigma}(s_0 \cdots s_{n-1}) \cdot \sigma(s_0 \cdots s_{n-1})(a_n) \cdot P(s_{n-1}, a_n)(s_n) \ .$$

We omit the subscripts from $\mathbb{P}_{\mathcal{M},s,\sigma}(\cdot)$ if they are clear from the context. Additionally, we extend $\mathbb{P}_{\mathcal{M},s,\sigma}(\cdot)$ to sets of paths of the same length by summing the probabilities of all the paths in the set.

In this paper, we focus on a special class of policies: A *(deterministic) Markov* policy is a function $\sigma : \mathbb{N} \times S \to A$. Intuitively, a controller following a Markov policy plays $\sigma(n, s)$ from s if it is the n-th visited state, irrespective of the other states in the path. Markov policies suffice for the problems we consider.

2.1 Finite-Horizon Problems

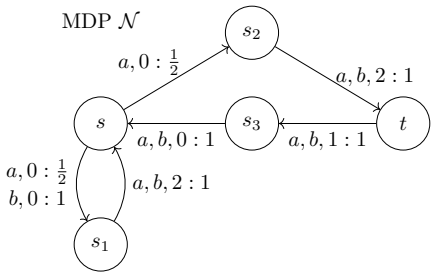
Given an MDP $\mathcal{M}$, the core problem of MDPs is computing the values of states with respect to the *maximum expected reward*. Let $\vec{v}_n \in \mathbb{Q}^S$ denote the vector of n-step maximum expected rewards obtainable from each state of the MDP. That is, for all $s \in S$ we have that

$$\vec{v}_n(s) = \max_{\sigma} \left(\sum_{|\varrho|=n} \mathbb{P}_{s,\sigma}(\varrho) \cdot R(\varrho) \right) \ .$$

Note that $\vec{v}_0 = \vec{0}$ by this definition. The vector $\vec{v}_n$ can be computed by *value iteration*, i.e. by iterating the recurrence stated in Equation (1). From that recurrence, for each $n \in \mathbb{N}$ and state s_0, one can extract an (optimal) Markov policy σ that achieves the maximum value $\vec{v}_n(s_0)$ after n steps: for each $s \in S$ and for $1 \leq i \leq n$ we have

$$\sigma(i-1, s) = \operatorname*{argmax}_{a \in A} \left\{ R(s, a) + \gamma \cdot \sum_{s' \in S} P(s, a)(s') \cdot \vec{v}_{n-i}(s') \right\} \ .$$

Papadimitriou and Tsitsiklis posed the **finite-horizon reward problem** which asks to compute such an optimal policy for the controller [27]. Formally, given an MDP $\mathcal{M}$, an initial state $s_0 \in S$, a distinguished action $a \in A$, and a horizon $H \in \mathbb{N}$ encoded in binary, the finite-horizon reward problem asks whether there exists a policy achieving $\vec{v}_H(s_0)$ by



$$\vec{v}_n(s) = \max\left(\frac{1}{4}\vec{v}_{n-1}(s_1) + \frac{1}{4}\vec{v}_{n-1}(s_2), \frac{1}{2}\vec{v}_{n-1}(s_1)\right)$$
$$\vec{v}_n(s_1) = 2 + \frac{1}{2}\vec{v}_{n-1}(s)$$
$$\vec{v}_n(s_2) = 2 + \frac{1}{2}\vec{v}_{n-1}(t)$$
$$\vec{v}_n(t) = 1 + \frac{1}{2}\vec{v}_{n-1}(s_3)$$
$$\vec{v}_n(s_3) = \frac{1}{2}\vec{v}_{n-1}(s)$$

Figure 2 The transitions are labelled with actions, rewards and their probabilities. For example, the reward of the transition from s to s_1 on action a is 0, and its probability is $\frac{1}{2}$.

choosing a as the first action from s_0. Note that this problem is equivalent to the ValIt problem defined in the introduction.

Consider the MDP $\mathcal{N}$ depicted in Figure 2 with $\gamma = \frac{1}{2}$. By iterating the indicated recurrence, we have that $\vec{v}_5(s) = \max(\frac{1}{4}\vec{v}_4(s_1) + \frac{1}{4}\vec{v}_4(s_2), \frac{1}{2}\vec{v}_4(s_1)) = \frac{41}{32}$. The value of $\vec{v}_5(s)$ is due to the second argument of max (corresponding to action b), hence a policy to maximize $\vec{v}_5(s)$ starts with b in s.

The finite-horizon reward problem can be decided by value iteration in exponential time by unfolding recurrence (1) for H steps [29], while the best known lower bound is **P**-hardness [27]. Our main result closes this long-standing complexity gap:

▶ **Theorem 1.** *The finite-horizon reward problem (and thus also the* ValIt *problem) is* **EXPTIME***-complete.*

To prove **EXPTIME**-completeness of the finite-horizon reward problem, we introduce a variant of reachability, which we call *synchronized reachability* [15]. Let $t \in S$ be a target state. For reachability, the objective is to maximize the probability of taking a path from s to t, whereas in synchronized reachability only a subset of such paths with the same length are considered.

Let $\mathcal{M}$ be an MDP, s_0 an initial state, and a an action. Define $\vec{p}_{\leq n} \in \mathbb{Q}^S$ as the vector of maximum probabilities of taking a path to t within n steps. Similarly, define $\vec{p}_{=n} \in \mathbb{Q}^S$ to be the vector of maximum probabilities of taking such a path with length exactly n. Formally, for all $s \in S$ we have that

$$\vec{p}_{\leq n}(s) = \max_{\sigma}\left(\mathbb{P}_{s,\sigma}(\{s \xrightarrow{\varrho} t : |\varrho| \leq n\})\right) \text{ and } \vec{p}_{=n}(s) = \max_{\sigma}\left(\mathbb{P}_{s,\sigma}(\{s \xrightarrow{\varrho} t : |\varrho| = n\})\right) .$$

Given a horizon H, encoded in binary, the **finite-horizon reachability problem** asks whether an optimal policy achieving $\vec{p}_{\leq H}(s_0)$ chooses action a as the first action from s_0; the **finite-horizon synchronized-reachability problem** asks whether an optimal policy achieving $\vec{p}_{=H}(s_0)$ chooses action a as the first action from s_0.

2.2 Connections Among Finite-Horizon Problems

We now prove the following theorem.

▶ **Theorem 2.** *The finite-horizon synchronized-reachability problem reduces, in polynomial time, to the finite-horizon reward problem.*

Consider an MDP $\mathcal{M}$, an initial state s_0, an action a and a target state t. The following recurrence can be used to compute $\vec{p}_{=n}(s)$:

$$\vec{p}_{=n}(s) = \max_{a \in A}\left\{\sum_{s' \in S} P(s,a)(s') \cdot \vec{p}_{=n-1}(s')\right\} , \tag{2}$$

where $\vec{p}_0(t) = 1$ and $\vec{p}_0(s) = 0$ for all $s \neq t$. We construct a new MDP $\mathcal{N}$ obtained from $\mathcal{M}$ by replacing all transitions by two consecutive transitions. The construction is such that the probability of going from s to t with a path of length n in $\mathcal{M}$ is equal to the probability of going from s to t with a path of length $2n$ in $\mathcal{N}$. More formally, for all s, s' and a with $P(s,a)(s') = p$, the transition  is replaced with  if $s = t$ and with  otherwise; where $0 < \gamma \leq 1$ is an arbitrary chosen discount factor for $\mathcal{N}$, and the intermediate state in both cases is a new state. The MDP $\mathcal{N}$ in Figure 2 is the result of applying the construction to $\mathcal{M}$ in Figure 3 with $\gamma = \frac{1}{2}$.

For the constructed MDP $\mathcal{N}$, one can show that for all states s, an action is optimal to maximize $\vec{p}_{=2H}(s)$ if and only if it is optimal to maximize $\vec{v}_{2H+1}(s)$. Consider the MDPs from Figure 2 as an example. We have previously argued that a policy maximizing $\vec{v}_5(s)$ in $\mathcal{N}$ starts with action b. Observe that the optimal first choice to maximize $\vec{p}_4(s)$ is also b. This implies that an optimal policy of $\mathcal{M}$ for synchronized-reachability with $H = 2$ starts with b, too. By the above argument, the finite-horizon synchronized-reachability problem reduces to the finite-horizon reward problem.

Hence, to obtain Theorem 1, it remains to determine the complexity of the finite-horizon synchronized-reachability problem. To this aim, we show a close connection between MDPs and a class of piecewise-affine functions represented by *straight line programs* (SLPs). Section 3 provides the details.

Finite-horizon reachability. We also show the finite-horizon synchronized-reachability problem reduces to the finite-horizon reachability problem. We remark that the natural probability-1 variants of these problems have different complexities: specifically, the problem of reaching t from s within H steps with probability 1 is in **P**; however, the analogous problem of reaching t from s in exactly H steps with probability 1 is **PSPACE**-complete [15].

▶ **Theorem 3.** *The finite-horizon synchronized reachability problem reduces, in polynomial time, to the finite-horizon reachability problem.*

3 Straight-Line Programs and The Powering Problem

We now establish the connection between MDPs and SLP powering. We start with preliminaries.

For all $n \in \mathbb{N}$, define the set $var_n := \{x_1, \ldots, x_n\}$ of variables and the collection of terms

$$\mathcal{T}_n := \{a_1 x_{j_1} + \cdots + a_n x_{j_n} + b \mid a_i, b \in \{-1, 0, 1\} \text{ and } 1 \leq j_i \leq n, \text{ for all } 1 \leq i \leq n\}.$$

A *straight-line program* (SLP) of *order* n is a sequence $c_1, \ldots, c_m$ of *commands* of the form $x \leftarrow \max(T)$, where $x \in var_n$ and $T \subseteq \mathcal{T}_n$ is non-empty. We refer to commands $x \leftarrow b$ as *initializations*. Recall that $\min(x, y) = -\max(-x, -y)$.

For complexity analyses we shall assume that T, for every command, is given explicitly as a list of terms. Each term is also assumed to be explicitly represented as a constant, a list of coefficients a_i, and a list of indices j_i, both lists having length n (i.e. the number of variables). The size of T, and also that of the command, corresponds to the length of its list of terms; the size of the SLP, the sum of the sizes of its commands.

A *valuation* ν is a vector in $\mathbb{Z}^n$, where the i-th coordinate gives the value of x_i. The semantics of a command c is a function $[\![c]\!] : \mathbb{Z}^n \to \mathbb{Z}^n$, transforming a valuation into another. An SLP $S = c_1, \ldots, c_m$ defines the function $[\![S]\!] : \mathbb{Z}^n \to \mathbb{Z}^n$ obtained by composing the

constituent commands: $[\![S]\!] = [\![c_m]\!] \circ \cdots \circ [\![c_1]\!]$. Clearly this is a piecewise-affine function. Given a function $f : \mathbb{Z}^n \to \mathbb{Z}^n$, we define its m-th power as $f^m : \mathbb{Z}^n \to \mathbb{Z}^n$ where

$$f^m = \underbrace{f \circ \cdots \circ f}_{m \text{ times}}$$

is the m-fold composition of f.

We denote by $\mathcal{T}_n^+$ the set of terms $a_1 x_{j_1} + \cdots + a_n x_{j_n} + b$ where the coefficients $a_1, \cdots, a_n, b$ are in $\{0, 1\}$. An SLP that only uses terms in $\mathcal{T}_n^+$ is called *monotone*. Note that monotone SLPs induce monotone functions from $\mathbb{Z}^n$ to $\mathbb{Z}^n$ (subtraction and min are not allowed).

3.1 The Powering Problem

For an SLP S of order n, a valuation $\nu \in \mathbb{N}^n$ and $m \in \mathbb{N}$ (encoded in binary), let $\nu' = [\![S]\!]^m(\nu)$. Given two variables $x, y \in var_n$ of the SLP, the **powering problem** asks whether $\nu'(x) \geq \nu'(y)$. Since the initial valuations ν are always non-negative, all valuations obtained by powering monotone SLPs are non-negative. The above problem is **P**-complete if the exponent m is written in unary [19].

Observe that all numbers generated by powering an SLP can be represented using exponentially-many bits in the bitsize of the exponent. It follows that the powered SLP can be explicitly evaluated in exponential time. We provide a matching lower bound in Section 4. Before that, we show the connection of SLP powering to MDPs.

3.2 Synchronized Reachability and SLP Powering

The connection is stated in the following Theorem.

▶ **Theorem 4.** *The powering problem for monotone SLPs reduces, in polynomial time, to the finite-horizon synchronized reachability problem in MDPs.*

To illustrate this reduction, let us consider the SLP S of order 2:

$$x_1 \leftarrow \max(x_1 + x_2, x_2 + x_2); \qquad x_2 \leftarrow \max(x_1 + x_1, x_1 + x_1).$$

This SLP is *normalized*, that is to say all its max commands have exactly two arguments $t_1, t_2 \in \mathcal{T}_n^+$ and furthermore t_1, t_2 have exactly two summands. (Note that focusing on normalized SLPs is no loss of generality.) We are interested in the 2-nd power of S with initial valuation $\nu(x_1) = 0$ and $\nu(x_2) = 1$. In Figure 3, two copies of S are shown on the right to visualize the concept of powering it. To obtain an MDP, we consider a set of actions $A = \{a, b\}$ and have each variable x_i become a state. In the example, s and t are the corresponding states for x_1 and x_2. The t_1, t_2 arguments of max commands determine the successors of actions a, b, respectively, where each successor has probability $\frac{1}{2}$. The command $x_1 \leftarrow \max(x_1 + x_2, x_2 + x_2)$ translates to $P(s, a)(s) = P(s, a)(t) = \frac{1}{2}$ and $P(s, b)(s) = 1$, as shown in the MDP in Figure 3. Since $\nu(x_2) = 1$, we make t a target state. Now the i-th iteration of value iteration of (2) (corresponding to the i-th step *before* the horizon) is tightly connected to the i-th power of the SLP. Indeed, letting $\nu_i = [\![S]\!]^i(\nu)$, one can prove that $\vec{p}_{=i}(s) = \frac{1}{2^i}\nu_i(s)$ and $\vec{p}_{=i}(t) = \frac{1}{2^i}\nu_i(t)$.

SLP vs. monotone SLP powering. It thus remains to provide a lower bound for the Monotone SLP powering problem. The crucial step, which we cover in Section 4, is providing lower bounds for the non-monotone variant. The remaining step from non-monotone to monotone powering can be made by adapting the techniques of Allender et al. [4].

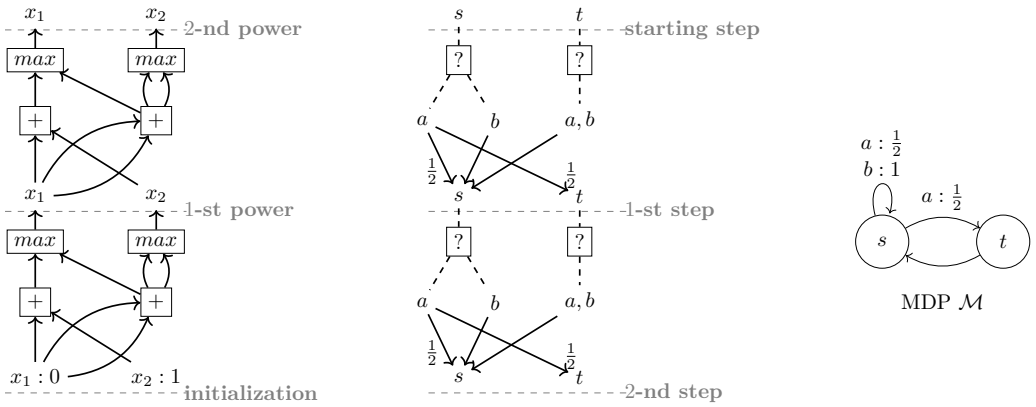


Figure 3 An example for the translation from SLPs to MDPs.

▶ **Theorem 5.** *The powering problem for arbitrary SLPs reduces, in polynomial time, to the powering problem for monotone SLPs.*

4 Main Reductions

To show **EXPTIME**-hardness of all the problems introduced so far, we introduce a class of counter programs that allow linear updates on counters and show that a (time-)bounded version of the termination problem for these programs is **EXPTIME**-complete. Finally, we reduce this bounded termination problem to the powering problem.

A *deterministic linear-update counter program* (CP) consists of n *counters* $\{c_i \mid 1 \leq i \leq n\}$, ranging over $\mathbb{Z}$, and a sequence of m instructions. We consider instructions of the form

$$p : c_1 \leftarrow c_2 + c_3 \qquad p : \texttt{if } c_1 \geq c_2 \texttt{ goto } t \qquad p : c_1 \leftarrow c_2 - c_3$$

where $1 \leq p < m$ and $1 \leq t \leq m$, and the final instruction is always $m : \texttt{halt}$. More precisely, the instructions allow

- **(i)** adding or subtracting two counters, assigning the result to a third one, and continuing to the next instruction;
- **(ii)** testing two counters against each other, and jumping to some given instruction if the result of the test is positive, continuing to the next instruction otherwise.

The `halt` instruction only loops to itself.

A *configuration* of a CP is a tuple $(p, v_1, \ldots, v_n) \in \{1, \ldots, m\} \times \mathbb{Z}^n$ consisting of an instruction p and values of the counters (e.g., v_1 is the value for the counter c_1). We equip CPs with a fixed initial configuration lying in $\{1\} \times \mathbb{N}^n$. Given a CP, the **termination problem** asks whether the `halt` instruction is reached. The **bounded termination problem** additionally takes as input an integer $N \in \mathbb{N}$, encoded in binary, and asks whether the `halt` instruction is reached within N steps.

The bounded termination problem is in **EXPTIME**: in a computation with N steps, the magnitude of the counters is bounded by 2^N, so each step can be simulated in time exponential in the bitsize of N. We will now show that the problem is **EXPTIME**-hard already for a certain subclass of CPs which facilitates the reductions to the powering problem.

Simple counter programs. A CP is *simple* if it satisfies the following conditions. First, all values in all reachable configurations $(p, v_1, \ldots, v_n)$ are non-negative: $v_i \in \mathbb{N}$ for all $1 \leq i \leq n$ (one may "guard" subtractions by test instructions to achieve this). Second, all test

instructions $q : \texttt{if } c_i \geq c_j \texttt{ goto } r$ use counters c_1 and c_2 exclusively. Moreover, for each such instruction q, there are counters $c_{\bar{q}_1}, c_{\bar{q}_2}$ such that in all reachable configurations $(q, v_1, \ldots, v_n)$ we have that

1. $v_1 = a_1 v_{\bar{q}_1}$ and $v_2 = a_2 v_{\bar{q}_2}$ with $a_1, a_2 \in \{64, 64 \cdot 10, 64 \cdot 12\}$. That is, the values of tested counters are "scaled-up" versions of the values of other counters.
2. Additionally, the absolute difference of the values of the tested counters is larger than the values of all other counters, in symbols $|v_1 - v_2| \geq \max\{v_k \mid 3 \leq k \leq n\}$.

Note that the class of simple CPs is a semantically defined subclass of all CPs. Further observe that for every test instruction we necessarily have that $\bar{q}_1, \bar{q}_2 \geq 3$.

The following proposition kick-starts our sequence of reductions.

▶ **Proposition 6.** *The bounded termination problem for simple CPs is* **EXPTIME***-complete.*

To prove the proposition, we follow the classical recipe of first simulating a Turing machine using a machine with two stacks, and then simulating the two-stack machine by a CP. We note two key differences between our construction and the classical reduction: (1) We use the expressiveness of linear updates in CPs to simulate pushing and popping on the stack in a linear number of steps of the CP. (2) We instrument the two-stack machine to ensure that the height of the two stacks differs by at most 1 along any computation. This is crucial to allow us to simulate the two-stack machine by a *simple* linear-update counter program.

4.1 From the Termination Problem to the Powering Problem

We now sketch the main ideas behind the last (and most technically involved) missing link in our sequence of reductions.

▶ **Theorem 7.** *The bounded termination problem for simple CPs reduces, in polynomial time, to the powering problem for SLPs.*

The encoding. Given a CP $\mathcal{C}$ we construct an SLP S of order $\geq 2n$ with variables including $\{x_1, \ldots, x_{2n}\}$. Let us denote x_{n+i} by Q_i for $1 \leq i \leq n$. The reduction is such that a configuration $(p, v_1, \ldots, v_n)$ of $\mathcal{C}$ is encoded as a valuation $\nu : var_{2n} \to \mathbb{Z}$ of the SLP with the property that $\nu(x_i) = v_i$ and $\nu(Q_i) = p\nu(x_i) = pv_i$ for all $1 \leq i \leq n$. In this way, the instruction p of the CP is encoded in the variables of the SLP (recall that SLPs are stateless).

Given this encoding, the main challenge is to realize the transition function of the CP as a function computed by an SLP. Once this is accomplished, for every $m \in \mathbb{N}$, the m-th power of the SLP S represents the m-step transition function of the CP.

Conditional commands. Intuitively, to encode the transition function we would like to equip the SLP with *conditional commands*, whose execution depends on a conditional. Specifically, we want to implement the following two kinds of conditional updates

$$(y \leftarrow y \pm x_k \text{ if } Q_k = px_k) \quad \text{and} \quad (Q_k \leftarrow p \cdot x_k \text{ if } x_i \geq x_j)$$

in terms of primitive commands of an SLP. In both commands, if the condition is not satisfied, the command is not executed, and the value of y or Q_k remains unchanged. For example, one can simulate the first type of conditional commands by executing $y \leftarrow y \pm \max(0, x_k + t)$, where t is an expression that is 0 if the test is passed and less than $-x_k$ otherwise. Intuitively, we think of t as "masking" the assignment if the test fails.

For the following result, which formalizes how we implement conditional commands, we call a valuation ν *valid* if there exists $q \in \{1, \ldots, m\}$ with $\nu(x_i) \geq 0$ and $\nu(Q_i) = q\nu(x_i)$ for all $1 \leq i \leq n$.

▶ **Lemma 8.** *Let $p \in \{1, \ldots, m\}$ and $i, j, k \in \{1, \ldots, n\}$ be distinct. The following equation holds for all valid valuations ν:*

$$\max(0, \nu(x_k) + \min(\nu(Q_k) - p\nu(x_k), p\nu(x_k) - \nu(Q_k))) = \begin{cases} \nu(x_k) & \text{if } \nu(Q_k) = p\nu(x_k) \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

Moreover, if $|\nu(x_i) - \nu(x_j)| \geq \nu(x_k)$, then the following holds:

$$\max(0, \nu(x_k) + \min(0, \nu(x_i) - \nu(x_j))) = \begin{cases} \nu(x_k) & \text{if } \nu(x_i) \geq \nu(x_j) \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

Proof. The equations follow directly from the assumption that ν is valid, since if $\nu(Q_j) \neq p\nu(x_j)$ then we also have $|\nu(Q_j) - p\nu(x_j)| \geq \nu(x_j)$. In addition, if $|\nu(x_i) - \nu(x_j)| \geq \nu(x_k)$ and $\nu(x_i) < \nu(x_j)$, we will have $\nu(x_k) + \nu(x_i) - \nu(x_j) \leq 0$. ◀

Using the property that the simulated program is simple, Equation (3) can be used to simulate the conditional update ($y \leftarrow y \pm x_k$ if $Q_k = px_k$) where $t = \min(Q_k - px_k, px_k - Q_k)$ masks the update. Likewise, Equation (4) can be used to simulate the second type of conditional update ($Q_k \leftarrow p \cdot x_k$ if $x_i \geq x_j$) where the masking expression is $t = \min(0, x_i - x_j)$. Finally, the multiplication-by-a-constant required for the second type of the conditional update is achieved via repeated addition.

Encoding the instructions. We recall that we encode being at the instruction p of the CP by a valuation ν such that $\nu(Q_i) = p\nu(x_i)$ for all $1 \leq i \leq n$.

Using the aforementioned conditional commands, we can construct the SLP S as the composition of m smaller SLPs. Each sub-SLP π_p simulates an instruction p from the given CP $\mathcal{C}$. Hence S, when applied upon a valid valuation ν (i.e., a properly-encoded configuration of $\mathcal{C}$), simulates all of its instructions at once. By using conditional commands, we make sure that only one sub-SLP results in a non-zero update: executing π_p has no effect on the valuation unless $p\nu(x_i) = \nu(Q_i)$ for all $1 \leq i \leq n$.

In this way, powering S allows us to simulate consecutive steps of $\mathcal{C}$. In particular, for all $N \in \mathbb{N}$ we have that $[\![S]\!]^N(\nu)(Q_1) \geq m \cdot [\![S]\!]^N(\nu)(x_1)$, where m is the *halt* instruction, holds if and only if $\mathcal{C}$ halts after at most N steps.

5 Conclusion

By the virtue of our chain of reductions (see Figure 1), we get the following theorem.

▶ **Theorem 9.** *All the following problems are* **EXPTIME***-complete:*

- *The finite-horizon reward problem for MDPs, and thus also the* ValIt *problem.*
- *The finite-horizon reachability and synchronized reachability problems for MDPs.*
- *The powering problem for SLPs and for monotone SLPs.*
- *The bounded termination problem for simple counter programs.*

The exact complexity of the following variant of the problem remains open: given an MDP and a horizon encoded in binary, determine whether there exists a policy achieving some given expected-reward threshold (with no restriction on the actions used to do so).

Abstract

Monadic decomposibility – the ability to determine whether a formula in a given logical theory can be decomposed into a boolean combination of monadic formulas – is a powerful tool for devising a decision procedure for a given logical theory. In this paper, we revisit a classical decision problem in automata theory: given a regular (a.k.a. synchronized rational) relation, determine whether it is recognizable, i.e., it has a monadic decomposition (that is, a representation as a boolean combination of cartesian products of regular languages). Regular relations are expressive formalisms which, using an appropriate string encoding, can capture relations definable in Presburger Arithmetic. In fact, their expressive power coincide with relations definable in a universal automatic structure; equivalently, those definable by finite set interpretations in WS1S (Weak Second Order Theory of One Successor). Determining whether a regular relation admits a recognizable relation was known to be decidable (and in exponential time for binary relations), but its precise complexity still hitherto remains open. Our main contribution is to fully settle the complexity of this decision problem by developing new techniques employing infinite Ramsey theory. The complexity for DFA (resp. NFA) representations of regular relations is shown to be NLOGSPACE-complete (resp. PSPACE-complete).

1 Introduction

Monadic decompositions for computable relations have been studied in many different guises, and applied to many different problem domains, e.g., see [17, 25, 38, 12, 27, 28, 37]. The notion of "monadic decomposability" essentially captures the intuitive notion that the components in a given n-ary relation $R \subseteq U^n$ are sufficiently independent from (i.e. not tightly coupled, or interdependent, with) each other. Some examples are in order. Given two subsets $X, Y \subseteq U$, then $X \times Y$ is an instance of relations whose two components are completely independent from each other. On the other hand, the equality relation $\{(x, x) : x \in U\}$ is an example of relations whose two components are tightly coupled. In this paper, we will adopt the commonly studied notion of component-independence[1] (e.g. [25, 38, 7, 37]) in a relation $R \subseteq U^n$ that lies between the extremes as exemplified in the above examples, i.e., that R is expressible as a *finite union* $\bigcup_{i=1}^{r} X_{i,1} \times \cdots \times X_{i,n}$ of products, where each $X_{i,j}$ is expressible in the same language $\mathcal{L}$ (e.g. a logic or a machine model) wherein R is expressed.

Why should one care about monadic decomposable relations? The main reason is that applying appropriate monadic restrictions could make an undecidable problem decidable, and in general turn a difficult problem into one more amenable to analysis. Several examples are in order. Firstly, the well-known cartesian abstractions in abstract interpretation [17] overapproximate the set $R \subseteq U^n$ of reachable states at a certain program point by a relation $R' \subseteq X_1 \times \cdots \times X_m$ such that $R \subseteq R'$. Having R' instead of R sometimes allows a static analysis tool to prove correctness properties about a program that is otherwise difficult to do with only R. Another example includes restrictions to monadic predicates in undecidable logics that result in decidability, e.g., monadic first-order logic and extensions ([9, 10, 4]), as well as monadic second-order theory of successors [10]. Monadic decomposability also found applications in more efficient variable elimination in constraint logic programming (e.g. [23]), as well as constraint processing algorithms for constraint database queries (e.g. [25, 24]). Finally, monadic decompositions in the context of SMT (Satisfiability Modulo Theories), whose study was recently initiated in [38], have numerous applications, including constraint solving over strings [38, 14].

The focus of this paper is to revisit a classical problem of determining monadic decomposability of *regular relations*, which are also known as *synchronized rational relations* [20, 6, 8]. The study of classes of relations over words definable by different classes of multi-tape (finite) automata is by now a well-established subfield of formal language theory. This study was initiated by Elgot, Mezei, and Nivat in the 1960s [18, 30]; also see the surveys [7, 15]. In particular, we have a strict hierarchy of classes of relations as follows: recognizable relations, synchronized rational relations, deterministic rational relations, and rational relations. All these classes over unary relations (i.e. languages) coincide with the class of regular languages. *Rational relations* are relations $R \subseteq (\Sigma^*)^n$ definable by multi-tape automata, where the tape heads move from left to right (in the usual way for finite automata) but possibly at different speeds (e.g. in a transition, the first head could stay at the same position, whereas the second head moves to the right by one position). *Deterministic rational relations* are simply those rational relations that can be described by deterministic multi-tape automata. So far, the heads of the tapes can move at different speeds. *Regular relations* (a.k.a. *synchronized rational relations*) are those relations that are definable by multi-tape automata, all of whose heads move to the right in each transition. Unlike (non)deterministic rational relations, regular relations are extremely well-behaved, e.g., they are closed under first-order operations

[1] Also called variable-independence.

and, therefore, have decidable first-order theories [22]. Regular relations are also known to coincide with those relations that are first-order definable over a universal automatic structure [6, 8]; equivalently, those relations that are definable by finite-set interpretations in the weak-monadic theory of one successor (WS1S) [16]. Finally, the weakest class of relations in the hierarchy are *recognizable relations*: those relations that are definable as a finite union of products of regular languages or, equivalently, relations that can be defined as a boolean combination of regular constraints (i.e. atomic formulas of the form $x \in L$, where L is a regular language, asserting that the word x is in L). Recognizable relations are, therefore, those relations definable by multi-tape automata that exhibit monadic decomposability.

One of the earliest results on deciding whether a relation is monadic decomposable follows from Stearns in 1967 [33] and the characterization of a binary relation $R \subseteq A^* \times B^*$ by $L_R = \{\mathsf{rev}(u)\#v \mid (u, v) \in R\}$, where $\mathsf{rev}(u)$ is the mirror image of u. In [12] it was proven that L_R is a regular language if and only if R has a monadic decomposition and if R is a deterministic rational relation, then L_R is a deterministic context-free language. Due to this characterization, Stearns's result implies that whether a deterministic n-ary rational relation is monadic decomposable (i.e. recognizable) is decidable in the case when $n = 2$. Shortly thereafter, Fischer and Rosenberg [19] showed that the same problem is unfortunately undecidable for the full class of binary rational relations. A few years later Valiant [37] improved the upper bound complexity for the case solved by Stearns to double exponential-time. This is still the best known upper bound for the monadic decomposability problem for deterministic binary rational relations to date and, furthermore, no specific lower bounds are known. More recently Carton *et al.* [12] adapted the techniques from [33, 37] to show that this decidability extends to general n-ary relations, though no complexity analysis was provided. The problem of monadic decomposability for regular relations has also been studied in the literature. Of course decidability with a double exponential-time upper bound for the binary case follows from [37]. In 2000 Libkin [25] gave general conditions for monadic decomposability for first-order theories, which easily implies decidability for monadic decomposability for general k-ary regular relations. This is because regular relations are simply those relations that are definable in a universal automatic structures [6, 8]. The result of Libkin was not widely known in the automata theory community and in fact the problem was posed as an open problem in French version of [31] in 2003 and later on, Carton *et al.* [12] provided a double-exponential-time algorithm for deciding whether an n-ary regular relation is monadic decomposable. More precisely, even though it was claimed in the paper that the algorithm runs in single-exponential time, it was noted in a recent paper by Löding and Spinrath [27, 28] (with which the authors of [12] also agreed, as claimed in [28]) that the algorithm actually runs in double-exponential time. Löding and Spinrath [27, 28] gave a single-exponential-time algorithm (inspired by techniques from [37]) for monadic decomposability of *binary* regular relations.

Contributions

In this paper we provide the precise complexity of monadic decomposability of regular relations, closing the open questions left by Carton *et al.* [12] and Löding and Spinrath [27, 28]. In particular, we show the following.

▶ **Theorem 1.** *Deciding whether a given regular relation R is monadic decomposable is* NLOGSPACE*-complete (resp.* PSPACE*-complete), if R is given by a DFA (resp. an NFA).*

The lower bounds hold already for binary relations (Lemma 5 and Lemma 6 in Section 3). To prove the upper bounds, we first prove the upper bounds for binary relations (Lemma 10 in Section 4) and then extend them to n-ary relations for any given $n > 2$ (Lemma 11 in Section 5).

The existing proof techniques (e.g. in [12, 28, 25]) for deciding monadic decomposability typically aim for finding proofs that the relations are monadic decomposable. In contrast, our proof technique relies on finding a proof that a relation is *not* monadic decomposable. As a brief illustration, suppose we want to show that the regular relation $R = \{(v, v) : v \in \Sigma^*\}$ is not monadic decomposable. We define an equivalence relation $\sim \subseteq \Sigma^* \times \Sigma^*$ as

$$x \sim y := \forall z([R(x, z) \leftrightarrow R(y, z)] \wedge [R(z, x) \leftrightarrow R(z, y)]).$$

This relation is regular since regular relations are closed under first-order operations [31] (a fact that was also used in [12]), but the size of the automaton for this relation is unfortunately quite large; see [27] for detailed discussion. Therefore, we will only use the complement $\not\sim$, which has a substantially smaller representation: polynomial (resp. exponential) size if R is given as a DFA (resp. an NFA). Now, that R is not monadic decomposable amounts to the existence of an ω-sequence $\sigma = \{v_i\}_{i\in\mathbb{N}}$ of words such that $v_i \not\sim v_j$ for each pair $i, j \in \mathbb{N}$. By applying the pigeonhole principle and König's lemma, we will first construct a nicer sequence α (see the top half of Figure 2) and then by exploiting Ramsey Theorem over infinite graphs, we will show that there is an even nicer sequence α' (see the bottom half of Figure 2), where the automaton for $\not\sim$ synchronizes its states in particular points of the computation, no matter which pair of words from the sequence is being read. Moreover, we prove that one of the synchronizing states has a pumping property. This leads to our NLOGSPACE algorithm as we can guess the synchronizing states and verify that there is an accepting run that can be pumped. This technique was inspired by a technique for proving recurrent reachability in regular model checking [34, 35].

The exponential-time upper bound for the binary case from Löding and Spinrath [28] (which is inspired by the techniques used by Stearns [33] and Valiant [37]) relied on characterization of a relation R using the language $L_R = \{\mathsf{rev}(u)\#v \mid (u, v) \in R\}$ and used a suitable machinery that is able to decide whether L_R is regular or not. Their result is not easily extensible to n-ary relations as the encoding of a binary rational relation as a context-free language L_R does not generalize to n-ary relations. In Section 5, we show that proving monadic decomposability for an n-ary regular relation is LOGSPACE-reducible to testing whether linearly many induced binary relations are monadic decomposable.

We conclude in Section 6 with some perspectives from formal verification and a future research direction. The proofs omitted due to length constraints can be found in [5].

2 Preliminaries

A finite alphabet is denoted by Σ and the free monoid it generates by Σ^*. That is, Σ^* consists of all finite words over Σ. The empty word is ε. We denote by $|w|$ the length of word $w \in \Sigma^*$. We have that $|\varepsilon| = 0$. The word $u \in \Sigma^*$ is a *prefix* of $w \in \Sigma^*$ if $w = uv$ for some $v \in \Sigma^*$. We denote this by $u \leq w$. We also write $v = u^{-1}w$, when u is a prefix of w, to state that v is the suffix of w that is obtained after prefix u is removed. Sometimes we want to consider a suffix of w after a prefix of particular length is removed without specifying the actual prefix as defined above. To this end, we define partial function $\sigma : \Sigma^* \times \mathbb{N} \to \Sigma^*$ such that $\sigma(w, i) = v$, where $w = uv$ for some $u \in \Sigma^*$ such that $|u| = i$. In particular, for $u \leq w$, $\sigma(w, |u|) = u^{-1}w$. Similarly, we define partial function $\tau : \Sigma^* \times \mathbb{N} \to \Sigma^*$ such that $\tau(w, i) = u$, where $|u| = i$ and $u \leq w$.

In this paper we study relations $R \subseteq \Sigma^* \times \cdots \times \Sigma^*$ with particular structural properties. Namely, *monadic decomposable* relations that are a finite union of direct products of regular languages, and *regular* relations defined by n-tape finite automata, where the heads move in synchronized manner. See, for example, [31] for more details on such relations.

▶ **Definition 2.** *An n-ary relation $R \subseteq \Sigma^* \times \cdots \times \Sigma^*$ is a* monadic decomposable *relation iff it is of the form $\bigcup_{i=1}^{m}(X_{1,i} \times \cdots \times X_{n,i})$, where m is finite and each $X_{j,i} \subseteq \Sigma^*$ is a regular language.*

As mentioned earlier, this can be intuitively seen as the components of R being independent in some sense. Note that in the literature, monadic decomposable relations are sometimes called *recognizable*. The monadic decomposable relations can be defined using multi-tape automata as is done, e.g., in [12]. The above definition is more suitable for our considerations.

Let $\perp$ be a fresh symbol not found in Σ. We use it to pad words in a relation $R \subseteq \Sigma^* \times \cdots \times \Sigma^*$ in order for each component to be of the same length. Formally, a tuple $(w_1, \ldots, w_n)$ is transformed into $(w_1\perp^{\ell_1}, \ldots, w_n\perp^{\ell_n})$, where $\ell_i = -|w_i| + \max_{1\leq j\leq n}|w_j|$ for each $i = 1, \ldots, n$. We extend this to the relation $R_\perp$ in the expected way. We also denote $\Sigma \cup \{\perp\}$ by $\Sigma_\perp$. An *n-tape automaton over alphabet $\Sigma_\perp$* is a tuple $(Q, \rightarrow_{\mathcal{A}}, q_0, F)$, where Q is the finite set of states, q_0 is the initial state, F is the set of final states, and $\rightarrow_{\mathcal{A}} \subseteq Q \times (\Sigma_\perp)^n \times \mathcal{P}(Q)$.

▶ **Definition 3.** *An n-ary relation $R \subseteq \Sigma^* \times \cdots \times \Sigma^*$ is* regular *iff $R_\perp$ is recognized by some n-tape automaton $\mathcal{A}_\perp$ over alphabet $\Sigma_\perp$.*

That is, in a regular relation the n heads of the automaton are moving in synchronized manner and the n-tuple of symbols seen determines the state transition. Naturally, the state transition can be deterministic or non-deterministic. We say that a regular relation is defined by an NFA if the underlying n-tape automaton is non-deterministic, otherwise we say that the relation is defined by a DFA. Note that in the literature, regular relations are sometimes called *synchronous rational* or *automatic* relations.

We recall a useful characterization from [12]. Consider an n-ary regular relation $R \subseteq \Sigma^* \times \cdots \times \Sigma^*$. For each $j = 1, \ldots, n-1$, let $\sim_j$ be the following induced equivalence relation:

$$\begin{aligned}(u_1, \ldots, u_j) \sim_j (v_1, \ldots, v_j) := \forall(w_{j+1}, \ldots, w_n) \in \Sigma^* \times \cdots \times \Sigma^* \text{ we have that}\\ (u_1, \ldots, u_j, w_{j+1}, \ldots, w_n) \in R \iff (v_1, \ldots, v_j, w_{j+1}, \ldots, w_n) \in R \text{ and}\\ (w_{j+1}, \ldots, w_n, u_1, \ldots, u_j) \in R \iff (w_{j+1}, \ldots, w_n, v_1, \ldots, v_j) \in R.\end{aligned}$$

▶ **Lemma 4** ([12])**.** *The n-ary regular relation R is monadic decomposable iff $\sim_j$ has finite index for each $j = 1, \ldots, n-1$. That is, there are finitely many equivalence classes over $\sim_j$.*

In other words, R is not monadic decomposable iff for some $j = 1, \ldots, n-1$, there is an infinite sequence $\{u_i\}_{i\geq 0}$, where each u_i is a j-tuple of words, such that for each $0 \leq i < \ell$ it is the case that $u_i \neq u_\ell$ and $u_i \not\sim_j u_\ell$.

In Section 4, we focus on binary relations for which we simplify the notation as there is only one possible value of j. We write $\sim$ instead of $\sim_j$ and $R^{\not\sim}$ for the binary regular relation

$$\begin{aligned}R^{\not\sim}(w, w') := \exists u \big((R(w, u) \wedge \neg R(w', u)) \vee (\neg R(w, u) \wedge R(w', u)) \vee\\ (R(u, w) \wedge \neg R(u, w')) \vee (\neg R(u, w) \wedge R(u, w'))\big).\end{aligned}$$

That is, $R^{\not\sim}$ consists of all words $w, w' \in \Sigma^*$ for which there exists a word $u \in \Sigma^*$ such that one of $R(w, u)$ and $R(w', u)$ is accepted while the other is not, or one of $R(u, w)$ and $R(u, w')$ is accepted while the other is not.

We assume that the reader is familiar with complexity classes and logarithmic space reductions via logarithmic space transducers; see for example [32].

3 Hardness of deciding monadic decomposability of regular relations

In this section, we consider binary regular relations given by NFA and provide a PSPACE lower bound for deciding if such a relation is monadic decomposable. Then, we prove that the same problem for DFA is NLOGSPACE-hard.

▶ **Lemma 5.** *The problem of deciding whether a binary regular relation given by an NFA is monadic decomposable is* PSPACE*-hard.*

Proof. We give a logarithmic space reduction from the universality problem for NFA, which is PSPACE-hard [29]. Recall that in this problem, we are asked to decide whether $L(\mathcal{A}) = \Sigma^*$ given an NFA $\mathcal{A}$ over Σ.

Let $\mathcal{A}$ be an NFA over alphabet Σ, and let $\{\#\}$ be a fresh symbol that we will use as a separator symbol. We assume that $\# \neq \bot$. We construct relation $R = R_1 \cup R_2$ using the language L of $\mathcal{A}$, where

$$R_1 = \{(u, u) \mid u \in (\Sigma \cup \{\#\})^*\} \qquad \text{and} \qquad R_2 = (L \cdot \{\#\})^* \times (\Sigma^* \cdot \{\#\})^*.$$

Intuitively, R_1 contains all pairs (w_1, w_2) such that $w_1 = w_2 = u_0\#u_1\# \cdots \#u_n\#$, where $u_i \in \Sigma^*$, and R_2 contains all pairs (w_1, w_2) such that $w_1 = v_0\#v_1\# \cdots \#v_m\#$, where $v_i \in L$, and $w_2 = u'_0\#u'_1\# \cdots \#u'_n\#$, where $u'_i \in \Sigma^*$. It is easy to construct an NFA that recognizes R in LOGSPACE. Next we show that $L = \Sigma^*$ iff R is monadic decomposable.

Assume first that $L = \Sigma^*$. Then $R_1 \subseteq R_2$, and thus $R = (\Sigma^* \cdot \{\#\})^* \times (\Sigma^* \cdot \{\#\})^*$ which has a trivial monadic decomposition.

For the other direction, assume that R is monadic decomposable, i.e., $R = \bigcup_{i=1}^{n}(A_i \times B_i)$ for some regular languages A_i, B_i. Let $w \in \Sigma^*$. We show that $w \in L$ as well. Consider a set $\{((w\#)^i, (w\#)^i) \mid i = 1, \ldots, n+1\} \subseteq R_1 \subseteq R$. By the pigeonhole principle, there are two elements $((w\#)^j, (w\#)^j)$ and $((w\#)^k, (w\#)^k)$ that belong to the same component of $\bigcup_{i=1}^{n}(A_i \times B_i)$, say to $A_1 \times B_1$. Therefore, $(w\#)^j \in A_1$ and $(w\#)^k \in B_1$, and hence their direct product, $((w\#)^j, (w\#)^k)$, is in $A_1 \times B_1 \subseteq R$. Recall that $R = R_1 \cup R_2$. Clearly, $((w\#)^j, (w\#)^k) \notin R_1$ as the lengths of the two words are different. It follows that $((w\#)^j, (w\#)^k) \in R_2$ and hence $(w\#)^j \in (L \cdot \{\#\})^*$. This implies that $w \in L$. ◀

▶ **Lemma 6.** *The problem of deciding whether a binary regular relation given by a DFA is monadic decomposable is* NLOGSPACE*-hard.*

The proof is straightforward by a reduction from reachability problem for directed acyclic graphs.

4 Deciding monadic decomposability of binary regular relations

In this section we prove our main technical result.

▶ **Lemma 7.** *There is an* NLOGSPACE *algorithm that takes as input an NFA for $R^{\curlywedge}$, where R is a binary regular relation, and decides whether R is monadic decomposable.*

We start by defining some notation. We assume any binary regular relation $R^{\curlywedge}$ to be given as an NFA with set of states Q. The *$R^{\curlywedge}$-type* of a pair (w_1, w_2) of words over Σ is an element of the *transition monoid*. Recall that the transition monoid transforms any given state $q \in Q$ to a set $Q' \subseteq Q$ of states when reading (w_1, w_2). We denote this by $R^{\curlywedge}_{w_1,w_2}(q)$ for each $q \in Q$. We write $\mathsf{types}(R^{\curlywedge})$ for the set of all $R^{\curlywedge}$-types.

Consider an infinite sequence $\{w_i\}_{i\geq 0}$ of words over Σ as defined in Lemma 4. Additionally, we assume that the words in the sequence are of strictly increasing length and that for each $i > 0$ the words w_i and w_{i+1} have a common prefix of length $|w_{i-1}|$. That is, w_i can be written as $\beta_0 \cdots \beta_{i-1}\alpha_i$, where each β_j and α_i is a non-empty word. To simplify notation, we denote $\rho(w_i) = \beta_0 \cdots \beta_i$. That is, $\rho(w_i)$ is of length $|w_i|$ and is a prefix of w_j, for each $0 \leq i < j$. We will show how to construct such sequence in Proposition 8. The words w_i, w_j and w_k are illustrated in the top of Figure 1.

With each pair (i, j), where $i < j$, we associate the following quinary tuple over $\mathsf{types}(R^\asymp)$:

$$\mathfrak{C}_{i,j} \;=\; \big(\, R^\asymp_{w_i,\rho(w_i)},\; R^\asymp_{\rho(w_i),\rho(w_i)},\; R^\asymp_{\sigma(w_j,|w_i|),\sigma(\rho(w_j),|w_i|)},\; R^\asymp_{\varepsilon,\sigma(w_j,|w_i|)},\; R^\asymp_{\varepsilon,\sigma(\rho(w_j),|w_i|)} \,\big).$$

Intuitively, the first component corresponds to the computation of $(\beta_0 \cdots \beta_{i-1}\alpha_i, \beta_0 \cdots \beta_{i-1}\beta_i)$, the second to $(\beta_0 \cdots \beta_{i-1}\beta_i, \beta_0 \cdots \beta_{i-1}\beta_i)$ needed in order to compute the third component, $(\beta_{i+1} \cdots \beta_{j-1}\alpha_j, \beta_{i+1} \cdots \beta_{j-1}\beta_j)$. The final two components are used to compute the set of states reachable after the whole word in the first component is read. That is $(\bot^{|\beta_{i+1}\cdots\beta_{j-1}\alpha_j|}, \beta_{i+1} \cdots \beta_{j-1}\alpha_j)$ and $(\bot^{|\beta_{i+1}\cdots\beta_{j-1}\beta_j|}, \beta_{i+1} \cdots \beta_{j-1}\beta_j)$. See Figure 1 for a pictorial depiction.

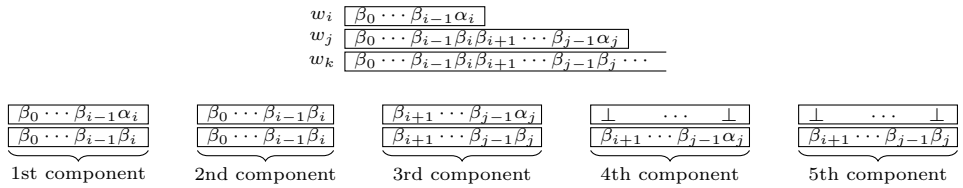

Figure 1 Correspondence between components of $\mathfrak{C}_{i,j}$ and parts of computation on w_i, w_j and w_k, where $i < j < k$.

We can then establish the following important proposition. Consider an infinite sequence of words that are pairwise from different equivalence classes as in Lemma 4. We show next that we can extract an infinite subsequence with additional structural properties. Perhaps the most important property is that $\mathfrak{C}_{i,j}$ is the same for all i, j. This subsequence will allow us to prove the main lemma.

▶ **Proposition 8.** *A binary regular relation R over $\Sigma^* \times \Sigma^*$ is not monadic decomposable iff there are infinite sequences $\{u_i\}_{i\geq 0}$, $\{\gamma_i\}_{i\geq 0}$, and $\{\delta_i\}_{i\geq 0}$ of words over Σ and a quinary tuple $\mathfrak{C}$ over $\mathsf{types}(R^\asymp)$ such that for each $i \geq 0$ it is the case that*

1. $|\gamma_i| = |\delta_i| > 0$,
2. $u_i = \delta_0 \cdots \delta_{i-1}\gamma_i$,
3. $(u_i, u_j) \in R^\asymp$, *for each* $j > i$, *and*
4. $\mathfrak{C}_{i,j} = \mathfrak{C}$, *for each* $j > i$.

Proof. By Lemma 4, the existence of such sequences directly implies that the relation is not monadic decomposable. Assume then that R is not monadic decomposable. By Lemma 4, there exists a sequence $\{v_i\}_{i\geq 0}$ such that $R^\asymp(v_j, v_\ell)$ for all $j \neq \ell$. It remains to show how to construct the three sequences satisfying the additional properties from $\{v_i\}_{i\geq 0}$. First, we construct an auxiliary sequence $\{w_i\}_{i\geq 0}$ in the following way. Let v_j be the first non-empty word of $\{v_i\}_{i\geq 0}$. Denote $v_j = w'_0 = \alpha_0$. Consider prefixes of v_i of length $|\alpha_0|$. Since $|\alpha_0|$ is finite and the sequence is infinite, there exists a prefix that appears infinitely often by the pigeonhole principle. Denote this prefix by β_0. Now we consider an infinite subsequence

$\{w'_i\}_{i\geq 0}$ of $\{v_i\}_{i\geq 0}$ where $w'_0 = v_j$ and w'_i, where $i > 0$, has β_0 as the proper prefix. We can write $w'_1 = \beta_0\alpha_1$ and repeat the procedure. By König's Lemma, we can always repeat the procedure and obtain the desired auxiliary sequence $\{w_i\}_{i\geq 0}$ in the limit.

From Infinite Ramsey's Theorem, there is an infinite sequence $0 \leq \ell_0 < \ell_1 < \cdots$ and a tuple $\mathfrak{C} \in \mathsf{types}(R^\curlywedge)^5$ such that for each $0 \leq i < j$ we have $\mathfrak{C}_{\ell_i,\ell_j} = \mathfrak{C}$. Namely, we consider a complete infinite graph with natural numbers as vertices. An edge between vertices i and j is coloured with $\mathfrak{C}_{i,j} \in \mathsf{types}(R^\curlywedge)^5$. Now there is an infinite clique coloured with $\mathfrak{C}$ which gives us our infinite sequence $0 \leq \ell_0 < \ell_1 < \cdots$.

We then define the u_is, γ_is, and δ_is, for $i \geq 0$, as follows.

- $\gamma_0 = w_{\ell_0}$ and γ_{i+1}, for $i > 0$, is the word $\sigma(w_{\ell_{i+1}}, |w_{\ell_i}|)$.
- δ_i is defined as $\rho(\gamma_i)$.
- $u_i = \delta_0 \cdots \delta_{i-1}\gamma_i$, for each $i \geq 0$.

It is easy to see then that $u_i = w_{\ell_i}$ and $\rho(u_i) = \delta_0 \cdots \delta_{i-1}\delta_i = \rho(w_{\ell_i})$, for each $i \geq 0$. Therefore, $\{u_i\}_{i\geq 0}$, $\{\gamma_i\}_{i\geq 0}$, $\{\delta_i\}_{i\geq 0}$, and $\mathfrak{C}$ satisfy the conditions in the statement of the proposition. See Figure 2 for a pictorial depiction of the construction. ◀

In other words, by Proposition 8, there is a sequence $\{u_i\}_{i\geq 0}$ and a $\mathfrak{C}$ such that for each i, j, the runs on $R^\curlywedge$ are synchronized after (γ_i, δ_i), (δ_i, δ_i), $(\delta_i^{-1}\gamma_j, \delta_i^{-1}\delta_j)$, $(\varepsilon, \delta_i^{-1}\gamma_j)$ and $(\varepsilon, \delta_i^{-1}\delta_j)$ have been read. In particular, the runs are synchronized in states of $R^\curlywedge_{\gamma_i,\delta_i}$, $R^\curlywedge_{\delta_i,\delta_i}$, $R^\curlywedge_{\delta_i^{-1}\gamma_j,\delta_i^{-1}\delta_j}$, $R^\curlywedge_{\varepsilon,\delta_i^{-1}\gamma_j}$ and $R^\curlywedge_{\varepsilon,\delta_i^{-1}\delta_j}$, respectively.

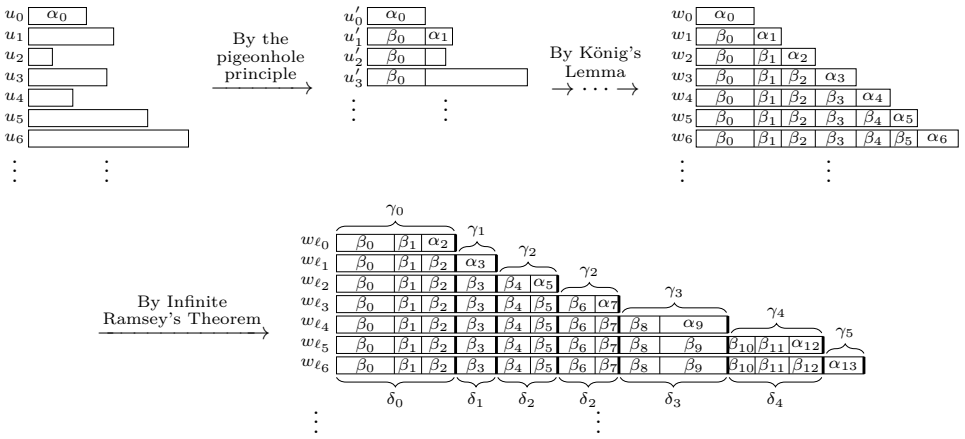

Figure 2 An illustration of construction of sequence $\{u_i\}_{i\geq 0}$ of Proposition 8 in two steps. Here $R^\curlywedge(u_i, u_j)$, $R^\curlywedge(u'_i, u'_j)$ and $R^\curlywedge(w_i, w_j)$ for every $i \neq j$. Moreover as $\mathfrak{C} = \mathfrak{C}_{i,j}$, the sets of states reachable after each δ_i and γ_i are the same (indicated by thick lines).

We can then prove the following crucial result. We assume here that R is a binary regular relation over $\Sigma \times \Sigma$ such that $R^\curlywedge$ is given as an NFA over $\Sigma \times \Sigma$ whose set of states is Q. We further assume that q_0 is the initial state of $R^\curlywedge$ and F its set of final states.

▶ **Lemma 9.** *Relation R is not monadic decomposable iff there are an infinite sequence $\{(x_i, y_i)\}_{i\geq 0}$ of pairs of words over Σ and states $q, q', p, r \in Q$, such that $p \in F$, it is the case that $q \in R^\curlywedge_{x_0,y_0}(q_0)$, and the following statements hold for each $i \geq 0$.*

1. *$|x_i| = |y_i|$ and y_i is a prefix of both x_{i+1} and y_{i+1}.*
2. *$q' \in R^\curlywedge_{y_i,y_i}(q_0)$; $\quad q \in R^\curlywedge_{y_i^{-1}x_{i+1},y_i^{-1}y_{i+1}}(q')$; $\quad p \in R^\curlywedge_{\varepsilon,y_i^{-1}x_{i+1}}(q)$; $\quad r \in R^\curlywedge_{\varepsilon,y_i^{-1}y_{i+1}}(q)$.*
3. *If $i > 0$, we also have that $p \in R^\curlywedge_{\varepsilon,y_i^{-1}x_{i+1}}(r)$ and $r \in R^\curlywedge_{\varepsilon,y_i^{-1}y_{i+1}}(r)$.*

Proof. Assume first that R is not monadic decomposable. By Proposition 8, there are infinite sequences $\{u_i\}_{i\geq 0}$, $\{\gamma_i\}_{i\geq 0}$, and $\{\delta_i\}_{i\geq 0}$ of words over Σ and a quinary tuple $\mathfrak{C}$ over $\mathsf{types}(R^\curlywedge)$ such that for each $i \geq 0$ it is the case that

1. $|\gamma_i| = |\delta_i| > 0$,
2. $u_i = \delta_0 \cdots \delta_{i-1}\gamma_i$,
3. $(u_i, u_j) \in R^\curlywedge$, for each $j > i$, and
4. $\mathfrak{C}_{i,j} = \mathfrak{C}$, for each $j > i$.

We then define a sequence $\{(x_i, y_i)\}_{i\geq 0}$ such that $x_i := u_i$, for each $i \geq 0$, and y_i is the prefix of $x_{i+1} = u_{i+1}$ that has the same length as $x_i = u_i$, i.e., $y_i = \tau(x_{i+1}, |x_i|)$. Hence, $y_i = \rho(u_i) = \delta_0 \cdots \delta_i$. Clearly, $|x_i| = |y_i| \geq 0$ and y_i is a prefix of both x_{i+1} and y_{i+1}, for each $i \geq 0$. We prove next that the sequence $\{(x_i, y_i)\}_{i\geq 0}$ also satisfies the remaining conditions.

Before defining $q, q', p, r \in Q$, let us highlight the intuition why such states exist for every i. We can find such states because by our assumption $\mathfrak{C}_{i,j} = \mathfrak{C}$ for each $i < j$. Further, whether q is reachable from q_0 is stored in the first component of $\mathfrak{C}$. Similarly, the second and third components of $\mathfrak{C}$ allow us to find q' that is reachable from q_0 and such that q is reachable from q'. Finally, the fourth component is for checking whether p is reachable from q and r, while the fifth component for checking that r is reachable from both q and r.

Let us define $q, q', p, r \in Q$ as follows.

- q and p are states such that $p \in F$ and it is the case that $q \in R^\curlywedge_{x_0,y_0}(q_0)$ and $p \in R^\curlywedge_{\varepsilon,y_0^{-1}x_1}(q)$. Notice that such q and p must exist as $(x_0, x_1) \in R^\curlywedge$, i.e., it holds that $R^\curlywedge_{x_0,x_1}(q_0) \cap F \neq \emptyset$, and $R^\curlywedge_{x_0,x_1}(q_0) = R^\curlywedge_{x_0,y_0}(q_0) \circ R^\curlywedge_{\varepsilon,y_0^{-1}x_1}$.
- q' is a state such that $q' \in R^\curlywedge_{y_0,y_0}(q_0)$ and $q \in R^\curlywedge_{y_0^{-1}x_1,y_0^{-1}y_1}(q')$. Notice that such a q' must exist. Indeed, since $\mathfrak{C}_{0,1} = \mathfrak{C}_{1,2} = \mathfrak{C}$, we have $R^\curlywedge_{u_0,\rho(u_0)} = R^\curlywedge_{x_0,y_0} = R^\curlywedge_{u_1,\rho(u_1)} = R^\curlywedge_{x_1,y_1}$. This implies that $q \in R^\curlywedge_{x_1,y_1}(q_0) = R^\curlywedge_{y_0,y_0}(q_0) \circ R^\curlywedge_{y_0^{-1}x_1,y_0^{-1}y_1}$, as we know that $q \in R^\curlywedge_{x_0,y_0}(q_0)$ and there must be an intermediate state q' that is reached after reading (y_0, y_0).
- We have that r is a state such that

$$r \in R^\curlywedge_{\varepsilon,y_0^{-1}y_1}(q); \qquad p \in R^\curlywedge_{\varepsilon,y_1^{-1}x_2}(r); \qquad \text{and} \qquad r \in R^\curlywedge_{\varepsilon,y_1^{-1}y_2}(r).$$

  The existence of such state r is not obvious but straightforward; see [5].

We now prove that q, q', p, r satisfy all the requirements in the statement of the Lemma. By definition, $q \in R^\curlywedge_{x_0,y_0}(q_0)$ and $p \in F$. We can then prove by induction that for each $i \geq 0$ it is the case that

$$q' \in R^\curlywedge_{y_i,y_i}(q_0); \quad q \in R^\curlywedge_{y_i^{-1}x_{i+1},y_i^{-1}y_{i+1}}(q'); \quad p \in R^\curlywedge_{\varepsilon,y_i^{-1}x_{i+1}}(q); \quad r \in R^\curlywedge_{\varepsilon,y_i^{-1}y_{i+1}}(q);$$

and, in addition, that for each $i > 0$ it is the case that $p \in R^\curlywedge_{\varepsilon,y_i^{-1}x_{i+1}}(r)$ and $r \in R^\curlywedge_{\varepsilon,y_i^{-1}y_{i+1}}(r)$. The base case $i = 0$ holds by definition. The inductive case is straightforward.

Let us assume now that there are an infinite sequence $\{(x_i, y_i)\}_{i\geq 0}$ of pairs of words over Σ and states $q, q', p, r \in Q$ that satisfy the conditions stated in the statement of the lemma. We prove next that R is not monadic decomposable by showing that there are infinite sequences $\{w_i\}_{i\geq 0}$, $\{\alpha_i\}_{i\geq 0}$ and $\{\beta_i\}_{i\geq 0}$ of words over Σ such that $\{w_i\}_{i\geq 0}$, $\{\alpha_i\}_{i\geq 0}$, and $\{\beta_i\}_{i\geq 0}$ satisfy the conditions stated in Lemma 4.

We define $w_i := x_i$ for each $i \geq 0$. Furthermore, $\alpha_0 := x_0$, $\beta_0 := y_0$, and for each $i > 0$ we set $\alpha_i := y_{i-1}^{-1}x_i$ and $\beta_i := y_{i-1}^{-1}y_i$. Clearly $|\alpha_i| = |\beta_i| > 0$ and $w_i = x_i = \beta_0 \cdots \beta_{i-1}\alpha_i$, for each $i \geq 0$. We prove next that $(w_i, w_j) \in R^\curlywedge$ for each $0 \leq i < j$. Actually, we prove a stronger claim: $p \in R^\curlywedge_{w_i,w_j}(q_0)$ and $r \in R^\curlywedge_{w_i,\rho(w_j)}(q_0)$, for each $0 \leq i < j$, where as before $\rho(w_j) = \tau(w_{j+1}, |w_j|) = \beta_0\beta_1 \cdots \beta_j$. The claim can be proved by induction. ◀

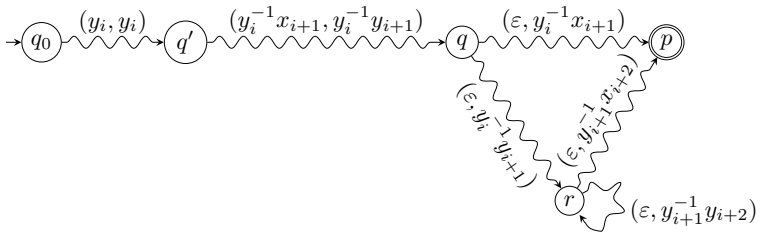

Figure 3 Runs in $R^{\nearrow}$ on states q, q', p and r as defined in Lemma 9. The runs exist for every $i \geq 0$.

The runs as extracted from the sequence $\{(x_i, y_i)\}_{i\geq 0}$ satisfying the conditions of Lemma 9 are depicted in Figure 3.

Lemma 9 allows us to reduce the monadic decomposability problem to a set of reachability checks on types. With the help of this property, we can then prove Lemma 7.

Proof of Lemma 7. For each $(q, q', p, r) \in Q \times Q \times Q \times Q$ with $p \in F$ do the following.

- Check if there are words w_0, v_0, w_1, v_1 such that $|w_0| = |v_0| > 0$, $|w_1| = |v_1| > 0$, and it holds that (i) $q \in R^{\nearrow}_{w_0,v_0}(q_0)$, (ii) $q' \in R^{\nearrow}_{v_0,v_0}(q_0)$, (iii) $q \in R^{\nearrow}_{w_1,v_1}(q')$, (iv) $q' \in R^{\nearrow}_{v_1,v_1}(q')$, (v) $p \in R^{\nearrow}_{\varepsilon,w_1}(q)$, and (vi) $r \in R^{\nearrow}_{\varepsilon,v_1}(q)$.
- Check if there are words w, v such that $|w| = |v| > 0$, and it holds that (i) $q \in R^{\nearrow}_{w,v}(q')$, (ii) $q' \in R^{\nearrow}_{v,v}(q')$, (iii) $p \in R^{\nearrow}_{\varepsilon,w}(q)$, (vi) $r \in R^{\nearrow}_{\varepsilon,v}(q)$, (v) $p \in R^{\nearrow}_{\varepsilon,w}(r)$, and (vi) $r \in R^{\nearrow}_{\varepsilon,v}(r)$.

If this holds for any such a tuple, then R is not monadic decomposable. Else, R is monadic decomposable. It is easy to see that this algorithm can be implemented in NLOGSPACE. ◀

We have the necessary ingredients to prove a part of Theorem 1.

▶ **Lemma 10.** *Deciding whether a given binary regular relation R is monadic decomposable is in* NLOGSPACE *(resp. in* PSPACE*), if R is given by a DFA (resp. an NFA).*

Proof. The claim follows from Lemma 7. Namely, from the definition of $R^{\nearrow}$, it follows that, if R is given by a DFA, then $R^{\nearrow}$ can be constructed in LOGSPACE. Indeed, this can be done as disjunctions, conjunctions and projections can all be done in LOGSPACE and then via composability of LOGSPACE transducers we can construct $R^{\nearrow}$ of logarithmic size. (Note that the output of a LOGSPACE transducer is of at most polynomial size.) Then by Lemma 7, we obtain the decidability of monadic decomposability in NLOGSPACE for R given by a DFA.

Similarly, if R is given by an NFA, we construct $R^{\nearrow}$ of polynomial size since an NFA can be transformed into a DFA using a PSPACE transducer. (Again, the output of a PSPACE transducer is of at most exponential size.) Thus monadic decomposability is in PSPACE. ◀

5 Deciding monadic decomposability of regular relations

In this section, we finish the proof of Theorem 1. The remaining component is showing that monadic decomposability of n-ary regular relations is decidable in NLOGSPACE for DFA and PSPACE for NFA.

▶ **Lemma 11.** *Deciding whether a given n-ary regular relation R is monadic decomposable is in* NLOGSPACE *(resp. in* PSPACE*), if R is given by a DFA (resp. an NFA).*

Proof of Theorem 1. The upper bounds follow from Lemma 11 and the lower bound follows from Lemma 5 for NFA and from Lemma 6 for DFA. ◀

In order to prove Lemma 11, we extend Lemma 10 to n-ary relations. Let us first define some helpful notation used throughout the section.

Recall that words of regular relations are padded to be of the same length using $\perp$. We denote this function by $\mathrm{PAD}_\perp$. For example, $\mathrm{PAD}_\perp((a,\varepsilon,ab)) = (a\perp,\perp\perp,ab)$. Let us now define a padding function δ_n that acts slightly differently. Instead of padding the words in a tuple to make them of the same length, the new function pads a sequence of tuples with tuples where some elements are $\perp$. Let us describe δ_n in more details. Define $\Sigma_n = (\Sigma_\perp)^n \setminus \{\perp^n\}$, i.e., an alphabet consisting of n-tuples of letters from $\Sigma_\perp$, excluding $(\perp,\ldots,\perp)$. Now $\delta_n : (\Sigma^*)^n \to \Sigma_n^*$ is an injective mapping that uses $\perp$ to extend the shorter words to the same length as the longest word. For example, δ_3 maps $(a,\varepsilon,ab) \in (\Sigma^*)^3$ to $(a,\perp,a)(\perp,\perp,b) \in \Sigma_3^*$ as follows:

$$(a,\varepsilon,ab) \to \begin{pmatrix} a \\ \varepsilon \\ ab \end{pmatrix} \to \begin{pmatrix} a\perp \\ \perp\perp \\ ab \end{pmatrix} \to \begin{pmatrix} a \\ \perp \\ a \end{pmatrix} \begin{pmatrix} \perp \\ \perp \\ b \end{pmatrix} \to (a,\perp,a)(\perp,\perp,b).$$

▶ **Lemma 12.** *For $n \geq 1$, $\{(x_1,\ldots,x_n,y) \mid \delta_n(x_1,\ldots,x_n) = y\} \subseteq (\Sigma^*)^n \times \Sigma_n^*$ is regular.*

Given an n-ary relation $R \subseteq (\Sigma^*)^n$ and positive integers $x_1,\ldots,x_m$ such that $\sum_{i=1}^m x_i = n$, an m-ary relation $R_{x_1,\ldots,x_m} \subseteq \Sigma_{x_1}^* \times \cdots \times \Sigma_{x_m}^*$ can be uniquely determined via the mappings $\delta_{x_1},\ldots,\delta_{x_m}$. More precisely, there exists a one-to-one correspondence $\Delta_{x_1,\ldots,x_m}$ between relations R and $R_{x_1,\ldots,x_m}$ that maps each $(w_1,\ldots,w_n) \in R$ to

$$(\delta_{x_1}(w_1,\ldots,w_{x_1}), \delta_{x_2}(w_{x_1+1},\ldots,w_{x_1+x_2}),\ldots,\delta_{x_m}(w_{x_1+\cdots+x_{m-1}+1},\ldots,w_n)) \in R_{x_1,\ldots,x_m}.$$

For example, a ternary relation $R = \{(a,\varepsilon,ab)\}$ over $(\Sigma^*)^3$ uniquely determines a binary relation $R_{1,2} = \{(a,(\perp,a)(\perp,b))\}$ over $\Sigma_1^* \times \Sigma_2^*$ through the correspondence $\Delta_{1,2}$. For the sake of readability, if the integers $x_1,\ldots,x_m$ have a constant subsequence of length k, i.e., $x_i = x_{i+1} = \cdots = x_{i+k-1}$ for some i, we write the relation as $R_{x_1,\ldots,x_{i-1},x_i^k,x_{i+k},\ldots,x_m}$.

In the following, we shall use R_k to denote the binary relation $R_{k,n-k}$ induced by R. It turns out that being able to check monadic decomposability for binary relations is sufficient to check monadic decomposability for general n-ary relations.

▶ **Lemma 13.** *Let R be an n-ary regular relation and let $R_1,\ldots,R_{n-1}$ be the induced binary relations. Then R is monadic decomposable iff $R_1,\ldots,R_{n-1}$ are monadic decomposable.*

Proof. Define $\delta_i(S) = \{\delta_i(s_1,\ldots,s_i) \mid (s_1,\ldots,s_i) \in S\}$. The only-if part of the lemma is immediate, since $R = \bigcup_i X_{i,1} \times \cdots \times X_{i,n}$ implies that $R_k = \bigcup_i \delta_k(X_{i,1} \times \cdots \times X_{i,k}) \times \delta_{n-k}(X_{i,k+1} \times \cdots \times X_{i,n})$ for $1 \leq k \leq n-1$, namely, $R_1,\ldots,R_{n-1}$ are monadic decomposable.

To see the other direction, we say that an n-ary relation R is *k-decomposable* if the induced k-ary relation $R_{1^{k-1},n-k+1}$ of R is monadic decomposable. Now it suffices to show that R is n-decomposable since $R = R_{1^n}$. We shall prove this by induction on $k \in \{2,\ldots,n\}$. Note that R is 2-decomposable by the assumption that R_1 is monadic decomposable. For $2 \leq k \leq n-1$, suppose that $R_k = \bigcup_j A_j \times B_j$ and R is k-decomposable, say $R_{1^{k-1},n-k+1} = \bigcup_i X_{i,1} \times \cdots \times X_{i,k-1} \times Y_i$. Then R is $(k+1)$-decomposable as we have

$$R_{1^k,n-k} = \bigcup_i \bigcup_j X_{i,1} \times \cdots \times X_{i,k-1} \times A_{i,j} \times B_j,$$

where $A_{i,j} = \{x \in \Sigma^* \mid \exists x_1 \in X_{i,1} \cdots \exists x_{k-1} \in X_{i,k-1}.\ \delta_k(x_1,\ldots,x_{k-1},x) \in A_j\}$, i.e., $A_{i,j}$ is the projection of $\delta_k^{-1}(A_j) \cap (X_{i,1} \times \cdots \times X_{i,k-1} \times \Sigma^*)$ on the k-th component. Note that $\delta_k^{-1}(A_j)$ is regular since A_j and $\{(x_1,\ldots,x_k,y) \mid \delta_k(x_1,\ldots,x_k) = y\}$ are regular (cf. [8]). Hence $A_{i,j}$ is also regular. The claim that R is n-decomposable then follows by induction. ◀

Proof (sketch) of Lemma 11. To prove the lemma, we show that if R is regular, then so are the induced relations $R_1, \ldots, R_{n-1}$. Moreover, given the automaton of R, one can construct the automaton for each R_i in logarithmic space from R. We then check if each R_i is monadic decomposable for $i = 1, \ldots, n-1$. From Lemma 10 the latter is in NLOGSPACE (resp. PSPACE), and thus the whole procedure is in NLOGSPACE (resp. PSPACE) if R is given by a DFA (resp. an NFA). ◀

6 Concluding Remarks

Monadic decomposability for rational relations (and subclasses thereof) is a classical problem in automata theory that dates back to the late 1960s (the work of Stearns [33] and Fischer and Rosenberg [19]). While the general problem is undecidable, the subcase of regular relations (i.e. those recognized by synchronized multi-tape automata) provides a good balance between decidability [25, 12] and expressiveness. The complexity of this subcase remained open for over a decade (exponential-time upper bound for the binary case [27, 28], double exponential-time upper bound in the general case [12], and no specific lower bounds). This paper closes this question by providing the precise complexity for the problem: NLOGSPACE (resp. PSPACE) for DFA (resp. NFA) representations.

Some perspectives from formal verification and future work. Researchers from the area of formal verification have increasingly understood the importance of the monadic decompositions techniques, e.g., see [38]. Directly pertinent to monadic decomposability of regular relations is the line of work of constraint solving over strings, wherein increasingly more complex string operations are needed and thus added to solvers [36, 3, 26, 1, 13, 2, 14]. As an example, let us take a look at the recent work of Chen *et al.* [14], which spells out a string constraint language with semantic conditions for decidability that directly use the notion of monadic decomposability of relations over strings. Loosely speaking, a constraint is simply a sequence of program statements, each being either an assignment or a conditional:

$$S ::= \quad y := f(x_1, \ldots, x_r) \mid \mathbf{assert}(g(x_1, \ldots, x_r)) \mid S; S$$

where $f : (\Sigma^*)^r \to \Sigma^*$ is a partial string function and $g \subseteq (\Sigma^*)^r$ is a string relation. The meaning of a constraint is what one would expect in a program written in a standard imperative programming language, which should support assignments and assertions. Note that loops are not allowed in the language since their target application is symbolic executions (e.g. see [11]). They provided two semantic conditions for ensuring decidability, one of which requires that each conditional g is effectively monadic decomposable. There is evidence (e.g. [21, 14]) that some form of length reasoning in g is indeed required for many applications of symbolic executions of string-manipulating programs, but much of the length constraints could be (not yet fully automatically) translated to regular constraints. A potential application for our results is therefore to provide support for complex string relations for g in the form of regular relations, which permit a rather expressive class of conditionals (e.g. some form of length reasoning, etc.). Despite this, this application also highlights what is currently missing in the entire literature of monadic decomposability of rational relations: a study of the problem of *outputting* the monadic decompositions of the relations, if monadic decomposable. (In fact, this is also true of other logical theories before the recent work of Veanes *et al.* [38].) What is the complexity of this problem with various representations of recognizable relations (e.g. finite unions of products, boolean combinations of regular constraints, etc.)? Although our results provide *a first step* towards solving this function problem, we strongly believe this to be a highly challenging open problem in its own right that deserves more attention.

Abstract

We study the boundedness problem for unions of conjunctive regular path queries with inverses (UC2RPQs). This is the problem of, given a UC2RPQ, checking whether it is equivalent to a union of conjunctive queries (UCQ). We show the problem to be ExpSpace-complete, thus coinciding with the complexity of containment for UC2RPQs. As a corollary, when a UC2RPQ is bounded, it is equivalent to a UCQ of at most triple-exponential size, and in fact we show that this bound is optimal. We also study better behaved classes of UC2RPQs, namely *acyclic UC2RPQs of bounded thickness*, and *strongly connected UCRPQs*, whose boundedness problem is, respectively, PSpace-complete and Π_2^P-complete. Most upper bounds exploit results on limitedness for distance automata, in particular extending the model with alternation and two-wayness, which may be of independent interest.

1 Introduction

Boundedness is an important property of formulas in logics with fixed-point features. At the intuitive level, a formula φ in any such logic is bounded if its *fixed-point depth*, *i.e.*, the number of iterations that are needed to evaluate φ on a structure $\mathbf{A}$, is fixed (and thus it is independent of $\mathbf{A}$). In databases and knowledge representation, boundedness is regarded as an interesting theoretical phenomenon with relevant practical implications [25, 8]. In

fact, while several applications in these areas require the use of recursive features, actual real-world systems are either not designed or not optimized to cope with the computational demands that such features impose. Bounded formulas, in turn, can be reformulated in non-recursive logics, such as FO, or even as a *union of conjunctive queries* (UCQ) when φ itself is positive. UCQs form the core of most systems for data management and ontological query answering, and, in addition, are the focus of advanced optimization techniques. It has also been experimentally verified in some contexts that recursive features encountered in practice are often used in a somewhat "harmless" way, and that many of such queries are in fact bounded [23]. Thus, checking if a recursive formula φ is bounded, and building an equivalent non-recursive formula φ' when the latter holds, are important optimization tasks.

The study of boundedness for *Datalog* programs, *i.e.*, the least fixed-point extension of the class of UCQs, received a lot of attention during the late 80s and early 90s. Two seminal results established that checking boundedness is undecidable in general for Datalog [22], but becomes decidable for *monadic* Datalog, *i.e.*, those programs in which each intensional predicate is monadic [19]. The past few years have seen a resurgence of interest in boundedness problems. This is due, in part, to the development of the theory of *cost automata* over trees (both finite and infinite) in a series of landmark results, in particular relating to its *limitedness* problem. In a few words, cost automata are generalizations of finite automata associating a *cost* from $\mathbb{N} \cup \{\infty\}$ to every input tree (instead of simply accepting or rejecting). The limitedness problem asks, given a cost automata, whether there is a uniform bound on the cost over all (accepting) input trees. Some deep results establish that checking limitedness is decidable for well-behaved classes of cost automata over trees [18, 35, 36, 7]. Remarkably, for several logics of interest the boundedness problem can be reduced to the limitedness for cost automata in such well-behaved classes. Those reductions have enabled powerful decidability results for the boundedness problem. As an example, it has been shown in this way that boundedness is decidable for monadic second-order logic (MSO) over structures of bounded treewidth [11], which corresponds to an extension of Courcelle's Theorem, and also for the *guarded negation* fragment of least fixed-point logic (LFP), even in the presence of unguarded parameters [6]. Cost automata have also been used to study the complexity of boundedness for guarded Datalog programs [7, 3].

Graph databases is a prominent area of study within database theory, in which the use of recursive queries is crucial [2, 1]. A graph database is a finite edge-labeled directed graph. The most basic navigational querying mechanism for graph databases corresponds to the class of *regular path queries* (RPQs), which check whether two nodes of the graph are connected by a path whose label belongs to a given regular language. RPQs are often extended with the ability to traverse edges in both directions, giving rise to the class of *two-way* RPQs, or 2RPQs [15]. The core of the most popular recursive query languages for graph databases is defined by *conjunctive* 2RPQs, or C2RPQs, which are the closure of 2RPQs under conjunction and existential quantifications [14]. We also consider *unions* of C2RPQs, or UC2RPQs. It can be shown that a UC2RPQ is bounded iff it is equivalent to some UCQ. In spite of the inherent recursive nature of UC2RPQs, their boundedness problem has not been studied in depth. Here we develop such a study by showing the following:

- The boundedness problem for UC2RPQs is ExpSpace-complete. The lower bound holds even for CRPQs. This implies that boundedness is not more difficult than *containment* for UC2RPQs, which was shown to be ExpSpace-complete in [14].
- From our upper bound construction it follows that if a UC2RPQ is bounded, then it is equivalent to a UCQ of triple exponential size. We show that this bound is optimal.
- Finally, we obtain better complexity bounds for some subclasses of UC2RPQs; namely, for acyclic UC2RPQs of *bounded thickness*, in which case boundedness becomes PSpace-complete, and for *strongly connected* UCRPQs, for which it is Π_2^P-complete.

It is important to stress that UC2RPQs can be easily translated into guarded LFP with unguarded parameters, for which boundedness was shown to be decidable by applying sophisticated cost automata techniques as mentioned above. However, the complexity of the boundedness problem for such a logic is currently not well-understood – and it is at least 2ExpTime-hard [7] – and hence this translation does not yield, in principle, optimal complexity bounds for our problem. To study the boundedness for UC2RPQs, we develop instead techniques especially tailored to UC2RPQs. In fact, since the recursive structure of UC2RPQs is quite tame, their boundedness problem can be translated into the limitedness problem for a much simpler automata model than cost automata on trees; namely, *distance* automata on finite words. Distance automata are nothing more than usual NFAs with two sorts of transitions: costly and non-costly. Such an automaton is limited if there is an integer $k \geq 1$ such that every word accepted by the NFA has an accepting run with at most k costly transitions. A beautiful result in automata theory established the decidability of the limitedness problem for distance automata [24], which is actually in PSpace [29]. While being a difficult result, by now we have quite transparent proofs of this fact (see, *e.g.*, [26]). We exploit our translation to obtain tight complexity upper bounds for boundedness of UC2RPQs. Some of the proofs in the paper require extending the study of limitedness to *alternating* and *two-way* distance automata, while preserving the PSpace bound for the limitedness problem. We believe these results to be of independent interest.

Organization of the paper. Section 2 contains preliminaries. We present characterizations of boundedness for UC2RPQs in Section 3 and an application of those to pinpoint the complexity of Boundedness for RPQs in Section 4. Distance automata and results about them are given in Section 5. We analyze the complexity of Boundedness for general UC2RPQs in Section 6 and present some classes of UC2RPQs with better complexity of Boundedness in Section 7. We finish with a discussion in Section 8.

2 Preliminaries

We assume familiarity with *non-deterministic finite automata* (NFA), *two-way* NFA (2NFA), and *alternating finite automata* (AFA) over finite words. We often blur the distinction between an NFA $\mathcal{A}$ and the language $L(\mathcal{A})$ it defines; similarly for regular expressions.

Graph databases and conjunctive regular path queries. A *graph database* over a finite alphabet $\mathbb{A}$ is a finite edge-labelled graph $G = (V, E)$ over $\mathbb{A}$, where V is a finite set of vertices and $E \subseteq V \times \mathbb{A} \times V$ is the set of labelled edges. We write $u \xrightarrow{a} v$ to denote an edge $(u, a, v) \in E$. We define the alphabet $\mathbb{A}^{\pm} := \mathbb{A} \dot{\cup} \mathbb{A}^{-1}$ that extends $\mathbb{A}$ with the set $\mathbb{A}^{-1} := \{a^{-1} \mid a \in \mathbb{A}\}$ of "inverses" of symbols in $\mathbb{A}$. An *oriented path* from u to v in a graph database $G = (V, E)$ over alphabet $\mathbb{A}$ is a pair $\pi = (\sigma, \ell)$ where σ and ℓ are (possibly empty) sequences $\sigma = (v_0, a_1, v_1), (v_1, a_2, v_2), \ldots, (v_{k-1}, a_k, v_k) \in V \times \mathbb{A} \times V$, and $\ell = \ell_1, \ldots, \ell_k \in \{-1, 1\}$, for $k \geq 0$, such that $u = v_0$, $v = v_k$, and for each $1 \leq i \leq k$, we have that $\ell_i = 1$ implies $(v_{i-1}, a_i, v_i) \in E$; and $\ell_i = -1$ implies $(v_i, a_i, v_{i-1}) \in E$. The *label* of π is the word $b_1 \ldots b_k \in (\mathbb{A}^{\pm})^*$, where $b_i = a_i$ if $\ell_i = 1$; otherwise $b_i = a_i^{-1}$. When $k = 0$ the label of π is the empty word ε. If $\ell_i = 1$ for every $1 \leq i \leq k$, we say that π is a *directed path*. Note that in this case, the label of π belongs to $\mathbb{A}^*$.

A *regular path query* (RPQ) over $\mathbb{A}$ is a regular language $L \subseteq \mathbb{A}^*$, which we assume to be given as an NFA. The evaluation of L on a graph database $G = (V, E)$ over $\mathbb{A}$, written $L(G)$, is the set of pairs $(u, v) \in V \times V$ such that there is a directed path from u to v in G

whose label belongs to L. 2RPQs extend RPQs with the ability to traverse edges in both directions. Formally, a 2RPQ L over $\mathbb{A}$ is simply an RPQ over $\mathbb{A}^{\pm}$. The evaluation $L(G)$ of L over a graph database $G = (V, E)$ over $\mathbb{A}$ is the set of pairs $(u, v) \in V \times V$ such that there is an oriented path from u to v in G whose label belongs to L.

Conjunctive 2RPQs (C2RPQs) are obtained by taking the closure of 2RPQs under conjunction and existential quantification, *i.e.*, a C2RPQ over $\mathbb{A}$ is an expression $\gamma := \exists \bar{z} \left((x_1 \xrightarrow{L_1} y_1) \wedge \cdots \wedge (x_m \xrightarrow{L_m} y_m) \right)$, where each L_i is a 2RPQ over $\mathbb{A}$ and $\bar{z}$ is a tuple of variables among those in $\{x_1, y_1, \ldots, x_m, y_m\}$. We say that γ is a CRPQ if each L_i is an RPQ. If $\bar{x} = (x^1, \ldots, x^n)$ is the tuple of *free variables* of γ, *i.e.*, those that are not existentially quantified in $\bar{z}$, then the evaluation $\gamma(G)$ of the C2RPQ γ over a graph database G is the set of all tuples $h(\bar{x}) = (h(x^1) \ldots, h(x^n))$, where h ranges over all mappings $h : \{x_1, y_1, \ldots, x_m, y_m\} \to V$ such that $(h(x_i), h(y_i)) \in L_i(G)$ for each $1 \leq i \leq m$.

A *union* of C2RPQs (UC2RPQ) is an expression of the form $\Gamma := \bigvee_{1 \leq i \leq n} \gamma_i$, where the γ_i's are C2RPQ, all of which have exactly the same free variables. The evaluation $\Gamma(G)$ of Γ over a graph database G is $\bigcup_{1 \leq i \leq n} \gamma_i(G)$. We often write $\Gamma(\bar{x})$ to denote that $\bar{x}$ is the tuple of free variables of Γ. A UC2RPQ Γ is *Boolean* if it contains no free variables.

Given UC2RPQs Γ and Γ', we write $\Gamma \subseteq \Gamma'$ if $\Gamma(G) \subseteq \Gamma'(G)$ for each graph database G. Hence, Γ and Γ' are *equivalent* if $\Gamma \subseteq \Gamma'$ and $\Gamma' \subseteq \Gamma$, *i.e.*, $\Gamma(G) = \Gamma'(G)$ for every G.

Boundedness of UC2RPQs. CRPQs, and even UC2RPQs, can easily be expressed in *Datalog*, the least fixed-point extension of the class of *union of conjunctive queries* (UCQs). Hence, we can directly define the boundedness of a UC2RPQ in terms of the boundedness of its equivalent Datalog program, which is a well-studied problem [25]. The latter, however, coincides with being equivalent to some UCQ [31]. In the setting of graph databases, a *conjunctive query* (CQ) over $\mathbb{A}$ is simply a CRPQ over $\mathbb{A}$ of the form $\exists \bar{z} \bigwedge_{1 \leq i \leq m} (x_i \xrightarrow{a_i} y_i)$ where the a_is range over $\mathbb{A} \cup \{\varepsilon\}$. Notice that atoms of the form $x \xrightarrow{\varepsilon} y$ correspond to *equality atoms* $x = y$. Analogously, one can define unions of CQs (UCQs). Note that, modulo equality atoms, a CQ over $\mathbb{A}$ can be seen as a graph database over $\mathbb{A}$. Hence, we shall slightly abuse notation and, in the setting of CQs, use notions defined for graph databases (such as oriented paths).

A UC2RPQ Γ is *bounded* if it is equivalent to some UCQ Φ. In this article we study the complexity of the problem Boundedness, which takes as input a UC2RPQ Γ and asks whether Γ is bounded.

▶ **Example 1.** Consider the Boolean UCRPQ $\Gamma = \gamma_1 \vee \gamma_2$ over the alphabet $\mathbb{A} = \{a, b, c, d\}$ such that $\gamma_1 = \exists x, y \, (x \xrightarrow{L_b} y \wedge x \xrightarrow{L_{b,d}} y)$ and $\gamma_2 = \exists x, y \, (x \xrightarrow{L_d} y \wedge x \xrightarrow{L_{b,d}} y)$, where $L_b := a^+b^+c$, $L_d := ad^+c^+$, and $L_{b,d} := a^+(b + d)c^+$. For $e \in \mathbb{A}$, recall that e^+ denotes the language $e(e^*)$. As we shall explain in Example 4, we have that γ_1 and γ_2 are unbounded. However, Γ is bounded, and in particular, it is equivalent to the UCQ $\Phi = \varphi_1 \vee \varphi_2$, where φ_1 and φ_2 correspond to $\exists x, y \, (x \xrightarrow{abc} y)$ and $\exists x, y \, (x \xrightarrow{adc} y)$, respectively. ◀

3 Characterizations of Boundedness for UC2RPQs

In this section we provide two simple characterizations of when a UC2RPQ is bounded that will be useful to analyze the complexity of Boundedness. Let $\varphi(\bar{x})$ and $\varphi'(\bar{x})$ be CQs over $\mathbb{A}$ with variable sets $\mathcal{V}$ and $\mathcal{V}'$, respectively. Let $=_\varphi$ and $=_{\varphi'}$ be the binary relations induced on $\mathcal{V}$ and $\mathcal{V}'$ by the equality atoms of φ and φ', respectively, and $=_\varphi^*$ and $=_{\varphi'}^*$ be their reflexive-transitive closure. A *homomorphism* from φ to φ' is a mapping $h : \mathcal{V} \to \mathcal{V}'$

such that: (i) $x =^*_\varphi y$ implies $h(x) =^*_{\varphi'} h(y)$; (ii) $h(\bar{x}) = \bar{x}$; and (iii) for each atom $x \xrightarrow{a} y$ in φ with $a \in \mathbb{A}$, there is an atom $x' \xrightarrow{a} y'$ in φ' such that $h(x) =^*_{\varphi'} x'$ and $h(y) =^*_{\varphi'} y'$. We write $\varphi \to \varphi'$ if such a homomorphism exists. It is known that $\varphi \to \varphi'$ iff $\varphi' \subseteq \varphi$ [16].

An *expansion* of a C2RPQ $\gamma(\bar{x})$ over $\mathbb{A}$ is a CQ $\lambda(\bar{x})$ over $\mathbb{A}$ with minimal number of variables and atoms such that (i) λ contains each variable of γ, (ii) for each atom $A = x \xrightarrow{L} y$ of γ, there is an oriented path π_A in λ from x to y with label $w_A \in L$ whose intermediate variables (*i.e.*, those not in $\{x, y\}$) are distinct from one another, and (iii) intermediate variables of different oriented paths π_A and $\pi_{A'}$ are disjoint. Note that the free variables of λ and γ coincide. Intuitively, the expansion λ is obtained from γ by choosing for each atom $A = x \xrightarrow{L} y$ a word $w_A \in L$, and "expanding" $x \xrightarrow{L} y$ into the "fresh oriented path" π_A from x to y with label w_A. When $w_A = \varepsilon$ then λ contains the equality atom $x = y$. An expansion of a UC2RPQ Γ is an expansion of some C2RPQ in Γ. Observe that a (U)C2RPQ is always equivalent to the (potentially infinite) UCQ given by its set of expansions. Even more, it is equivalent to the UCQ defined by its *minimal* expansions, as introduced below.

If λ is an expansion of a UC2RPQ Γ, we define the *size* of λ, denoted by $\|\lambda\|$, to be the number of (non-equality) atoms in λ. We say that λ is *minimal*, if there is no expansion λ' such that $\lambda' \to \lambda$ and $\|\lambda'\| < \|\lambda\|$. Intuitively, an expansion is minimal if its answers cannot be covered by a smaller expansion. We can then establish the following.

▶ **Lemma 2.** *Every UC2RPQ Γ is equivalent to the (potentially infinite) UCQ given by its set of minimal expansions.*

We can now provide our basic characterizations of boundedness.

▶ **Proposition 3.** *The following conditions are equivalent for each UC2RPQ Γ.*

1. *Γ is bounded.*
2. *There is $k \geq 1$ such that for every expansion λ of Γ there exists an expansion λ' of Γ with $\|\lambda'\| \leq k$ such that $\lambda \subseteq \lambda'$ (i.e., such that $\lambda' \to \lambda$).*
3. *Γ has finitely many minimal expansions.*

▶ **Example 4.** Consider the Boolean UCRPQ $\Gamma = \gamma_1 \vee \gamma_2$ over $\mathbb{A} = \{a, b, c, d\}$ from Example 1. To see that γ_1 is unbounded (the case of γ_2 is similar) we can apply Proposition 3. Indeed, the expansions of γ_1 corresponding to $\{\exists x, y\,(x \xrightarrow{ab^n c} y \wedge x \xrightarrow{adc} y) : n \geq 1\}$ are all minimal. On the other hand, Γ is bounded as its minimal expansions correspond to $\exists x, y\,(x \xrightarrow{abc} y \wedge x \xrightarrow{abc} y)$ and $\exists x, y\,(x \xrightarrow{adc} y \wedge x \xrightarrow{adc} y)$. ◀

4 Boundedness for Existentially Quantified RPQs

As a first application of Proposition 3, we study Boundedness for CRPQs consisting of a single RPQ; that is, RPQs or existentially quantified RPQs. Let v, w be words over $\mathbb{A}$. Recall that a word v is a *prefix* [resp. *suffix* and *factor*] of w if $w \in v \cdot \mathbb{A}^*$ [resp. $w \in \mathbb{A}^* \cdot v$ and $w \in \mathbb{A}^* \cdot v \cdot \mathbb{A}^*$]. If in addition we have $v \neq w$, then we say that v is a *proper* prefix [resp. suffix and factor] of w. For a language $L \subseteq \mathbb{A}^*$, we define its *prefix-free* sub-language L_{pf} to be the set of words $w \in L$ such that w has no proper prefix in L. Similarly, we define L_{sf} and L_{ff} with respect to the suffix and factor relation. We have the following:

▶ **Proposition 5.** *The following statements hold.*

1. *An RPQ L is bounded iff L is finite.*
2. *A CRPQ $\exists y(x \xrightarrow{L} y)$ [resp. $\exists x(x \xrightarrow{L} y)$] with $x \neq y$ is bounded iff L_{pf} [resp. L_{sf}] is finite.*
3. *A Boolean CRPQ $\exists x, y(x \xrightarrow{L} y)$ with $x \neq y$ is bounded iff L_{ff} is finite.*

▶ **Theorem 6.** *The problem of, given an NFA accepting the language L, checking whether L_{pf} is finite is* PSPACE*-complete. The same holds if we replace L_{pf} by L_{sf} or L_{ff}.*

Proof. We focus on upper bounds, the lower bounds are in the appendix. Given an NFA $\mathcal{A}$ accepting the language L, we can construct an NFA $\mathcal{B}$ of polynomial size in $\mathcal{A}$ that accepts precisely those words that have a proper prefix in L. By complementing and intersecting with $\mathcal{A}$, we obtain an NFA $\mathcal{B}'$ of exponential size in $\mathcal{A}$ that accepts the language L_{pf}. Hence, we only need to check whether the language accepted by $\mathcal{B}'$ is finite, which can be done *on-the-fly* in NL w.r.t. $\mathcal{B}'$, and hence in PSPACE. The other two cases are analogous. ◀

By applying Theorem 6 and Proposition 5, we can now pinpoint the complexity of BOUNDEDNESS for CRPQs with a single RPQ.

▶ **Corollary 7.** *The following statements hold.*

1. BOUNDEDNESS *for RPQs is* NL*-complete.*
2. BOUNDEDNESS *for CRPQs of the form $\exists y(x \xrightarrow{L} y)$, with $x \neq y$, is* PSPACE*-complete. The same holds for CRPQs $\exists x(x \xrightarrow{L} y)$ and Boolean CRPQs $\exists x, y(x \xrightarrow{L} y)$, where $x \neq y$.*

It is not clear, though, how usual automata techniques, as the ones applied in the proof of Theorem 6, can be used to solve BOUNDEDNESS for more complex CRPQs. To solve this problem we develop an approach based on distance automata, as introduced next. Our approach also handles inverses and unions, thus dealing with arbitrary UC2RPQs.

5 Distance Automata

Distance automata [24] (equivalent to weighted automata over the $(\min, +)$-semiring [21], min-automata [12], or $\{\varepsilon, ic\}$-B-automata [17]) are an extension of finite automata which associate to each word in the language a natural number or "cost". They can be represented as non-deterministic finite automata with two sorts of transitions: costly and non-costly. For a given distance automaton, the cost of a run on a word is the number of costly transitions, and the cost of a word $w \in \mathbb{A}^*$ is the minimum cost of an accepting run on w. We will use this automaton model to encode boundedness as the problem of whether there is a uniform bound on the cost of words, known as the *limitedness problem*.

Formally, a *distance automaton* (henceforth *DA*) is a tuple $\mathcal{A} = (\mathbb{A}, Q, q_0, F, \delta)$, where $\mathbb{A}$ is a finite alphabet, Q is a finite set of states, $q_0 \in Q$ is the initial state, $F \subseteq Q$ is the set of finals states and $\delta \subseteq Q \times \mathbb{A} \times \{0, 1\} \times Q$ is the transition relation. A word $w \in \mathbb{A}^*$ is *accepted* by $\mathcal{A}$ if there is an *accepting run* of $\mathcal{A}$ on w, *i.e.*, a (possibly empty) sequence of transitions $\rho = (p_1, a_1, c_1, r_1) \cdots (p_n, a_n, c_n, r_n) \in \delta^*$ with the usual properties: (1) if $\rho = \varepsilon$ then $q_0 \in F$ and $w = \varepsilon$, (2) $p_1 = q_0$ and $r_n \in F$, (3) for every $1 \leq i < n$ we have $r_i = p_{i+1}$, and (4) $w = a_1 \cdots a_n$. The *cost* of the run ρ is $cost(\rho) = c_1 + \cdots + c_n$ (or 0 if $\rho = \varepsilon$); and the cost $cost_{\mathcal{A}}(w)$ of a word w accepted by $\mathcal{A}$ is the minimum cost of an accepting run of $\mathcal{A}$ on w. For convenience, we assume the cost of words not accepted by $\mathcal{A}$ to be 0.

The *limitedness problem* for DA is defined as follows: given a DA $\mathcal{A}$, determine whether $\sup_{w \in \mathbb{A}^*} cost_{\mathcal{A}}(w) < \infty$. This problem is known to be PSPACE-complete.

▶ **Theorem 8** ([28, 29])**.** *The following statements hold:*

1. *The limitedness problem for DA is* PSPACE*-complete.*
2. *If a DA with n states is limited, then $\sup_{w \in \mathbb{A}^*} cost_{\mathcal{A}}(w) \leq 2^{O(n^3)}$.*

We use two extensions of DA: *alternating* and *two-way*. Two-way DA is defined as for NFA, extending the cost function accordingly. The cost of a word is still the minimum over the cost of all (potentially infinitely many) runs. Alternating DA is defined as usual by having

two sorts of states: universal and existential. Existential states can be seen as computing the minimum among the cost of all possible continuations of the run, and universal states as computing the maximum (or supremum if the automaton is also two-way). As we will see, these extensions preserve the above PSPACE upper bound for the limitedness problem.

Formally, an *alternating two-way DA with epsilon transitions* (A2DA$^\varepsilon$) over $\mathbb{A}$ is a tuple $\mathcal{A} = (\mathbb{A}, Q_\exists, Q_\forall, q_0, F, \delta)$ is an A2DA$^\varepsilon$ if $q_0 \in Q_\exists$, $F \subseteq Q_\exists$ and

$$\delta \subseteq (Q_\exists \cup Q_\forall) \times (\mathbb{A}^\pm \cup \{\varepsilon\}) \times \{end, \overline{end}\} \times \{0,1\} \times (Q_\exists \cup Q_\forall);$$

where *end* indicates that after reading the letter we arrive at the end of the word (*i.e.*, either the leftmost or the rightmost end) and $\overline{end}$ indicates that we do not. When the automaton $\mathcal{A}$ is two-way, it is convenient to think of its head as being *between* the letter positions of the word, so an *end*-flagged transition can be applied only if it moves the head to be right before the first letter of the word, or right after the last one.

For any given word $w \in \mathbb{A}^*$, consider the edge-labelled graph $G_{\mathcal{A},w} = (V, E)$ over δ, where $V = Q \times \{0, \ldots, |w|\}$, with $Q = Q_\exists \cup Q_\forall$, and $E \subseteq V \times \delta \times V$ consists of all edges $(q,i) \xrightarrow{(q,a,e,c,p)} (p,j)$ such that $e = end$ iff $j = 0$ or $j = |w|$ and either (a) $i < |w|$, $a = w[i+1]$, and $j = i+1$; (b) $i > 0$, $a = (w[i])^{-1}$, and $j = i-1$; or (c) $a = \varepsilon$ and $j = i$.

An *accepting run of* $\mathcal{A}$ *on* w *from* $(q,i) \in Q \times \{0, \ldots, |w|\}$ is a finite (possibly empty) edge-labelled directed rooted tree[1] t over δ and a labelling h from the nodes of t to the nodes of $G_{\mathcal{A},w}$, such that if t is empty then $q \in F$, and otherwise h maps the root of t to (q,i), every leaf of t to $F \times \{0, \ldots, |w|\}$, and for every node x of t:

- if (x, α, y) is an (labeled) edge in t for some y, then $(h(x), \alpha, h(y))$ is an edge in $G_{\mathcal{A},w}$;
- if $h(x) \in Q_\forall \times \{0, \ldots, |w|\}$, then for every edge $(h(x), \alpha, c)$ in $G_{\mathcal{A},w}$, there is an edge (x, α, y) in t so that $h(y) = c$;
- if $h(x) \in Q_\exists \times \{0, \ldots, |w|\}$, then x has at most one child.

Each branch of t with label $(q_1, a_1, e_1, c_1, p_1), \ldots, (q_n, a_n, e_n, c_n, p_n)$ has an associated cost of $c_1 + \cdots + c_n$; and the cost associated with t is the maximum among the costs of its branches, or 0 if t is empty. The cost $cost_\mathcal{A}(w, q, i)$ is the minimum cost of an accepting run on w from (q,i), or 0 if none exists; $cost_\mathcal{A}(w)$ is defined as $cost_\mathcal{A}(w, q_0, 0)$.

An A2DA$^\varepsilon$ with $\delta \subseteq Q \times (\mathbb{A} \cup \{\varepsilon\}) \times \{end, \overline{end}\} \times \{0,1\} \times Q$ is an *alternating DA* with ε transitions (ADA$^\varepsilon$). An A2DA$^\varepsilon$ with $Q_\forall = \emptyset$ is a *two-way DA* with ε transitions (2DA$^\varepsilon$). An A2DA with both the aforementioned conditions is (equivalent to) a DA with ε transitions (DA$^\varepsilon$). Notice that in the last two cases, accepting runs can be represented as words from δ^* rather than trees. By A2DA (resp., ADA, 2DA, DA) we denote an A2DA$^\varepsilon$ (resp., ADA$^\varepsilon$, 2DA$^\varepsilon$, DA$^\varepsilon$) with no ε-transitions. Note that DA as just defined is in every sense equivalent to the distance automata model we have defined at the beginning of this section – this is why we overload the same "DA" name.

We first observe that 2DA can be transformed into DA while preserving both the language and limitedness problems by adapting the standard "crossing sequence" construction for translating 2NFA into NFA [34]. This fact will be useful for proving the EXPSPACE upper bound for BOUNDEDNESS of general UC2RPQs in Section 6.

▶ **Proposition 9.** *There is an exponential time procedure which for every 2DA* $\mathcal{A}$ *over* $\mathbb{A}$ *produces a DA* $\mathcal{B}$ *over* $\mathbb{A}$ *such that the languages accepted by* $\mathcal{A}$ *and* $\mathcal{B}$ *are the same, and* $cost_\mathcal{B}(w) \leq cost_\mathcal{A}(w) \leq f(cost_\mathcal{B}(w))$ *for every* $w \in \mathbb{A}^*$*, where* f *is a polynomial function that depends on the number of states of* $\mathcal{A}$*.*

[1] That is, a tree-shaped finite edge-labelled graph over δ with edges directed in the root-to-leaf sense.

Recall that the universality problem for NFAs is known to be PSPACE-complete [27]; and that this bound actually extends to two-way and even alternating automata. We show that, likewise, the limitedness problem remains in PSPACE for A2DA$^\varepsilon$. This result will be useful to show in Section 7 that BOUNDEDNESS for the class of acyclic UC2RPQs of bounded thickness is in PSPACE.

▶ **Theorem 10.** *The limitedness problem for A2DA$^\varepsilon$ is* PSPACE*-complete.*

The novelty of this result is the PSPACE upper bound. In fact, decidability follows from known results, and in particular [7, Theorem 14] claims EXPTIME-membership in the more challenging setup of infinite trees. However, this is obtained via an involved construction spanning through several papers. The proof of Theorem 10, instead, is obtained by the composition of the following reductions:

$$\text{lim. A2DA}^\varepsilon \xrightarrow{(1)} \text{lim. A2DA} \xrightarrow{(2)} \text{lim. 2DA} \xrightarrow{(3)} \text{lim. ADA}^\varepsilon \xrightarrow{(4)} \text{lim. ADA} \xrightarrow{(5)} \text{lim. DA.}$$

Reductions (1), (3) and (4) are in polynomial time, while reductions (2) and (5), which are basically the same, are in exponential time. Specifically, reductions (2) and (5) preserve the statespace but the size of the alphabet grows exponentially in the number of states and linearly in the size of the source alphabet. However, the alphabet and transition set resulting from these reductions can be succinctly described: letters are encoded in polynomial space, and checking for membership in the transition set is polynomial time computable.

In summary, the composition (1)+(2)+(3)+(4)+(5) yields a DA with the following characteristics: (i) it has a polynomial number of states Q; (ii) it runs on an exponential alphabet $\mathbb{A}$ –and every letter is encoded in polynomial space–; and (iii) one can check in polynomial time whether a tuple $t \in Q \times \mathbb{A} \times \{end, \overline{end}\} \times \{0,1\} \times Q$ is in its transition relation. This, coupled with Theorem 8, item (2) (which offers a bound depending only on the number of states), provides a polynomial space algorithm for the limitedness of A2DA$^\varepsilon$: We can non-deterministically check the existence of a word with cost greater than the single exponential bound N using only polynomial space, by guessing one letter at a time and keeping the set of reachable states together with the associated costs, where each cost is encoded in binary using polynomial space if it is smaller than N, or with a "∞" flag otherwise. The algorithm accepts if at least one final state is reached and the costs of all reachable final states are marked ∞. Since NPSPACE =PSPACE (Savitch's Theorem), Theorem 10 follows.

We now provide a brief description of the reductions used in the proof of Theorem 10.

(1) From A2DA$^\varepsilon$ to A2DA. This is a trivial reduction obtained by simulating ε-transitions by reading $a \cdot a^{-1}$ for some $a \in \mathbb{A}$.

(2) From A2DA to 2DA. Given an A2DA $\mathcal{A} = (\mathbb{A}, Q_\forall, Q_\exists, q_0, F, \delta)$, we build a 2DA $\mathcal{B}$ over a larger alphabet $\mathbb{B}$, where we trade alternation for extra alphabet letters. The alphabet $\mathbb{B}$ consists of triples $(f^\rightarrow, a, f^\leftarrow)$, where $a \in \mathbb{A}$ and $f^\rightarrow, f^\leftarrow : Q_\forall \to \delta$. The idea is that $f^\rightarrow, f^\leftarrow$ are "choice functions" for the alternation: whenever we are to the left (resp., right) of a position of the word labelled $(f^\rightarrow, a, f^\leftarrow)$ in state $q \in Q_\forall$, instead of exploring all transitions departing from q and taking the maximum cost over all such runs (this is what alternation does in $\mathcal{A}$), $\mathcal{B}$ chooses to just take the transition $f^\rightarrow(q)$ (resp., $f^\leftarrow(q)$). Note that $\mathbb{B}$ is exponential in the number of states but not in the size of $\mathbb{A}$. In this way, we build a 2DA $\mathcal{B}$ having the same set of states as $\mathcal{A}$ but with a transition function which is essentially deterministic on the states of $Q_\forall$. In the end we obtain that

- for every $w \in \mathbb{B}^*$, $cost_\mathcal{B}(w) \leq cost_\mathcal{A}(w_\mathbb{A})$; and
- for every $w \in \mathbb{A}^*$ there is $\widetilde{w} \in \mathbb{B}^*$ so that $\widetilde{w}_\mathbb{A} = w$ and $cost_\mathcal{A}(w) = cost_\mathcal{B}(\widetilde{w})$,

where $w_\mathbb{A}$ and $\widetilde{w}_\mathbb{A}$ denote the projections onto the alphabet $\mathbb{A}$. This implies that the limitedness problem is preserved.

(3) From 2DA to ADA$^\varepsilon$. We show a polynomial-time translation from 2DA to ADA$^\varepsilon$ which preserves limitedness. In the case of finite automata, there are language-preserving reductions from 2NFA to AFA with a quadratic blowup in the statespace [9, 32]. However, these translations, when applied blindly to reduce from 2DA to ADA$^\varepsilon$, preserve neither the cost semantics nor the limitedness of languages. On the other hand, [10] shows an involved construction that results in a reduction from 2DA to ADA$^\varepsilon$ on *infinite trees*, which preserves limitedness but it is not polynomial in the number of states. We show a translation from 2DA to ADA$^\varepsilon$ which serves our purpose: it preserves limitedness and it is polynomial time computable. The translation is close to the language-preserving reduction from 2NFA to AFA of [32], upgraded to take into account the cost of different alternation branches, somewhat in the same spirit as the *history summaries* from [10].

(4) From ADA$^\varepsilon$ to ADA. This is a straightforward polynomial time reduction which preserves limitedness but – as opposed to (1) – does not preserve the language: we need to add an extra letter to the alphabet in order to make the reduction work in polynomial time.

(5) From ADA to DA. This is exactly the same reduction as (2), noticing that the alphabet will still be single exponential in the original A2DA$^\varepsilon$.

6 Complexity of Boundedness for UC2RPQs

Here we show that Boundedness for UC2RPQs is ExpSpace-complete. We do so by applying distance automata results presented in the previous section on top of the semantic characterizations presented in Section 3. The lower bound applies even for CRPQs. We further show that there is a triple exponential tight bound for the size of the equivalent UCQ of a UC2RPQ (and even CRPQ), whenever this exists. This is summarized in the following theorem. If Γ is a UC2RPQ, we write $\|\Gamma\|$ for the length of an arbitrary reasonable encoding of Γ – in particular, encodings in which regular languages are described through NFA or regular expressions.

▶ **Theorem 11.** *The following statements hold.*

1. Boundedness *for UC2RPQs is* ExpSpace*-complete. The problem remains* ExpSpace*-hard even for Boolean CRPQs.*
2. *If a UC2RPQ Γ is bounded, there is a UCQ Φ that is equivalent to Γ and such that Φ has at most triple-exponentially many CQs, each one of which is at most of double exponential size with respect to $\|\Gamma\|$.*
3. *There is a family $\{\Gamma_n\}_{n\geq 1}$ of Boolean CRPQs such that for each $n \geq 1$ it is the case that: (1) $\|\Gamma_n\| = O(n)$, (2) Γ_n is bounded, and (3) every UCQ that is equivalent to Γ_n has at least triple-exponentially many CQs with respect to n.*

6.1 Upper bounds

Our upper bound proof builds on top of techniques developed by Calvanese et al. [14] for studying the *containment problem for UC2RPQs*: Given UC2RPQs Γ, Γ', is it the case that $\Gamma \subseteq \Gamma'$? It is shown in [14] that from Γ, Γ' it is possible to construct exponentially sized NFAs $\mathcal{A}_{\Gamma,\Gamma'}$ and $\mathcal{A}'_{\Gamma,\Gamma'}$, such that $\Gamma \subseteq \Gamma'$ iff there is a word in $\mathcal{A}_{\Gamma,\Gamma'} \cap \overline{\mathcal{A}'_{\Gamma,\Gamma'}}$. It is a well-known result that the latter is solvable in NL in the combined size of $(\mathcal{A}_{\Gamma,\Gamma'}, \overline{\mathcal{A}'_{\Gamma,\Gamma'}})$, *i.e.*, in ExpSpace. We modify this construction to study the boundedness of a given UC2RPQ Γ. In particular, we construct from Γ in exponential time a DA $\mathcal{D}_\Gamma$ such that Γ is bounded iff $\mathcal{D}_\Gamma$ is limited. The result then follows from Theorem 8, which establishes that limitedness for $\mathcal{D}_\Gamma$ can be solved in polynomial space on the number of its states, and thus in ExpSpace.

▶ **Proposition 12.** *There is a single exponential time procedure that takes as input a UC2RPQ* Γ *and constructs a DA* $\mathcal{D}_\Gamma$ *such that* Γ *is bounded iff* $\mathcal{D}_\Gamma$ *is limited.*

Proof. Similarly as done in [14], the DA $\mathcal{D}_\Gamma$ will run over encodings of expansions of the UC2RPQ Γ, *i.e.*, words over the alphabet $\mathbb{A}_1 := \mathbb{A}^\pm \cup \mathcal{V} \cup \{\$\}$, where $\mathbb{A}$ is the alphabet of Γ, $\mathcal{V}$ is the set of variables of Γ, and $\$$ is a fresh symbol. If $\gamma = \exists \bar{z} \bigwedge_{1 \leq i \leq m} (x_i \xrightarrow{L_i} y_i)$ is a C2RPQ in Γ and λ is the expansion of γ obtained by expanding each $x_i \xrightarrow{L_i} y_i$ into an oriented path π_i from x_i to y_i with label $w_i \in L_i$, then we encode λ as the word

$$w_\lambda = \$x_1 w_1 y_1 \$ x_2 w_2 y_2 \$ \cdots \$ x_m w_m y_m \$ \ \in \ \mathbb{A}_1^*$$

Note how the subword $x_i w_i y_i$ encodes the oriented path π_i. Every position $j \in \{1, \ldots, |w_\lambda|\}$ with $w_\lambda[j] \neq \$$ represents a variable in λ: either x_i or y_i if $w_\lambda[j] = x_i$ or $w_\lambda[j] = y_i$, respectively; or the $(\ell+1)$-th variable in the oriented path π_i if $w_\lambda[j]$ is the ℓ-th symbol in the subword w_i. Hence different positions in w_λ could represent the same variable in λ, *e.g.*, in the encoding $\$xabcy\$$, the $5th$ position containing a "c" and the $6th$ position containing a "y", represent the same variable, namely, the last vertex y of the oriented path. It is then easy to build, in polynomial time, an NFA $\mathcal{A}_1$ over $\mathbb{A}_1$ recognizing the language of all such encodings of expansions of Γ. Our automaton $\mathcal{D}_\Gamma$ is the product of $\mathcal{A}_1$ and the DA $\mathcal{C}_\Gamma$ defined below. In particular, $\mathcal{D}_\Gamma$ is limited iff $\mathcal{C}_\Gamma$ is limited over words of the form w_λ, for λ an expansion of Γ.

Fix a disjunct γ of Γ. As in [14], we consider words over the alphabet $\mathbb{A}_2 := \mathbb{A}_1 \times (2^\mathcal{V} \cup \{\#\})$ of the form $(\ell_1, \alpha_1) \cdots (\ell_n, \alpha_n)$, such that $w_\lambda = \ell_1 \cdots \ell_n$, for some expansion λ of Γ, and the α_i's are *valid* γ*-annotations*, *i.e.*, (1) $\alpha_i = \#$ if $\ell_i = \$$, (2) $\alpha_1, \ldots, \alpha_n \in 2^\mathcal{V}$ induce a partition of the variable set $\mathcal{V}_\gamma$ of γ, and (3) for each free variable $x \in \mathcal{V}_\gamma$ there is some (ℓ_i, α_i) such that $\ell_i = x$ and $x \in \alpha_i$. It is easy to construct an NFA $\mathcal{B}_1^\gamma$ of exponential size that given $w = (\ell_1, \alpha_1) \cdots (\ell_n, \alpha_n)$ with $w_\lambda = \ell_1 \cdots \ell_n$, checks if the α_i's are valid γ-annotations. Note that if the latter holds, then the annotations encode a mapping h_w from $\mathcal{V}_\gamma$ to the variables of λ such that $h_w(\bar{x}) = \bar{x}$, where $\bar{x}$ are the free variables of γ.

Now, given $w = (\ell_1, \alpha_1)(\ell_2, \alpha_2) \cdots (\ell_n, \alpha_n)$ with $w_\lambda = \ell_1 \cdots \ell_n$ and the α_i's being valid γ-annotations, it is shown in [14] that one can construct in polynomial time a 2NFA $\mathcal{B}_2^\gamma$ that checks the existence of an expansion λ' of γ and a homomorphism h from λ' to λ consistent with h_w. For each atom $x \xrightarrow{L} y$ of γ, the automaton $\mathcal{B}_2^\gamma$ guesses an oriented path π in λ from $h_w(x)$ to $h_w(y)$ with label $w' \in L$, directly over the encoding w_λ starting at a position j_x and ending at a position j_y in $\{0, \ldots, n\}$ (recall that the head moves in $\{0, \ldots, n\}$) with $j_x, j_y > 0$, $w[j_x] = (\ell, \alpha)$, $w[j_y] = (\ell', \alpha')$, $x \in \alpha$ and $y \in \alpha'$. Note that we have two types of transitions: (1) transitions that consume $a \in \mathbb{A}^\pm$ and actually guess an atom of π, and (2) transitions to "jump" from position j to j' in $\{0, \ldots, n\}$ representing *equivalent* variables of λ. The latter means that $j, j' > 0$ and either $w_\lambda[j]$ and $w_\lambda[j']$ represents exactly the *same* variable of λ, or $w_\lambda[j]$ and $w_\lambda[j']$ represent variables z, z' of λ such that $z =_\lambda^* z'$, where $=_\lambda^*$ is the reflexive-transitive closure of the relation induced by the equality atoms in λ.

Let $\mathcal{D}_2^\gamma$ be the 2DA obtained from the 2NFA $\mathcal{B}_2^\gamma$ by setting to 0 and 1 the cost of transitions of type (2) and (1), respectively. Hence, for a word w such that the projection of w to $\mathbb{A}_1$ is w_λ, and the one to $(2^\mathcal{V} \cup \{\#\})$ is a valid γ-annotation, we have that $cost_{\mathcal{D}_2^\gamma}(w)$ is precisely the minimum size of an expansion λ' that can be mapped to λ via a homomorphism compatible with h_w. By Proposition 9, we can construct in exponential time in $\mathcal{D}_2^\gamma$ a DA $\mathcal{C}_2^\gamma$ accepting the same language as $\mathcal{D}_2^\gamma$ and having an exponential number of states, so that for every word w', we have $cost_{\mathcal{C}_2^\gamma}(w') \leq cost_{\mathcal{D}_2^\gamma}(w') \leq f(cost_{\mathcal{C}_2^\gamma}(w'))$ for some polynomial function f. Let $\exists \mathcal{C}^\gamma$ be the result of taking the product of $\mathcal{B}_1^\gamma$ and $\mathcal{C}_2^\gamma$ and then projecting over the alphabet $\mathbb{A}_1$.

For every expansion λ of Γ, if λ' is a minimal size expansion of γ such that $\lambda' \to \lambda$, then we obtain that $cost_{\exists\mathcal{C}^\gamma}(w_\lambda) \leq \|\lambda'\| \leq f(cost_{\exists\mathcal{C}^\gamma}(w_\lambda))$. We define our desired $\mathcal{C}_\Gamma$ to be the union of $\exists\mathcal{C}^\gamma$ over all γ in Γ. We have that for every expansion λ, if λ_{min} is a minimal size expansion of Γ such that $\lambda_{min} \to \lambda$, then $cost_{\mathcal{C}_\Gamma}(w_\lambda) \leq \|\lambda_{min}\| \leq f(cost_{\mathcal{C}_\Gamma}(w_\lambda))$. By Proposition 3, item (2), Γ is bounded iff $\|\lambda_{min}\|$ is bounded over all λ. The latter condition holds iff $\mathcal{C}_\Gamma$ is limited over words w_λ, for all expansion λ. By definition, the latter is equivalent to $\mathcal{D}_\Gamma$ being limited. Summing up, we obtain that Γ is bounded iff $\mathcal{D}_\Gamma$ is limited, as required. Note that the whole construction can be done in exponential time. ◀

As a corollary to Proposition 12 and Theorem 8 we obtain the desired upper bound for part (1) of Theorem 11.

▶ **Corollary 13.** Boundedness *for UC2RPQs is in* ExpSpace.

Size of equivalent UCQs. Here we prove part (2) of Theorem 11. Since Γ is bounded we have from Proposition 12 that $\mathcal{D}_\Gamma$ is limited. Then, from Theorem 8 we obtain that the maximum cost that it takes $\mathcal{D}_\Gamma$ over a word is N, where N is exponential in the number of states of $\mathcal{D}_\Gamma$, and thus double exponential in $\|\Gamma\|$ by construction. Therefore, for every expansion λ of Γ, if λ_{min} is a minimal size expansion Γ such that $\lambda_{min} \to \lambda$, then $\|\lambda_{min}\| \leq f(N)$, where f is the polynomial function of the proof of Proposition 12. In particular, all minimal expansions of Γ are of size $\leq f(N)$. By Lemma 2, the UC2RPQ Γ is equivalent to the union of all its minimal expansions. The number of such minimal expansions is thus at most exponential in $f(N)$, and hence triple exponential in $\|\Gamma\|$.

6.2 Lower bounds

We reduce from the 2^n-tiling problem, that is, a tiling problem restricted to 2^n many columns, which is ExpSpace-complete (see, *e.g.*, [14]). We show that for every 2^n-tiling problem T there is a CRPQ γ, computable in polynomial time from T, whose number of minimal expansions is essentially the number of solutions to T in the following sense.

▶ **Lemma 14.** *For every 2^n-tiling problem T with m solutions there is a Boolean CRPQ γ, computable in polynomial time from T, such that the number of minimal expansions of γ is $O((g(|T|) + m)^{n+1})$ and $\Omega(m)$, for some double exponential function g. Further, γ consists of a Boolean CRPQ of the form $\exists x, y \bigwedge_{0 \leq i \leq n}(x \xrightarrow{L_i} y)$, where each L_i is given as a regular expression.*

As a corollary, this yields an ExpSpace lower bound for the boundedness problem (part (1) of Theorem 11), as well as a triple exponential lower bound for the size of the UCQ equivalent to any bounded CRPQ (part (3) of Theorem 11), since one can produce 2^n-tiling problems having triple-exponentially many solutions.

7 Better-behaved Classes of UC2RPQs

Here we present two restrictions of UC2RPQs that exhibit a better behavior in terms of the complexity of Boundedness than the general case, namely, *acyclic UC2RPQs of bounded thickness* and *strongly connected UCRPQs*. The improved bounds are PSpace and Π_2^P, respectively, which turn out to be optimal.

Acyclic UC2RPQs of Bounded Thickness. For any two distinct variables x, y of a C2RPQ γ, we denote by $\text{Atoms}_\gamma(x, y)$ the set of atoms in γ of the form $x \xrightarrow{L} y$ or $y \xrightarrow{L} x$. The *thickness* of a C2RPQ γ is the maximum cardinality of a set of the form $\text{Atoms}_\gamma(x, y)$, for x, y variables of γ with $x \neq y$. The thickness of a UC2RPQ Γ is the maximum thickness over all the C2RPQs in Γ. The *underlying undirected graph* of γ has as vertex set the set of variables of γ and contains an edge $\{x, y\}$ iff $x \neq y$ and $\text{Atoms}_\gamma(x, y) \neq \emptyset$. A C2RPQ γ is *acyclic* if its underlying undirected graph is an acyclic graph (*i.e.*, a forest). A UC2RPQ Γ is acyclic if each C2RPQ in Γ is.

We show next that Boundedness for acyclic UC2RPQs of bounded thickness is PSpace-complete. These classes of UC2RPQs have been previously studied in the literature [4, 5]. In particular, it follows from [5, Theorem 4.2] that the containment problem for the acyclic UC2RPQs of bounded thickness is PSpace-complete, and hence Theorem 15 below shows that Boundedness is not more costly than containment for these classes.

▶ **Theorem 15.** *Fix $k \geq 1$. The problem* Boundedness *is* PSpace*-complete for acyclic UC2RPQs of thickness at most k.*

Proof (sketch). The lower bound follows directly from PSpace-hardness of Boundedness for RPQs (see Corollary 7). For the PSpace upper bound, we follow a similar strategy as in the case of arbitrary UC2RPQs (Section 6.1), *i.e.*, we reduce boundedness of Γ to DA limitedness. The main difference is that, since Γ is acyclic, we can exploit the power of alternation and construct an A2DA$^\varepsilon$ $\mathcal{B}$ (instead of a 2DA, as in the proof of Proposition 12), such that Γ is bounded iff $\mathcal{B}$ is limited. The constant upper bound on the thickness of Γ implies that $\mathcal{B}$ is actually of polynomial size. The result follows then as limitedness of an A2DA$^\varepsilon$ can be decided in PSpace in virtue of Theorem 10. ◀

Both conditions in Theorem 15, *i.e.*, acyclicity and bounded thickness, are necessary. Indeed, it follows from Lemma 14 that Boundedness is ExpSpace-hard even for:

- Boolean acyclic CRPQs.
- Boolean CRPQs of thickness one, whose underlying undirected graph is of *treewidth* two. Recall that the treewidth is a measure of how much a graph resembles a tree (cf., [20]) – acyclic graphs are precisely the graphs of treewidth one.

Indeed, the CRPQs of the form $\exists x, y \bigwedge_i (x \xrightarrow{L_i} y)$ used in Lemma 14 are Boolean and acyclic (but have unbounded thickness). Replacing each $(x \xrightarrow{L_i} y)$ with $(x \xrightarrow{\varepsilon} z_i) \wedge (z_i \xrightarrow{L_i} y)$, yields an equivalent CRPQ of thickness one whose underlying undirected graph has treewidth two.

Strongly Connected UCRPQs. We conclude this section with an even better behaved class of CRPQs in terms of Boundedness. Unlike the previous case, the definition of this class depends on the underlying *directed* graph of a CRPQ γ. This contains a directed edge from variable x to y iff there is an atom in γ of the form $x \xrightarrow{L} y$. A CRPQ γ is *strongly connected* if its underlying directed graph is strongly connected, *i.e.*, every pair of variables is connected by some directed path. A UCRPQ Γ is strongly connected if every CRPQ in Γ is. We can then establish the following.

▶ **Theorem 16.** Boundedness *is Π_2^P-complete for strongly connected UCRPQs.*

8 Discussion and Future Work

The main conclusion of our work is that techniques previously used in the study of containment of UC2RPQs can be naturally leveraged to pinpoint the complexity of Boundedness by using DA instead of NFA. This, however, requires extending results on limitedness to alternating and two-way DA. For all the classes of UC2RPQs studied in the paper we show in fact that the complexity of Boundedness coincides with that of the containment problem. We leave open what is the exact size of UCQ rewritings for the classes of acyclic UC2RPQs of bounded thickness and the strongly connected UCRPQs that are bounded.

The most natural next step is to study Boundedness for the class of *regular queries* (RQs), which are the closure of UC2RPQs under binary transitive closure. RQs are one of the most powerful recursive languages for which containment is decidable in elementary time. In fact, containment of RQs has been proved to be 2EXPSPACE-complete by applying sophisticated techniques based on NFA [33]. We will study if it is possible to settle the complexity of Boundedness for RQs with the help of DA techniques.

Another interesting future line of work is the study of Boundedness for UC2RPQs based on the restricted classes of regular expressions often found in practical applications [13]. As it has been shown lately, the complexity of some query evaluation problems is alleviated under this restriction [30], and it would be nice to see if the same holds for the boundedness problem. This would be good news for the applicability of boundedness techniques in practical applications. In fact, it would be an indication that the high complexity lower bounds obtained in this paper are mostly witnessed by complicated interactions between regular expressions not commonly arising in practice.

Polynomially Ambiguous Probabilistic Automata on Restricted Languages

Paul C. Bell

Abstract

We consider the computability and complexity of decision questions for Probabilistic Finite Automata (PFA) with sub-exponential ambiguity. We show that the emptiness problem for non-strict cut-points of polynomially ambiguous PFA remains undecidable even when the input word is over a bounded language and all PFA transition matrices are commutative. In doing so, we introduce a new technique based upon the Turakainen construction of a PFA from a Weighted Finite Automata which can be used to generate PFA of lower dimensions and of subexponential ambiguity. We also study freeness/injectivity problems for polynomially ambiguous PFA and study the border of decidability and tractability for various cases.

Acknowledgements We thank the referees for their careful reading of this manuscript and their helpful improvements.

1 Introduction

Probabilistic finite automata (PFA) are a simple yet expressive model of computation, obtained by extending nondeterministic finite automata so that transitions from each state (and for each input letter) form probability distributions. As input letters are read from some alphabet Σ, the automaton transitions among states according to these probabilities. The probability of accepting a word $w \in \Sigma^*$ is given by the probability of the automaton being in one of its final states, denoted $f_{\mathcal{P}}(w) = \mathbf{x}^T M_{w_1} M_{w_2} \cdots M_{w_k} \mathbf{y}$, where $\mathbf{x}$ represents the initial state, $\mathbf{y}$ represents the final state and each M_{w_i} is a row stochastic matrix representing the transition probabilities for letter $w_i \in \Sigma$.

The PFA model has been studied extensively over the years, ever since its introduction by Rabin [27]; for example see [10] for a survey of 416 research papers related to PFA in the eleven years since their introduction to just 1974. They have been used to study Arthur-Merlin games [2], space bounded interactive proofs [15], quantum complexity theory [33], the joint spectral radius and semigroup boundedness [8], Markov decision processes and planning questions [9], and text and speech processing [24] among many others.

There are a variety of interesting questions that one may ask about PFA. A central question is the emptiness problem for cut-point languages; given some probability $\lambda \in [0, 1]$, does there exist a finite input word whose probability of acceptance is greater than λ (i.e. does there exist $w \in \Sigma^*$ such that $f_{\mathcal{P}}(w) > \lambda$, see Section 2.2). This problem is known to be undecidable [26], even for a fixed number of dimensions and for two input matrices [7, 19].

A second natural question is the *freeness problem* (or *injectivity problem*) for PFA, studied in [3] – given a PFA $\mathcal{P}$ over alphabet Σ determine whether the acceptance function $f_{\mathcal{P}}(w)$ is injective (i.e. do there exist two distinct words with the same acceptance probability).

When studying the frontiers of decidability of a problem, there are two competing objectives, namely, determine the most general version of the problem which is decidable, and the most restricted specialization which is undecidable; the latter being the focus of this paper.

Various classes of restrictions may be studied for PFA depending upon the structure of the PFA or on possible input words. Some restrictions relate to the number of states of the automaton, the alphabet size and whether one defined the PFA over the algebraic real numbers or the rationals. One may also study PFA with finite, polynomial or exponential ambiguity (in terms of the underlying NFA), PFA defined for restricted input words (for example those coming from regular, bounded or letter monotonic languages), PFA with isolated thresholds (a probability threshold is isolated if it cannot be approached arbitrarily closely) and PFA where all matrices commute, for which cut-point languages and non-free languages generated by such automata necessarily become commutative.

The cut-point emptiness problem for PFA is known to be undecidable for rational matrices [26], even over a binary alphabet when the PFA has dimension 46 in [7]; later improved to dimension 25 [19]. The authors of [6] show that the problem of determining if a threshold is isolated (resp. if a PFA has any isolated threshold) is undecidable and this was shown to hold even for PFA with 420 (resp. 2354) states over a binary alphabet [7].

A natural restriction on PFA was studied in [4], where possible input words of the PFA are restricted to be from some letter monotonic language of the form $\mathcal{L} = a_1^* a_2^* \cdots a_k^*$ with each $a_i \in \Sigma$ (analogous to a 1.5 way PFA, whose read head may "stay put" on an input word letter but never moves left), then the problem remains undecidable. In other words, does there exist $w \in \mathcal{L}$ such that $f_{\mathcal{P}}(w) > \lambda$? This restriction is inspired by the well-known property that many language-theoretic problems become decidable or tractable when restricted to bounded languages, and especially letter-monotonic languages [13]. Nevertheless, the emptiness problem for PFA on letter-monotonic languages was shown to be undecidable for high (but finite) dimensional matrices over the rationals via an encoding of Hilbert's tenth problem on the solvability of Diophantine equations and the utilization of Turakainen's method to transform weighted integer automata to a PFA [4].

The authors of [17] recently studied decision problems for PFA of various degrees of ambiguity in order to map the frontier of decidability for restricted classes of PFA. The degree of ambiguity of a PFA is defined as the maximum number of accepting runs over all possible words and can be used to give various classifications of ambiguity including finite, polynomial and exponential ambiguity. The ambiguity of a PFA is a property of the underlying NFA and is independent of the transition probabilities in so much as we only need care if the probability is zero or positive. The degree of ambiguity of automata is a well-known and well-studied property in automata theory [31]. The authors of [17] show that the emptiness problem for PFA remains undecidable even for polynomially ambiguous automata (quadratic ambiguity), before going on to show **PSPACE**-hardness results for finitely ambiguous PFA and that emptiness is in **NP** for the class of k-ambiguous PFA for every $k > 0$. The emptiness problem for PFA was later shown to also be undecidable even for linearly ambiguous automata in [16].

1.1 Our Contributions

In this paper, we show that the emptiness problem is undecidable even for polynomially ambiguous PFA defined over letter monotonic languages when all matrices are rational and commutative. This combination of restrictions on the PFA significantly increases the

difficulty of proving undecidability. The study of PFA over letter monotonic languages is a particularly interesting intermediate model, lying somewhere between single letter alphabets, for which we have decidability results, and PFA defined with multi-letter alphabets, for which most decision problems are undecidable.

▶ **Theorem 1.** *The emptiness problem for polynomially ambiguous probabilistic finite automata on letter monotonic languages is undecidable for non-strict cut-points, even when all matrices are commutative.*

We note a few difficulties with proving this result. Firstly, Post's correspondence problem, whose variants are often used for showing undecidability results in such settings, is actually decidable over letter monotonic languages [18][1]. Secondly, although other reductions of undecidable computational problems to matrices are possible, the standard technique of Turakainen (shown in [30]) to modify such matrices to stochastic matrices introduces exponential ambiguity (indeed all such matrices are strictly positive, and thus we might think of such matrices as being *maximally exponentially ambiguous*)[2]. Finally, we note that matrix problems for commutative matrices are often decidable; indeed there are polynomial time algorithms for solving the orbit problem [22, 14] and the vector reachability problem for commutative matrices [1]. Since the matrices commute, it is the Parikh vector of letters of the input word which is important.

We use a reduction of Hilbert's tenth problem and various new encoding techniques to avoid the use of Turakainen's method for converting from weighted to probabilistic automata, so as to retain polynomial ambiguity. We then move on to the freeness/injectivity problem to show the following two results.

▶ **Theorem 2.** *The injectivity problem for linearly ambiguous four state probabilistic finite automata is undecidable.*

▶ **Theorem 3.** *The injectivity problem for linearly ambiguous three-state probabilistic finite automata over letter-monotonic languages is NP-hard.*

These results are proven via an encoding of the mixed modification PCP and our new encoding technique and the injectivity problem for three state PFA over letter monotonic languages is **NP**-hard via an encoding of the variant of the subset sum problem and a novel encoding technique. We conclude with some open problems.

2 Preliminaries

2.1 Linear Algebra

Given $A = (a_{ij}) \in \mathbb{F}^{m\times m}$ and $B \in \mathbb{F}^{n\times n}$, we define the direct sum $A \oplus B$ and Kronecker product $A \otimes B$ of A and B by:

$$A \oplus B = \left[\begin{array}{c|c} A & \mathbf{0}_{m,n} \\ \hline \mathbf{0}_{n,m} & B \end{array}\right], \quad A \otimes B = \begin{bmatrix} a_{11}B & a_{12}B & \cdots & a_{1m}B \\ a_{21}B & a_{22}B & \cdots & a_{2m}B \\ \vdots & \vdots & & \vdots \\ a_{m1}B & a_{m2}B & \cdots & a_{mm}B \end{bmatrix},$$

[1] Although it is undecidable in general (i.e. not over a letter monotonic language) with an alphabet with at least five letters [25].

[2] This is due to an essential step of the Turakainen procedure that adds a positive constant offset to each element of every generator matrix, thus making all matrices strictly positive [30].

where $\mathbf{0}_{i,j}$ denotes the zero matrix of dimension $i \times j$. Note that neither $\oplus$ nor $\otimes$ are commutative in general. Given a finite set of matrices $\mathcal{G} = \{G_1, G_2, \ldots, G_m\} \subseteq \mathbb{F}^{n\times n}$, $\langle \mathcal{G} \rangle$ is the semigroup generated by $\mathcal{G}$. We will use the following notations:

$$\bigoplus_{j=1}^{m} G_j = G_1 \oplus G_2 \oplus \cdots \oplus G_m, \qquad \bigotimes_{j=1}^{m} G_j = G_1 \otimes G_2 \otimes \cdots \otimes G_m$$

Given a single matrix $G \in \mathbb{F}^{n\times n}$, we inductively define $G^{\otimes k} = G \otimes G^{\otimes(k-1)} \in \mathbb{F}^{n^k \times n^k}$ for $k > 0$ with $G^{\otimes 0} = 1$ as the k-fold Kronecker power of G. Similarly, $G^{\oplus k} = G \oplus G^{\oplus(k-1)} \in \mathbb{F}^{n^k \times n^k}$ for $k > 0$ with $G^{\oplus 0}$ being a zero dimensional matrix. The rationalle for the base cases is that $G \otimes G^{\otimes 0} = 1 \otimes G = G$ and that $G \oplus G^{\oplus 0} = G$ as expected.

The following properties of $\oplus$ and $\otimes$ are well known, see [20] for proofs.

▶ **Lemma 4.** *Let $A, B, C, D \in \mathbb{F}^{n\times n}$. We note that:*

- *Associativity - $(A \otimes B) \otimes C = A \otimes (B \otimes C)$ and $(A \oplus B) \oplus C = A \oplus (B \oplus C)$, thus $A \otimes B \otimes C$ and $A \oplus B \oplus C$ are unambiguous.*
- *Mixed product properties: $(A \otimes B)(C \otimes D) = (AC \otimes BD)$ and $(A \oplus B)(C \oplus D) = (AC \oplus BD)$.*
- *If A and B are stochastic matrices, then so are $A \oplus B$ and $A \otimes B$.*

It is trivial to prove that if $A, B \in \mathbb{F}^{n\times n}$ are both upper-triangular then so are $A \oplus B$ and $A \otimes B$. This follows directly from the definition of the Kronecker sum and product.

2.2 Probabilistic Finite Automata (PFA)

Probabilistic Finite Automata (PFA) with n states over an alphabet Σ are defined as $\mathcal{P} = (\mathbf{x}, \{M_a | a \in \Sigma\}, \mathbf{y})$ where $\mathbf{x} \in \mathbb{R}^n$ is the initial probability distribution; $\mathbf{y} \in \{0,1\}^n$ is the final state vector and each $M_a \in \mathbb{R}^{n\times n}$ is a (row) stochastic matrix. For a word $w = w_1 w_2 \cdots w_k \in \Sigma^*$, we define the acceptance probability $f_{\mathcal{P}} : \Sigma^* \to \mathbb{R}$ of $\mathcal{P}$ as:

$$f_{\mathcal{P}}(w) = \mathbf{x}^T M_{w_1} M_{w_2} \cdots M_{w_k} \mathbf{y},$$

which denotes the acceptance probability of w.

For any $\lambda \in [0,1]$ and PFA $\mathcal{A}$ over alphabet Σ, we define a cut-point language to be: $L_{\geq\lambda}(\mathcal{A}) = \{w \in \Sigma^* | f_{\mathcal{A}}(w) \geq \lambda\}$, and a strict cut-point language $L_{>\lambda}(\mathcal{A})$ by replacing $\geq$ with $>$. The (strict) emptiness problem for a cut-point language is to determine if $L_{\geq\lambda}(A) = \emptyset$ (resp. $L_{>\lambda}(A) = \emptyset$).

Let $\Sigma_\ell = \{x_1, x_2, \ldots, x_\ell\}$ be an ℓ-letter alphabet for some $\ell > 0$. A language $L \subseteq \Sigma_\ell^*$ is called a *bounded language* if and only if there exist words $w_1, w_2, \ldots, w_m \in \Sigma_\ell^+$ such that $L \subseteq w_1^* w_2^* \cdots w_m^*$. A language L is called *letter-monotonic* if there exists letters $u_1, u_2, \ldots, u_m \in \Sigma_\ell$ such that $L \subseteq u_1^* u_2^* \cdots u_m^*$. One thus sees that letter monotonic languages are more restricted than bounded languages. We will be interested in PFA which are defined over a bounded language or a letter monotonic language $\mathcal{L}$, whereby all input words necessarily come from $\mathcal{L}$. In this case a cut-point language for a PFA $\mathcal{P}$ over bounded/letter monotonic language $\mathcal{L}$ and a probability $\lambda \in [0,1]$ is defined as $L_{\geq\lambda}(\mathcal{A}) = \{w \in L | f_{\mathcal{A}}(w) \geq \lambda\}$; similarly for nonstrict cut point languages. We may then ask similar emptiness questions for such languages, as before.

We also study the *freeness/injectivity problem* for PFA. Given a PFA $\mathcal{P}$ over alphabet Σ determine whether the acceptance function $f_{\mathcal{P}}(w)$ is injective (i.e. do there exist two distinct words with the same acceptance probability). Such problems can readily be studied when the input words are necessarily derived from a bounded or letter-monotonic language.

2.3 PFA Ambiguity

The degree of ambiguity of a finite automaton is a structural parameter, roughly indicating the number of accepting runs for a given input word [31]. We here define only those notions required for our later proofs, see [31] for full details of these notions and a thorough discussion.

Let $w \in \Sigma^*$ be an input word of an NFA $\mathcal{N} = (Q, \Sigma, \delta, Q_I, Q_F)$. For each $(p, w, q) \in Q \times \Sigma^* \times Q$, let $\mathrm{da}_{\mathcal{N}}(p, w, q)$ be defined as the number of all paths for w in $\mathcal{N}$ leading from state p to state q. The degree of ambiguity of w in $\mathcal{N}$, denoted $\mathrm{da}_{\mathcal{N}}(w)$, is defined as the number of all *accepting paths* for w. The degree of ambiguity of $\mathcal{N}$, denoted $\mathrm{da}(\mathcal{N})$ is the supremum of the set $\{\mathrm{da}_{\mathcal{N}}(w) | w \in \Sigma^*\}$. $\mathcal{N}$ is called infinitely ambiguous if $\mathrm{da}(\mathcal{N}) = \infty$, finitely ambiguous if $\mathrm{da}(\mathcal{N}) < \infty$, and unambiguous if $\mathrm{da}(\mathcal{N}) \leq 1$. The degree of growth of the ambiguity of $\mathcal{N}$, denoted $\deg(M)$ is defined as the minimum degree of a univariate polynomial h with positive integral coefficients such that for all $w \in \Sigma^*$, $\mathrm{da}_{\mathcal{N}}(w) \leq h(|w|)$ if such a polynomial exists, or infinity otherwise.

The above notions relate to NFA. We may derive an analogous notation of ambiguity for PFA by considering an embedding of a PFA $\mathcal{P}$ to an NFA $\mathcal{N}$ with the property that for each letter $a \in \Sigma$, if the probability of transitioning from a state i to state j is nonzero under $\mathcal{P}$, then there is an edge from state i to j under $\mathcal{N}$ for letter a. The degree of (growth of) ambiguity of $\mathcal{P}$ is then defined as the degree of (growth of) ambiguity of $\mathcal{N}$.

We may use the following notions to determine the degree of ambiguity of a given NFA (and thus a PFA) $\mathcal{A}$ as is shown in the theorem which follows. A state $q \in Q$ is called *useful* if there exists an accepting path which visits q.

EDA. There is a useful state $q \in Q$ such that, for some word $v \in \Sigma^*$, $da_{\mathcal{A}}(q, v, q) \geq 2$.

IDA$_d$. There are useful states $r_1, s_1, \ldots, r_d, s_d \in Q$ and words $v_1, u_2, v_2, \ldots, u_d, v_d \in \Sigma^*$ such that for all $1 \leq \lambda \leq d$, r_λ and s_λ are distinct and $(r_\lambda, v_\lambda, r_\lambda), (r_\lambda, v_\lambda, s_\lambda), (s_\lambda, v_\lambda, s_\lambda) \in \delta$ and for all $2 \leq \lambda \leq d$, $(s_{\lambda-1}, u_\lambda, r_\lambda) \in \delta$.

▶ **Theorem 5** ([21, 28, 31]). *An NFA (or PFA) $\mathcal{A}$ having the EDA property is equivalent to it being exponentially ambiguous. For any $d \in \mathbb{N}$, an NFA (or PFA) $\mathcal{A}$ having property IDA$_d$ is equivalent to $\deg(\mathcal{A}) \geq d$.*

Clearly, if $\mathcal{N}$ agrees with IDA$_d$ for some $d > 0$, then it also agrees with IDA$_1, \ldots,$ IDA$_{d-1}$. One must be careful with these notions of ambiguity when considering NFA/PFA $\mathcal{A}$, where inputs are necessarily from a bounded language $\mathcal{L}$. In such cases, the above criteria do not suffice to determine the ambiguity of $\mathcal{A}$, since the number of paths must be determined not over Σ^*, but over all paths from $\mathcal{L}$. Of course, the degree of ambiguity of $\mathcal{A}$ cannot *increase* by restricting to a bounded input language, but it may decrease.

As an example, if an NFA has property EDA, then there exists three words w_1, w_2 and w_3 such that $w_1w_2w_3$ is an accepting word and $da_{\mathcal{A}}(q, w_2, q) \geq 2$, thus $w_1w_2w_3$ has at least two distinct accepting runs. However, this implies that $da_{\mathcal{A}}(w_1w_2^kw_3) \geq 2^k$ and thus $w_1w_2^kw_3$ has at least 2^k accepting runs. Now, if we are given some bounded language $\mathcal{L}$ such that $w_1w_2w_3 \in \mathcal{L}$ and $da_{\mathcal{A}}(q, w_2, q) \geq 2$ then the same implication is not possible, unless $w_2 \in \Sigma$ is a single letter, otherwise there is no guarantee that $w_1w_2^kw_3 \in \mathcal{L}$. Nevertheless, in the results of this paper we will use the standard definitions of ambiguity since the distinction is not relevant in our results as will become clear.

We note the following trivial lemma, which will be useful later.

▶ **Lemma 6.** *Probabilistic finite automata defined over upper-triangular matrices are polynomially ambiguous.*

Proof. This lemma is immediate from Theorem 5 and property (EDA), since a PFA defined over upper-triangular matrices clearly does not have property (EDA). This is since a transition matrix (for a letter "a") which is upper-triangular only defines transitions of the form $\delta(i,a) = j$ where $i \leq j$ and thus the states entered for any run are monotonically nondecreasing. ◀

2.4 Reducible Undecidable Problems

We will require the following undecidable problems for proving later results. The first is a variant of the famous *Post's Correspondence Problem* (PCP).

▶ **Problem 7** (Mixed Modification PCP (MMPCP)). *Given a binary alphabet Σ_2, a finite set of letters $\Sigma = \{s_1, s_2, \ldots, s_{|\Sigma|}\}$, and a pair of homomorphisms $h, g : \Sigma^* \to \Sigma_2^*$, the MMPCP asks to decide whether there exists a word $w = x_1 \ldots x_k \in \Sigma^+, x_i \in \Sigma$ such that*

$$h_1(x_1)h_2(x_2)\ldots h_k(x_k) = g_1(x_1)g_2(x_2)\ldots g_k(x_k),$$

where $h_i, g_i \in \{h, g\}$, and there exists at least one j such that $h_j \neq g_j$.

▶ **Theorem 8** ([12]). *The Mixed Modification PCP is undecidable for $|\Sigma| \geq 9$.*

A second useful undecidable problem is *Hilbert's tenth problem*: Let $P(n_1, n_2, \ldots, n_k)$ be an integer polynomial with k variables - determine if there exists a procedure to find if there exist $x_1, x_2, \ldots, x_k \in \mathbb{Z}$ such that: $P(x_1, x_2, \ldots, x_k) = 0$. It is well known that this may be reduced to a problem in formal power series. It was shown in [29, p.73] that the above problem can be reduced to that of determining for a $\mathbb{Z}$-rational formal power series $S \in \mathbb{Z}\langle\langle A \rangle\rangle$, whether there exists any word $w \in A^*$ such that $(S, w) = 0$. The undecidability of this problem was shown in 1970 by Y. Matiyasevich (building upon work of Davis, Putman, Robinson and others). For more details, see the excellent reference [23]. We may, without loss of generality, restrict the variables to be natural numbers [23, p.6].

3 Cut-point languages for polynomially ambiguous PFA over letter monotonic languages

It was proven in [4] that the emptiness problem is undecidable for probabilistic finite automata even when input words are given over a letter-monotonic language, i.e., given a letter-monotonic language $\mathcal{L}$, it is undecidable to determine if $\{w \in \mathcal{L} | f_{\mathcal{P}}(w) \Delta \lambda\}$ is empty for $\Delta \in \{\leq, <, >, \geq\}$. The constructed PFA $\mathcal{P}$ of [4] has exponential ambiguity, due to the well-known Turakainen conversion of arbitrary integer matrices into stochastic matrices. Here, we show that the emptiness problem for PFA over letter-monotonic languages can also be achieved even when all matrices have polynomial ambiguity by a modified Turakainen procedure.

The following property of the Kronecker product will also be required for the proof of Theorem 1.

▶ **Lemma 9.** *Let $A_1, \ldots, A_\ell \in \mathbb{F}^{n \times n}$. Then for any index sequence $(i_1, j_1), \ldots, (i_\ell, j_\ell)$ with each $(i_s, j_s) \in [1, n] \times [1, n]$ then there exists $1 \leq i, j \leq n^\ell$ such that*

$$\prod_{m=1}^{\ell} (A_m)_{i_m, j_m} = \left(\bigotimes_{m=1}^{\ell} A_m \right)_{i,j}$$

Proof. The proof proceeds by induction. For the base case when $\ell = 1$, we just set $(i, j) = (i_1, j_1)$ and we are done. Assume then that the result holds for some $\ell - 1$, then for sequence $(i_1, j_1), (i_2, j_2), \ldots, (i_{\ell-1}, j_{\ell-1})$ there exists $1 \leq i', j' \leq n^{\ell-1}$ such that:

$$\prod_{m=1}^{\ell-1} (A_m)_{i_m, j_m} = \left(\bigotimes_{m=1}^{\ell-1} A_m \right)_{i', j'}$$

By the definition of Kronecker product,

$$\left(\left(\bigotimes_{m=1}^{\ell-1} A_m \right) \otimes A_\ell \right)_{ni'+i_\ell, nj'+j_\ell} = \prod_{m=1}^{\ell-1} (A_m)_{i_m, j_m} \times (A_\ell)_{i_\ell, j_\ell}$$

as required. ◀

Note that we can of course work out the particular value of i and j, but in general the formula for i, j does not have a nice form when $\ell > 2$, and anyway will not be necessary for us, so we settle for an existential proof of such i and j.

3.1 Proof of Theorem 1

Proof. We will construct a polynomially ambiguous probabilistic finite automaton $\mathcal{P}$, a cut-point $\lambda \in [0, 1]$ and a letter monotonic language $\mathcal{L}$.

We begin by encoding an instance of Hilbert's tenth problem into a set of integer matrices. Let $P(x_1, x_2, \ldots, x_t) = 0$ be a Diophantine equation. Homogenenization of polynomials is a well known technique, as is used for example in the study of Gröbner bases [11], which allows us to convert such a Diophantine equation to $P^h(x_0, x_1, x_2, \ldots, x_t) = 0$ with a new dummy variable x_0 such that P^h is a homogeneous polynomial (each term having the same degree d) and for which $P^h(x_0, x_1, \ldots, x_t) = P(x_1, x_2, \ldots, x_t)$ when $x_0 = 1$. We thus assume a homogeneous Diophantine equation $P^h(x_0, x_1, \ldots, x_t) = 0$ with implied constraint $x_0 = 1$ which will be dealt with later. Furthermore, we assume that P^h gives nonnegative values, which may be assumed by redefining $P^h = (P^h)^2$, which clearly does not affect whether a zero exists for such a polynomial.

Notice that given $A = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$, then $A^k = \begin{pmatrix} 1 & k \\ 0 & 1 \end{pmatrix}$. We will generalise this property to a set of $t+1$ matrices $A_0, A_1, \ldots, A_t \in \mathbb{Z}^{(t+3)\times(t+3)}$ so that given any tuple $(x_0, x_1, x_2, \ldots, x_t)$, then x_i appears as an element on the superdiagonal of $A_0^{x_0} A_1^{x_1} \cdots A_t^{x_t}$ for each $0 \leq i \leq t$. We will also have the property that each A_i has the same row sum of 2 for every row, which will be useful when we later convert to stochastic matrices.

We define each matrix A_i for $0 \leq i \leq t+1$ in the following way:

$$A_i = \begin{pmatrix} 1 & \delta_{0,i} & 0 & \cdots & 0 & 0 & 1-\delta_{0,i} \\ 0 & 1 & \delta_{1,i} & \cdots & 0 & 0 & 1-\delta_{1,i} \\ 0 & 0 & 1 & \cdots & 0 & 0 & 1-\delta_{2,i} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & \delta_{t,i} & 1-\delta_{t,i} \\ 0 & 0 & 0 & \cdots & 0 & 1 & 1 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 2 \end{pmatrix} \in \mathbb{N}^{(t+3)\times(t+3)}, \tag{1}$$

where $0 \leq j \neq i \leq t$ and $\delta_{\ell,i} \in \{0, 1\}$ is the Kronecker delta (thus $\delta_{i,i} = 1$ and $\delta_{\ell,i} = 0$ for $\ell \neq i$). We also denote $J = A_{t+1}$, noting that this is the matrix (1) when all $\delta_{\ell,i}$ have the

value 0. Notice then that every row sum of A_i and J is 2. This structure is retained under matrix powers and it is easy to see that:

$$A_i^k = \begin{pmatrix} 1 & k\delta_{0,i} & 0 & \cdots & 0 & 0 & 2^k - k\delta_{0,i} - 1 \\ 0 & 1 & k\delta_{1,i} & \cdots & 0 & 0 & 2^k - k\delta_{1,i} - 1 \\ 0 & 0 & 1 & \cdots & 0 & 0 & 2^k - k\delta_{2,i} - 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & k\delta_{t,i} & 2^k - k\delta_{t,i} - 1 \\ 0 & 0 & 0 & \cdots & 0 & 1 & 2^k - 1 \\ 0 & 0 & 0 & \cdots & 0 & 0 & 2^k \end{pmatrix} \in \mathbb{N}^{(t+3)\times(t+3)} \tag{2}$$

All row sums of A_i^k are 2^k and exactly one element of the superdiagonal is equal to k, with all other elements on the superdiagonal (excluding that on row $t+2$) zero. Taking powers of A_i will allow us to choose any positive value of variable x_i. Note that J^k has the same form as the matrix of (2) with all $\delta_{\ell,i} = 0$ and acts as a kind of identity matrix, (in its upperleft block) while retaining the 2^k row sum. Indeed, one sees that for all $0 \leq i, j \leq t+1$, then $A_iA_j = A_jA_i$, i.e. these matrices commute (as does J since $J = A_{t+1}$). We now show how to compute terms of P^h.

We may write $P^h(x_0, x_1, \ldots, x_t) = \sum_{j=1}^{r} T_j(x_0, x_1, \ldots, x_t)$, where T_j denotes the j'th term of P^h, with P^h having r terms. Since P^h is a homogeneous polynomial, each term has the same degree d. We may thus write each term as:

$$T_j(x_0, x_1, \ldots, x_t) \quad = \quad c_j R_j(x_0, x_1, \ldots, x_t), \tag{3}$$

with $c_j \in \mathbb{Z}$ and $R_j(x_0, x_1, \ldots, x_t) = \prod_{\ell=0}^{t} x_\ell^{r_{j,\ell}}$ with $r_{j,\ell} \geq 0$ and $\sum_{\ell=0}^{t} r_{j,\ell} = d$. For convenience, we define a d-dimensional vector $s_j = \bigotimes_{\ell=0}^{t} \ell^{\otimes r_{j,\ell}} \in [0,t]^d$. For example, if $t = 4, d = 8$ and $T_j(x_0, x_1, x_2, x_3, x_4) = 6x_1^2x_3^5x_4$, then $R_j(x_0, x_1, x_2, x_3, x_4) = x_0^0x_1^2x_2^0x_3^5x_4^1$ and thus $s_j = (1,1,3,3,3,3,3,4)^T \in [0,4]^8$. By $s_j[i]$ we denote the i'th element of vector s_j.

We now define $t+1$ matrices corresponding to term T_j:

$$X_{j,i} = \bigotimes_{\ell=0}^{i-1} J^{\otimes r_{j,\ell}} \otimes A_i^{\otimes r_{j,i}} \otimes \bigotimes_{\ell=i+1}^{d} J^{\otimes r_{j,\ell}},$$

where $0 \leq i \leq t$. The dimension of such matrices is $(t+3)^d \times (t+3)^d$ since each submatrix has dimension $(t+3) \times (t+3)$ and we take the d-fold Kronecker product. Similarly, we see that the row sum of each $X_{j,i}$ is 2^d since the row sum of each A_i and J is 2 and we take a d-fold Kronecker product. Clearly then, by the mixed product property (see Lemma 4):

$$X_{j,i}^k = \bigotimes_{\ell=0}^{i-1} (J^k)^{\otimes r_{j,\ell}} \otimes (A_i^k)^{\otimes r_{j,i}} \otimes \bigotimes_{\ell=i+1}^{d} (J^k)^{\otimes r_{j,\ell}},$$

for any $k \geq 0$. In the example when $r_{j,0} = 0$, $r_{j,1} = 2$, $r_{j,2} = 0$, $r_{j,3} = 5$ and $r_{j,4} = 1$, then $X_{j,3} = J^{\otimes 0} \otimes J^{\otimes 2} \otimes J^{\otimes 0} \otimes A_i^{\otimes 5} \otimes J^{\otimes 1} = J^{\otimes 2} \otimes A_i^{\otimes 5} \otimes J$. We then see that $X_{j,3}^k = (J^k)^{\otimes 2} \otimes (A_3^k)^{\otimes 5} \otimes J^k$.

Now, we see that:

$$X_{j,0}^{x_0} X_{j,1}^{x_1} \cdots X_{j,t}^{x_t} \quad = \quad \prod_{i=0}^{t} \left(\bigotimes_{\ell=0}^{i-1} (J^{x_i})^{\otimes r_{j,\ell}} \otimes (A_i^{x_i})^{\otimes r_{j,i}} \otimes \bigotimes_{\ell=i+1}^{d} (J^{x_i})^{\otimes r_{j,\ell}} \right) \tag{4}$$

$$\quad = \quad \bigotimes_{\ell=0}^{d} \left(D_{\ell,0}^{x_0} D_{\ell,1}^{x_1} \cdots D_{\ell,t}^{x_t} \right), \tag{5}$$

where $D_{\ell,i} \in \{J, A_i\}$ for $0 \leq i \leq t$. The derivation of Eqn (5) from Eqn (4) follows by the mixed product property of the Kronecker product (Lemma 4). For each product $D_{\ell,0}^{x_0} D_{\ell,1}^{x_1} \cdots D_{\ell,t}^{x_t}$, we see that $D_{\ell,s_j[\ell]} = A_{s_j[\ell]}$ and $D_{\ell,j} = J$ for all $0 \leq j \leq d$ with $j \neq s_j[\ell]$. As discussed earlier, matrices A_i and J commute, for any $0 \leq i \leq t$ and thus we may rewrite (5) as:

$$X_{j,0}^{x_0} X_{j,1}^{x_1} \cdots X_{j,t}^{x_t} = \bigotimes_{\ell=0}^{d} \left(A_{s_j[\ell]}^{x_{s_j[\ell]}} \otimes J^{\overline{x_{s_j[\ell]}}} \right), \text{ where } \overline{x_{s_j[\ell]}} = \sum_{\substack{0 \leq q \leq d \\ q \neq s_j[l]}} x_q \tag{6}$$

By Lemma 9, we see that some element of $X_{j,0}^{x_0} X_{j,1}^{x_1} \cdots X_{j,t}^{k_t}$ is thus equal to $R_j(x_0, x_1, \ldots, x_t)$ as required, since there is an element on the superdiagonal of $A_{s_j[\ell]}^{x_{s_j[\ell]}}$ equal to $x_{s_j[\ell]}$ for each $0 \leq \ell \leq d$. Let us assume that $R_j(x_0, x_1, \ldots, x_t)$ appears at row i_1 and column i_2. Now, we may define a vector $u'_j = c_j e_{i_1}$ and $v'_j = e_{i_2}$ where c_j is the coefficient of term T_j as in Eqn (3) and $e_{i_1}, e_{i_2} \in \mathbb{Z}^{(t+3)^d}$ are basis vectors. We may now see that

$$(u'_j)^T X_{j,0}^{x_0} X_{j,1}^{x_1} \cdots X_{j,t}^{x_t} v'_j = c_j R_j(x_0, x_1, \ldots, x_t) = T_j(x_0, x_1, \ldots, x_t) \tag{7}$$

In order to derive the sum of the r such terms $\sum_{j=1}^{r} T_j(x_0, x_1, \ldots, x_t)$, we will utilise the *direct sum*. For $0 \leq \ell \leq d$, we define Y'_ℓ by:

$$Y'_\ell = \bigoplus_{j=1}^{r} X_{j,\ell} \in \mathbb{N}^{r(t+3)^d \times r(t+3)^d}$$

We shall now modify each Y'_ℓ so that they are row stochastic. We recall that the row sum of each A_ℓ and J is 2. Therefore, the row sum of each $X_{j,\ell}$ is 2^d, since $X_{j,\ell}$ is a d-fold Kronecker product of A_i and J matrices. Then the row sum of each Y'_ℓ is also 2^d since direct sums do not modify the row sum. We thus see that $Y_\ell = \frac{1}{2^d} Y'_\ell$ is row stochastic.

We now consider the coefficients of each term. We previously multiplied each initial vector u_j by c_j and we may consider taking the Kronecker sum of each u_j before normalising the resulting vector (normalising according to L^1 norm). We face an issue however, since some coefficients c_j may be negative and thus the resulting vector is not stochastic (it must be nonnegative). Fortunately we may modify a technique utilised by Bertoni [5] to solve this issue. Given a PFA for which $u^T X v = \lambda \in [0, 1]$, then by defining $v' = \mathbf{1} - v$ where $\mathbf{1}$ is the all-one vector of appropriate dimension (i.e. swapping between final and non final states), then $u^T X v = 1 - \lambda \in [0, 1]$.

Now, since each $X_{j,\ell}$ has a row sum of 2^d and u'_j is of unit length (L^1 norm), then Eqn. (7) can be adapted to the following:

$$\begin{aligned} (u'_j)^T X_{j,0}^{x_0} X_{j,1}^{x_1} \cdots X_{j,t}^{x_t} (\mathbf{1} - v'_j) &= 2^{d(x_0+x_1+\ldots+x_t)} - c_j R_j(x_0, x_1, \ldots, x_t) \\ &= 2^{d(x_0+x_1+\ldots+x_t)} - T_j(x_0, x_1, \ldots, x_t) \end{aligned} \tag{8}$$

Let us assume, without loss of generality, that we have arranged the terms of P^h such that those terms with a positive coefficient (positive terms) appear first, followed by those with a negative coefficient (negative terms). Since we have r terms in P^h, there exists some $1 \leq r' < r$ such that we have r' postive and $r - r'$ negative terms. Let us define $u_j = |c_j| e_{i_1}$, which is similar to u'_j defined previously, but using the absolute value of the corresponding coefficient.

We define $v = \bigoplus_{j=1}^{r'} v_j \oplus \bigoplus_{j=r'+1}^{r} (\mathbf{1} - v_j) \in \{0, 1\}^{r(t+3)^d}$ as the final vector, so that we take the Kronecker sum of all final vectors, but we swap final and non-final states for the negative terms.

We now define the initial vector u, which must be a probability distribution. Let $g = \sum_{j=1}^{r} |c_j|$ be the sum of absolute values of coefficients and define $u = \frac{1}{g} \bigoplus_{j=1}^{r} u_j \in [0,1]^{r(t+3)^d}$. Note that u is stochastic (a probability distribution).

We now see that:

$$u^T Y_0 Y_1^{a_1} \cdots Y_t^{a_t} v \tag{9}$$

$$= \frac{\sum_{j=1}^{r'} u_j \left(\bigotimes_{\ell=0}^{d} A_{s_j[\ell]}^{x_{s_j[\ell]}} \otimes J^{\overline{x_{s_j[\ell]}}} \right) v_j + \sum_{j=r'+1}^{r} u_j \left(\bigotimes_{\ell=0}^{d} A_{s_j[\ell]}^{x_{s_j[\ell]}} \otimes J^{\overline{x_{s_j[\ell]}}} \right) (\mathbf{1} - v_j)}{g 2^{d(1+a_1+\cdots+a_t)}}$$

Here we used the definition of matrices Y_i and Eqn. (6) to rewrite the expressions for $X_{j,0} \cdots X_{j,t}$. Notice that the power of Y_0 is set at 1, since that constraint is required by the conversion from a standard Diophantine polynomial to a homogeneous one as explained previously. Now, using Eqn. (7) and Eqn. (8), we can rewrite Eqn. (9) as:

$$\frac{\sum_{j=1}^{r'} T_j(x_0, \ldots, x_t) + \sum_{j=r'+1}^{r} \left(2^{d(1+a_1+\ldots+a_t)} - |T_j(x_0, \ldots, x_t)| \right)}{g 2^{d(1+a_1+\cdots+a_t)}} \tag{10}$$

$$= \frac{(r - r' + 1)}{g} + \frac{\sum_{j=1}^{r'} T_j(x_0, \ldots, x_t) + \sum_{j=r'}^{r} T_j(x_0, \ldots, x_t)}{g 2^{d(1+a_1+\cdots+a_t)}} \tag{11}$$

$$= \frac{(r - r' + 1)}{g} + \frac{P^h(x_0, x_1, \ldots, x_t)}{g 2^{d(1+a_1+\cdots+a_t)}} \tag{12}$$

We therefore define $\mathcal{P} = (u, \{Y_a | a \in \Sigma_t\}, v)$ and $\Sigma_t = \{0, 1, \ldots, t\}$ as our PFA, with letter monotonic language $\mathcal{L} = 01^*2^* \cdots t^*$ and $\lambda = \frac{r-r'+1}{g} \in [0,1] \cap \mathbb{Q}$ as the cut-point. There exists some word $w = 01^{x_1}2^{x_2} \cdots t^{x_t} \in \mathcal{L}$ such that $f_{\mathcal{P}}(w) \leq \lambda$ if and only if $P^h(1, x_1, x_2, \ldots, x_t) = 0$. Therefore the strict emptiness problem for $\mathcal{P}$ is undecidable on letter monotonic languages. Since $\mathcal{P}$ is upper-triangular, then it is polynomially ambiguous. We note the surprising fact that all generator matrices are in fact *commutative* (each $X_{j,i}$ is commutative and direct sums do not affect commutativity), which leads to the undecidability of non-strict cut-points for polynomially ambiguous PFA defined over commutative matrices. In this case, the order of the input word in irrelevant, only the Parikh vector of alphabet letters is important. In fact we may redefine $u = uY_0$ and $\mathcal{L} = 1^*2^* \cdots t^*$ to remove Y_0 and all constraints on $\mathcal{L}$. ◀

4 Injectivity problems for polynomially ambiguous PFA

We now study the injectivity of acceptance probabilities of polynomially ambiguous PFA. The next result begins with a proof technique from [4], where the undecidability of the injectivity problem (called the freeness problem in [4], although we here rename it injectivity) was shown for exponentially ambiguous PFA over five states. We show that the injectivity problem remains undecidable even when the PFA is polynomially ambiguous and over four states by using our new encoding technique (avoiding the Turakainen procedure which increases the matrix dimensions by two and generates an exponentially ambiguous PFA).

4.1 Proof of Theorem 2

Proof. Let $\Sigma = \{x_1, x_2, \ldots, x_{n-2}\}$ and $\Delta = \{x_{n-1}, x_n\}$ be distinct alphabets and $h, g : \Sigma^* \to \Delta^*$ be an instance of the mixed modification PCP. The naming convention will become apparent below. We define two injective mappings $\alpha, \beta : (\Sigma \cup \Delta)^* \to \mathbb{Q}$ by:

$$\alpha(x_{i_1} x_{i_2} \cdots x_{i_m}) = \Sigma_{j=1}^{m} i_j (n+1)^{j-1},$$
$$\beta(x_{i_1} x_{i_2} \cdots x_{i_m}) = \Sigma_{j=1}^{m} i_j (n+1)^{-j},$$

and $\alpha(\varepsilon) = \beta(\varepsilon) = 0$. Thus α represents $x_{i_1}x_{i_2}\cdots x_{i_m}$ as a reverse $(n+1)$-adic number and β represents $x_{i_1}x_{i_2}\cdots x_{i_m}$ as a fractional number $(0.x_{i_1}x_{i_2}\cdots x_{i_m})_{(n+1)}$ (e.g. if $n = 9$, then $x_1x_2x_3$ is represented as $\alpha(x_1x_2x_3) = 321_{10}$ and $\beta(x_1x_2x_3) = 0.123_{10}$, where subscript 10 denotes base 10). Note that $\forall w \in (\Sigma \cup \Delta)^*, \alpha(w) \in \mathbb{N}$ and $\beta(w) \in [0,1) \cap \mathbb{Q}$. It is not difficult to see that $\forall w_1, w_2 \in (\Sigma \cup \Delta)^*, (n+1)^{|w_1|}\alpha(w_2) + \alpha(w_1) = \alpha(w_1w_2)$ and $(n+1)^{-|w_1|}\beta(w_2) + \beta(w_1) = \beta(w_1w_2)$.

Define $\gamma'' : (\Sigma \cup \Delta)^* \times (\Sigma \cup \Delta)^* \to \mathbb{Q}^{3\times 3}$ by

$$\gamma''(u,v) = \begin{pmatrix} (n+1)^{|u|} & 0 & \alpha(u) \\ 0 & (n+1)^{-|v|} & \beta(v) \\ 0 & 0 & 1 \end{pmatrix}.$$

It is easy to verify that $\gamma''(u_1,v_1)\gamma''(u_2,v_2) = \gamma''(u_1u_2, v_1v_2)$, i.e., γ'' is a homomorphism.

Let $\mathcal{G}'' = \{\gamma''(x_i, g(x_i)), \gamma''(x_i, h(x_i)) | x_i \in \Sigma, 1 \leq i \leq n-2\}$, $\mathcal{S}'' = \langle \mathcal{G}'' \rangle$, $\rho'' = (1,1,0)^T$ and $\tau'' = (0,0,1)^T$. Assume that there exist $M_1 = G_{i_1}G_{i_2}\cdots G_{i_t} \in \langle \mathcal{G}'' \rangle$ and $M_2 = G_{j_1}G_{j_2}\cdots G_{j_{t'}} \in \langle \mathcal{G}'' \rangle$ such that $t \neq t'$ or else at least one $G_{i_p} \neq G_{j_p}$ where $1 \leq p \leq t$ and $\lambda = \rho''^T M_1 \tau'' = \rho''^T M_2 \tau''$. We see that:

$$\lambda = \rho''^T M_1 \tau'' = \alpha(x_{i_1}x_{i_2}\cdots x_{i_t}) + \beta(f_1(x_{i_1})f_2(x_{i_2})\cdots f_t(x_{i_t})),$$
$$\lambda = \rho''^T M_2 \tau'' = \alpha(x_{j_1}x_{j_2}\cdots x_{j_{t'}}) + \beta(f'_1(x_{j_1})f'_2(x_{j_2})\cdots f'_{t'}(x_{j_{t'}})),$$

where each $f_i, f'_i \in \{g, h\}$. Since $\alpha(w) \in \mathbb{N}$ and $\beta(w) \in (0,1) \cap \mathbb{Q}$, $\forall w \in (\Sigma \cup \Delta)^*$, injectivity of α and β implies that if $\rho''^T M_1 \tau'' = \rho''^T M_2 \tau''$, then $t = t'$ and $i_k = j_k$ for $1 \leq k \leq t$. Furthermore, if $\rho^T M_1 \tau = \rho^T M_2 \tau$, we have that $\beta(f_1(x_{i_1})f_2(x_{i_2})\cdots f_t(x_{i_t})) = \beta(f'_1(x_{i_1})f'_2(x_{i_2})\cdots f'_t(x_{i_t}))$ and since at least one $f_p \neq f'_p$ for $1 \leq p \leq t$ by our above assumption, then this corresponds to a correct solution to the MMPCP instance (h, g). On the other hand, if there does not exist a solution to (h, g), then $\beta(f_1(x_{i_1})f_2(x_{i_2})\cdots f_t(x_{i_t})) \neq \beta(f'_1(x_{i_1})f'_2(x_{i_2})\cdots f'_t(x_{i_t}))$, and injectivity of β implies that $\rho''^T M_1 \tau'' \neq \rho''^T M_2 \tau''$.

We now use our new technique to encode such matrices and vectors to a linearly ambiguous four state PFA. We first define a mapping $\gamma' : (\Sigma \cup \Delta)^* \times (\Sigma \cup \Delta)^* \to \mathbb{N}^{3\times 3}$ to make all matrices be nonnegative integral:

$$\gamma'(u,v) \quad = \quad (n+1)^{|v|}\gamma''(u,v) = \begin{pmatrix} (n+1)^{|u|+|v|} & 0 & (n+1)^{|v|}\alpha(u) \\ 0 & 1 & (n+1)^{|v|}\beta(v) \\ 0 & 0 & (n+1)^{|v|} \end{pmatrix} \in \mathbb{N}^{3\times 3}$$

We next define the following morphism $\gamma : (\Sigma \cup \Delta)^* \times (\Sigma \cup \Delta)^* \to \mathbb{Q}^{4\times 4}$ to make all such matrices be row stochastic:

$$\gamma(u,v) = (n+1)^{-k} \begin{pmatrix} (n+1)^{|u|+|v|} & 0 & (n+1)^{|v|}\alpha(u) & \delta_1 \\ 0 & 1 & (n+1)^{|v|}\beta(v) & \delta_2 \\ 0 & 0 & (n+1)^{|v|} & \delta_3 \\ 0 & 0 & 0 & \delta_4 \end{pmatrix},$$

where $\delta_j \in \mathbb{N}$ are chosen so that the row sum of each row of $\gamma(u,v)$ is $(n+1)^k$ for some k. Any sufficiently large k can be used so long as each row has the same sum $(n+1)^k$ and thus $\gamma(u,v)$ becomes row stochastic. We use the same k value for all matrices of $\mathcal{G}$ which we define as $\mathcal{G} = \{\gamma(x_i, g(x_i)), \gamma(x_i, h(x_i)) | x_i \in \Sigma, 1 \leq i \leq n-2\}$, so that $\mathcal{S} = \langle \mathcal{G} \rangle$, and finally $\rho = (1,1,0,0)^T$ and $\tau = (0,0,1,0)^T$ are the initial and final state vectors respectively.

Assume that there exist $M_1 = G_{i_1} \cdots G_{i_t} \in \langle \mathcal{G} \rangle$ and $M_2 = G_{j_1} \cdots G_{j_{t'}} \in \langle \mathcal{G} \rangle$ such that $t \neq t'$ or else at least one $G_{i_p} \neq G_{j_p}$ for $1 \leq p \leq t$ and $\lambda = \rho^T M_1 \tau = \rho^T M_2 \tau$. We see that:

$$\lambda = \rho^T M_1 \tau = (n+1)^{-kt} \left(\alpha(x_{i_1} x_{i_2} \cdots x_{i_t}) + \beta(f_1(x_{i_1}) f_2(x_{i_2}) \cdots f_t(x_{i_t}))\right),$$
$$\lambda = \rho^T M_2 \tau = (n+1)^{-kt'} \left(\alpha(x_{j_1} x_{j_2} \cdots x_{j_{t'}}) + \beta(f'_1(x_{j_1}) f'_2(x_{j_2}) \cdots f'_{t'}(x_{j_{t'}}))\right),$$

where each $f_i, f'_i \in \{g, h\}$. If $t = t'$, then the same argument as previously shows that $i_k = j_k$ for $1 \leq k \leq t$. If $t \neq t'$, assume without loss of generality that $t' < t$. In this case we see that:

$$(n+1)^{-kt''} \left(\alpha(x_{i_1} \cdots x_{i_t}) + \beta(f_1(x_{i_1}) \cdots f_t(x_{i_t}))\right) = \alpha(x_{j_1} \cdots x_{j_{t'}}) + \beta(f'_1(x_{j_1}) \cdots f'_{t'}(x_{j_{t'}})),$$

where $t'' = t - t'$. This is a contradiction however since the number of nonzero digits (where a digit is understood base $(n+1)$ here) in the left hand side of this expression is exactly $2t$, and the number of digits in the right expression is $2t' < 2t$. Note that the multiplication by $(n+1)^{-kt''}$ does not alter the number of nonzero digits, it is only a right shift of all digits, kt'' times. Thus, since the left and right sides have a different number of nonzero digits they cannot be equal and thus $t = t'$ as required. ◀

4.2 Proof of Theorem 3

Proof. We use a reduction from the equal subset sum problem, defined thus: given a set of positive integers $S = \{x_1, x_2, \ldots, x_k\} \subseteq \mathbb{N}$, do there exist two disjoint nonempty subsets $S_1, S_2 \subseteq S$ such that $\sum_{\ell \in S_1} \ell = \sum_{m \in S_2} m$? This problem is known to be NP-complete [32]. Note that although there is a requirement that the sets S_1 and S_2 be disjoint, this is not crucial so long as $S_1 \neq S_2$ (since if some element x_j is in both S_1, S_2, then the equality also holds when x_j is removed from both sets). We may therefore require that $S_1 \neq S_2$, with both nonempty such that the sum of elements of each set is identical. We define the set of matrices $M = \{A_i, B_i | 1 \leq i \leq k\} \subseteq \mathbb{Q}^{3\times 3}$ in the following way:

$$A_i = \frac{1}{x_i+1} \begin{pmatrix} 1 & x_i & 0 \\ 0 & 1 & x_i \\ 0 & 0 & x_i+1 \end{pmatrix}, \quad B_i = \frac{1}{x_i+1} \begin{pmatrix} 1 & 0 & x_i \\ 0 & 1 & x_i \\ 0 & 0 & x_i+1 \end{pmatrix}$$

Note that A_i and B_i are thus row stochastic. Let $u = (1,0,0)^T$ be the initial probability distribution, $v = (0,1,0)^T$ be the final state vector and let $\mathcal{P} = (u, \{A_i, B_i\}, v)$ be our PFA. Define letter monotonic language $\mathcal{L} = (a_1|b_1)(a_2|b_2)\cdots(a_k|b_k) \subseteq a_1^* b_1^* a_2^* b_2^* \cdots a_k^* b_k^*$ and define a morphism $\varphi : \{a_i, b_i | 1 \leq i \leq k\}^* \to \{A_i, B_i | 1 \leq i \leq k\}^*$ in the natural way (e.g. the morphism induced by $\varphi(a_i) = A_i$ and $\varphi(b_i) = B_i$). Now, for a word $w = w_1 w_2 \cdots w_k \in \mathcal{L}$, note that $w_j \in \{a_j, b_j\}$ for $1 \leq j \leq k$. Define that $\mathfrak{v}(a_i) = x_i$ and $\mathfrak{v}(b_i) = 0$. In this case, we see that (due to the structure of A_i and B_i)

$$u^T \varphi(w_1 w_2 \cdots w_k) v = \frac{1}{\sum_{j=1}^k (x_j + 1)} \sum_{\ell=1}^k \mathfrak{v}(w_\ell)$$

Note of course that the factor $\frac{1}{\sum_{j=1}^k (x_j+1)}$ is the same for any $w \in \mathcal{L}$.

Assume then that there exists two words $\alpha, \beta \in \mathcal{L}$ with $\alpha \neq \beta$ such that $u^T \varphi(\alpha) v = u^T \varphi(\beta) v$ (i.e. assume that $\mathcal{P}$ is not free). Then $\sum_{\ell=1}^k \mathfrak{v}(\alpha_\ell) = \sum_{i \in S_1}^k x_i = \sum_{i \in S_2}^k x_i = \sum_{\ell=1}^k \mathfrak{v}(\beta_\ell)$, where $S_1 = \{x_i; |\alpha|_{a_i} > 0\}$ and $S_2 = \{x_i; |\beta|_{a_i} > 0\}$. This is true if and only if the instance S of the equal subset sum problem has a solution as required (note that only the empty set has a sum of zero which has unique representation $b_1 \cdots b_k$). Since A_i and B_i are upper-triangular, with initial state 1 and final state 2, then $\mathcal{P}$ is linearly ambiguous. ◀

5 Conclusion

There are a variety of open problems remaining. For example, does Theorem 1 still hold for quadratic ambiguity, when taken alongside the other constraints (letter monotonic language and commutative matrices). Another direction is to improve the complexity lower bound of Theorem 3 to show it is either PSPACE-hard, EXPSPACE-hard or undecidable, under the same constraints as in the theorem statement.

Abstract

String-to-string MSO interpretations are like Courcelle's MSO transductions, except that a single output position can be represented using a tuple of input positions instead of just a single input position. In particular, the output length is polynomial in the input length, as opposed to MSO transductions, which have output of linear length. We show that string-to-string MSO interpretations are exactly the polyregular functions. The latter class has various characterisations, one of which is that it consists of the string-to-string functions recognised by pebble transducers.

Our main result implies the surprising fact that string-to-string MSO interpretations are closed under composition.

1 Introduction

A string-to-string function is called *regular* if it is computed by a deterministic two-way automaton with output. There are many equivalent models for the same class of functions: string-to-string MSO transductions [11], streaming string transducers [1], and various kinds of combinator-based formalisms [2, 5, 9].

A deterministic two-way automaton can visit each input position at most once in each state, otherwise it would loop forever. This means that the length of the run – and also the size of the output word – is linear in the input string. One way to go beyond linear-sized outputs was proposed by Milo, Suciu and Vianu [17], following earlier work by Globerman and Harel [12]: equip the automaton with k pebbles which can be used to mark positions in the input word. To avoid making the model Turing-powerful, the pebbles are required to observe a so-called stack discipline: they are organised in a stack, and only the top-most pebble can be moved. In [3], it is shown that pebble transducers are equivalent to multiple other models: a higher-order functional programming language [3, Section 4], an imperative programming language with for-loops [3, Section 3], combinators [3, end of Section 4], and

compositions of certain simple atomic functions [3, Section 1]. Because of the multitude of models and their polynomial-size outputs, the class of functions recognised by these models is called *polyregular functions*.

The list of models for polyregular functions described in [3] does not include any logical model. In this paper, we fix that omission. As mentioned above, for the regular functions, which have linear-size output, the logical model consists in string-to-string MSO transductions. In an MSO transduction, each position of the output string is interpreted as a single position of the input string. A natural idea to capture polyregular functions is to consider what we call *string-to-string* MSO *interpretations*, where a position of the output string is represented by a k-tuple of positions in the input string. At first glance, this idea looks suspicious: if string-to-string MSO interpretations were equivalent to polyregular functions, then they would be closed under composition, because the class of polyregular functions is. However, composing two string-to-string MSO interpretations

$$\Sigma^* \xrightarrow{f} \Gamma^* \xrightarrow{g} \Delta^*$$

raises the following issue. Suppose that positions of the intermediate word in Γ^* are represented by k-tuples of positions in the input word from Σ^*. If an MSO formula defining g quantifies over a set of positions in the intermediate word to define a property of the output word in Δ^*, then this corresponds to quantifying over a set of k-tuples of positions in the input word. If we assume dimension $k = 1$, then the problem dissolves, and this is why MSO transductions have dimension $k = 1$, whereas dimension $k > 1$ is never used in the context of MSO (as opposed to first-order logic, where the standard notion of transformation, i.e. first-order interpretation, uses higher dimensions).

As our main result, we show that the problems discussed above only invalidate the natural construction for composing MSO interpretations, which uses substitutions of formulas. Still, and surprisingly, for structures that represent strings there exists a (less natural) construction. This follows from our main result, which states that polyregular functions are exactly the string-to-string MSO interpretations. Indeed, corollaries of the main result are that (a) string-to-string MSO interpretations are closed under composition; and (b) for every regular string language, its inverse image under a string-to-string MSO interpretation is also regular. This is because (a) and (b) are true for polyregular functions. Proving (a) and (b) directly for string-to-string MSO interpretations seems hard; in fact an understandable (but wrong) first reaction to the claims (a) and (b) would be that they are false, for the reasons discussed in the previous paragraph.

It is easy to see that every polyregular function is a special case of a string-to-string MSO interpretation. One argument is that a k-pebble automaton can be simulated using a string-to-string MSO interpretation, by representing configurations of the pebble automaton using k-tuples of positions in the input word. The difficulty lies in proving the opposite direction and it comes from the stack discipline required in a pebble automaton. A k-tuple of positions used by an MSO interpretation can of course be viewed as a configuration of a pebble automaton, but there does not seem to be any reason why the resulting pebble automaton should observe stack discipline. It turns out – and this is the main technical insight of this paper – that any MSO formula which defines a linear ordering on k-tuples of positions in strings must necessarily observe an implicit stack discipline, which makes it possible to translate a string-to-string MSO interpretation into a pebble automaton.

Outline. After describing string-to-string MSO interpretations in Section 2, we revise polyregular functions via the formalism of for-programs in Section 3. In Section 4, we show that the models are equivalent.

Due to space limits, we omit some of the technical details and proofs in this article. For a full version, we defer the reader to [6]

2 Interpretations

In this section, we revise first-order and MSO interpretations, which are transformations of relational structures using formulas.

2.1 Logic and interpretations

Relational vocabularies and logic. A *(relational) vocabulary* is a set of relation names, each one associated with a natural number called its *arity*. For short, we refer to relational vocabularies simply as *vocabularies*. A *structure* over a vocabulary σ consists of a set called the *universe* and for each relation name of σ a corresponding relation of the same arity over the universe. To define properties of relational structures, we use monadic second-order logic and its first-order fragment with the usual syntax and semantics [19]. We use the convention that lower-case variables x, y, z range over elements and upper-case variables X, Y, Z range over sets of elements.

Interpretations. Intuitively speaking, an interpretation is a function from relational structures to relational structures where each element of the universe of the output structure is a tuple of elements of the input structure, and the relations of the output structure are defined using formulas evaluated over the input structure.

▶ **Definition 1** (Interpretations over general structures). *For $k \geq 1$, the syntax of a k-*dimensional first-order interpretation *consists of:*

1. *two vocabularies, called the* input vocabulary *and the* output vocabulary
2. *an* FO *formula over the input vocabulary with k free variables, called the* universe formula.
3. *for each n and each n-ary relation name R of the output vocabulary, an associated* FO *formula φ_R over the input vocabulary, with $k \cdot n$ free variables.*

MSO interpretations *are defined analogously, except that formulas of* MSO *are used, but the free variables still range over elements and not over sets.*

The semantics of an interpretation is a function from structures over the input vocabulary to structures over the output vocabulary, defined as follows.

- The universe of the output structure is the set of k-tuples of elements in the universe of the input structure which satisfy the universe formula from item 2 in Definition 1.
- An n-ary relation name R of the output vocabulary is interpreted as the set of n-tuples of k-tuples from the input structure for which (a) each k-tuple is in the output universe, and (b) the entire $(n \cdot k)$-tuple satisfies the formula φ_R in item 3 in Definition 1.

Composition. First-order interpretations are closed under composition [14, p. 218]. Let us recall the proof. Suppose that we want to compose interpretations

$$\text{structures over } \sigma_1 \xrightarrow{\mathcal{I}_1} \text{structures over } \sigma_2 \xrightarrow{\mathcal{I}_2} \text{structures over } \sigma_3$$

of dimensions k_1 and k_2, respectively. The $(k_1 \cdot k_2)$-dimensional composition is obtained from $\mathcal{I}_2$ as follows: (a) quantification over elements of $\mathcal{I}_2$ is replaced by a quantification over k_1-tuples of elements; and (b) relation names from σ_2 that appear in the input of $\mathcal{I}_2$ are replaced by the corresponding formulas from $\mathcal{I}_1$. This idea does not work for MSO in general,

since set quantification in $\mathcal{I}_2$ would need to be replaced by quantification over sets of k_1-tuples. It does work when $k_1 = 1$. This essentially corresponds to Courcelle's transductions, for which closure under composition follows naturally [8, Theorem 7.14]. To recover closure under composition for $k_1 \geq 2$, one can use (not necessarily monadic) second-order logic, which by Fagin's Theorem [16, Corollary 9.9] corresponds to the polynomial hierarchy of computational complexity and is outside the scope of this paper.

2.2 String-to-string interpretations

In this paper we are interested in interpretations that transform structures which represent strings. While there are two natural ways to model strings as relational structures, namely with an order relation or with a successor relation, only the order relation is useful in our context.

▶ **Definition 2** (String-to-string interpretations). *For a string $w \in \Sigma^*$, its* ordered model *is defined to be the following relational structure, denoted by $\underline{w}$:*

- *the universe consists of the positions in the string, i.e., natural numbers;*
- *there is a binary relation for the natural order on positions;*
- *for each $a \in \Sigma$ there is a unary relation which is satisfied by every position with label a.*

For alphabets Σ and Γ, a function $f\colon \Sigma^* \to \Gamma^*$ is called first-order string-to-string interpretation *if the corresponding transformation on ordered models is a first-order interpretation for strings with length at least two*[1]*. Likewise we define* MSO string-to-string interpretations.

▶ **Example 3.** Consider the function $f\colon \{a,b\}^* \to \{a,b\}^*$ which maps a word to the concatenation of all of its reversed prefixes, as in the following example (with prefixes grouped for better readability):

$$abbb \quad \mapsto \quad \underbrace{a}\,\underbrace{ba}\,\underbrace{bba}\,\underbrace{bbba}.$$

This transformation is the running example in [3]. We show that f can be seen as a string-to-string first-order interpretation. The dimension is 2, i.e. positions in the output word represent pairs of positions in the input word. A pair (x_1, x_2) of positions in the input word is used in the output word if it satisfies the universe formula $x_2 \leq x_1$. The idea is that x_1 represents the length of the prefix, while x_2 is the position in that prefix. The label of a position (x_1, x_2) is inherited from the second coordinate, as expressed by the formulas corresponding to labels on the output structure:

$$\varphi_a(x_1, x_2) = a(x_2) \quad \varphi_b(x_1, x_2) = b(x_2)$$

The order on the positions of the output word is defined by the formula

$$\varphi_{\leq}\Big(\underbrace{x_1, x_2}_{\substack{\text{a position of}\\ \text{the output word}}}, \underbrace{x_1', x_2'}_{\substack{\text{another position of}\\ \text{the output word}}}\Big) = (x_1 < x_1') \vee (x_1 = x_1' \wedge x_2 \geq x_2').$$

[1] A typical operation we want to model is string duplication. When the input length is at least two, one can represent additional copies of the input string using a higher dimension. For input length $n \leq 1$, the output length will be $n^k \leq 1$ regardless of the dimension k. Another solution to this issue would be to have duplication built into the definition of interpretations.

Note that the above formula defines the lexicographic ordering on pairs of positions, with the first coordinate being used in increasing order, and the second coordinate being used in decreasing order. This, as it will turn out, is not a coincidence, since our main technical result says that it is impossible to define a linear order on tuples of positions without implicitly using some kind of lexicographic ordering.

Successor instead of order. When modelling a string as a relational structure, we use the order on positions. An alternative solution would be to use just the successor relation. The difference between the two solutions is that it is harder to define an order on k-tuples of positions than it is to define a successor relation. It turns out that the difference is crucial, and functions that output strings with successor can be ill-behaved. Note that whether or not the input string is equipped with an order or a successor relation makes no difference, since the order on the positions of the input string can be recovered in MSO, which can compute the transitive closure of binary relations on positions.

Define the *successor model* of a string in the same way as the ordered model from Definition 2, except that a binary relation for successor is used instead of the order. Define a *successor*-MSO *string-to-string interpretation* to be a string-to-string function which is computed by an MSO interpretation, assuming that strings are represented by their successor models. Likewise, we define successor-first-order string-to-string interpretations. These are closed under composition, because first-order interpretations are closed under composition. On the other hand, successor-MSO string-to-string interpretations are not closed under composition and lead to undecidability, as summarised in the following theorem.

▶ **Theorem 4.**

1. *The class of successor-*MSO *string-to-string interpretations is not closed under composition, and strictly contains the class of (order-)*MSO *string-to-string interpretations.*
2. *The following is undecidable: given a successor-first-order string-to-string interpretation f and a regular language L over the output alphabet, decide if $f^{-1}(L)$ is nonempty.*

3 Polyregular functions

Here we describe the class of polyregular functions. It has several equivalent characterisations, see [3, Theorem 4.4], one of which consists in the afore-mentioned pebble transducers. For the purposes of this paper, it will be most convenient to use a slightly more abstract characterisation in terms of for-programs, a machine model for string-to-string functions. We just explain the formalism on short examples, for a more detailed description see [3].

```
for x in first..last
  for y in last..first
    if y≤x and a(y) then
      output a
    if y≤x and b(y) then
      output b
```

(a) A for-program for the function in Example 3.

```
for x in first..last
  var P : Bool
  for y in last..first
    if y≥x then
      P := not P
  if P and a(x) then
    output a
  if P and b(x) then
    output b
```

(b) A for-program with a Boolean variable `P`.

```
for y in first..last
  if x1≤y and y≤x2 and a(y)
      P := true
```

(c) A for-program which checks if there is an `a` between the positions `x1` and `x2`.

Figure 1 Example for-programs.

Most of the syntactic constructions that can be used in a for-program are illustrated in Figure 1a: (1) variables that range over positions in the input word; (2) for-loops in which a variable iterates over all positions in the input word in increasing or decreasing order; (3) if-statements which depend on the order/labels of variables; (4) instructions which output letters. Position variables cannot be declared or written to, they are implicitly declared by for-loops and their only updates are the iterations performed by the for-loops.

The only feature of for-programs that is not used in Figure 1a is (5) Boolean variables. Figure 1b shows a program that outputs only those letters in the input word which have even distance to the last position. In the program, the Boolean variable `P` is declared in the scope of a for-loop. On each iteration of the loop, the variable is reinitialised to false.

A for-program is called *first-order definable* if Boolean variables can only be updated from `false`, which is their initial value upon declaration, to `true`. In other words, the only allowed update for Boolean variables is `P := true`. For the first-order restriction, it is important that Boolean variables can be declared inside for-loops, and that they are reinitialised to `false` at each iteration of the loop that they are declared in. The reason for the name "first-order definable" is that one can define in first-order logic the reachability relation on program states of the for-program, see [3, Lemma 5.3].

▶ **Definition 5.** *A string-to-string function is called* polyregular *if it is computed by a for-program. It is called* first-order polyregular *if it is computed by a first-order definable for-program.*

The class of polyregular functions has other characterisations, including the string-to-string pebble transducers introduced by Milo, Suciu and Vianu [17], as well as a higher-order functional programming language [3, Section 4]. The main result of this paper, Theorem 7 in the next section, adds a logical characterisation, namely string-to-string MSO interpretations.

Evaluating first-order formulas. The for-programs described above take as input strings and also output strings. One can also consider for-programs which input a string with distinguished positions and which output a Boolean value, as in Figure 1c. The distinguished positions are represented by free variables (here `x1` and `x2`), while the output value is taken from some distinguished Boolean variable, here `P`.

▶ **Lemma 6.** *Let $\varphi(x_1, \dots, x_k)$ be an* FO *formula over strings. There is a first-order for-program which computes the following.*

- ***Input.*** *A word $w \in \Sigma^*$ and positions $x_1, \dots, x_k$ in w;*
- ***Output.*** *Yes or No, depending on whether w satisfies $\varphi(x_1, \dots, x_k)$.*

Proof. The for-program implements the semantics of an FO formula. For each quantifier, it loops over all possible values for the quantified position, and a Boolean variable is used to remember if some value has already been found which renders the formula true. ◀

A similar result is true for MSO formulas, but the proof for that statement uses automata.

4 Equivalence

We show that the models defined in Sections 2 and 3 are equivalent.

▶ **Theorem 7.**

1. *String-to-string* MSO *interpretations are exactly the polyregular functions.*
2. *First-order string-to-string interpretations are exactly the first-order polyregular functions.*

Since the class of polyregular functions is closed under composition[2], we obtain:

▶ **Corollary 8.** *String-to-string* MSO *interpretations are closed under composition.*

By using Theorem 7, the proof of the corollary passes through for-programs. We are not aware of any direct proof that does not exploit the equivalence to polyregular functions.

The rest of this paper is dedicated to the proof of Theorem 7. We begin with a reduction of the first to the second item. This reduction illustrates a general phenomenon, namely that results about first-order polyregular functions often imply results about general polyregular functions, despite the latter class being larger. The reason behind this phenomenon is the following lemma, which says that for every polyregular function, all of the behaviour that is not first-order definable can be pushed into a simple preprocessing step. Define a *rational function*, see [4, Section 13.2], to be a string-to-string function which is recognised by a nondeterministic automaton, where every transition is labelled by a pair consisting of a letter from the input alphabet and a string over the output alphabet, and which is unambiguous in the sense that every input string admits exactly one accepting run.

▶ **Lemma 9.**

1. *A function is polyregular if and only if it is a composition consisting of:*
   a. *a (letter-to-letter) rational function; followed by*
   b. *a first-order polyregular function.*
2. *A function is an* MSO *string-to-string interpretation if and only if it is a composition consisting of:*
   a. *a (letter-to-letter) rational function; followed by*
   b. *a first-order string-to-string interpretation.*

The proof of Lemma 9 can be found in [6]. It is based on ideas from [7, 15, 3] and uses factorisation forests. With the lemma, we show that item 2 in Theorem 7 implies item 1, i.e. if first-order string-to-string interpretations are exactly the first-order polyregular functions, then MSO interpretations are exactly the polyregular functions:

$$\begin{aligned} \text{polyregular} &= && \text{by item 1 of Lemma 9} \\ (\text{first-order polyregular}) \circ \text{rational} &= && \text{by item 2 of Theorem 7} \\ (\text{first-order interpretations}) \circ \text{rational} &= && \text{by item 2 of Lemma 9} \\ \text{MSO interpretations} & && \end{aligned}$$

It remains to prove item 2 in Theorem 7, i.e. that first-order string-to-string interpretations are exactly the first-order polyregular functions. The right-to-left inclusion follows immediately from [3, Lemma 5.3], which says that a formula in first-order logic can define the reachability relation on program states in first-order for-programs. We are left with the left-to-right-inclusion:

$$\text{first-order string-to-string interpretations} \subseteq \text{first-order definable for-programs} \qquad (1)$$

The rest of the paper is devoted to showing the above inclusion. When simulating a first-order interpretation by a for-program, we will mainly be concerned with the universe of the output string (which is a set of k-tuples of positions in the input string) and its ordering. The labelling of the k-tuples can then be recovered using the for-program from Lemma 6.

[2] Closure under composition was proved for pebble transducers in [10, Theorem 11] and for the class of for-programs in [3, Section 8.1] as a step in proving equivalence with the other models of polyregular functions.

The main result is that every first-order definable linear ordering on tuples of positions can be implemented by a for-program. To be able to speak about this result, we introduce some notation for devices that produce lists of tuples of positions.

Enumerators. Let $k \in \mathbb{N}$. A *k-enumerator* over an alphabet Σ is a function of the following form:

- **Input.** A string $w \in \Sigma^*$;
- **Output.** A list of k-tuples of positions in w, that is nonrepeating[3].

We compare the following two ways of implementing k-enumerators:

1. A k-enumerator is called *definable* if there are two FO formulas: one with k variables, which says when a tuple is part of the output list, and one with $2k$ variables, which defines a total order on the tuples selected by the first formula.
2. A k-enumerator is called *programmable* if its output can be computed by a first-order for-program that instead of outputting letters uses instructions of the form `output (x1,...,xk)` where `x1`, ..., `xk` are position variables.

For definable k-enumerators, the order on tuples in the output list is given explicitly by the formula φ, while in programmable ones, the order is implicit from the order in which the output instructions are executed during the computation.

▶ **Example 10.** We present an enumerator based on Example 3. Consider the 2-enumerator which outputs all pairs of positions (x_1, x_2) with $x_2 \leq x_1$, listed in lexicographic order, where x_1 is ordered in increasing order and x_2 is ordered in decreasing order. Here is an example:

$$abbb \quad \mapsto \quad (1,1),(2,2),(2,1),(3,3),(3,2),(3,1),(4,4),(4,3),(4,2),(4,1)$$

This enumerator is definable, as witnessed by the formula $\varphi_{\leq}$ in Example 3. The formula $\varphi_{\leq}$ is quantifier-free, but in general, quantifiers are allowed. Here is a for-program that computes the same function:

```
for x1 in first..last
  for x2 in last..first
    if x2 ≤ x1 then
      output (x1,x2)
```

The following lemma is the main technical result of this paper.

▶ **Lemma 11.** *Every definable k-enumerator is also programmable.*

Our proof of Lemma 11 uses two fundamental ingredients. The first is by now standard: this is Simon's factorisation forest theorem [18], which roughly says that every string can be cut into pieces that are similar to each other. The second ingredient is new: the Domination Lemma, presented in Section 4.1, roughly says that if a string is cut into pieces that are similar to each other, then any first-order definable linear order on tuples of positions must observe an implicit stack discipline. These two results are combined in Section 4.2 to prove Lemma 11. Before we proceed with the proof of Lemma 11, we use it to complete the proof of Theorem 7.

[3] Every tuple appears at most once, but positions can appear in multiple tuples. We need this for the existence of the formulas stated in the following definitions.

Proof of Theorem 7, second part. The only part of Theorem 7 that has not been proved yet is that every first-order string-to-string interpretation is polyregular. Suppose that f is a k-dimensional first-order string-to-string interpretation. Consider the k-enumerator that inputs a string w and outputs the list of k-tuples of positions in w used to represent output positions of $f(w)$, in the appropriate order. Apply Lemma 11 to obtain a first-order for-program g which computes the same list. To compute the original function f, we use a for-program which behaves as g, except that instead of outputting a k-tuple of positions like g, it uses the program described in Lemma 6 as a subroutine to check what is the output letter that should be produced for this tuple, and outputs that letter. ◀

4.1 The Domination Lemma

In this section we present the Domination Lemma, which says that if $\prec$ is a first-order definable linear order on k-tuples of positions in a string, then there is an implicit stack discipline in the following sense. For every type (see below) t of tuples of positions there is a coordinate $d \in \{1, \ldots, k\}$ such that for the subset of k-tuples of positions formed by all of type t, the order $\prec$ is uniquely determined by the order of the d-th coordinates in the string.

We begin by explaining the notions of types. For $r \in \{0, 1, \ldots\}$, the *rank r type* of a structure $\mathfrak{A}$ with k distinguished positions $\bar{x} \coloneqq (x_1, \ldots, x_k)$ is defined to be the set of first-order formulas of quantifier rank at most r and with k free variables that are true in $\mathfrak{A}, \bar{x}$. The number k is the *arity* of the type. For arity 0, we talk about the rank r *type of the structure* $\mathfrak{A}$. If the structure $\mathfrak{A}$ is implicit from the context, then we talk about the rank r type of the tuple $\bar{x}$. For every finite vocabulary, there are finitely many types of given arity and rank. We write $\equiv_r$ for the equivalence relation on structures with distinguished elements of having the same rank r type. For a binary relation R, its *inverse* is the set $\{(v, u) \mid (u, v) \in R\}$. For $p \in \{1, -1\}$, define R^p to be either R or its inverse, depending on the value of p.

▶ **Lemma 12** (Domination Lemma). *For all $k, m, r \in \{1, 2, \ldots\}$, there is an $\omega \in \{1, 2, \ldots\}$ with the following property. Let $n \in \{1, 2, \ldots\}$, let $w_1, \ldots, w_n$ be strings over some alphabet Σ and let $\mathfrak{A}$ be the ordered structure of the concatenation $w_1 \cdots w_n$ extended with the* block order *defined by*

$$x \sqsubset y \qquad \text{if} \qquad x \text{ is a position in } w_i \text{ and } y \text{ is a position in } w_j \text{ for some } i < j.$$

Let $\prec$ be a linear order on k-tuples in $\mathfrak{A}$ defined by a first-order formula of quantifier rank r, and let t be a k-ary rank ω type over the vocabulary of $\mathfrak{A}$. If

$$w_i \equiv_\omega w_{i+1} \qquad \text{holds for all } i \in \{1, \ldots, n-1\} \text{ with at most } m \text{ exceptions,}$$

then there is a $d \in \{1, \ldots, k\}$, called the dominating coordinate*, and a $p \in \{-1, 1\}$, called the* polarity*, such that*

$$x_d \sqsubset^p y_d \quad \text{implies} \quad (x_1, \ldots, x_k) \prec (y_1, \ldots, y_k) \qquad \text{for all } \underbrace{x_1, \ldots, x_k}_{\text{of type } t}, \underbrace{y_1, \ldots, y_k}_{\text{of type } t} \text{ in } \mathfrak{A}.$$

The Domination Lemma is the technical heart of this paper. The full proof can be found in [6]. To explain some of the ideas that we use, we treat a special case in detail. In the Domination Lemma, the structure $\mathfrak{A}$ consists of blocks organised in a linear way. A very simple linear order – although infinite – is the natural one on the rational numbers; one reason for its simplicity is that quantifiers can be eliminated (see [13, Section 5.6.2]). Because of this, it is quite easy to prove a version of the Domination Lemma for the rational numbers and still its proof bears some similarity to the proof of the general case.

▶ **Lemma 13** (Rational Domination Lemma). *Let $\prec$ be a linear ordering on k-tuples of rational numbers defined by a quantifier-free (equivalently, first-order) formula using only the usual ordering $<$ on rational numbers. Then there is a coordinate $d \in \{1, \ldots, k\}$ and a polarity $p \in \{-1, 1\}$ such that*

$$x_d <^p y_d \quad \textit{implies} \quad (x_1, \ldots, x_k) \prec (y_1, \ldots, y_k)$$

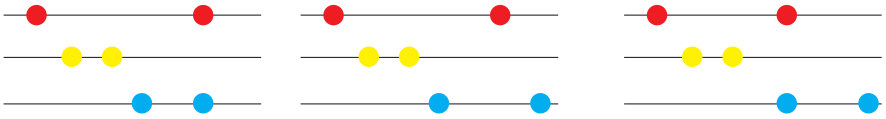
for all tuples of rational numbers satisfying $x_1 < \cdots < x_k$ and $y_1 < \cdots < y_k$.

Proof. We first prove the statement for $k = 1$ and $k = 2$ and then we deduce the general case.

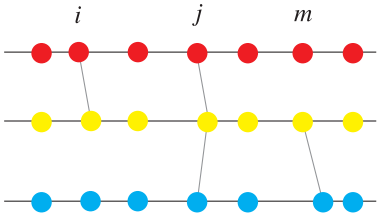
1. When $k = 1$, then the formula defining $\prec$ must be either $x < y$ or $x > y$.
2. For $k = 2$, we do a case analysis. Note that whether $\bar{x} \prec \bar{y}$ or $\bar{y} \prec \bar{x}$ holds depends only on the order relationship of the positions in $\bar{x}$ and $\bar{y}$ in the rational numbers and not on the precise values in $\bar{x}$ and $\bar{y}$.

   The following picture shows the two possible relationships for two pairs $\bar{x}$ and $\bar{y}$ when they are "consecutive" and the two possible relationships when they are "nested":

   Suppose we are given a pair $\bar{x}$ and without loss of generality, assume the "consecutive growing" case for some second pair $\bar{y}$. We only show the proof for the case that there is a pair $\bar{y}'$ such that $\bar{x}$ and $\bar{y}$ are "nested growing" ("nested decreasing" works analogously). We prove that $d = 1$ is dominating for $\prec$ with polarity $p = 1$. Consider all three remaining configurations of pairs $\bar{x}$ and $\bar{y}$ with $x_1 < y_1$. In all cases, $\bar{x} \prec \bar{y}$ is proved by finding an intermediate pair (drawn in yellow), whose order with respect to $\bar{x}$ and $\bar{y}$ follows from the assumptions "consecutive/nested growing" (in the pictures below, we assume that lower lines represent bigger tuples in the ordering $\prec$):



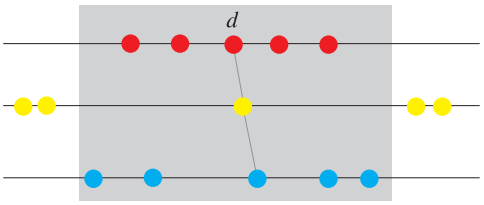
3. Consider the case $k > 2$. Fix a "growing" tuple of k rational numbers, i.e. a tuple $\bar{z}$ such that for $1 \leq i < j \leq k$, it holds that $z_1 \leq z_i < z_j \leq z_k$. Define $\prec_{ij}^{\bar{z}}$ to be the restriction of $\prec$ to tuples that agree with $\bar{z}$ on coordinates from $\{1, \ldots, k\} \setminus \{i, j\}$. Using the reasoning from the previous item, the ordering $\prec_{ij}^{\bar{z}}$ must admit some dominating coordinate $d \in \{i, j\}$ and one of the cases "growing" or "decreasing". This must hold for every choice of $\bar{z}$ and i, j. Furthermore, the dominating coordinate d depends only on i and j and not on $\bar{z}$, likewise for the choice of "growing" or "decreasing". Let us write $i \to j$ if j dominates, otherwise we write $j \to i$. The reasoning in the following picture shows that $\to$ is transitive, i.e. $i \to j$ and $j \to m$ implies $i \to m$:



Step 1. Move coordinate i to its final position, and move j so that the tuple grows

Step 2. Move coordinate j back to the initial, position and move m to its final position

Therefore, $\to$ is in fact a total order on $\{1, \ldots, k\}$. Let d be the maximum with respect to this order. The following picture explains why d is the dominating coordinate d from the statement of Lemma 12.



Step 1. For every $i \neq d$, use $i \to d$ to move coordinates $i \neq d$ outside the gray interval (the gray interval contains $\bar{x}$ and $\bar{y}$)

Step 2. Move coordinates $i \neq d$ to their final positions

Suppose without loss of generality that we are in the "growing" case for each pair of coordinates. Then we can first move all coordinates apart from d to positions smaller than $\min\{x_1, y_1\}$ or bigger than $\max\{x_k, y_k\}$ and then use the dominations $i \to d$ to move them, one by one, to their final positions (always increasing the d-th coordinate slightly to a value in the open interval (x_d, y_d)). ◀

4.2 Proof of Lemma 11

We now return to Lemma 11, i.e., we prove that every definable k-enumerator is also programmable. In the proof, we use the following version of the Factorisation Forest Theorem. We use the term *interval* for a connected set of positions in a string.

▶ **Theorem 14** (Factorisation Forest Theorem, aperiodic variant). *Let $h\colon \Sigma^+ \to S$ be a semigroup homomorphism, where S is finite and aperiodic. Then there exists a function which assigns to each string in Σ^+ a partition of the positions into intervals (so-called* blocks*) such that:*

1. *All blocks are nonempty, and for each string in Σ^+ of length at least 2, there are at least two blocks.*
2. *If a string has at least three blocks, then all of the blocks have the same value under h.*
3. *There exists $M \in \mathbb{N}$ such that all strings have height at most M, where the height of a string is defined as follows: letters have height 1, for other strings the height is the maximum of the heights of its blocks + 1.*
4. *There is a first-order formula φ such that for every string w, the positions satisfying $\varphi(x)$ are exactly the first positions of the blocks of w.*

Apart from the Factorisation Forest Theorem and the Domination Lemma, our proof uses the following straightforward result on combining outputs of two for-programs. As a convention, if ψ is a first-order formula with k free variables and f is a k-enumerator, then $f|\psi$ denotes the k-enumerator where the output list of f is filtered so that it contains only tuples satisfying ψ.

▶ **Lemma 15** (Merging Lemma). *Let f be a definable k-enumerator. Let Φ be a finite set of* FO *formulas ψ, each one with k free variables, such that every k-tuple of positions satisfies at least one formula from Φ. Then f is programmable if and only if every $f|\psi$ is programmable.*

We are now ready to prove Lemma 11. Let f be a definable k-enumerator. We need to describe a for-program that outputs the same list of tuples as f. Let r be the maximal quantifier rank of the first-order formulas used in the definition of f. Apply the Domination Lemma to k, $m \coloneqq 5k$, and r, yielding a constant ω. Define h to be the function which maps a string $w \in \Sigma^+$ to the rank ω type of the corresponding ordered model of w. Compositionality of first-order logic (see [16, Section 3.4]) on strings says that the image of h, the set of rank ω types of strings, is a finite aperiodic semigroup and h is a semigroup homomorphism. Apply the Factorisation Forest Theorem to h, yielding a function that partitions each string into blocks and an upper bound M on heights of strings. By abuse of notation, we lift notions about strings to intervals inside strings: the height of an interval X in a string w is defined to be the height (in the sense of item 3 in Theorem 14) of the infix of w induced by X. Likewise, we define the blocks of X as the blocks of the infix induced by X, viewed as intervals contained in X.

To show that f is also programmable, we use an induction over heights in factorisation forests. More precisely, we prove that for every $i \in \mathbb{N}$ there is a for-program which computes the following:

- **Input.** A string $w \in \Sigma^+$ with distinguished nonempty intervals $X_1, \dots, X_k$ that are pairwise equal or disjoint, and such that the sum of their heights (in the sense of Theorem 14) is at most i. Each interval is represented by its first and its last position.
- **Output.** The list $f(w)$ restricted to tuples in $X_1 \times \cdots \times X_k$.

By item 3 in Theorem 14, the for-program with parameter $i \coloneqq kM$ will work for every choice of pairwise equal or disjoint intervals, in particular when all of the intervals are the entire string. The induction base $i = k$ (where every interval has the height 1) is straightforward: each interval is a singleton, and the for-program simply checks if the unique tuple in $X_1 \times \cdots \times X_k$ belongs to the output of f by using the subroutines from Lemma 6. The rest of the proof is devoted to the induction step, more specifically, to producing the correct order of the tuples: whether a tuple belongs to the output or not can again be checked using the subroutines from Lemma 6.

Let $X_1, \dots, X_k$ be intervals in an input string w that are pairwise disjoint or equal. Define $\mathcal{X}$ to be the coarsest partition of the positions in the input string into intervals that satisfies $X_1, \dots, X_k \in \mathcal{X}$. This partition uses at most $2k + 1$ intervals. Consider a factorisation

$$w = w_1 \cdots w_n$$

where each w_j is a block of one of the elements of $\mathcal{X}$. Define $\mathfrak{A}$ as in the Domination Lemma, i.e. as the ordered structure of w extended with an extra order $\sqsubset$ that describes the partition into factors $w_1, \dots, w_n$. By item 4 of the Factorisation Forest Theorem, the order $\sqsubset$ can be defined by a first-order formula which uses the input string and the endpoints of the intervals $X_1, \dots, X_k$. It follows that for every k-ary rank ω type t over the vocabulary of $\mathfrak{A}$, there is a corresponding first-order formula that selects the k-tuples of positions in w that have type t in $\mathfrak{A}$. Since there are finitely many choices of t, it follows from the Merging Lemma that it is enough to show that for every t, there is a for-program which outputs the tuples of type t.

Let t be a k-ary rank ω type over the vocabulary of $\mathfrak{A}$. We show a for-program which outputs all tuples in

$$T \coloneqq \{\bar{x} \in X_1 \times \cdots \times X_k : \bar{x} \text{ has type } t \text{ and is in the output of } f(w)\}$$

according to their order given by $f(w)$, call this order $\prec$.

If an interval from $\mathcal{X}$ has more than two blocks, then, by item 2 of the Factorisation Forest Theorem, all of these blocks have the same image under h, i.e., the same rank ω type. Since there are at most $2k+1$ intervals, it follows that with at most $2(2k+1)-1 = 4k+1 < 5k$ exceptions, consecutive strings w_j and w_{j+1} have the same rank ω type. Hence, for the order $\prec$ defined by $f(w)$, the Domination Lemma yields $d \in \{1,\dots,k\}$ and $p \in \{-1,1\}$ such that

$$x_d \sqsubset^p y_d \quad \text{implies} \quad (x_1,\dots,x_k) \prec (y_1,\dots,y_k) \qquad \text{for all } \underbrace{x_1,\dots,x_k}_{\text{of type } t}, \underbrace{y_1,\dots,y_k}_{\text{of type } t} \text{ in } \mathfrak{A}.$$

This means that the tuples in T are $\prec$-ordered as $T_1 \prec^p T_2 \prec^p \cdots \prec^p T_s$, where s is the number of blocks in X_d and T_j consists of the tuples from T where the coordinate x_d is in the j-th block of X_d. Our for-program can simply loop over all the blocks of X_d – in increasing or decreasing order depending on the choice of p – because the endpoints of each block can be identified in first-order logic due to item 4 of the Factorisation Forest Theorem. In each iteration of the loop, the for-program outputs the tuples in the corresponding T_j using the following claim, thus completing the proof of the lemma.

▷ Claim 16. There is a for-program which inputs the i-th block of X_d, given by its endpoints, and outputs the tuples from T_j ordered according to $\prec$.

Proof of the claim. The general idea is to replace X_d with its j-th block (call this block X) and use the induction assumption. However, if there is some $j \neq d$ such that $X_j = X_d$, then replacing X_d with X would violate the assumption that the intervals are pairwise disjoint or equal (since $X \subsetneq X_j$). To overcome this issue, we use the following simple case disjunction. For each of the 3^k possible values of

$$v \in \{\text{positions before } X,\ X,\ \text{positions after } X\}^k$$

construct a for-program that outputs all tuples from $Y_1 \times \cdots \times Y_k$, where Y_j is the intersection of X_j with the j-th entry of v. Since each Y_j is a union of blocks of X_j, it is empty or its height is at most the height of X_j. Furthermore, if Y_d is nonempty, then it is X, which is a block of X_d, and therefore its height is strictly smaller than the height of X_d. It follows that the induction assumption can be applied to produce all tuples in $Y_1 \times \cdots \times Y_k$, for any given choice of v. These choices can be combined using the Merging Lemma. ◁

Abstract

Nominal automata are a widely studied class of automata designed to recognise languages over infinite alphabets. In this paper, we present a Kleene theorem for nominal automata by providing a syntax to denote regular nominal languages. We use regular expressions with explicit binders for creation and destruction of names and pinpoint an exact property of these expressions – namely memory-finiteness – identifying a subclass of expressions denoting exactly regular nominal languages.

1 Introduction

Languages over infinite alphabets have been studied in a variety of contexts: query-based languages [8], XML processing [19], URLs [1], process calculi [5], etc. Accordingly, a number of automata models have been introduced for these languages, either register-based, where the state space is finite but registers are available for storing data, or based on nominal sets, where the state space is infinite but can be represented finitely due to symmetries. The most general classes of such automata are Kaminski and Francez's finite-memory automata (FMA) [8], in the register-based style, and Bojańczyk, Klin and Lasota's nondeterministic orbit-finite automata (NOFA) [4], in the nominal style. These two kinds of automata have been shown to have the same expressivity [4], and equivalence is known to be undecidable [8, 16].

While automata are useful to process and compare languages, to specify languages it is often more natural to use regular expressions; this is for instance the standard way of denoting a path in an XML tree. To that effect, many classes of expressions have been proposed [9, 12, 11, 18, 14]. The expressions from [14] capture the full class of languages recognised by either FMA of NOFA, but having been developed for FMAs they are not straightforwardly suitable to describe NOFA languages. Some of the other formalisms are more natural in the context of nominal automata, but all fail to capture the full class, and instead coincide with some (usually decidable) sub-classes.

We define in this paper a new class of regular expressions for data languages, originally motivated by applications to program verification, as part of larger framework called *bracket algebra*. These expressions feature explicit allocation $\langle_a$ and deallocation $_a\rangle$ binders, and may be used to generate nominal languages. We prove in this paper that they are in fact able to describe every language recognisable by a NOFA.

Let us illustrate our syntax on simple examples. To make this discussion simpler, we assume for now that our alphabet is an infinite set of names $\mathbb{A}$. The first notion we present is that of α-equivalence of words with binders. Here we choose to define α-equivalence as the smallest congruence stable by permutation of bound or fresh names. For instance the following pair of words is equivalent: $\langle_a\, a\langle_b\, b\,{}_a\rangle\langle_a\, a\,{}_b\rangle\langle_b\, b\,{}_a\rangle\,{}_b\rangle =_\alpha \langle_b\, b\langle_c\, c\,{}_b\rangle\langle_d\, d\,{}_c\rangle\langle_a\, a\,{}_d\rangle\,{}_a\rangle$. Indeed, we may derive this as follows (we underline the redex at each step):

$$\begin{aligned}\langle_a\, a\underline{\langle_b\, b\,{}_a\rangle\langle_a\, a\,{}_b\rangle}\langle_b\, b\,{}_a\rangle\,{}_b\rangle &=_\alpha \langle_a\, a\langle_c\, c\,{}_a\rangle\underline{\langle_a\, a\,{}_c\rangle\langle_b\, b\,{}_a\rangle}\,{}_b\rangle \\ &=_\alpha \underline{\langle_a\, a\langle_c\, c\,{}_a\rangle}\langle_d\, d\,{}_c\rangle\langle_b\, b\,{}_d\rangle\,{}_b\rangle =_\alpha \langle_b\, b\langle_c\, c\,{}_b\rangle\langle_d\, d\,{}_c\rangle\langle_a\, a\,{}_d\rangle\,{}_a\rangle.\end{aligned}$$

We then define well-formed words to be those without name capture, i.e. for every prefix $u\langle_a$, every $\langle_a$ in u must be matched with a corresponding $_a\rangle$. For instance $\langle_a\, a\langle_b\, b\,{}_b\rangle\,{}_a\rangle$ is well-formed, but $\langle_a\, a\langle_a\, a\,{}_a\rangle\,{}_a\rangle$ is not, even though the two are equivalent. Now, consider regular expressions over an alphabet composed of names from $\mathbb{A}$ and binders $\langle_a$ and $_a\rangle$. We associate to such an expression e a nominal language $(\!|e|\!)$ in several steps:

1) take the regular language $[\![e]\!]$ denoted by e;
2) compute its closure by α-equivalence $[\![e]\!]^\alpha$, adding every word that is equivalent to some word in the initial language;
3) restrict this language to its well-formed members;
4) erase the brackets.

Here are some examples:

L1 $:= (\!|\langle_a\, a\,{}_a\rangle|\!) = \mathbb{A}$: the set of all atoms;
L2 $:= (\!|\langle_a\, \langle_b\, ab\,{}_b\rangle\,{}_a\rangle|\!) = \{ab \mid a \neq b\}$: two letter words made of different letters;
L3 $:= (\!|\langle_a\, a\,{}_a\rangle^\star|\!) = \mathbb{A}^\star$: the set of all words;
L4 $:= (\!|\langle_a\, a\langle_a\, a\,{}_a\rangle^\star\,{}_a\rangle|\!) = \{a_1 \dots a_n \mid n > 0, \forall 1 < i, a_i \neq a_1\}$: the set of words such that the first letter is different from all others;
L5 $:= (\!|\langle_a\, \langle_a\, a\,{}_a\rangle^\star a\,{}_a\rangle|\!) = \{a_1 \dots a_n \mid n > 0, \forall i < n, a_i \neq a_n\}$: the set of words such that the last letter is different from all others;
L6 $:= (\!|\langle_a\, a\,(\langle_b\, b\,{}_a\rangle\langle_a\, a\,{}_b\rangle)^\star\,(1 + \langle_b\, b\,{}_b\rangle)\,{}_a\rangle|\!) = \{a_1a_2 \dots a_n \mid n > 0, \forall i, a_i \neq a_{i+1}\}$: the set of non-empty words such that two consecutive letters are different;
L7 $:= (\!|(\langle_a\, x)^\star\,(y\,{}_a\rangle)^\star|\!) = \{x\} \cup \{x^n y^m \mid n \leqslant m\}$.

As one can see, this technique allows for the definition of a large class of nominal languages. In fact this class is in some sense "too large" and contains languages that are not regular, like for instance L7. To get a Kleene theorem, we therefore introduce a tractability condition: we ask regular expressions to have a memory-finite language. Intuitively this means there should be a number N such that any prefix of a word in the language has less than N unmatched brackets. This condition is decidable by induction on expressions, and such expressions generate exactly the class of languages recognisable by NOFAs. The main result of the paper is an exact correspondence between memory-finite nominal languages and NOFA:

▶ **Theorem 1** (Kleene Theorem). *Let L be a nominal language. The following are equivalent:*
(i) *L is rational, that is $L = (\!|e|\!)$ for some memory-finite regular expression e.*
(ii) *L is regular nominal, that is recognisable by a NOFA.*

The paper is structured as follows. In Section 2, we define our notations, and recall some elements of nominal automata theory. We introduce in Section 3 words with explicit binders and define an α-equivalence relation for these words. To recognise this relation we construct in Section 4 a nominal transducer. We then present in Section 5 our syntax for regular expressions with binders, and prove in Section 6 our main result, a Kleene theorem for NOFA. We briefly discuss related work in Section 7. We omit some proofs in this paper, but a longer version is available on HAL.

This paper is part of a larger research program developing a framework to reason about programs with explicit resource (de)allocation. A companion paper describing the algebraic framework of *bracket algebra* and a hierarchy of nominal languages can be found online, as well as a Coq formalisation of the framework.

2 Preliminaries

The set of finite subsets of a set A is denoted by $\mathcal{P}_f(A)$. If A is finite, its cardinal is denoted by $\#A \in \mathbb{N}$. The set of words over an alphabet Σ is written $\Sigma^\star$. The empty word is denoted by ε, concatenation of words u and v is written uv, and $|u|$ is the length of word u. For $w \in \Sigma^\star$ and $x \in \Sigma$, $|w|_x$ is the number of occurrences of x in w. We write $\lfloor w \rfloor$ for the set of letters appearing in the word w, i.e. $\lfloor w \rfloor := \{x \in \Sigma \mid |w|_x > 0\}$. We denote the i^{th} letter of a word u by u_i, for $0 < i \leqslant |u|$. The set of prefixes of a language is defined as: $\mathbf{pref}(L) := \{u \in \Sigma^\star \mid \exists v : uv \in L\}$.

Given a set A, and $B \subseteq A$, the set $B^{\bowtie}$ of shuffles of B consists of the lists without repetitions of elements from B: $B^{\bowtie} := \{l \in B^\star \mid |l| = \#B \wedge (\forall 0 < i < j \leqslant |l|\,,\ l_i \neq l_j)\}$. Observe that if $w \in B^{\bowtie}$, then $\{a \mid \exists 0 < i \leqslant |w| : w_i = a\} = B$. We say that a list $l \in A^\star$ is duplication-free, written $l \in A^{(\star)}$ when $l \in \{a \mid \exists 0 < i \leqslant |l| : l_i = a\}^{\bowtie}$.

Rational expressions over an alphabet Σ are terms generated by the following grammar: $e, f \in \mathrm{Rat}\,\langle\Sigma\rangle ::= 0 \mid 1 \mid l \mid e + f \mid e \cdot f \mid e^\star$, where l ranges over the alphabet Σ. Such a term e denotes a language $[\![e]\!]$, defined in the usual way:

$$[\![0]\!] := \emptyset, \qquad [\![1]\!] := \{\varepsilon\}\,, \quad [\![e \cdot f]\!] := \{uv \mid u \in [\![e]\!] \wedge v \in [\![f]\!]\}\,,$$
$$[\![e + f]\!] := [\![e]\!] \cup [\![f]\!]\,, \quad [\![l]\!] := \{l\}\,, \qquad [\![e^\star]\!] := [\![e]\!]^\star = \{u_1 \dots u_n \mid n \in \mathbb{N} \wedge \forall i, u_i \in [\![e]\!]\}\,.$$

2.1 Nominal sets

We fix an infinite set $\mathbb{A}$ of atoms (also called names), and write $\mathfrak{S}_{\mathbb{A}}$ the set of finitely supported permutations over $\mathbb{A}$. These are bijections π such that there is a finite set $\bar{a} \subseteq \mathbb{A}$ such that $a \notin \bar{a} \Rightarrow \pi(a) = a$. In the following we let $a, b, \dots$ range over $\mathbb{A}$ and $\bar{a}, \bar{b}, \dots$ range over finite sets of atoms. The inverse of a permutation π is written π^{-1} . The permutation exchanging a and b, and leaving every other name unchanged, is written $(a\ b)$. We say that a permutation π fixes a finite set $\bar{a} \subseteq \mathbb{A}$, written $\pi \perp \bar{a}$, when $\forall a \in \bar{a},\ \pi(a) = a$.

A set X is called nominal if it can be equipped with two functions, respectively action $- \cdot - : \mathfrak{S}_{\mathbb{A}} \times X \to X$ and support $\mathbf{supp}(-) : X \to \mathcal{P}_f(\mathbb{A})$, satisfying $\forall x \in X,\ \forall \pi, \pi' \in \mathfrak{S}_{\mathbb{A}}$,:

$$\pi \perp \mathbf{supp}(x) \Rightarrow \pi \cdot x = x. \tag{$\dagger_1$}$$
$$\mathbf{supp}(\pi \cdot x) = \left\{a \in \mathbb{A} \;\middle|\; \pi^{-1}(a) \in \mathbf{supp}(x)\right\}. \tag{$\dagger_2$}$$
$$\pi \cdot (\pi' \cdot x) = (\pi \circ \pi') \cdot x. \tag{$\dagger_3$}$$

Intuitively, this means that we may replace a name by another in any element of X, and that each element of X only depends on a finite number of names. We say that a permutation π fixes a subset $Y \subseteq X$, also written $\pi \perp Y$ if $\forall y \in Y, \pi \cdot y = y$. This enables use to state $(\dagger_1)$ as $\pi \perp \mathbf{supp}\,(x) \Rightarrow \pi \perp x$. We say that the name a is fresh for x, and write $a \# x$, whenever $a \notin \mathbf{supp}\,(x)$. We will also use the notation $X \restriction_{\bar{a}}$ to mean $\{x \in X \mid \mathbf{supp}\,(x) \subseteq \bar{a}\}$.

▶ Remark 2. In Pitts' book [17] a nominal set is defined as a $\mathfrak{S}_{\mathbb{A}}$-action such that every element has some finite support. From conditions $(\dagger_1)$ and $(\dagger_3)$ we infer that X is a nominal set as in [17]. Furthermore, condition $(\dagger_2)$ enforces that $\mathbf{supp}\,(x)$ is the least finite set that supports x, so our notion of support coincides with the one introduced in [17]. For Coq implementation considerations, we chose to include the support function in the definition.

For the rest of this section, we fix a nominal set X. Given $x, y \in X$, we say that x and y are in the same orbit, written $x \sim_{\mathcal{O}} y$, if there exists $\pi \in \mathfrak{S}_{\mathbb{A}}$ such that $x = \pi \cdot y$. This is an equivalence relation, and its equivalence classes are called orbits. A subset $Y \subseteq X$ is called:

- strict if it has no symmetries, i.e. $(\dagger_1)$ holds as an equivalence: $\pi \perp \mathbf{supp}\,(y) \Leftrightarrow \pi \perp y$;
- equivariant if for every permutation $\pi \in \mathfrak{S}_{\mathbb{A}}$, we have $\pi \cdot Y = Y$, meaning

$$\forall \pi \in \mathfrak{S}_{\mathbb{A}}, \forall y \in X,\ y \in Y \Leftrightarrow \pi \cdot y \in Y;$$

- finitely supported if there is a finite $\bar{a} \subseteq \mathbb{A}$ such that $\pi \perp \bar{a}$ entails $\pi \cdot Y = Y$;
- orbit-finite if Y only intersects finitely many orbits;
- tractable if it is both orbit-finite and finitely supported.

▶ Remark 3. In Bojańczyk [2, 3] terminology, what we call tractable sets are simply called orbit-finite, even though these are sets that are both orbit-finite and finitely supported. We chose a different name to avoid confusion as in other papers orbit-finite sets are not necessarily finitely supported.

In the following, we will use the following results adapted from [3]:

▶ **Lemma 4** (Simple extension of Lemma 3.5 in [3]). *Every tractable set can be expressed as the image of a tractable set of words from $\mathbb{A}^\star$ by some equivariant function.*

▶ **Lemma 5** (Fact 3.6 in [3]). *Tractable sets are closed under finite unions and products, and under finitely supported subsets.*

2.2 Nominal automata

Let Σ be an orbit-finite nominal alphabet. A nominal automaton (NOFA) over Σ is a structure $\mathcal{A} = \langle Q, \Sigma, \Delta, I, F \rangle$ where Q is a tractable state space, $I, F \subseteq Q$ are finitely supported sets of respectively initial and final states, and $\Delta \subseteq Q \times \Sigma \times Q$ is a finitely supported transition relation. This definition corresponds to Bojańczyk, Klin, and Lasota's "orbit-finite automata" [4]. We define the automaton's path relation in the usual way, by saying that $p \xrightarrow{\varepsilon}_{\mathcal{A}} p$ and whenever $p \xrightarrow{w}_{\mathcal{A}} q'$ and $\langle q', x, q \rangle \in \Delta$ then we also have $p \xrightarrow{wx}_{\mathcal{A}} q$. Notice that since Δ is finitely supported, so is the path relation. The language recognised by such an automaton is defined as usual as the set of traces leading from an initial state to a final state:

$$\mathcal{L}_{\mathcal{A}} := \left\{ w \in \Sigma^\star \;\middle|\; \exists \langle q_i, q_f \rangle \in I \times F : q_i \xrightarrow{w}_{\mathcal{A}} q_f \right\}.$$

Nominal regular languages are those recognised by nominal automata.

▶ Remark 6. In the literature, the name "Nominal automaton" is sometimes used to refer to a different class of automata, where the tractability requirement is replaced by orbit-finite and equivariant. These two classes define the same languages: an equivariant automaton is a particular case of a tractable one, and any tractable automaton with support $\bar{a}$ might be seen as an equivariant automaton by replacing the set of atoms $\mathbb{A}$ with the set $\mathbb{A} \setminus \bar{a}$. However, we feel that our approach leads to more intuitive encoding of some natural languages. Consider for instance the language $a \cdot \mathbb{A}^\star$ of words over $\mathbb{A}$ starting with the letter $a \in \mathbb{A}$. This language is not equivariant, therefore to represent it with an equivariant automaton one needs to remove the name a from the set of names, considering instead the alphabet $\mathbb{A}$ as a nominal set over the set of names $\mathbb{A} \setminus \{a\}$. We feel this is a bit counter-intuitive. However, it may be represented by a simple tractable automaton with two states p and q, with p initial, q final, a transition $p \xrightarrow{a} q$, and transitions $q \xrightarrow{b} q$ for every name $b \in \mathbb{A}$.

We will later on rely on the following properties of nominal automata.

▶ **Lemma 7.** *Every nominal automaton is language equivalent to a nominal automaton whose state space is strict.*

▶ **Lemma 8.** *Nominal automata enjoy ε-elimination.*

A nominal automaton is called deterministic (DOFA) if it has a single initial state and its transition relation is a deterministic function, i.e. if we have two transitions $\langle p, x, q\rangle \in \Delta \wedge \langle p, x, q'\rangle \in \Delta$, then $q = q'$. Languages recognised by DOFA form a strict subclass of the regular nominal languages. E.g. the language over $\mathbb{A}$ of words with the last letter distinct from all others is regular nominal but cannot be recognised by a DOFA: intuitively to check for membership one needs to guess what will be the last letter before reading the word. There is also a significant complexity difference: equivalence of DOFA is decidable in polynomial time [15], the corresponding problem for NOFA is undecidable [16].

▶ **Lemma 9.** *Regular languages can be recognised by deterministic nominal automata.*

Proof. Regular languages can be recognised by deterministic finite state automata. Being finite, such automata are also tractable, thus deterministic nominal automata. ◀

2.3 Nominal transductions

We will make intensive use of transductions in this paper. A nominal transducer is a nominal automaton over an alphabet of the shape $(\Sigma \cup \{\varepsilon\}) \times (\Gamma \cup \{\varepsilon\})$. For a nominal transducer $\mathcal{T}$, we may define its path relation $-[-/-]\!\to_{\mathcal{T}}$ and the binary relation $\mathcal{R}_{\mathcal{T}}$ it recognises:

$$\frac{}{p \,-[\varepsilon/\varepsilon]\!\to_{\mathcal{T}} p} \qquad \frac{p \,-[w/w']\!\to_{\mathcal{T}} q' \quad \langle q', \langle x, x'\rangle, q\rangle \in \Delta}{p \,-[wx/w'x']\!\to_{\mathcal{T}} q}$$

$$\mathcal{R}_{\mathcal{T}} := \{\langle u, v\rangle \in \Sigma^\star \times \Gamma^\star \mid \exists \langle q_i, q_f\rangle \in I \times F : q_i \,-[u/v]\!\to_{\mathcal{T}} q_f\}\,.$$

A binary relation $R \subseteq \Sigma^\star \times \Gamma^\star$ is called a nominal transduction if it is recognised by some nominal transducer. For a transduction R, we will sometimes see R as either a function $\Sigma^\star \to \mathcal{P}(\Gamma^\star)$ or a function $\mathcal{P}(\Sigma^\star) \to \mathcal{P}(\Gamma^\star)$, writing:

$$u \in \Sigma^\star,\ R(u) := \{v \in \Gamma^\star \mid u\ R\ v\} \qquad L \subseteq \Sigma^\star,\ R(L) := \{v \in \Gamma^\star \mid \exists u \in L : u\ R\ v\}\,.$$

This should not introduce any ambiguity, thanks to typing considerations.

▶ **Lemma 10.** *Nominal regular languages are stable under nominal transductions.*

Proof. Let Σ, Δ be two tractable alphabets, and $\Sigma' := (\Sigma \cup \{\varepsilon\}) \times (\Gamma \cup \{\varepsilon\})$. Consider a nominal automaton $\mathcal{A} = \langle Q_1, \Sigma, \Delta_1, I_1, F_1 \rangle$ and a nominal transducer $\mathcal{T} = \langle Q_2, \Sigma', \Delta_2, I_2, F_2 \rangle$. We want to show that the language $\mathcal{R}_{\mathcal{T}}(\mathcal{L}_{\mathcal{A}})$ is regular nominal, by building a nominal automaton $\mathcal{T}(\mathcal{A})$ with ε-transitions. Its states are in $Q_1 \times Q_2$, with initial and final states respectively $I_1 \times I_2$ and $F_1 \times F_2$. Its transition relation is given by:

$$\Delta := \{\langle \langle p_1, p_2 \rangle, x, \langle q_1, q_2 \rangle \rangle \mid \exists y : \langle p_1, y, q_1 \rangle \in \Delta_1 \wedge \langle p_2, \langle y, x \rangle, q_2 \rangle \in \Delta_2\}$$
$$\cup \{\langle \langle p_1, p_2 \rangle, x, \langle p_1, q_2 \rangle \rangle \mid \langle p_2, \langle \varepsilon, x \rangle, q_2 \rangle \in \Delta_2\}.$$ ◀

3 Words over an alphabet with binders

For the rest of the paper, we fix an orbit-finite nominal set $\mathbb{X}$ of variables, to represent our alphabet. We consider words built out of variables, left and right binders, respectively written $\langle_a$ and $_a\rangle$. These binders are meant to represent the creation and destruction of names.

We now introduce a notion of α-equivalence for these words. This relation will be a congruence stable under substitution of "local" names: for instance the words $\langle_a\ {}_a\rangle$ and $\langle_b\ {}_b\rangle$ are equivalent. The definitions in this section are straightforward adaptations from [7].

Formally, we define our alphabet by $\mathbb{\Sigma} := \mathbb{X} \cup \{\langle_a \mid a \in \mathbb{A}\} \cup \{{}_a\rangle \mid a \in \mathbb{A}\}$. This alphabet can be endowed with a nominal structure in the obvious way, by setting $\pi \cdot \langle_a = \langle_{\pi(a)}$, $\pi \cdot {}_a\rangle = {}_{\pi(a)}\rangle$, and $\mathbf{supp}(\langle_a) = \mathbf{supp}({}_a\rangle) = \{a\}$. In the following, a word with binders will be an element of $\mathbb{\Sigma}^\star$, that is a finite sequence of letters from the alphabet $\mathbb{\Sigma}$. Words with binders come with a natural nominal structure: the action is defined by applying the alphabet action letter by letter, and the support of a word is the union of the supports of its letters.

Before we define α-equivalence, we need to introduce the notion of *binding power* of a word with binders. The purpose of this notion is to keep track of the occurrences of each name along a word, and enable us to decide whether a particular name is local to the word, and more generally to get a precise account of the way the name is used in the word, from the point of view of the context. The binding monoid $\mathcal{B}$ is defined as the free monoid over the three element set $\{\mathbf{c}, \mathbf{f}, \mathbf{d}\}$, quotiented by the identities: $\mathbf{f} \cdot \mathbf{f} = \mathbf{f}$, $\mathbf{c} \cdot \mathbf{f} = \mathbf{c}$, $\mathbf{f} \cdot \mathbf{d} = \mathbf{d}$, and $\mathbf{c} \cdot \mathbf{d} = \varepsilon$. The letters $\mathbf{c}$, $\mathbf{f}$, $\mathbf{d}$ are meant to represent that a name might be *created*, *free* or *destroyed*. An important property of this monoid is the following, as noticed in [7]: every element of $\mathcal{B}$ can be uniquely represented in the form $\mathbf{d}^m\mathbf{f}^n\mathbf{c}^p$, with $\langle m, n, p \rangle \in \mathbb{N} \times \{0, 1\} \times \mathbb{N}$. We use this remark to define the *size*[1] of a binding element $b \in \mathcal{B}$ as $|\mathbf{d}^m\mathbf{f}^n\mathbf{c}^p| = m + p$.

The binding power of a letter $l \in \mathbb{\Sigma}$ with respect to a name $a \in \mathbb{A}$, written $\mathcal{F}_a(l)$, is computed as follows:

$$\mathcal{F}_a(\langle_b) := \begin{cases} \mathbf{c} & (a = b) \\ \varepsilon & (a \neq b) \end{cases} \qquad \mathcal{F}_a({}_b\rangle) := \begin{cases} \mathbf{d} & (a = b) \\ \varepsilon & (a \neq b) \end{cases} \qquad \mathcal{F}_a(x) := \begin{cases} \mathbf{f} & (a \in \mathbf{supp}(x)) \\ \varepsilon & (a \# x) \end{cases}$$

The function $\mathcal{F}$ may be extended to words naturally as a monoid homomorphism, by setting $\mathcal{F}_a(\varepsilon) = \varepsilon$ and $\mathcal{F}_a(lw) = \mathcal{F}_a(l) \cdot \mathcal{F}_a(w)$. If $\mathcal{F}_a(u) = \mathbf{d}^m\mathbf{f}^n\mathbf{c}^p$ with $n \in \{0, 1\}$, we define $d_a(u) := m$, $f_a(u) := n$, and $c_a(u) := p$. This is well defined thanks to the uniqueness of such representations. This function is equivariant, in the sense that $\mathcal{F}_{\pi(a)}(\pi \cdot u) = \mathcal{F}_a(u)$.

The weight of a word u is the sum of the sizes of its binding powers: $\|u\| := \sum_{a \in \mathbb{A}} |\mathcal{F}_a(u)|$. This sum is finite, since for every name a outside the finite set $\mathbf{supp}(u)$ we know that the binding power of u with respect to a is ε, so $|\mathcal{F}_a(u)| = 0$. The memory of a word u is the maximum weight of a prefix of u, i.e. $\mathbf{m}(u) := \max\{\|v\| \mid \exists w \in \mathbb{\Sigma}^\star : vw = u\}$.

[1] Since the size of a Boolean is constant, we do not count n in the size of $\mathbf{d}^m\mathbf{f}^n\mathbf{c}^p$. This simplifies a number of computations.

Table 1 Alpha-equivalence.

$$\frac{}{\varepsilon =_\alpha \varepsilon}\ (\alpha\varepsilon) \qquad \frac{u =_\alpha v \quad v =_\alpha w}{u =_\alpha w}\ (\alpha\mathbf{t}) \qquad \frac{w_1 =_\alpha w_2}{w_1 l =_\alpha w_2 l}\ (\alpha\mathbf{r}) \qquad \frac{w_1 =_\alpha w_2}{l w_1 =_\alpha l w_2}\ (\alpha\mathbf{l})$$

$$\frac{a \diamond u \quad b \#_\alpha u}{\langle_a u\, {}_a\rangle =_\alpha \langle_b (a\ b) \cdot u\, {}_b\rangle}\ (\alpha\alpha).$$

(a) Definition of Alpha-equivalence.

$$u =_\alpha v \Rightarrow v =_\alpha u \quad (1) \qquad u =_\alpha v \Rightarrow \forall \pi,\ \pi \cdot u =_\alpha \pi \cdot v \quad (4)$$
$$u =_\alpha v \wedge u' =_\alpha v' \Rightarrow uu' =_\alpha vv' \quad (2) \qquad u =_\alpha v \Rightarrow |u| = |v| \quad (5)$$
$$u =_\alpha v \Rightarrow \forall a,\ \mathcal{F}_a(u) = \mathcal{F}_a(v) \quad (3)$$

(b) Properties of Alpha-equivalence.

We use the binding power to define the following: a is balanced in the word w, written $a \diamond w$, if $\mathcal{F}_a(w) \in \{\mathbf{f}, \varepsilon\}$; a is α-fresh in w, written $a \#_\alpha w$, if $\mathcal{F}_a(w) = \varepsilon$; the α-support of w, written $\mathbf{supp}_\alpha(w)$, is the set of names a such that $\mathcal{F}_a(w) \neq \varepsilon$. Notice that $\mathbf{supp}_\alpha(w) \subseteq \mathbf{supp}(w)$. Therefore, we get that $\pi(a) \#_\alpha \pi \cdot u$ if and only if $a \#_\alpha u$, and similarly for $\pi(a) \in \mathbf{supp}_\alpha(\pi \cdot u)$ and $\pi(a) \diamond \pi \cdot u$.

We may now define the α-equivalence relation over words. It is the smallest congruence such that applying the transposition $(a\ b)$ to a word where a and b are α-fresh yields an equivalent word. We give the formal definition of $=_\alpha$ in Table 1a and list some of its properties in Table 1b. The propositions (1) and (2) state that $=_\alpha$ is symmetric and that concatenation is compatible with $=_\alpha$, which together with $(\alpha\varepsilon)$and $(\alpha\mathbf{t})$establishes $=_\alpha$ as a congruence, while (3), (4), and (5) are necessary preservation properties of $=_\alpha$. The proofs of these results follow a simple induction of proof trees.

Note that the deduction system we provided for $=_\alpha$ is not a priori equivalent to the informal description we gave before. However, the correspondence can be proved in the sense that the same relation is obtained if we replace rule $(\alpha\alpha)$ with the following rule:

$$\frac{a \#_\alpha u \quad b \#_\alpha u}{u =_\alpha (a\ b) \cdot u}\ (\alpha\alpha')$$

However, this proof is not straightforward: $(\alpha\alpha')$ obviously implies $(\alpha\alpha)$ (as the latter may be seen as an instance of the former), but the converse direction is more subtle. Unfortunately, this is the most interesting direction, as it is necessary to show that words quotiented by $=_\alpha$ form a nominal set, with the support function $\mathbf{supp}_\alpha()$. This property may however be established using the transducer presented in the next section.

We say that a word u is well-formed when for every decomposition $u = u_1 \langle_a u_2$, we have $c_a(u_1) = 0$. Intuitively, this means that there is no name capture for bound variables. The set of well-formed words is written $\mathcal{WF}$, and we define $\mathbf{wf}(u) := \{v \mid u =_\alpha v \wedge v \in \mathcal{WF}\}$.

4 A transducer for α-equivalence-checking

The problem that arises when trying to prove statements like $(\alpha\alpha)$is that α-equivalence is not preserved in the inductive calls: the property $ux =_\alpha vy$ does not entail $u =_\alpha v$. In this section we introduce a nominal transducer recognising the relation $=_\alpha$. The reachability

relation in this transducer will give us more powerful proof techniques, allowing us to perform proofs by induction. This transducer serves several purposes: it provides us with a decision procedure for $=_\alpha$, enables us to show that $(\alpha\alpha')$ is admissible, and will be used here as a bridge between nominal automata and rational expressions over $\mathbb{\Sigma}$.

4.1 Stacks

The states of this transducer will consist of lists of pairs of atoms, called stacks in the following. Before we define the transducer, we introduce some useful notations. Stacks are generated by the following grammar: $s \in \mathbb{S} ::= [] \mid s :: \langle a, b\rangle$, where a, b range over names. Hence $\mathbb{S}$ is isomorphic to $(\mathbb{A} \times \mathbb{A})^\star$. We will also use the notation $s :: t$ for the concatenation of the two stacks $s, t \in \mathbb{S}$. We write $\mathfrak{p}_1(s)$ for the word over $\mathbb{A}$ obtained by erasing the second components of every pair in s, and symmetrically $\mathfrak{p}_2(s)$ when we erase the first components. For instance $\mathfrak{p}_1([] :: \langle a, b\rangle :: \langle c, d\rangle) = ac$, and $\mathfrak{p}_2([] :: \langle a, b\rangle :: \langle c, d\rangle) = bd$.

Stacks can be endowed with a canonical nominal structure defined by:

$$\pi \cdot [] := [] \qquad \pi \cdot (s :: \langle a, b\rangle) := \pi \cdot s :: \langle \pi(a), \pi(b)\rangle$$
$$\mathbf{supp}([]) := \emptyset \qquad \mathbf{supp}(s :: \langle a, b\rangle) := \mathbf{supp}(s) \cup \{a, b\}.$$

Note that $\mathbf{supp}(s) = \mathbf{supp}(\mathfrak{p}_1(s)) \cup \mathbf{supp}(\mathfrak{p}_2(s)) = \lfloor \mathfrak{p}_1(s) \rfloor \cup \lfloor \mathfrak{p}_2(s) \rfloor$.

The pivotal notions for stacks are the validates predicate and the pop function. We say that a stack s validates the pair $\langle a, b\rangle$, written $s \models \langle a, b\rangle$, when either $a = b$ and $a \# s$, or s can be decomposed as $s = s' :: \langle a, b\rangle :: s''$ in such a way that $a \notin \lfloor \mathfrak{p}_1(s'') \rfloor$ and $b \notin \lfloor \mathfrak{p}_2(s'') \rfloor$. When s validates $\langle a, b\rangle$, we may pop the pair from s, yielding the stack $s \ominus \langle a, b\rangle$ defined by:

$$\frac{a \notin \mathbf{supp}(s)}{s \ominus \langle a, a\rangle := s} \qquad \frac{a \notin \lfloor \mathfrak{p}_1(s') \rfloor \quad b \notin \lfloor \mathfrak{p}_2(s') \rfloor}{(s :: \langle a, b\rangle :: s') \ominus \langle a, b\rangle := s :: s'}.$$

4.2 Equivalence transducer

We now define the equivalence transducer $\mathcal{T}_\alpha$, recognising $=_\alpha$. Strictly speaking, this will not be a nominal transducer, as we will discuss later on. Its state space is $\mathbb{S}$, with initial state $[]$, and the set of accepting states $\mathbb{S}^{acc}$ consists of all stacks s containing only reflexive pairs, i.e. such that $\mathfrak{p}_1(s) = \mathfrak{p}_2(s)$. The transition relation $-[-/-]\to_{\mathcal{T}_\alpha}$ is defined by:

$$\begin{array}{rcl} & & s \,-[\langle_a / \langle_b]\to_{\mathcal{T}_\alpha}\, s :: \langle a, b\rangle \\ s \models \langle a, b\rangle & \Rightarrow & s \,-[\,_a\rangle / \,_b\rangle]\to_{\mathcal{T}_\alpha}\, s \ominus \langle a, b\rangle \\ \forall a \in \mathbf{supp}(x),\ s \models \langle a, \pi(a)\rangle & \Rightarrow & s \,-[x/\pi \cdot x]\to_{\mathcal{T}_\alpha}\, s \end{array}$$

Note that this relation is functional, in the sense that for every triple $\langle s, l, l'\rangle \in \mathbb{S} \times \mathbb{\Sigma} \times \mathbb{\Sigma}$ there exists at most one stack s' such that $s \,-[l/l']\to_{\mathcal{T}_\alpha}\, s'$. This transducer over an infinite state space is equivariant, as one can easily check that $s \,-[u/v]\to_{\mathcal{T}_\alpha}\, s'$ entails $\pi \cdot s \,-[\pi \cdot u/\pi \cdot v]\to_{\mathcal{T}_\alpha}\, \pi \cdot s'$. However, it is not orbit finite. This seems to be unavoidable since there are infinitely many α-equivalence classes (in particular, words of different length cannot be equivalent).

▶ **Theorem 11.** *The relation $\mathcal{R}_{\mathcal{T}_\alpha}$ is exactly $=_\alpha$.*

The full proof has been done in Coq. The following technical lemma allows one to relate the binding power of a word with the stack contents:

▶ **Lemma 12.** *Whenever* $s \xrightarrow{-[u/v]\to_{\mathcal{T}_\alpha}} s'$ *the following identities hold:*

$$|\mathfrak{p}_1(s')|_a = (|\mathfrak{p}_1(s)|_a \dot{-} d_a(u)) + c_a(u) \qquad |\mathfrak{p}_2(s')|_a = (|\mathfrak{p}_2(s)|_a \dot{-} d_a(v)) + c_a(v).$$

(Where $\dot{-}$ *is the truncated subtraction.)*

This lemma has the following corollaries:

▶ **Corollary 13.** *If* $[] \xrightarrow{-[u/v]\to_{\mathcal{T}_\alpha}} s \xrightarrow{-[u'/v']\to_{\mathcal{T}_\alpha}} s'$ *then* $|s| \leqslant \mathbf{m}(uu')$.

Proof. By Lemma 12, and since $[] \xrightarrow{-[u/v]\to_{\mathcal{T}_\alpha}} s$, we have $|s| = \sum_a c_a(u) \leqslant \|u\|$. Since $\|u\| \leqslant \mathbf{m}(uu')$, the result follows. ◀

▶ **Corollary 14.** *For any words* u, v *of length* n*, the following are equivalent:*

(i) $u =_\alpha v$ *and* $v \in \mathcal{WF}$*;*

(ii) *there are stacks* $s_0 \dots s_n$ *such that* $s_0 = []$*,* $s_n \in \mathbb{S}^{acc}$*, for every index* $0 \leqslant i < n$ *we have* $s_i \xrightarrow{-[u_{i+1}/v_{i+1}]\to_{\mathcal{T}_\alpha}} s_{i+1}$*, and for any index* $0 \leqslant i \leqslant n$ *and name* a *we have* $|\mathfrak{p}_2(s_i)|_a \leqslant 1$.

These results allow us to show that the following are nominal transductions:

$$=_\alpha^{\leqslant n} := \{\langle u, v\rangle \mid u =_\alpha v \wedge \mathbf{m}(u) \leqslant n\}$$
$$\mathbf{wf}^n := \{\langle u, v\rangle \mid u =_\alpha v \wedge \mathbf{m}(u) \leqslant n \wedge v \in \mathcal{WF}\}.$$

▶ **Theorem 15.** *For any* $n \in \mathbb{N}$*, both* $=_\alpha^{\leqslant n}$ *and* $\mathbf{wf}^n$ *are nominal transductions.*

Proof. Thanks to Corollary 13, we know that $=_\alpha^{\leqslant n}$ is recognised by $\mathcal{T}_\alpha$ restricted to states $\mathbb{S}^{\leqslant n}$, made up of stacks of length less that n. This is a tractable set, by Lemma 5. Combined with Corollary 14, this proves that $\mathbf{wf}^n$ is recognised by $\mathcal{T}_\alpha$ restricted to stacks such that $|s| \leqslant n$ and $\forall a, |\mathfrak{p}_2(s)|_a \leqslant 1$. This set of stacks being an equivariant subset of $\mathbb{S}^{\leqslant n}$, by Lemma 5 it is also tractable. ◀

5 Memory-finite rational languages

In this section we consider regular languages over $\mathbb{\Sigma}$, i.e. languages $[\![e]\!]$ for some $e \in \mathrm{Rat}\langle\mathbb{\Sigma}\rangle$. We may lift α-equivalence to languages by first defining the α-closure of a language L as:

$$L^\alpha := \{u \in \mathbb{\Sigma}^\star \mid \exists v \in L,\ u =_\alpha v\}.$$

Now we say that two languages are equivalent if their α-closures are equal.

We lift the support function from $\mathbb{\Sigma}$ to $\mathrm{Rat}\langle\mathbb{\Sigma}\rangle$ in the canonical way: for letters in $\mathbb{\Sigma}$ we use the $\mathbf{supp}(-)$ function from the nominal structure of the alphabet, the support of 0 and 1 is the empty set, the support of $e^\star$ is that of e and the support of both $e + f$ and $e \cdot f$ is $\mathbf{supp}(e) \cup \mathbf{supp}(f)$. This definition is an over approximation of the pointwise lifting of the support function on words: indeed $\bigcup_{u \in [\![e]\!]} \mathbf{supp}(u) \subseteq \mathbf{supp}(e)$. Note that $\mathbf{supp}(e)$ is always finite, and supports $[\![e]\!]$ in the sense that whenever $\pi \perp \mathbf{supp}(e)$, we have $\pi \cdot [\![e]\!] = [\![e]\!]$.

A language $L \subseteq \mathbb{\Sigma}^\star$ is called memory-finite if there exists a bound N such that $\forall u \in L, \mathbf{m}(u) \leqslant N$. A rational expression is memory-finite if its language is memory-finite.

▶ **Lemma 16.** *For any rational expression* e*, the following are equivalent:*

(i) e *is memory-finite;*

(ii) *the set* $\{\mathcal{F}_a(u) \mid u \in [\![e]\!],\ a \in \mathbb{A}\}$ *is finite;*

(iii) $\forall u \in [\![e]\!], \mathbf{m}(u) \leqslant 2 \times |e|$.

(Where $|e|$ *is the number of occurrences of letters in* e*.)*

This lemma was proved in Coq. The following result is of independent interest:

▶ **Theorem 17.** *If e is memory-finite, then $[\![e]\!]^\alpha$ is recognisable by DOFA.*

Proof. Let N be the memory of $[\![e]\!]$. By definition, this means that $[\![e]\!]^\alpha$ is equal to the language $=_\alpha^{\leqslant N}([\![e]\!])$. However, the automaton built by applying the construction from Lemma 10 does not yield a deterministic automaton, even if the input automaton is deterministic. Fortunately, in the present case we can determinise the resulting automaton. To do so, we will rely on the following technical result about $\mathcal{T}_\alpha$, which was established using Coq: for every word $u \in \mathbb{\Sigma}^\star$, there is a word $tr(u) \in \mathbb{A}^\star$ such that for any stack s and word v:

$$[] -[u/v]\to_{\mathcal{T}} s \Rightarrow \mathfrak{p}_1(s) = tr(u) \qquad [] -[v/u]\to_{\mathcal{T}} s \Rightarrow \mathfrak{p}_2(s) = tr(u).$$

Notice that this implies that $\mathbf{supp}(tr(u)) \subseteq \mathbf{supp}(u)$: indeed since $u =_\alpha u$ there is a stack s such that $[] -[u/u]\to_{\mathcal{T}_\alpha} s$, so $tr(u) = \mathfrak{p}_1(s)$, and according to Lemma 12 whenever $a \in \mathfrak{p}_1(s)$ we have $c_a(u) \neq 0$ which implies $a \in \mathbf{supp}(u)$.

Let $\mathcal{A} = \langle Q, \Sigma, \delta, q_0, F\rangle$ be some deterministic finite-state automaton for $[\![e]\!]$, with $\Sigma \in \mathcal{P}_f(\mathbb{\Sigma})$. We write $\bar{a}$ for the finite set of names mentioned in the finite alphabet Σ: $\bar{a} := \bigcup_{l\in\Sigma} \mathbf{supp}(l) \subseteq \mathbf{supp}(e)$. Notice that this means that $\pi \perp \bar{a} \Rightarrow \pi \perp \Sigma^\star$. Without loss of generality, we assume that δ is a partial function $Q \times \Sigma \to Q$ and that $\mathcal{A}$ has no sink-state: for any state $q \in Q$, there exists a word $u \in \Sigma^\star$ such that $\delta(q,u) \in F$. If we look back at the proof of Lemma 10, we see that the states in the automaton we get for $=_\alpha^{\leqslant N}(\mathcal{A})$ are pairs of a state from Q and a stack from $\mathbb{S}^{\leqslant N} := \left(\mathbb{A}^2\right)^{\leqslant N}$. Now, let us do the standard powerset construction on this automaton: we get an automaton $\mathcal{A}' := \langle Q', \mathbb{\Sigma}, \delta', q_0', F'\rangle$ where:

$$Q' = \mathcal{P}\left(Q \times \mathbb{S}^{\leqslant N}\right); \qquad q_0' = \{\langle q_0, []\rangle\}; \qquad F' = \{\bar{q} \in Q' \mid \bar{q} \cap (F \times \mathbb{S}^{acc}) \neq \emptyset\};$$
$$\delta'(\bar{q}, l) = \{\langle q', s'\rangle \mid \exists \langle q, s\rangle \in \bar{q}, \exists l' \in \Sigma : q' = \delta(q,l) \wedge s -[l'/l]\to_{\mathcal{T}_\alpha} s'\}.$$

Unfortunately, the state space Q' is not tractable, since it is not orbit-finite. However, as we will now prove, the subset of reachable states is tractable. Therefore if we restrict $\mathcal{A}'$ to its reachable part we get a language-equivalent DOFA. A state $\bar{q} \in Q'$ is reachable if there exists a word v such that $\delta'(q_0', v) = \bar{q}$. By unfolding the definitions, we can see that $\bar{q}$ is reachable by the word v when the following equivalence is satisfied:

$$\forall q, s : \langle q, s\rangle \in \bar{q} \Leftrightarrow \exists u : q = \delta(q_0, u) \wedge [] -[u/v]\to_{\mathcal{T}_\alpha} s.$$

This implies that $\forall \langle q, s\rangle \in \bar{q}$, $\mathfrak{p}_2(s) = tr(v)$, and $\mathfrak{p}_1(s) = tr(u)$ for some $u \in \mathbf{pref}([\![e]\!])$. This second condition tells us that $\mathfrak{p}_1(s) \in \bar{a}^{\leqslant N}$ which is a finite set. Hence the set of reachable states is contained (modulo isomorphism) in the set: $\mathcal{Q} := \mathcal{P}\left(Q \times \bar{a}^{\leqslant N}\right) \times \mathbb{A}^{\leqslant N}$. This set being the product of a finite set with a tractable one, it is tractable. Notice that the set of reachable states is supported by the finite set $\bar{a}$: indeed if $\pi \perp \bar{a}$, then we already know that $\pi \perp \Sigma^\star$ so if $\bar{q}$ is reachable by the word v, then $\pi \cdot \bar{q}$ is reachable by $\pi \cdot v$ since:

$$\begin{aligned}\langle q, s\rangle \in \pi \cdot \bar{q} \Leftrightarrow \left\langle q, \pi^{-1} \cdot s\right\rangle \in \bar{q} &\Leftrightarrow \exists u : q = \delta(q_0, u) \wedge [] -[u/v]\to_{\mathcal{T}_\alpha} \pi^{-1} \cdot s \\ &\Leftrightarrow \exists u : q = \delta(q_0, u) \wedge \pi \cdot [] -[\pi \cdot u/\pi \cdot v]\to_{\mathcal{T}_\alpha} s \\ &\Leftrightarrow \exists u : q = \delta(q_0, u) \wedge [] -[u/\pi \cdot v]\to_{\mathcal{T}_\alpha} s.\end{aligned}$$

We conclude that the set of reachable states is tractable by applying Lemma 5, which tells us that a finitely supported subset of a tractable set is tractable. ◀

We may use expressions over $\mathbb{\Sigma}$ to generate languages over $\mathbb{X}$ as follows: the language generated by a term $e \in \mathrm{Rat}\langle\mathbb{\Sigma}\rangle$, written $(\!|e|\!)$, is the set of words obtained by erasing the brackets from the well-formed words from $[\![e]\!]^\alpha$. In other words, if we denote by η the monoid homomorphism defined by $\eta(\langle_a) = \eta(\,_a\rangle) = \varepsilon$ and $\eta(x) = x$, we have $(\!|e|\!) := \eta(\mathbf{wf}([\![e]\!]))$.

6 Kleene Theorem

In this section, we show that regular nominal languages over $\mathbb{X}$ are exactly those generated by memory-finite rational expressions. To that end, we call a language L rational if there is some memory-finite expression e such that $L = (\!|e|\!)$. One direction is immediate:

▶ **Lemma 18.** *For any memory-finite expression e, $(\!|e|\!)$ is regular nominal.*

Proof. Since e is memory-finite, according to Lemma 16, every word in e has memory less than $2 \times |e|$. Therefore, $\mathbf{wf}\left([\![e]\!]\right) = \mathbf{wf}^{2\times|e|}\left([\![e]\!]\right)$. By the classic Kleene theorem $[\![e]\!]$ is regular and thanks to Theorem 15 we know that $\mathbf{wf}^{2\times|e|}$ is a nominal transduction. Since we may also see easily that η is a nominal transduction, the statement follows from Lemma 10. ◀

We now show that nominal regular languages are rational. We fix a nominal automaton $\mathcal{A} = \langle Q, \mathbb{X}, \Delta, I, F\rangle$, and assume without loss of generality that its state space is strict, equivariant and orbit-finite. We also fix a finite set $\bar{\mathbf{a}}_0 \subseteq \mathbb{A}$ that supports I, F and Δ. As a first step, we will find a finite sub-automaton of $\mathcal{A}$ that is "large enough" to describe the language of $\mathcal{A}$. We do this by picking a finite set $\bar{\mathbf{a}} \subseteq \mathbb{A}$ such that:

$$\forall \alpha \in I \cup F \cup \Delta, \exists \beta \in I \cup F \cup \Delta : \mathbf{supp}\left(\beta\right) \subseteq \bar{\mathbf{a}} \wedge \exists \pi : \pi \perp \bar{\mathbf{a}}_0 \wedge \pi \cdot \beta = \alpha.$$

Such a set always exists: we just need to pick a representative per orbit, and take the union of their supports. As a shorthand, we write $\mathfrak{S}_0$ for the set of permutations over $\mathbb{A} \setminus \bar{\mathbf{a}}_0$, i.e. the permutations $\pi \in \mathfrak{S}_{\mathbb{A}}$ such that π fixes $\bar{\mathbf{a}}_0$. We then define the finite automaton $\mathcal{A} \restriction_{\bar{\mathbf{a}}} := \langle Q \restriction_{\bar{\mathbf{a}}}, \mathbb{X} \restriction_{\bar{\mathbf{a}}}, \Delta \restriction_{\bar{\mathbf{a}}}, I \restriction_{\bar{\mathbf{a}}}, F \restriction_{\bar{\mathbf{a}}}\rangle$. We can relate the runs of $\mathcal{A} \restriction_{\bar{\mathbf{a}}}$ to those in $\mathcal{A}$ as follows.

▶ **Lemma 19.** *For any letters $(x_i)_{1,\dots,n}$ and any states $(q_i)_{0,\dots,n}$, t.f.a.e.:*

(i) *there is a run $p_0 \xrightarrow{x_1}_{\mathcal{A}} p_1 \dots \xrightarrow{x_n}_{\mathcal{A}} p_n$*

(ii) *there is a run $q_0 \xrightarrow{y_1}_{\mathcal{A}\restriction_{\bar{\mathbf{a}}}} q_1 \cdots \xrightarrow{y_n}_{\mathcal{A}\restriction_{\bar{\mathbf{a}}}} q_n$ and a sequence $(\pi_i)_{0,\dots,n}$ from $\mathfrak{S}_0$ such that $\pi_0 \cdot q_0 = p_0$ and $\forall i > 0$ we have $\pi_i \cdot \langle q_{i-1}, y_i, q_i\rangle = \langle p_{i-1}, x_i, p_i\rangle$.*

We now define a finite automaton $\mathcal{A}'$ over the alphabet $\mathbb{\Sigma} \restriction_{\bar{\mathbf{a}}}^{\star}$. The state space of this automaton will be $Q' := Q \restriction_{\bar{\mathbf{a}}} \cup \{q_0, q_f\}$, with q_0 and q_f fresh states, respectively the initial and final states. We build its transitions as follows:

1. we have $q_0 \xrightarrow{\langle a_1 \cdots \langle a_n}$ $q \in \Delta'$ for any $q \in I \restriction_{\bar{\mathbf{a}}}$, and any word $a_1 \dots a_n \in \left(\bar{\mathbf{a}}_0 \cup \mathbf{supp}\left(q\right)\right)^{\bowtie}$;
2. we have $q \xrightarrow{a_1 \rangle \cdots a_n \rangle}$ $q_f \in \Delta'$ for any $q \in F \restriction_{\bar{\mathbf{a}}}$, and any word $a_1 \dots a_n \in \left(\mathbf{supp}\left(q\right) \setminus \bar{\mathbf{a}}_0\right)^{\bowtie}$;
3. we have $p \xrightarrow{\langle a_1 \cdots \langle a_n\, x\, b_1 \rangle \cdots b_m \rangle}$ $q \in \Delta'$ for every transition $p \xrightarrow{x}_{\mathcal{A}\restriction_{\bar{\mathbf{a}}}} q$ and any pair of words:

$$a_1 \dots a_n \in \left(\left(\mathbf{supp}\left(q\right) \cup \mathbf{supp}\left(x\right)\right) \setminus \left(\mathbf{supp}\left(p\right) \cup \bar{\mathbf{a}}_0\right)\right)^{\bowtie}$$
$$b_1 \dots b_m \in \left(\left(\mathbf{supp}\left(p\right) \cup \mathbf{supp}\left(x\right)\right) \setminus \left(\mathbf{supp}\left(q\right) \cup \bar{\mathbf{a}}_0\right)\right)^{\bowtie}.$$

Since we have only a finite number of transitions, we know that this automaton may be transformed into a finite state automaton over $\mathbb{\Sigma} \restriction_{\bar{\mathbf{a}}}$, therefore thanks to Kleene's theorem there is a rational expression $e \in \mathrm{Rat}\,\langle \mathbb{\Sigma} \rangle$ such that $[\![e]\!] = \mathcal{L}_{\mathcal{A}'}$. We now need to check that e is memory-finite and that $(\!|e|\!) = \mathcal{L}_{\mathcal{A}}$. For the first property, we show the following lemma:

▶ **Lemma 20.** *For every run $q_0 \xrightarrow{w}_{\mathcal{A}'} q \in Q \restriction_{\bar{\mathbf{a}}}$, the word $w \in \mathcal{WF}$, $\mathbf{m}\left(w\right) \leqslant \#\bar{\mathbf{a}}$ and either $a \in \mathbf{supp}\left(q\right) \cup \bar{\mathbf{a}}_0$ and $\mathcal{F}_a\left(w\right) = \mathbf{c}$, or $a \notin \mathbf{supp}\left(q\right) \cup \bar{\mathbf{a}}_0$ and $\mathcal{F}_a\left(w\right) = \varepsilon$.*

This entails that $[\![e]\!] \subseteq \mathcal{WF}$ and $\mathbf{m}\left(e\right) \leqslant \#\bar{\mathbf{a}}$. Lemma 20 will also serve in the next proof.

▶ **Lemma 21.** *For any $w \in \mathbb{\Sigma}^\star$, the word w belongs to $\mathbf{wf}\left(\mathcal{L}_{\mathcal{A}'}\right)$ if and only if there is a sequence of permutations $\pi_0 \dots \pi_{n+1} \in \mathfrak{S}_0$ and a run $q_0 \xrightarrow{u_0}_{\mathcal{A}'} q_1 \xrightarrow{u_1}_{\mathcal{A}'} \cdots \xrightarrow{u_n}_{\mathcal{A}'} q_{n+1} \xrightarrow{u_{n+1}}_{\mathcal{A}'} q_f$ such that $w = (\pi_0 \cdot u_0) \dots (\pi_{n+1} \cdot u_{n+1})$ and $\forall 0 < i \leqslant n,\ \pi_{i-1} \cdot q_i = \pi_i \cdot q_i$.*

From Lemmas 19 and 21 it is not hard to see that our construction is correct, thus proving that every regular nominal language is rational.

▶ **Theorem 1** (Kleene Theorem)**.** *Let L be a nominal language. The following are equivalent:*

(i) *L is rational, that is $L = (\!|e|\!)$ for some memory-finite regular expression e.*

(ii) *L is regular nominal, that is recognisable by a NOFA.*

7 Related work

Schröder at al.'s *regular bar-expressions* [18] enjoy a Kleene-like theorem. Regular bar-expressions add an operator $|_a$ to the alphabet, intuitively writing an a on the right-hand side of the bar, and hiding it from the left-hand side. These expressions are equipped with two semantics, called "local" and "global" freshness. Under "local" freshness, the class of automata represented by these expressions is a strict subset of the class of nominal automata, where no name may be guessed (i.e. for every transition $p \xrightarrow{x} q$ we have $\mathbf{supp}\,(q) \subseteq \mathbf{supp}\,(p) \cup \mathbf{supp}\,(x)$), and where a policy of "name dropping" is enforced: a name may be in the support of a state only if it will appear later. For instance, this precludes recognising the languages L_2 and L_5 from the introduction. Under "global" freshness however the situation is more contrasted. With this semantics, the expressive power of bar-expressions is incomparable with that of memory-finite expressions. Indeed, they can denote the language of words where all the letters are different by $|a^\star$, but cannot denote $L_3 := (\!|\langle_a\, a\, {}_a\rangle^\star|\!) = \mathbb{A}^\star$. However if we drop the memory-finite requirement, one can translate bar-expressions into regular expressions over $\mathbb{\Sigma}$ by replacing every occurrence of $|a$ with $\langle_a\, a$ and suffixing the expression with $\left(\sum_{a \in \mathbf{supp}(e)} {}_a\rangle\right)^\star$. For instance the term $|a^\star$ is sent to the expression $(\langle_a\, a)^\star\ {}_a\rangle^\star$. In this case, our well-formed predicate corresponds to the *clean* predicate used to define the global freshness semantics, and this transformation preserves languages. This means that unrestricted expressions with brackets are strictly more expressive than bar-expressions.

In a study of Nominal Kleene Algebra [11, 10, 6], *NKA expressions* were introduced, and half a Kleene theorem for NOFA was proved. These expressions feature a unary $\nu_a(e)$ operator to make a name a local to an expression e. These expressions do not allow the interleaving of scopes, thus failing to capture languages such as 5 from the introduction.

Kurz et al. [13] considered regular expressions with binders. However, their framework only accounts for well nested brackets, thus not covering many of the languages we consider. They present a Kleene theorem for history-dependent automata that incorporates a bound on the nesting depth of binding, rejecting words that exceed this depth, which is the analogue restriction at the automaton level of our memory-finiteness property at the language level. It is unclear whether HD-automata could be generalised to accommodate interleaving of scopes.

On the other hand Libkin and Vrgoč's *regular expressions with memory* [14] enjoy a full Kleene theorem with register automata. Since register automata and nominal automata are equi-expressive, this means that regular expressions with memory are as expressive as our memory-finite expressions. They are however quite different in style. The point of view they choose is that of data words: they assume a finite alphabet Σ and an infinite set of data values $\mathcal{D}$, and consider languages over the alphabet $\Sigma \times \mathcal{D}$, i.e. each letter carries a data value. The key feature of their syntax is to use annotation on letters. They fix a number of variables $x_1 \dots x_k$, and use regular expressions over an alphabet made of elements of the shape $a[c]{\downarrow}I$ where a is a letter from Σ, I is a subset of the variables, and c is a boolean

formula that may use atomic predicates $x_i^{=}$ and $x_i^{\neq}$. These expressions are then interpreted as ternary relations, linking two k-tuples of data values with data words. In effect, this amounts to simulating the run of a register automaton where the k-tuples of data values represent the content of the registers.

Abstract

There exist several graphical languages for quantum information processing, like quantum circuits, ZX-Calculus, ZW-Calculus, etc. Each of these languages forms a †-symmetric monoidal category (†-SMC) and comes with an interpretation functor to the †-SMC of (finite dimension) Hilbert spaces. In the recent years, one of the main achievements of the categorical approach to quantum mechanics has been to provide several equational theories for most of these graphical languages, making them complete for various fragments of pure quantum mechanics.

We address the question of the extension of these languages beyond pure quantum mechanics, in order to reason on mixed states and general quantum operations, i.e. completely positive maps. Intuitively, such an extension relies on the axiomatisation of a *discard* map which allows one to get rid of a quantum system, operation which is not allowed in pure quantum mechanics.

We introduce a new construction, the *discard construction*, which transforms any †-symmetric monoidal category into a symmetric monoidal category equipped with a discard map. Roughly speaking this construction consists in making any isometry causal.

Using this construction we provide an extension for several graphical languages that we prove to be complete for general quantum operations. However this construction fails for some fringe cases like the Clifford+T quantum mechanics, as the category does not have enough isometries.

1 Introduction

Graphical languages that speak of quantum information can be formalised through the notion of symmetric monoidal categories. Hence, it has a nice graphical representation using string diagrams [41]. Qubits are represented by wires, and morphisms by graphical elements where some wires go in, and some others go out, just as in quantum circuits (which is actually a particular case of symmetric monoidal category), and where these graphical elements can be composed either in sequence (usual composition) or in parallel (tensor product). They usually come with an additional structure, a contravariant functor called dagger.

Examples of graphical languages for quantum mechanics and quantum computing are the quantum circuits and the ZX-Calculus [11]. Some variants of the ZX-calculus have been introduced more recently like the ZW-calculus [26] and the ZH-calculus [6]. All these languages are defined using generators (elementary gates) and come with an interpretation functor which associates to any diagram a pure quantum evolution, i.e. a morphism in the category of Hilbert spaces. Given a graphical language, there are generally several ways to represent a quantum evolution, thus a graphical language is also equipped with an equational theory which allows to transform a diagram into another equivalent diagram. A fundamental property, generally hard to prove, is the completeness of the language: given two diagrams representing the same quantum evolution, one can be turned into the other using only the transformation rules in the theory.

The languages considered have usually been built so as to be able to represent any pure quantum evolution, i.e. any perfectly isolated quantum system which hence does not interact with the environment. In this case, the language is called universal for pure quantum mechanics. The hardness of the completeness problem, as well as constraints given by the complexity to physically achieve some gates, focused the research on some restrictions of the languages. On the one hand, finite presentations for the quantum circuits were shown to be complete for some restrictions – namely Clifford [42], one-qubit Clifford+T [37], two-qubit Clifford+T [43], CNot-dihedral [1] –, however none of these restrictions is universal, nor approximately universal. Regarding the ZX-calculus, completeness results exist for non-universal restrictions of the ZX-Calculus [3, 4, 16, 24], but also for the many-qubit Clifford+T ZX-Calculus [31], which was the first completeness result for an approximately universal fragment of the language. Then complete theories have been introduced for the universal ZX-Calculus [28, 33, 32, 44] and ZW-Calculus [27, 28]. The completeness of the graphical languages for pure quantum mechanics is one of the main achievements of the categorical approach to quantum mechanics, and is the cornerstone for the application of this formalism in many areas of quantum information processing. The ZX-Calculus already proved to be useful for quantum information processing [14] (e.g. measurement-based quantum computing [18, 23, 29], quantum codes [17, 9, 20, 22], circuit optimisation [21], foundations [5, 19] ...). Moreover the ZX-calculus can be concretely used through two softwares: Quantomatic [36] and PyZX [34].

The existence of complete graphical languages beyond pure quantum mechanics for more general, not necessarily pure, quantum evolutions is an open question that we address in the present paper.

While pure quantum evolutions correspond to linear maps over Hilbert spaces, probability distributions over quantum states as well as some quantum evolutions like discarding a quantum system can be represented, following the von Neumann approach, by means of density matrices and completely positive maps. The category of completely positive maps has been already studied [39], and in particular the connections between the pure and the van Neumann approaches is a central question in categorical quantum mechanics. Selinger

introduced a construction called CPM to turn a category for pure quantum mechanics into a category for density matrices and completely positive maps [40]. Another approach to relate pure quantum mechanics to the general one is the notion of environment structure [10, 12, 15]. The notion of *purification* is central in the definition of environment structure. The CPM-construction and the environment structure approaches have been proved to be equivalent [12].

In terms of graphical languages, the environment structure approach cannot be used in a straightforward way to extend a graphical language beyond pure quantum mechanics. Roughly speaking the environment structure approach provides second order axioms which associates with any equation on arbitrary (non necessarily pure) evolutions an equivalent equation on pure evolutions. Such a second order axiom cannot be easily handled by a equational theory on diagrams. Regarding the CPM-construction, the main property which has been exploited in [14] is that CPM($\mathbf{C}$) is essentially a subcategory of $\mathbf{C}$, thus one can use a graphical language which has been designed for $\mathbf{C}$ in order to represent morphisms in CPM($\mathbf{C}$): Given a complete graphical language for $\mathbf{C}$, we can use a subset of the pure diagrams to represent the evolutions in CPM($\mathbf{C}$). The main caveat of this approach is that this subset is not necessarily closed under the equational theory on pure diagrams, and as a consequence does not provide a complete graphical language for CPM($\mathbf{C}$).

Our contributions. In [30] was shown that the category **CPTPM** of completely positive trace-preserving maps is the universal monoidal category with a terminal unit and a functor from the category of isometries. We build upon this result by introducing a new construction, the *discard construction*, which transforms any †-symmetric monoidal category into a symmetric monoidal category equipped with a discard map. Roughly speaking this construction consists in making any isometry causal. Indeed, in quantum mechanics, the isometries (linear maps U such $U^\dagger \circ U = I$) are known to be causal, i.e. applying U and then discarding the subsystem on which it has been applied is equivalent to discarding the subsystem straightaway. Specifically, the discard construction proceeds as follows: first the discard is added to the subcategory of isometries, making the unit of the tensor a terminal object in this sub-category , as pointed out in [30]. Then the discard construction is obtained as the pushout of the resulting category and the initial one.

We show that the discard construction does not always produce an environment structure for the original category, and thus is not equivalent to the CPM construction. We show that a necessary and sufficient condition for the two constructions to be equivalent is that the initial category has enough isometries. We show that most of the categories usually used in the context of the categorical quantum mechanics, like **FHilb** and **Stab**, do have enough isometries, however **Clifford+T** does not.

Finally, we show that the discard construction provides a simple recipe to extend graphical languages beyond pure quantum mechanics. We provide an extension for several graphical languages that we prove to be complete for general quantum operations.

Structure of the paper. In section 2, we review some categorical notions used in categorical quantum mechanics. Section 3 is dedicated to the definition of the discard construction and the relation with the CPM construction. Finally, in section 4 we use the discard construction to extend the ZX-calculus to make it complete for general (not necessarily pure) quantum evolutions. The construction is also applied to other graphical languages.

2 Background

2.1 Dagger symmetric monoidal categories

To avoid any size issue, all our categories are small, the homset of a category $\mathbf{C}$ will be denoted $\mathbf{C}[A, B]$. For simplicity, all the monoidal categories considered in the following will be *strict*. Recall that a *strict symmetric monoidal category* (SMC) $\mathbf{C}$ is a category together with a tensor product bifunctor $\otimes : \mathbf{C} \times \mathbf{C} \to \mathbf{C}$, a unit object I such that $A \otimes I = I \otimes A = A$ and $A \otimes (B \otimes C) = (A \otimes B) \otimes C$, and a symmetry natural isomorphism: $\sigma_{A,B} : A \otimes B \to B \otimes A$ satisfying $\sigma_{A,I} = 1_A$, $\sigma_{A,B\otimes C} = (1_B \otimes \sigma_{A,C}) \circ (\sigma_{A,B} \otimes 1_C)$, and $\sigma_{A,B} \circ \sigma_{B,A} = 1_{B\otimes A}$. A *prop* is an SMC whose set of objects is freely spanned by one object. There is an associated notion of strict symmetric monoidal functor $F : \mathbf{C} \to \mathbf{D}$ which preserves unit, tensors and symmetries. We will use *string diagram* notations for SMC where morphisms are described as boxes and

$g \circ f :=$  $f \otimes g :=$  $1_A :=$ $1_I :=$  $\sigma_{A,B} :=$ 

A †-SMC $\mathbf{C}$, is an SMC with an i.o.o. (identity on object) involutive and contravariant SMC-functor $(.)^\dagger : \mathbf{C} \to \mathbf{C}$. That is, every morphism $f : A \to B$ has a dagger $f^\dagger : B \to A$ such that $f^{\dagger\dagger} = f$, moreover the dagger respects the symmetries $\sigma^\dagger_{A,B} = \sigma_{B,A}$. The dagger is a central notion in categorical quantum computing and can be used to define specific properties of morphisms:

▶ **Definition 1.** *$f : A \to B$ is an* isometry *if $f^\dagger \circ f = 1_A$, i.e.* 

In this paper most of the categories considered are furthermore compact closed: A dagger compact category (†-CC) is a †-SMC where every object A has a dual object A^* such that for all objects A, there are two morphisms $^A\smile^{A^*} : A \otimes A^* \to I$ and $_{A^*}\frown_A : I \to A^* \otimes A$ satisfying  and  .

2.2 Examples

We will consider two kinds of SMCs in this paper: the categories of quantum evolutions and the graphical languages.

Quantum evolutions. Pure quantum evolutions correspond the category of Hilbert spaces. We will consider several of its subcategories: **FHilb** is the category of finite dimensional Hilbert spaces whose objects are $\mathbb{C}^n$ and morphisms are linear maps. Its tensor is the usual tensor product of vector spaces and its dagger is the adjoint with respect to the usual scalar product. It is the mathematical model for pure quantum mechanics. In quantum information processing, quantum data is usually carried by qubits, hence **Qubit** is the full subcategory of **FHilb** with objects of the form $\mathbb{C}^{2^n}$. **Stab** is the sub-category of **Qubit** which is finitely generated by the Clifford operators: H, S, CNot, the state $|0\rangle$, the projector $\langle 0|$, and the scalar 2 where:

$$\mathrm{H} = \frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\ 1 & -1\end{pmatrix} \quad \mathrm{S} = \begin{pmatrix}1 & 0\\ 0 & i\end{pmatrix} \quad \mathrm{CNot} = \begin{pmatrix}1 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 0 & 1\\ 0 & 0 & 1 & 0\end{pmatrix} \quad |0\rangle = \begin{pmatrix}1\\ 0\end{pmatrix} \quad \langle 0| = \begin{pmatrix}1 & 0\end{pmatrix}$$

Those are amongst the most commonly used gates in quantum computation (see [38] for details). **Clifford+T** is the same as **Stab** but with the additional generator $T = \left(\begin{smallmatrix} 1 & 0 \\ 0 & e^{i\frac{\pi}{4}} \end{smallmatrix}\right)$, the morphisms of **Clifford+T** are exactly the matrices with entries in the ring $\mathbb{Z}[i, \frac{1}{\sqrt{2}}]$ [31]. Contrary to **Stab**, **Clifford+T** is *approximately universal* in the sense that $\forall n, m \in \mathbb{N}$, $\forall f \in \mathbf{Qubit}[\mathbb{C}^{2^n}, \mathbb{C}^{2^m}]$ and $\forall \epsilon > 0$, there exists $g \in \mathbf{Clifford+T}[\mathbb{C}^{2^n}, \mathbb{C}^{2^m}]$ such that $||f - g|| < \epsilon$. **FHilb**, **Qubit**, **Clifford+T**, and **Stab** are all †-CC. Notice that **Qubit**, **Clifford+T**, and **Stab** are props, but **FHilb** is not.

Probability distributions over pure quantum states as well as some quantum evolutions like discarding a quantum system are not *pure* but can be represented, following the von Neumann approach, by means of density matrices and completely positive maps. Let **CPM** be the category of completely positive maps of finite dimension whose objects are $\mathbb{C}^n$ and $\mathbf{CPM}[\mathbb{C}^n, \mathbb{C}^m] = \{U : \mathbb{C}^{n\times n} \to \mathbb{C}^{m\times m} \mid U \text{ is a completely positive linear map}\}$. Similarly to the pure case, one can define various subcategories of **CPM**. Notice that it can be achieved by the CPM construction described in the next section.

Graphical languages. The second kind of categories we are considering in this paper are graphical languages. They are props which come with interpretation functors defining their semantics. A prop is in fact the equivalent of Lawvere theories for symmetric monoidal theories. They can be presented by generators and relations as one would do for usual theories, see [45] and [7] for a detailed discussion.

▶ **Definition 2.** *A* graphical language $\mathcal{G}$ *is a prop presented by a set of* generators Σ *and a set of* equations E *together with a function* $[\![.]\!] : \Sigma \to \hom(S)$ *called the* interpretation *of* $\mathcal{G}$ *in* S*.* $\mathcal{G}$ *is said to be* sound *if* $[\![.]\!]$ *defines an interpretation functor* $[\![.]\!] : \mathcal{G} \to S$*, and* universal *(resp.* complete*) when this functor is surjective (resp. faithful).*

The ZX-, ZW- and ZH-calculi or the quantum circuits are examples of such categories with semantics in **Qubit**.

2.3 Environment structures and CPM-construction

Connecting the Hilbert approach – for pure quantum mechanics – and the von Neumann approach – for open systems – is a central question in categorical quantum mechanics. Selinger pointed out that any †-CC for pure quantum mechanics can be turned into a category for density matrices and completely positive maps via the CPM construction [40]:

▶ **Definition 3.** *Given a* †*-CC* $\mathbf{C}$*, let* $\mathrm{CPM}(\mathbf{C})$ *be the* †*-CC with the same objects as* $\mathbf{C}$ *such that* $\mathrm{CPM}(\mathbf{C})[A, B] = \left\{ \begin{array}{c} A \\ \boxed{f} \\ B \quad C \end{array} \; \begin{array}{c} A^* \\ \boxed{f^*} \\ C^* \quad B^* \end{array} , f \in \mathbf{C}[A, B \otimes C] \right\}$*, where* $\begin{array}{c} A^* \\ \boxed{g^*} \\ B^* \end{array} := \begin{array}{c} \quad B \\ \boxed{g^\dagger} \\ B^* \quad A \end{array} A^*$.

Applying it to **FHilb** one obtains the category **CPM** of completely positives maps. The CPM construction can also be applied to **Qubit**, **Clifford+T**, and **Stab**. Notice that the CPM-construction has been then extended to the non necessarily compact categories [12].

Another approach to relate pure quantum mechanics to the general one is the notion of environment structure [10, 12, 15]. The notion of *purification* is central in the definition of environment structure. Intuitively, it means that (1) there is a discard morphism for every object; (2) any morphism can be purified, i.e. decomposed into a pure morphism followed by a discarding map, and (3) this purification is essentially unique. More formally:

▶ **Definition 4.** *An environment structure for a †-CC* $\mathbf{C}$ *is a CC* $\overline{\mathbf{C}}$ *with the same objects as* $\mathbf{C}$*, an i.o.o SMC-functor* $\iota : \mathbf{C} \to \overline{\mathbf{C}}$ *and for each object* A *a morphism* $\perp_A : A \to I$ *such that:*

(1) $\perp_I = 1_I$*, and for all* $A, B : \mathbf{C}$, $\perp_A \otimes \perp_B = \perp_{A\otimes B}$.

(2) *For all* $f : A \to B$ *in* $\overline{\mathbf{C}}$*, there is an* $f' : A \to B \otimes X$ *in* $\mathbf{C}$ *such that:* 
(3) *For any* $f : A \to B \otimes X$ *and* $g : A \to B \otimes Y$ *in* $\mathbf{C}$*:* $f \sim_{\text{cp}} g \Leftrightarrow$ 
where the relation $\sim_{\text{cp}}$ *is defined as:* $f \sim_{\text{cp}} g \Leftrightarrow$ 
Notice that $\sim_{\text{cp}}$ is technically not a relation on morphisms but on tuples (A, B, X, f) with $f \in \mathbf{C}[A, B \otimes X]$: $(A, B, X, f) \sim_{\text{cp}} (C, D, Y, g)$ if $A = C, B = D$ and f, g satisfy the graphical condition represented above. By abuse of notation, we write $f \sim_{\text{cp}} g$, as the other components of the tuple will be usually obvious from context. We will do the same for our relation $\sim_{\text{iso}}$ below.

CPM is actually an environment structure for the category **FHilb**, and more generally for any †-CC $\mathbf{C}$, CPM($\mathbf{C}$) is an environment structure for $\mathbf{C}$ and conversely any environment structure for $\mathbf{C}$ is equivalent to CPM($\mathbf{C}$) [12]. Actually one can notice that CPM($\mathbf{C}$)$[A, B]$ is nothing but the set of equivalent classes of $\sim_{\text{cp}}$.

The notion of environment structures has also been generalised to the non compact case [12]. We chose here to focus on the compact case.

3 The Discard Construction

We introduce a new construction, the *discard construction*, which consists in adding a discard map for every object of a †-SMC, and thus intuitively transforming a category for pure quantum mechanics into a category for general quantum evolutions.

Causality is a central notion in quantum mechanics which has been axiomatised using a discard map as follows [35]: $f : A \to B$ is *causal* if and only if  $= \perp$. Amongst the pure quantum evolutions, the isometries are causal evolutions. The discard construction essentially consists in making any isometry causal. Thus, whereas the CPM construction relies on completely positive maps and the environment structures on the concept of purification, the discard construction relies on causality.

3.1 Definition

We introduce the new construction in three steps. First, given a †-SMC, one can consider its subcategory of isometries:

▶ **Definition 5.** *Given a †-SMC* $\mathbf{C}$*,* $\mathbf{C}_{\text{iso}}$ *is the subcategory with the same objects as* $\mathbf{C}$ *and isometries as morphisms, i.e. for all* $A, B : \mathbf{C}$*,* $\mathbf{C}_{\text{iso}}[A, B] = \{f : \mathbf{C}[A, B], f^\dagger \circ f = 1_A\}$.

Notice that $\mathbf{C}_{\text{iso}}$ is an SMC but usually not a †-SMC. Any †-SMC-functor $F : \mathbf{C} \to \mathbf{D}$ between two †-SMC can be restricted to their subcategories of isometries leading to an SMC-functor $F_{\text{iso}} : \mathbf{C}_{\text{iso}} \to \mathbf{D}_{\text{iso}}$. Thus there is a restriction functor iso : †-**SMC** → **SMC**. Remark that this functor preserves fullness and faithfulness. One always has an inclusion i.o.o. faithful SMC-functor: $i_{\text{iso}} : \mathbf{C}_{\text{iso}} \to \mathbf{C}$.

In quantum mechanics, isometries are causal evolutions, i.e. applying an isometry and then discarding all outputs is equivalent to discarding the inputs straight away. As pointed out in [30], adding discard maps to the category of isometries would make I a terminal object. Such a category is said to be *affine symmetric monoidal category* (ASMC). We define the affine completion of an SMC:

▶ **Definition 6.** *Given an SMC* $\mathbf{C}$*, we define* $\mathbf{C}^!$ *as* $\mathbf{C}$ *with an additional morphism* $!_A : A \to I$ *for each object* $A : \mathbf{C}$*. We denote the inclusion functor* $i^! : \mathbf{C} \to \mathbf{C}^!$ *which is strict monoidal and i.o.o. We further impose that* $1_I = !_I$*, and that for all* $f : \mathbf{C}[A, B]$*,* $!_B \circ i^!(f) = !_A$*. This makes* I *a terminal object in* $\mathbf{C}^!$*, and thus* $\mathbf{C}^!$ *is an ASMC.*

Notice by the way that $!_A \otimes !_B = 1_I \circ (!_A \otimes !_B) = !_I \circ (!_A \otimes !_B) = !_{A\otimes B}$. Again given a functor $F : \mathbf{C} \to \mathbf{D}$, one can define a functor $F^! : \mathbf{C}^! \to \mathbf{D}^!$ by $F^!(!_A) = !_{i^!(F(A))}$ and $F^!(f) = i^!(F(f))$ for the other morphisms. In [30], Huot and Staton show that **CPTPM**, the category of completely positive trace preserving maps, is equivalent to $\mathbf{FHilb}^!_{\text{iso}}$, thus giving a caracterisation of it via a universal property. We extend this idea to non-trace preserving maps by proceeding to a local affine completion of the subcategory of isometries.

We define the category $\mathbf{C}^{\fallingdotseq}$ as the pushout of $\mathbf{C}$ and $\mathbf{C}^!_{\text{iso}}$:

▶ **Definition 7.** *Given a* †*-SMC* $\mathbf{C}$*,* $\mathbf{C}^{\fallingdotseq}$ *is defined as the pushout in the category of symmetric monoidal categories:*

$$\begin{array}{ccc} \mathbf{C}_{\text{iso}} & \xrightarrow{i_{\text{iso}}} & \mathbf{C} \\ {\scriptstyle i^!}\downarrow & & \downarrow{\scriptstyle \iota_{\mathbf{C}}} \\ \mathbf{C}^!_{\text{iso}} & \xrightarrow[\iota_{\mathbf{C}^!_{\text{iso}}}]{} & \mathbf{C}^{\fallingdotseq} \end{array}$$

The existence of this pushout follows from the fact that the forgetful functor from strict symmetric monoidal categories to categories **StrictSymMonCat** → **Cat** preserves coequalizers, and from [8, Theorem 9.3.9]. As all our functors are i.o.o., we can also describe it simply combinatorially. The objects of $\mathbf{C}^{\fallingdotseq}$ are the same as $\mathbf{C}$. Its morphisms are equivalence classes generated by formal composition and tensoring of morphisms in $\mathbf{C}^!_{\text{iso}}$ and $\mathbf{C}$. The equivalence relation is generated by the equations of both categories augmented with equations $i^!(f) = i_{\text{iso}}(f)$ for all f in $\mathbf{C}_{\text{iso}}$. The functors $\iota_{\mathbf{C}}$ and $\iota_{\mathbf{C}^!_{\text{iso}}}$ are the natural ways to embed $\mathbf{C}$ and $\mathbf{C}^!_{\text{iso}}$. We will see those formal compositions as string diagrams whose components are morphisms of $\mathbf{C}$ and $\mathbf{C}^!_{\text{iso}}$ wired to each others. Two diagrams represent the same morphism if we can rewrite one into the other applying the equations of both categories and $i^!(f) = i_{\text{iso}}(f)$ for all f in $\mathbf{C}_{\text{iso}}$. This forms a well defined SMC.

Since the only morphisms in $\mathbf{C}_{\text{iso}}$ which are not identified with the morphisms of $\mathbf{C}$ are those that contain $!_A$, we can see $\mathbf{C}^{\fallingdotseq}$ as $\mathbf{C}$ augmented with discard maps which delete isometries.

▶ **Definition 8.** *The discard map on an object* A *is defined in* $\mathbf{C}^{\fallingdotseq}$ *by* $\overset{A}{\perp\!\!\!\fallingdotseq} := \iota_{\mathbf{C}^!_{\text{iso}}}(!_A)$.

Notice, that for any isometry $f : A \to B$ in $\mathbf{C}^{\fallingdotseq}$, $\boxed{f}$ $= \perp\!\!\!\fallingdotseq$, thus any isometry is causal.

3.2 Relation to environment structures and CPM

In order to compare the $\mathbf{C}^{\fallingdotseq}$ construction with environment structures and the CPM construction we need to study in details the purification process in $\mathbf{C}^{\fallingdotseq}$. First notice that any morphism of $\mathbf{C}^{\fallingdotseq}$ admits a purification:

▶ **Lemma 9.** *Let* $\mathbf{C}$ *be a* †*-SMC. For all* $f : \mathbf{C}^{\neq}[A, B]$*, there is an* $X : \mathbf{C}$ *and an* $f' : \mathbf{C}[A, B \otimes X]$ *such that*  $= \iota_{\mathbf{C}}(f')$.

The purification needs not be unique, however it satisfies an essential uniqueness condition. To state it we define the relation $\sim_{\text{iso}}$.:

▶ **Definition 10.** *Let* $\mathbf{C}$ *be a* †*-SMC, and two morphisms* $f : A \to B \otimes X$*,* $g : A \to B \otimes Y$*.* $f \sim_{\text{iso}} g$ *if there are two isometries* $u : X \to Z$ *and* $v : Y \to Z$*, such that*  .

Notice that the relation $\sim_{\text{iso}}$ is not transitive, thus we consider $\sim_{\text{iso}}^{+}$ its transitive closure to make it an equivalence relation. It is easy to show that if $f \sim_{\text{iso}}^{+} g$ then f and g purify the same morphism of $\mathbf{C}^{\neq}$. The converse is also true:

▶ **Lemma 11.** *For all* $f : A \to B \otimes X$ *and* $g : A \to B \otimes Y$*:* $f \sim_{\text{iso}}^{+} g \Leftrightarrow$ 
So the purification is unique up to $\sim_{\text{iso}}^{+}$. Lemma 11 also gives an alternative definition of $\mathbf{C}^{\neq}$ which relates more easily to the CPM construction. It is the same construction as CPM with $\sim_{\text{cp}}$ replaced by $\sim_{\text{iso}}^{+}$. In other words $\mathbf{C}^{\neq}[A, B]$ is the set of equivalent classes of $\sim_{\text{iso}}^{+}$.

As we have introduced a new discard construction, a natural question is whether $\mathbf{C}^{\neq}$ is an environment structure for $\mathbf{C}$. To be an environment structure, three conditions are required. The first two are satisfied: $\mathbf{C}^{\neq}$ has a discard morphism for every object, and every morphism can be purified. The third one is the uniqueness of the purification: according to the definition of the environment structures, f and g purify the same morphism if and only if $f \sim_{\text{cp}} g$ whereas according to Lemma 11, f and g purify the same morphism if and only if $f \sim_{\text{iso}}^{+} g$. As a consequence $\mathbf{C}^{\neq}$ is an environment structure for $\mathbf{C}$ if and only if $\sim_{\text{cp}} = \sim_{\text{iso}}^{+}$. It turns out that one of the inclusions is always true:

▶ **Lemma 12.** *For any* †*-SMC category* $\mathbf{C}$*, we have* $\sim_{\text{iso}}^{+} \subseteq \sim_{\text{cp}}$.

As a consequence, if $\sim_{\text{cp}} \neq \sim_{\text{iso}}^{+}$, it means that there are some morphisms f, g that are equal in $\sim_{\text{cp}}$ but cannot be proved equal in $\sim_{\text{iso}}^{+}$. Intuitively it means the category has not enough isometries to prove those terms equal, which leads to the following definition:

▶ **Definition 13.** *A* †*-SMC category* $\mathbf{C}$ *has* enough isometries *if the equivalences relations* $\sim_{\text{cp}}$ *and* $\sim_{\text{iso}}^{+}$ *of* $\mathbf{C}$ *are equal.*

▶ **Lemma 14.** *Given a* †*-SMC* $\mathbf{C}$*, the following properties are equivalent:*

1. $\mathbf{C}$ *has enough isometries;*
2. $\mathbf{C}^{\neq}$ *is an environment structure for* $\mathbf{C}$*;*
3. $\mathbf{C}^{\neq} \simeq \text{CPM}(\mathbf{C})$.

Notice that if $\mathbf{C}$ has enough isometries, the discard construction provides a definition of $\text{CPM}(\mathbf{C})$ via a universal property. This gives a more direct way to build the environment, avoiding to deal with the equivalence classes of the CPM construction.

▶ Remark 15. Let's focus for a moment on the category $\text{Causal}\,\text{CPM}(\mathbf{C})$ of causal maps, that is the subcategory of maps cancelled by the discards in $\text{CPM}(\mathbf{C})$. We have that: $\sim_{\text{cp}} \subseteq \sim_{\text{iso}}^{+} \Rightarrow \mathbf{C}_{\text{iso}}^{!} \simeq \text{Causal}\,\text{CPM}(\mathbf{C})$. In fact by Lemma 14, $\text{CPM}(\mathbf{C}) \simeq \mathbf{C}^{\neq}$, and then the subcategory $\text{Causal}\,\text{CPM}(\mathbf{C})$ is equivalent to the subcategory of maps cancelled by the discards in $\mathbf{C}^{\neq}$ which is equivalent to $\mathbf{C}_{\text{iso}}^{!}$. $\text{Causal}\,\text{CPM}(\mathbf{FHilb})$ being exactly $\mathbf{CPTPM}$, we have recovered the result of [30].

3.3 Examples

We consider the usual subcategories of **FHilb** used for pure quantum mechnanics and show in each case whether the discard construction produces an environment structure or not. First of all, thanks to the Stinespring dilation theorem, $\mathbf{FHilb}^{\doteqdot}$ is not only an environment structure for **FHilb**, but the relation $\sim_{\text{iso}}$ is also transitive in this case:

▶ **Proposition 16.** $\mathbf{FHilb}^{\doteqdot}$ *is an environment structure for* **FHilb**. *Furthermore* $\sim_{\text{iso}}^{+}=\sim_{\text{iso}}$.

When dealing with graphical languages we will be more interested in the full subcategory **Qubit** of **FHilb**:

▶ **Proposition 17.** $\mathbf{Qubit}^{\doteqdot}$ *is an environment structure for* **Qubit**.

Notice that in general, the property of having enough isometries does not transfer to full subcategories: If **D** is a full subcategory of **C**, we might have $f \sim_{\text{iso}}^{+} g$ on **C** but $f \not\sim_{\text{iso}}^{+} g$ on **D**. This could happen for two reasons: First the chain of intermediate morphisms that prove that $f \sim_{\text{iso}}^{+} g$ might live outside of **D**. Second, the isometries that "prove" that $f \sim_{\text{iso}}^{+} g$ on **C** might have codomain outside of **D**.

If our category is not a full subcategory, then everything falls apart, and finding conditions that guarantee that $\mathbf{C}^{\doteqdot}$ is an environment structure for **C** is not easy.

For subcategories of **Qubit**, necessary conditions can be given. This category has the peculiarity that $\cdot^*$ is the identity on objects and that $f^{**} = f$ for all morphisms ($\cdot^*$ maps a matrix to its conjugate matrix). In particular, for any state $\phi : I \to I \otimes X$, we have $\phi^* \sim_{\text{cp}} \phi$. Indeed  .

So a necessary condition for a subcategory of **Qubit** to behave nicely is that for all states ϕ, we have $\phi^* \sim_{\text{iso}}^{+} \phi$. This is the case in **Stab**: Given a stabilizer state ϕ, there always exists a stabilizable unitary U s.t. $U\phi = \phi^*$. In fact:

▶ **Proposition 18.** $\mathbf{Stab}^{\doteqdot}$ *is an environment structure for* **Stab**.

The main idea of the proof is to use the map/state duality, and structural results about bipartite stabilizer states [2].

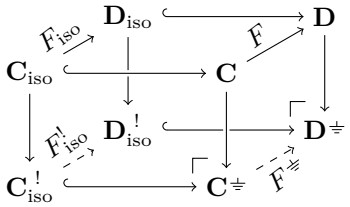
No such unitary exists in general in **Clifford+T**: For almost all states ϕ, there is no unitary U (and actually no morphism at all) s.t. $U\phi = \phi^*$. **Clifford+T** therefore has not got enough isometries:

▶ **Proposition 19.** $(\mathbf{Clifford+T})^{\doteqdot}$ *is not an environment structure for* **Clifford+T**. *More precisely, there exists a state* ϕ *s.t.* $\phi \sim_{\text{cp}} \phi^*$ *but* $\phi \not\sim_{\text{iso}}^{+} \phi^*$. *One can take for example* $\phi = 1 + 2i$ *(in this case* ϕ *is a state with no input and outputs, hence a scalar).*

Note that for all categories above, we have $\sim_{\text{iso}}^{+}=\sim_{\text{iso}}$. That it holds in **Qubit** and **FHilb** is a consequence of the Witt extension theorem: Every isometry $f : A \to B$ is equal to a unitary $g : B \to B$ precomposed with a canonical embedding from A to B. It it well known in **Stab** and it is true in **Clifford** + **T** by [25, Lemma 5].

4 Application to the ZX-Calculus and other graphical languages

We now focus on the behavior of interpretation functors with respect to the discard construction. The discard construction defines a functor $(\_)^{\doteqdot} : \dagger\text{-}\mathbf{SMC} \to \mathbf{SMC}$. Indeed, given a †-SMC functor F, F_{iso} and $F_{\text{iso}}^{!}$ uniquely define a functor $F^{\doteqdot}$ by pushout.



The following lemma and theorem are the main tools to apply the discard construction to graphical languages:

▶ **Lemma 20.** *If F is faithful and if $F_{\text{iso}} : \mathbf{C}_{\text{iso}} \to \mathbf{D}_{\text{iso}}$ is surjective, then $F(f) \sim^+_{\text{iso}} F(g) \Rightarrow f \sim^+_{\text{iso}} g$.*

▶ **Theorem 21.** *Let $\mathbf{C}$ and $\mathbf{D}$ be two †-SMCs and $F : \mathbf{C} \to \mathbf{D}$ a †-SMC-functor. If F is faithful and if $F_{\text{iso}} : \mathbf{C}_{\text{iso}} \to \mathbf{D}_{\text{iso}}$ is surjective, then $F^{\doteq} : \mathbf{C}^{\doteq} \to \mathbf{D}^{\doteq}$ is faithful. If furthermore F is surjective then $F^{\doteq}$ is surjective and faithful.*

Notice that the hypothesis on F_{iso} is very strong, as it makes it an isomorphism: We want it to be surjective as we do not want to lose even one isometry. In particular we do not know if the theorem still applies if F is merely an equivalence of categories.

Reformulating for graphical languages this gives:

▶ **Corollary 22** (of Theorem 21)**.** *Given a †-CC $\mathbf{C}$ with enough isometries, if $\mathcal{G}$ is a †-CC universal complete graphical language for $\mathbf{C}$ then $\mathcal{G}^{\doteq}$ is a universal complete language for* CPM($\mathbf{C}$)*.*

This provides a general recipe. We start with a universal complete graphical language $\mathcal{G}$. We build $\mathcal{G}^{\doteq}$, by Theorem 21, $[\![.]\!]^{\doteq} : \mathcal{G}^{\doteq} \to \mathbf{C}^{\doteq}$ is full and faithful. Furthermore $\mathbf{C}^{\doteq} \simeq \text{CPM}(\mathbf{C})$. $\mathcal{G}^{\doteq}$ as a prop can be presented by adding one new generator $\frac{\perp}{=}$ to the signature Σ and one equation for each isometry of $\mathcal{G}$. In general, if one is provided with a spanning set of the isometries, the number of equations can be drastically reduced. We just need one equation for each element of this set. We then obtain a universal complete graphical language.

We will now briefly review the ZX-calculus and some of its twin languages. They are all universal and complete for subcategories of **Qubit**. Each time we will apply the recipe with a well chosen spanning set and provide the additional axioms involving $\frac{\perp}{=}$. We will not discuss minimality, i.e. if adding these new axioms can help to simplify others.

4.1 The ZX-calculus

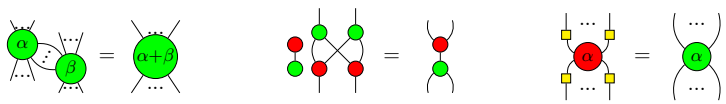
The ZX-Calculus was introduced in [11] by Coecke and Duncan for pure quantum evolutions. It is a †-compact prop generated by:

$R_Z^{(n,m)}(\alpha) : n \to m ::$  $\qquad R_X^{(n,m)}(\alpha) : n \to m ::$  $\qquad H : 1 \to 1 ::$

and the two compositions: spacial $(. \otimes .)$ and sequential $(. \circ .)$. The symmetric and compact structure are provided by $\sigma : 2 \to 2 ::$  , $\epsilon : 2 \to 0 ::$  and $\eta : 0 \to 2 ::$.

To simplify, the red and green nodes are represented empty when holding a 0 angle:

 $\qquad$ and $\qquad$ 
The language is universal [11]. So far, it has two complete axiomatisations [28, 33]. Some of the main axioms are:



ZX-diagrams represent quantum evolutions, so there exists a functor $[\![.]\!] : \mathrm{ZX} \to \mathbf{Qubit}$, called the *standard interpretation*, which associates to any diagram $D : n \to m$ a linear map $[\![D]\!] : \mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$ inductively defined as follows:

$[\![.]\!]$

$$[\![D_1 \otimes D_2]\!] := [\![D_1]\!] \otimes [\![D_2]\!] \qquad [\![D_2 \circ D_1]\!] := [\![D_2]\!] \circ [\![D_1]\!]$$

$$[\![\text{⊓}]\!] := (1) \qquad [\![\text{|}]\!] := \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \qquad [\![\text{⏚}]\!] := \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$

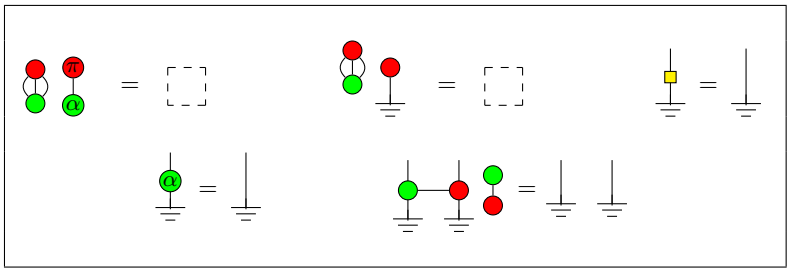
$$[\![\cup]\!] := (1 \ 0 \ 0 \ 1) \qquad [\![\times]\!] := \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \qquad [\![\cap]\!] := \begin{pmatrix} 1 \\ 0 \\ 0 \\ 1 \end{pmatrix}$$

$$[\![\alpha]\!] := (1 + e^{i\alpha}) \qquad \left[\!\!\left[\begin{smallmatrix} n \\ \alpha \\ m \end{smallmatrix} \right]\!\!\right] := 2^m \begin{pmatrix} \overbrace{\begin{matrix} 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 \end{matrix}}^{2^n} \\ \begin{matrix} \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & e^{i\alpha} \end{matrix} \end{pmatrix} \quad (n+m>0)$$

For any $n, m \geq 0$ and $\alpha \in \mathbb{R}$: $\left[\!\!\left[\begin{smallmatrix} n \\ \alpha \\ m \end{smallmatrix} \right]\!\!\right] = [\![\text{⏚}]\!]^{\otimes m} \circ \left[\!\!\left[\begin{smallmatrix} n \\ \alpha \\ m \end{smallmatrix} \right]\!\!\right] \circ [\![\text{⏚}]\!]^{\otimes n}$
$\big($where $M^{\otimes 0} = (1)$ and $M^{\otimes k} = M \otimes M^{\otimes k-1}$ for $k \in \mathbb{N}^*\big)$.

Theorem 21 provides a recipe for transforming the language for mixed states and CPMs. The resulting language $\mathrm{ZX}^{\doteq}$ can be seen as a prop with the generators of the ZX-Calculus, augmented with ⏚ and with the axiomatisation enriched with $\{⏚ \circ D = ⏚ \mid D^\dagger \circ D = I\}$. We actually do not need an infinite axiomatisation. Indeed, the set of isometries of the ZX-Calculus can be finitely generated.

Using ($e^{i\alpha}$, $|0\rangle$, H, $R_Z(\alpha)$, CNot) as spanning set of the isometries [38], we obtain only five axioms:



4.2 The $\frac{\pi}{2}$ fragment of ZX-calculus

The $\mathrm{ZX}_{\frac{\pi}{2}}$ is obtained from ZX by restricting phases α to $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$. It is universal and complete for **Stab** [3] with the adequate axiomatisation. Moreover according to Lemma 18 $\mathbf{Stab}^{\doteq}$ is an environment structure for **Stab**.

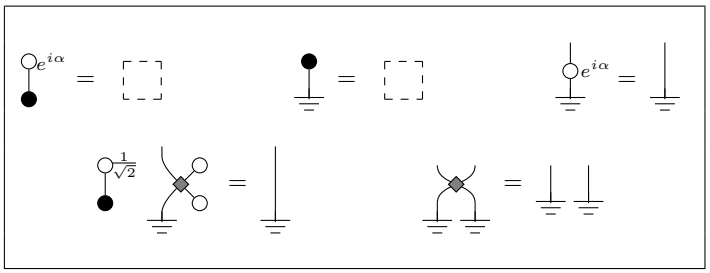
The set ($e^{i\frac{\pi}{4}}$, $|0\rangle$, H, $R_Z(\alpha)$, CNot), with α restricted to multiples of $\frac{\pi}{2}$, is a spanning set of isometries in **Stab** (notice that $e^{i\frac{\pi}{4}} = 2\langle 0|HSH|0\rangle\langle 0|H|0\rangle$ is in **Stab**), so adding the same set of equations than in $\mathrm{ZX}^{\doteq}$ with additional rule  will provide a complete axiomatisation for $\mathrm{ZX}^{\doteq}_{\frac{\pi}{2}}$.

4.3 The Clifford+T fragment of ZX-calculus

Restricting ZX to angles multiples of $\pi/4$, we obtain a language which is known to be universal and complete for **Clifford+T** [31]. However, as shown by Lemma 19, the semantic category **Clifford+T** does not have enough isometries. The discard construction is strictly coarser than CPM for this fragment. So we leave open the complete axiomatisation of quantum operations for this fragment.

4.4 The ZW-calculus

The ZW-Calculus was introduced in [26], deriving from the GHZ/W-Calculus [13], where the main two generators are two non-equivalent ways to entangle three qubits, the so-called GHZ and W states. The language was made complete for pure quantum mechanics in [28]. Since CNot is hard to express in this calculus, we choose another set of universal diagrams, more suited to ZW, namely ($e^{i\alpha}$, $|1\rangle$, $R_Z(\alpha)$, H, CZ $\circ$ SWAP). The resulting rules for $\mathrm{ZW}^{\doteq}$ are:



4.5 The ZH-Calculus

The ZH-Calculus was introduced and proved to be complete in [6]. The point of this language is to easily represent hypergraph-states, a generalisation of graph-states, a useful resource for quantum computing. This language has been specifically designed to easily represent the multi-controlled Z (which constitute the hyperedges in the hypergraph-states). So in particular, CZ and $R_Z(\alpha)$ are easily representable. Up to a scalar, H is also easily doable, and $[\![X^{(0,1)}]\!] = |0\rangle$. Hence, choosing ($e^{i\alpha}$, $|0\rangle$, H, $R_Z(\alpha)$, CZ) as spanning set, we only need the axioms:

Abstract

We investigate the locality number, a recently introduced structural parameter for strings (with applications in pattern matching with variables), and its connection to two important graph-parameters, cutwidth and pathwidth. These connections allow us to show that computing the locality number is NP-hard but fixed-parameter tractable (when the locality number or the alphabet size is treated as a parameter), and can be approximated with ratio $O(\sqrt{\log \mathsf{opt}} \log n)$. As a by-product, we also relate cutwidth via the locality number to pathwidth, which is of independent interest, since it improves the best currently known approximation algorithm for cutwidth. In addition to these main results, we also consider the possibility of greedy-based approximation algorithms for the locality number.

1 Introduction

Graphs, on the one hand, and strings, on the other, are two different types of data objects and they have certain particularities. Graphs seem to be more popular in fields like classical and parameterised algorithms and complexity (due to the fact that many natural graph problems are intractable), while fields like formal languages, pattern matching, verification or compression are more concerned with strings. Moreover, both the field of graph algorithms as well as string algorithms are well established and provide rich toolboxes of algorithmic techniques, but they differ in that the former is tailored to computationally hard problems (e.g., the approach of treewidth and related parameters), while the latter focuses on providing efficient data-structures for near-linear-time algorithms. Nevertheless, it is sometimes possible to bridge this divide, i.e., by "flattening" a graph into a sequential form, or by "inflating" a string into a graph, to make use of respective algorithmic techniques otherwise not applicable. This paradigm shift may provide the necessary leverage for new algorithmic approaches.

In this paper, we are concerned with certain structural parameters (and the problems of computing them) for graphs and strings: the *cutwidth* $\mathsf{cw}(G)$ of a graph G (i.e., the maximum number of "stacked" edges if the vertices of a graph are drawn on a straight line), the *pathwidth* $\mathsf{pw}(G)$ of a graph G (i.e., the minimum width of a tree decomposition the tree structure of which is a path), and the *locality number* $\mathsf{loc}(\alpha)$ of a string α (explained in more detail in the next paragraph). By Cutwidth, Pathwidth and Loc, we denote the corresponding decision problems and with the prefix Min, we refer to the minimisation variants. The two former graph-parameters are very classical. Pathwidth is a simple (yet still hard to compute) subvariant of treewidth, which measures how much a graph resembles a path. The problems Pathwidth and MinPathwidth are intensively studied (in terms of exact, parameterised and approximation algorithms) and have numerous applications (see the surveys and textbook [10, 34, 8]). Cutwidth is the best-known example of a whole class of so-called *graph layout problems* (see the survey [17, 39] for detailed information), which are studied since the 1970s and were originally motivated by questions of circuit layouts.

The locality number is rather new and we shall discuss it in more detail. A word is k-local if there exists an order of its symbols such that, if we *mark* the symbols in the respective order (which is called a *marking sequence*), at each stage there are at most k contiguous blocks of marked symbols in the word. This k is called the *marking number* of that marking sequence. The *locality number* of a word is the smallest k for which that word is k-local, or, in other words, the minimum marking number over all marking sequences. For example, the marking sequence $\sigma = (\mathtt{x}, \mathtt{y}, \mathtt{z})$ marks $\alpha = \mathtt{xyxyzxz}$ as follows (marked blocks are illustrated by overlines): $\mathtt{xyxyzxz}$, $\overline{\mathtt{x}}\mathtt{y}\overline{\mathtt{x}}\mathtt{yz}\overline{\mathtt{xz}}$, $\overline{\mathtt{xyxy}}\mathtt{z}\overline{\mathtt{xz}}$, $\overline{\mathtt{xyxyzxz}}$; thus, the marking number of σ is 3. In fact, all marking sequences for α have a marking number of 3, except $(\mathtt{y}, \mathtt{x}, \mathtt{z})$, for which it is 2: $\mathtt{x}\overline{\mathtt{y}}\mathtt{x}\overline{\mathtt{y}}\mathtt{zxz}$, $\overline{\mathtt{xyxy}}\mathtt{z}\overline{\mathtt{xz}}$, $\overline{\mathtt{xyxyzxz}}$. Thus, the locality number of α, denoted by $\mathsf{loc}(\alpha)$, is 2.

The locality number has applications in pattern matching with variables [14]. A *pattern* is a word that consists of *terminal symbols* (e.g., $\mathtt{a}, \mathtt{b}, \mathtt{c}$), treated as constants, and *variables* (e.g., $x_1, x_2, x_3, \ldots$). A pattern is mapped to a word by substituting the variables by strings of terminals. For example, $x_1x_1\mathtt{bab}x_2x_2$ can be mapped to $\mathtt{acacbabcc}$ by the substitution $(x_1 \to \mathtt{ac}, x_2 \to \mathtt{c})$. Deciding whether a given pattern matches (i.e., can be mapped to) a given word is one of the most important problems that arise in the study of patterns with variables (note that the concept of patterns with variables arises in several different domains like combinatorics on words (word equations [30], unavoidable patterns [36]), pattern matching [1], language theory [2], learning theory [2, 19, 38, 42, 31, 22], database theory [7], as well as in practice, e.g., extended regular expressions with backreferences [26, 27, 44, 28], used in

programming languages like Perl, Java, Python, etc.). Unfortunately, the *matching problem* is NP-complete [2] in general (it is also NP-complete for strongly restricted variants [23, 21] and also intractable in the parameterised setting [24]). As demonstrated in [43], for the matching problem a paradigm shift as sketched in the first paragraph above yields a very promising algorithmic approach. More precisely, any class of patterns with bounded treewidth (for suitable graph representations) can be matched in polynomial-time. However, computing (and therefore algorithmically exploiting) the treewidth of a pattern is difficult (see the discussion in [21, 43]), which motivates more direct string-parameters that bound the treewidth and are simple to compute (virtually all known structural parameters that lead to tractability [14, 21, 43, 45] are of this kind (the efficiently matchable classes investigated in [15] are one of the rare exceptions)). This also establishes an interesting connection between ad-hoc string parameters and the more general (and much better studied) graph parameter treewidth. The locality number is a simple parameter directly defined on strings, it bounds the treewidth and the corresponding marking sequences can be seen as instructions for a dynamic programming algorithm. However, compared to other "tractability-parameters", it seems to cover best the treewidth of a string, but whether it can be efficiently computed is unclear.

In this paper, we investigate the problem of computing the locality number and, by doing so, we establish an interesting connection to the graph parameters cutwidth and pathwidth with algorithmic implications for approximating cutwidth. In the following, we first discuss related results in more detail and then outline our respective contributions.

Known Results and Open Questions. For Loc, only exact exponential-time algorithms are known and whether it can be solved in polynomial-time, or whether it is at least fixed-parameter tractable is mentioned as open problems in [14]. Approximation algorithms have not yet been considered. Addressing these questions is the main purpose of this paper.

Pathwidth and Cutwidth are NP-complete, but fixed-parameter tractable with respect to parameter $\mathsf{pw}(G)$ or $\mathsf{cw}(G)$, respectively (even with "linear" fpt-time $g(k)\,\mathrm{O}(n)$ [9, 11, 47]). With respect to approximation, their minimisation variants have received a lot of attention, mainly because they yield (like many other graph parameters) general algorithmic approaches for numerous graph problems, i.e., a good linear arrangement or path-decomposition can often be used for a dynamic programming (or even divide and conquer) algorithm. More generally speaking, pathwidth and cutwidth are related to the more fundamental concepts of small balanced vertex or edge separators for graphs (i.e., a small set of vertices (or edges, respectively) that, if removed, divides the graph into two parts of roughly the same size. More precisely, $\mathsf{pw}(G)$ and $\mathsf{cw}(G)$ are upper bounds for the smallest balanced *vertex* separator of G and the smallest balanced *edge* separator of G, respectively (see [20] for further details and explanations of the algorithmic relevance of balanced separators). The best known approximation algorithms for MinPathwidth and MinCutwidth (with approximations ratios of $\mathrm{O}(\sqrt{\log(\mathsf{opt})}\log(n))$ and $\mathrm{O}(\log^2(n))$, respectively) follow from approximations of vertex separators (see [20]) and edge separators (see [35]), respectively.

Our Contributions. There are two natural approaches to represent a word α over alphabet Σ as a graph $G_\alpha = (V_\alpha, E_\alpha)$: (1) $V_\alpha = \{1, 2, \ldots, |\alpha|\}$ and the edges are somehow used to represent the actual symbols, or (2) $V_\alpha = \Sigma$ and the edges are somehow used to represent the positions of α. We present a reduction of type (2) such that $|E_\alpha| = \mathrm{O}(|\alpha|)$ and $\mathsf{cw}(G_\alpha) = 2\,\mathsf{loc}(\alpha)$, and a reduction of type (1) such that $|E_\alpha| = \mathrm{O}(|\alpha|^2)$ and $\mathsf{loc}(\alpha) \leq \mathsf{pw}(G_\alpha) \leq 2\,\mathsf{loc}(\alpha)$. Since these reductions are parameterised reductions and also allow transferring approximation

results, we conclude that Loc is fixed-parameter tractable if parameterised by $|\Sigma|$ or by the locality number (answering the respective open problem from [14]), and also that there is a polynomial-time $O(\sqrt{\log(\mathsf{opt})}\log(n))$-approximation algorithm for MinLoc.

In addition, we also show a way to represent an arbitrary multi-graph $G = (V, E)$ by a word α_G over alphabet V, of length $|E|$ and with $\mathsf{cw}(G) = \mathsf{loc}(\alpha)$. This describes a Turing-reduction from Cutwidth to Loc which also allows to transfer approximation results between the minimisation variants. As a result, we can conclude that Loc is NP-complete (which solves the other open problem from [14]). Finally, by plugging together the reductions from MinCutwidth to MinLoc and from MinLoc to MinPathwidth, we obtain a reduction which transfers approximation results from MinPathwidth to MinCutwidth, which yields an $O(\sqrt{\log(\mathsf{opt})}\log(n))$-approximation algorithm for MinCutwidth. This improves, to our knowledge for the first time since 1999, the best approximation for Cutwidth from [35].

To our knowledge, this connection between cutwidth and pathwidth has not yet been reported in the literature so far. This is rather surprising since Cutwidth and Pathwidth have been jointly investigated in the context of exact and approximation algorithms, especially in terms of balanced vertex and edge separators. More precisely, the approximation of pathwidth and cutwidth follows from the approximation of vertex and edge separators, respectively, and the approximation of vertex separators usually relies on edge separators: the edge separator approximation from [35] can be used as a black-box for vertex separator approximation, and the best vertex separator algorithm from [20] uses a technique for computing edge separators from [4] as component. Our improvement, on the other hand, is achieved by going in the opposite direction: we use pathwidth approximation (following from [20]) in order to improve the currently best cutwidth approximation (from [35]). This might be why the reduction from cutwidth to pathwidth has been overlooked in the literature. Another reason might be that this relation is less obvious on the graph level and becomes more apparent if linked via the string parameter of locality, as in our considerations. Nevertheless, since pathwidth and cutwidth are such crucial parameters for graph algorithms, we also translate our locality based reduction into one from graphs to graphs directly.

2 Preliminaries

Basic Definitions. The set of strings (or words) over an alphabet X is denoted by X^*, by $|\alpha|$ we denote the length of a word α, $\mathsf{alph}(\alpha)$ is the smallest alphabet X with $\alpha \in X^*$. A string β is called a *factor* of α if $\alpha = \alpha'\beta\alpha''$; if $\alpha' = \varepsilon$ or $\alpha'' = \varepsilon$, where ε is the empty string, β is a *prefix* or a *suffix*, respectively. For a position j, $1 \leq j \leq |\alpha|$, we refer to the symbol at position j of α by the expression $\alpha[j]$, and $\alpha[j..j'] = \alpha[j]\alpha[j+1]\dots\alpha[j']$, $1 \leq j \leq j' \leq |\alpha|$. For a word α and $x \in \mathsf{alph}(\alpha)$, let $\mathsf{ps}_x(\alpha) = \{i \mid 1 \leq i \leq |\alpha|, \alpha[i] = x\}$ be the set of all positions where x occurs in α. For a word α, let $\alpha^0 = \varepsilon$ and $\alpha^{i+1} = \alpha\alpha^i$ for $i \geq 0$.

Let α be a word and let $X = \mathsf{alph}(\alpha) = \{x_1, x_2, \dots, x_n\}$. A *marking sequence* is an enumeration, or ordering on the letters, and hence may be represented either as an ordered list of the letters or, equivalently, as a bijection $\sigma : \{1, 2, \dots, |X|\} \to X$. Given a word α and a marking sequence σ, the *marking number* $\pi_\sigma(\alpha)$ (of σ with respect to α) is the maximum number of marked blocks obtained while marking α according to σ. We say that α is k-local if and only if, for some marking sequence σ, we have $\pi_\sigma(\alpha) \leq k$, and the smallest k such that α is k-local is the *locality number* of α, denoted by $\mathsf{loc}(\alpha)$. A marking sequence σ with $\pi_\sigma(\alpha) = \mathsf{loc}(\alpha)$ is *optimal* (for α). For a marking sequence $\sigma = (x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(m)})$ and a word α, by *stage i of σ* we denote the word α with exactly positions $\bigcup_{j=1}^{i} \mathsf{ps}_{x_{\sigma(j)}}(\alpha)$ marked.

For a word α, the *condensed form of α*, denoted by $\mathsf{cond}(\alpha)$, is obtained by replacing every maximal factor x^k with $x \in \mathsf{alph}(\alpha)$ by x. For example, $\mathsf{cond}(x_1x_1x_2x_2x_2x_1x_2x_2) = x_1x_2x_1x_2$. A word α is *condensed* if $\alpha = \mathsf{cond}(\alpha)$.

▶ Remark 1. For a word α, we have $\mathsf{loc}(\mathsf{cond}(\alpha)) = \mathsf{loc}(\alpha)$ [14]. Hence, by computing $\mathsf{cond}(\alpha)$ in time $O(|\alpha|)$, algorithms for computing the locality number (and the respective marking sequences) for *condensed* words extend to algorithms for general words.

Examples and Word Combinatorial Considerations. The structure of 1-local and 2-local words is characterised in [14]. The simplest 1-local words are repetitions x^k for some $k \geq 0$. Furthermore, if α is 1-local, then $y^\ell \alpha y^r$ is 1-local, where $y \notin \mathsf{alph}(\alpha), \ell, r \geq 0$. Marking sequences for 1-local words can be obtained by going from the "inner-most" letters to the "outer-most" ones. The English words *radar*, *refer*, *blender*, and *rotator* are all 1-local.

Generally, in order to have a high locality number, a word needs to contain many alternating occurrences of (at least) two letters. For instance, $(x_1x_2)^n$ is n-local. In general, one can show that if $\mathsf{loc}(w) = k$, then $\mathsf{loc}(w^i) \in \{ik - i + 1, ik\}$.

The well-known *Zimin words* [36] also have high locality numbers compared to their lengths. These words are important in the domain of avoidability, as it was shown that a terminal-free pattern is unavoidable (i.e., it occurs in every infinite word over a large enough finite alphabet) if and only if it occurs in a Zimin word. The Zimin words Z_i, for $i \in \mathbb{N}$, are inductively defined by $Z_1 = x_1$ and $Z_{i+1} = Z_i x_{i+1} Z_i$. Clearly, $|Z_i| = 2^i - 1$ for all $i \in \mathbb{N}$. Regarding the locality of Z_i, note that marking x_2 leads to 2^{i-2} marked blocks; further, marking x_1 first and then the remaining symbols in an arbitrary order only extends or joins marked blocks. Thus, we obtain a sequence with marking number 2^{i-2}. In fact, it can be shown that $\mathsf{loc}(Z_i) = \frac{|Z_i|+1}{4} = 2^{i-2}$ for $i \in \mathbb{N}_{\geq 2}$. Notice that both Zimin words and 1-local words have an obvious palindromic structure. However, in the Zimin words, the letters occur multiple times, but not in large blocks, while in 1-local words there are at most 2 blocks of each letter. One can show that if w is a palindrome, with $w = uau^R$ or $w = uu^R$, and $\mathsf{loc}(u) = k$, then $\mathsf{loc}(w) \in \{2k - 1, 2k, 2k + 1\}$ (u^R denotes the reversal of u).

The number of occurrences of a letter alone is not always a good indicator of the locality of a word. The German word *Einzelelement* (a basic component of a construction) has 5 occurrences of e, but is only 3-local, as witnessed by marking sequence (*l,m,e,i,n,z,t*). Nevertheless, a repetitive structure often leads to high locality. The Finnish word *tutustuttu* (perfect passive of *tutustua* – to meet) is nearly a repetition and 4-local, while *pneumonoultramicroscopicsilicovolcanoconiosis* is an (English) 8-local word, and *lentokonesuihkuturbiinimoottoriapumekaanikkoaliupseerioppilas* is a 10-local (Finnish) word.

Complexity and Approximation. We briefly summarise the fundamentals of parameterised complexity [25, 18] and approximation [5].

A *parameterised problem* is a decision problem with instances (x, k), where x is the actual input and $k \in \mathbb{N}$ is the *parameter*. A parameterised problem P is *fixed-parameter tractable* if there is an *fpt-algorithm* for it, i.e., one that solves P on input (x, k) in time $f(k) \cdot p(|x|)$ for a recursive function f and a polynomial p. We use the $O^*(\cdot)$ notation which hides multiplicative factors polynomial in $|x|$.

A minimisation problem P is a triple (I, S, m), where I is the *set of instances*, S is a function that maps instances $x \in I$ to the *set of feasible solutions* for x, and m is the *objective function* that maps pairs (x, y) with $x \in I$ and $y \in S(x)$ to a positive rational number. For every $x \in I$, we denote $m^*(x) = \min\{m(x, y) \colon y \in S(x)\}$. For $x \in I$ and $y \in S(x)$, the value $R(x, y) = \frac{m(x,y)}{m^*(x)}$ is the *performance ratio* of y with respect to x. An algorithm $\mathcal{A}$ is an *approximation algorithm* for P with ratio $r : \mathbb{N} \to \mathbb{Q}$ (or an r-approximation algorithm, for short) if, for every $x \in I$, $\mathcal{A}(x) = y \in S(x)$, and $R(x, y) \leq r(|x|)$. We also let r be of the form $\mathbb{Q} \times \mathbb{N} \to \mathbb{Q}$ when the ratio r depends on $m^*(x)$ and $|x|$; in this case, we write $r(\mathsf{opt}, |x|)$. We further assume that the function r is monotonically non-decreasing. Unless stated otherwise, all approximation algorithms run in polynomial time with respect to $|x|$.

Pathwidth, Cutwidth and Problem Definitions. Let $G = (V, E)$ be a (multi)graph with the vertices $V = \{v_1, \ldots, v_n\}$. A *cut* of G is a partition (V_1, V_2) of V into two disjoint subsets V_1, V_2, $V_1 \cup V_2 = V$; the (multi)set of edges $\mathcal{C}(V_1, V_2) = \{\{x, y\} \in E \mid x \in V_1, y \in V_2\}$ is called the cut-set or the (multi)set of edges crossing the cut, while V_1 and V_2 are called the sides of the cut. The *size* of this cut is the number of crossing edges, i.e., $|\mathcal{C}(V_1, V_2)|$. A *linear arrangement* of the (multi)graph G is a sequence $(v_{j_1}, v_{j_2}, \ldots, v_{j_n})$, where $(j_1, j_2, \ldots, j_n)$ is a permutation of $(1, 2, \ldots, n)$. For a linear arrangement $L = (v_{j_1}, v_{j_2}, \ldots, v_{j_n})$, let $L(i) = \{v_{j_1}, v_{j_2}, \ldots, v_{j_i}\}$. For every i, $1 \leq i < n$, we consider the cut $(L(i), V \setminus L(i))$ of G, and denote the cut-set $\mathcal{C}_L(i) = \mathcal{C}(L(i), V \setminus L(i))$ (for technical reasons, we also set $\mathcal{C}_L(0) = \mathcal{C}_L(n) = \emptyset$). We define the *cutwidth* of L by $\mathsf{cw}(L) = \max\{|\mathcal{C}_L(i)| \mid 0 \leq i \leq n\}$. Finally, the cutwidth of G is the minimum over all cutwidths of linear arrangements of G, i.e., $\mathsf{cw}(G) = \min\{\mathsf{cw}(L) \mid L \text{ is a linear arrangement for } G\}$.

A path decomposition (see [11]) of a connected graph $G = (V, E)$ is a tree decomposition whose underlying tree is a path, i.e., a sequence $Q = (B_0, B_1, \ldots, B_m)$ (of *bags*) with $B_i \subseteq V$, $0 \leq i \leq m$, satisfying the following two properties:

- *Cover property*: for every $\{u, v\} \in E$, there is an index i, $0 \leq i \leq m$, with $\{u, v\} \subseteq B_i$.
- *Connectivity property*: for every $v \in V$, there exist indices i_v and j_v, $0 \leq i_v \leq j_v \leq m$, such that $\{j \mid v \in B_j\} = \{i \mid i_v \leq i \leq j_v\}$. In other words, the bags that contain v occur on consecutive positions in $(B_0, \ldots, B_m)$.

The *width* of a path decomposition Q is $\mathsf{w}(Q) = \max\{|B_i| \mid 0 \leq i \leq m\} - 1$, and the *pathwidth* of a graph G is $\mathsf{pw}(G) = \min\{\mathsf{w}(Q) \mid Q \text{ is a path decomposition of } G\}$. A path decomposition is *nice* if $B_0 = B_m = \emptyset$ and, for every i, $1 \leq i \leq m$, either $B_i = B_{i-1} \cup \{v\}$ or $B_i = B_{i-1} \setminus \{v\}$, for some $v \in V$.

It is convenient to treat a path decomposition Q as a scheme marking the vertices of the graph based on the order in which the bags occur in the bag sequence. More precisely, all vertices are initially marked as `open`. Then we process the bags one by one, as they occur in Q. When we process the first bag that contains a vertex v, then v becomes `active`. When we process the last bag that contains v, it becomes `closed`. The connectivity property enforces that vertices that are `closed` cannot be marked as `active` again, while the cover property enforces that adjacent vertices must be both `active` at some point. The width is the maximum number of vertices which are marked `active` at the same time minus one. If the path decomposition is nice, then whenever a bag is processed as described above, we change the marking of exactly one vertex.

We next formally define the computational problems of computing the parameters defined above. By Loc, Cutwidth and Pathwidth, we denote the problems to check for a given word α or graph G and integer $k \in \mathbb{N}$, whether $\mathsf{loc}(\alpha) \leq k$, $\mathsf{cw}(G) \leq k$, and $\mathsf{pw}(G) \leq k$, respectively. Note that since we can assume that $k \leq |\alpha|$ and $k \leq |G|$, whether k is given in binary or unary has no impact on the complexity. With the prefix Min, we refer to the minimisation variants. More precisely, MinLoc $= (I, S, m)$, where I is the set of words, $S(\alpha)$ is the set of all marking sequences for α and $m(\alpha, \sigma) = \pi_\sigma(\alpha)$ (note that $m^*(\alpha) = \mathsf{loc}(\alpha)$); MinCutwidth $= (I, S, m)$, where I are all multigraphs, $S(G)$ is the set of linear arrangements of G, and $m(G, L) = \mathsf{cw}(L)$ (note that $m^*(G) = \mathsf{cw}(G)$); finally, MinPathwidth $= (I, S, m)$, where I are all graphs, $S(G)$ is the set of path decompositions of G, and $m(G, Q) = \mathsf{w}(Q)$ (note that $m^*(G) = \mathsf{pw}(G)$).

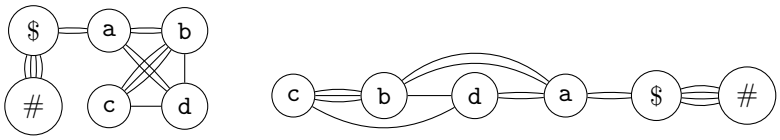

Figure 1 The graph $H_{\alpha,k}$ for $\alpha = \mathtt{abcbcdbada}$ and $k = 2$; an optimal linear arrangement of $H_{\alpha,k}$ with cutwidth 4 induces the optimal marking sequence $(\mathtt{c}, \mathtt{b}, \mathtt{d}, \mathtt{a})$ for α with marking number 2.

3 Locality and Cutwidth

In this section, we introduce polynomial-time reductions from Loc to Cutwidth and vice versa. The established close relationship between these two problems lets us derive several complexity-theoretic and algorithmic results for Loc. We also discuss approximation-preserving properties of our reductions.

First, we show a reduction from Loc to Cutwidth. For a word α and an integer $k \in \mathbb{N}$, we build a multigraph $H_{\alpha,k} = (V, E)$ whose set of nodes $V = \mathsf{alph}(\alpha) \cup \{\$, \#\}$ consists of symbols occurring in α and two additional characters $\$, \# \notin \mathsf{alph}(\alpha)$. The multiset of edges E contains an edge between nodes $x, y \in \mathsf{alph}(\alpha)$ for each occurrence of the factors xy and yx in α, as well as $2k$ edges between \$ and #, one edge between \$ and the first letter of α, and one edge between \$ and the last letter of α. An example is given in Figure 1.

▶ **Lemma 2.** *The graph $H_{\alpha,k}$ satisfies $\mathsf{cw}(H_{\alpha,k}) = 2k$ if and only if $\mathsf{loc}(\alpha) \leq k$.*

Proof. Suppose firstly that α is k-local, and let $\sigma = (x_1, x_2, \ldots, x_n)$ be an optimal marking sequence of α. Consider the linear arrangement $L = (x_1, x_2, \ldots, x_n, \$, \#)$. Clearly, $|\mathcal{C}(\{x_1, x_2, \ldots, x_n, \$\}, \{\#\})| = 2k$ and $|\mathcal{C}(\{x_1, x_2, \ldots, x_n\}, \{\$, \#\})| = 2$. Now consider a cut $(K_1, K_2) = (\{x_1, x_2, \ldots, x_i\}, \{x_{i+1}, \ldots, x_n, \$, \#\})$ for $1 \leq i < n$. Every edge $e \in \mathcal{C}(K_1, K_2)$ is of the form $\{x_j, x_h\}$ with $j \leq i < h$, or of the form $\{\alpha[1], \$\}$ or $\{\$, \alpha[|\alpha|]\}$. Consequently, every edge $e \in \mathcal{C}(K_1, K_2)$ corresponds to a unique factor $x_j x_h$ or $x_h x_j$ of α with $j \leq i < h$ and, after exactly the symbols $x_1, x_2, \ldots, x_i$ are marked, x_j is marked and x_h is not, or to a unique factor $\alpha[1]$ or $\alpha[|\alpha|]$ and, after exactly the symbols $x_1, x_2, \ldots, x_i$ are marked, $\alpha[1]$ or $\alpha[|\alpha|]$ is marked. Since there can be at most k marked blocks in α after marking the symbols $x_1, \ldots, x_i$, there are at most $2k$ such factors, which means that $|\mathcal{C}(K_1, K_2)| \leq 2k$. Thus $\mathsf{cw}(H_{\alpha,k}) \leq 2k$. Note that any linear arrangement must at some point separate the nodes \$ and #, meaning $\mathsf{cw}(H_{\alpha,k}) \geq 2k$, so we get that $\mathsf{cw}(H_{\alpha,k}) = 2k$.

Now suppose that the cutwidth of $H_{\alpha,k}$ is $2k$ and let L be an optimal linear arrangement witnessing this fact. Firstly, we note that L must either start with # followed by \$ (i.e., have the form $(\#, \$, \ldots)$) or end with # preceded by \$ (i.e., have the form $(\ldots, \$, \#)$. Otherwise, since $H_{\alpha,k}$ is connected, every cut separating \$ and # would be of size strictly greater than $2k$. Because a linear ordering and its mirror image have the same cutwidth, we may assume that the optimal linear arrangement has the form $L = (x_{\tau(1)}, x_{\tau(2)}, \ldots, x_{\tau(n)}, \$, \#)$ for some permutation τ of $\{1, \ldots, n\}$. Let σ be the marking sequence $(x_{\tau(1)}, x_{\tau(2)}, \ldots, x_{\tau(n)})$ of α induced by τ. Suppose, for contradiction, that for some i, with $1 \leq i < n$, after marking $x_{\tau(1)}, \ldots, x_{\tau(i)}$, we have $k' > k$ marked blocks. Furthermore, let $K_1 = \{x_{\tau(1)}, \ldots, x_{\tau(i)}\}$ and $K_2 = \{x_{\tau(i+1)}, \ldots, x_{\tau(n)}, \$, \#\}$. For every marked block $\alpha[s..t]$ that is not a prefix or a suffix of α, we have $\alpha[s], \alpha[t] \in K_1$ and $\alpha[s-1], \alpha[t+1] \in K_2$ and therefore $\{\alpha[s-1], \alpha[s]\}, \{\alpha[t], \alpha[t+1]\} \in \mathcal{C}(K_1, K_2)$. Moreover, for a marked prefix $\alpha[1..s]$, we have $\alpha[1], \alpha[s] \in K_1$ and $\$, \alpha[s+1] \in K_2$ and therefore $\{\alpha[1], \$\}, \{\alpha[s], \alpha[s+1]\} \in \mathcal{C}(K_1, K_2)$. Analogously, the existence of a marked suffix $\alpha[t..|\alpha|]$

leads to $\{\alpha[|\alpha|], \$\}, \{\alpha[t-1], \alpha[t]\} \in \mathcal{C}(K_1, K_2)$. Consequently, for each marked block, we have two unique edges in $\mathcal{C}(K_1, K_2)$, which implies $|\mathcal{C}(K_1, K_2)| \geq 2k' > 2k$. This contradicts the assumption that L is a witness that $H_{\alpha,k}$ has cutwidth $2k$. Thus, α must be k-local. ◀

In the following, we briefly discuss the complexity of this reduction. Suppose we are given a word α and an integer $k \leq |\alpha|$. It is usual in string algorithmics to assume that α is over an integer alphabet, i.e., $\mathsf{alph}(\alpha) \subseteq \{1, \ldots, |\alpha|\}$. In this framework, the multigraph $H_{\alpha,k}$ can be constructed in $\mathrm{O}(|\alpha|)$ time (e.g., represented as a list of vertices and a list of edges).

▶ **Lemma 3.** *If there is an $r(\mathsf{opt}, h)$-approximation algorithm for* MinCutwidth *running in $\mathrm{O}(f(h))$ time for an input multigraph with h edges, then there is an $(r(2\,\mathsf{opt}, |\alpha|) + \frac{1}{\mathsf{opt}})$-approximation algorithm for* MinLoc *running in $\mathrm{O}(f(|\alpha|) + |\alpha|)$ time on an input word α.*

Proof. As already indicated in the proof of Lemma 2, for $k = \mathsf{loc}(\alpha)$, every linear arrangement for $H_{\alpha,k}$ naturally translates to a marking sequence for α. However, in an approximate linear arrangement, the vertices # and \$ do not have to be at the first (or last) position. Still, the marking sequence corresponding to the linear arrangement L can have not more than $\frac{\mathsf{cw}(L)}{2}+1$ blocks, since only suffix and prefix can be marked blocks which correspond to only one instead of two edges in a cut in $H_{\alpha,k}$. This observation remains valid if we do not include the extra vertices # and \$ in $H_{\alpha,k}$ in the reduction. Let H_α be the graph obtained from $H_{\alpha,k}$ (for some k) by removing the extra vertices # and \$ (observe that this also removes the dependence on k). Removing vertices only decreases the cutwidth, so Lemma 2 implies that $\mathsf{cw}(H_\alpha) \leq 2m^*(\alpha)$. Let α be an instance of MinLoc and $\mathcal{A}$ an $r(\mathsf{opt}, h)$-approximation for MinCutwidth on multigraphs. The approximation algorithm $\mathcal{A}$ run on H_α returns a linear arrangement $L = \mathcal{A}(H_\alpha)$ with $\mathsf{cw}(L) \leq r(\mathsf{opt}, h)\,\mathsf{cw}(H_\alpha)$. Let σ be the marking sequence corresponding to L, then $R(\alpha, \sigma) = \frac{\pi_\sigma(\alpha)}{m^*(\alpha)} \leq \frac{2}{\mathsf{cw}(H_\alpha)}(\frac{\mathsf{cw}(L)}{2}+1) = \frac{\mathsf{cw}(L)}{\mathsf{cw}(H_\alpha)} + \frac{1}{m^*(\alpha)} = R(H_\alpha, L) + \frac{1}{m^*(\alpha)}$. The performance ratio $R(H_\alpha, L)$ is at most $r(\mathsf{opt}, h)$, where $h = |\alpha|$ is the number of edges in H_α. For the optimum value $k = m^*(\alpha)$, the cutwidth of $H_{\alpha,k}$ is at least $2k-2$ and σ has performance ratio at most $r(2\,\mathsf{opt}, |\alpha|)$ (with respect to the optimum value k for MinLoc). The approximation procedure builds the graph H_α in $\mathrm{O}(|\Sigma|)$, runs $\mathcal{A}$ on H_α in $\mathrm{O}(f(|\alpha|))$ and translates the linear arrangement into a marking sequence σ in $\mathrm{O}(|\Sigma|)$. This gives an $(r(2\,\mathsf{opt}, |\alpha|) + \frac{1}{\mathsf{opt}})$-approximation for MinLoc running time in $\mathrm{O}(f(|\alpha|) + |\alpha|)$ time. ◀

For a reduction from Cutwidth to Loc, let $H = (V, E)$ be a connected multigraph, where V is the set of nodes and E the multiset of edges (for technical reasons, we assume $|V| \geq 2$). Let $H' = (V, E')$ be the multigraph obtained by duplicating every edge in H. As such, each node in H' has even degree, so there exists an Eulerian cycle C (i.e., a cycle visiting each edge exactly once) in H', and, moreover, $\mathsf{cw}(H') = 2\,\mathsf{cw}(H)$. For each edge $e \in E'$, let α_e be the word over V that corresponds to an arbitrary traversal of the Eulerian path P obtained from C by deleting e; see Figure 2 for an example.

▶ **Lemma 4.** *For any edge e in E', the word α_e satisfies $\mathsf{cw}(H) \leq \mathsf{loc}(\alpha_e) \leq \mathsf{cw}(H)+1$. Moreover, there is a vertex $v \in V$ such that $\mathsf{loc}(\alpha_e) = \mathsf{cw}(H)$ for every edge e incident to v.*

Consequences. In the following, we overview a series of complexity-theoretic and algorithmic consequences of the reductions provided above. We first discuss negative results and note that we can close one of the main problems left open in [14].

▶ **Theorem 5.** *The* Loc *problem is NP-complete.*

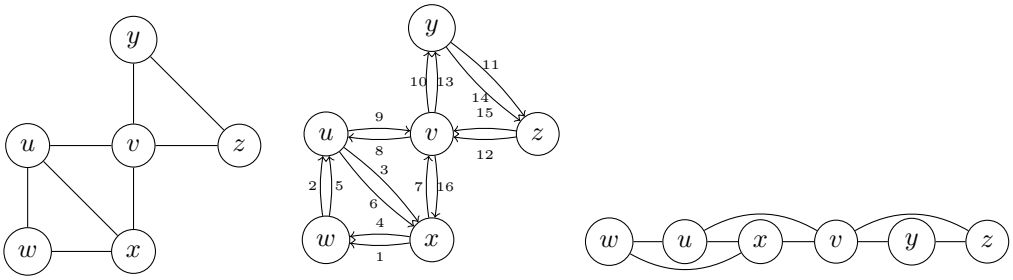

Figure 2 A graph H and its multigraph H' obtained by doubling the edges; the edge labels describe a Eulerian cycle that starts and ends in x. Deleting the edge (v, x) in this cycle yields the word $\alpha_{(v,x)} = xwuxwuxvuvyzvyzv$, which has an optimal marking sequence (w, u, x, v, y, z) with marking number 3, and, thus, induces an optimal linear arrangement of H with cutwidth 3.

Theorem 5 follows from the Turing reduction from CUTWIDTH to LOC, but it can also be proved using a polynomial-time one-to-many reduction from the well known NP-complete problem CLIQUE. This alternative approach is more technically involved but has the merit of emphasising how the combinatorial properties of the locality number can be used to construct computationally hard instances of LOC. Moreover, by the word-combinatorial observations about locality made in Section 2, it is clear that LOC is NP-complete also for words with special structure, e.g., palindromes and repetitions.

With respect to approximation, it is known that, assuming the Small Set Expansion Conjecture (denoted SSE; see [40]), there exists no constant-ratio approximation for MINCUTWIDTH (see [48]). Consequently, approximating MINLOC within any constant factor is also SSE-hard. In particular, we point out that stronger inapproximability results for MINCUTWIDTH are not known. Positive approximation results for MINLOC will be discussed in Section 4.

On certain graph classes, the SSE conjecture is equivalent to the Unique Games Conjecture [32] (see [40, 41]), which, at its turn, was used to show that many approximation algorithms are tight [33] and is considered a major conjecture in inapproximability. However, some works seem to provide evidence that could lead to a refutation of SSE; see [3, 6, 29]. In this context, we show in Section 4 a series of unconditional results which state that multiple natural greedy strategies do not provide low-ratio approximations of MINLOC.

As formally stated next, Lemma 2 extends algorithmic results for computing cutwidth to determining the locality number (we formulate this result so that it also covers fpt-algorithms with respect to the standard parameters $\mathsf{cw}(G)$ and $\mathsf{loc}(\alpha)$). Note that the maximum degree in a multigraph G is bounded from above by $2\,\mathsf{cw}(G)$, so the number of nodes n and the number of edges h satisfy $h \leq n \cdot \mathsf{cw}(G)$. Hence, we state the complexity in terms of n and $\mathsf{cw}(G)$ rather than with respect to h, which is the actual input size.

▶ **Lemma 6.** *If* MINCUTWIDTH *(resp.* CUTWIDTH*) can be solved in* $\mathrm{O}(f(\mathsf{cw}(G), n))$ *time for a multigraph* G *with* n *vertices, then the* MINLOC *(resp.,* LOC*) problem can be solved in* $\mathrm{O}(f(2\,\mathsf{loc}(\alpha), |\Sigma| + 2) + |\alpha|)$ *time for a word* α *over an alphabet* Σ*.*

In particular, we can draw the following corollaries using Lemma 6 and known results from the literature. Due to the algorithms of [12], which also work for multigraphs[1], MINLOC can be solved in $\mathrm{O}^*(2^{|\Sigma|})$ time and space, or in $\mathrm{O}^*(4^{|\Sigma|})$ time and polynomial space. In

[1] These algorithms actually support weighted graphs without any major modification and in the same complexity. In this setting, parallel edges connecting two vertices are replaced by a single "super-edge" whose weight is the number of parallel edges.

particular, this also implies that Loc is fixed-parameter tractable with respect to the alphabet size. Moreover, the fpt-algorithm from [47] directly implies that MinLoc is fixed-parameter tractable for parameter $\mathsf{loc}(\alpha)$ with linear fpt-running-time $g(\mathsf{loc}(\alpha))\,\mathrm{O}(n)$. Since Cutwidth is NP-complete already for graphs with maximum degree 3 (see [37]), we also derive a stronger statement compared to Theorem 5: Loc is NP-complete even if every symbol has at most 3 occurrences; if every symbol has at most 2 occurrences, the complexity of Loc is open, while the case where every symbol has only one occurrence is trivial. If, on the other hand, the symbols have many occurrences in comparison to $|\alpha|$, i.e., $|\Sigma| = \mathrm{O}(\log(|\alpha|))$, then Loc can be solved in polynomial time, e.g., using the $\mathrm{O}^*(2^{|\Sigma|})$-time algorithm mentioned above.

4 Locality and Pathwidth

In this section, we consider the approximability of the minimisation problem MinLoc. Since a marking sequence is just a linear arrangement of the symbols of the input word, this problem seems to be well tailored to greedy algorithms: until all symbols are marked, we choose an unmarked symbol according to some greedy strategy and mark it. There are two aspects that motivate the investigation of such approaches. Firstly, ruling out simple strategies is a natural initial step in the search for approximation algorithms for a new problem. Secondly, due to the results of Section 3, the obvious greedy approaches for computing the locality number may also provide a new angle to approximating the cutwidth of a graph, i.e., some greedy strategies may only become apparent in the locality number point of view and hard to see in the graph formulation of the problem. Given the fact that, as formally stated later as Theorem 10, approximating the cutwidth via approximation of the locality number does, in fact, improve the best currently known cutwidth approximation ratio, this seems to be a rather important aspect.

Unfortunately, we can formally show that many natural candidates for greedy strategies fail to yield promising approximation algorithms (and are therefore also not helpful for cutwidth approximation). We just briefly mention these negative results. The four considered basic strategies are the following: (1) prefer symbols with few occurrences, (2) symbols with many occurrences, (3) symbols leading to fewer blocks after marking, (4) symbols with earlier leftmost occurrence. All these strategies fail in a sense that there are arbitrarily long (condensed) words α with constant locality numbers for which these strategies yield marking sequences with marking numbers $\Omega(|\alpha|)$.

A more promising approach is to choose among symbols that extend at least one already marked block (except when marking the first symbol). We denote this strategy by BlockExt and marking sequences that can be obtained by it are called BlockExt-marking sequences. Intuitively, marking a symbol that has only isolated occurrences, and therefore will increase the current number of marked blocks by the number of its occurrences, seems a bad choice. This raises a general question of whether every word has a BlockExt-marking sequence that is also optimal for this word. We answer this question negatively: all BlockExt-marking sequences for words like $x_1yx_2yx_3y\dots x_{2k}y$ achieve a marking number of at least $2k-1$, while first marking $x_2, x_3, \dots, x_{k+1}$ in this order (which all have only isolated occurrences), then y, and then the rest of the symbols in some order, yields at most k marked blocks. However, this only shows a lower bound of roughly 2 for the approximation ratio of algorithms based on BlockExt, so BlockExt might still be a promising candidate. However, in order to devise a BlockExt-based approximation algorithm, we still face the problem of deciding which of the extending symbols should be chosen; trying out all of them is obviously too costly. Unfortunately, if we handle this decision by one of the basic strategies (1)–(4) from above,

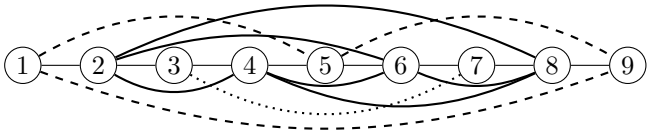

Figure 3 The graph G_α for $\alpha = \texttt{cabacabac}$; the three cliques are drawn with different edge-types.

e.g., choosing among all extending symbols one that leads to fewer new blocks, we again end up with poor approximation ratios. More precisely, we can again find arbitrarily long words α with constant locality numbers for which these algorithms yield marking numbers $\Omega(|\alpha|)$. Moreover, this is also true if we choose among all extending symbols one that has a maximum number of extending occurrences or one that maximises the ratio $\frac{\#\text{extending occ.}}{\#\text{occ.}}$.

While we obviously have not investigated *all* reasonable greedy strategies, we consider our negative results as sufficient evidence that a worthwhile approximation algorithm for computing the locality number most likely does not follow from such simple greedy strategies.

In the following, we adopt a more sophisticated approach of approximating the locality number: we devise a reduction to the problem of computing the pathwidth of a graph. To this end, we first have to describe how a (condensed) word can be represented as a graph: For a condensed word α, the graph $G_\alpha = (V_\alpha, E_\alpha)$ is defined by $V_\alpha = \{1, 2, \ldots, |\alpha|\}$ and $E_\alpha = \{\{i, i+1\} \mid 1 \leq i \leq |\alpha|-1\} \cup \{\{i, j\} \mid \{i, j\} \subseteq \mathsf{ps}_x(\alpha) \text{ for some } x \in \mathsf{alph}(\alpha)\}$. Intuitively, G_α is obtained by interpreting every position of α as a vertex, connecting neighbouring positions by edges, and turning every set $\mathsf{ps}_x(\alpha)$, $x \in \mathsf{alph}(\alpha)$, into a clique (see Figure 3).

We use G_α as a unique graph representation for condensed words and whenever we talk about a path decomposition for α, we actually refer to a path decomposition of G_α and, since G_α has the positions of α as its vertices, the marking scheme behind a path decomposition (and its respective terminology) directly translates to a marking scheme of the positions of α.

▶ **Lemma 7.** *Let α be a condensed word with $|\alpha| \geq 2$. Then $\mathit{loc}(\alpha) \leq \mathit{pw}(G_\alpha) \leq 2\,\mathit{loc}(\alpha)$.*

Proof Sketch. We only sketch how a marking sequence translates into a path decomposition and vice versa. Let $\sigma = (x_1, x_2, \ldots, x_m)$ be a marking sequence for a condensed word α with $\pi_\sigma(\alpha) = k$. We describe a path decomposition Q of G_α as a marking scheme. First, for every i, $1 \leq i \leq m$, let p_i be a step of Q (corresponding to one of the bags of Q) that represents stage i of σ: every position that is a border position of a marked block is `active`, every other marked position is `closed`, and all other positions are `open`. The path decomposition produces these steps in the order $p_1, p_2, \ldots, p_m$ and such a step p_i is reached from the predecessor step p_{i-1} by a sequence of intermediate steps as follows. Step p_1 is obtained from the initial one by setting all positions in $\mathsf{ps}_{x_1}(\alpha)$ to `active`, the final step of Q, where all positions are `closed`, is obtained from step p_m by setting the only `active` positions 1 and $|\alpha|$ to `closed`. In order to produce step p_{i+1} from step p_i, we do the following. For every $j \in \mathsf{ps}_{x_{i+1}}(\alpha)$ that does not create a new marked block of size 1, we set position j to `active` and immediately after that, we set all `active` neighbours of j to `closed` if they do not have `open` neighbours anymore. Next, we set all remaining positions from $\mathsf{ps}_{x_{i+1}}(\alpha)$ to `active` and, finally, we set all positions from $\mathsf{ps}_{x_{i+1}}(\alpha)$ that have no `open` neighbours to `closed`. It can be verified with a moderate effort that we have now obtained step p_{i+1} and also that Q is, in fact, a valid path decomposition of G_α. In order to see that $\mathsf{pw}(Q) \leq 2k$, we first note that the number of `active` positions in each step p_i is clearly bounded by $2k$. In going

from p_i to p_{i+1}, we necessarily reach a step where all positions of $\mathsf{ps}_{x_{i+1}}(\alpha)$ are now `active`, while some of the previous border positions might also still be `active`. It requires a more involved and careful counting argument to see that the total number of `active` positions in these intermediate steps never exceeds $2k+1$.

For the other direction, let $Q = (B_0, B_1, B_2, \ldots, B_{2|\alpha|})$ be an arbitrary nice path decomposition of G_α. For every i, $1 \leq i \leq m$, let p_i be the first step of Q where all positions of $\mathsf{ps}_{x_i}(\alpha)$ are `active`. We order the characters x_i so that $p_1 < p_2 < \ldots < p_m$ and define a marking sequence for α by setting $\sigma = (x_1, x_2, \ldots, x_m)$. It is comparatively easy to show that at every step p_i of Q there is at least one `active` position per marked block of stage i of σ. However, this only shows that $\pi_\sigma(\alpha) - 1 \leq \mathsf{pw}(Q)$ and in order to prove that, in fact, $\pi_\sigma(\alpha) \leq \mathsf{pw}(Q)$ holds, we show that either there is a step of Q with at least $\pi_\sigma(\alpha)+1$ `active` positions or, if this is not the case, then there must be a marking sequence σ' with $\pi_{\sigma'}(\alpha) = \pi_\sigma(\alpha) - 1$. This implies that, for every path decomposition Q of G_α, $\mathsf{loc}(\alpha) \leq \mathsf{pw}(Q)$ and therefore also $\mathsf{loc}(\alpha) \leq \mathsf{pw}(G_\alpha)$. Proving this claim requires a long and technically involved case analysis. ◀

Note that Lemma 7 is not true for condensed words α of size 1, since then $\mathsf{loc}(\alpha) = 1$ and $\mathsf{pw}(G_\alpha) = 0$. The reason why $\mathsf{pw}(G_\alpha)$ can range between $\mathsf{loc}(\alpha)$ and $2\,\mathsf{loc}(\alpha)$ (rather than $\mathsf{pw}(G_\alpha) = 2\,\mathsf{loc}(\alpha)$) is that in a marking sequence, every marked block accounts for one unit of the quantity $\mathsf{loc}(\alpha)$, while in the path decomposition, a marked block is represented either by two `active` vertices or by only one (if the block has size one). There are (condensed) examples that reach the extremes $\mathsf{loc}(\alpha)$ and $2\,\mathsf{loc}(\alpha)$, i.e., the bounds of Lemma 7 are tight.

▶ **Proposition 8.** *Let $\alpha = (x_1 x_2 \ldots x_n x_{n-1} \ldots x_2)^k x_1$ with $n \geq 3$, and let $\beta = (x_1 x_2)^k$. Then we have $\mathsf{loc}(\alpha) = k$ and $\mathsf{pw}(G_\alpha) = 2k$, and $\mathsf{loc}(\beta) = \mathsf{pw}(G_\beta) = k$.*

Note that the construction of a graph G_α from a word α does not technically provide a reduction from the decision problem Loc to Pathwidth (due to the fact that $\mathsf{pw}(G_\alpha)$ lies between $\mathsf{loc}(\alpha)$ and $2\,\mathsf{loc}(\alpha)$) and therefore cannot be used to solve MinLoc exactly. Its main purpose is to carry over approximation results from MinPathwidth to MinLoc, which is formally stated by the next lemma (in this regard, note that exact algorithms for MinLoc are obtained in Section 3 via a reduction to MinCutwidth instead).

▶ **Lemma 9.** *If* MinPathwidth *admits an $\mathrm{O}(f(n))$-time $r(\mathsf{opt}, n)$-approximation algorithm, then* MinLoc *admits an $\mathrm{O}(f(|\alpha|) + |\alpha|^2)$-time $2r(2\,\mathsf{opt}, |\alpha|)$-approximation algorithm.*

Consequently, approximation algorithms for MinPathwidth carry over to MinLoc. To the knowledge of the authors, the currently best approximation algorithm for MinPathwidth is due to [20], with an approximation ratio of $\mathrm{O}(\sqrt{\log(\mathsf{opt})}\log(n))$. This implies the following.

▶ **Theorem 10.** *There is an $\mathrm{O}(\sqrt{\log(\mathsf{opt})}\log(n))$-approximation algorithm for* MinLoc.

Another consequence that is worth mentioning is due to the fact that an optimal path decomposition can be computed faster than $\mathrm{O}^*(2^n)$. More precisely, it is shown in [46] that for computing path decompositions, there is an exact algorithm with running time $\mathrm{O}^*((1.9657)^n)$, and even an additive approximation algorithm with running time $\mathrm{O}^*((1.89)^n)$. Consequently, there is a 2-approximation algorithm for MinLoc with running time $\mathrm{O}^*((1.9657)^n)$ and an asymptotic 2-approximation algorithm with running time $\mathrm{O}^*((1.89)^n)$ for MinLoc.

By combining the reduction from MinCutwidth to MinLoc from Section 3 with the reduction from MinLoc to MinPathwidth defined above, we obtain a reduction from MinCutwidth to MinPathwidth that carries over the pathwidth-approximation from [20] to MinCutwidth as follows (in particular, this improves the state-of-the-art approximation algorithm for MinCutwidth from [35]).

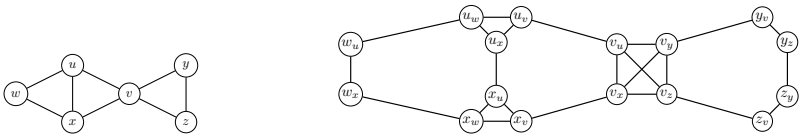

Figure 4 A graph G and the corresponding graph G' obtained by the reduction.

▶ **Theorem 11.** *There is a* $O(\sqrt{\log(\mathsf{opt})}\log(n))$*-approximation for* MinCutwidth.

Note that Theorem 11 only applies to simple graphs; see Section 5 for the case of multigraphs.

Many existing algorithms constructing path decompositions are of theoretical interest only, and this disadvantage carries over to the possible algorithms computing the locality number or cutwidth based on them. However, the reduction of Lemma 7 is also applicable in a purely practical scenario, since any kind of practical algorithm constructing path decompositions can be used in order to compute marking sequences (the additional tasks of building G_α and the translation of a path decomposition for it back to a marking sequence are computationally simple). This observation is particularly interesting since developing practical algorithms constructing tree and path decompositions of small width is a vibrant research area.[2]

5 Pathwidth and Cutwidth

Since pathwidth and cutwidth are classical graph parameters that play an important role for graph algorithms, independent from our application for computing the locality number, we also present a direct reduction from MinCutwidth to MinPathwidth.

For a graph $G = (V, E)$, we construct the graph $G' = (V', E')$ with $V' = \{v_u \mid \{u, v\} \in E\}$ and $E' = \{\{u_v, v_u\} \mid \{u, v\} \in E\} \cup \{\{v_u, v_w\} \mid \{u, v\}, \{w, v\} \in E, u \neq w\}$; see Figure 4.

▶ **Lemma 12.** *Let G be a graph with at least one edge. Then* $\mathsf{cw}(G) \leq \mathsf{pw}(G') \leq 2\,\mathsf{cw}(G)$.

Lemma 12 does not only prove that $\mathsf{cw}(G) \leq \mathsf{pw}(G') \leq 2\,\mathsf{cw}(G)$, but also yields a constructive way to compute a linear arrangement for G of cut at most k from a path decomposition of width k for G'. Further, Lemma 12 remains true if G is a multigraph; observe that the reduction still constructs a simple graph G'. This gives the following result.

▶ **Lemma 13.** *If there is an $r(\mathsf{opt}, |V|)$-approximation algorithm for* MinPathwidth *with running-time $O(f(|V|))$, then there is also an $2r(2\,\mathsf{opt}, h)$-approximation algorithm for* MinCutwidth *on multigraphs with running time $O(f(h) + h^2 + n)$, where n is the number of vertices and h is the number of edges.*

With the $O(\sqrt{\log(\mathsf{opt})}\log(n))$-approximation for MinPathwidth from [20], Lemma 13 gives the following approximation for MinCutwidth on multigraphs.

▶ **Theorem 14.** *There is a (polynomial-time)* $O(\sqrt{\log(\mathsf{opt})}\log(h))$*-approximation algorithm for* MinCutwidth *on multigraphs with h edges.*

In accordance with Theorem 11, Theorem 14 yields an $O(\sqrt{\log(\mathsf{opt})}\log(n))$-approximation algorithm for simple graphs. Analogously, Theorem 11 could be formulated for multigraphs, which would also change the approximation-ratio to $O(\sqrt{\log(\mathsf{opt})}\log(h))$.

[2] See, e.g., the work [13] and the references therein for practical algorithms constructing path decompositions; also note that designing exact and heuristic algorithms for constructing tree decompositions was part of the "PACE 2017 Parameterized Algorithms and Computational Experiments Challenge" [16].

Abstract

We show that the full set of solutions to systems of equations and inequations in a hyperbolic group, with or without torsion, as shortlex geodesic words, is an EDT0L language whose specification can be computed in NSPACE$(n^2 \log n)$ for the torsion-free case and NSPACE$(n^4 \log n)$ for the torsion case. Our work combines deep geometric results by Rips, Sela, Dahmani and Guirardel on decidability of existential theories of hyperbolic groups, work of computer scientists including Plandowski, Jeż, Diekert and others on PSPACE algorithms to solve equations in free monoids and groups using compression, and an intricate language-theoretic analysis.

The present work gives an essentially optimal formal language description for all solutions in all hyperbolic groups, and an explicit and surprising low space complexity to compute them.

1 Introduction

Hyperbolic groups were introduced by Gromov in 1987 [25], and play a significant role in group theory and geometry [12, 33, 40]. Virtually free groups, small cancellation groups, and the fundamental groups of extensive classes of negative curvature manifolds are important examples (see [1] for background). In a certain probabilistic sense made precise in [26, 37, 41], almost all finitely generated groups are hyperbolic. They admit very efficient solutions to the word and conjugacy problems [21, 27, 28], and extremely nice language-theoretic properties, for example the set of all geodesics over any generating set is regular (see Lemma 16), and forms a biautomatic structure [22]. They are exactly the groups which admit context-free multiplication tables [23], and have a particularly simple characterisation in terms of rewriting systems [6, 35] (see Lemma 13).

In this paper we consider systems of equations and inequations in hyperbolic groups, building on and generalising work done in the area of solving equations over various groups and monoids in PSPACE. Starting with work of Plandowski [38], many prominent researchers have given PSPACE algorithms [7, 14, 16, 17, 18, 30, 31] to find (all) solutions to systems of equations over free monoids, free groups, partially commutative monoids and groups, and virtually free groups (that is, groups which have a free subgroup of finite index).

The satisfiability of equations over torsion-free hyperbolic groups is decidable by the work of Rips and Sela [39], who reduced the problem in hyperbolic groups to solving equations in free groups, and then calling on Makanin's algorithm [36]. Kufleitner proved PSPACE for decidability in the torsion-free case [34], without an explicit complexity bound, by following Rips-Sela and then using Plandowski's result [38]. Dahmani and Guirardel radically extended Rips and Sela's work to all hyperbolic groups (with torsion), by reducing systems of equations to systems over virtually free groups, which they then reduced to systems of *twisted* equations over free groups [11]. In terms of describing solution sets, Grigorchuck and Lysionok gave efficient algorithms for the special case of quadratic equations [24].

Here we combine Rips, Sela, Dahmani and Guirardel's approach with recent work of the authors with Diekert [7, 14, 15] to obtain the following results.

▶ **Theorem 1** (Torsion-free). *Let G be a torsion-free hyperbolic group with finite symmetric generating set S. Let Φ be a system of equations and inequations of size n (see Section 2 for a precise definition of input size). Then the set of all solutions, as tuples of shortlex geodesic words over S, is EDT0L. Moreover there is an* $\mathsf{NSPACE}(n^2 \log n)$ *algorithm which on input Φ prints a description for the EDT0L grammar.*

▶ **Theorem 2** (Torsion). *Let G be a hyperbolic group with torsion with finite symmetric generating set S. Let Φ be a system of equations and inequations of size n (see Section 2 for a precise definition of input size). Then the set of all solutions, as tuples of shortlex geodesic words over S, is EDT0L. Moreover there is an* $\mathsf{NSPACE}(n^4 \log n)$ *algorithm which on input Φ prints a description for the EDT0L grammar.*

A corollary of Theorems 1 and 2 is that the existential theory for hyperbolic groups can be decided in $\mathsf{NSPACE}(n^2 \log n)$ for torsion-free and $\mathsf{NSPACE}(n^4 \log n)$ for groups with torsion. Another consequence of our work is that we can decide in the same space complexity as above whether or not the solution set is empty, finite or infinite (see [8]).

EDT0L is a surprisingly low language complexity for this problem. EDT0L languages are playing an increasingly useful role in group theory, not only in describing solution sets to equations in groups [7, 14, 17], but more generally [4, 5, 9].

The paper is organised as follows. We briefly set up some notation for solution sets and input size in Section 2. We then give an informal description of the entire argument for the torsion-free case in Section 3. This overview uses various concepts which are defined more carefully afterwards, but we hope that having the entire argument in one place is useful for the reader to understand the "big picture" before descending into the details. Section 4 develops necessary material on EDT0L and space complexity. Section 5 covers the necessary background on hyperbolic groups, including the key step to obtain a full solution set (as tuples of shortlex geodesics) from a *covering solution set* (see Definition 3(iii)). In Section 6 we use Rips and Sela's *canonical representatives* (see [8, Appendix A]) in torsion-free hyperbolic groups, to reduce the problem of finding solutions in a torsion-free hyperbolic group to finding solutions in the free group on the same generators as the hyperbolic one. We show that if the input system has size n then the resulting system in the free group has size $O(n^2)$. Applying [7] produces a covering solution set in $O(n^2 \log n)$ nondeterministic space, from

which we obtain the full set of solutions as shortlex geodesics in the original group, as an EDT0L language, in the same space complexity. In Section 7 we prove the general case for hyperbolic groups with torsion, following Dahmani and Guirardel who construct canonical representatives in a graph containing the Cayley graph of the hyperbolic group, and working in an associated virtually-free group.

2 Notations for equations and solution sets

Let G be a fixed group with finite symmetric generating set S. Let $\pi\colon S^* \to G$ be the natural projection map. Let $\{X_1, \ldots, X_m\}$, $m \geqslant 1$, be a set of variables to which we adjoin their formal inverses X_i^{-1} and denote by $\mathcal{X}$ the union $\{X_i, X_i^{-1} \mid 1 \leqslant i \leqslant m\}$. Let $\mathcal{C} = \{a_1, \ldots, a_k\} \subseteq G$ be a set of constants and

$$\Phi = \{\varphi_j(\mathcal{X}, \mathcal{C}) = 1\}_{j=1}^{h} \cup \{\varphi_j(\mathcal{X}, \mathcal{C}) \neq 1\}_{j=h+1}^{s} \tag{1}$$

be a set of s equations and inequations in G, where the length of each (in)equation is l_i. Then the total length of the equations is $n = \sum_{i=1}^{s} l_i$, and we take $|\Phi| = n$ as the input size in the remainder of the paper.

A tuple $(g_1, \ldots, g_m) \in G^m$ *solves* an equation [resp. inequation] φ_j in Φ if replacing each variable X_i by g_i (and X_i^{-1} by g_i^{-1}) produces an identity [resp. inequality] in the group as follows:

$$\varphi_j(g_1, \ldots, g_m, a_1, \ldots, a_k) = 1 \text{ [resp. } \varphi_j(g_1, \ldots, g_m, a_1, \ldots, a_k) \neq 1\text{]}.$$

A tuple $(g_1, \ldots, g_m) \in G^m$ solves Φ if it simultaneously solves φ_j for all $1 \leqslant j \leqslant s$.

▶ **Definition 3.**

(i) *The* group element solution set *to* Φ *is the set*

$$Sol_G(\Phi) = \{(g_1, \ldots, g_m) \in G^m \mid (g_1, \ldots, g_m) \text{ solves } \Phi\}.$$

(ii) *Let* $T \subseteq S^*$ *and* $\#$ *a symbol not in* S. *The* full set of T-solutions *is the set*

$$Sol_{T,G}(\Phi) = \{w_1 \# \ldots \# w_m \mid w_i \in T, (\pi(w_1), \ldots, \pi(w_m)) \text{ solves } \Phi\}.$$

(iii) *A set* $L \subseteq \{w_1 \# \ldots \# w_m \mid w_i \in S^*, 1 \leqslant i \leqslant m\}$ *is a* covering solution set *to* Φ *if*

$$\{(\pi(w_1), \ldots, \pi(w_k)) \mid w_1 \# \ldots \# w_m \in L\} = Sol_G(\Phi).$$

3 Overview of the proof

In a free group, the equation $xy = z$ has a solution in reduced words (that is, words which do not contain factors aa^{-1} for any $a \in S$) if and only if there exist words P, Q, R with $x = PQ, y = Q^{-1}R, z = PR$ in the free monoid with involution over S ([7, Lemma 4.1]). In a hyperbolic group this direct reduction to cancellation-free equations is no longer true: a triangle $xy = z$ where x, y, z are replaced by geodesics looks as in Figure 1a.

Rips and Sela [39] proved that in a torsion-free hyperbolic group one can define certain special words called *canonical representatives* so that a system of equations of the form $X_jY_j = Z_j, 1 \leqslant j \leqslant O(n)$ has solutions which are canonical representatives with the properties that their prefixes and suffixes coincide, as shown in Figure 1b, and the inner circle is the concatenation of three words with lengths in $O(n)$. Moreover, these canonical representatives are (λ, μ)-quasigeodesics (Definition 15) where the constants λ, μ depend only on the group.

(a) Using geodesics. **(b)** Using canonical representatives.

Figure 1 Solutions to $xy = z$ in the Cayley graph of a hyperbolic group.

We use these facts to devise the following algorithm, presented here for the torsion-free case. We treat the hyperbolic group G with finite generating set S as a constant. On input a system of equations and inequations as in (1) of size n:

1. Replace inequations by equations (by using a new variable and requiring that this variable is not trivial in the group, as explained in Section 6.3).
2. Triangulate the system, so that all equations have the form $X_jY_j = Z_j$. The size of the resulting system is still in $O(n)$. Suppose there are $q \in O(n)$ such equations.
3. Enumerate, one at a time, all possible tuples $\mathbf{c} = (c_{11}, c_{12}, c_{13}, \ldots, c_{q1}, c_{q2}, c_{q3})$ of words (say, in lex order) so that the length $\ell(c_{ji})$ with respect to S is bounded by a constant in $O(n)$. Note that the size of each tuple (the sum of the lengths of the c_{ij}) is in $O(n^2)$.
4. For each tuple $\mathbf{c}$, run Dehn's algorithm to check $c_{j1}c_{j2}c_{j3} =_G 1$ for $1 \leqslant j \leqslant q$. If this holds for all j, write down a system of $3q$ equations

$$X_j = P_j c_{j1} Q_j, Y_j = Q_j^{-1} c_{j2} R_j, Z_j = P_j c_{j3} R_j.$$

   Note that the resulting system, $\Phi_{\mathbf{c}}$, has size in $O(n^2)$.
5. We now call the algorithm of the authors and Diekert [7] to find all solutions to $\Phi_{\mathbf{c}}$ in the free group generated by S. This algorithm, on input of size $O(n^2)$, runs in $\mathsf{NSPACE}(n^2 \log n)$, and prints a description of the EDT0L grammar which generates all tuples of solutions as reduced words in S^*. Specifically it prints nodes and edges of a trim NFA which is the rational control for the EDT0L grammar (see Definition 4 below). Modify the algorithm so that the nodes printed include the label $\mathbf{c}$ which has length $O(n^2)$ (so does not affect the complexity).
6. Delete the current system stored, and move to the next tuple $\mathbf{c}$.
7. At the end, print out a new start node and ϵ edges to the start node of the NFA for the system $\Phi_{\mathbf{c}}$ for all $\mathbf{c}$ already printed.

The NFA that is printed gives an EDT0L grammar that generates a language of tuples which is a covering solution to the original system in the hyperbolic group. To obtain the full set of solutions as shortlex geodesic words we need to perform further steps. Using the facts that canonical representatives are (λ, μ)-quasigeodesics, and

- the full set of (λ, μ)-quasigeodesics, $Q_{S,\lambda,\mu}$
- the set of all pairs $\{(u, v) \in Q_{S,\lambda,\mu} \mid u =_G v\}$
- the set of all shortlex geodesics in G

are all regular, we can obtain from the covering solution an ET0L language, in the same space complexity (by Proposition 9 below), which represents the full set of solutions in shortlex geodesic words. Then finally, because of the special form of our solutions, we can apply a version of the *Copying Lemma* of Ehrenfeucht and Rozenberg [19] to show that in fact the resulting language of shortlex representatives is EDT0L in $\mathsf{NSPACE}(n^2 \log n)$.

Details for handling the case of hyperbolic groups with torsion also follows this general scheme, however finding the analogue of canonical representatives is harder in this case, so further work is required, and we describe this in Section 7.

4 E(D)T0L in PSPACE

4.1 ET0L and EDT0L languages

Let C be an alphabet. A *table* for C is a finite subset of $C \times C^*$. If (c, v) is in some table t, we say that (c, v) is a *rule* for c. A table t is *deterministic* if for each $c \in C$ there is exactly one $v \in C^*$ with $(c, v) \in t$.

If t is a table and $u \in C^*$ then we write $u \longrightarrow^t v$ to mean that v is obtained by applying rules from t to each letter of u. That is, $u = a_1 \dots a_n$, $a_i \in C$, $v = v_1 \dots v_n$, $v_i \in C^*$, and $(a_i, v_i) \in t$ for $1 \leqslant i \leqslant n$. If H is a set of tables and $r \in H^*$ then we write $u \longrightarrow^r v$ to mean that there is a sequence of words $u = v_0, v_1, \dots, v_n = v \in C^*$ such that $v_{i-1} \longrightarrow^{t_i} v_i$ for $1 \leqslant i \leqslant n$ where $r = t_1 \dots t_n$. If $R \subseteq H^*$ we write $u \longrightarrow^R v$ if $u \longrightarrow^r v$ for some $r \in R$.

▶ **Definition 4** ([2]). *Let Σ be an alphabet. We say that $L \subseteq \Sigma^*$ is an* ET0L *language if there is an alphabet C with $\Sigma \subseteq C$, a finite set $H \subset \mathcal{P}(C \times C^*)$ of tables, a regular language $R \subseteq H^*$ and a letter $c_0 \in C$ such that*

$$L = \{w \in \Sigma^* \mid c_0 \longrightarrow^R w\}.$$

In the case when every table $h \in R$ is deterministic, i.e. each $h \in R$ is in fact a homomorphism, we write $L = \{r(c_0) \in \Sigma^* \mid r \in R\}$ and say that L is EDT0L*. The set R is called the* rational control*, the symbol c_0 the* start symbol *and C the* extended alphabet*.*

4.2 Space complexity for E(D)T0L

Let $f\colon \mathbb{N} \to \mathbb{N}$ be a function. Recall an algorithm is said to run in $\mathsf{NSPACE}(f(n))$ if it can be performed by a non-deterministic Turing machine with a read-only input tape, a write-only output tape, and a read-write work tape, with the work tape restricted to using $O(f(n))$ squares on input of size n. The following definition formalises the idea of producing some E(D)T0L language (such as the solution set of some system of equations) in $\mathsf{NSPACE}(f(n))$, where the language is the output of a computation with input (such as a system of equations) of size n. We use the notation $L(\mathcal{A})$ to denote the language accepted by an automaton $\mathcal{A}$.

▶ **Definition 5.** *Let Σ be a (fixed) alphabet and $f\colon \mathbb{N} \to \mathbb{N}$ a function. If there is an $\mathsf{NSPACE}(f(n))$ algorithm that on input Ω of size n outputs the specification of an ET0L language $L_\Omega \subseteq \Sigma^*$, then we say that L_Ω is* ET0L in $\mathsf{NSPACE}(f(n))$*.*

Here the specification of L_Ω consists of:

- *an extended alphabet $C \supseteq \Sigma$,*
- *a start symbol $c_0 \in C$,*
- *a finite list of nodes of a (trim) NFA $\mathcal{A}$, labeled by some data, some possibly marked as initial and/or final,*
- *a finite list $\{(u, v, h)\}$ of edges of $\mathcal{A}$ where u, v are nodes and $h \in \mathcal{P}(C \times C^*)$ is a table such that $L_\Omega = \{w \in \Sigma^* \mid c_0 \to^{L(\mathcal{A})} w\}$.*

A language L_Ω is ET0L in $\mathsf{NSPACE}(f(n))$ *if, in addition, every table h labelling an edge of $\mathcal{A}$ is deterministic.*

Note that the entire print-out is not required to be in $O(f(n))$ space. Previous results of the authors with Diekert can now be restated as follows.

▶ **Theorem 6** ([7, Theorem 2.1]). *The set of all solutions to a system of size n of equations (with rational constraints), as reduced words, in a free group is EDT0L in* $\mathsf{NSPACE}(n \log n)$.

▶ **Theorem 7** ([15, Theorem 45]). *The set of all solutions to a system of size n of equations (with rational constraints), as words in a particular quasigeodesic normal form over a certain finite generating set, in a virtually free group is EDT0L in* $\mathsf{NSPACE}(n^2 \log n)$.

▶ Remark 8. In our applications below we have Ω representing some system of equations and inequations, with $|\Omega| = n$, and we construct algorithms where the extended alphabet C has size $|C| \in O(n)$ in the torsion-free case and $|C| \in O(n^2)$ in the torsion case. This means we can write down the entire alphabet C as binary strings within our space bounds. Moreover, each element (c, v) of any table we construct has v of (fixed) bounded length, so we can write down entire tables within our space bounds.

4.3 Closure properties

It is well known [32, Theorem 2.8] that ET0L is a full AFL (closed under homomorphism, inverse homomorphism, finite union, intersection with regular languages). Here we show the space complexity of an ET0L language is not affected by these operations.

▶ **Proposition 9.** *Let Σ, Γ be finite alphabets of fixed size, M an NFA of constant size with $L(M) \subseteq \Sigma^*$, and $\varphi\colon \Gamma^* \to \Sigma^*$, $\psi\colon \Sigma^* \to \Gamma^*$ homomorphisms. If $L_{\Omega_1}, L_{\Omega_2} \subseteq \Sigma^*$ are E(D)T0L in* $\mathsf{NSPACE}(f(n))$ *(on inputs Ω_1, Ω_2, respectively, with $|\Omega_1|, |\Omega_2| \in O(n)$) then*

- *(homomorphism) $\psi(L_{\Omega_1})$ is E(D)T0L in* $\mathsf{NSPACE}(f(n))$,
- *(intersection with regular) $L_{\Omega_1} \cap L(M)$ is E(D)T0L in* $\mathsf{NSPACE}(f(n))$,
- *(union) $L_{\Omega_1} \cup L_{\Omega_2}$ is E(D)T0L in* $\mathsf{NSPACE}(f(n))$,
- *(inverse homomorphism) $\varphi^{-1}(L_{\Omega_1})$ is ET0L in* $\mathsf{NSPACE}(f(n))$.

The proof is straightforward keeping track of complexity in the standard proofs [3, 10]. Note EDT0L is not closed under inverse homomorphism [20].

▶ **Proposition 10** (Projection onto a factor). *If $L_\Omega \subseteq \Sigma^*$ is E(D)T0L in* $\mathsf{NSPACE}(f(n))$ *on an input Ω of size n, and for some fixed integer s all words in L_Ω have the form $u_1 \# \ldots \# u_s$ with $u_i \in (\Sigma \setminus \{\#\})^*$, and $1 \leqslant i \leqslant j \leqslant s$, then*

$$L = \{u_i \# \ldots \# u_j \mid u_1 \# \ldots \# u_i \# \ldots \# u_j \# \ldots \# u_s \in L_\Omega\}$$

is E(D)T0L in $\mathsf{NSPACE}(f(n))$.

4.4 From ET0L to EDT0L

In computing the full solution set to equations as shortlex geodesic words, we will need to take inverse homomorphism. Even though in general the image under an inverse homomorphism of an EDT0L language is just ET0L, because of the special structure of solution sets we can apply the *Copying Lemma* of Ehrenfeucht and Rozenberg [19] to show the following.

▶ **Proposition 11.** *Let S be an alphabet and $h : S \to S'$ be a homomorphism of from S to a disjoint alphabet $S' = \{s' \mid s \in S\}$ defined by $h(s) = s'$. Let $\wr$ be a symbol not in $S \cup S'$ and define $h(\wr) = \wr$. Let L_1 be a set of words of the form $w \wr h(w)$ where $w \in S^*$. If L_1 is ET0L in* $\mathsf{NSPACE}(f(n))$, *then $L_2 = \{w \mid w \wr h(w) \in L_1\}$ is EDT0L in* $\mathsf{NSPACE}(f(n))$.

Proof. By [19], any nondeterministic table in the grammar for L_1 can be replaced by a finite number of deterministic tables (essentially, if nondeterminism allowed some letter $c \in C$ to produce two different results, then some word in L_1 would not have the form $w \wr h(w)$). So without loss of generality we can replace a table f containing $(c, v_1), \ldots, (c, v_k)$ by k tables f_i containing (c, v_i) only). This modification is clearly in the same space bound. Project onto the prefix using Proposition 10. ◀

5 Hyperbolic groups

5.1 Definitions

Recall the *Cayley graph* for a group G with respect to a finite symmetric generating set S is a directed graph $\Gamma(G, S)$ with vertices labeled by $g \in G$ and a directed edge (g, h) labeled by $s \in S$ whenever $h =_G gs$. Let $\ell(p)$, $i(p)$ and $f(p)$ resp. be the length, initial and terminal vertices of a path p in the Cayley graph. A path p is *geodesic* if $\ell(p)$ is minimal among the lengths of all paths q with the same endpoints. If x, y are two points in $\Gamma(G, S)$, we define $d(x, y)$ to be the length of a shortest path from x to y in $\Gamma(G, S)$.

▶ **Definition 12** (δ-hyperbolic group (Gromov)). *Let G be a group with finite symmetric generating set S, and let $\delta \geqslant 0$ be a fixed real number. If p, q, r are geodesic paths in $\Gamma(G, S)$ with $f(p) = i(q), f(q) = i(r), f(r) = i(p)$, we call $[p, q, r]$ a* geodesic triangle. *A geodesic triangle is* δ-slim *if p is contained in a δ-neighbourhood of $q \cup r$, that is, every point on one side of the triangle is within δ of some point on one of the other sides. (See for example Figure 1a.) We say (G, S) is* δ-hyperbolic *if every geodesic triangle in $\Gamma(G, S)$ is δ-slim. We say (G, S) is* hyperbolic *if it is δ-hyperbolic for some $\delta \geqslant 0$.*

It is a straightforward to show that being hyperbolic is independent of choice of finite generating set. Thus we say G is hyperbolic if (G, S) is for some finite generating set S.

▶ **Lemma 13** (Dehn presentation). *G is hyperbolic if and only if there is a finite list of pairs of words $(u_i, v_i) \in S^* \times S^*$ with $|u_i| > |v_i|$ and $u_i =_G v_i$ such that the following holds: if $w \in S^*$ is equal to the identity of G then it contains some u_i as a factor.*

This gives an algorithm to decide whether or not a word $w \in S^*$ is equal to the identity: while $\ell(w) > 0$, look for some u_i factor. If there is none, then $w \neq_G 1$. Else replace u_i by v_i (which is shorter). This procedure is called *Dehn's algorithm.*

▶ **Lemma 14.** *Dehn's algorithm runs in (linear time and) linear space.*

▶ **Definition 15** (Quasigeodesic). *For $\lambda \geqslant 1, \mu \geqslant 0$ real numbers, a path p in $\Gamma(G, S)$ is a* (λ, μ)-quasigeodesic *if for any subpath q of p we have $\ell(q) \leqslant \lambda d(i(q), f(q)) + \mu$.*

Throughout this article, we assume G is a fixed hyperbolic group which we treat as a constant for complexity purposes. We assume we are given (G, S), the constant δ, the finite list of pairs for Dehn's algorithm, and any other constants depending only on the group.

5.2 Languages in hyperbolic groups

▶ **Proposition 16.** *Let G be a fixed hyperbolic group with finite generating set S, $\lambda \geqslant 1, \mu \geqslant 0$ constants with $\lambda \in \mathbb{Q}$ and μ sufficiently large. Then the following sets are regular languages.*

1. *The set of all geodesics over S.*
2. *The set of all shortlex geodesics over S.*
3. *The set of all (λ, μ)-quasigeodesics, $Q_{S,\lambda,\mu} \subseteq S^*$.*

Furthermore, the set of all pairs of words $(u, v) \in Q^2_{S,\lambda,\mu}$ such that $u =_G v$ is accepted by an asynchronous 2-tape automaton.

See [22, 29].

5.3 Main reduction result

Here is our key technical result.

▶ **Proposition 17** (Covering to full solution sets). *Let G be a hyperbolic group with finite symmetric generating set S. Let $h : S \to S'$ and $Q_{S,\lambda,\mu}$ be as defined above, $\#, \wr$ symbols not in $S \cup S'$, $h(\#) = \#, h(\wr) = \wr$, and $\mathcal{T} \subseteq Q_{S,\lambda,\mu}$ a regular set of quasigeodesic words in bijection with G. Suppose $L_1 \subseteq (S \cup S' \cup \{\#, \wr\})^*$ consists of words of the form*

$$u_1 \# \dots \# u_r \wr h(v_1) \# \dots \# h(v_r),\ u_i, v_i \in Q_{S,\lambda,\mu}, u_i =_G v_i, 1 \leqslant i \leqslant r.$$

If L_1 is ET0L in NSPACE$(f(n))$*, then*

1. $L_Q = \{w_1 \# \dots \# w_r \wr h(z_1) \# \dots \# h(z_r) \mid \exists u_1 \# \dots \# u_r \wr h(v_1) \# \dots \# h(v_r) \in L_1, w_i =_G z_i =_G u_i, w_i, z_i \in Q_{S,\lambda,\mu}\}$ *is ET0L in* NSPACE$(f(n))$.
2. $L_{\mathcal{T}} = \{w_1 \# \dots \# w_r \mid \exists u_1 \# \dots \# u_r \wr h(v_1) \# \dots \# h(v_r) \in L_1, w_i =_G u_i, w_i \in \mathcal{T}\}$ *is EDT0L in* NSPACE$(f(n))$.

The proof involves a series of operations as in Proposition 9–11, see [8] for further details. Note that the set of all shortlex geodesics is a suitable choice for $\mathcal{T}$ in the proposition.

6 Reduction from torsion-free hyperbolic to free groups

Section 3 contains an overview of the general algorithm for solving equations in torsion-free hyperbolic groups. Here we provide further details, and give a proof of the soundness and completeness of our algorithm. The algorithm relies on the existence and special properties of canonical representatives, whose construction is very technical (details are provided in [8]). Their existence guarantees that the solutions of a system in a torsion-free hyperbolic group generated by S can be found by solving an associated system in the free group on S, while the fact that they are quasigeodesics (see [8, Prop. 30]) allows us to apply the results of the previous sections to obtain the EDT0L characterisation of solutions in shortlex normal form.

▶ **Proposition 18.** *Let G be a torsion-free hyperbolic group, with finite symmetric generating set S. Let Φ be a system of equations and inequations of input size n as in Section 2. Let $h : S \to S', \#, \wr$ be as in Proposition 17. Then there exist $\lambda \geqslant 1, \mu \geqslant 0$ and*

$$L = \{w_1 \# \dots \# w_m \wr h(w_1) \# \dots \# h(w_m) \mid w_i \in Q_{S,\lambda,\mu}, 1 \leqslant i \leqslant m\}$$

such that $\{w \mid w \wr h(w) \in L\}$ is a covering solution for Φ, and L is EDT0L in NSPACE$(n^2 \log n)$.

Applying Proposition 17 immediately gives Theorem 1.

Proof. We produce a language L of quasigeodesic words over S such that the projection of any tuple in L is in the group element solution set $\mathrm{Sol}_G(\Phi)$ (soundness). We then prove (using [39, Corollary 4.4]) that any solution in $\mathrm{Sol}_G(\Phi)$ is the projection of some tuple in L (completeness). Our proof follows the outline presented in Section 3.

1. **Preprocessing.**
   - (Remove inequations) We first transform Φ into a system consisting entirely of equations by adding a variable x_D to $\mathcal{X}$ and replacing any inequation $\varphi_j(\mathcal{X}, \mathcal{A}) \neq 1$ by $\varphi_j(\mathcal{X}, \mathcal{A}) = x_D$, with the constraint $x_D \neq_G 1$.

- (Triangulation) We transform each equation into several equations of length 3, by introducing new variables. This can always be done (see the discussion in [7, Section 4]), and it produces approximately $\sum_{i=1}^{s} l_i \in O(n)$ triangular equations with set of variables $\mathcal{Z}$ where $m \leqslant |\mathcal{Z}| \in O(n)$ and $\mathcal{X} \subset \mathcal{Z}$. From now on assume that the system Φ consists of $q \in O(n)$ equations of the form $X_j Y_j = Z_j$ where $1 \leqslant j \leqslant q$.

2. **Lifting Φ to the free group on S.** In [39, Theorem 4.2] Rips and Sela define a constant, which they call "*bp*", that roughly bounds the circumference of the "centres" of the triangles whose edges are canonical representatives. We denote here *bp* by ρ, and note that $\rho \in O(q) = O(n)$ depends on δ and linearly on q. As described in Section 3 we run in lex order through all possible tuples of words $\mathbf{c} = (c_{11}, c_{12}, c_{13}, \ldots, c_{q1}, c_{q2}, c_{q3})$ with $c_{ji} \in S^*, \ell(c_{ji}) \leqslant \rho \in O(n)$. For each tuple $\mathbf{c}$ we use Dehn's algorithm to check $c_{j1}c_{j2}c_{j3} =_G 1$, and if this holds for all $1 \leqslant j \leqslant q$ we then construct a system $\Phi_{\mathbf{c}}$ of equations of the form

$$X_j = P_j c_{j1} Q_j,\ Y_j = Q_j^{-1} c_{j2} R_j,\ Z_j = P_j c_{j3} R_j,\ \ 1 \leqslant j \leqslant q, \tag{2}$$

which has size $O(n^2)$. In order to avoid an exponential size complexity we write down each system $\Phi_{\mathbf{c}}$ one at a time, so the space required for this step is $O(n^2)$. Let $\mathcal{Y} \supset \mathcal{Z} \supset \mathcal{X}$ be the new set of variables.

3. **Some observations.** We pause to make the following observations. Any solution to $\Phi_{\mathbf{c}}$ in the free group $F(S)$ is guaranteed to be a solution to Φ in the original hyperbolic group G. Thus if $S_1 \subseteq F(S)^m$ is a group element solution to $\Phi_{\mathbf{c}}$ then $\pi(S_1)$ is a group element solution to Φ in G. This will show soundness below.
   Secondly, if $(g_1, \ldots, g_m) \in G^m$ is a solution to Φ in the original hyperbolic group, [39, Theorem 4.2 and Corollary 4.4] (see Theorem 31 in [8]) guarantees that there exist canonical representatives $w_i \in Q_{S,\lambda,\mu}$ with $w_i =_G g_i$ for $1 \leqslant i \leqslant m$, which have reduced forms $u_i =_G w_i$ for $1 \leqslant i \leqslant m$, and our construction is guaranteed to capture any such collection of words. This will show completeness below.
   Thirdly, note that the constraint that a word $w \in S^*$ must be a (λ, μ)-quasigeodesic and satisfy $w =_G 1$ implies that $\ell(w) \leqslant \mu$. Therefore we can construct a DFA $\mathcal{D}$ which accepts all words in S^* equal to 1 in the hyperbolic group G of length at most μ in constant space (using for example Dehn's algorithm). In our next step, we will use this rational constraint to handle the variable x_D added in the first step above (to remove inequalities).
   Now let us complete the construction by finding the covering solution required.

4. **Covering solution set.** We now run the algorithm from [7] (which we will refer to as the CDE algorithm) which takes input $\Phi_{\mathbf{c}}$, which has size in $O(n^2)$, plus the rational constraint $x_D \notin L(\mathcal{D})$, plus for each $y \in \mathcal{Y}$ the rational constraint that the solution for y is a word in $Q_{S,\lambda,\mu}$. Since these constraints have constant size (depending only on the group G, not the system Φ), they do not contribute to the $O(n^2)$ size of the input to the CDE algorithm.
   We make two modifications to the details of the CDE algorithm. First, every node printed by the algorithm should include the additional label $\mathbf{c}$. (This ensures the NFA we print for each system $\Phi_{\mathbf{c}}$ is distinct.) This does not affect the complexity since $\mathbf{c}$ has size in $O(n^2)$.
   Second, so that we can apply Proposition 11 later, we modify the form of "extended equations" in [7] by inserting the factor $\wr h(W)$ in the appropriate position(s). This simply increases the size of the nodes by a factor (of two).

We run the CDE algorithm to print an NFA (possibly empty) for each $\Phi_{\mathbf{c}}$, which is the rational control for an EDT0L grammar that produces all solutions as freely reduced words for elements of $F(S)$ which correspond to solutions as (λ, μ)-quasigeodesics to the same system $\Phi_{\mathbf{c}}$ in the hyperbolic group. If $(w_1, \ldots, w_m)$ is a solution in canonical representatives to Φ then $(u_1, \ldots, u_m, \ldots u_{|\mathcal{Y}|})$ will be included in the solution to $\Phi_{\mathbf{c}}$ output by the CDE algorithm, with u_i the reduced forms of w_i for $1 \leqslant i \leqslant m$. This shows completeness once we union the grammars from all systems $\Phi_{\mathbf{c}}$ together.
Adding a new start node with edges to each of the start nodes of the NFA's with label $\mathbf{c}$, we obtain a rational control for the EDT0L grammar generating L as required. The space required is exactly that required by the CDE algorithm on input $O(n^2)$, which is $\mathsf{NSPACE}(n^2 \log n)$. ◀

7 Reduction from hyperbolic with torsion to virtually free groups

In the case of a hyperbolic group G with torsion, the general approach of Rips and Sela can still be applied, but the existence of canonical representatives is not always guaranteed (see Delzant [13, Rem.III.1]). To get around this, Dahmani and Guirardel "fatten" the Cayley graph $\Gamma(G, S)$ of G to a larger graph $\mathcal{K}$ which contains $\Gamma(G, S)$ (in fact $\Gamma(G, S)$ with midpoints of edges included), and solve equations in G by considering equalities of paths in $\mathcal{K}$. More precisely, $\mathcal{K}$ is the 1-skeleton of the barycentric subdivision of a Rips complex of G (see [8] for definitions).

▶ **Definition 19.** *Let γ, γ' be paths in $\mathcal{K}$.*

- **(i)** *We denote by $i(\gamma)$ the initial vertex of γ, by $f(\gamma)$ the final vertex of γ, and by $\overline{\gamma}$ the reverse of γ starting at $f(\gamma)$ and ending at $i(\gamma)$.*
- **(ii)** *We say that γ is* reduced *if it contains no backtracking, that is, no subpath of length 2 of the form $e\overline{e}$.*
- **(iii)** *We write $\gamma\gamma'$ for the concatenation of γ, γ' if $i(\gamma') = f(\gamma)$.*
- **(iv)** *Two paths in $\mathcal{K}$ are homotopic if one can obtain a path from the other by adding or deleting backtracking subpaths. Each homotopy class has a unique reduced representative.*

Let V be the set of all homotopy classes $[\gamma]$ of paths γ in $\mathcal{K}$ with $i(\gamma) = 1_G$, and $f(\gamma) \in G$. For $[\gamma]$, $[\gamma'] \in V$ define their product $[\gamma][\gamma'] = [\gamma^v \gamma']$, where $\gamma^v \gamma'$ denotes the concatenation of γ and the translate ${}^v\gamma'$ of γ' by $v = f(\gamma)$, and let $[\gamma]^{-1}$ be the homotopy class of ${}^{v^{-1}}\overline{\gamma}$. Then V is a group that projects onto G by the final vertex map f, that is, $f : V \twoheadrightarrow G$ is a surjective homomorphism. Moreover, since G has an action on $\mathcal{K}$ induced by the natural action on its Rips complex, V will act on $\mathcal{K}$ as well. This gives rise to an action of V onto the universal cover T (which is a tree) of $\mathcal{K}$, and [11, Lemma 9.9] shows that the quotient T/V is a finite graph (isomorphic to $\mathcal{K}/G$) of finite groups, and so V is virtually free.

We assume that the algorithmic construction (see [11, Lemma 9.9]) of a presentation for V is part of the preprocessing of the algorithm, will be treated as a constant, and will not be included in the complexity discussion.

The first step in solving a system Φ of equations in G is to translate Φ into identities between quasigeodesic paths (with start and end point in G) in $\mathcal{K}$, defined as $\mathcal{QG}_{\lambda_1,\mu_1}(V)$ in (5) in [8], paths which can be seen as the analogues of the canonical representatives from the torsion-free case. This can be done by Proposition 9.8 [11]. The second step in solving Φ is to express the equalities of quasigeodesic paths in $\mathcal{K}$ in terms of equations in the virtually free group V based on $\mathcal{K}$. Finally, Proposition 9.10 [11] shows it is sufficient to solve the systems of equations in V in order to obtain the solutions of the system Φ in G.

In the virtually free group V we will use the results from [15]. Let Y be the generating set of V and $T \subseteq Y^*$ the set of normal forms for V over Y as in [15, Remark 44, page 50], and let

$$\mathrm{Sol}_{T,V}(\Psi) = \{w_1 \# \dots \# w_m) \in T^n \mid (\pi(w_1), \dots, \pi(w_m)) \text{ solves } \Psi \text{ in } V\}$$

be the language of T-solutions in V of a system Ψ of size $|\Psi| = O(k)$; by [15] the language $\mathrm{Sol}_{T,V}(\Psi)$ consists of (λ_Y, μ_Y)-quasigeodesics and is EDT0L in $\mathsf{NSPACE}(k^2 \log k)$ over Y.

▶ **Proposition 20.** *Let G be a hyperbolic group with torsion, with finite symmetric generating set S. Let Φ be a system of equations and inequations with $|\Phi| = n$ as in Section 2. Let $h : S \to S', \#, \wr$ be as in Proposition 17. Then there exist $\lambda \geqslant 1, \mu \geqslant 0$ and*

$$L = \{w_1 \# \dots \# w_m \wr h(v_1) \# \dots \# h(v_m) \mid w_i, v_i \in Q_{S,\lambda,\mu}, w_i =_G v_i, 1 \leqslant i \leqslant m\}$$

such that $\{w \mid w \wr h(v) \in L\}$ is a covering solution for Φ, and L is ET0L in $\mathsf{NSPACE}(n^4 \log n)$.

Again applying Proposition 17 immediately gives Theorem 2.

Before proving Proposition 20 we need to show how one can translate between elements and words in V over the generating set Y, and elements and words in G over S via the graph $\mathcal{K}$, so that the EDT0L characterisation of languages is preserved.

▶ **Notation.** *Let Z be some generating set of V and let $\pi \colon Z^* \to V$ be the standard projection map from words to group elements in V.*

(i) *For each $z_i \in Z$ there exists a unique reduced path p_i in $\mathcal{K}$ with $i(p_i) = 1_G$ and $f(p_i) \in G$; by concatenation for each word $w = z_{i_1} \dots z_{i_k}$ over Z there is then a unique path denoted*

$$p_w = p_{i_1} \dots p_{i_k} \tag{3}$$

with $i(p_w) = 1_{\mathcal{K}} = 1_G$ and $f(p_w) \in G$.

(ii) *For each $z_i \in Z$, assign a geodesic path γ_i in the Cayley graph $\Gamma(G, S)$ such that $i(\gamma_i) = 1_G$ and $f(\gamma_i) = f(p_i) \in G$, where p_i as in (i). Let $\sigma \colon Z^* \to S^*$ be the map/substitution given by $\sigma(z_i) = \gamma_i$; by concatenation one can associate to each word $w = z_{i_1} \dots z_{i_k}$ over Z a path in $\Gamma(G, S)$ denoted*

$$\gamma_w = \gamma_{i_1} \dots \gamma_{i_k} = \sigma(w) \tag{4}$$

with $i(p_w) = 1_G$ and $f(\gamma_w) = f(w) \in G$.

(iii) *There exists a unique reduced path, denoted $p_{\pi(w)}$, which is homotopic to p_w.*

Proof of Proposition 20. The algorithm to produce the language of solutions for Φ is similar to that outlined in Section 3 and detailed in the proof of Proposition 18, but it applies to different groups. The triangulation of Φ and introduction of a variable with rational constraint to deal with the inequations proceeds in the same manner. Again, we suppose after preprocessing we have $q \in O(n)$ triangular equations.

Then for $\kappa \in O(n)$ as in [8, Prop 36] define $V_{\leqslant \kappa} = \{[\gamma] \in V \mid \gamma \text{ reduced and } \ell_{\mathcal{K}}(\gamma) \leqslant \kappa\}$. One lifts the system Φ in G to a finite set of systems $\Psi_{\mathbf{c}}$ in the virtually free group V, one system for each q-tuple $\mathbf{c}$ of triples (c_1, c_2, c_3) with $c_i \in V_{\leqslant \kappa}$ and such that $f(c_1 c_2 c_3) = 1_G$, as in [8, Prop 36]. We enumerate these tuples by enumerating triples of words (v_1, v_2, v_3) over the generating set Y of V with $\ell_Y(v_i) \leqslant \kappa_Y$, where $\kappa_Y \in O(q)$ is a constant depending on κ, as in Lemma 21(ii). By Lemma 21(ii) the tuples of path triples $(p_{v_1}, p_{v_2}, p_{v_3})$ (see (3))

in $\mathcal{K}$ contain all q-tuples of triples (c_1, c_2, c_3) with $c_i \in V_{\leqslant \kappa_Y}$, up to homotopy. Then for each triple (v_1, v_2, v_3) we check whether $f(v_1v_2v_3) = 1_G$, and this is done by checking whether $\sigma(v_1)\sigma(v_2)\sigma(v_3) =_G 1$ using the Dehn algorithm in G.

Then each system $\Psi_{\mathbf{c}}$ is obtained as in (2) in the proof of Proposition 18 and has input size $O(q^2) \in O(n^2)$ since it has $O(q)$ equations, each of length in $O(q)$, and the factors c_i inserted also have length in $O(q)$. For each system $\Psi_{\mathbf{c}}$ over V we apply the algorithm in [15] and obtain the set of solutions $\mathrm{Sol}_{T,V}(\Psi_{\mathbf{c}})$ as an EDT0L in $\mathsf{NSPACE}((q^2)^2 \log(q^2)) = \mathsf{NSPACE}(n^4 \log n)$ of (λ_Y, μ_Y)-quasigeodesics over Y.

Now let $\mathcal{Q}\mathrm{Sol}_{T,V}(\Psi_{\mathbf{c}})$ be the set of all (λ_1', μ_1')-quasigeodesics which represent solutions of $\Psi_{\mathbf{c}}$ in V over Y. By Proposition 17 this language is ET0L and by Corollary 22 it contains at least one word over Y for each solution in $\mathcal{QG}_{\lambda_1,\mu_1}(V)$.

Then $\sigma(\mathcal{Q}\mathrm{Sol}_{T,V}(\Psi_{\mathbf{c}}))$ is ET0L since ET0L languages are preserved by substitutions, and by [8, Prop 36] $\mathcal{S} = \cup_{\mathbf{c}}\sigma(\mathcal{Q}\mathrm{Sol}_{T,V}(\Psi_{\mathbf{c}}))$ contains $\mathrm{Sol}_G(\Phi)$, so it is a covering solution set of Φ. By Lemma 23 the set $\mathcal{S}$ consists of at least one (λ_G, μ_G)-quasigeodesic over S for each solution, and then by intersection with the regular set Q_{S,λ_G,μ_G} of quasigeodesics in G over S we obtain a set of solutions for Φ consisting of (λ_G, μ_G)-quasigeodesics.

Finally, we run the modified DE algorithm (inserting the additional $\wr h(W)$ and label $\mathbf{c}$ for each node printed) to print an NFA for each $\Phi_{\mathbf{c}}$ for the EDT0L grammar for $\mathrm{Sol}_{T,V}(\Psi_{\mathbf{c}})$, which we union using an extra start node as before. From the above work this grammar generates the language L as required. ◀

▶ **Lemma 21.**

(i) *If $c \in V$ and the reduced path representing c in $\mathcal{K}$ is an (a, b)-quasigeodesic, then there exists a word w on Y representing c such that w is an (a', b')-quasigeodesic, where a', b' depend on a, b and Y.*

(ii) *If $c \in V$ and the length of the reduced path representing c in $\mathcal{K}$ is $\leqslant L$, then there exists a word w on Y representing c such that $\ell_Y(w) \leqslant L_Y$, where L_Y depends on L and Y.*

▶ **Corollary 22.** *For any element $v \in \mathcal{QG}_{\lambda_1,\mu_1}(V)$ there is a (λ_1', μ_1')-quasigeodesic word over Y representing v, where λ_1', μ_1' depend on λ_1, μ_1 and Y.*

▶ **Lemma 23.** *Let w be a (λ_1', μ_1')-quasigeodesic word over Y. Then if the reduced path $p_{\pi(w)}$ is (a, b)-quasigeodesic in $\mathcal{K}$ the (unreduced) path p_w is $(a_\mathcal{K}, b_\mathcal{K})$-quasigeodesic in $\mathcal{K}$, where $(a_\mathcal{K}, b_\mathcal{K})$ depend on a, b, λ_1', μ_1' and Y.*

Moreover, $\sigma(w)$ is a (λ_G, λ_G)-quasigeodesic over S in the hyperbolic group G, where λ_G, λ_G depend on λ_1, μ_1 and Y.

Proof. Consider the generating set $Z = Y \cup V_{\leqslant 3}$ for V and let λ_Z, μ_Z be such that any (λ_1', μ_1')-quasigeodesic over Y is (λ_Z, μ_Z)-quasigeodesic over Z. Let $M = \max\{l_\mathcal{K}(p_y) \mid y \in Y\}$. That is, M is the maximal length of a generator in Y with respect to the associated reduced path length in $\mathcal{K}$. We will show the statement in the lemma holds for $(a_\mathcal{K}, b_\mathcal{K}) = (a, b + M\mu_Z)$.

We say that a subpath s_w of p_w is a maximal backtrack if $p_w = ps_wp'$, s_w is homotopic to an empty path (via the elimination of backtrackings), and s_w is not contained in a longer subpath of p_w with the same property. This implies there is a point A on p_w such that s_w starts and ends at A, and such a maximal backtrack traces a tree in $\mathcal{K}$. We can then write $p_w = a_1s_1a_2 \dots s_{n-1}a_n$, where a_i are (possibly empty) subpaths of p_w and s_i are maximal backtracks; thus $p_{\pi(w)} = a_1a_2 \dots a_n$. If $l_\mathcal{K}(s_i) \leqslant M\mu_Z$ for all i, then the result follows immediately. Otherwise there exists an s_i with $l_\mathcal{K}(s_i) > M\mu_Z$, and we claim that we can write s_i in terms of a word over Z that is not a quasigeodesic, which contradicts the assumption that w is quasigeodesic.

To prove the claim, suppose $i(s_i) = f(s_i) = A$. We have two cases: in the first case $A \in G$ then $\pi(s_i) =_V 1$ and s_i corresponds to a subword v of w for which $l_{\mathcal{K}}(p_v) \geqslant M\mu_Z$. But v represents a word over Z, so $l_{\mathcal{K}}(p_v) \leqslant l_Z(v)M$, and altogether $M\mu_Z \leqslant l_{\mathcal{K}}(p_v) \leqslant l_Z(v)M$. Since $|v|_Z = 0$ and v is a (λ_Z, μ_Z)-quasigeodesic word over Z^*, $l_Z(v) \leqslant \mu_Z$, which contradicts $l_Z(v) \geqslant \mu_Z$ from above.

In the second case $A \notin G$, so take a point $B \in G$ at distance 1 from A in $\mathcal{K}$ (this can always be done), and modify the word w to get w' over Z so that $p_{w'}$ in $\mathcal{K}$ includes the backtrack $[AB, BA]$ off the path p_w. Also modify s_i to obtain a new backtrack s'_i. Clearly $\pi(p_w) = \pi(p_{w'})$ and $\pi(s_i) = \pi(s'_i)$, and s'_i becomes a maximal backtrack of $p_{w'}$ which can be written as a word over the generators Z that represents the trivial element in V. We can the apply the argument from the first case.

The fact that $\sigma(w)$ is a (λ_G, μ_G)-quasigeodesic over S in the hyperbolic group G follows from the fact that $\mathcal{K}$ and $\Gamma(G, S)$ are quasi-isometric. ◀

Abstract

We introduce a new form of logical relation which, in the spirit of metric relations, allows us to assign each pair of programs a quantity measuring their distance, rather than a boolean value standing for their being equivalent. The novelty of differential logical relations consists in measuring the distance between terms not (necessarily) by a numerical value, but by a mathematical object which somehow reflects the interactive complexity, i.e. the type, of the compared terms. We exemplify this concept in the simply-typed lambda-calculus, and show a form of soundness theorem. We also see how ordinary logical relations and metric relations can be seen as instances of differential logical relations. Finally, we show that differential logical relations can be organised in a cartesian closed category, contrarily to metric relations, which are well-known *not* to have such a structure, but only that of a monoidal closed category.

1 Introduction

Modern software systems tend to be heterogeneous and complex, and this is reflected in the analysis methodologies we use to tame their complexity. Indeed, in many cases the only way to go is to make use of compositional kinds of analysis, in which *parts* of a large system can be analysed in isolation, without having to care about the rest of the system, the *environment*. As an example, one could consider a component A and replace it with another (e.g. more efficient) component B without looking at the context $\mathcal{C}$ in which A and B are supposed to operate, see Figure 1. Of course, for this program transformation to be safe, A should be *equivalent* to B or, at least, B should be a *refinement* of A.

Program equivalences and refinements, indeed, are the cruxes of program semantics, and have been investigated in many different programming paradigms. When programs have an interactive behaviour, like in concurrent or higher-order languages, even *defining* a notion of

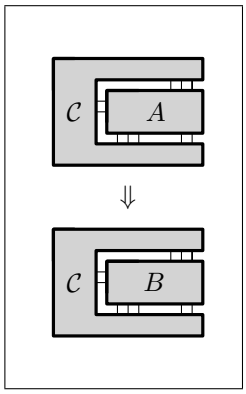

Figure 1 Replacing A with B.

program equivalence is not trivial, while coming out with handy methodologies for *proving* concrete programs to be equivalent can be quite challenging, and has been one of the major research topics in programming language theory, stimulating the development of techniques like logical relations [23, 20], applicative bisimilarity [1], and to some extent denotational semantics [26, 27] itself.

Coming back to our example, may we say anything about the case in which A and B are *not* equivalent, although behaving very similarly? Is there anything classic program semantics can say about this situation? Actually, the answer is negative: the program transformation turning such an A into B cannot be justified, simply because there is no guarantee about what the possible negative effects that turning A into B could have on the overall system formed by $\mathcal{C}$ and A. There are, however, many cases in which program transformations like the one we just described are indeed of interest, and thus desirable. Many examples can be, for instance, drawn from the field of *approximate computing* [21], in which equivalence-breaking program transformations are considered as beneficial *provided* the overall behaviour of the program is not affected too much by the transformation, while its intensional behaviour, e.g. its performance, is significantly improved.

One partial solution to the problem above consists in considering program *metrics* rather than program *equivalences*. This way, any pair of programs are dubbed being at a certain numerical distance rather than being merely equivalent (or not). This, for example, can be useful in the context of differential privacy [24, 6, 32] and has also been studied in the realms of domain theory [13, 5, 14, 16, 4] (see also [28] for an introduction to the subject) and coinduction [30, 29, 15, 9]. The common denominator among all these approaches is that on the one hand, the notion of a congruence, crucial for compositional reasoning, is replaced by the one of a *Lipschitz-continuous* map: any context should not amplify (too much) the distance between any pair of terms, when it is fed with either the former or the latter:

$$\delta(C[M], C[N]) \leq c \cdot \delta(M, N).$$

This enforces compositionality, and naturally leads us to consider metric spaces and Lipschitz functions as the underlying category. As is well known, this is not a cartesian closed category, and thus does *not* form a model of typed λ-calculi, unless one adopts linear type systems, or type systems in which the number of uses of each variable is kept track of, like FUZZ [24]. This somehow limits the compositionality of the metric approach [13, 17].

Even if one considers affine calculi, there are program transformations which are intrinsically unjustifiable in the metric approach. Consider the following two programs of type $REAL \to REAL$

$$M_{SIN} := \lambda x.\mathtt{sin}(x) \qquad M_{ID} := \lambda x.x.$$

The two terms compute two very different functions on the real numbers, namely the sine trigonometric function and the identity on $\mathbb{R}$, respectively. The euclidean distance $|\sin x - x|$ is unbounded when x ranges over $\mathbb{R}$. As a consequence, comparing M_{SIN} and M_{ID} using the so-called sup metric[1] as it is usually done in metric logical relations [24, 13] and applicative distances [17, 10], we see that their distance is infinite, and that the program transformation turning M_{SIN} into M_{ID} cannot be justified this way, for very good reasons. As highlighted by Westbrook and Chaudhuri [31], this is not the end of the story, at least if the environment in which M_{SIN} and M_{ID} operate feed either of them *only with* real numbers close to 0. If this is the case, M_{SIN} can be substituted with M_{ID} without affecting *too much* the overall behaviour of the system.

The key insight by Westbrook and Chaudhuri is that justifying program transformations like the one above requires taking the difference $\delta(M_{SIN}, M_{ID})$ between M_{SIN} and M_{ID} not merely as a number, but as a more structured object. What they suggest is to take $\delta(M_{SIN}, M_{ID})$ as *yet another program*, which however describes the difference between M_{SIN} and M_{ID}:

$$\delta(M_{SIN}, M_{ID}) := \lambda x.\lambda\varepsilon.|\sin x - x| + \varepsilon.$$

This reflects the fact that the distance between M_{SIN} and M_{ID}, namely the discrepancy between their output, depends not only on the discrepancy on the input, namely on ε, but also *on the input itself*, namely on x. It both x and ε are close to 0, $\delta(M_{SIN}, M_{ID})$ is itself close to 0.

In this paper, we develop Westbrook and Chaudhuri's ideas, and turn them into a framework of *differential logical relations*. We will do all this in a simply-typed λ-calculus with real numbers as the only base type. Starting from such a minimal calculus has at least two advantages: on the one hand one can talk about meaningful examples like the one above, and on the other hand the induced metatheory is simple enough to highlight the key concepts.

The contributions of this paper can be summarised as follows:

- After introducing our calculus $ST^{\lambda}_{\mathbb{R}}$, we define differential logical relations inductively on types, as ternary relations between pairs of programs and *differences*. The latter are mere set theoretic entities here, and the nature of differences between terms depends on terms' types.
- We prove a soundness theorem for differential logical relations, which allows us to justify compositional reasoning about terms' differences. We also prove a *finite difference theorem*, which stipulates that the distance between two simply-typed λ-terms is finite if mild conditions hold on the underlying set of function symbols.
- We give embeddings of logical and metric relations into differential logical relations. This witnesses that the latter are a generalisation of the former two.

[1] Recall that given (pseudo)metric spaces (X, d_X), (Y, d_Y) we can give the set Y^X of non-expansive maps between X and Y a (pseudo)metric space structure setting $d_{Y^X}(f, g) = \sup_{x \in X} d_Y(f(x), g(x))$

$$\frac{x:\tau\in\Gamma}{\Gamma\vdash x:\tau}\qquad\frac{}{\Gamma\vdash r:REAL}\qquad\frac{f_n\in\mathcal{F}_n}{\Gamma\vdash f_n:REAL^n\to REAL}\qquad\frac{\Gamma,x:\tau\vdash M:\rho}{\Gamma\vdash\lambda x.M:\tau\to\rho}$$

$$\frac{\Gamma\vdash M:\tau\to\rho\quad\Gamma\vdash N:\tau}{\Gamma\vdash MN:\rho}\qquad\frac{\Gamma\vdash M:\tau\quad\Gamma\vdash N:\rho}{\Gamma\vdash\langle M,N\rangle:\tau\times\rho}\qquad\frac{}{\Gamma\vdash\pi_1:\tau\times\rho\to\tau}\qquad\frac{}{\Gamma\vdash\pi_2:\tau\times\rho\to\rho}$$

$$\frac{\Gamma\vdash M:\tau\quad\Gamma\vdash N:\tau}{\Gamma\vdash \texttt{iflz}\ M\ \texttt{else}\ N:REAL\to\tau}\qquad\frac{\Gamma\vdash M:\tau\to\tau\quad\Gamma\vdash N:\tau}{\Gamma\vdash \texttt{iter}\ M\ \texttt{base}\ N:REAL\to\tau}$$

Figure 2 Typing rules for $ST^{\lambda}_{\mathbb{R}}$.

- Finally, we show that generalised metric domains, the mathematical structure underlying differential logical relations, form a cartesian closed category, contrarily to the category of metric spaces, which is well known not to have the same property.

Due to space constraints, many details have to be omitted, but can be found in an Extended Version of this work [12].

2 A Simply-Typed λ-Calculus with Real Numbers

In this section, we introduce a simply-typed λ-calculus in which the only base type is the one of real numbers, and constructs for iteration and conditional are natively available. The choice of this language as the reference calculus in this paper has been made for the sake of simplicity, allowing us to concentrate on the most crucial aspects, at the same time guaranteeing a minimal expressive power.

Terms and Types

$ST^{\lambda}_{\mathbb{R}}$ is a typed λ-calculus, so its definition starts by giving the language of *types*, which is defined as follows:

$$\tau,\rho ::= REAL \mid \tau\to\rho \mid \tau\times\rho.$$

The expression τ^n stands for $\underbrace{\tau\times\cdots\times\tau}_{n\text{ times}}$. The set of *terms* is defined as follows:

$$M,N ::= x \mid r \mid f_n \mid \lambda x.M \mid MN \mid \langle M,N\rangle \mid \pi_1 \mid \pi_2 \mid \texttt{iflz}\ M\ \texttt{else}\ N \mid \texttt{iter}\ M\ \texttt{base}\ N$$

where x ranges over a set $\mathbb{V}$ of variables, r ranges over the set $\mathbb{R}$ of real numbers, n is a natural number, and f_n ranges over a set $\mathcal{F}_n$ of total real functions of arity n. We do not make any assumption on $\{\mathcal{F}_n\}_{n\in\mathbb{N}}$, apart from the predecessor $pred_1$ being part of $\mathcal{F}_1$. The family, in particular, could in principle contain non-continuous functions. The expression $\langle M_1,\ldots,M_n\rangle$ is simply a shortcut for $\langle\ldots\langle\langle M_1,M_2\rangle,M_3\rangle\ldots,M_n\rangle$. All constructs are self-explanatory, except for the `iflz` and `iter` operators, which are conditional and iterator combinators, respectively. An *environment* Γ is a set of assignments of types to variables in $\mathbb{V}$ where each variable occurs at most once. A *type judgment* has the form $\Gamma\vdash M:\tau$ where Γ is an environment, M is a term, and τ is a type. Rules for deriving correct typing judgments are in Figure 2, and are standard. The set of terms M for which $\cdot\vdash M:\tau$ is derivable is indicated as $CT(\tau)$.

$$\frac{}{V \Downarrow V} \qquad \frac{M \Downarrow f_n \quad N \Downarrow \langle L_1, \ldots, L_n \rangle \quad L_i \Downarrow r_i}{MN \Downarrow f(r_1, \ldots, r_n)} \qquad \frac{M \Downarrow \lambda x.L \quad N \Downarrow V \quad L\{V/x\} \Downarrow W}{MN \Downarrow W}$$

$$\frac{M \Downarrow \pi_1 \quad N \Downarrow \langle L, P \rangle \quad L \Downarrow V}{MN \Downarrow V} \qquad \frac{M \Downarrow \pi_2 \quad N \Downarrow \langle L, P \rangle \quad P \Downarrow V}{MN \Downarrow V}$$

$$\frac{M \Downarrow \texttt{iflz}\ L\ \texttt{else}\ P \quad N \Downarrow r \quad r < 0 \quad L \Downarrow V}{MN \Downarrow V} \qquad \frac{M \Downarrow \texttt{iflz}\ L\ \texttt{else}\ P \quad N \Downarrow r \quad r \geq 0 \quad P \Downarrow V}{MN \Downarrow V}$$

$$\frac{M \Downarrow \texttt{iter}\ L\ \texttt{base}\ P \quad N \Downarrow r \quad r < 0 \quad P \Downarrow V}{MN \Downarrow V}$$

$$\frac{M \Downarrow \texttt{iter}\ L\ \texttt{base}\ P \quad N \Downarrow r \quad r \geq 0 \quad L((\texttt{iter}\ L\ \texttt{base}\ P)(pred_1(r))) \Downarrow V}{MN \Downarrow V}$$

Figure 3 Operational semantics for $ST^{\lambda}_{\mathbb{R}}$.

Call-by-Value Operational Semantics

A static semantics is of course not enough to give meaning to a paradigmatic programming language, the dynamic aspects being captured only once an *operational* semantics is defined. The latter turns out to be very natural. *Values* are defined as follows:

$$V, W ::= r \mid f_n \mid \lambda x.M \mid \langle M, N \rangle \mid \pi_1 \mid \pi_2 \mid \texttt{iflz}\ M\ \texttt{else}\ N \mid \texttt{iter}\ M\ \texttt{base}\ N$$

The set of closed values of type τ is $CV(\tau) \subseteq CT(\tau)$, and the evaluation of $M \in CT(\tau)$ produces a value $V \in CV(\tau)$, as formalised by the rules in Figure 3, through the judgment $M \Downarrow V$. We write $M \Downarrow$ if $M \Downarrow V$ is derivable *for some* V. The absence of full recursion has the nice consequence of guaranteeing a form of termination:

▶ **Theorem 1.** *The calculus $ST^{\lambda}_{\mathbb{R}}$ is terminating: if $\cdot \vdash M : \tau$ then $M \Downarrow$.*

Theorem 1 can be proved by way of a standard reducibility argument. Termination implies the following.

▶ **Corollary 2.** *If $\cdot \vdash M : REAL$ then there exists a unique $r \in \mathbb{R}$ satisfying $M \Downarrow r$, which we indicate as $NF(M)$.*

Context Equivalence

A *context* C is nothing more than a term containing a single occurrence of a placeholder $[\cdot]$. Given a context C, $C[M]$ indicates the term one obtains by substituting M for the occurrence of $[\cdot]$ in C. Typing rules in Figure 2 can be lifted to contexts by generalising judgments to the form $\Gamma \vdash C[\Delta \vdash \cdot : \tau] : \rho$, by which one captures that whenever $\Delta \vdash M : \tau$, it holds that $\Gamma \vdash C[M] : \rho$. Two terms M and N such that $\Gamma \vdash M, N : \tau$ are said to be *context equivalent* [22] if for every C such that $\emptyset \vdash C[\Gamma \vdash \cdot : \tau] : REAL$ it holds that $NF(C[M]) = NF(C[N])$. Context equivalence is the largest adequate congruence, and is thus considered as the coarsest "reasonable" equivalence between terms. It can also be turned into a pseudometric [11, 10] – called *context distance* – by stipulating that

$$\delta(M, N) = \sup_{\emptyset \vdash C[\Gamma \vdash \cdot : \tau] : REAL} |NF(C[M]) - NF(C[M])|.$$

The obtained notion of distance, however, is bound to trivialise [11], given that $ST^{\lambda}_{\mathbb{R}}$ is not affine. Trivialisation of context distance highlights an important limit of the metric approach to program difference which, ultimately, can be identified with the fact that program distances

are sensitive to interactions with the environment. Our notion of a differential logical relation tackles such a problem from a different perspective, namely refining the concept of program distance to something which is not just a number, but is now able to take into account interactions with the environment.

Set-Theoretic Semantics

Before introducing differential logical relations, it is useful to remark that we can give $ST^{\lambda}_{\mathbb{R}}$ a standard set-theoretic semantics. To any type τ we associate the set $[\![\tau]\!]$, the latter being defined by induction on the structure of τ as follows:

$$[\![REAL]\!] = \mathbb{R}; \qquad [\![\tau \to \rho]\!] = [\![\tau]\!] \to [\![\rho]\!]; \qquad [\![\tau \times \rho]\!] = [\![\tau]\!] \times [\![\rho]\!].$$

This way, any closed term $M \in CT(\tau)$ is interpreted as an element $[\![M]\!]$ of $[\![\tau]\!]$ in a natural way (see, e.g. [20]). Up to now, everything we have said about $ST^{\lambda}_{\mathbb{R}}$ is absolutely standard, and only serves to set the stage for the next sections.

3 Making Logical Relations Differential

Logical relations can be seen as one of the *many* ways of defining when two programs are to be considered equivalent. Their definition is type driven, i.e., they can be seen as a *family* $\{\delta_\tau\}_\tau$ of binary relations indexed by types such that $\delta_\tau \subseteq CT(\tau) \times CT(\tau)$. This section is devoted to showing how all this can be made into differential logical relations.

The first thing that needs to be discussed is how to define the space of *differences* between programs. These are just boolean values in logical relations, become real numbers in ordinary metrics, and is type-dependent itself. A function $(\!|\cdot|\!)$ that assigns a set to each type is defined as follows:

$$(\!|REAL|\!) = \mathbb{R}^{\infty}_{\geq 0}; \qquad (\!|\tau \to \rho|\!) = [\![\tau]\!] \times (\!|\tau|\!) \to (\!|\rho|\!); \qquad (\!|\tau \times \rho|\!) = (\!|\tau|\!) \times (\!|\rho|\!);$$

where $\mathbb{R}^{\infty}_{\geq 0} = \mathbb{R}_{\geq 0} \cup \{\infty\}$. The set $(\!|\tau|\!)$ is said to be the *difference space* for the type τ and is meant to model the outcome of comparisons between closed programs of type τ. As an example, when τ is $REAL \to REAL$, we have that $(\!|\tau|\!) = \mathbb{R} \times \mathbb{R}^{\infty}_{\geq 0} \to \mathbb{R}^{\infty}_{\geq 0}$. This is the type of the function $\delta(M, N)$ we used to compare the two programs described in the Introduction.

Now, which structure could we endow $(\!|\tau|\!)$ with? First of all, we can define a partial order $\leq_\tau$ over $(\!|\tau|\!)$ for each type τ as follows:

$$\begin{array}{ll} r \leq_{REAL} s & \text{if } r \leq s \text{ as the usual order over } \mathbb{R}^{\infty}_{\geq 0}; \\ f \leq_{\tau\to\rho} g & \text{if } \forall x \in [\![\tau]\!].\forall t \in (\!|\tau|\!).f(x,t) \leq_\rho g(x,t); \\ (t,u) \leq_{\tau\times\rho} (s,r) & \text{if } t \leq_\tau s \text{ and } u \leq_\rho r. \end{array}$$

This order has least upper bounds and greater lower bounds, thanks to the nice structure of $\mathbb{R}^{\infty}_{\geq 0}$:

▶ **Proposition 3.** *For each type τ, $((\!|\tau|\!), \leq_\tau)$ forms a complete lattice.*

The fact that $(\!|\tau|\!)$ has a nice order-theoretic structure is not the end of the story. For every type τ, we define a binary operation $*_\tau$ as follows:

$$\begin{array}{ll} r *_{REAL} s = r + s \text{ if } r, s \in \mathbb{R}_{\geq 0}; & (f *_{\tau\to\rho} g)(V,t) = f(V,t) *_\rho g(V,t); \\ r *_{REAL} s = \infty \text{ if } r = \infty \vee s = \infty; & (t,s) *_{\tau\times\rho} (u,r) = (t *_\tau u, s *_\rho r). \end{array}$$

This is precisely what it is needed to turn $(\!|\tau|\!)$ into a *quantale*[2] [25].

▶ **Proposition 4.** *For each type τ, $(\!|\tau|\!)$ forms a commutative unital non-idempotent quantale.*

The fact that $(\!|\tau|\!)$ is a quantale means that it has, e.g., the right structure to be the codomain of generalised metrics [19, 18]. Actually, a more general structure is needed for our purposes, namely the one of a generalised metric domain, which will be thoroughly discussed in Section 6 below. For the moment, let us concentrate our attention to programs:

▶ **Definition 5** (Differential Logical Relations). *We define a* differential logical relation $\{\delta_\tau \subseteq \Lambda_\tau \times (\!|\tau|\!) \times \Lambda_\tau\}_\tau$ *as a set of ternary relations indexed by types satisfying*

$$\begin{aligned}
\delta_{REAL}(M, r, N) &\Leftrightarrow |NF(M) - NF(N)| \leq r;\\
\delta_{\tau\times\rho}(M, (d_1, d_2), N) &\Leftrightarrow \delta_\tau(\pi_1 M, d_1, \pi_1 N) \wedge \delta_\rho(\pi_2 M, d_2, \pi_2 N)\\
\delta_{\tau\to\rho}(M, d, N) &\Leftrightarrow (\forall V \in CV(\tau).\ \forall x \in (\!|\tau|\!).\ \forall W \in CV(\tau).\\
&\qquad \delta_\tau(V, x, W) \Rightarrow \delta_\rho(MV, d([\![V]\!], x), NW) \wedge \delta_\rho(MW, d([\![V]\!], x), NV)).
\end{aligned}$$

An intuition behind the condition required for $\delta_{\tau\to\rho}(M, d, N)$ is that $d([\![V]\!], x)$ overapproximates both the "distance" between MV and NW and the one between MW and NV, this *whenever* W is within the error x from V.

3.1 A Fundamental Lemma

Usually, the main result about any system of logical relations is the so-called *Fundamental Lemma*, which states that any typable term is in relation *with itself*. But how would the Fundamental Lemma look like here? Should any term be at *somehow minimal distance* to itself, in the spirit of what happens, e.g. with metrics [24, 13]? Actually, there is no hope to prove anything like that for differential logical relations, as the following example shows.

▶ **Example 6.** Consider again the term $M_{ID} = \lambda x.x$, which can be given type $\tau = REAL \to REAL$ in the empty context. Please recall that $(\!|\tau|\!) = \mathbb{R} \times \mathbb{R}^\infty_{\geq 0} \to \mathbb{R}^\infty_{\geq 0}$. Could we prove that $\delta_\tau(M_{ID}, 0_\tau, M_{ID})$, where 0_τ is the constant-0 function? The answer is negative: given two real numbers r and s at distance ε, the terms $M_{ID}r$ and $M_{ID}s$ are themselves ε apart, thus at nonnull distance. The best one can say, then, is that $\delta_\tau(M_{ID}, f, M_{ID})$, where $f(x, \varepsilon) = \varepsilon$.

As the previous example suggests, a term M being at self-distance d is a witness of M being *sensitive to changes* to the environment according to d. Indeed, the only terms which are at self-distance 0 are the constant functions. This makes the underlying theory more general than the one of logical or metric relations, although the latter can be proved to be captured by differential logical relations, as we will see in the next section.

Coming back to the question with which we opened the section, we can formulate a suitable fundamental lemma for differential logical relations.

▶ **Theorem 7** (Fundamental Lemma, Version I). *For every $\cdot \vdash M : \tau$ there is a $d \in (\!|\tau|\!)$ such that $(M, d, M) \in \delta_\tau$.*

Proof sketch. The proof proceeds, as usual, by induction on the derivation of $\cdot \vdash M : \tau$. In order to deal with e.g. λ-abstractions we have to strengthen our statement taking into account *open* terms. This turns out to be non-trivial and requires to extend our notion of

[2] Recall that a quantale $\mathbb{Q} = (Q, \leq_Q, 0_Q, *_Q)$ consists of a complete lattice $(Q, \leq_Q)$ and a monoid $(Q, 0_Q, *_Q)$ such that the lattice and monoid structures properly interact (meaning that monoid multiplication distributes over joins). We refer to [25, 18] for details.

a differential logical relation to arbitrary terms. First of all, we need to generalise $(\!|\cdot|\!)$ and $[\![\cdot]\!]$ to environments. For instance, $(\!|\Gamma|\!)$ is the set of families in the form $\alpha = \{\alpha_x\}_{(x:\rho)\in\Gamma}$, where $\alpha_x \in (\!|\rho|\!)$. Similarly for $[\![\Gamma]\!]$. This way, a natural space for differences between terms $\Gamma \vdash M, N : \tau$ can be taken as $(\!|\tau|\!)^{[\![\Gamma]\!]\times(\!|\Gamma|\!)}$, namely the set of maps from $[\![\Gamma]\!] \times (\!|\Gamma|\!)$ to $(\!|\tau|\!)$. Given an environment Γ, a family $\mathbf{V} = \{V_x\}_{(x:\rho_x)\in\Gamma}$ such that $V_x \in CV(\rho_x)$ is said to be a Γ-*family of values*. Such a Γ-family of values can naturally be seen as a substitution $\mathbf{V}$ mapping each variable $(x : \rho) \in \Gamma$ to $V_x \in CV(\rho_x)$. As it is customary, for a term $\Gamma \vdash M : \tau$ we write $M\mathbf{V}$ for the closed term of type τ obtained applying the substitution $\mathbf{V}$ to M. We denote by $CV(\Gamma)$ the set of all Γ-family of values. Given a set Z, an environment Γ, and two Γ-indexed families $\alpha = \{\alpha_x\}_{(x:\rho)\in\Gamma}$, $\beta = \{\beta_x\}_{(x:\rho)\in\Gamma}$ over Z (meaning that e.g. $\alpha_x \in Z$, for each $(x : \rho) \in \Gamma$), we introduce the following notational convention. For a Γ-indexed family $B = \{b_x\}_{(x:\rho)\in\Gamma}$ such that $b_x \in \{0, 1\}$, we can construct a "choice" Γ-indexed family B^α_β as follows:

$$(B^\alpha_\beta)_x = \begin{cases} \alpha_x & \text{if } b_x = 0 \\ \beta_x & \text{if } b_x = 1. \end{cases}$$

Moreover, given a family B as above, we can construct the *inverse* family $\overline{B}$ as the family $\{1 - b_x\}_{(x:\rho)\in\Gamma}$. We can now talk about *open terms*, and from a differential logical relation $\{\delta_\tau \subseteq \Lambda_\tau \times (\!|\tau|\!) \times \Lambda_\tau\}_\tau$ construct a family of relations $\{\delta^\Gamma_\tau \subseteq \Lambda^\Gamma_\tau \times (\!|\tau|\!)^{[\![\Gamma]\!]\times(\!|\Gamma|\!)} \times \Lambda^\Gamma_\tau\}_{\tau,\Gamma}$ by stipulating that $\delta^\Gamma_\tau(M, d, N)$ iff

$$\delta_\Gamma(\mathbf{V}, Y, \mathbf{W}) \Longrightarrow \forall B \in \{0, 1\}^\Gamma.\delta_\tau(MB^{\mathbf{V}}_{\mathbf{W}}, d([\![\mathbf{V}]\!], Y), N\overline{B}^{\mathbf{V}}_{\mathbf{W}}).$$

We now prove the following strengthening of our main thesis: for any term $\Gamma \vdash M : \tau$, there is a $d \in (\!|\tau|\!)^{[\![\Gamma]\!]\times(\!|\Gamma|\!)}$ such that $\delta^\Gamma_\tau(M, d, M)$. At this point the proof is rather standard, and proceeds by induction on the derivation of $\Gamma \vdash M : \tau$. ◀

But what do we gain from Theorem 7? In the classic theory of logical relations, the Fundamental Lemma has, as an easy corollary, that logical relations are compatible: it suffices to invoke the theorem with any context C *seen as a term* $C[x]$, such that $x : \tau, \Gamma \vdash C[x] : \rho$. Thus, ultimately, logical relations are proved to be a *compositional* methodology for program equivalence, in the following sense: if M and N are equivalent, then $C[M]$ and $C[N]$ are equivalent, too.

In the realm of differential logical relations, the Fundamental Lemma plays a similar role, although with a different, *quantitative* flavor: once C has been proved sensitive to changes according to d, and V, W are proved to be at distance e, then, e.g., the impact of substituting V with W in C can be measured by composing d and e (and $[\![V]\!]$), i.e. by computing $d([\![V]\!], e)$. Notice that the sensitivity analysis on C and the relational analysis on V and W are decoupled. What the Fundamental Lemma tells you is that d can *always* be found.

3.2 Our Running Example, Revisited

It is now time to revisit the example we talked about in the Introduction. Consider the following two programs, both closed and of type $REAL \to REAL$:

$$M_{SIN} = \lambda x.sin_1(x); \qquad M_{ID} = \lambda x.x.$$

First of all, let us observe that, as already remarked, comparing M_{SIN} and M_{ID} using the sup metric on $\mathbb{R} \to \mathbb{R}$, as it is done in metric logical relations and applicative distances, naturally assigns them distance ∞, the euclidean distance $|x - sin(x)|$ being unbounded when x ranges over $\mathbb{R}$.

Let us now prove that $(M_{SIN}, f, M_{ID}) \in \delta_{REAL \to REAL}$, where $f(x,y) = y + |x - \sin x|$. Consider any pair of real numbers $r, s \in \mathbb{R}$ such that $|r - s| \leq \varepsilon$, where $\varepsilon \in \mathbb{R}^{\infty}_{\geq 0}$. We have that:

$$\begin{aligned} |\sin r - s| &= |\sin r - r + r - s| \leq |\sin r - r| + |r - s| \leq |\sin r - r| + \varepsilon = f(r, \varepsilon) \\ |\sin s - r| &= |\sin s - \sin r + \sin r - r| \leq |\sin s - \sin r| + |\sin r - r| \leq |s - r| + |\sin r - r| \\ &\leq \varepsilon + |\sin r - r| = f(r, \varepsilon). \end{aligned}$$

The fact that $|\sin s - \sin r| \leq |s - r|$ is a consequence of sin being 1-Lipschitz continuous (see, e.g., [12] for a simple proof).

Now, consider a context C which makes use of either M_{SIN} or M_{ID} by feeding them with a value close to 0, call it θ. Such a context could be, e.g., $C = (\lambda x.x(x\theta))[\cdot]$. C can be seen as a term having type $\tau = (REAL \to REAL) \to REAL$. A self-distance d for C can thus be defined as an element of

$$(\!|\tau|\!) = [\![REAL \to REAL]\!] \times (\!|REAL \to REAL|\!) \to \mathbb{R}^{\infty}_{\geq 0}.$$

namely $F = \lambda\!\!\lambda \langle g, h \rangle . h(g(\theta), h(\theta, 0))$. This allows for compositional reasoning about program distances: the overall impact of replacing M_{SIN} by M_{ID} can be evaluated by computing $F([\![M_{SIN}]\!], f)$. Of course the context C needs to be taken into account, but *once and for all*: the functional F can be built without knowing with which term(s) it will be fed with.

4 Logical and Metric Relations as DLRs

The previous section should have convinced the reader about the peculiar characteristics of differential logical relations compared to (standard) metric and logical relations. In this section we show that despite the apparent differences, logical and metric relations can somehow be retrieved as specific kinds of program differences. This is, however, bound to be nontrivial. The naïve attempt, namely seeing program equivalence as being captured by *minimal* distances in logical relations, fails: the distance between a program *and itself* can be nonnull.

How should we proceed, then? Isolating those distances which witness program equivalence is indeed possible, but requires a bit of an effort. In particular, the sets of those distances can be, again, defined by induction on τ. For every τ, we give $(\!|\tau|\!)^0 \subseteq (\!|\tau|\!)$ by induction on the structure of τ:

$$(\!|REAL|\!)^0 = \{0\}; \qquad (\!|\tau \times \rho|\!)^0 = (\!|\tau|\!)^0 \times (\!|\rho|\!)^0;$$

$$(\!|\tau \to \rho|\!)^0 = \{f \in (\!|\tau \to \rho|\!) \mid \forall x \in [\![\tau]\!] . \forall y \in (\!|\tau|\!)^0 . f(x,y) \in (\!|\rho|\!)^0\}.$$

Notice that $(\!|\tau \to \rho|\!)^0$ is not defined as $[\![\tau]\!] \times (\!|\tau|\!)^0 \to (\!|\rho|\!)^0$ (doing so would violate $(\!|\tau \to \rho|\!)^0 \subseteq (\!|\tau \to \rho|\!)$). The following requires some effort, and testifies that, indeed, program equivalence in the sense of logical relations precisely corresponds to being at a distance in $(\!|\tau|\!)^0$:

▶ **Theorem 8.** *Let $\{\mathcal{L}_\tau\}_\tau$ be a logical relation. There exists a differential logical relation $\{\delta_\tau\}_\tau$ satisfying $\mathcal{L}_\tau(M,N) \iff \exists d \in (\!|\tau|\!)^0 . \delta_\tau(M, d, N)$.*

What if we want to generalise the argument above to metric relations, as introduced, e.g., by Reed and Pierce [24]? The set $(\!|\tau|\!)^0$ becomes a set of distances parametrised by a single real number:

$$(\!|REAL|\!)^r = \{r\}; \qquad (\!|\tau \times \rho|\!)^r = (\!|\tau|\!)^r \times (\!|\rho|\!)^r;$$

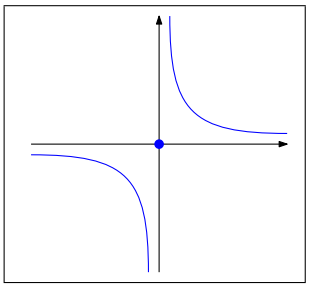

Figure 4 A total, but highly discontinuous, function.

$$(\!|\tau \to \rho|\!)^r = \{f \in (\!|\tau \to \rho|\!) \mid \forall x \in [\![\tau]\!].\forall y \in (\!|\tau|\!)^s.f(x,y) \in (\!|\rho|\!)^{r+s}\}.$$

A result similar to Theorem 8 is unfortunately outside the scope of this paper, but can be found in the Extended Version [12]. In particular, metric relations are only available in calculi, like FUZZ [24], which rely on *linear* type systems, thus more refined than the one we endow $ST^{\lambda}_{\mathbb{R}}$ with.

5 Strengthening the Fundamental Theorem through Finite Distances

Let us now ask ourselves the following question: given any term $M \in CT(\tau)$, what can we say about its sensitivity, i.e., about the values $d \in (\!|\tau|\!)$ such that $\delta_\tau(M,d,M)$? Two of the results we have proved about $ST^{\lambda}_{\mathbb{R}}$ indeed give partial answers to the aforementioned question. On the one hand, Theorem 7 states that such a d can *always* be found. On the other hand, Theorem 8 tells us that such a d can be taken in $(\!|\tau|\!)^0$. Both these answers are not particularly informative, however. The mere existence of such a $d \in (\!|\tau|\!)$, for example, is trivial since d can always be taken as d_∞, the maximal element of the underlying quantale. The fact that such a d can be taken from $(\!|\tau|\!)^0$ tells us that, e.g. when $\tau = \rho \to \xi$, M returns equivalent terms when fed with equivalent arguments: there is no quantitative guarantee about the behaviour of the term when fed with non-equivalent arguments.

Is this the best one can get about the sensitivity of $ST^{\lambda}_{\mathbb{R}}$ terms? The absence of full recursion suggests that we could hope to prove that infinite distances, although part of the underlying quantale, can in fact be useless. In other words, we are implicitly suggesting that self-distances could be elements of $(\!|\tau|\!)^{<\infty} \subset (\!|\tau|\!)$, defined as follows:

$$(\!|REAL|\!)^{<\infty} = \mathbb{R}_{\geq 0}; \qquad (\!|\tau \times \rho|\!)^{<\infty} = (\!|\tau|\!)^{<\infty} \times (\!|\rho|\!)^{<\infty};$$

$$(\!|\tau \to \rho|\!)^{<\infty} = \{f \in (\!|\tau \to \rho|\!) \mid \forall x \in [\![\tau]\!].\forall t \in (\!|\tau|\!)^{<\infty}.f(x,t) \in (\!|\rho|\!)^{<\infty}\}.$$

Please observe that $(\!|\tau|\!)^{<\infty}$ is in general a much larger set of differences than $\bigcup_{r \in \mathbb{R}^{\infty}_{\geq 0}} (\!|\tau|\!)^r$: the former equals the latter only when τ is $REAL$. Already when τ is $REAL \to REAL$, the former includes, say, functions like $f(r,\varepsilon) = (r+\varepsilon)^2$, while the latter does not.

Unfortunately, there are terms in $ST^{\lambda}_{\mathbb{R}}$ which cannot be proved to be at self-distance in $(\!|\tau|\!)^{<\infty}$, and, surprisingly, this is *not* due to the higher-order features of $ST^{\lambda}_{\mathbb{R}}$, but to $\{\mathcal{F}_n\}_{n\in\mathbb{N}}$ being arbitrary, and containing functions which do not map finite distances to finite distances, like

$$h(r) = \begin{cases} 0 & \text{if } r = 0 \\ \frac{1}{r} & \text{otherwise} \end{cases}$$

(see Figure 4). Is this phenomenon *solely* responsible for the necessity of finite self-distances in $ST^{\lambda}_{\mathbb{R}}$? The answer is positive, and the rest of this section is devoted precisely to formalising and proving the aforementioned conjecture.

First of all, we need to appropriately axiomatise the absence of unbounded discontinuities from $\{\mathcal{F}_n\}_{n\in\mathbb{N}}$. A not-so-restrictive but sufficient axiom turns out to be weak boundedness: a function $f_n : \mathbb{R}^n \to \mathbb{R}$ is said to be *weakly bounded* if and only if it maps bounded subsets of $\mathbb{R}^n$ into bounded subsets of $\mathbb{R}$. As an example, the function h above is *not* weakly bounded, because $h([-\varepsilon, \varepsilon])$ is

$$\left(-\infty, -\frac{1}{\varepsilon}\right] \cup \{0\} \cup \left[\frac{1}{\varepsilon}, \infty\right)$$

which is unbounded for any as $\varepsilon > 0$. Any term M is said to be weakly bounded iff any function symbol f_n occurring in M is itself weakly bounded. Actually, this is precisely what one needs to get the strengthening of the Fundamental Theorem we are looking for.

▶ **Theorem 9** (Fundamental Theorem, Version II). *For any weakly bounded term $\cdot \vdash M : \tau$, there is $d \in (\!|\tau|\!)^{<\infty}$ such that $(M, d, M) \in \delta_\tau$.*

The reader may have wondered about how restrictive a condition weak boundedness really is. In particular, whether it corresponds to some form of continuity. In fact, the introduced condition only rules out unbounded discontinuities. In other words, weak boundedness can be equivalently defined by imposing local boundedness *at any point* in the domain $\mathbb{R}$. This is weaker than asking for boundedness, which requires the existence of a global bound.

6 A Categorical Perspective

Up to now, differential logical relations have been treated very concretely, without looking at them through the lens of category theory. This is in contrast to, e.g., the treatment of metric relations from [13], in which soundness of metric relations for FUZZ is obtained as a byproduct of a proof of symmetric monoidal closedness for the category **MET** of pseudometric spaces and Lipschitz functions.

But what could take the place of pseudometric spaces in a categorical framework capturing differential logical relations? The notion of a metric needs to be relaxed along at least two axes. On the one hand, the codomain of the "metric" δ is not necessarily the set of real numbers, but a more general structure, namely a quantale. On the other, as we already noticed, it is not necessarily true that equality implies indistancy, but rather than indistancy implies inequality. What comes out of these observations is, quite naturally, the notion of a generalized metric domain, itself a generalisation of partial metrics [7]. The rest of this section is devoted to proving that the category of generalised metric domains is indeed cartesian closed, thus forming a model of simply typed λ-calculi.

Formally, given a quantale $\mathbb{Q} = (Q, \leq_Q, 0_Q, *_Q)$[3], a *generalised metric domain* on $\mathbb{Q}$ is a pair (A, δ_A), where A is a set and δ_A is a subset of $A \times \mathbb{Q} \times A$ satisfying some axioms akin to those of a metric domain:

$$\begin{aligned}
\delta_A(x, 0_Q, y) &\Rightarrow x = y; && \text{(Indistancy Implies Equality)}\\
\delta_A(x, d, y) &\Rightarrow \delta_A(y, d, x); && \text{(Symmetry)}\\
\delta_A(x, d, y) \wedge \delta_A(y, e, y) \wedge \delta_A(y, f, z) &\Rightarrow \delta_A(x, d * e * f, z). && \text{(Triangularity)}
\end{aligned}$$

[3] When unambiguous, we will omit subscripts in $\leq_Q$, 0_Q, and $*_Q$.

Please observe that δ_A is a *relation* rather than a function. Moreover, the first axiom is dual to the one typically found in, say, pseudometrics. The third axiom, instead, resembles the usual triangle inequality for pseudometrics, but with the crucial difference that since objects can have non-null self-distance, such a distance has to be taken into account. Requiring equality to imply indistancy (and thus $\delta_A(x, 0_Q, y) \Leftrightarrow x = y$), we see that (Triangularity) gives exactly the usual triangle inequality (properly generalised to quantale and relations [18, 19]).

In this section we show that generalised metric domains form a cartesian closed category, unlike that of metric spaces (which is known to be non-cartesian closed). As a consequence, we obtain a firm categorical basis of differential logical relations. The category of generalised metric domain, denoted by **GMD**, is defined as follows.

▶ **Definition 10.** *The category* **GMD** *has the following data.*

- *An object $\mathcal{A}$ is a triple $(A, \mathbb{Q}, \delta)$ where $\mathbb{Q}$ is a quantale and (A, δ) is a generalized metric domain on $\mathbb{Q}$.*
- *An arrow $(A, \mathbb{Q}, \delta) \to (B, \mathbb{S}, \rho)$ is a pair (f, ζ) consisting of a function $f \colon A \to B$ and another function $\zeta \colon Q \times A \to S$ satisfying $\forall a, a' \in A. \forall q \in Q. \delta(a, q, a') \Rightarrow \rho(f(a), \zeta(q, a), f(a'))$ and $\rho(f(a), \zeta(q, a'), f(a'))$.*

We can indeed give **GMD** the structure of a category. In fact, the identity on the object $\mathcal{A} = (A, \mathbb{Q}, \delta)$ in **GMD** is given by $(\mathrm{id}_{\mathcal{A}}, \mathrm{id}'_{\mathcal{A}})$ where $\mathrm{id}_{\mathcal{A}} \colon A \to A$ is the set-theoretic identity on A and $\mathrm{id}'_{\mathcal{A}} \colon Q \times A \to Q$ is defined by $\mathrm{id}'_{\mathcal{A}}(q, a) = q$. The composition of two arrows $(f, \zeta) \colon (A, \mathbb{Q}, \delta) \to (B, \mathbb{S}, \rho)$ and $(g, \eta) \colon (B, \mathbb{S}, \rho) \to (C, \mathbb{T}, \nu)$ is the pair (h, θ) where $h \colon A \to C$ is given by the function composition $g \circ f \colon A \to C$ and $h \colon Q \times A \to T$ is given by $\theta(q, a) = \eta(\zeta(q, a), f(a))$. Straightforward calculations show that composition is associative, and that the identity arrow behaves as its neutral element.

Most importantly, we can give **GMD** a cartesian closed structure, as shown by the following result[4].

▶ **Theorem 11.** **GMD** *is a cartesian closed category.*

Proof sketch. Before entering details, it is useful to remark that the cartesian product of two quantales is itself a quantale (with lattice and monoid structure defined pointwise). Similarly, for any quantale $\mathbb{Q}$ and set X, the function space $\mathbb{Q}^X$ inherits a quantale structure from $\mathbb{Q}$ pointwise. Let us now show that **GMD** is cartesian closed. We begin showing that **GMD** has a terminal object and binary products. The former is defined as $(\{*\}, \mathbb{O}, \delta_0)$, where $\mathbb{O}$ is the one-element quantale $\{0\}$, and $\delta_0 = \{(*, 0, *)\}$ (notice that $(\{*\}, \delta_0)$ is a generalized metric domain on $\mathbb{O}$), whereas the binary product $\mathcal{A} \times \mathcal{B}$ of two objects $\mathcal{A}$ and $\mathcal{B}$ in **GMD** is given by a triple $(A \times B, \mathbb{Q} \times \mathbb{S}, \delta \times \rho)$. Finally, we define exponentials in **GMD**. Given $\mathcal{C}$, $\mathcal{B}$ in **GMD**, their exponential $\mathcal{C}^{\mathcal{B}}$ is the triple $(C^B, \mathbb{T}^{\mathbb{S} \times B}, \nu^{\rho})$, where C^B is the function space $\{f \mid f \colon B \to C\}$, $\mathbb{T}^{\mathbb{S} \times B}$ is the exponential quantale, and ν^{ρ} is a ternary relation over $C^B \times T^{S \times B} \times C^B$ defined by: if $\rho(b, s, b')$ then $\nu(f(b), d(s, b), f'(b'))$ and $\nu(f(b), d(s, b'), \zeta(b'))$. Please notice that the relation ν^{ρ} is indeed a differential logical relation. ◀

Interestingly, the constructions of product and exponential objects in the proof of Theorem 11 closely match the definition of a differential logical relation. In other words, differential logical relations as given in Definition 5 can be seen as providing a denotational model of $ST^{\lambda}_{\mathbb{R}}$ in which base types are interpreted by the generalised metric domain corresponding to the Euclidean distance.

[4] See [12] for a detailed proof.

7 Conclusion

In this paper, we introduced differential logical relations as a novel methodology to evaluate the "distance" between programs of higher-order calculi akin to the λ-calculus. We have been strongly inspired by some unpublished work by Westbrook and Chaudhuri [31], who were the first to realise that evaluating differences between interactive programs requires going beyond mere real numbers. We indeed borrowed our running example from the aforementioned work.

This paper's contribution, then consists in giving a simple definition of differential logical relations, together with some results about their underlying metatheory: two formulations of the Fundamental Lemma, a result relating differential logical relations and ordinary logical relations, and a proof that generalised metric domains – the metric structure corresponding to differential logical relations – form a cartesian closed category. Such results give evidence that, besides being *more expressive* than metric relations, differential logical relations are somehow *more canonical*, naturally forming a model of simply-typed λ-calculi.

As the title of this paper suggests, we see the contributions above just as a very first step towards understanding the nature of differences in a logical environment. In particular, at least two directions deserve to be further explored.

- The first one concerns *language features*: admittedly, the calculus $ST^{\lambda}_{\mathbb{R}}$ we consider here is very poor in terms of its expressive power, lacking full higher-order recursion and thus not being universal. Moreover, $ST^{\lambda}_{\mathbb{R}}$ does not feature any form of effect, including probabilistic choices, in which evaluating differences between programs would be very helpful. Addressing such issues seems to require to impose a domain structure on generalised metric domains, on one hand, and to look at monads on **GMD**, on the other hand (for the latter, the literature on monadic lifting for quantale-valued relations might serve as a guide [18]).
- The second one is about *abstract differences*: defining differences as functions with *the same rank* as that of the compared programs implies that reasoning about them is complex. Abstracting differences so as to facilitate differential reasoning could be the way out, given that deep connections exist between logical relations and abstract interpretation [2]. Another way to understand program difference better is to investigate whether differential logical relations can be related to abstract structures for differentiation, as in [3]. Indeed, Example 6 suggests that an interesting distance between a program and itself can be taken as its derivative, the latter being defined as in [8].

Abstract

Invertible map equivalences are approximations of graph isomorphism that refine the well-known Weisfeiler-Leman method. They are parameterized by a number k and a set Q of primes. The intuition is that two equivalent graphs $G \equiv^{\mathrm{IM}}_{k,Q} H$ cannot be distinguished by means of partitioning the set of k-tuples in both graphs with respect to *any* linear-algebraic operator acting on vector spaces over fields of characteristic p, for any $p \in Q$. These equivalences have first appeared in the study of rank logic, but in fact they can be used to delimit the expressive power of any extension of fixed-point logic with linear-algebraic operators. We define $\mathrm{LA}^k(Q)$, an infinitary logic with k variables and all linear-algebraic operators over finite vector spaces of characteristic $p \in Q$ and show that $\equiv^{\mathrm{IM}}_{k,Q}$ is the natural notion of elementary equivalence for this logic. The logic $\mathrm{LA}^\omega(Q) = \bigcup_{k\in\omega} \mathrm{LA}^k(Q)$ is then a natural upper bound on the expressive power of any extension of fixed-point logics by means of Q-linear-algebraic operators.

By means of a new and much deeper algebraic analysis of a generalized variant, for any prime p, of the CFI-structures due to Cai, Fürer, and Immerman, we prove that, as long as Q is not the set of *all* primes, there is no k such that $\equiv^{\mathrm{IM}}_{k,Q}$ is the same as isomorphism. It follows that there are polynomial-time properties of graphs which are not definable in $\mathrm{LA}^\omega(Q)$, which implies that no extension of fixed-point logic with linear-algebraic operators can capture PTIME, unless it includes such operators for all prime characteristics. Our analysis requires substantial algebraic machinery, including a homogeneity property of CFI-structures and Maschke's Theorem, an important result from the representation theory of finite groups.

1 Introduction

The graph isomorphism problem (or more generally, the structure isomorphism problem) is an important computational problem which is also very interesting from the point of view of complexity theory. It is not known to be in P nor known to be NP-complete. It is known to be solvable in quasi-polynomial time by Babai's algorithm [3].

An important theoretical approach to understanding the nature of the graph isomorphism problem is the Weisfeiler-Leman method. For each positive integer k, the k-dimensional Weisfeiler-Leman method (k-WL method for short) defines an equivalence relation $\equiv^k$ which

over-approximates isomorphism in the sense that if $G \cong H$ for a pair of graphs G and H, then $G \equiv^k H$ for any k. The relations form a refining family in the sense that if $G \not\equiv^k H$ then $G \not\equiv^{k'} H$ for all $k' > k$. Thus, the equivalence relation gets finer with increasing k and approaches isomorphism in the limit. Moreover, if G and H are n-vertex graphs then $G \equiv^n H$ if, and only if, $G \cong H$. For each fixed k, the equivalence relation $\equiv^k$ is decidable in polynomial time, indeed in time $n^{O(k)}$. Thus, if there were a fixed k such that $\equiv^k$ were the same as isomorphism, we would have a polynomial-time algorithm for graph isomorphism. However, we know this is not the case. Cai, Fürer and Immerman [6] showed that there are pairs of non-isomorphic graphs G and H with $O(k)$ vertices such that $G \equiv^k H$. We call the construction of such graphs the CFI construction.

The Weisfeiler-Leman equivalences arise naturally in the study of graphs in many different guises. We have definitions based on combinatorics (such as Babai's original definition, see [6]); in logic as the equivalences induced by bounded variable fragments of first-order logic with counting; linear programming (see [2, 21]); and algebra (as in the original definition of Weisfeiler and Leman, extended to dimension k in [13]). The equivalences have proved to be of central importance in the area of descriptive complexity theory. In particular, they delimit the power of fixed-point logic with counting (FPC), an important logic in the study of symmetric polynomial-time computation (see [9]). On many important classes of structures, it turns out that there is a fixed k for which k-WL suffices to distinguish all non-isomorphic graphs. Most significantly, Grohe [20] has shown that for any proper minor-closed class $\mathcal{C}$ of graphs, there is a k such that $\equiv^k$ coincides with isomorphism on graphs in $\mathcal{C}$.

Despite its importance in the interplay of graph structure theory and logic, and its theoretical significance in understanding the graph isomorphism problem, the Weisfeiler-Leman method does not give the most efficient algorithms for solving the isomorphism problem. The CFI construction demonstrates that using the WL method to decide isomorphism would yield an algorithm of complexity $n^{\Omega(n)}$ which is asymptotically no better than trying all permutations and far removed from the quasi-polynomial time algorithms known. This has inspired the search for other structured families of equivalences (see for example [4, 16]). One particularly interesting such family are the *invertible-map equivalences* defined in [14]. This gives, for each k and each set Q of prime numbers, an equivalence relation $\equiv^{\mathrm{IM}}_{k,Q}$. The precise definition is given in Section 2 but the intuition is that if $G \equiv^{\mathrm{IM}}_{k,Q} H$, then G and H are not distinguishable by a refinement of k-tuples given by linear operators acting on vector spaces over fields of characteristic p, for any $p \in Q$. The reason for considering such equivalences stems from the realisation that the CFI-construction codes in graph form the problem of solving equations over $\mathbb{F}_2$ – the 2-element field (see [1]). It can then be shown that the family of equivalences $\equiv^{\mathrm{IM}}_{k,\{2\}}$ properly refine the Weisfeiler-Leman equivalences in that $G \equiv^{\mathrm{IM}}_{k',\{2\}} H$ for sufficiently large k' implies $G \equiv^k H$ for all k, yet $G \not\equiv^{\mathrm{IM}}_{3,\{2\}} H$ for the pairs G, H obtained in the CFI construction.

Furthermore, for any finite Q, the relation $\equiv^{\mathrm{IM}}_{k,Q}$ is decidable in time $n^{O(k)}$. We can also vary Q with n. For instance, we could let Q_s be the collection of all primes up to $s(n)$ for some growing function s. In this case $\equiv^{\mathrm{IM}}_{k,Q_s}$ is decidable in time $s(n)n^{O(k)}$. It is therefore an interesting question whether the family of equivalence relations is (like the Weisfeiler-Leman equivalences) infinitely refining. Do increasing values of k yield ever finer equivalence relations? The rôle of the parameter Q is also worth investigating. If there were a fixed polynomial s and constant k for which $\equiv^{\mathrm{IM}}_{k,Q_s}$ was the same as isomorphism, we would have a polynomial-time test for isomorphism. Even if we could prove this for k growing poly-logarithmically, and s quasi-polynomial, this would yield a new (and more systematic) quasi-polynomial algorithm for isomorphism. We have no reason to conjecture that either of these upper bounds holds, but they have not been ruled out.

One reason for the interest in the invertible-map equivalences is the connection with logic. In the long-running quest for a logic for PTIME (see [19]), an important direction is the study of extensions of fixed-point logic with rank operators (FPR) [12] or other algebraic operators (see [10]). The relations $\equiv^{\mathrm{IM}}_{k,Q}$ were introduced first as a tool to study the expressive power of FPR. It was shown in [14] that for every formula φ of FPR (as originally defined in [12]) there is a k and a finite Q such that the class of models of φ is closed under $\equiv^{\mathrm{IM}}_{k,Q}$. For the more powerful rank logic FPR^* defined in [18], we can show that for any formula φ, there is a k and a polynomial s such that φ is invariant under $\equiv^{\mathrm{IM}}_{k,Q_s}$. This implies, in particular that, if we could show that there is no fixed k such that $\equiv^{\mathrm{IM}}_{k,Q}$ is the same as isomorphism when Q is the set of all primes, we could, by means of padding and results from [14], separate FPR^* from PTIME. In short, any advance in understanding the structure of these equivalence relations is a significant step for resolving important questions.

The equivalence relations tell us about more than just rank logic. They can be used to delimit the expressive power of any extension of fixed-point logic with linear-algebraic operators. In this paper we introduce $\mathrm{LA}^k(Q)$, an infinitary logic with k variables and all linear-algebraic operators (which we define formally below) over finite vector spaces of characteristic $p \in Q$. This is the logic for which $\equiv^{\mathrm{IM}}_{k,Q}$ is the natural notion of elementary equivalence. Then, $\mathrm{LA}^\omega(Q) = \bigcup_{k\in\omega} \mathrm{LA}^k(Q)$ is a natural upper bound on the expressive power of any extension of fixed-point logics by means of Q-linear-algebraic operators.

Our main results can now be stated as follows. As long as Q is not the set of all primes, there is no k such that $\equiv^{\mathrm{IM}}_{k,Q}$ is the same as isomorphism. From this, it follows that there are classes of graphs which are not definable in $\mathrm{LA}^\omega(Q)$. Moreover, we can construct polynomial-time decidable such classes. This implies that any logic with linear-algebraic operators, unless it includes such operators for all prime characteristics, does not capture PTIME. Note, this does not separate FPR^* from PTIME, due to the restriction on Q, but it shows that if FPR^* is to capture PTIME, we need to use the set of all primes.

Establishing the result requires significant technical innovation. In particular, we develop novel algebraic machinery that has not previously been deployed in the field of finite model theory. As noted above, the CFI construction codes, in graph form, the problem of solving systems of linear equations over $\mathbb{F}_2$. We can give a similar construction that codes linear equations over $\mathbb{F}_p$ for any prime p. Such a construction was given in [22], where it was used to establish that the resulting non-isomorphic graphs were not distinguished by a variant of $\equiv^{\mathrm{IM}}_{k,\{q\}}$ for any $q \neq p$, where the matrix operations are restricted to a particularly simple form. A more refined analysis of the construction was used in [18] to separate the expressive power of FPR from that of FPR^*. To be precise, they showed that the formulas of FPR that do not use an operator with the prime p are no more expressive than formulas of FPC over these graphs. Our result uses the same graph construction but brings significant new algebraic machinery to its analysis.

We are able to show, in this paper, that, on graphs obtained by the CFI construction for $\mathbb{F}_p$, the distinguishing power of $\equiv^{\mathrm{IM}}_{k,Q}$, where $p \notin Q$, is no greater than $\equiv^{k'}$ for some fixed k'. Note that the graphs are definitely distinguished in $\equiv^{\mathrm{IM}}_{k,Q}$ when $p \in Q$. We establish the result by showing that on these graphs, the equivalence relation $\equiv^{\mathrm{IM}}_{k,\{q\}}$ is itself definable in FPC when $q \neq p$. This is done by implementing a matrix similarity test in FPC, based on the module isomorphism algorithm of Chistov et al. [8]. There are two key ingredients by which this yields an FPC definition. The first is that, on the graphs obtained in the construction, the equivalence relation $\equiv^k$ (now understood as an equivalence relation on k-tuples of vertices rather than on graphs) coincides with the partition into automorphism orbits, for sufficiently large but constantly bounded k. We say that the graphs are C^k-homogeneous for large

enough k. The second ingredient is that, because the automorphism groups of the graphs are Abelian p-groups, this partition induces a matrix algebra over $\mathbb{F}_q$, when $q \neq p$, which is semisimple and so admits a nice decomposition by Maschke's theorem. Maschke's theorem is a central result in the representation theory of finite groups, which states conditions under which a linear-algebraic representation of a finite group admits a decomposition into irreducible representations. It is a powerful tool and we hope that its use opens the door to further applications of representation theory in the context of finite model theory. Indeed, we see a major contribution of the present work as being the introduction of Maschke's theorem and related tools into the subject.

Much technical detail is omitted due to space reasons. Full proofs, and more detailed background on the algebra we use, can be found in the full version of the paper that is available [11].

2 The Invertible Map Equivalence and Linear-Algebraic Logics

The invertible map equivalence relation was introduced in [14, 22] as a family of approximations of isomorphism. It was shown that it is at least as fine an approximation as that induced by the infinitary logic with rank quantifiers, introduced in [12]. Dawar and Holm posed the question whether there is a logic which corresponds to the invertible map equivalences. Here we answer the question by showing that these equivalence relations are the right notions of elementary equivalence for an infinitary logic extended with *all* linear algebraic operations.

We begin by defining the equivalence relations $\equiv^{\mathrm{IM}}_{k,Q}$ for $k \in \mathbb{N}$ and Q a set of prime numbers. It is worth reviewing the definition of the counting-logic equivalence $\equiv^k$ first. This is not only an equivalence relation among finite structures, it also induces an equivalence on the set of A^k (the set k-tuples over A) inside (any) structure $\mathfrak{A}$ that yields an approximation to the partition of A^k into orbits.

On a structure $\mathfrak{A}$, the relation $\equiv^k$ can be obtained by an iterative refinement process. Suppose we are given a partition $\mathcal{P} = \{P_i\}_{i\in I}$ of A^k indexed by a set I. Now, we say that a pair of tuples $\bar{a}_1$ and $\bar{a}_2$ are *$\mathcal{P}$-similar* if they are in the same part of $\mathcal{P}$ *and* for each $i \in I$ and each $j \in [k]$ the sets $\{b \in A \mid \bar{a}_1[b/j] \in P_i\}$ and $\{b \in A \mid \bar{a}_2[b/j] \in P_i\}$ have the same number of elements. The equivalence relation $\equiv^k$ can then be characterised as the coarsest partition $\mathcal{P}$ of A^k that refines the partition into atomic types, such that any two tuples in the same part of $\mathcal{P}$ are $\mathcal{P}$-similar. This means that we can arrive at this partition by starting with the partition of A^k into atomic types and repeatedly refine it until we get a partition $\mathcal{P}$ for which the notions of $\mathcal{P}$-equivalence and $\mathcal{P}$-similarity are the same.

We now modify this in two ways to obtain the definition of $\equiv^{\mathrm{IM}}_{k,Q}$. First we define similarity not in terms of the substitution of a single element b into a tuple $\bar{a} \in A^k$ but of an ℓ-tuple $\bar{b} \in A^\ell$ for some $\ell < k$. So, for each injective function $\gamma : [\ell] \to [k]$, let $\bar{a}[\bar{b}/\gamma]$ denote the tuple in A^k obtained from $\bar{a}$ by simultaneously substituting b_i in position $\gamma(i)$ for all $i \in [\ell]$. If Γ denotes the set of all injective functions from $[\ell]$ to $[k]$, we say tuples $\bar{a}_1$ and $\bar{a}_2$ are *$\mathcal{P}$-similar* if they are in the same part of $\mathcal{P}$ *and* for each $\gamma \in \Gamma$ and each $i \in I$, the sets $\{\bar{b} \in A^\ell \mid \bar{a}_1[\bar{b}/\gamma] \in P_i\}$ and $\{\bar{b} \in A^\ell \mid \bar{a}_2[\bar{b}/\gamma] \in P_i\}$ have the same size. Taking the coarsest relation that is stable in this sense still gives us $\equiv^k$ (though see [15] for some nuances when comparing with the Weisfeiler-Leman equivalences).

For our purposes, we want a different notion of similarity. Assume that $\ell = 2m$ for some m. We can view any set $C \subseteq A^\ell$ as giving us an $A^m \times A^m$ 0-1 matrix, which we denote M. So the entry in row $\bar{b}_1 \in A^m$ and column $\bar{b}_2 \in A^m$ of M is 1 if, and only if, the ℓ-tuple $\bar{b}_1\bar{b}_2$ is in C. Hence, given, as before, a partition $\mathcal{P} = \{P_i\}_{i\in I}$ of A^k, and an

injective function $\gamma : [\ell] \to [k]$, each tuple $\bar{a}$ induces a partition of tuples $\bar{b}$ in A^ℓ according to which part P_i contains $\bar{a}[\bar{b}/\gamma]$. We think of this partition as a collection $(M_i^{\bar{a}})_{i\in I}$ of 0-1 matrices. For a prime number p, we say that two tuples $\bar{a}_1$ and $\bar{a}_2$ are *$\mathcal{P}$-p-m-similar* if they are in the same part of $\mathcal{P}$ *and* for every γ there is an invertible matrix $S \in \mathbb{F}_p^{A^m \times A^m}$ such that for each $i \in I$ we have $SM_i^{\bar{a}_1}S^{-1} = M_i^{\bar{a}_2}$. In other words, the sequences $(M_i^{\bar{a}_1})_{i\in I}$ and $(M_i^{\bar{a}_2})_{i\in I}$ are simultaneously similar, witnessed by S. We say the tuples are *$\mathcal{P}$-p-similar* if they are $\mathcal{P}$-p-m-similar for all $m \leq k/2$. The equivalence relation $\equiv^{\mathrm{IM}}_{k,p}$ is then the coarsest partition $\mathcal{P}$ that refines the partition into atomic types and such that any two tuples in the same part of $\mathcal{P}$ are $\mathcal{P}$-p-similar. Finally, for a set Q of prime numbers, $\bar{a}_1 \equiv^{\mathrm{IM}}_{k,Q} \bar{a}_2$ if, and only if, $\bar{a}_1 \equiv^{\mathrm{IM}}_{k,p} \bar{a}_2$ for each $p \in Q$. So, $\equiv^{\mathrm{IM}}_{k,Q}$ is the coarsest common refinement of the relations $(\equiv^{\mathrm{IM}}_{k,p})_{p\in Q}$.

Given a fixed set Q of primes with $|Q| = s$, it is possible to compute, for a structure $\mathfrak{A}$ with n elements, the partition of A^k into $\equiv^{\mathrm{IM}}_{k,Q}$ equivalence classes in time $sn^{O(k)}$. To see this, we note that the equivalence relation can be obtained by an iterated refinement process. First, let $\mathcal{P}_0$ be the partition of A^k into atomic types. Then, for each i, let $\mathcal{P}_{i+1}$ be the partition which places two tuples in the same class if, and only if, they are $\mathcal{P}_i$-p-similar for all $p \in Q$. This refinement process converges in at most n^k steps to the partition into $\equiv^{\mathrm{IM}}_{k,Q}$-equivalence classes. At each stage we compute, for each tuple $\bar{a} \in A^k$ and each injective function $\gamma\colon [2m] \to [k]$, the partition of A^{2m} into types, where $m = \lfloor k/2 \rfloor$. This suffices because $\mathcal{P}$-p-m-similarity implies $\mathcal{P}$-p-m'-similarity for all $m' < m$. Having computed the partition, we need to check for each pair of tuples and for each p in Q, whether the induced partitions are simultaneously similar. For this, we use the simultaneous matrix similarity test of Chistov et al. [8]. Since this runs in polynomial time, it follows that the whole procedure can be completed in time $sn^{O(k)}$.

Linear-Algebraic Logic. The study of logics with linear-algebraic operators over finite fields was initiated in [12], where FPR, the fixed-point logic with rank operators, was first introduced. As with fixed-point logics generally, the expressive power of FPR is naturally analysed by seeing it as a fragment of an infinitary logic, in this case with rank *quantifiers*. The notion of elementary equivalence that corresponds to this logic was given in terms of a game characterisation in [14], where the invertible map equivalences were also introduced. Here, we define, for any set Q of primes, an infinitary logic $\mathrm{LA}^\omega(Q)$ with quantifiers for *all* linear-algebraic operators over finite fields of characteristics in Q. This logic is not really intended for practical use. Instead it is designed to be strong enough so that inexpressibility results for $\mathrm{LA}^\omega(Q)$ carry over to any well-defined logic that extends first-order or fixed-point logic by any kind of linear-algebraic operators over Q.

We begin with a definition of linear-algebraic operators. Let $\mathbb{F}$ be a field and let $\mathcal{B}$ be a (non-empty, finite) set that serves as a supply of abstract basis elements. We consider the $\mathbb{F}$-vector space $\mathbb{F}^{\mathcal{B}}$. For each subset $K \subseteq \mathcal{B}$ we identify the vector space $\mathbb{F}^K$ with a subspace of $\mathbb{F}^{\mathcal{B}}$ in the natural way: since $\mathbb{F}^{\mathcal{B}} = \mathbb{F}^K \oplus \mathbb{F}^{\mathcal{B}\setminus K}$ we can (implicitly) set $\mathbb{F}^K = \mathbb{F}^K \oplus \{0\}$.

Let $m \geq 1$. Generally speaking, an *m-ary linear-algebraic operator* is just a function f that defines a linear-algebraic property $f(M_1, \ldots, M_m)$ of m-tuples of $\mathbb{F}$-linear transformations M_i on (subspaces of) $\mathbb{F}^{\mathcal{B}}$. To make things more precise, let $K_i, L_i \subseteq \mathcal{B}$, for $i \in [m]$, denote pairs of (non-empty) subsets of basis elements. We set $V_i = \mathbb{F}^{K_i}$ and $W_i = \mathbb{F}^{L_i}$. We consider m-tuples $(M_1, \ldots, M_m)$ consisting of $\mathbb{F}$-linear mappings $M_i\colon V_i \to W_i$ which are represented succinctly in terms of m-tuples $(M_1, \ldots, M_m)$ of $L_i \times K_i$-matrices with entries in $\mathbb{F}$. Then an m-ary linear-algebraic operator over $\mathbb{F}$ is a function f that takes such sequences $(M_1, \ldots, M_m)$ to some kind of linear-algebraic information $f(M_1, \ldots, M_m)$ about the sequence.

Now, to say that f outputs a "linear-algebraic information" means that the output of f is invariant under $\mathbb{F}$-vector space isomorphisms. Formally, let $\mathcal{C}$ be another (abstract) set of basis elements, where $|\mathcal{B}| = |\mathcal{C}|$, let $K'_i, L'_i \subseteq \mathcal{C}$ where $|K_i| = |K'_i|$ and $|L_i| = |L'_i|$ for $i \in [m]$, and let $(N_1, \dots, N_m)$ be a sequence of matrices $N_i \colon L'_i \times K'_i \to \mathbb{F}$, $i \in [m]$, analogously to the above. Moreover, let $V'_i = \mathbb{F}^{K'_i}$ and $W'_i = \mathbb{F}^{L'_i}$ for $i \in [m]$. Then we say that $(N_1, \dots, N_m)$ results from $(M_1, \dots, M_m)$ by means of an $\mathbb{F}$-vector space isomorphism if we can find an invertible $\mathbb{F}$-linear mapping $S \colon \mathbb{F}^{\mathcal{B}} \to \mathbb{F}^{\mathcal{C}}$ such that the following holds:

- For all $i \in [m]$, S maps each of the subspaces V_i and W_i in $\mathbb{F}^{\mathcal{B}}$ to the respective subspaces V'_i and W'_i in $\mathbb{F}^{\mathcal{C}}$. That is, if we represent S in terms of a $\mathcal{C} \times \mathcal{B}$-matrix with entries in $\mathbb{F}$, then we have that for each of the subblocks $K'_i \times K_i$, $i \in [m]$, the restriction $S \restriction_{(K'_i \times K_i)} \colon K'_i \times K_i \to \mathbb{F}$ of the matrix S to this block is invertible and we have that $S(a, b) = 0$ for all $a \in \mathcal{C} \setminus K'_i$ and $b \in K_i$ (and the analogous holds for all subblocks $L'_i \times L_i$ and the corresponding restrictions $S \restriction_{(L'_i \times L_i)} \colon L'_i \times L_i \to \mathbb{F}$ of S to the subblocks $L'_i \times L_i$).
- For each $i \in [m]$, the $\mathbb{F}$-vector space isomorphism S simultaneously transforms all linear operators $M_i \colon V_i \to W_i$ to the corresponding operators $N_i \colon V'_i \to W'_i$, that is for all $i \in [m]$ we have: $N_i \cdot S = S \cdot M_i$. Note that if we want to read this as a matrix equation, then we formally have to replace the matrix S by its restrictions to the subblocks $K'_i \times K_i$ and $L'_i \times L_i$ as we described above, that is $S \restriction_{(L'_i \times L_i)} \cdot M_i = N_i \cdot S \restriction_{(K'_i \times K_i)}$.

We require that a linear algebraic operator f outputs the same result for all pairs of matrix sequences $(M_1, \dots, M_m)$ and $(N_1, \dots, N_m)$ that are related via an $\mathbb{F}$-vector space isomorphism S (as above), that is $f(M_1, \dots, M_m) = f(N_1, \dots, N_m)$. This condition guarantees that f is not able to distinguish between isomorphic objects and here, in the realm of linear algebra, isomorphisms are $\mathbb{F}$-vector space isomorphisms. Besides this we do not put any kind of additional restrictions on f. For instance, f may not even be a computable function. Note that, though in introducing the function f, we considered a fixed set $\mathcal{B}$, really f defines, for any $\mathcal{B}$, a function on m-tuples of linear operators over subspaces of $\mathbb{F}^{\mathcal{B}}$. Without this, the notion of invariance would not make sense.

Now, we can associate with f a family of *Lindström quantifiers*. For simplicity, we restrict our attention to operators of a specific form without loss of generality. For an explanation of why no generality is lost, we refer the reader to the full paper [11]. Specifically, we assume that $K_i = L_i = \mathcal{B}$ for all i in the above definition, and we assume that the matrices are all 0-1 matrices. In other words, f is defined for a tuple of *square* 0-1 matrices all with the same index set.

Let τ_m denote a vocabulary with m distinct binary relations. Given an operator that defines such an f for each finite $\mathcal{B}$, for each $t \in \mathbb{N}$ we define a class of structures $\mathcal{K}^t_f$ in the vocabulary τ_m. We can think of an index set $\mathcal{B}$ with a collection $M_1, \dots, M_m$ of 0-1 $\mathcal{B} \times \mathcal{B}$ matrices as a τ_m-structure $(\mathcal{B}, M_1, \dots, M_m)$. The class $\mathcal{K}^t_f$ is then the collection of those τ_m-structures where $f(M_1, \dots, M_m) \geq t$. For each $\ell \geq 1$ we then have a quantifier $\mathcal{Q}^{t,\ell}_f$ such that if $I(\bar{x})$ is an $L[\sigma, \tau_m]$-interpretation of dimension ℓ, then $\mathcal{Q}^{t,\ell}_f I(\bar{x})$ is a formula true in a σ structure $\mathcal{A}$ if $I(\mathcal{A}) \in \mathcal{K}^t_f$.

The infinitary logic LA is defined as the closure of first-order logic under *infinitary* disjunction and conjunction, along with quantification $\mathcal{Q}^{t,\ell}_f$ for any linear algebraic operator f over any finite field. That is, if Φ is any set of formulas of LA, then $\bigvee \Phi$ and $\bigwedge \Phi$ are both formulas of LA. And, if f is an m-ary linear algebraic operator over a finite field, and $\Theta(\bar{x})$ is an ℓ-ary LA-interpretation of σ_m in τ, then $\mathcal{Q}^{t,\ell}_f \bar{x} \Theta$ is an LA τ-formula. We are interested in various fragments of the logic LA for which we introduce notation in the following definition.

▶ **Definition 1.** LA^k *is the collection of formulas of* LA *that contain at most* k *distinct variables, and* $\mathrm{LA}^\omega = \bigcup_{k\in\omega} \mathrm{LA}^k$. *For any set* Q *of primes, we write* $\mathrm{LA}(Q)$, $\mathrm{LA}^k(Q)$ *and* $\mathrm{LA}^\omega(Q)$ *to denote the restrictions of these logics to using only linear-algebraic operators over fields of characteristic* $p \in Q$.

If $\mathcal{L}$ *is any of the logics* LA, LA^ω, LA^k, $\mathrm{LA}(Q)$, $\mathrm{LA}^\omega(Q)$ *or* $\mathrm{LA}^k(Q)$, *and* $\ell \in \mathbb{N}$ *we write* ℓ-$\mathcal{L}$ *to denote the fragment of* $\mathcal{L}$ *where all algebraic quantifiers are* $\mathcal{Q}_f^{t,\ell}$ *for some* t *and* f. *In other words, interpretations are restricted to be of dimension* ℓ.

As pointed out above, the LA-logics are merely interesting from a theoretical point of view: in a precise sense they form a maximal extension of infinitary logics by linear-algebraic operators. On the other hand, we do not know of any (non-trivial) property that has a natural definition in the LA-logic, but not already in (infinitary) rank logic for instance (and it is open whether such example exists at all). Having introduced the linear-algebraic logic LA^ω and the invertible-map equivalences $\equiv^{\mathrm{IM}}_{k,Q}$, we are in a position to formulate their tight relationship.

▶ **Theorem 2.** *Let* $k \geq 2$ *be a positive integer and* Q *a set of prime numbers. For any finite structure* $\mathfrak{A}$ *and* $\bar{a}, \bar{b} \in A^k$, *the following are equivalent:*

1. $\bar{a} \equiv^{IM}_{k,Q} \bar{b}$; *and*
2. *for every formula* φ *of* $\mathrm{LA}^k(Q)$, $\mathfrak{A} \models \varphi[\bar{a}]$ *if, and only if,* $\mathfrak{A} \models \varphi[\bar{b}]$.

3 Cai-Fürer-Immerman Structures and Logic

In this section we describe a generalised variant of the *CFI-construction* due to Cai, Fürer, and Immerman [6]. It associates with each

- connected, 3-regular, and ordered (undirected) graph $G = (V, E, \leq)$,
- every prime field $\mathbb{F}_p$, $p \in \mathbb{P}$ (in this article, $\mathbb{P}$ denotes the set of all primes), and
- every vector $\lambda \in \mathbb{F}_p^V$

a structure we call the *CFI-structure* $\mathsf{CFI}[G; p; \lambda]$. Its signature is $\tau_{\mathsf{CFI}} = \{\preceq, R, C, I\}$ where R is a ternary relation symbol and where $\preceq, I, C$ are binary relation symbols. The universe A of $\mathsf{CFI}[G; p; \lambda]$ is $A = E \times \mathbb{F}_p$. The linear order $\leq$ on the vertex set V extends to a linear order on the edge set E (as the lexicographic order, for example). We use this linear order on E to define the following *total preorder* $\preceq$ on A: $(e, x) \preceq (f, y)$ if $e \leq f$. Note that $\preceq$ induces a linear order on the corresponding equivalence classes $e^p = e \times \mathbb{F}_p$. Clearly, each of these classes e^p is of size p. Since G is undirected every edge $e = (v, w) \in E$ comes with its corresponding *dual edge* $f = (w, v) \in E$. In what follows, we use the notation $e^{-1} = f$ to denote the dual of the edge $e \in E$. The relations I and C are defined as follows.

- The *cycle relation* C defines the cyclic structure of the additive group of $\mathbb{F}_p$ on each of the edge classes e^p. More precisely,

$$C = \bigcup_{e\in E} \{((e, x), (e, x + 1 \bmod p)) : x \in \mathbb{F}_p\}.$$

- The *inverse relation* I relates additive inverses for dual edges. Formally,

$$I = \bigcup_{e\in E} \{((e, x), (e^{-1}, -x) : x \in \mathbb{F}_p\}.$$

Note that while the cycle relation C defines a directed graph, the inverse relation I is symmetric. Furthermore, observe that the relations $\preceq, C$ and I are defined independently of the load vector λ and so only depend on the underlying graph G and the prime field $\mathbb{F}_p$. In

contrast, the *CFI-relation* $R = R^\lambda$ is defined using the load vector λ as follows. For each $v \in V$, we let $vE \subseteq V$ denote the set of neighbours of v in G, that is $E(v) = \{v\} \times vE \subseteq E$ is the set of edges outgoing from v. Since G is 3-regular we have that $|vE| = 3$ for each $v \in V$. For $v \in V$ let $vE = \{w_1, w_2, w_3\}$ where $w_1 < w_2 < w_3$. The *CFI-relation* $R^\lambda(v)$ at vertex v is defined as follows:

$$R^\lambda(v) = \{((w_1, x_1), (w_2, x_2), (w_3, x_3)) : x_1 + x_2 + x_3 = \lambda(v) \bmod p\}.$$

The full CFI-relation R^λ of $\mathsf{CFI}\,[G; p; \lambda]$ is given as $R^\lambda = \bigcup_{v \in V} R^\lambda(v)$.

▶ **Theorem 3.** *Two CFI-structures* $\mathsf{CFI}\,[G; p; \lambda], \mathsf{CFI}\,[G; p; \sigma]$ *over the same graph* G *are isomorphic, if, and only if,*

$$\sum \lambda := \sum_{v \in V} \lambda(v) = \sum_{v \in V} \sigma(v) =: \sum \sigma.$$

The CFI-construction unfolds its full power when it is based on a family of underlying graphs that is highly connected. A good choice is to take 3-regular *expander graphs* with $\mathcal{O}(n)$ vertices, as such graphs have a linear lower bound on the size of their separators (which means that we cannot disconnect the graphs into components of size $\leq n/2$ by removing fewer than $\Omega(n)$ vertices).

▶ **Theorem 4** (see e.g. Example 2.2 in [23])**.** *There exists a family of 3-regular, connected expander graphs* $\mathcal{F} = \{G_n : n \in \mathbb{N}\}$ *such that each graph* G_n*,* $n \in \mathbb{N}$*, has* $\mathcal{O}(n)$ *vertices.*

Of course, we can also assume that the graphs in $\mathcal{F}$ are *ordered* just by adding to each graph $G_n = (V_n, E_n) \in \mathcal{F}$ an arbitrary linear order on V_n. From this family $\mathcal{F}$ of 3-regular, connected, ordered expander graphs G_n with $\mathcal{O}(n)$ many vertices we construct, for every $p \in \mathbb{P}$, the CFI-class $\mathsf{CFI}\,[\mathcal{F}; p]$ consisting of all CFI-structures over graphs from $\mathcal{F}$ that is

$$\mathsf{CFI}\,[\mathcal{F}; p] = \bigcup_{n,\lambda} \mathsf{CFI}\,[G_n; p; \lambda].$$

The *CFI-problem* (over $\mathcal{F}$ and $p \in \mathbb{P}$) is to decide, given a structure $\mathsf{CFI}\,[G; p; \lambda] \in \mathsf{CFI}\,[\mathcal{F}; p]$ whether $\sum \lambda = 0$. For the original form of the CFI-construction, it was shown in [6] that this problem is undefinable in counting logic with sublinearly many variables. Also the generalization to more powerful variants, and in particular to our class $\mathsf{CFI}\,[\mathcal{F}; p]$ is well-known.

▶ **Theorem 5.** *For any two structures* $\mathsf{CFI}\,[G_n; p; \lambda], \mathsf{CFI}\,[G_n; p; \sigma] \in \mathsf{CFI}\,[\mathcal{F}; p]$ *we have*

$$\mathsf{CFI}\,[G_n; p; \lambda] \equiv^{\Omega(n)} \mathsf{CFI}\,[G_n; p; \sigma].$$

Thus, from the perspective of counting logic (with $\Omega(n)$ many variables) CFI-structures over the same underlying graph G_n look the same although, for load vectors λ and σ with $\sum \lambda \neq \sum \sigma$, we know that $\mathsf{CFI}\,[G_n; p; \lambda]$ and $\mathsf{CFI}\,[G_n; p; \sigma]$ are not isomorphic.

▶ **Definition 6.** *Let* $\ell \geq 1$*. We say that a structure* $\mathfrak{A}$ *with automorphism group* Γ *is* ℓ-homogeneous *if for all* $k \geq 1$ *and all* k*-tuples* $\bar{a}, \bar{b} \in A^k$ *we have that*

$$(\mathfrak{A}, \bar{a}) \equiv^{\ell \cdot k} (\mathfrak{A}, \bar{b}) \text{ if, and only if, } \Gamma(\bar{a}) = \Gamma(\bar{b}).$$

In other words, the equivalence relation $\equiv^{\ell \cdot k}$ *refines* k*-tuples in* $\mathfrak{A}$ *up to orbits. Moreover, we say that a class* $\mathcal{K}$ *of structures is* homogeneous *if for some constant* $\ell \geq 1$ *each structure* $\mathfrak{A} \in \mathcal{K}$ *is* ℓ*-homogeneous.*

▶ **Theorem 7.** *For every prime p, the class $\mathsf{CFI}[\mathcal{F};p]$ is homogeneous.*

This theorem has been established in [17]. Homogeneity of CFI-structures is very useful because it implies that counting logic (indeed, FPC) can order k-tuples up to orbits. There are counting-type formulae $\mathrm{CT}_{\ell\cdot k}(\bar{x},\bar{y}) \in \mathrm{FPC}$ (see [24]) that define a linear preorder on k-tuples which distinguishes between all pairs of k-tuples in different orbits, and these formulae use only $\mathcal{O}(\ell\cdot k)$ many variables. One key consequence of homogeneity is that on the class of CFI structures, the relations $\equiv^k$ and $\equiv^{\mathrm{IM}}_{k,Q}$ coincide for k above some constant threshold. Indeed, $\equiv^{\mathrm{IM}}_{k,Q}$ is always at least as fine as $\equiv^k$ and no finer than the equivalence given by the partition into automorphism orbits. When the former and the latter are the same, $\equiv^{\mathrm{IM}}_{k,Q}$ must be the same. In particular, this means that the counting-type formulas $\mathrm{CT}_{\ell\cdot k}(\bar{x},\bar{y})$ define a pre-order on the $\equiv^{\mathrm{IM}}_{k,Q}$ equivalence classes.

4 Indistinguishability of CFI-structures using Linear-Algebraic Operators

In this section, we state our main technical result, that CFI-structures over a prime field $\mathbb{F}_p$ cannot be distinguished by means of *any* linear-algebraic operator over a field $\mathbb{F}$ with $\mathrm{char}(\mathbb{F}) \neq p$ if we apply such linear-algebraic operators to $\mathrm{C}^{\Omega(n)}$-definable matrices. For what follows, recall that we consider CFI-structures over a fixed class of expander graphs $\mathcal{F} = \{G_n : n \in \mathbb{N}\}$ where each graph G_n has $\mathcal{O}(n)$ vertices and is ordered, connected, and three-regular.

The exact formulation of the results requires some background from associative algebra. This can be found in the monograph [26], for example. The definitions and results we use are also summarized in the full version of this paper [11, Sec. 5].

The partition of 2ℓ-tuples in a structure $\mathfrak{A}$ into $\equiv^k$-classes (when $k \geq 3\ell$) induces a *coherent configuration* in the sense of [7, Chap. 3]. This implies, in particular, that if we think of this partition as a collection $M_1,\dots,M_s$ of 0-1 matrices with rows and columns indexed by A^ℓ then, for any field $\mathbb{F}$, they form the basis of an $\mathbb{F}$-algebra. That is to say, they are the basis of an $\mathbb{F}$-vector space that is also closed under matrix multiplication. We denote this algebra $\mathsf{Alg}[\mathfrak{A};\ell;\mathrm{C}^k;\mathbb{F}]$ and the *ordered* collection of matrices that forms its basis $\mathrm{Basis}[\mathfrak{A};\ell;\mathrm{C}^k]$. Note that the latter does not depend on the choice of $\mathbb{F}$.

We say that two structures $\mathfrak{A}$ and $\mathfrak{B}$ are $(\mathbb{F};\ell;\mathrm{C}^k)$-isomorphic if $\mathfrak{A} \equiv^k \mathfrak{B}$ and, if $\mathcal{M} = \mathrm{Basis}[\mathfrak{A};\ell;\mathrm{C}^k] = (M_1,\dots,M_s)$ and $\mathcal{N} = \mathrm{Basis}[\mathfrak{B};\ell;\mathrm{C}^k] = (N_1,\dots,N_s)$, then there is an invertible map $S : \mathbb{F}^{A^\ell} \to \mathbb{F}^{B^\ell}$ such that for each $i \in [s]$, $SM_iS^{-1} = N_i$. In short, the two sequences of matrices $\mathrm{Basis}[\mathfrak{A};\ell;\mathrm{C}^k]$ and $\mathrm{Basis}[\mathfrak{B};\ell;\mathrm{C}^k]$ are *simultaneously similar* as witnessed by S. In particular, the $\mathbb{F}$-algebras $\mathsf{Alg}[\mathfrak{A};\ell;\mathrm{C}^k;\mathbb{F}]$ and $\mathsf{Alg}[\mathfrak{B};\ell;\mathrm{C}^k;\mathbb{F}]$ are isomorphic.

For CFI-structures, $\mathfrak{A} = \mathsf{CFI}[G_n;p;\lambda]$ and $\mathfrak{B} = \mathsf{CFI}[G_n;p;\sigma]$, by the homogeneity property, we know that the partition into $\equiv^k$-classes is the same as the partition into automorphism orbits. This allows us to show that when such structures are $(\mathbb{F};\ell;\mathrm{C}^k)$-isomorphic, they cannot be distinguished by any $\mathbb{F}$-linear-algebraic operators. Hence, the key technical theorem we prove is the following.

▶ **Theorem 8.** *There is $\epsilon > 0$ s.t. for large enough $n > 0$ the following holds. Let $\mathfrak{A} = \mathsf{CFI}[G_n;p;\lambda]$ and $\mathfrak{B} = \mathsf{CFI}[G_n;p;\sigma]$ denote CFI-structures over G_n and let $\mathbb{F}$ be a field such that $\mathrm{char}(\mathbb{F}) \neq p$. Then $\mathfrak{A}$ and $\mathfrak{B}$ are $(\mathbb{F};\ell;\mathrm{C}^k)$-isomorphic where $\ell = \lfloor \epsilon n \rfloor$ and $k = 3\ell$.*

Theorem 8 is a consequence of Theorem 9 where we show that, for the above scenario, the simultaneous similarity of the counting-logic bases is definable in counting logic. To state Theorem 9, we introduce some terminology. Consider two sequences of matrices

$\mathcal{M} = (M_i)_{i\in[s]}$ and $\mathcal{N} = (N_i)_{i\in[s]}$, where each M_i is an $I \times I$ matrix over $\mathbb{F}$ and each N_i is a $J \times J$ matrix over $\mathbb{F}$. Here I and J are two arbitrary index sets of the same size. We define the set $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ of $I \times J$-matrices X over $\mathbb{F}$ which satisfy $M_i X = X N_i$ for all $i \in [s]$. Note that the two sequences $\mathcal{M} = (M_i)_{i\in[s]}$ and $\mathcal{N} = (N_i)_{i\in[s]}$ are simultaneously similar if, and only if, $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ contains an *invertible* matrix.

Note that $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ is an $\mathbb{F}$-vector space. Next, consider the set $\mathrm{C}_{\mathcal{M}}$ of $I \times I$-square matrices Z over $\mathbb{F}$ such that $M_k Z = Z M_k$ for all $k \in K$. The set $\mathrm{C}_{\mathcal{M}}$ is called the *centraliser* of the matrix family $\mathcal{M}$. It is easy to verify that $\mathrm{C}_{\mathcal{M}}$ forms an $\mathbb{F}$-algebra. Moreover, by considering matrix multiplication (from the left) by elements from $\mathrm{C}_{\mathcal{M}}$, the $\mathbb{F}$-vector space $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ turns into a $\mathrm{C}_{\mathcal{M}}$-module. With this, we can state the technical result.

▶ **Theorem 9.** *Let $t \geq 3$ be a constant such that all CFI-structures in $\mathsf{CFI}[\mathcal{F}; p]$ are t-homogeneous for all $p \in \mathbb{P}$. Then there exists a constant $c \geq 1$ such that the following holds. Let $\ell \geq 1$ and let $k \geq t\ell$. Then for each $p \in \mathbb{P}$ there exists a C^{ck}-sentence φ such that for all pairs of CFI-structures $\mathfrak{A} = \mathsf{CFI}[G_n; p; \lambda]$ and $\mathfrak{B} = \mathsf{CFI}[G_n; p; \sigma]$ over the same underlying graph $G_n \in \mathcal{F}$ we have that $(\mathfrak{A}, \mathfrak{B}) \models \varphi$ if, and only if, over every field $\mathbb{F}$ with $\mathrm{char}(\mathbb{F}) \neq p$, the $C_{\mathcal{M}}$-module $H_{\mathcal{M},\mathcal{N}}$ contains an invertible matrix $S \in H_{\mathcal{M},\mathcal{N}}$ where $\mathcal{M} = \mathit{Basis}[\mathfrak{A}, \ell, k]$ and $\mathcal{N} = \mathit{Basis}[\mathfrak{B}, \ell, k]$.*

We can derive Theorem 8 from Theorem 9 as follows. First of all, let $c \geq 1$ and $t \geq 3$ be the constants according to Theorem 9. Let $p \in \mathbb{P}$. Then, by Theorem 5, we can find $\delta > 0$ such that for all large enough $n > 1$ we have $\mathfrak{A} \equiv^{\lfloor \delta n \rfloor} \mathfrak{B}$ where $\mathfrak{A} = \mathsf{CFI}[G_n; p; \lambda]$ and $\mathfrak{B} = \mathsf{CFI}[G_n; p; \sigma]$ are two CFI-structures over $\mathbb{F}_p$ and the same underlying expander graph $G_n \in \mathcal{F}$ with $\mathcal{O}(n)$ many vertices. Let $\epsilon = \frac{1}{tc}\delta$. Then $(\mathfrak{A}, \mathfrak{A}) \equiv^{\lfloor t c \epsilon n \rfloor} (\mathfrak{A}, \mathfrak{B})$. Let $\mathbb{F}$ be a field such that $\mathrm{char}(\mathbb{F}) \neq p$. Let $\ell = \lfloor \epsilon n \rfloor$ and $k = \lfloor t \epsilon n \rfloor$. We consider $\mathcal{M} = \mathrm{Basis}[\mathfrak{A}, \ell; \mathrm{C}^k]$ and $\mathcal{N} = \mathrm{Basis}[\mathfrak{B}, \ell; \mathrm{C}^k]$. Since the formula φ according to Theorem 9 contains at most $ck = c \cdot \lfloor t \epsilon n \rfloor \leq \lfloor \delta n \rfloor$ many variables, this formula cannot distinguish between the ordered pairs of CFI-structures $(\mathfrak{A}, \mathfrak{A})$ and $(\mathfrak{A}, \mathfrak{B})$. On the other hand, by its properties stated in Theorem 9, φ would need to distinguish between $(\mathfrak{A}, \mathfrak{A})$ and $(\mathfrak{A}, \mathfrak{B})$ if no invertible matrix $S \in \mathrm{H}_{\mathcal{M},\mathcal{N}}$ would exist. Indeed, note that the $\mathrm{C}_{\mathcal{M}}$-module $\mathrm{H}_{\mathcal{M},\mathcal{M}}$ contains an invertible matrix $S \in \mathrm{H}_{\mathcal{M},\mathcal{M}}$ over every field $\mathbb{F}$ for trivial reasons; for instance it contains the permutation matrix that corresponds to the identity automorphism of $\mathfrak{A}$. Hence, we can conclude that $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ contains an invertible matrix which shows that $\mathfrak{A}$ and $\mathfrak{B}$ are $(\mathbb{F}; \ell; \mathrm{C}^k)$-isomorphic, and thus Theorem 8 follows, because $(\mathbb{F}; \ell; \mathrm{C}^k)$-isomorphic structures are also $(\mathbb{F}; \ell; \mathrm{C}^{3\ell})$-isomorphic since $k \geq 3\ell$.

We now outline a proof strategy for Theorem 9. The full proof is rather long, and is presented in detail in the full paper [11]. First, we fix a *prime field* $\mathbb{F}$ with $\mathrm{char}(\mathbb{F}) \neq p$. We construct a sentence $\varphi_{\mathbb{F}} \in \mathrm{C}^\omega$, with at most $c \cdot k$ many variables, which holds in the ordered pair $(\mathfrak{A}, \mathfrak{B})$ of CFI-structures $\mathfrak{A}$ and $\mathfrak{B}$ if, and only if, $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ (considered as a $\mathrm{C}_{\mathcal{M}}$-module over the $\mathbb{F}$-algebra $\mathrm{C}_{\mathcal{M}}$) contains an invertible matrix S. The desired sentence φ according to Theorem 9 is then the conjunction over all sentences $\varphi_{\mathbb{F}}$ for *prime fields* $\mathbb{F}$ with $\mathrm{char}(\mathbb{F}) \neq p$.

Step (I). As a first step we show that it suffices to restrict our considerations to *prime fields*. This is because the matrix families $\mathcal{M}$ and $\mathcal{N}$ we are interested in only contain 0-1 matrices. Such families are simultaneously similar over a field $\mathbb{F}$ if, and only if, they are simultaneously similar over the prime subfield of $\mathbb{F}$. The restriction is important because we need to use the result (originally proved in [18]) about defining solutions to system of linear equations. The result is that if a system of linear equations over a prime field $\mathbb{F}$ is represented by a homogeneous structure $\mathfrak{A}$ with Abelian automorphism group, and such that

the order of the automorphism group of $\mathfrak{A}$ is co-prime with char($\mathbb{F}$), then a solution to the system can be defined by a formula of counting logic. This is because we can show that in this case, there must exist a solution that is symmetric, i.e. invariant under the action of the automorphism group. In fact, we need here a stronger result saying that not only single solutions, but whole solution spaces are definable in counting logic. This was recently shown in [17] and our full paper [11] also contains a proof sketch.

Now, the CFI structures in $\mathsf{CFI}[\mathcal{F}; p]$ have Abelian automorphism groups of order a power of p, so systems of linear equations suitably defined from them will have the required property. Our aim is to reduce the problem of deciding whether $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ contains an invertible matrix to solving a system of linear equations over $\mathbb{F}$. The condition $M_i X = X N_i$ for all i easily yields a system of such equations with unknowns for the enrtries of X. The question is how to enforce that X is invertible.

Step (II). To carry out the reduction, we use the result from [8] that if $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ contains an invertible matrix, then it is *cyclic* as a $\mathrm{C}_{\mathcal{M}}$-module. This means that $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ is generated by a single element: there is a matrix $X \in \mathrm{H}_{\mathcal{M},\mathcal{N}}$ such that $\mathrm{C}_{\mathcal{M}} X = \{ZX : Z \in \mathrm{C}_{\mathcal{M}}\} = \mathrm{H}_{\mathcal{M},\mathcal{N}}$. This gives a necessary but not sufficient condition for the existence of an invertible matrix in $\mathrm{H}_{\mathcal{M},\mathcal{N}}$. To obtain a necessary and sufficient condition, we use the particular structure of the matrix families $\mathcal{M}$ and $\mathcal{N}$ that follow from the fact that they are generated by the $\equiv^k$-equivalence classes. Roughly speaking, the equivalence relation $\equiv^k$ partitions the row-column index sets of these matrices into classes, and we can think of the matrices as linear combinations of "small" matrices, which are over these individual blocks. This means that the invertible S we are looking for can also be decomposed into the sum of smaller block matrices. Our families $\mathcal{M}$ and $\mathcal{N}$ have the property that they are *locally simultaneously similar*, i.e. we can find similarity transformations for each small block. With this, it becomes possible to prove that the cyclicity of $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ is both necessary and sufficient for the existence of an invertible matrix. It also means that we can restrict ourselves to a certain substructure of this module. To be precise, we let $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$ be the subalgebra of $\mathrm{C}_{\mathcal{M}}$ consisting of those matrices that are zero outside the relevant blocks. Then, $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is similarly the collection of matrices in $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ that are zero outside the relevant blocks and this can be seen as a $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$-module. For the particular matrix families $\mathcal{M} = \mathrm{Basis}[\mathfrak{A}, \ell, k]$ and $\mathcal{N} = \mathrm{Basis}[\mathfrak{B}, \ell, k]$, we are able to show that they are simultaneously similar if, and only if, $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is cyclic as a $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$-module.

As a consequence, to check whether $\mathrm{H}_{\mathcal{M},\mathcal{N}}$ contains an invertible matrix, it suffices to check whether the $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$-module $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is cyclic.

Step (III). The third step is the core of our whole argument. We combine results on the FPC-definability of the automorphism groups and orbits of CFI-structures with Maschke's Theorem, an important result from the representation theory of finite groups, to show that the $\mathbb{F}$-algebra $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$ is *semisimple*.

Recall that for a finite group G and a field $\mathbb{F}$, the *group algebra* $\mathbb{F}[G]$ is the $\mathbb{F}$-algebra whose elements are formal sums of the form $\sum_{g \in G} r_g g$ with coefficients $r_g \in \mathbb{F}$. Addition and scalar multiplication are defined component-wise and multiplication is defined by convolution on the group elements. Maschke's theorem tells us that $\mathbb{F}[G]$ is semisimple if, and only if, char($\mathbb{F}$) does not divide the order of G.

For an algebra A, an A-module M is called *simple* if every submodule of M is trivial (either 0 or M itself) and *semisimple* if it is the direct sum of simple modules. From the semi-simplicity of $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$ we are able to show that the $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$-module $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is semisimple.

Step (IV). The key property of semisimple modules is that they have an essentially canonical decomposition as the sum of simple modules. So, $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ can be decomposed as the sum of simple modules, and the isomorphism types of modules that occur in that decomposition and their respective multiplicities completely determine the isomorphism type of $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$. Moreover, we show that we can define generating sets for the respective submodules in counting logic by using at most $c \cdot k$ many variables. This is because, essentially, these generating sets can be obtained as the solution sets of a system of linear equations, and we are able to use the results mentioned in Step (I) above.

Step (V). Finally, we construct the formula $\varphi_{\mathbb{F}}$. By (II), the formula $\varphi_{\mathbb{F}}$ needs to verify that the *semisimple* $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$-module $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is cyclic. We approach this problem by expressing a more general query, namely we determine the full isomorphism type of the module $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ by means of a formula of counting logic. First of all, we start by determining the isomorphism types of all simple subalgebras of $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$. This we can easily do in counting logic because $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$ has an (FPC-definable) ordered basis. This implies that the isomorphism type of $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ is (uniquely) determined by the multiplicities of the simple subalgebras of $\mathrm{C}^{\mathrm{D}}_{\mathcal{M}}$ as they occur in a decomposition of $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$ into a direct sum of simple submodules. By using our decomposition from Step (IV), we can easily determine those multiplicities componentwise, since we can linearly order (again in an FPC-definable way) each of the "small" submodules that occur in the decomposition of $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$. In this way we can determine the multiplicities for each individual component which add up to the total multiplicities for the whole module $\mathrm{H}^{\mathrm{D}}_{\mathcal{M},\mathcal{N}}$. Since the isomorphism type determines the cyclicity of the module, we can obtain our desired formula $\varphi_{\mathbb{F}}$ by selecting modules with appropriate isomorphism types.

5 Main results

In this section we spell out the consequences of the main technical result, Theorem 8, for approximations of isomorphism and for logics with linear-algebraic operators.

With regard to the relations $\equiv^{\mathrm{IM}}_{k,Q}$ as approximations of isomorphism, it follows immediately that as long as $Q \neq \mathbb{P}$, i.e. Q is not the set of all primes, there is no k for which $\equiv^{\mathrm{IM}}_{k,Q}$ coincides with isomorphism on all structures.

▶ **Corollary 10.** *If $Q \neq \mathbb{P}$, there is no fixed k such that $\equiv^{IM}_{k,Q}$ coincides with isomorphism on all structures.*

Proof. Fix a prime $p \notin Q$. Then, for each k, we have, by Theorem 8 a pair of structures $\mathfrak{A} = \mathsf{CFI}\,[G_n; p; \lambda]$ and $\mathfrak{B} = \mathsf{CFI}\,[G_n; p; \sigma]$ that are $(\mathbb{F}_q; \ell; \mathrm{C}^k)$-isomorphic, for all $q \neq p$, though $\sum \lambda \neq \sum \sigma$. It follows that $\mathfrak{A} \equiv^{\mathrm{IM}}_{k,Q} \mathfrak{B}$, but $\mathfrak{A} \ncong \mathfrak{B}$, by Theorem 3. ◀

The consequences for the expressive power of the logic LA^{ω} are also immediate.

▶ **Corollary 11.** *If $Q \neq \mathbb{P}$, there is a class of structures that is not definable in $\mathrm{LA}^{\omega}(Q)$.*

Proof. Fix a prime $p \notin Q$ and consider the class $\mathcal{C}$ of structures of the form $\mathsf{CFI}\,[G_n; p; \lambda]$ where $\sum \lambda = 0$. This is an isomorphism-closed class of structures by Theorem 3. Suppose it were defined by a sentence φ of $\mathrm{LA}^{\omega}(Q)$. Let ℓ be the maximum dimension of an interpretation used with any quantifier in φ and choose k such that $k \geq 3\ell$ and k is greater than the number of variables in φ. Then, by Theorem 8, we have a structure $\mathfrak{A} = \mathsf{CFI}\,[G_n; p; \lambda] \in \mathcal{C}$ which is $(\mathbb{F}_q; \ell; \mathrm{C}^k)$-isomorphic to every structure $\mathsf{CFI}\,[G_n; p; \sigma]$. Letting $\mathfrak{B}$ be such a structure where $\sigma \neq 0$, we have that $\mathfrak{B} \models \varphi$, contradicting the assumption that φ defines $\mathcal{C}$. ◀

It should be noted that the class of structures $\mathcal{C}$ defined in the proof of Corollary 11 is decidable in polynomial time. This is because the class can be decided by solving systems of linear equations, for example by Gaussian elimination. Thus, we know that there exists a PTIME property that $\mathrm{LA}^{\omega}(Q)$ cannot express as long as $Q \neq \mathbb{P}$. Since this logic subsumes any extension of fixed-point logic with Q-linear algebraic operators, we also have the following conclusion.

▶ **Corollary 12.** *If $Q \neq \mathbb{P}$, no extension of fixed-point logic with Q-linear algebraic operators captures PTIME.*

We can say more. The class $\mathcal{C}$ is not just decidable in PTIME, but also definable in *choiceless polynomial time* (CPT) (see [25]). We do not define the class CPT here but details may be found in [5]. Thus, the following corollary is immediate.

▶ **Corollary 13.** *If $Q \neq \mathbb{P}$, no extension of fixed-point logic with Q-linear algebraic operators captures CPT.*

On the other hand it remains an intriguing open question whether CPT captures all of rank logic, for example.

Abstract

Conjunctive queries select and are expected to return certain tuples from a relational database. We study the potentially easier problem of *counting* all selected tuples, rather than enumerating them. In particular, we are interested in the problem's parameterized and data complexity, where the query is considered to be small or even fixed, and the database is considered to be large. We identify two structural parameters for conjunctive queries that capture their inherent complexity: The dominating star size and the linked matching number. If the *dominating star size* of a conjunctive query is large, then we show that counting solution tuples to the query is at least as hard as counting dominating sets, which yields a fine-grained complexity lower bound under the Strong Exponential Time Hypothesis (SETH) as well as a #W[2]-hardness result in parameterized complexity. Moreover, if the *linked matching number* of a conjunctive query is large, then we show that the structure of the query is so rich that arbitrary queries up to a certain size can be encoded into it; in the language of parameterized complexity, this essentially establishes a #A[2]-completeness result.

Using ideas stemming from Lovász (1967), we lift complexity results from the class of conjunctive queries to arbitrary existential or universal formulas that might contain inequalities and negations on constraints over the free variables. As a consequence, we obtain a complexity classification that refines and generalizes previous results of Chen, Durand, and Mengel (ToCS 2015; ICDT 2015; PODS 2016) for conjunctive queries and of Curticapean and Marx (FOCS 2014) for the subgraph counting problem. Our proof also relies on graph minors, and we show a strengthening of the Excluded-Grid-Theorem which might be of independent interest: If the linked matching number (and thus the treewidth) is large, then not only can we find a large grid somewhere in the graph, but we can find a large grid whose diagonal has disjoint paths leading into an assumed node-well-linked set.

1 Introduction

Conjunctive query evaluation is a core problem in database theory. Using first-order logic, conjunctive queries can be expressed by formulas of the form

$$x_1 \dots x_k \exists y_1 \dots \exists y_\ell (a_1 \wedge \dots \wedge a_m)\,, \tag{1}$$

where the x_i are the *free variables*, the y_i are the (existentially) *quantified variables*, and the a_i are *atomic formulas* (such as edge $E(x_1, y_4)$ or relational $R(x_7, y_3, y_6)$ constraints on the variables). Conjunctive queries exactly correspond to select-project-join queries; a detailed introduction can be found in the textbook of Abiteboul, Hull, and Vianu [1]. The *conjunctive query evaluation problem* is given a conjunctive query and a relational database, and is tasked to compute the set of all assignments to the free variables such that the formula is satisfied. Since enumerating all solution tuples $s_1 \dots s_k$ can be costly for reasons not inherent to the problem's complexity, it is more meaningful to consider the decision problem (Does there exist a solution tuple?) or the more general counting problem (How many solution tuples exist?). The decision problem is equivalent to setting $k = 0$ and also called the constraint satisfaction problem (CSP). In this paper, we study the problem of counting the number of all solution tuples for conjunctive and more general queries.

Perhaps the most naïve way to study the complexity of this problem is via its *combined complexity*, in which both the query and the database are considered to be worst-case inputs. Since conjunctive queries generalize the clique problem on graphs, the problem is clearly NP-hard in this setting [2]. In the real world, however, the database is much larger than the query, and thus the combined complexity may fixate on instances that we do not care about. Instead, we consider two other models in this paper: the data complexity and the parameterized complexity of conjunctive query evaluation.

The *data complexity* considers the query to be completely fixed and only the database to be worst-case input. If the query is fixed, the number of variables $k + \ell$ is a constant, and so the problem is polynomial-time solvable: even the exhaustive search algorithm just needs to try out and check all $n^{k+\ell}$ possible assignments to the variables, where n is the size of the universe. Unsurprisingly, exhaustive search is not the best strategy for every query. For example, Chekuri and Rajaraman [3] showed that the decision and counting problems can be solved in time $O(n^{t+1})$ where t is the treewidth of the query's Gaifman graph, that is, the graph containing a vertex for every variable and an edge between two vertices whenever the corresponding variables are contained in a common constraint. Since $t + 1$ is typically much smaller than $k + \ell$, this algorithm is better than exhaustive search. For each fixed query Q, the guiding question for a fine-grained understanding of data complexity is this: What is the smallest constant c_Q such that the query evaluation problem can be solved in time $O(n^{c_Q})$?

Parameterized complexity offers a third vantage point from which conjunctive query evaluation can be studied. Here the query isn't completely fixed, but it's also not completely free either. Instead, it is assumed that only certain types of queries will be used, meaning that the class of queries that are allowed as input is restricted. As a hybrid between data complexity and combined complexity, the parameterized complexity of query evaluation is more difficult to study than the combined complexity, but easier than the data complexity, while still offering some insight. For example, Grohe, Schwentick, and Segoufin [18] show that the conjunctive query evaluation problem is W[1]-hard if the class of allowed input queries has Gaifman graphs of unbounded treewidth.

1.1 Context and Previous Work

When only one constraint type E of arity two is allowed, the conjunctive query evaluation problem specializes to the graph homomorphism problem: The decision problem (where $k = 0$) is given two graphs H, G to decide whether there is a homomorphism from H to G. Dalmau et al. [9] prove that this problem can be solved in polynomial time if the homomorphic core of H has bounded treewidth, and conversely, Grohe [17] shows that the graph homomorphism problem is W[1]-complete even if H is restricted to be from an arbitrary class of graphs whose homomorphic cores have unbounded treewidth. Taken together, these two results yield a *dichotomy theorem* for the complexity of detecting graph homomorphisms: Depending on the class of allowed graphs H, the problem is either polynomial-time computable or W[1]-complete, and in particular there are not infinitely many cases of intermediate complexity. For the counting problem without quantified variables (where $\ell = 0$), such a dichotomy is also known: Dalmau and Jonsson [8] show that the number of homomorphisms from H to G is polynomial-time computable if H itself has bounded treewidth, and it is #W[1]-complete if H comes from any class of unbounded treewidth. In the mixed situation when both free and quantified variables may exist (and thus $k, \ell > 0$), then the resulting counting problem actually counts *partial homomorphisms*, that is, homomorphisms from k vertices of H that can be extended to a homomorphism on all $k + \ell$ vertices of H. A line of work [27, 25], culminating in Durand and Mengel [12] and Chen and Mengel [4], studies the parameterized complexity of this mixed problem, and depending on the class of graphs H that are allowed, they classify the complexity either as polynomial-time, W[1]-equivalent, or #W[1]-hard. A corollary to the present work is a finer classification that splits up the #W[1]-hard cases into three classes.

One way to go beyond homomorphisms is to consider *injective* homomorphisms, which leads to the corresponding decision problem that is given H, G to decide whether H is a subgraph of G – this problem can be solved in time $f(H)n^{O(t)}$ if t is the treewidth of H (e.g., [15]), that is, it is *fixed-parameter tractable* when parameterized by $|H|$ and if the treewidth is bounded. However, it is an important open problem [24] whether the subgraph detection problem is W[1]-hard when H is restricted to be from an arbitrary class of unbounded treewidth. The counting problem is better understood: Vassilevska Williams and Williams [33] (also cf. [21, 7]) show that the number of times H occurs as a subgraph in G can be computed in time $f(H)n^{\mathsf{vc}(H)+O(1)}$ where $\mathsf{vc}(H)$ is the size of the smallest vertex cover, but Curticapean and Marx [7] (also cf. [6]) show that the problem is #W[1]-complete if H is from any class of graphs whose minimum vertex cover is not bounded. Now, what do injective homomorphisms have to do with conjunctive queries? As it turns out, what we are doing is to add *inequalities* as an additional, but very restricted constraint type: Injective homomorphisms correspond to queries without quantified variables that have edge constraints and are augmented with inequalities $(x_i \neq x_j)$ for all distinct i, j. If some, but not all, inequality constraints are present, we obtain partially injective homomorphisms, the complexity of which has a known dichotomy theorem for the counting version [30], and has been studied to some extent for the decision version [20]. As part of the present work, we are able to classify the mixed situation with free and quantified variables $(k, \ell > 0)$ *as well as* some inequalities on the free variables.

The mentioned complexity classification for counting partial homomorphisms into three cases [12, 4] was actually proved in the more general setting of conjunctive queries. Chen and Mengel [5] extended their classification to queries that are monotone, but not necessarily conjunctive. That is, the corresponding formula is supposed to be an existential positive formula, which may contain existential quantifiers $\exists$, logical ands $\wedge$, and ors $\vee$.

In the present work, we are able to further extend (our finer version of) the classification to existential formulas that may have negations on constraints involving only free variables; we truly study the complexity of *counting answers to existential questions*.

1.2 Our Contributions

As already indicated in Section 1.1, we make simultaneous progress on two fronts: Our complexity classifications are finer than previous work, and we can prove the classification for more general classes of queries. An important feature of our work is that the proofs are modular and largely self-contained: We first prove the complexity results for counting partial homomorphisms, then lift them to conjunctive queries, and then further to a more general class of queries. So what is the most general class of queries that we study? We allow queries φ of the form

$$x_1 \dots x_k \exists y_1 \dots \exists y_\ell : \psi\,, \tag{2}$$

where ψ is a quantifier-free formula in first-order logic and all negations in ψ must be directly applied to constraints that only involve free variables (e.g. $E(x_1, x_7) \vee (R(x_7, y_7, y_9) \wedge \neg R(x_1, x_4, x_9))$). Constraints of the form $\neg R(x_1, x_4, x_9)$ are referred to as *non-monotone constraints* in the remainder of the paper. Furthermore φ may be equipped with a set of inequalities over the free variables (eg. $x_3 \neq x_5$).

All of our theorems also apply to the corresponding *universal* queries, where each $\exists$ in (2) is replaced with $\forall$, but for the sake of readability we will often omit this fact. We are able to generalize from conjunctive queries to queries of the form (2) by using ideas that go back to Lovász's work from 1967 [22] (also cf. [23]): We prove that queries φ of the form (2) can be expressed in a meaningful way as an abstract linear combination of conjunctive queries (which are of the form (1)); positive results (algorithms) as well as negative results (hardness) for each "summand" translate to the abstract linear combination and thus to φ.

Data Complexity

To study the data complexity of the problem, we employ the Strong Exponential Time Hypothesis (SETH) by Impagliazzo and Paturi [19], which was developed in the context of fine-grained complexity. The k-dominating set problem can be easily expressed as a (universal) conjunctive query, and Williams and Pătraşcu [28] show that this problem cannot be solved in time $O(n^{k-\varepsilon})$ unless SETH is false. We are able to lift this hardness result to all queries φ that have the k-dominating set query as a *query minor*, a notion that we translate from graphs and formalize later. The *dominating star size* $\mathsf{dss}(\varphi)$ of a conjunctive query φ is the maximum number k such that the k-dominating set query is a query minor. Equivalently, this means that some connected component in the quantified variables of φ has k neighbors in the free variables.[1] We obtain the following result:

▶ **Theorem 1.** *Let φ be a fixed query of the form (2). Given a logical structure B with a domain of size n, we wish to compute the number of solutions of φ in B. If SETH holds, this problem cannot be solved in time $O(n^{\mathsf{dss}(\varphi)-\varepsilon})$ for any $\varepsilon > 0$.*

In the full version, we also obtain an algorithm for the problem in Theorem 1, with a running time of $O(n^{\mathsf{dss}(\varphi)+t+1} + n^{t'+1})$, where t and t' are treewidths related to the query φ. Neglecting many technical details, the proof of Theorem 1 reduces the k-dominating set

[1] The dominating star size coincides with the *strict star size* from [4].

problem to the model counting problem for φ by following operations of the query minor. If φ is a query of the form (2), then it can be represented by an abstract linear combination of conjunctive queries φ'; in this case, we define $\mathsf{dss}(\varphi)$ as the maximum $\mathsf{dss}(\varphi')$ over all constituents φ' that occur in this abstract linear combination.

Theorem 1 is similar in spirit to other known conditional lower bounds for first-order model checking, such as the one of Williams [32] and Gao et al. [16]. One of their results is that first-order sentences with $k+1$ variables cannot be decided in time $O(m^{k-\varepsilon})$, where m is the size of the structure, unless SETH fails. However, these results are incomparable to Theorem 1 for several reasons: The results in [32, 16] allow negations and consider the decision problem, while we allow only limited negations and consider the counting problem. More fundamentally, however, Theorem 1 gives a hardness result for every fixed query φ, while the results in [32, 16] show that there exists a query φ that is hard. Moreover, the lower bounds in [32, 16] are in terms of the size m of the structure, not merely the size n of the domain.

Parameterized Complexity

We refine the classification of Chen and Mengel [4] for counting answers to conjunctive queries. For every class of allowed queries they show the problem to be either fixed-parameter tractable, W[1]-equivalent or #W[1]-hard. Here, W[1]-equivalent means that there are parameterized Turing reductions from and to the decision version of the k-Clique problem. Understanding the parameterized complexity of problems even beyond the usual classes W[1] and #W[1] is interesting from a structural complexity point of view, and it also provides meaningful information about the studied problem. Indeed we show that the dominating star size, i.e., the parameter considered in Theorem 1, is a structural parameter for conjunctive queries that, if unbounded, makes the problem #W[2]-hard and that, if bounded, keeps the problem #W[1]-easy.

This extension to #W[2]-hard cases only partially resolves the parameterized complexity of the problem of counting answers to conjunctive queries. It is known that the general problem of counting answers to formulas of the form

$$x_1 \dots x_k \exists y_1 \dots \exists y_\ell : \psi\,, \qquad \text{where } \psi \text{ is a quantifier-free first-order formula,} \tag{3}$$

is #A[2]-equivalent.[2] For which families of *conjunctive* queries is the counting problem as hard as for unrestricted queries as in (3)? Such families have the hardest counting problems, even harder than the #W[2]-hard cases unless #A[2] = #W[2] holds, which seems unlikely.[3] We prove that families of conjunctive queries are #A[2]-hard if their *linked matching number* is unbounded. Intuitively a conjunctive query φ with free variables X and quantified variables Y has a large linked matching if there is a large well-linked set in Y that cannot be separated from X by removing a small number of variables. We obtain the following refined complexity classification.

[2] Due to a technicality in the original definition of #A[2], we cannot establish #A[2]-completeness and will instead only talk about *equivalence* to a #A[2]-complete problem under parameterized Turing reductions.

[3] See Chapt. 8 and 14 in [14] for a discussion.

▶ **Theorem 2.** *Let Φ be a family of conjunctive queries. Given a formula φ from Φ and a logical structure B, we wish to compute the number of solutions of φ in B. When parameterized by $|\varphi|$ this problem is*

1. #W[1]*-easy if the dominating star size of Φ is bounded,*
2. #W[2]*-hard if the dominating star size of Φ is unbounded, and*
3. #A[2]*-equivalent if the linked matching number of Φ is unbounded.*

It is instructive to provide examples for the application of the above theorem. First consider the problem of, given a graph G without self-loops and a natural number k, computing the number of cliques of size k that are not maximal. While the problem of counting cliques of size k is #W[1]-complete, adding the non-maximality constraint makes the problem hard for #W[2]. To see this, we will express the problem as a conjunctive query

$$\varphi_k := x_1 \dots x_k \exists y : \bigwedge_{1 \leq i < j \leq k} E(x_i, x_j) \wedge \bigwedge_{1 \leq i \leq k} E(x_i, y)\,. \tag{4}$$

Note that the number of solutions to φ_k in G is precisely $k!$ times the number of non-maximal cliques of size k in G. Furthermore, it holds that φ_k has dominating star size k and hence that $\Phi = \{\varphi_k \mid k \in \mathbb{N}\}$ has unbounded dominating star size. By Theorem 2 the problem of counting answers to queries in Φ is #W[2]-hard. Furthermore, invoking Theorem 1, we obtain that counting non-maximal cliques of size k cannot be done in time $O(n^{k-\varepsilon})$ for any $\varepsilon > 0$. Note that this is also in sharp contrast to the problem of counting (not necessarily non-maximal) cliques of size k which can be done in time $O(n^{\omega k/3})$ [26]. Furthermore deciding the existence of a non-maximal clique of size k is equivalent to deciding the existence of a clique of size $k+1$ and hence the lower bound under SETH crucially depends on the fact that we count the solutions.

On the other hand, counting non-maximal cliques of size k is most likely not #A[2]-hard as it is #W[2]-easy[4]. An example for a #A[2]-hard problem would be the following. Assume a graph G and a natural number k are given. Then the goal is to compute the number of k-vertex sets that can be (perfectly) matched to a k-clique. Let us express the problem as a conjunctive query

$$\psi_k := x_1 \dots x_k \exists y_1 \dots \exists y_k : \bigwedge_{1 \leq i < j \leq k} E(y_i, y_j) \wedge \bigwedge_{1 \leq i \leq k} E(x_i, y_i)\,. \tag{5}$$

We point out that ψ_k does not correspond directly to the vertex sets we would like to count as x_i and x_j could be the same vertex in G. However, it can be shown that an oracle for counting answers to ψ_k allows us to compute the desired number efficiently and vice versa. Finally, as the linked matching number of ψ_k is not bounded for $k \to \infty$, #A[2]-hardness follows from Theorem 2.

Building up on Theorem 2 and using the framework of linear combinations, we obtain the following, extensive classification result.

[4] If there is a constant bound on the number of quantified variables then the problem of counting answers to conjunctive queries is reducible to a #W[2]-complete problem w.r.t. parameterized Turing reductions. We omit a proof of this statement but point out that it can be done by lifting the results of Chapt. 7.4 in [14] to the realm of counting problems.

▶ **Theorem 3.** *Let Φ be a family of existential or universal positive formulas with inequalities and non-monotone constraints, both over the free variables. Given a formula φ from Φ and a logical structure B, we wish to compute the number of solutions of φ in B.*

When parameterized by $|\varphi|$, this problem is either fixed parameter tractable, W[1]*-equivalent,* #W[1]*-equivalent,* #W[2]*-hard or* #A[2]*-equivalent.*

Note that allowing the inequalities and non-monotone constraints over all variables, not just the free ones, would in particular include the subgraph decision problem. However, the parameterized complexity of finding a subgraph in G that is isomorphic to a small pattern graph P is a long-standing open question in parameterized complexity [11, Chapt. 33.1].

1.3 Techniques and Overview

Our paper brings together questions and techniques from a wide variety of areas, such as parameterized and fine-grained complexity, logics, database theory, matroid theory, lattice theory, graph minor theory, and the theory of graph limits. The interested reader should not be alarmed, however, as we put considerable effort into making the presentation as self-contained and smooth as possible, introducing the required background material carefully and only once needed in both, the extended abstract as well as in the full version this paper: After reviewing some basic preliminaries (Section 2), we formally present our refined complexity classifications in Section 3 for the special case of partial graph homomorphisms, rather than the full query evaluation problem. Due to the incompatibility of the space constraints and the amount of results and techniques required, we deferred all proofs as well as the treatment of the full query evaluation problem over arbitrary signatures of bounded arity to the full version of this paper.

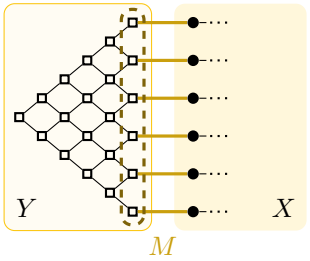
Colors and Query Minors

We will mainly work with a color-prescribed variant of the problem of counting answers to conjunctive queries. Here we assume that the elements of a given database B are colored according to the variables of the given conjunctive query φ and the goal is to compute the number of solutions that are additionally color-preserving. For this variant we will show and heavily exploit that the problem of counting answers to a conjunctive query φ is at least as hard as counting answers to any query that is a minor of φ. Minors of a query are defined via the (graph theoretic) minors of its Gaifman graph. It is then required to show that the color-prescribed variant and the uncolored variant are interreducible for all minimal queries. Intuitively, a query is minimal if it does not contain a proper subquery that produces the same set of solutions for each database. The proof of the interreducibility relies on the theory of homomorphic equivalence.

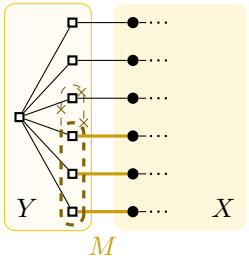
For Theorem 1 and the second case of Theorem 2 we construct a tight reduction from the problem of counting dominating sets of size k which cannot be solved in time $O(n^{k-\varepsilon})$ for any $\varepsilon > 0$ unless SETH fails [28] and which is hard for #W[2] [13].

Minor Theory

For #A[2]-hardness in Theorem 2 we take a detour to graph minor theory: Given a graph G, we call a set $S \subseteq V(G)$ *node-well-linked* if, for every pair of disjoint, equal-sized subsets A, B of S, there are $|A| = |B|$ vertex disjoint paths in G that connect the vertices in A with the vertices in B. Now, we obtain the following strengthening of the Excluded-Grid-Theorem, which might be of independent interest.



(a) A query (H, X) with a large linked matching number ($\mathsf{lmn}(H, X) = 6$): There is a large matching M (gold-colored) connecting vertices in X with a node-well-linked set in Y (enclosed within the dashed line).



(b) A query (H, X) with a small linked matching number ($\mathsf{lmn}(H, X) = 3$): While there may be larger matchings between vertices of X and Y, a largest matching M into a node-well-linked set in Y has size 3.

Figure 1 Examples for queries with large and small linked matching number.

▶ **Theorem 4** (Intuitive version). *There exists an unbounded function f such that every graph with a node-well-linked set S of k vertices has an $(f(k) \times f(k))$-grid minor with the property that there are $f(k)$ vertex-disjoint paths leading from S to the $f(k)$ vertices of the first column of the grid and without touching the grid minor elsewhere.*

If we drop the requirement that the minor model can be reached by disjoint paths from S, then this theorem is well-known and due to Diestel et al. [10].

Intuitively, we use Theorem 4 in the following way: If the quantified variables of a query contain a node-well-linked set S, we obtain a large grid-like structure that is connected to S by many vertex-disjoint paths. Next, we show that if that set S also has a large matching to a subset of the free variables of the query, then the query becomes #A[2]-hard. For this last step, we use an #A[2]-normalization theorem, which we will provide at the end of the paper.

Formally, we define the *linked matching number* of a query and prove #A[2]-hardness if this parameter is unbounded. Consider Figure 1 for examples for the linked matching number.

▶ **Definition 5** (Linked matching number). *Let (H, X) be graphical conjunctive query, let $Y = V(H) \setminus X$ be the set of quantified variables, and let M be a matching from X to Y. We call the matching M* linked *if the set $V(M) \cap Y$ is node-well-linked in $H[Y]$. The* linked matching number lmn *of (H, X) is defined as the size of the largest linked matching of H.*

Abstract Linear Combinations

To prove Theorem 3, we use abstract linear combinations that are called *quantum graphs* (or rather, quantum queries in our setting) and were developed in the theory of graph limits [23]. For our computational questions, the *complexity monotonicity property* [6] is the useful phenomenon that the quantum graph and its constituents (i.e., its abstract summands) often lead to computational problems that have precisely the same complexity. Using elementary linear-algebraic and polynomial interpolation arguments, we prove that this property holds, and we use Rota's NBC Theorem from lattice theory [29] to determine which graphs are constituents of the relevant quantum graphs. The complexity monotonicity property has been used (implicitly) by Chen and Mengel [5] for their extension from conjunctive queries to monotone queries; and the extension from homomorphisms to partially injective homomorphism [30] used Rota's Theorem in a similar fashion as we do in the present work.

2 Preliminaries

We use the notation $[n] = \{1, \ldots, n\}$ and $[m, n] = \{m, \ldots, n\}$ for natural numbers with $m < n$. We write $\#M$ for the cardinality of a finite set M. We write $f|_M$ for the restriction of a function f to elements of M. For a function $f\colon A \times B \to C$ and $a \in A$, we write $f(a, \star)$ for the function $b \mapsto f(a, b)$.

Graphs, Homomorphisms, and Formulas

Graphs in this paper are unlabeled, undirected, simple and without self-loops, unless stated otherwise. Let $V(G)$ denote the set of vertices and $E(G)$ denote the set of edges of G. We define the *size* of a graph G to be the number of vertices. Given a subset Y of $V(G)$, we write $G[Y]$ for the subgraph induced by the vertices of Y. The *complement graph* $\overline{G}$ has the same vertices as G and contains an edge uv if and only if $u \neq v$ and $uv \notin E(G)$. A *homomorphism* h from a graph F to a graph G is a mapping from $V(F)$ to $V(G)$ that is edge-preserving, that is, all $uv \in E(F)$ satisfy $h(u)h(v) \in E(G)$. We write $\mathsf{Hom}(F \to G)$ for the set of all homomorphisms from F to G. A bijective homomorphism whose inverse is also a homomorphism is called an *isomorphism*, and a homomorphism from F to F itself is called *endomorphism*. An endomorphism that is also an isomorphism is called an *automorphism*. We write $\mathsf{Aut}(F)$ for the set of all automorphisms of F.

Parameterized Counting Complexity

A *counting problem* is a function $P\colon \{0,1\}^* \to \mathbb{N}$, and a *parameterized counting problem* is a pair (P, π) where $\pi\colon \{0,1\}^* \to \mathbb{N}$ is computable and called a *parameterization*. Parameterized *decision* problems are defined likewise for decision problems $P\colon \{0,1\}^* \to \{0,1\}$. A parameterized (decision or counting) problem is *fixed-parameter tractable* if there is a computable function $t\colon \mathbb{N} \to \mathbb{N}$ such that, for every input $x \in \{0,1\}^*$, the function P can be computed in time $t(\pi(x)) \cdot \mathsf{poly}(|x|)$. We denote the class of all fixed-parameter tractable problems as FPT.

A *parameterized Turing-reduction* from (P, π) to (P', π') is an algorithm $\mathbb{A}$ with oracle access to P' that solves P, such that $\mathbb{A}$ runs in fixed-parameter tractable time when parameterized by π and there exists a computable function r such that, for every input x, the parameter $\pi'(y)$ of every query y is bounded by $r(\pi(x))$. A *parameterized parsimonious reduction* is a parameterized Turing-reduction with the additional requirement that $\mathbb{A}$ is only allowed to query the oracle a single time at the very end of the computation and then outputs the result of the query without further modification.

Clique is the parameterized (decision) problem to decide whether a given graph G contains a k-clique. Similarly, DomSet is to decide whether G has a dominating set of size k. The parameterized counting problems #Clique and #DomSet count the number of the respective objects. We define the parameterized complexity classes that appear in this paper by their well-known complete problems: W[1] contains all parameterized problems that are reducible to Clique with respect to parameterized parsimonious reductions. Similarly, #W[1], W[2], and #W[2] contain all problems reducible to #Clique, DomSet, and #DomSet, respectively. Furthermore #A[2] is the class of all parameterized counting problems that are expressible as model counting problem with one quantifier alternation. It is known that

$$\text{FPT} \leq^T \text{W[1]} \leq^T \#\text{W[1]} \subseteq \#\text{W[2]} \subseteq \#\text{A[2]}\,,$$

where $\text{C} \leq^T \text{D}$ denotes that every problem in C can be reduced to a problem in D with respect to parameterized Turing-reductions.

(a) **(b)**

Figure 2 (a) Graphical representation of the conjunctive query in (6). **(b)** A graphical conjunctive query that is "equivalent" to the example on the left in the sense that an assignment $a\colon \{x_1, \ldots, x_k\} \to V(G)$ is a partial homomorphism from the left graph to G if and only if it is a partial homomorphism from the right graph to G.

For further background on parameterized counting complexity, see [14, Chapter 14]. While the parameterized complexity classes are defined via parsimonious reductions, we will rely on Turing reductions. Hence we cannot speak of completeness but instead of equivalence.

▶ **Definition 6.** *Let* C *be a parameterized complexity class. A parameterized counting problem* (P, π) *is* C-easy *if it can be reduced to a problem in* C *and it is* C-hard *if every problem in* C *reduces to* (P, π)*, both with respect to parameterized Turing-reductions. A problem is* C-equivalent *if it is* C-easy *and* C-hard*.*

Exponential-Time Hypotheses

The strong exponential time hypothesis (SETH) asserts that for all $\delta > 0$ there is some $k \in \mathbb{N}$ such that k-SAT cannot be computed in time $O(2^{(1-\delta)n})$, where n is the number of variables of the input formula [19]. A dominating set of size k in an n-vertex graph cannot be computed in time $O(n^{k-\varepsilon})$ for any $\varepsilon > 0$ unless SETH is false [28]. The exponential time hypothesis (ETH) asserts that 3-SAT cannot be computed in time $\exp(o(m))$, where m is the number of clauses of the input formula [19].

3 Formal Statements of Our Results

It is instructive to first focus on conjunctive queries with one relation symbol E of arity two. An example of such a query is the following formula:

$$x_1 \ldots x_k \exists y : Ex_1y \wedge \cdots \wedge Ex_ky\,. \tag{6}$$

The relation E corresponds to a graph G and the free and quantified variables will be assigned vertices of G. In this example, an assignment $a_1, \ldots, a_k \in V(G)$ to the free variables satisfies the formula if and only if the vertices $a_1, \ldots, a_k$ have a common neighbor in G. It will be convenient for us to view the formula as a graph H as depicted in Figure 2. The vertices of H are partitioned into a set $X = \{x_1, \ldots, x_k\}$ of free variables and a set $Y = \{y\}$ of quantified variables. An assignment to the free variables corresponds to a function $a : X \to V(G)$, and such an assignment satisfies the formula if it can be consistently extended to a homomorphism from H to G. This motivates the following definition, where we only consider simple graphs without loops, so we do not allow atomic subformulas of the form Ezz.

▶ **Definition 7.** *A* graphical conjunctive query (H, X) *consists of a graph* H *and a set* X *of vertices of* H*. We let* $\mathsf{Hom}(H, X \to G)$ *be the set of all mappings from* X *to* $V(G)$ *that can be extended to a homomorphism from* H *to* G*, and we call these mappings partial homomorphisms. Formally, the set of partial homomorphisms is defined via*

$$\mathsf{Hom}(H, X \to G) = \left\{ a : X \to V(G) \;\middle|\; \exists h \in \mathsf{Hom}(H \to G) : h|_X = a \right\}. \tag{7}$$

Given two different graphical conjunctive queries (H, X) and $(\hat{H}, \hat{X})$ it might be the case that $\#\mathsf{Hom}(H, X \to \star)$ and $\#\mathsf{Hom}(\hat{H}, \hat{X} \to \star)$ are the same functions. An example for this is given in Figure 2. In this case, we say that (H, X) and $(\hat{H}, \hat{X})$ are *equivalent*, denoted as $(H, X) \sim (\hat{H}, \hat{X})$, and the subgraph-minimal elements of the induced equivalence classes are called *minimal*. In what follows, we classify the complexity of counting homomorphisms for classes of graphical conjunctive queries. More precisely, we consider the parameterized counting problem $\#\mathsf{Hom}(\Delta)$ for each fixed class Δ of graphical conjunctive queries. This problem is given as input a query $(H, X) \in \Delta$ and a graph G and the task is to compute the number $\#\mathsf{Hom}(H, X \to G)$. The problem is parameterized by the size of H. We start with the formal definitions of the different structural parameters of graphical conjunctive queries and present the classification theorem thereafter. All parameters, along with five example classes, are depicted in Figure 3.

▶ **Definition 8** (Contract). *The* contract *of a graphical conjunctive query (H, X) is a graph on the vertex set X, obtained by adding an edge between two vertices u and v in X if uv is an edge of H or if there exists a connected component C in $H \setminus X$ that is adjacent to both u and v. Given a class Δ of conjunctive queries, we write $\mathsf{contract}(\Delta)$ for the set of all of its contracts.*

▶ **Definition 9** (Dominating star size). *Let (H, X) be graphical conjunctive query and let $Y_1, \ldots, Y_\ell$ be the connected components of the subgraph $H[V(H) \setminus X]$ induced by the quantified variables. Further, let k_i be the number of vertices $x \in X$ for which there exists a vertex $y \in Y_i$ that is adjacent to x. The* dominating star size *of (H, X) is defined via*

$$\mathsf{dss}(H, X) = \max\{\, k_i \mid i \in \ell \,\}.$$

We are now in position to state our main result, the full classification for counting answers to conjunctive queries. Note that Theorem 2 is subsumed by the full classification in the case of graphs. The general version, that is, the case of arbitrary logical signatures with bounded arity, is stated and proved in the full version.

▶ **Theorem 10.** *Let Δ be a recursively enumerable class of minimal conjunctive queries.*

1. *If the treewidth of Δ and $\mathsf{contract}(\Delta)$ is bounded, then $\#\mathsf{Hom}(\Delta)$ can be computed in polynomial time.*
2. *If the treewidth of Δ is unbounded and the treewidth of $\mathsf{contract}(\Delta)$ is bounded, then $\#\mathsf{Hom}(\Delta)$ is $\mathrm{W}[1]$-equivalent.*
3. *If the treewidth of $\mathsf{contract}(\Delta)$ is unbounded and the dominating star size of Δ is bounded, then $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{W}[1]$-equivalent.*
4. *If the dominating star size of Δ is unbounded, then $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{W}[2]$-hard. Moreover, for any fixed query δ with $\mathsf{dss}(\delta) \geq 3$, the problem $\#\mathsf{Hom}(\delta \to \star)$ cannot be computed in time $O(n^{\mathsf{dss}(\delta)-\varepsilon})$ for any $\varepsilon > 0$ unless SETH fails.*
5. *If the linked matching number of Δ is unbounded, then $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{A}[2]$-equivalent.*

In proving the last case of Theorem 10, we establish the following generalization of the Excluded-Grid-Theorem which applies for conjunctive queries with a large linked matching number and is essentially equivalent to Theorem 4; consult Figure 3 for the notion of a *grate*.

▶ **Theorem 11.** *Let Δ be a class of graphical conjunctive queries. If the linked matching number of Δ is unbounded, then Δ contains arbitrarily large grates as minors.*

Query Classes	Δ_{poly}	$\Delta_{\mathrm{W}[1]}$	$\Delta_{\#\mathrm{W}[1]}$	$\Delta_{\#\mathrm{W}[2]}$	$\Delta_{\#\mathrm{A}[2]}$
Query for $k = 4$					contract for $k = 4$		$\emptyset$			
tw	$O(1)$	∞	∞	$O(1)$	∞

Complexity	P	W[1]-eq.	#W[1]-eq.	#W[2]-hard	#A[2]-eq.$^{(*)}$

Figure 3 Example problems for each case of the complexity classification (Theorem 10):

$$\Delta_{\mathrm{poly}} = \{\, \varphi_k \mid k \in \mathbb{N} \,\}, \quad \text{where } \varphi_k := x_1 \dots x_k \; \exists y_1 \dots \exists y_{k-1} : \bigwedge_{1 \le i < k} Ex_iy_i \wedge Ey_ix_{i+1}$$

$$\Delta_{\mathrm{W}[1]} = \{\, \psi_k \mid k \in \mathbb{N} \,\}, \quad \text{where } \psi_k := \exists y_1 \dots \exists y_k : \bigwedge_{1 \le i < j \le k} Ey_iy_j$$

$$\Delta_{\#\mathrm{W}[1]} = \{\, \upsilon_k \mid k \in \mathbb{N} \,\}, \quad \text{where } \upsilon_k := x_1 \dots x_k : \bigwedge_{1 \le i < j \le k} \exists y_{ij} : Ex_iy_{ij} \wedge Ey_{ij}x_j$$

$$\Delta_{\#\mathrm{W}[2]} = \{\, \delta_k \mid k \in \mathbb{N} \,\}, \quad \text{where } \delta_k := x_1 \dots x_k \exists y : \bigwedge_{1 \le i \le k} Ex_iy$$

Furthermore, $\Delta_{\#\mathrm{A}[2]}$ is the set of all *grates*. Here, a k-grate is the conjunctive query whose quantified variables constitute half of a $k \times k$ grid whose diagonal is connected to k free variables by a matching of size k. The formal definition is given in the full version.
Depicted is the query (H, X) for $k = 4$, where free variables (i.e., vertices in X) are drawn as solid discs and quantified variables (i.e., vertices in $V(G) \setminus X$) are drawn as hollow squares. We also display the contract (see Definition 8) of each query. We write $O(1)$ whenever a parameter is bounded by a constant in the entire query class, and ∞ whenever it is unbounded. Finally, we show the complexity of counting answers to conjunctive queries in each of the classes in terms of polynomial-time tractability (P) and equivalence (-eq.) or hardness for one of the parameterized complexity classes.

$(*)$ The observant reader might have noticed that a k-grate is not a minimal conjunctive query. For this reason, #A[2]-equivalence in the last column refers to minimal conjunctive queries that contain arbitrary large grates as minors. Alternatively, #A[2]-equivalence is shown to hold for k-grates in the color-prescribed case. Details are given in the full version.

Building upon Theorem 10, we invoke the complexity monotonicity property of linear combinations of conjunctive queries to classify the complexity of counting answers to queries of the form (2), that is, existential or universal first-order queries for which we allow inequalities and non-monotone constraints, both over the free variables. Specifically, we prove the classification as given by Theorem 3. Again, we refer to the full version for the general case of arbitrary logical structures of bounded arity. We also discuss conjunctive queries that may contain inequalities over the free variables. Note that in that case, we are able to give explicit criteria for the five different cases in Theorem 3.

4 Conclusions

We established a comprehensive classification of the complexity of counting answers to conjunctive queries and linear combinations thereof. Depending on the structural parameters of the class of allowed queries, the problem is either polynomial-time solvable, W[1]-equivalent, #W[1]-equivalent, #W[2]-hard or #A[2]-equivalent. This classification, however, leaves out a gap between the latter two cases. More precisely, the following question remains open:

Does a class of conjunctive queries Δ exist for which $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{W}[2]$-hard but neither equivalent for $\#\mathrm{W}[2]$ nor for $\#\mathrm{A}[2]$?

We conjecture a positive answer; the interested reader is encouraged to make themself familiar with the parameterized complexity class $\mathsf{W}_{\mathsf{func}}[2]$ (see e.g. [14, Chapter 8.8]). This class has a canonical counting version which we call $\#\mathsf{W}_{\mathsf{func}}[2]$ and which interpolates between $\#\mathrm{W}[2]$ and $\#\mathrm{A}[2]$. In particular, we conjecture that there exists a class of conjunctive queries Δ for which $\#\mathsf{Hom}(\Delta)$ is $\#\mathsf{W}_{\mathsf{func}}[2]$-equivalent. Consequently, a negative answer to the previous question would imply that either $\#\mathsf{W}_{\mathsf{func}}[2] = \#\mathrm{W}[2]$ or $\#\mathsf{W}_{\mathsf{func}}[2] = \#\mathrm{A}[2]$, which seems to be very unlikely (see e.g. the discussion of $\mathsf{W}_{\mathsf{func}}[2]$ in [14, Chapter 8.8]).

A further question that remains open, and which should be considered a stronger version of the previous question, reads as follows:

Does a class of conjunctive queries Δ exist such that Δ has bounded linked matching number and the problem $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{A}[2]$-equivalent?

In other words, the above question asks whether the absence of a bound on the linked matching number is not only sufficient, but also necessary for $\#\mathrm{A}[2]$-equivalence. In contrast to the previous question, we conjecture a negative answer. Let us provide some intuition for the latter conjecture: It seems that a constant bound on the linked matching number of a class of conjunctive queries Δ yields a separator decomposition of the quantified variables of queries in Δ in components that have either small treewidth or a small matching number to the free variables. We conjecture that such a decomposition implies the existence of what is called a κ-restricted nondeterministic Turing machine $\mathbb{M}$ such that the number of accepting paths of $\mathbb{M}$ on input $(H, X) \in \Delta$ and a graph G is precisely $\#\mathsf{Hom}(H, X \to G)$ (see e.g. [14, Definition 14.15]). If additionally $\#\mathsf{Hom}(\Delta)$ is $\#\mathrm{A}[2]$-equivalent, this would imply that the set of $\#\mathrm{A}[2]$-equivalent problems is a subset of the set of $\#\mathsf{W}[\mathsf{P}]$-equivalent problems; consult e.g. [14, Chapter 3 and 14.2] for a treatment of the class $\#\mathsf{W}[\mathsf{P}]$. However, the latter inclusion seems to be unlikely and we refer the interested reader to [14, Chapter 8] for a detailed treatment of the corresponding question whether $\mathrm{A}[2] \subseteq \mathsf{W}[\mathsf{P}]$ in the decision world. We conclude with the remark that even a proof of $\mathrm{A}[2] \subseteq \#\mathsf{W}[\mathsf{P}]$ would be a major breakthrough as it constitutes the first step of a parameterized analogue of Toda's theorem [31], which is one of the fundamental open problems in (structural) parameterized counting complexity.

Abstract

We present an improved exponential time algorithm for Energy Games, and hence also for Mean Payoff Games. The running time of the new algorithm is $O\left(\min\left(mnW, mn2^{n/2}\log W\right)\right)$, where n is the number of vertices, m is the number of edges, and when the edge weights are integers of absolute value at most W. For small values of W, the algorithm matches the performance of the pseudopolynomial time algorithm of Brim et al. on which it is based. For $W \geq n2^{n/2}$, the new algorithm is faster than the algorithm of Brim et al. and is currently the fastest *deterministic* algorithm for Energy Games and Mean Payoff Games. The new algorithm is obtained by introducing a technique of forecasting repetitive actions performed by the algorithm of Brim et al., along with the use of an edge-weight *scaling* technique.

1 Introduction

Energy Games (EGs) and Mean Payoff Games (MPGs) are simple and natural infinite-duration games played on graphs that can be used to model quantitative properties of interactive systems. They are also interesting as they are perhaps the most natural combinatorial problems that are in $NP \cap \text{co-}NP$ and yet not known to be in P or in BPP. Mean Payoff Games (MPGs) were introduced by Ehrenfeucht and Mycielski [9]. Energy Games (EGs) were introduced by Chakrabarti et al. [7] and later by Bouyer et al. [4] who also showed their equivalence to MPGs.

Energy Games are games played by two players, player 0 and player 1, on a weighted directed graph whose vertices are partitioned among the two players. The two players construct an infinite path, that starts at a designated start vertex, in the following way. The player controlling the end-point u of the path constructed so far extends the path by

choosing an edge emanating from u. Let $w_1, w_2, \ldots$ be the weights of the edges on the path constructed. Player 0 wins this play if $\liminf_{n\to\infty} \sum_{i=1}^{n} w_i > -\infty$, i.e., if there exists an initial finite *energy level* c such that $c + \sum_{i=1}^{n} w_i \geq 0$, for every $n \geq 1$. Player 1 wins otherwise. Player 0 wins the game from an initial vertex u if she can ensure a winning play from u, no matter what player 1 does. It is known that if player 0 can win from a certain vertex, then she can also do it using a *positional strategy*, i.e., a deterministic strategy in which the edge chosen depends only on the current vertex. Furthermore, she has a single positional strategy using which she wins from all the vertices from which she can win. Solving an EGs amounts to finding the winner from each vertex, and possibly an optimal positional strategy and the minimal energy level required from every winning vertex.

Parity Games (PGs) form a very special sub-class of MPGs. In a recent breakthrough, Calude et al. [6] obtained a deterministic quasipolynomial $n^{O(\log n)}$-time algorithm for PGs, where n is the number of vertices. (Variants of their algorithm were obtained by [3, 10, 13, 18, 21].) Unfortunately, these techniques do not seem applicable to MPGs and EGs. (See [11].) The currently fastest algorithm for these games, as well as the more general (turn-based) Stochastic Games (SGs), is a sub-exponential $2^{\tilde{O}(\sqrt{n})}$ ([1, 2, 16, 17, 23]). These sub-exponential algorithms are based on randomized pivoting rules for the simplex algorithm devised by Kalai [19, 20] and Matoušek, Sharir and Welzl [24]. The fastest known deterministic algorithms for EGs and MPGs are the exponential $O(mn2^n \log W)$-time algorithm of Lifshits and Pavlov [22],[1] and a pseudo-polynomial $O(mnW)$-time algorithm of Brim et al. [5].[2] Polynomial time algorithms for EGs with very special weight structures were obtained by Chatterjee et al. [8].

The simple and elegant $O(mnW)$-time algorithm of Brim et al. [5], henceforth referred to as the BCDGR algorithm, is a *progress measure lifting* algorithm for solving EGs. MPGs are essentially equivalent to EGs ([4]), hence the algorithm can also be used to solve MPGs. The lifting technique used by Brim et al. is similar to the *value iteration* technique used by Zwick and Paterson [26] on MPGs.

We present an improvement of the BCDGR algorithm that runs in $O(\min\{mnW, mn2^{n/2} \log W\})$-time. The new algorithm is always as fast as the BCDGR algorithm and strictly faster when $W = \omega(n2^{n/2})$. The running time of the new algorithm can be made to be $O(poly(n)2^{n/2})$, without any dependence on W, assuming that arithmetic operations on integers of absolute value $O(nW)$ take constant time. (Details will appear in the full version of the paper.) The new algorithm is currently the fastest *deterministic* algorithm for EGs and MPGs when $W \geq n2^{n/2}$.

The new algorithm uses two new ideas. The first is a technique for predicting sequences of update steps that are performed repetitively by the BCDGR algorithm, and achieving the net effect of these repetitions much more quickly. To make this approach work, a second idea, that of *scaling*, needs to be used. Scaling is a well-known technique used in various combinatorial optimization problems such as shortest paths, flow problems, matching problems etc. (See, e.g., [12, 14, 15].) A scaling algorithm first divides all edge weights by 2, rounds them up so that they remain integers, solves the reduced problem recursively, and then converts the solution of the reduced problem to a solution of the original algorithm. It is quite natural to try to use the scaling technique on EGs or MPGs. However, naïve or

---

[1] For solving EGs, and for deciding whether the values of a MPG are non-negative, the $\log W$ factor in the running time of [22] is not needed.

[2] Recently, Fijalkow et al. [11] gave an $O(mn(nW)^{1-1/n})$-time algorithm for solving MPGs. This, however, is never asymptotically better than $O(\min\{mnW, mn2^n\})$, as $W^{1-1/n} < \frac{1}{2}W$ only if $W \geq 2^n$.

direct approaches do not seem to give any improvement. To the best of our knowledge, the algorithm presented here is the first algorithm that successfully uses scaling for speeding up the solution of EGs and MPGs.

An EG, MPG or SG is said to be *binary* if the outdegree of each vertex is 2. It is known that binary EGs, MPGs and SGs can be modeled as *Acyclic Unique Sink Orientations* (AUSOs) (see, e.g., [23, 25]). Solving a game is then equivalent to finding the *sink* of the associated AUSO. The fastest deterministic sink-finding algorithm runs in $O(1.606^n)$-time. Our new algorithm is faster than this algorithm and works for all games, not only binary.

The rest of the paper is organized as follows. In the next section we provide some definitions and basic results and briefly review the algorithm of Brim et al. [5] on which our new algorithm is based. In Section 3 we present our new algorithm. In the full version of the paper we describe energy games on which the new algorithm requires $\Omega(2^{n/2})$ time, showing that our analysis is essentially tight. We end in Section 4 with concluding remarks and open problems.

2 Preliminaries

A **game graph** is a tuple $\Gamma = (V_0, V_1, E, w)$, where $V = V_0 \cup V_1$ is the set of vertices, $E \subseteq V \times V$ is the set of edges, and $w : E \to \mathbb{Z}$ is a weight function. We assume that $V_0 \cap V_1 = \emptyset$ and that each vertex has at least one outgoing edge. The sets V_0 and V_1 are the sets of vertices controlled by player 0 and player 1. A *positional strategy* of player i is a mapping $\sigma : V_i \to E$ such that for every $v \in V_i$ we have $(v, \sigma(v)) \in E$. Given *positional strategies* σ_0, σ_1 of player 0 and player 1 and an initial vertex v_0, $play(v_0, \sigma_0, \sigma_1) = v_0, v_1, \ldots, v_i, \ldots$ is the infinite walk resulting from σ_0 and σ_1 starting at v_0.

An **Energy-Game** is an infinite game on a game graph Γ. Player 0 wins from an initial vertex $v_0 \in V$ if and only if there exists a positional strategy σ_0, and a finite *energy level* $c = c(v_0)$, such that for every positional strategy σ_1 of player 1, we have $c + \sum_{i=0}^{n-1} w(v_i, v_{i+1}) \geq 0$, for every $n \geq 1$, where $play(v, \sigma_0, \sigma_1) = v_0, v_1, \ldots$.

We shall refer to a function $f : V \to \mathbb{N} \cup \{\infty\}$ as a *potential* function.

▶ **Definition 2.1.** *Let $\Gamma = (V_0, V_1, E, w)$ be an energy-game. A function $f : V \to \mathbb{N} \cup \{\infty\}$ is a feasible potential iff for every $v \in V$:*

- *if $v \in V_0$, then $f(v) + w(v, v') \geq f(v')$ for some $(v, v') \in E$.*
- *if $v \in V_1$, then $f(v) + w(v, v') \geq f(v')$ for all $(v, v') \in E$.*

We call the potential function $g(v) = \min\{f(v) \mid f \text{ feasible potential}\}$ the solution *of Γ.*

Brim et al. [5] proved that g is a *feasible* potential and that player 0 wins from v if and only if $g(v) < \infty$, in which case $g(v)$ is the minimal required initial energy.

Let $\Gamma = (V_0, V_1, E, w)$ be an energy-game and let $f : V \to \mathbb{N} \cup \{\infty\}$ be a *potential* function. We denote by $w_f(u, v) = w(u, v) + f(u) - f(v)$ the *modified* weight of (u, v). An edge (u, v) is *valid* with respect to f if $w_f(u, v) \geq 0$. A vertex $v \in V_0$ (V_1) is *valid* with respect to f if (v, v') is *valid* with respect to f for some (all) $(v, v') \in E$, otherwise we say that v is *invalid* with respect to f (we say just *valid* when f is clear from the context). An edge (v, v') is *tight* if $w_f(v, v') = 0$. A path p is *tight* if all its edges are tight. A vertex $v \in V_0$ is *tight* if it is *valid* and $w_f(v, v') \leq 0$ for all $(v, v') \in E$. A vertex $v \in V_1$ is *tight* if it is *valid* and $w_f(v, v') = 0$ for some $(v, v') \in E$. We denote by $in(u)$ and $out(u)$ the sets of incoming and outgoing edges from u, respectively.

2.1 The algorithm of Brim et al.

Brim et al. [5] suggested the following algorithm: maintain $f : V \to \mathbb{N} \cup \{\infty\}$, starting with $f \equiv 0$. As long as there are *invalid* vertices, pick some *invalid* vertex v and increase $f(v)$ to the minimal value that would make v *valid*. It is known that if player 0 can win from a certain vertex, then she can win with an initial energy of at most nW. Thus, if $f(v)$ reaches nW, we know that v is a losing vertex for player 0, and we can let $f(v) \leftarrow \infty$.

To efficiently find an invalid vertex, the algorithm maintains a list L of *invalid* vertices. When $f(v)$ of some *invalid* vertex $v \in V$ is updated, the algorithm checks for every edge $(v', v) \in in(v)$ that became *invalid* whether v' is now also *invalid*. If $v' \in V_1$, then this is the case, and v' is added to L, if it is not already there. If $v' \in V_0$, then increasing $f(v)$ does not necessarily make v' *invalid*, as v' may have had other valid edges. The algorithm maintains $count[v']$, the number of valid edges in $out(v')$. If (v', v) was valid, then $count[v']$ is decremented. If $count[v']$ becomes 0, then v' is now *invalid* and it is added to L. It is not hard to check that the running time of the resulting algorithm is $O(mnW)$, which is also known to be tight.

2.2 A reduction to games with finite values

The description and the correctness proof of algorithms for solving EGs are often simplified if it assumed that all vertices have finite values, i.e., are all winning for player 0. (This does not trivialize the problem, as we still want to find the minimum energy level needed from each vertex, and corresponding optimal positional strategies for the two players.) We describe a simple reduction, inspired by a reduction of Björklund et al. [2], that shows that the solution of a general EG can be reduced to the solution of an EG with finite values.

Let $\Gamma = (V_0, V_1, E, w)$ be an EG, and let $n = |V|$ and $W = \max_{e \in E} |w(e)|$. Let f be the solution of Γ. For every $v \in V$, we know that either $0 \leq f(v) < nW$, or $f(v) = \infty$. To convert Γ into a game Γ' in which all values are finite, we add a *sink* vertex s, with a self-loop of weight 0, and add an edge (v, s) of weight $-2nW$ for every $v \in V_0$. This ensures that the values of all vertices in V_0 are finite. (In particular, their value is at most $2nW$.)

To ensure that the values of all vertices in V_1 are also finite, we need to perform a simple preprocessing step. If $u \in V_1$ and player 0 has a strategy for reaching a vertex of V_0, starting at u, then the value of u is also finite. We are thus left with vertices of V_1 from which player 1 can win the game, i.e., reach a negative cycle, without leaving V_1. It is easy to identify these vertices and remove them from the game. The value of all remaining vertices is now finite.

If it is to player 0's advantage to escape to the sink, she might as well do it without closing any cycles. Player 0 can therefore gain at most $(n-1)W$ units of energy by following original edges before deciding to take an edge to the sink. The energy needed in such a case is therefore at least nW. We thus have:

▶ **Lemma 2.2.** *Let $\Gamma = (V_0, V_1, E, w)$ be an EG and let Γ' be the EG obtained by the reduction above. Let f and f' be the solutions of Γ and Γ'. Then, for every $u \in V = V_0 \cup V_1$, we have*

$$f(u) = \begin{cases} f'(u) & \text{if } f'(u) < nW, \\ \infty & \text{otherwise.} \end{cases}$$

Note that the reduction introduces only one new vertex which is important if we want to use it in conjunction with exponential time algorithms. The maximal edge weight is increased from W to $2nW$, but this is not an issue if the running time of the algorithm depends only logarithmically on W.

3 The new algorithm

We now describe our new algorithm. For simplicity, we assume that all the values in the input game are finite. This can be achieved, for example, using the simple reduction above. In the full version we show that the algorithm presented actually works, as is, even if some values are infinite, but the correctness proof becomes slightly more complicated.

Given an EG $\Gamma = (V_0, V_1, E, w)$, we construct a scaled down version $\Gamma' = (V_0, V_1, E, w' = \lceil \frac{w}{2} \rceil)$, where $\lceil \frac{w}{2} \rceil(e) = \lceil \frac{w(e)}{2} \rceil$, for every $e \in E$, and solve it recursively, obtaining the solution f' of Γ'. (Note that Γ' is "easier" for player 0 because of the rounding up. In particular, if all values in Γ are finite, so are all the values in Γ'.) We now scale Γ' back up to $\Gamma'' = (V_0, V_1, E, 2\lceil \frac{w}{2} \rceil)$. Note that $f'' \equiv 2f'$ is the solution of Γ'' and that Γ'' is very close to Γ: $2\lceil \frac{w}{2} \rceil$ and w only differ, by 1, on edges e for which $w(e)$ is *odd*. To convert f'' into a solution of Γ, we consider each vertex $v \in V$ with odd outgoing edges, decrease the corresponding edge weights in $2\lceil \frac{w}{2} \rceil$ by 1, and update the solution f'' accordingly. (This is, of course, the hardest part of the algorithm.) These operations are carried out by algorithms COMPUTE-ENERGY and UPDATE-ENERGY given in Figure 1.

UPDATE(u, L, B).

```
1 L ← L \ {u}
2 f(u) ← f(u) + 1
3 if u ∈ V_0 then count[u] ← |{(u, u') ∈ E | w_f(u, u') ≥ 0}|
4 foreach u' ∈ in(u) such that w_f(u', u) < 0 do
5     if u' ∈ V_0 then
6         if w_f(u', u) = −1 then count[u'] ← count[u'] − 1
7         if count[u'] = 0 then L ← L ∪ {u'}, B ← B ∪ {u'}
8     if u' ∈ V_1 then L ← L ∪ {u'}, B ← B ∪ {u'}
```

DELTA(B).

```
1 p_1 ← min{−w_f(u, u') | (u, u') ∈ E(B ∩ V_0, B̄)}
2 p_2 ← min{γ(u) | u ∈ B̄ ∩ V_0, ∀u' ∈ B̄  w_f(u, u') < 0}
3 p_3 ← min{w_f(u, u') | (u, u') ∈ E(B̄ ∩ V_1, B)}
4 return min{p_1, p_2, p_3}
```

Figure 2 The remaining two function of the new $O\left(\min\left(mnW, mn2^{n/2}\log W\right)\right)$-time algorithm.

UPDATE-ENERGY updates the solution f after the decrease of the weights of some of the edges emanating from v by 1. As in [5], UPDATE-ENERGY maintains a list L of all vertices that are currently *invalid*. Initially only v may be *invalid*. To quickly determine whether a vertex $u \in V_0$ becomes *invalid*, we maintain in $count[u]$ the number of *valid* edges from u. A vertex $u \in V_0$ is thus *invalid* iff $count[u] = 0$.

Lines 1–2 of UPDATE-ENERGY determine whether v is *invalid*. If v is *valid*, we are done. Otherwise, we add v to L and *fix* v by increasing $f(v)$ by 1. This makes v *valid*, but vertices u with edges (u, v) may become *invalid* and need to be added to L. Updating v's potential and checking for new *invalid* vertices is carried out by UPDATE given in Figure 2. If we fix *invalid* vertices from L in an arbitrary order, as done by [5], we get the running time of [5].

The main point in which our algorithm differs from the algorithm of [5], in addition to the use of scaling, is that we fix at first only *invalid* vertices *different* from v, delaying an additional fixing of v, if required, by as much as possible. Lemma 3.2 below shows that no vertex needs to be fixed twice, before v is fixed again.

If v does not become *invalid* again, then UPDATE-ENERGY is done. Otherwise, let B be the set of vertices, including v, updated until v is the only *invalid* vertex. (Lemma 3.2 shows that this must eventually happen.) When we update v again, it could be that the *same* set of vertices B will eventually become *invalid*, and hence updated, again. Furthermore, in worst-case examples of [5], the same sequences of update operations may be repeated many times. Instead of carrying out these updates again and again, we *predict* how many times the same sequence of updates will be repeated and perform all these updates at once. This approach seems to work only when the weights of edges are decreased by 1, which is why the scaling idea needs to be used.

The computation of Δ, the number of repetitions of the current sequence, carried out by DELTA(B) in Figure 2, is based on the following observation. Let B be the set of vertices that became *invalid* after updating v and let B' be the set of vertices that became *invalid* after updating v again. Assume $B' \neq B$. If $B' \setminus B \neq \emptyset$, let $u \in B' \setminus B$ be the first vertex in $B' \setminus B$ that became *invalid*. It must be the case that at least one of u's *valid* edges to B became *invalid*. If $u \in V_1$ this could be any edge from u, and if $u \in V_0$ this edge is the edge with maximal *modified* weight from u and u had no *valid* edges to $\bar{B} \equiv V \setminus B$.

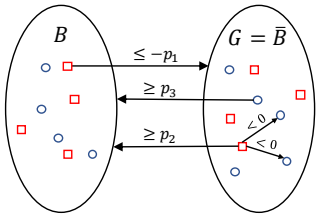

Figure 3 Calculating DELTA(B): Vertices in V_0 are red squares; Vertices in V_1 are blue circles.

If $B \setminus B' \neq \emptyset$, then $(B \setminus B') \cap V_0 \neq \emptyset$. To see this, let $v_0 = v, v_1, \ldots$ be the vertices of B in the order in which they were updated. Let v_j be the first vertex in this order which is not in B'. Vertex v_j must have an *invalid* edge (v_j, v_ℓ) such that $\ell < j$. This edge became *invalid* when we updated v_ℓ and caused the addition of v_j to B. Since v_j is the first vertex which is not in B', $v_\ell \in B'$ and therefore the edge (v_j, v_ℓ) becomes *invalid* when we collect B' following the second update of v. So $v_j \in V_0$, as otherwise it should have been added to B'. Vertex v_j is not added to L since it has an edge (v_j, w), $w \notin B$ that had a *modified* weight of -1 that became 0 (i.e., *valid*) following the update of v_j.

Therefore, to compute Δ, we must consider all *valid* edges from $\bar{B}$ to B (to detect new vertices that might become *invalid*) and all *invalid* edges from vertices in $V_0 \cap B$ to $\bar{B}$, see Figure 3. We refer to minimum and maximum of an empty set as ∞ and $-\infty$, respectively. We let $\Delta = \min\{p_1, p_2, p_3\}$ were p_1, p_2 and p_3 are defined as follows. The value p_1 is minus the maximum modified edge weight of an edge from $B \cap V_0$ to $\bar{B}$. Note that $p_1 \geq 0$. To define p_2 consider every vertex $u \in V_0 \cap \bar{B}$ that does not have a valid edge (u, w) to $w \in \bar{B}$. For every such u let $\gamma(u)$ be the maximum modified weight of an edge (u, w), $w \in B$. Note that $\gamma(u) \geq 0$. We define p_2 to be the minimum value of $\gamma(u)$ over all such vertices u. The value p_3 is the minimum modified edge weight of an edge from $V_1 \cap \bar{B}$ to B. Note that p_2 and p_3 are nonnegative. Pseudo-code of DELTA(B) is given in Figure 2.

3.1 Correctness

As explained, we assume for simplicity that all values are finite. This assumption is removed in the full version of the paper. The correctness of the new algorithm follows from the fact that the potential function kept by the algorithm is always a lower bound on the values of the vertices, and hence the updates performed are justified, as in the correctness proof of the BCDGR algorithm. As the new algorithm predicts sequence of updates that are going to be performed repeatedly, and performs all these repetitions at once, what remains to be shown is that the predictions of the algorithm are correct.

▶ **Lemma 3.1.** *Let* $\Gamma^1 = (V_0, V_1, E, w^1)$, $\Gamma^2 = (V_0, V_1, E, w^2)$ *be two games graphs with solutions* f^1 *and* f^2*, respectively. If* $w^1 \leq w^2$ *then* $f^1 \geq f^2$ *(coordinate-wise).*

It follows Lemma 3.1 that the solution of Γ'' is a lower bound on the solution of the original game Γ. All that remains, therefore, is to show that the updates performed by UPDATE-ENERGY are justified.

Let UPDATE($v_1 \equiv v$), UPDATE(v_2), ..., UPDATE(v_k) be the sequence of vertex updates performed by UPDATE-ENERGY($\ldots, f, v$). A *round* is one iteration of the outer while loop of UPDATE-ENERGY, i.e., all vertex updates starting with UPDATE(v) until and not including the next UPDATE(v). We number the rounds starting from 1 and let f^r be f at the end of round r. For convenience, we define $f^0 \equiv f$. We let B^r be the set of vertices that were updated during round r ("bad" vertices). Thus, B^r is B at the end of round r of the outer while loop of UPDATE-ENERGY. Let $G^r = \overline{B^r} = V \setminus B^r$ be the set of "good" vertices.

▶ **Lemma 3.2.** *In each round, each vertex is updated at most once.*

Proof. By contradiction, let u be the first vertex that joined L for the second time during a round. We have that $u \neq v$ by the definition of a *round*. Assume $u \in V_0$. Since $u \neq v$ (i.e., u is *valid* at the beginning of the round), $w_f(u, u') \geq 0$ for some vertex u' at the beginning of the round. From the beginning of the round until u's second update, u' is updated at most once and u is updated exactly once so we have that $w_f(u, u') \geq 0$ right before u's second update which is a contradiction (u is *valid*). A similar argument works when $u \in V_1$. ◀

▶ **Lemma 3.3.** *During* Update-Energy, $u \in L$ *if and only if* u *is* invalid.

Proof. By induction on the iterations of the algorithm. ◀

Note that vertices u that were never updated (in any call to Update-Energy) are those with $f(u) = 0$. Also, note that every *tight* vertex u has at least one *tight* edge.

▶ **Lemma 3.4.** *During* Update-Energy, *if* $u \notin L$ *and* $f(u) > 0$, *then* u *is tight.*

Proof. Following an update, u becomes *tight* and it remains *tight* as long as it is *valid*. Since $f(u) > 0$, u was updated and since $u \notin L$, u is *valid* (Lemma 3.3). ◀

▶ **Lemma 3.5.** *At the end of round* r, *every* $u \in (G^r \setminus \{v \mid f(v) = 0\}) \cap V_0$ *is tight and for every tight edge* (u, u') *it holds that* $u' \in G^r$. *Also, there exists* $u' \in G^r$ *such that* $(u, u') \in E$ *is* tight *during round* r.

Proof. We prove the first part by contradiction. Let (u, u') be a *tight* edge at the end of round r such that $u' \in B^r$. Since $u' \in B^r$, u' was updated during round r and therefore at the beginning of round r it holds that $w_f(u, u') > 0$, so u was not *tight* at the beginning of the round. This contradicts Lemma 3.4 that implies that u is always *tight* during round r.

We now prove the second part. Since u is *tight* during the round and in particular at the end of the round, $(u, u') \in E$ is *tight* for some u' at the end of the round. By the first part of the Lemma $u' \in G^r$. Thus, (u, u') is *tight* during the entire round (since both $f(u)$ and $f(u')$ remain unchanged during the round). ◀

▶ **Lemma 3.6.** *At the end of round* r, *if* $u \in (B^r \setminus \{v\}) \cap V_1$ *and* $(u, u') \in E$ *is* tight, *then* $u' \in B^r$.

Proof. If $u' \in G^r$ then (u, u') was *invalid* at the beginning of round r (since $f(u)$ but not $f(u')$ was increased during the round), and therefore u was *invalid* at the beginning of round r, but only v is invalid at the beginning of each round, a contradiction. ◀

▶ Remark. Note that we cannot guarantee that u has a *tight* edge during the round (as in Lemma 3.5). This is because when u becomes *invalid*, it might be the case that all of its edges became *invalid* (u is ensured to have a *tight* edge only when it is *valid*).

The proof of the following lemma is given in the full version of the paper.

▶ **Lemma 3.7.** *Consider round* r. *If we would have performed* Update-Energy *without lines* 11–12, *then in the following* Δ *rounds* $r + 1, ..., r + \Delta$ *we would have* $B^r = B^{r+i}$, *for* $1 \leq i \leq \Delta$, *where* Δ *is the value returned by* Delta(B). *Furthermore, if* $r + \Delta$ *is not the last round then* $B^{r+\Delta+1} \neq B^r$.

As a consequence we get:

▶ **Theorem 3.8.** Update-Energy (V_0, V_1, E, w, f, v) *updates* f *correctly.*

The rest of the lemmas in this section are used in the next section to bound the complexity of the algorithm.

Let u be a *valid* vertex such that $f^r(u) > f^0(u)$ (i.e., the potential of u was changed at least once before the end of round r). We let $t_r(u)$ be the time right after the last UPDATE(u) that occurred before the end of round r. We remove the subscript r when it is clear from the context.

▶ **Lemma 3.9.** *At the end of round r, for any $u \in G^r$ with $f^r(u) > f^0(u)$:*
1. *If $u \in V_0$ then for any* tight *edge (u, u') with $u' \in G^r$, either $f^r(u') = f^0(u')$ or $t_r(u') < t_r(u)$.*
2. *If $u \in V_1$ then there exists a* tight *edge (u, u') such that $u' \in G^r$ and $t_r(u') < t_r(u)$.*

Proof. Note that since $u \in G^r$, $t_r(u)$ is before round r begins. We begin with the first part. Let (u, u') be such an edge. If $f^r(u') = f^0(u')$ then we are done. Otherwise, u' must have been updated at least once (and therefore $t(u')$ is defined). Assume by contradiction that $t(u') > t(u)$. Since (u, u') is *tight* at the end of round r then $w_f(u, u') > 0$ at $t_r(u)$. This contradicts Lemma 3.4 since at $t_r(u)$ it holds that u is *valid* and not *tight*.

We now prove the second part. Since u must be *tight* at $t(u)$ there exists $u' \in V$ such that (u, u') is *tight* at $t(u)$. Note that u' must be *valid* from $t(u)$ until the end of round r, since otherwise u will become *invalid* after $t(u')$ which is a contradiction. Thus, $u' \in G^r$ and $t(u') < t(u)$. Since u and u' remain *valid* from $t(u)$ until the end of round r, (u, u') is *tight* at the end of round r. ◀

▶ **Lemma 3.10.** *At the end of round r the following holds for all $u \in V$:*
1. *If $u \in B^r$ then u has a* tight *path of vertices in B^r to v.*
2. *If $u \in G^r$ then u has a* tight *path of vertices in G^r to a vertex u' with $f^r(u') = f^0(u')$.*

Proof. We begin by proving the first claim. Every vertex $u \in B^r$, $u \neq v$ joins L because of some edge (u, u') which is *invalid* after we update u'. This edge must be *tight* at the end of the round. So each vertex u has a *tight* edge to a vertex u' which was updated before u during round r. This implies the first part.

We now prove the second claim. If $f^r(u) = f^0(u)$ then we are done. Otherwise, assume $f^r(u) > f^0(u)$. We continue the proof by induction on $t(u)$. Base case, $t(u)$ is minimal (i.e., u was updated first). By Lemma 3.9, u has a *tight* edge (u, u') with $u' \in G^r$ such that $f^r(u') = f^0(u')$ (since $t(u)$ is minimal) and we are done. Assume that the claim follows for all vertices u' with $t(u') < t(u)$. By Lemma 3.9, u has a *tight* edge (u, u') with $u' \in G^r$ such that either $f^r(u') = f^0(u')$ or $t(u') < t(u)$. If $f^r(u') = f^0(u')$ then we are done. Otherwise, $t(u') < t(u)$ and therefore by the induction hypothesis, u' has a *tight* path to some vertex u'' with $f^r(u'') = f^0(u'')$. ◀

3.2 Complexity

Recall that $|V| = n, |E| = m$ and W is the maximal absolute value weight.

▶ **Theorem 3.11.** *The running time of compute–energy is* $O\big(\min\big(mnW, mn \cdot 2^{n/2} \log W\big)\big)$.

The $O(mnW)$ bound follows immediately since each vertex u is updated at most $O(|V| \cdot W)$ times and each such update takes $O(|in(u)| + |out(u)|)$ time, where $in(u)$ and $out(u)$ are the sets of ingoing and outgoing edges of u, respectively. To prove the latter bound we must have a better understanding of the relation between B^r and G^r. In the rest of this section we prove the $O\left(mn \cdot 2^{n/2} \log W\right)$ bound.

For this we define a potential function that maps rounds (as defined in Section 3.1) into integers. The *good anchor* of round r is defined as the set $GA^r = V \setminus \bigcup_{i=1}^{r} B^i$, i.e., vertices whose potential was not changed yet ($f^r(u) = f^0(u)$). Following each round the *good anchor* can only lose vertices. The *bad anchor* of round r is defined as the set $BA^r = \{u \in B^r \mid \exists \textit{tight}$ path of vertices in $V_0 \cap B^r$ from u to $v\}$, i.e., BA^r contains v and all vertices in $V_0 \cap B^r$ that have a *tight* path of vertices in $V_0 \cap B^r$ to v. Note that if $GA^r = \emptyset$, then no vertex is winning for player 0: To see this, note that in this case $f(u) > 0$ for all $u \in V$. Therefore, the potential $f'(v) \equiv f(v) - 1$, for all $v \in V$ is *feasible*, a contradiction (since f is the *solution*).

We partition B^r and G^r into layers BL_i^r, GL_i^r, $i = 0, 1 \ldots$, respectively, see Figure 4. The layer BL_i^r/GL_i^r is called the i'th layer of B^r/G^r, respectively. The 0'th layers are the anchors, i.e., $BL_0^r = BA^r, GL_0^r = GA^r$. The layers are defined inductively as follows.

$$\begin{aligned} BL_i^r &= \{u \in B^r \cap V_p \mid \ u \text{ has a tight path of vertices in } u \in B^r \cap V_p \text{ to } BL_{i-1}^r\} \\ GL_i^r &= \{u \in G^r \cap V_{1-p} \mid \ u \text{ has a tight path of vertices in } u \in G^r \cap V_{1-p} \text{ to } GL_{i-1}^r\}. \end{aligned} \tag{1}$$

where $p = i \ (mod\ 2)$.

The following lemmas prove that only the first layers have tight edges to the anchors.

▶ **Lemma 3.12.** *At the end of round r, if $(u, u') \in E$ is a tight edge s.t $u \in G^r \setminus GA^r$ and $u' \in GA^r$, then $u \in GL_1^r$.*

Proof. It suffices to show that $u \in V_0$. By contradiction, assume that $u \in V_1$. Since $u \notin GA^r$, u was in $B^{r'}$ at some round $r' < r$. Let UPDATE(z) be the update that added u into L in round r' and let f_1 be f right before this UPDATE(z). Clearly, $z \neq u'$ (since $u' \in GA^r$). Since u is was *valid* before UPDATE(z) in round r', and $u \in V_1$, we have that $f_1(u) + w(u, u') \geq f_1(u')$. Therefore, since $f(u')$ did not change until the end of round r and u must have been updated following the update of z and before the end of round r, we have that $f(u) + w(u, u') > f_1(u) + w(u, u') \geq f_1(u') = f(u')$ at the end of round r, a contradiction to the assumption that (u, u') is *tight* at the end of round r. ◀

▶ **Lemma 3.13.** *At the end of round r, if $(u, u') \in E$ is a tight edge s.t $u \in B^r \setminus BA^r$ and $u' \in BA^r$, then $u \in BL_1^r$.*

Proof. Immediate from the definition of BA^r. ◀

The following lemma, which follows immediately from Lemma 3.10, shows that every vertex belongs either to an *anchor* or to some layer of B^r or G^r.

▶ **Lemma 3.14.** *For any round r, $B^r = \bigcup_{i=0}^{n} BL_i^r$, $G^r = \bigcup_{i=0}^{n} GL_i^r$.*

We associate with B^r and G^r binary numbers b^r and g^r, respectively of length $n+1$ defined as follows. Let k be maximal such that $|BL_k^r| > 0$. Then, b^r is:

$$b^r = \begin{cases} \underbrace{1.....1}_{|BL_1^r|}\underbrace{0.....0}_{|BL_2^r|}.....\underbrace{1.....1}_{|BL_k^r|}\ \underbrace{10.........0}_{n+1-|\bigcup_i BL_i^r|} & \text{if } k \text{ is odd} \\ \underbrace{1.....1}_{|BL_1^r|}\underbrace{0.....0}_{|BL_2^r|}.....\underbrace{0.....0}_{|BL_k^r|}\ \underbrace{10.........0}_{n+1-|\bigcup_i BL_i^r|} & \text{if } k \text{ is even.} \end{cases}$$

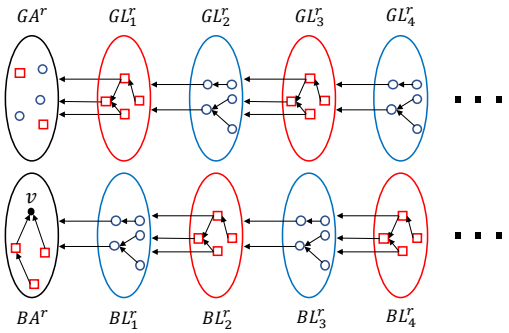

Figure 4 The layer graph of round r. Red vertices refer to V_0 and blue vertices refer to V_1. All drawn edges are *tight* at the end of round r. By Definition (1), each layer is either contained in V_0 or in V_1.

That is, for an odd layer we add a sequence of 1's whose length is the size of the layer. Similarly, for even layers we add sequences of 0's. At the end we pad the number with a single 1 followed by zeros. The number g^r is defined similarly with respect to the layers of G^r. Finally, the potential ϕ^r of round r is defined as $\phi^r = b^r + g^r$. Clearly $\phi^r \leq 2 \cdot 2^{n+1}$. In Lemma 3.18 we prove that for every round r, under certain conditions (that can be violated in at most $|V|^2$ rounds), $\phi^{r+1} \geq \phi^r + 2^{n/2}$, yielding the desired runtime.

The following lemmas consider UPDATE-ENERGY at the end of round r.

▶ **Lemma 3.15.** *For every r, $GA^{r+1} \subseteq GA^r$ and if $GA^{r+1} = GA^r$, then $BA^{r+1} \subseteq BA^r$.*

Proof. Since f only grows the first claim follows directly from the definition of the algorithm. We prove the second claim by contradiction. Assume $GA^{r+1} = GA^r$ and let $u \in BA^{r+1} \setminus BA^r$. By definition of *bad anchor* $u \in V_0$ and at the end of round $r+1$ there exists a *tight* path $p = v_0 v_1 ... v_k$ from $u = v_0$ to $v = v_k$ such that $v_i \in V_0 \cap B^{r+1}$ for all $i < k$. Let j be maximal such that $v_j \in BA^{r+1} \setminus BA^r$ (therefore $v_{j+1} \in BA^{r+1} \cap BA^r$, j is well defined since $u \in BA^{r+1} \setminus BA^r$). If $v_j \in B^r$ then (v_j, v_{j+1}) was tight also at the end of round r (since both $v_j, v_{j+1} \in B^r \cap B^{r+1}$) and thus $v_j \in BA^r$, a contradiction. So we have that $v_j \in G^r$. Therefore, at the beginning of round r it must hold that $f(v_j) + w(v_j, v_{j+1}) > f(v_{j+1})$ (i.e., v_j is not *tight* at the beginning of round r). By Lemma 3.3, $v_j \in GA^r$, a contradiction to the assumption that $GA^r = GA^{r+1}$. ◀

The following lemma is similar to Lemma 3.7. Its proof is given in the full version of the paper.

▶ **Lemma 3.16.** *For every r, $B^{r+1} \neq B^r$.*

▶ **Lemma 3.17.** *Suppose that $GA^{r+1} = GA^r$ and $BA^{r+1} = BA^r$.*

1. *Let i be the smallest such that $GL_i^{r+1} \neq GL_i^r$. Then, if i is odd then $GL_i^r \subset GL_i^{r+1}$, and if i is even then $GL_i^{r+1} \subset GL_i^r$.*
2. *Let i be the smallest such that $BL_i^{r+1} \neq BL_i^r$. Then, if i is odd then $BL_i^r \subset BL_i^{r+1}$, and if i is even then $BL_i^{r+1} \subset BL_i^r$.*

Proof. We prove only the first claim as the latter is similar. We divide the proof into cases according to the parity of i.

i **is *odd***: We show that $GL_i^r \subset GL_i^{r+1}$. By contradiction, assume that $\exists u \in GL_i^r \setminus GL_i^{r+1}$. By Definition (1), $u \in V_0$ and at the end of round r there exists a tight path $p = u_0, u_1, ... u_k$ from $u_0 = u \in GL_i^r$ to $u_k \in GA^r = GL_0^r$ that traverses the "good" layers in non-increasing

order. Let j be the maximal such that $u_j \in GL_i^r \setminus GL_i^{r+1}$. Thus, either $u_{j+1} \in GL_{i-1}^r$ or $u_{j+1} \in GL_i^r \cap GL_i^{r+1}$. Note that in both cases $u_{j+1} \in G^{r+1}$ and therefore we have that also $u_j \in G^{r+1}$ (since (u_j, u_{j+1}) was tight at the end of round r and remains tight during round $r+1$). Assume $u_{j+1} \in GL_{i-1}^r$. Since $GL_{i-1}^r = GL_{i-1}^{r+1}$ and since (u_j, u_{j+1}) is *tight* at the end of round $r+1$, we have that $u_j \in GL_\ell^{r+1}$ for some $\ell \leq i$, a contradiction (since $u_j \notin GL_i^{r+1}$ and because lower layers are equal in both rounds by our assumption). Assume now that $u_{j+1} \in GL_i^r \cap GL_i^{r+1}$. We get a contradiction since $u_j \in GL_\ell^{r+1}$ for some $\ell \leq i$.

i **is *even***: We that show $GL_i^{r+1} \subset GL_i^r$. By contradiction, assume that $\exists u \in GL_i^{r+1} \setminus GL_i^r$. By Definition (1), $u \in V_1$ and at the end of round $r+1$ there exists a tight path $p = u_0, u_1, ...u_k$ from $u_0 = u \in GL_i^{r+1}$ to $u_k \in GA^{r+1} = GL_0^{r+1}$ that traverses the "good" layers in non-increasing order. Assume $u \in B^r$. By Lemma 3.6, at the end of round r, all of u's *tight* edges are directed to B^r. Let ℓ be minimal such that $u_\ell \in V_0$. Hence, by Lemma 3.6 $u_\ell \in B^r$. Therefore $u_\ell \in GL_m^{r+1}$ for some $m < i$ (since $u_\ell \in V_0$ and $GL_i^{r+1} \subset V_1$), this contradicts our assumption $GL_m^{r+1} = GL_m^r$. Thus, $u \in G^r$.

Let j be maximal such that $u_j \in GL_i^{r+1} \setminus GL_i^r$. Hence, either $u_{j+1} \in GL_{i-1}^r$ or $u_{j+1} \in GL_i^r \cap GL_i^{r+1}$. In both cases $u_j, u_{j+1} \in G^r \cap G^{r+1}$ and thus (u_j, u_{j+1}) is *tight* in both rounds. Therefore $u_j \in GL_\ell^r$ for some $\ell \leq i$. Note that $\ell > i-1$ since otherwise $GL_\ell^r \neq GL_\ell^{r+1}$ which contradicts our assumption. Therefore $\ell = i$ and this contradict the assumption $u_j \in GL_i^{r+1} \setminus GL_i^r$. ◀

Note that if the conditions of Lemma 3.17 are satisfied, then by Lemma 3.17 and by the definition of b^r and g^r we have that $b^{r+1} \geq b^r$ and $g^{r+1} \geq g^r$.

▶ **Lemma 3.18.** *For every r, If $GA^{r+1} = GA^r$ and $BA^{r+1} = BA^r$, then $\phi^{r+1} \geq \phi^r + 2^{(n+k)/2}$, where $k = |GA^r| + |BA^r|$.*

Proof. Assume $|B^r \setminus BA^r| \geq |G^r \setminus GA^r|$, so $|G^r \setminus GA^r| \leq (n-k)/2$ and therefore g^r contains at least $(n+k)/2$ "padding bits". Hence, by Lemma 3.17 we have that $g^{r+1} \geq g^r + 2^{(n+k)/2}$ and $b^{r+1} \geq b^r$. Thus, $\phi^{r+1} \geq \phi^r + 2^{(n+k)/2}$ and we are done.

The case $|B^r \setminus BA^r| < |G^r \setminus GA^r|$ is identical. ◀

We are now ready to present the proof of our main result.

Proof of Theorem 3.11. By Lemma 3.18, there can be at most $2^{(n-k)/2}$ consecutive rounds satisfying $GA^{r+1} = GA^r$ and $BA^{r+1} = BA^r$, where $k = |GA^r| + |BA^r|$. Thus, by Lemma 3.15 we get that the following bounds the number of rounds during Update-Energy

$$\sum_{i_1=1}^{n} \sum_{i_1=1}^{n-i_1} 2^{(n-(i_1+i_2))/2} = O(2^{n/2}) \,,$$

where i_1 and i_2 represent $|GA^r|$ and $|BA^r|$, respectively. Hence, since a round takes $O(m)$ time and Compute-Energy calls Update-Energy at most $n \cdot \log W$ times, we get that Compute-Energy terminates in $O\left(mn \cdot 2^{n/2} \log W\right)$ time. ◀

4 Concluding remarks and open problems

We presented an $O\left(\min\left(mnW, mn2^{n/2} \log W\right)\right)$-time algorithm for solving EGs and MPGs. The algorithm is always at least as fast as the algorithm of Brim et al. [5], and is the fastest known deterministic algorithm when $W \geq n2^{n/2}$. (As mentioned the $\log W$ factor can be replaced by a $poly(n)$ factor.) The exponential running time of the new algorithm is

still far from what we would wish for. We hope, however, that the techniques used in our paper may lead to further improvements. The ultimate goal of using scaling is to obtain an algorithm whose running time is $O(poly(n) \log W)$. We are, of course, still extremely far from achieving this goal.

Many open problems remain: (1) Improve the pseudopolynomial running time to $O(mnf(W))$, where $f(W) = o(W)$. A more ambitious open problem is: (2) Obtain a deterministic sub-exponential time algorithm for solving EGs and MPGs, matching the running time of the fastest randomized algorithms. Even more ambitious open problem is: (3) obtain a quasipolynomial time algorithm for EGs and MPGs, matching the running time of the fastest algorithm for solving PGs. The most ambitious problem, of course, is: (4) obtain a polynomial time algorithm for PGs, EGs and MPGs.

Abstract

We give polynomial time algorithms for deciding almost-sure and limit-sure reachability in Branching Concurrent Stochastic Games (BCSGs). These are a class of infinite-state imperfect-information stochastic games that generalize both finite-state concurrent stochastic reachability games ([8]) and branching simple stochastic reachability games ([13]).

1 Introduction

Branching Processes (BP) are infinite-state stochastic processes that model the stochastic evolution of a population of entities of distinct types. In each generation, every entity of each type t produces, as offsprings, a set of entities of various types in the next generation, according to a given probability distribution on offsprings associated with type t. BPs are fundamental stochastic models that have been used to model phenomena in many fields, including biology (see, e.g., [24]), population genetics ([20]), physics and chemistry (e.g., particle systems, chemical chain reactions), medicine (e.g. cancer growth [2, 28]), marketing, and others. In many cases, the process is not purely stochastic but there is the possibility of taking actions (for example, adjusting the conditions of reactions, applying drug treatments in medicine, advertising in marketing, etc.) which can influence the probabilistic evolution of the process to bias it towards achieving desirable objectives. Some of the factors that affect the reproduction may be controllable (to some extent) while others are not and also may not be sufficiently well-understood to be modeled accurately by specific probability distributions, and thus it may be more appropriate to consider their effect in an adversarial (worst-case)

sense. *Branching Concurrent Stochastic Games* (BCSG) are a natural model to represent such settings. There are two players and, for each type t, each player has a set of available actions, which can affect the reproduction of entities of type t. The evolution of the process starts with some initial population of entities. For each entity of type t, the two players each select (concurrently and independently) an action from their available set (possibly in a randomized manner) and their join choices of actions determine the probability distribution for the offsprings of that entity. The first player represents a controller who can control some of the parameters of the reproduction and the second player represents other parameters that are not controlled and are treated adversarially. The first player wants to select a strategy that optimizes some objective. In this paper we focus on *reachability objectives*, a basic and natural class of objectives. Some types are designated as undesirable (for example, malignant cells), in which case we want to minimize the probability of ever reaching any entity of such a type. Or conversely, some types may be designated as desirable, in which case we want to maximize the probability of reaching an entity of such a type.

BCSGs generalize purely stochastic multi-type BPs as well as Branching Markov Decision Processes (BMDP) and Branching Simple Stochastic Games (BSSG) which were studied for reachability objectives in [13]. In BMDPs there is only one player who aims to maximize or minimize a reachability objective. In BSSGs there are two opposing players, but they control different types. These models were studied previously also under another basic objective, namely optimization of *extinction probability*, i.e., the probability that the process will eventually become extinct, that is, that the population will become empty [11, 15]. We will later discuss in detail the prior results and compare them with the results in this paper.

BCSGs can also be seen as a generalization of finite-state concurrent (stochastic) games [8] (see also [18]); namely they extend such finite-state games with branching. Concurrent games have been used in the verification area to model the dynamics of open systems, where one player represents the system and the other player the environment. Such a system moves sequentially from state to state depending on the actions of the two players (the system and the environment). Branching concurrent games model the more general setting in which processes can spawn new processes that then proceed independently in parallel (e.g., new threads are created and terminated). We note incidentally that even if there are no probabilities in the system itself, in the case of concurrent games, probabilities arise naturally from the fact that the optimal strategies are in general randomized; as a consequence it can be shown that branching concurrent stochastic games are expressively and computationally equivalent to the non-stochastic version (see [15]).

We now summarize our main results and compare and contrast them with previous results on related models. First, we show that a Branching concurrent stochastic game (BCSG), G, with a reachability objective has a well-defined *value*, i.e., given an initial (finite) population μ of entities of various types and a target type t^*, if the sets of all possible (mixed) strategies of the two players are respectively Ψ_1, Ψ_2, and if $\Upsilon_{\sigma,\tau}(\mu, t^*)$ denotes the probability of eventually reaching an entity of type t^* when starting from initial population μ under strategy $\sigma \in \Psi_1$ for player 1 and strategy $\tau \in \Psi_2$ for player 2, then $\inf_{\sigma\in\Psi_1} \sup_{\tau\in\Psi_2} \Upsilon_{\sigma,\tau}(\mu, t^*)$ $= \sup_{\tau\in\Psi_2} \inf_{\sigma\in\Psi_1} \Upsilon_{\sigma,\tau}(\mu, t^*)$, which is the *value*, v^*, of the game. Furthermore, we show that the player who wants to minimize the reachability probability always has an optimal (mixed) *static strategy* that achieves the value, i.e., a strategy σ^* which uses, for all entities of each type t generated over the entire history of the game, the same probability distribution on the available actions for type t, independent of the past history, and which has the property that $v^* = \sup_{\tau\in\Psi_2} \Upsilon_{\sigma^*,\tau}(\mu, t^*)$. The optimal strategy in general has to be mixed (randomized); this is the case even for finite-state concurrent games [8]. On the other hand,

the player that wants to maximize the reachability probability of a BCSG need not have any optimal strategy (whether static or not), and it was known that this holds even for BMDPs, i.e., even when there is only one player [13]. The same holds for finite-state CSGs: the player maximizing reachability probability need not have any optimal strategy [8].

To analyze BCSGs reachability games, we model them by a system of equations $x = P(x)$, called a *minimax Probabilistic Polynomial System* (minimax-PPS for short), where x is a tuple of variables corresponding to the types of the BCSG. There is one equation $x_i = P_i(x)$ for each type t_i, where $P_i(x)$ is the value of a (one-shot) two-player zero-sum matrix game, whose payoff for every pair of actions is given by a polynomial in x whose coefficients are positive and sum to at most 1 (a probabilistic polynomial). The function $P(x)$ defines a monotone operator from $[0,1]^n$ to itself, and thus it has, in particular, a *greatest fixed point* (GFP) g^* in $[0,1]^n$. We show that the coordinates g_i^* of the GFP give the optimal *non-reachability* probabilities for the BCSG game when started with a population that consists of a single entity of type t_i. The value of the game for any initial population μ can be derived easily from the GFP g^* of the minimax-PPS. This generalizes a result in [13], which established an analogous result for the special case of BSSGs. It also follows from our minimax-PPS equational characterization that *quantitative* decision problems for BCSGs, such as deciding whether the reachability game value is $\geq p$ for a given $p \in (0,1)$ are all solvable in PSPACE.

Our main algorithmic results concern the *qualitative* analysis of the reachability problem, that is, the problem of determining whether one of the players can win the game with probability 1, i.e., if the value of the game is 0 or 1. We provide the first polynomial-time algorithms for qualitative reachability analysis for branching concurrent stochastic games. For the value=0 problem, the algorithm and its analysis are very simple. If the value is 0, the algorithm computes an optimal strategy σ^* for the player that wants to minimize the reachability probability, where σ^* is in fact static and deterministic, i.e., it selects for each type, deterministically, a single available action, and guarantees $\Upsilon_{\sigma^*,\tau}(\mu, t^*) = 0$ for all $\tau \in \Psi_2$. If the value is positive then the algorithm computes a static mixed strategy τ for the player maximizing reachability probability that guarantees $\inf_{\sigma\in\Psi_1} \Upsilon_{\sigma,\tau}(\mu, t^*) > 0$.

The value=1 problem is much more complicated. There are two versions of it, because it is possible that the game value is 1 but no strategy for the maximizing player guarantees reachability with probability 1. Thus, we have two versions of the problem. In the first version, called the *almost-sure problem*, we want to decide whether there exists a strategy τ^* for player 2 that guarantees that the target type t^* is reached with probability 1 regardless of the strategy of player 1, i.e., such that $\Upsilon_{\sigma,\tau^*}(\mu, t^*) = 1$ for all $\sigma \in \Psi_1$. In the second version, called the *limit-sure problem*, we want to decide if the value $v^* = \sup_{\tau\in\Psi_2} \inf_{\sigma\in\Psi_1} \Upsilon_{\sigma,\tau}(\mu, t^*)$ is 1, i.e., if for every $\epsilon > 0$ there is a strategy τ_ϵ of player 2 that guarantees that the probability of reaching the target type is at least $1 - \epsilon$ regardless of the strategy σ of player 1; such a strategy τ_ϵ is called *ϵ-optimal*. We provide polynomial-time algorithms for both versions of the problem. The algorithms non-trivially generalize the algorithms of both [8] and [13], both of which address different special subcases of qualitative BCSG reachability. Our positive results on qualitative reachability for BCSG are surprising especially in view of the known major obstacles in resolving the analogous questions for the extinction problem for BCSG, as explained below in the review of related work.

In the almost-sure problem, if the answer is positive, our algorithm constructs (a compact description of) a strategy τ^* of player 2 that achieves value 1; the strategy is a randomized non-static strategy, and this is inherent (i.e., there may not exist a static strategy that achieves value 1). If the answer is negative, our algorithm constructs a (non-static, randomized)

strategy σ for the opposing player 1 such that $\Upsilon_{\sigma,\tau}(\mu, t^*) < 1$ for all strategies τ of player 2. In the limit-sure problem, if the answer is positive, i.e., the value is 1, our algorithm constructs for any given $\epsilon > 0$, a static, randomized ϵ-optimal strategy, i.e., a strategy τ_ϵ such that $\Upsilon_{\sigma,\tau_\epsilon}(\mu, t^*) \geq 1 - \epsilon$ for all $\sigma \in \Psi_1$. If the answer is negative, i.e., the value is < 1, our algorithm constructs a static randomized strategy σ' for player 1 such that $\sup_{\tau \in \Psi_2} \Upsilon_{\sigma',\tau} < 1$. Due to space limits, most proofs are omitted; see the full version.

Related Work. As mentioned, the two works most closely related to ours are [8] and [13]. Our results generalize both. de Alfaro, Henzinger, and Kupferman [8] studied finite-state concurrent (stochastic) games (CSGs) with reachability objectives and provided polynomial time algorithms for their qualitative analysis, both for the almost-sure and the limit-sure reachability problem. See also [22, 19, 21, 5] for more recent results on finite-state CSG reachability; in particular, there are finite-state CSGs with value$= 1$ for which (near-)optimal strategies need to have some action probabilities that are doubly-exponentially small [22, 5] (unlike simple, turned-based stochastic games), and thus must be represented succinctly to ensure polynomial space. This is of course the case also for branching CSGs, and the optimal or ϵ-optimal strategies constructed by our algorithms are represented compactly so that the algorithms run in polynomial time.

BMDPs and BSSGs with reachability objectives were studied in [13], which provided polynomial-time algorithms for their qualitative analysis, and also gave polynomial time algorithms for approximate quantitative analysis of BMDPs, i.e., approximate computation of the optimal reachability probability for maximizing and minimizing BMDPs, and it showed that this problem for BSSGs is in TFNP. Note that even for finite-state simple stochastic games the question of whether the value of the game can be computed in polynomial time is a well-known long-standing open problem [7]. It was also shown in [13] that the optimal non-reachability probabilities of maximizing or minimizing BMDPs and BSSGs are captured by the GFP of a system of min/max-PPS equations, $x = P(x)$, where each right-hand side $P_i(x)$ is the maximum or minimum of a set of probabilistic polynomials in x; note that these types of equation systems are special cases of minimax-PPSs and are much simpler.

Another important objective, the probability of *extinction*, has been studied previously for Branching Concurrent Stochastic Games, as well as BMDPs and BSSGs, and the purely stochastic model of Branching Processes (BPs). These branching models under the extinction objective are equivalent to corresponding subclasses of recursive Markov models, called respectively, 1-exit Recursive Concurrent Stochastic Games (1-RCSG), Markov Decision Processes (1-RMDP), and Markov Chains (1-RMC), and related subclasses of probabilistic pushdown processes under a termination objective [16, 12, 17, 11, 15, 10]. The extinction probabilities for these models are captured by the *least fixed point* (LFP) solutions of similar systems of probabilistic polynomial equations; for example, the optimal extinction probabilities of a BCSG are given by the LFP of a minimax-PPS. Polynomial time-algorithms for qualitative analysis, as well as for the approximate computation of the optimal extinction probabilities of Branching MDPs (and 1-RMDPs) were given in [17, 11]. However, negative results were shown also which indicate that the problem is much harder for branching concurrent (or even simple) stochastic games, even for the qualitative extinction problem. Specifically, it was shown in [17] that the qualitative extinction (termination) problem for BSSG (equivalently, 1-RSSG) is at least as hard as the well-known open problem of computing the value of a finite-state simple stochastic game [7]. Furthermore, it was shown in [15] that (both the almost-sure and limit-sure) qualitative extinction problems for BCSGs (equivalently 1-RCSGs) are at least as hard as the square-root sum problem, which is not even known to be

in NP. Thus, *the qualitative reachability problem for BCSGs seems to be very different than the extinction problem for BCSGs*: obtaining analogous results for the qualitative extinction to those of the present paper for qualitative reachability would resolve two major open problems. This is despite the fact that there is a natural "duality" between the extinction and reachability objectives (see [13]).

The equivalence between branching models (like BMDPs, BCSGs) and recursive Markov models (like 1-RMDPs, 1-RCSGs) with respect to extinction does *not* hold for the reachability objective. For example, almost-sure and limit-sure reachability coincide for a BMDP, i.e., if the supremum probability of reaching the target is 1 then there exists a strategy that ensures reachability with probability 1. However, this is not the case for 1-RMDPs. Furthermore, almost-sure reachability for 1-RMDPs can be decided in polynomial time [3, 4], but limit-sure reachability for 1-RMDPs is not even known to be decidable. The qualitative reachability problem for 1-RMDPs and 1-RSSGs (and equivalent probabilistic pushdown models) was studied in [4, 1]. These results do not apply to the corresponding branching models (BMDP, BSSG). Another objective considered in prior work is the *expected total reward* objective for 1-RSSGs ([14]) and 1-RCSGs ([31]) with positive rewards. None of these prior results have any implications for BCSGs with reachability objectives.

For richer objectives beyond reachability or extinction, Chen et. al. [6] studied model checking of purely stochastic branching processes (BPs) with respect to properties expressed by deterministic parity tree automata, and showed that the qualitative problem is in P-time (hence this holds in particular for reachability probability in BPs), and that the quantitative problem of comparing the probability with a rational is in PSPACE. Michalevski and Mio [25] extended this to properties of BPs expressed by "game automata", a subclass of alternating parity tree automata. More recently, Przybyłko and Skrzypczak [27] considered existence and complexity of game values of Branching turn-based (i.e., simple) stochastic games, with regular objectives, where the two players aim to maximize/minimize the probability that the generated labeled tree belongs to a regular language (given by a tree automaton). They showed that (unlike our case of simpler reachability games) already for some basic regular properties these games are not even determined, meaning they do not have a value. They furthermore showed that for a probabilistic turn-based branching game, with a regular tree objective, it is undecidable to compare the value that a given player can force to 1/2; whereas for deterministic turn-based branching games they showed it is decidable and 2-EXPTIME-complete (respectively, EXPTIME-complete), to determine whether the player aiming to satisfy (respectively, falsify) a given regular tree objective has a pure winning strategy. Other past research includes work in operations research on (one-player) Branching MDPs [26, 29, 9]. None of these prior works bear on any of the results on BCSG reachability problems established in this paper.

2 Background

A *Branching Concurrent Stochastic Game* (BCSG) consists of a finite set $V = \{T_1, \ldots T_n\}$ of types, two finite non-empty sets $\Gamma^i_{max}, \Gamma^i_{min} \subseteq \Sigma$ of actions (one for each player) for each type T_i (Σ is a finite action alphabet), and a finite set $R(T_i, a_{max}, a_{min})$ of probabilistic rules associated with each tuple (T_i, a_{max}, a_{min}), where $i \in [n]$, $a_{max} \in \Gamma^i_{max}$, & $a_{min} \in \Gamma^i_{min}$. Each rule $r \in R(T_i, a_{max}, a_{min})$ is a triple (T_i, p_r, α_r), which we can denote by $T_i \xrightarrow{p_r} \alpha_r$, where $\alpha_r \in \mathbb{N}^n$ is a n-vector of natural numbers that denotes a finite multi-set over the set V, and where $p_r \in (0, 1] \cap \mathbb{Q}$ is the probability of the rule r (which we assume to

be a rational number, for computational purposes), where we assume that for all $T_i \in V$ and $a_{max} \in \Gamma^i_{max}$, $a_{min} \in \Gamma^i_{min}$, the rule probabilities in $R(T_i, a_{max}, a_{min})$ sum to 1, i.e., $\sum_{r \in R(T_i, a_{max}, a_{min})} p_r = 1$.

If for all types $T_i \in V$, either $|\Gamma^i_{max}| = 1$ or $|\Gamma^i_{min}| = 1$, then the model is a "turn-based" perfect-information game and is called a *Branching Simple Stochastic Game* (BSSG). If for all $T_i \in V$, $|\Gamma^i_{max}| = 1$ (respectively, $|\Gamma^i_{min}| = 1$), then it is called a *minimizing Branching Markov Decision Process* (BMDP) (respectively, a *maximizing* BMDP). If both $|\Gamma^i_{min}| = 1 = |\Gamma^i_{max}|$ for all $i \in [n]$, then the process is a classic, purely stochastic, *multi-type Branching Process* (BP) ([23]).

A *play* of a BCSG defines a (possibly infinite) node-labeled forest, whose nodes are labeled by the type of the object they represent. A play contains a sequence of "generations", $X_0, X_1, X_2, \ldots$ (one for each integer time $t \geq 0$, corresponding to nodes at depth/level t in the forest). For each $t \in \mathbb{N}$, X_t consists of the population (set of objects of given types), at time t. X_0 is the initial population at generation 0 (these are the roots of the forest). X_{k+1} is obtained from X_k in the following way: for each object e in the set X_k, assuming e has type T_i, both players select simultaneously and independently actions $a_{max} \in \Gamma^i_{max}$, and $a_{min} \in \Gamma^i_{min}$ (or distributions on such actions), according to their strategies; thereafter a rule $r \in R(T_i, a_{max}, a_{min})$ is chosen randomly and independently (for object e) with probability p_r; each such object e in X_k is then replaced by the set of objects specified by the multi-set α_r associated with the corresponding randomly chosen rule r. This process is repeated in each generation, as long as the current generation is not empty, and if for some $k \geq 0$, $X_k = \emptyset$ then we say the process *terminates* or becomes *extinct*.

The strategies of players can in general be arbitrary functions from any finite *history* tree, to (distributions on) actions, for each object in the current population. The *history* of the process up to time k is a forest of depth k that includes not only the populations $X_0, X_1, \ldots, X_k$, but also all the information regarding past actions and rules applied at each object, and all the parent-child relationships between objects up to generation k. The history can be represented by a forest of depth k, with internal nodes labeled by rules and actions, and whose leaves at level k form the current population X_k. Thus, formally, a strategy of player 1 (player 2, respectively) is a function that maps every finite history (i.e., a labelled forest of some finite depth, k, as above) and each object e in the current population X_k (leaf at depth k) to a probability distribution on the actions Γ^i_{max} (to the actions Γ^i_{min}, respectively), assuming that object e has type T_i.[1]

Let Ψ_1, Ψ_2 be the set of all strategies of players 1, 2. We say that a strategy is *deterministic* if for every history it maps each object e in the current population to a single action with probability 1 (in other words, it does not randomize on actions). We say that a strategy is *static* if for each type $T_i \in V$, and for any object e of type T_i, the player always chooses the same distribution on actions, irrespective of the history.

Different objectives can be considered for BCSGs. This paper considers (existential) *reachability*, where the aim of the players is to maximize/minimize the probability of reaching a generation that contains at least one object of a given target type T_{f^*}. The BCSG reachability game can of course also be viewed as a "non-reachability" ("safety") game, by just reversing the role of the players. We will exploit this alternative view in crucial ways (and this was also exploited in [13] for BSSGs). Given an initial population $\mu \in \mathbb{N}^n$,

[1] Note: this very general notion of a "strategy" permits the action (or distribution on actions) chosen for a given object e to depend not only on e's "ancestors" in the history forest, but also on siblings, cousins, etc., in the entire forest, up to and including the generation of the population that e belongs to.

with $\mu_{f^*} = 0$, and given strategies $\sigma \in \Psi_1, \tau \in \Psi_2$, let $g^*_{\sigma,\tau}(\mu)$ denote the probability that $(X_l)_{f^*} = 0$ for all $l \geq 0$. Let $g^*_{\sigma,*}(\mu) = \inf_{\tau\in\Psi_2} g^*_{\sigma,\tau}(\mu)$, let $g^*_{*,\tau}(\mu) = \sup_{\sigma\in\Psi_1} g^*_{\sigma,\tau}(\mu)$, and let $g^*(\mu) = \sup_{\sigma\in\Psi_1} \inf_{\tau\in\Psi_2} g^*_{\sigma,\tau}(\mu)$ denote the *value* of the game under the non-reachability objective and for the initial population μ. We will show that these games do have a *value*, meaning $g^*(\mu) = \sup_{\sigma\in\Psi_1} \inf_{\tau\in\Psi_2} g^*_{\sigma,\tau}(\mu) = \inf_{\tau\in\Psi_2} \sup_{\sigma\in\Psi_1} g^*_{\sigma,\tau}(\mu)$.

In the case where the initial population μ is a single object of some type T_i, then for the value of the game we write g^*_i, and similarly, when one or both of the strategies σ, τ are fixed, we write $(g^*_{\sigma,*})_i$, $(g^*_{*,\tau})_i$, or $(g^*_{\sigma,\tau})_i$. The vector g^* of g^*_i's, is called the vector of the non-reachability values of the game. We will see that, having the vector of g^*_i's, the non-reachability value for any starting population μ can be computed simply as $g^*(\mu) = \prod_i (g^*_i)^{\mu_i}$. So given a BCSG, the goal is to compute the vector g^* of non-reachability values. As our original objective is reachability, we point out that the vector of reachability values is $r^* = \mathbf{1} - g^*$ (where $\mathbf{1}$ is the all-1 vector), and hence the reachability value $r^*(\mu)$ of the game starting with population μ is $r^*(\mu) = 1 - g^*(\mu)$.

We will associate with any given BCSG a system of *minimax probabilistic polynomial equations* (minimax-PPS), $x = P(x)$, for the non-reachability objective. This system will have one variable x_i, and one equation $x_i = P_i(x)$, for each type T_i other than the target type T_{f^*}. We will show that the vector of non-reachability values g^* for different starting types is precisely the Greatest Fixed Point (GFP) solution of the system $x = P(x)$ in $[0,1]^n$. To define these equations, some shorthand notation will be useful. We use x^v to denote the monomial $x_1^{v_1} x_2^{v_2} \cdots x_n^{v_n}$ for an n-vector of variables $x = (x_1, \cdots, x_n)$ and a vector $v \in \mathbb{N}^n$. Considering a multi-variate polynomial $P_i(x) = \sum_{r\in R} p_r x^{\alpha_r}$ for some rational coefficients $p_r, r \in R$, we will call $P_i(x)$ a *probabilistic polynomial*, if $p_r \geq 0$ for all $r \in R$ and $\sum_{r\in R} p_r \leq 1$. A *minimax probabilistic polynomial system of equations* (minimax-PPS), $x = P(x)$, is a system of n equations in n variables $x = (x_1, \ldots, x_n)$, where for each $i \in \{1, \ldots, n\}$, $P_i(x) := Val(A_i(x))$, where $A_i(x)$ is a matrix whose entries are probabilistic polynomials, and $Val(A_i(x))$ is the minimax value of the finite two-player zero-sum game with payoff matrix $A_i(x)$ for each $x \in \mathbb{R}^n$. Note that as special cases, when $A_i(x)$ has only one row or only one column, then $Val(A_i(x))$ is the maximum or minimum of a set of probabilistic polynomials, and when it has only one row and column, then $Val(A_i(x))$ is simply a probabilistic polynomial.

For computational purposes, we assume that all coefficients are rational and that there are no zero terms in the probabilistic polynomials, and we assume the coefficients and non-zero exponents of each term are given in binary. We denote by $|P|$ the total bit encoding length of a system $x = P(x)$ under this representation. Since $P(x)$ defines a monotone function $P : [0,1]^n \to [0,1]^n$, it follows from Tarski's theorem ([30])) that any such system has both a *Least Fixed Point* (LFP) solution $q^* \in [0,1]^n$, and a *Greatest Fixed Point* (GFP) solution, $g^* \in [0,1]^n$. In other words, $q^* = P(q^*)$ and $g^* = P(g^*)$ and moreover, for all $s^* \in [0,1]^n$ such that $s^* = P(s^*)$, we have $q^* \leq s^* \leq g^*$ (coordinate-wise inequality).

For convenience in proofs and algorithms throughout the paper and to simplify the structure of the matrices involved, we shall observe that minimax-PPSs can always be cast in the following normal form. A minimax-PPS in *simple normal form* (SNF), $x = P(x)$, is a system of n equations in n variables $\{x_1, \cdots, x_n\}$, where each $P_i(x)$ for $i = 1, 2, \ldots, n$ is one of three forms:

- Form L: $P_i(x) = a_{i,0} + \sum_{j=1}^n a_{i,j} x_j$, where for all j, $a_{i,j} \geq 0$, and $\sum_{j=0}^n a_{i,j} \leq 1$
- Form Q: $P_i(x) = x_j x_k$ for some j, k
- Form M: $P_i(x) = Val(A_i(x))$, where $A_i(x)$ is a $(n_i \times m_i)$ matrix, such that for all $j \in [n_i]$ and $k \in [m_i]$, the entry $(A_i(x))_{j,k} \in \{x_1, \ldots, x_n\} \cup \{1\}$.

We shall often assume a minimax-PPS in its SNF form, and say that a variable x_i is "of form/type" L, Q, or M, meaning that $P_i(x)$ has the corresponding form.

▶ **Proposition 1** (informal statement; see full version for formal statement and proof)**.** *Every minimax-PPS, $x = P(x)$, can be transformed in P-time to an "equivalent" minimax-PPS, $y = Q(y)$ in SNF form, such that $|Q| \in O(|P|)$.*

Thus, for the rest of this paper *we may assume, without loss of generality, that all minimax-PPSs are in SNF normal form.*

3 Non-reachability values for BCSGs and the Greatest Fixed Point

We show that for a given BCSG with a target type T_{f^*}, a minimax-PPS, $x = P(x)$, can be constructed such that its *greatest fixed point* (GFP) $g^* \in [0,1]^n$ is precisely the vector g^* of non-reachability values for the BCSG. For simplicity, from now on let us call a *maximizer* (respectively, a *minimizer*) the player that aims to *maximize* (respectively, *minimize*) the probability of *not* reaching the target type. That is, we swap the roles of the players for the benefit of less confusion in analysing the minimax-PPS which captures non-reachability values in its GFP.

For each type $T_i \neq T_{f^*}$, the minimax-PPS will have an associated variable x_i and an equation $x_i = P_i(x)$, and the $P_i(x)$ is defined as follows. For each action $a_{max} \in \Gamma^i_{max}$ of the maximizer (i.e., the player aiming to maximize the probability of *not* reaching the target) and action $a_{min} \in \Gamma^i_{min}$ of the minimizer, in T_i, let $R'(T_i, a_{max}, a_{min}) = \{r \in R(T_i, a_{max}, a_{min}) \mid (\alpha_r)_{f^*} = 0\}$ be the set of probabilistic rules r for type T_i and players' action pair (a_{max}, a_{min}) that generate a multi-set α_r which does not contain an object of the target type. For each action pair for T_i, there is a probabilistic polynomial $q_{i,a_{max},a_{min}}(x) := \sum_{r \in R'(T_i,a_{max},a_{min})} p_r x^{\alpha_r}$. Now we let $P_i(x) \equiv Val(A_i(x))$ be the value of a finite zero-sum game with matrix $A_i(x)$, where the matrix is constructed as follows: (1) rows belong to the max player in the minimax-PPS (i.e., the player trying to maximize the non-reachability probability), and columns belong to the min player; (2) for each row and column (i.e., pair of actions (a_{max}, a_{min})) the matrix entry $A_i(x)_{a_{max},a_{min}}$ is the corresponding probabilistic polynomial $q_{i,a_{max},a_{min}}(x)$.

The following theorem captures the fact that the optimal *non-reachability values* g^* in the BCSG game exist (meaning these game do have a value) and correspond to the GFP of the minimax-PPS $x = P(x)$ that was just defined.

▶ **Theorem 2.** *The non-reachability game values $g^* \in [0,1]^n$ of a BCSG reachability game exist, and correspond to the GFP of the minimax-PPS, $x = P(x)$, in $[0,1]^n$. That is, $g^* = P(g^*)$, and for all other fixed points $g' = P(g')$ in $[0,1]^n$, it holds that $g' \leq g^*$. Moreover, for an initial population μ, the optimal non-reachability value is $g^*(\mu) = \prod_i (g^*_i)^{\mu_i}$ and the game is determined, i.e., $g^*(\mu) = \sup_{\sigma \in \Psi_1} \inf_{\tau \in \Psi_2} g^*_{\sigma,\tau}(\mu) = \inf_{\tau \in \Psi_2} \sup_{\sigma \in \Psi_1} g^*_{\sigma,\tau}(\mu)$. Finally, the player maximizing non-reachability probability in the BCSG has a (mixed) static optimal strategy.*

▶ **Corollary 3.** *Given a BCSG reachability game, and a probability $p \in (0,1)$, deciding whether the game value is $\geq p$ is in PSPACE.*

The PSPACE upper bound follows from Theorem 2, by appealing to decision procedures for the (existential) theory of reals to answer quantitative questions about the GFP of the corresponding minimax-PPS equations. This is entirely analogous to very similar arguments in [15, 13, 16], so we do not elaborate. Any substantial improvement on PSPACE for such quantitative decision problems would require a major breakthrough on exact numerical computation, even for BPs or BMDPs (see [16, 13, 15]).

4 P-time algorithm for almost-sure reachability for BCSGs

Before considering almost-sure reachability, we first show there is a simple P-time algorithm for computing the variables x_i with value $q_i^* = 1$ for the GFP in a given minimax-PPS, $x = P(x)$, or in other words, for a given BCSG, deciding whether the reachability value, starting with an object of a given type T_i, is 0. The algorithm is easy, amounts to an AND-OR graph reachability analysis, and is very similar to the algorithm given for deciding $q_i^* = 1$ for BSSGs in [13]. Let $W = \{x_1, \ldots, x_n\}$ denote the set of all variables of the minimax-PPS. The algorithm is given in Figure 1.

1. Initialize $S := \{x_i \in W \mid P_i(\mathbf{1}) < 1\}$.
2. Repeat until no change has occurred:
   a. if there is a variable $x_i \notin S$ of form L or Q such that $P_i(x)$ contains a variable already in S, then add x_i to S.
   b. if there is a variable $x_i \notin S$ of form M such that for every action $a_{max} \in \Gamma^i_{max}$, there exists an action $a_{min} \in \Gamma^i_{min}$, such that $A_i(x)_{(a_{max},a_{min})} \in S$, then add x_i to S.
3. Output the set $\bar{S} := W - S$.

Figure 1 Simple P-time algorithm for computing the set of types with reachability value 0 in a given BCSG, or equivalently the set of variables $\{x_i \mid q_i^* = 1\}$ of the associated minimax-PPS.

▶ **Proposition 4.** *There is a P-time algorithm that, given a BCSG or equivalently a corresponding minimax-PPS, $x = P(x)$, with n variables and with GFP $q^* \in [0,1]^n$, and given $i \in [n]$, determines whether $q_i^* = 1$ or $q_i^* < 1$. In case $q_i^* = 1$, the algorithm can produce a deterministic static strategy σ for the max player (maximizing non-reachability) that forces $q_i^* = 1$. Otherwise, if $q_i^* < 1$, the algorithm can produce a mixed static strategy τ for the min player (minimizing non-reachability) that guarantees $q_i^* < 1$.*

We are now ready to present a P-time algorithm for almost-sure reachability for BCSGs. First, as a preprocessing step, we apply the algorithm of Proposition 4, which identifies in P-time all the variables x_i where $q_i^* = 1$. We then remove these variables from the system, substituting the value 1 in their place. We then simplify and reduce the resulting SNF-form minimax-PPS into a reduced form, with GFP $q^* < 1$. Note that the resulting reduced SNF-form minimax-PPS may contain some variables x_j of form M, whose corresponding matrix $A_j(x)$ has some entries that contain the value 1 rather than a variable (because we substituted 1 for removed variables x_j, where $q_j^* = 1$). Note also that in the reduced SNF-form minimax-PPS each variable x_i of form Q has an associated quadratic equation $x_i = x_j x_k$, because if one of the variables (say x_k) on the right-hand side was set to 1 during preprocessing, the resulting equation ($x_i = x_j$) would have been declared to have form L in the reduced minimax-PPS. We henceforth assume that the minimax-PPS is in SNF-form, with $q^* < 1$, and we let X be its set of (remaining) variables. We now apply the algorithm of Figure 2 to the minimax-PPS with $q^* < 1$, which identifies the variables x_i in the minimax-PPS (equivalently, the types in the BCSG), from which we can almost-surely reach the target type T_{f^*} (i.e., $q_i^* = 0$ *and* there is a strategy τ^* for the player minimizing non-reachability probability that achieves this value, no matter what the other player does).

▶ **Theorem 5.** *Given a BCSG with minimax-PPS, $x = P(x)$, such that the GFP $q^* < \mathbf{1}$, the algorithm in Figure 2 terminates in polynomial time and returns the set of variables $\{x_i \in X \mid \exists \tau \in \Psi_2\ (q^*_{*,\tau})_i = 0\}$.*

1. Initialize $S := \{x_i \in X \mid P_i(\mathbf{0}) > 0$, that is $P_i(x)$ has a constant term $\}$.
   Let $\gamma_0^i := \Gamma_{min}^i$ for every variable $x_i \in X - S$. Let $t := 1$.
2. Repeat until no change has occurred to S:
   a. if there is a variable $x_i \in X - S$ of form L where $P_i(x)$ contains a variable already in S, then add x_i to S.
   b. if there is a variable $x_i \in X - S$ of form Q where both variables in $P_i(x)$ are already in S, then add x_i to S.
   c. if there is a variable $x_i \in X - S$ of form M and if for all $a_{min} \in \Gamma_{min}^i$, there exists a $a_{max} \in \Gamma_{max}^i$ such that $A_i(x)_{(a_{max},a_{min})} \in S \cup \{1\}$, then add x_i to S.
3. For each $x_i \in X - S$ of form M, let:
   $\gamma_t^i := \{a_{min} \in \gamma_{t-1}^i \mid \forall a_{max} \in \Gamma_{max}^i,\ A_i(x)_{(a_{max},a_{min})} \notin S \cup \{1\}\}$. (Note that $\gamma_t^i \subseteq \gamma_{t-1}^i$.)
4. Let $F := \{x_i \in X - S \mid P_i(\mathbf{1}) < 1$, or $P_i(x)$ is of form Q $\}$
5. Repeat until no change has occurred to F:
   a. if there is a variable $x_i \in X - (S \cup F)$ of form L where $P_i(x)$ contains a variable already in F, then add x_i to F.
   b. if there is a variable $x_i \in X - (S \cup F)$ of form M such that for $\forall a_{max} \in \Gamma_{max}^i$, there is a min player's action $a_{min} \in \gamma_t^i$ such that $A_i(x)_{(a_{max},a_{min})} \in F$, then add x_i to F.
6. If $X = S \cup F$, **return** F, and halt.
7. Else, let $S := X - F$, $t := t + 1$, and go to step 2.

Figure 2 P-time algorithm for computing almost-sure reachability types $\{x_i \mid \exists \tau \in \Psi_2\ (g_{*,\tau}^*)_i = 0\}$ for a minimax-PPS (in SNF), associated with a given BCSG.

The proof is in the full version. Here we give very brief intuition for why the algorithm works. The set S will accumulate variables $x_i \in X$, such that regardless of the strategy $\tau \in \Psi_2$ of the player minimizing non-reachability (i.e., maximizing reachability), the probability of reaching the target type is < 1. The loop in Step (2.) is a basic "attractor set" construction that adds to S any variable x_i that should be in S by virtue of prior membership in S of variables (types) occurring in $P_i(x)$. In step (3.), for each variable $x_i \in X - S$ we maintain the remaining "useful" set of actions $\gamma_t^i \subseteq \Gamma_{min}^i$ that can avoid the set S (or extinction). The loop in Step (5.) accumulates a set $F \subseteq X - S$, such that for every $x_i \in F$ there is a strategy $\tau \in \Psi_2$ to either reach the target or a branching (quadratic) type in F, with positive probability, regardless of the opponent's strategy. The key assertion is this: if in step (6.) we find all variables are already either in S or in F, we are done; F must be the set of types from which we can force almost-sure reachability of the target type; otherwise, all variables in $X - (F \cup S)$ can be added to S. The reason this assertion holds is not obvious (see the detailed proof). The proof of the theorem also yields the following:

▶ **Corollary 6.** *Let F be the set of variables output by the algorithm in Figure 2.*

1. *Let $S = X - F$. There is a randomized non-static strategy $\hat{\sigma}$ for the max player (maximizing non-reachability) such that for all $x_i \in S$, and for all strategies τ of the min player (minimizing non-reachability), starting with one object of type T_i the probability of reaching the target type is < 1.*
2. *There is a randomized non-static strategy $\hat{\tau}$ for the min player (minimizing non-reachability) such that for all strategies σ of the max player (maximizing non-reachability), and for all $x_i \in F$, starting at one object of type T_i the probability of reaching the target type is 1.*

The non-static strategies $\hat{\sigma}$ and $\hat{\tau}$ mentioned above both have suitably compact descriptions (as functions that map finite histories to distributions over actions for entities in the current population) and can be described in such a compact form in polynomial time, as a function of the encoding size of the input BCSG.

The strategies need to be represented compactly because some of the actions probabilities may be doubly-exponentially small (or doubly-exponentially close to 1), and this is inherent.

5 P-time algorithm for limit-sure reachability for BCSGs

In this section we focus on the limit-sure reachability problem, i.e., starting with one object of a type T_i, decide whether the reachability value is 1. Since we translate reachability into non-reachability when analysing the corresponding minimax-PPS, we are asking whether there exists a sequence of strategies $\langle \tau^*_{\epsilon_j} \mid j \in \mathbb{N} \rangle$ for the min player, such that $\forall j \in \mathbb{N}$, $\epsilon_j > \epsilon_{j+1} > 0$, and where $\lim_{j\to\infty} \epsilon_j = 0$, such that the strategy $\tau^*_{\epsilon_j}$ forces non-reachability probability to be at most ϵ_j, regardless of the strategy σ used by the max player. In other words, for a given starting object of type T_i, we ask whether $\inf_{\tau\in\Psi_2}(g^*_{*,\tau})_i = 0$.

1. Initialize $S := \{x_i \in X \mid P_i(\mathbf{0}) > 0$, that is $P_i(x)$ has a constant term $\}$.
2. Repeat until no change has occurred to S:
   a. if there is a variable $x_i \in X - S$ of form L where $P_i(x)$ contains a variable already in S, then add x_i to S.
   b. if there is a variable $x_i \in X - S$ of form Q where both variables in $P_i(x)$ are already in S, then add x_i to S.
   c. if there is a variable $x_i \in X - S$ of form M and if for all $a_{min} \in \Gamma^i_{min}$, there exists $a_{max} \in \Gamma^i_{max}$ such that $A_i(x)_{(a_{max},a_{min})} \in S \cup \{1\}$, then add x_i to S.
3. Let $F := \{x_i \in X - S \mid P_i(\mathbf{1}) < 1$, or $P_i(x)$ is of form Q $\}$
4. Repeat until no change has occurred to F:
   a. if there is a variable $x_i \in X - (S \cup F)$ of form L where $P_i(x)$ contains a variable already in F, then add x_i to F.
   b. if there is a variable $x_i \in X - (S \cup F)$ of form M and if the following procedure returns "Yes", then add x_i to F.
      i. Set $L_0 := \emptyset$, $B_0 := \emptyset$, $k := 0$. Let $O := X - (S \cup F)$.
      ii. Repeat:
         - $k := k + 1$.
         - $L_k := \{a_{min} \in \Gamma^i_{min} - \bigcup_{j=0}^{k-1} L_j \mid \forall a_{max} \in \Gamma^i_{max} - B_{k-1},\ A_i(x)_{(a_{max},a_{min})} \in F \cup O\}$.
         - $B_k := B_{k-1} \cup \{a_{max} \in \Gamma^i_{max} - B_{k-1} \mid \exists a_{min} \in L_k \ s.t.\ A_i(x)_{(a_{max},a_{min})} \in F\}$.

         Until $B_k = B_{k-1}$.
      iii. Return: "Yes" if $B_k = \Gamma^i_{max}$, and "No" otherwise.
5. If $X = S \cup F$, **return** F, and halt.
6. Else, let $S := X - F$, and go to step 2.

Figure 3 P-time algorithm for computing the set of types that satisfy limit-sure reachability in a given BCSG, i.e., the set of variables $\{x_i \mid g^*_i = 0\}$ in the associated minimax-PPS.

Again, as in the almost-sure case, we first, as a preprocessing step, use the P-time algorithm from Proposition 4 to remove all variables x_i such that $g^*_i = 1$, and we substitute 1 for these variables in the remaining equations. We hence obtain a reduced SNF-form

minimax-PPS, for which we can assume $g^* < 1$. The set of all remaining variables in the SNF-form minimax-PPS is again denoted by X. Thereafter, we apply the algorithm in Figure 3, which computes the set of variables, x_i, such that $g^*_i = 0$. In other words, we compute the set of types, such that starting from one object of that type the value of the reachability game is 1.

▶ **Theorem 7.** *Given a BCSG with minimax-PPS, $x = P(x)$, with GFP $g^* < \mathbf{1}$, the algorithm in Figure 3 terminates in polynomial time, and returns the set of variables $\{x_i \in X \mid g^*_i = 0\}$.*

The proof is in the full version. We again give very brief intuition for why the algorithm works. The algorithm is similar in structure to that of almost-sure reachability, but differs in crucial aspects. Firstly, step (2.) now accumulates the variables x_i for which we know $g^*_i > 0$. In step (3.), as before, the set F is initialized to variables $x_i \in X - S$ (types) where either $P_i(x)$ is quadratic, or the target type is generated with positive probability in the next step, i.e., $(P_i(\mathbf{1}) < 1)$. In step (4.) the algorithm makes crucial use of a "limit-escape" set construction (inside inner loop 4.(b)), a variant of which was used by de Alfaro, Henzinger, and Kupferman in [8], in the context of finite-state CSGs, but which has been adapted here to the context of BCSGs. This loop adds a variable x_i to the set F whenever it is the case that, for any $\epsilon > 0$, the player minimizing non-reachability can play a distribution on actions (depending on ϵ) at any object e of type T_i such that (regardless of the action distribution of the other player) the probability that e produces an offspring in the next generation whose type is in S is at most ϵ times the probability that it produces an offspring that is already in F. Unlike the almost-sure case (where we maintain remaining sets of "useful" actions $\gamma^i_t \subset \Gamma^i_{min}$ that can avoid the set S), in the limit-sure case the player minimizing non-reachability may not have any (distribution on) actions that entirely avoid the set S, but it nevertheless may have a series of distributions on actions that make the ratio of the probability of the "bad" event of generating an offspring in S, compared to the probability of the "good" event of generating an offspring in F, arbitrarily small. Similar to the case of almost-sure reachability, a key assertion is that if in step (5.) all variables in X are already in $S \cup F$ then we are done: F consists of precisely those variables (types) that satisfy limit-sure reachability; otherwise, we can add $X - (S \cup F)$ to the set S. The reason why this holds is again subtle (see the detailed proof in the full version).

The proof of the theorem also yields the following corollary:

▶ **Corollary 8.** *Suppose the algorithm in Figure 3 outputs the set F when it terminates. Let $S := X - F$.*

1. *There is a randomized static strategy $\hat{\sigma}$ for the max player (maximizing non-reachability) such that for all variables $x_i \in S$, we have $(g^*_{\hat{\sigma},*})_i > 0$.*
2. *For all $\epsilon > 0$, there is a randomized static strategy τ_ϵ, for the min player (minimizing non-reachability), such that for all variables $x_i \in F$, $(g^*_{*,\tau_\epsilon})_i \leq \epsilon$.*

The static strategies $\hat{\sigma}$ and τ_ϵ mentioned above can both be described, in a suitably compact form, in polynomial time, as a function of the encoding size of the input BCSG. However, these static strategies, specifically in the case of τ_ϵ, involve probabilities that are double-exponentially small (and double-exponentially close to 1), as a function of the encoding size of the BCSG, so these probabilities have to be encoded in a suitable succinct notation in order for the output to have polynomial encoding size.

FO = FO^3 for Linear Orders with Monotone Binary Relations

Marie Fortin
LSV, CNRS & ENS Paris-Saclay, Université Paris-Saclay, France
fortin@lsv.fr

Abstract

We show that over the class of linear orders with additional binary relations satisfying some monotonicity conditions, monadic first-order logic has the three-variable property. This generalizes (and gives a new proof of) several known results, including the fact that monadic first-order logic has the three-variable property over linear orders, as well as over $(\mathbb{R}, <, +1)$, and answers some open questions mentioned in a paper from Antonopoulos, Hunter, Raza and Worrell [FoSSaCS 2015]. Our proof is based on a translation of monadic first-order logic formulas into formulas of a star-free variant of Propositional Dynamic Logic, which are in turn easily expressible in monadic first-order logic with three variables.

1 Introduction

Logics with a bounded number of variables have been extensively studied, in particular in the context of descriptive complexity [17, 18, 10, 21] and temporal logics [20, 7, 14, 16]. One recurring question of interest [7, 25, 19, 4, 26, 1] is to determine, in a given class $\mathcal{C}$ of structures, whether all properties expressible in monadic first-order logic (FO) can be defined in the fragment FO^k consisting of formulas which use at most k variables. (A same variable may be quantified over several times in a formula.) In fact, several non-equivalent versions of this question appear in the literature, many of which are compared in [15]. We say that $\mathcal{C}$ has the *k-variable property* if every formula of FO with at most k free variables is equivalent over $\mathcal{C}$ to a formula of FO^k. Note that this is strictly stronger than requiring that all *sentences* (without free variables) of FO are equivalent to some FO^k formulas. Indeed, Hodkinson and Simon gave an example of a class of structures where no sentence requires more than 3 variables, but which does not have the k-variable property for any k [15].

The problem of whether a given class of structures has the k-variable property is closely related to the question of the existence of an expressively complete temporal logic (with a finite set of FO-definable modalities). A temporal logic is called expressively complete if any first-order formula with a single free variable can be expressed in it. For instance, it is well-known that linear temporal logic (LTL) over Dedekind-complete time flows, or its extension with Stavi connectives over all time flows, are expressively complete for first-order logic [20, 8]. More recently, it was shown that over the real numbers equipped with binary relations $+q$ for all $q \in \mathbb{Q}$, metric temporal logic (MTL) is expressively complete [16]. However, the questions of having the k-variable property for some k or admitting an expressively complete temporal logic are incomparable in general: there exists a class of structures which admits a finite expressively complete set of temporal connectives but which does not have the k-variable

property for any k [15], and there exists one which has the 3-variable property but for which no temporal logic is expressively complete [14]. However, Gabbay established that having the k-variable property implies the existence of a *multi-dimensional* expressively complete temporal logic, with multiple reference points [7].

Another classical approach to proving or disproving that a class of structures has the k-variable property is through Ehrenfeucht-Fraïssé games, with a bounded number of pebbles [12, 25, 19, 1]. Immerman and Kozen applied this to linear orders and bounded-degree trees [19], and Antonopoulos et al. to real-time signals [1].

Natural candidates for classes $\mathcal{C}$ which might have the k-variable property are classes of linearly ordered structures. Indeed, a typical counter-example to unrestricted structures having the k-variable property is a formula such as "there exists $k+1$ distinct elements which satisfy some predicate P". It is in general not expressible in FO^k, but it is easily expressible in FO^2 if all models are equipped with a linear order $<$. For instance for $k=2$, we take the formula $\exists x.\ P(x) \wedge \exists y.(x < y \wedge P(y) \wedge \exists x.(y < x \wedge P(x)))$. As mentioned before, Immerman and Kozen showed that the class of linear orders has the 3-variable property [19]. However, adding a single binary relation suffices to obtain a class of linearly ordered structures which does not have the k-variable property for any k. Venema gave an example of a dense linear order with a single equivalence relation which does not have the k-variable property for any k [29]; this was adapted in [1] to give another example where the equivalence relation is replaced with a bijection. In fact, even for finite linear orders, Rossman [26] proved that the class of linearly ordered graphs does not have the k-variable property for any k, resolving a problem which had been open for more than 25 years [17]. Therefore, adding binary relations to linear orders while keeping the k-variable property requires some restrictions on the interpretation of the relation symbols.

On the positive side, Antonopoulos et al. proved that the class of structures over $(\mathbb{R}, <, +1)$ (or signals) has the 3-variable property [1]. Such structures have been studied in the context of real-time verification. As a corollary, they also showed that $(\mathbb{R}, <, f)$ has the 3-variable property for any linear function $f : x \mapsto ax + b$.

Contribution. We consider the class of linearly ordered structures with an additional (finite or infinite) number of binary *interval-preserving* relations. These are binary relations $\mathcal{R}$ such that, for all intervals I, any point which is in between two points of $\mathcal{R}(I)$ and has a preimage by $\mathcal{R}$ must have one in I. (We also require a symmetric condition of the converse relation $\mathcal{R}^{-1}$.) We show that FO over this class of structures also has the 3-variable property.

This generalizes results from [19] and [1] described above. Moreover, this answers some open questions mentioned in the conclusion of [1], which asked if the result could be extended from linear functions to polynomials over the reals, or other linear orders and families of monotone functions. In fact, all increasing or decreasing partial functions (over arbitrary linear orders) are special cases of interval-preserving relations, and thus covered by our result.

Our proof relies on different techniques than [19, 1], which were based on Ehrenfeucht-Fraïssé games. We give an effective translation from FO to FO^3 which goes through a star-free variant of Propositional Dynamic Logic (PDL) with converse. Propositional dynamic logic was introduced by Fischer and Ladner [6] to reason about program schemes, and has now found a large range of applications in artificial intelligence and verification [11, 5, 23, 22, 9]. It combines local formulas containing modal operators, and path formulas using the concatenation, union and Kleene star operations. Several extensions have been studied, including PDL with converse [27], intersection [3], or negation of atomic programs

[24]. The particular *star-free* variant of PDL we use here is in fact very similar to Tarski's relation algebras [28], which was used as a basis for formalizing set theory. It also corresponds to a *two-dimensional* temporal logic in the sense of Gabbay [7].

We applied similar proof techniques in [2], where we introduced a star-free variant of PDL and proved that it is equivalent to FO over *message sequence charts* (MSCs) (and thus obtained a 3-variable property result for MSCs as a corollary). MSCs are discrete partial orders which represent behaviors of concurrent message passing systems. They consist of a fixed, finite number of linear orders called process orders (one for each process in the system), together with FIFO binary message relations connecting matching send and receive actions. Having a (fixed) finite number of total orders instead of a single one is not an important difference, as we could always put them one after the other to extend them into a single linear order. FIFO relations are a special case of interval-preserving relations, thus the result of the present paper can in fact be seen as a strict generalization of our previous result in [2]. More importantly, a major difference between MSCs studied in [2] and the setting we consider here is that MSCs are *discrete* structures, whereas here we allow arbitrary linear orders. In fact, [2] relied on the definition of formulas describing the minimum or the maximum of some binary relations. As such, it is interesting to see that the same kind of techniques can still be applied to a priori very different linear orders.

Outline. In Section 2, we introduce interval-preserving relations and monadic first-order logic. In Section 3, we define star-free PDL, and prove some properties of its formulas. In Section 4, we give an effective translation from FO to star-free PDL, and explain its consequences. We conclude in Section 5.

2 Interval-preserving relations and first-order logic

In this section, we define the class of structures covered by our results, and recall the syntax of first-order logic.

Interval-preserving binary relations. Let $\mathcal{R} \subseteq A \times B$ be a binary relation between sets A and B. We write $a\ \mathcal{R}\ b$ if $(a,b) \in \mathcal{R}$, and $\mathcal{R}(a) = \{b \in B \mid a\ \mathcal{R}\ b\}$. For a subset $A' \subseteq A$, we also write $\mathcal{R}(A') = \bigcup_{a \in A'} \mathcal{R}(a)$. We define the *converse* of a relation $\mathcal{R}$ as $\mathcal{R}^{-1} = \{(b,a) \in B \times A \mid (a,b) \in \mathcal{R}\}$, and the *composition* of two binary relations $\mathcal{R}_1 \subseteq A \times B$ and $\mathcal{R}_2 \subseteq B \times C$ as $\mathcal{R}_1 \cdot \mathcal{R}_2 = \{(a,c) \in A \times C \mid \exists b \in B.\ (a,b) \in \mathcal{R}_1 \wedge (b,c) \in \mathcal{R}_2\}$. Finally, we write $\mathcal{R}^{\mathsf{c}} = (A \times B) \setminus \mathcal{R}$ for the *complement* of $\mathcal{R}$. Note that we have the following identities:

$$(\mathcal{R}_1 \cdot \mathcal{R}_2)^{-1} = {\mathcal{R}_2}^{-1} \cdot {\mathcal{R}_1}^{-1} \qquad (\mathcal{R}^{\mathsf{c}})^{-1} = \left(\mathcal{R}^{-1}\right)^{\mathsf{c}} \qquad (\mathcal{R}_1 \cap \mathcal{R}_2)^{-1} = \mathcal{R}_1^{-1} \cap \mathcal{R}_2^{-1}\,.$$

A linear order $\leq$ over a set A is a reflexive, transitive and antisymmetric relation $\leq \subseteq A \times A$ such that for all $a, b \in A$, we have $a \leq b$ or $b \leq a$. Let $(A, \leq)$ be a linearly ordered set. For $A' \subseteq A$, we also denote by $\leq$ the restriction of $\leq$ to A', so that $(A', \leq)$ is still a linearly ordered set. Moreover, for $a \in A$, we write $a < A'$ if for all $a' \in A'$, $a < a'$, and $A' < a$ if for all $a' \in A'$, $a' < a$.

An *interval* of $(A, \leq)$ is a set $I \subseteq A$ such that for all $a \leq b \leq c$ with $a, c \in I$, we have $b \in I$. For $a, b \in A$, we denote by $[a,b)$ the interval $\{c \in A \mid a \leq c < b\}$, and similarly for the intervals $[a,b]$, $(a,b]$, (a,b). We call a relation $\mathcal{R} \subseteq A \times B$ between two linearly ordered sets $(A, \leq_A)$ and $(B, \leq_B)$ *interval-preserving* if:

- For all intervals I of $(A, \leq_A)$, $\mathcal{R}(I)$ is an interval of $(\mathcal{R}(A), \leq_B)$.
- For all intervals J of $(B, \leq_B)$, $\mathcal{R}^{-1}(J)$ is an interval of $(\mathcal{R}^{-1}(B), \leq_A)$.

Figure 1 Definition of interval-preserving relations.

In other terms, for all $a_1 \mathcal{R} b_1$ and $a_2 \mathcal{R} b_2$ with $a_1, a_2 \in I$, for all $b_1 \leq_B b \leq_B b_2$, if there exists some $a \in A$ such that $a \mathcal{R} b$, then there exists one in I (cf. Figure 1). Note that we do not require that *all* elements between b_1 and b_2 are in $\mathcal{R}(I)$, but only those which are in the image of $\mathcal{R}$. The second condition is symmetric: for all $a_1 \mathcal{R} b_1$ and $a_2 \mathcal{R} b_2$ with $b_1, b_2 \in J$, for all $a_1 \leq_A a \leq_A a_2$, if there exists some $b \in B$ such that $a \mathcal{R} b$, then there exists one in J.

▶ **Example 1.** For any linear order $(A, \leq)$ and partial function $f : A \to A$, if f is increasing or decreasing then the relation $\{(a, f(a)) \mid a \in \mathrm{dom}(f)\}$ is interval-preserving.

As another example, consider a temporal structure $(A, \leq, \lambda)$ over a set of atomic propositions AP, where $\lambda : A \to 2^{\mathrm{AP}}$ indicates the set of propositions which are true at a given point. For $P, Q \in \mathrm{AP}$, we let $\mathsf{until}_{P,Q} = \{(a, b) \in A \times A \mid a < b \wedge Q \in \lambda(b) \wedge \forall a < c < b, P \in \lambda(c)\}$. Then $\mathsf{until}_{P,Q}$ is interval-preserving.

The following lemma states some simple closure properties of interval-preserving relations.

▶ **Lemma 2.** *Let $(A, \leq_A)$, $(B, \leq_B)$, $(C, \leq_C)$ be linearly ordered sets.*

1. *For all interval-preserving relation $\mathcal{R} \subseteq A \times B$, $\mathcal{R}^{-1}$ is interval-preserving.*
2. *For all interval-preserving relations $\mathcal{R}_1, \mathcal{R}_2 \subseteq A \times B$, $\mathcal{R}_1 \cap \mathcal{R}_2$ is interval-preserving.*
3. *For all interval-preserving relations $\mathcal{R}_1 \subseteq A \times B$ and $\mathcal{R}_2 \subseteq B \times C$, $\mathcal{R}_1 \cdot \mathcal{R}_2$ is interval-preserving.*

Proof. Part 1 follows from the fact that $(\mathcal{R}^{-1})^{-1} = \mathcal{R}$.

Let us prove 2. Since $(\mathcal{R}_1 \cap \mathcal{R}_2)^{-1} = \mathcal{R}_1^{-1} \cap \mathcal{R}_2^{-1}$, by symmetry, it suffices to prove that for all interval I of $(A, \leq)$, $(\mathcal{R}_1 \cap \mathcal{R}_2)(I)$ is an interval of $((\mathcal{R}_1 \cap \mathcal{R}_2)(A), \leq)$. Let $a_1, a_2 \in I$ and $b_1 \leq b \leq b_2$ such that $(a_1, b_1), (a_2, b_2) \in (\mathcal{R}_1 \cap \mathcal{R}_2)$ and $(a, b) \in (\mathcal{R}_1 \cap \mathcal{R}_2)$ for some $a \in A$. If $a \in I$, then we are done. Otherwise, suppose for instance that $a < a_1 \leq a_2$ (the other cases are similar). Since $\mathcal{R}_1$ is interval-preserving, there exists $a_1 \leq a' \leq a_2$ such that $a' \mathcal{R}_1 b$. Then, since $a < a_1 \leq a'$ and $\mathcal{R}_1^{-1}(b)$ is an interval of $(\mathcal{R}_1^{-1}(B), \leq_A)$, we obtain $a_1 \mathcal{R}_1 b$. Similarly, $a_1 \mathcal{R}_2 b$. Hence $a_1 (\mathcal{R}_1 \cap \mathcal{R}_2) b$.

Let us show that 2 implies 3. Again, by symmetry, it suffices to prove that for all interval I of $(A, \leq_A)$, $(\mathcal{R}_1 \cdot \mathcal{R}_2)(I)$ is an interval of $((\mathcal{R}_1 \cdot \mathcal{R}_2)(A), \leq_C)$. Let $\mathcal{R}_3 \subseteq B \times C$ denote the relation $\mathcal{R}_1(A) \times C$. It is an interval-preserving relation between $(B, \leq_B)$ and $(C, \leq_C)$. Moreover, we have $(\mathcal{R}_1 \cdot \mathcal{R}_2)(A) = (\mathcal{R}_2 \cap \mathcal{R}_3)(B)$. Now, let I be some interval of $(A, \leq_A)$, and $J = \{b \in B \mid \exists b_1, b_2 \in \mathcal{R}_1(I), b_1 \leq b \leq b_2\}$. Then J is an interval of $(B, \leq_B)$. Moreover, since $\mathcal{R}_1$ is interval-preserving, we have $\mathcal{R}_1(I) = J \cap \mathcal{R}_1(A)$, hence

$$(\mathcal{R}_1 \cdot \mathcal{R}_2)(I) = \mathcal{R}_2(\mathcal{R}_1(I)) = \mathcal{R}_2(J \cap \mathcal{R}_1(A)) = (\mathcal{R}_2 \cap \mathcal{R}_3)(J)\,.$$

Then, according to 2, $(\mathcal{R}_1 \cdot \mathcal{R}_2)(I)$ is an interval of $((\mathcal{R}_2 \cap \mathcal{R}_3)(B), \leq_C)$, i.e., an interval of $((\mathcal{R}_1 \cdot \mathcal{R}_2)(A), \leq_C)$. ◀

Models. Let $\mathcal{P} = \{P, Q, \ldots\}$ be an infinite set of monadic predicates, and $\Gamma = \{\alpha, \beta, \ldots\}$ be a finite or infinite set of binary relation symbols. Throughout the paper, $\mathcal{M}$ will denote a structure $\mathcal{M} = (A, \leq, (\alpha^{\mathcal{M}})_{\alpha \in \Gamma}, (P^{\mathcal{M}})_{P \in \mathcal{P}})$ where $\leq$ is a linear order over A, $\alpha^{\mathcal{M}} \subseteq A \times A$ is an interval-preserving relation for all $\alpha \in \Gamma$, and $P^{\mathcal{M}} \subseteq A$ for all $P \in \mathcal{P}$.

Monadic first-order logic. We assume an infinite supply of variables $\mathcal{X} = \{x, y, \ldots\}$. The set $\mathrm{FO}[\Gamma, \leq]$ of monadic first-order logic formulas over Γ is defined as follows:

$$\Phi ::= P(x) \mid x \leq y \mid x = y \mid \alpha(x, y) \mid \Phi \vee \Phi \mid \neg\Phi \mid \exists x.\Phi\,, \qquad \text{where } x, y \in \mathcal{X}, P \in \mathcal{P}, \alpha \in \Gamma\,.$$

We assume that all formulas are interpreted over structures $\mathcal{M}$ defined as above. Given an $\mathrm{FO}[\Gamma, \leq]$ formula Φ, we denote by $\mathsf{Free}(\Phi)$ its set of free variables. We define the satisfaction relation $\mathcal{M}, \nu \models \Phi$ as usual, where $\mathcal{M} = (A, \leq, (\alpha^{\mathcal{M}})_{\alpha\in\Gamma}, (P^{\mathcal{M}})_{P\in\mathcal{P}})$ and $\nu : \mathsf{Free}(\Phi) \to A$ is an interpretation of the free variables of Φ. We say that two formulas $\Phi, \Psi \in \mathrm{FO}[\Gamma, \leq]$ are *equivalent*, written $\Phi \equiv \Psi$, if for all $\mathcal{M} = (A, \leq, (\alpha^{\mathcal{M}})_{\alpha\in\Gamma}, (P^{\mathcal{M}})_{P\in\mathcal{P}})$ and $\nu : \mathsf{Free}(\Phi) \cup \mathsf{Free}(\Psi) \to A$, we have $\mathcal{M}, \nu|_{\mathsf{Free}(\Phi)} \models \Phi$ if and only if $\mathcal{M}, \nu|_{\mathsf{Free}(\Psi)} \models \Psi$.

For $k \in \mathbb{N}$, we denote by $\mathrm{FO}^k[\Gamma, \leq]$ the set of first-order formulas with at most k variables. Note that a same variable may be quantified over several times in the formula.

▶ **Example 3.** Let $p : \mathbb{R} \to \mathbb{R}$ be a polynomial function, and $m_1 < \cdots < m_n$ its local extrema (we suppose that $n \geq 1$). Fix $\Gamma = \{p\}$. For convenience, we write $p(x) = y$ instead of $p(x, y)$ in $\mathrm{FO}[\Gamma, \leq]$ formulas. We focus on models of the form $\mathcal{M} = (\mathbb{R}, \leq, p^{\mathcal{M}}, (P^{\mathcal{M}})_{P\in\mathcal{P}})$ where $\leq$ is the usual ordering of the reals, and $p^{\mathcal{M}} = \{(x, p(x)) \mid x \in \mathbb{R}\}$. Let us describe an $\mathrm{FO}^3[\Gamma, \leq]$ formula $m_i \leq x$ such that for all $\mathcal{M}$ and $r \in \mathbb{R}$, we have $\mathcal{M}, [x \mapsto r] \models m_i \leq x$ if and only if $m_i \leq r$. First, we write $p(x) \leq p(y)$ for the $\mathrm{FO}^3[\Gamma, \leq]$ formula

$$\exists z.\, p(x) = z \wedge \exists x.\, (p(y) = x \wedge z \leq x)\,.$$

We can then define formulas $\min(x) \in \mathrm{FO}^3[\Gamma, \leq]$ and $\max(x) \in \mathrm{FO}^3[\Gamma, \leq]$ which state that x is a local minimum (resp. maximum) of p, for instance:

$$\begin{aligned}\min(x) = {} & (\exists z.\, z < x \wedge \forall y.\, (z < y \leq x \implies p(x) \leq p(y))) \wedge \\ & (\exists z.\, x < z \wedge \forall y.\, (x \leq y < z \implies p(x) \leq p(y)))\,.\end{aligned}$$

The formula $m_i \leq x$ then states that there exist at least i local extrema before x, alternating existential quantifications over y and z to identify them; for instance, $m_3 \leq x$ is the formula

$$\exists y.\, y \leq x \wedge (\min(y) \vee \max(y)) \wedge \exists z.\, z < y \wedge (\min(z) \vee \max(z)) \wedge \exists y.\, y < z \wedge (\min(y) \vee \max(y))\,.$$

3 Star-free Propositional Dynamic Logic

Star-free Propositional Dynamic Logic. Propositional dynamic logic (PDL) [6] consists of two sorts of formulas: state formulas which are evaluated at single elements, and path formulas which are evaluated at pairs of elements and allow to navigate inside the model. Here we consider a star-free variant of PDL (with converse). The syntax of *star-free propositional dynamic logic* over Γ, written $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$, is given below:

$$\begin{aligned}&\varphi ::= P \mid \varphi \vee \varphi \mid \neg\varphi \mid \langle\pi\rangle\,\varphi && \text{(state formulas)}\\ &\pi ::= \alpha \mid \leq \mid \{\varphi\}? \mid \pi^{-1} \mid \pi \cdot \pi \mid \pi \cup \pi \mid \pi \cap \pi \mid \pi^{\mathsf{c}} && \text{(path formulas)}\end{aligned}$$

where $P \in \mathcal{P}$ and $\alpha \in \Gamma$.

Compared to classical PDL, star-free PDL uses the operators $(\cdot, \cup, \cap, \mathsf{c})$ of star-free expressions, instead of the rational operators $(\cdot, \cup, *)$.

Let $\mathcal{M} = (A, \leq, (\alpha^{\mathcal{M}})_{\alpha\in\Gamma}, (P^{\mathcal{M}})_{P\in\mathcal{P}})$. The semantics $[\![\varphi]\!]^{\mathcal{M}} \subseteq A$ or $[\![\pi]\!]^{\mathcal{M}} \subseteq A \times A$ of a state or path formula in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ is defined below. The state formula $\langle\pi\rangle\,\varphi$ is true at a point $a \in A$ in $\mathcal{M}$ (that is, $a \in [\![\langle\pi\rangle\,\varphi]\!]^{\mathcal{M}}$) if there exists some $b \in A$ such that (a, b) satisfies

π and φ is true at b. The path formula $\{\varphi\}?$ is stationary and tests if the state formula φ is true. The semantics of other formulas is straightforward:

$$\begin{aligned}
[\![P]\!]^{\mathcal{M}} &:= P^{\mathcal{M}} & [\![\varphi_1 \vee \varphi_2]\!]^{\mathcal{M}} &:= [\![\varphi_1]\!]^{\mathcal{M}} \cup [\![\varphi_2]\!]^{\mathcal{M}} \\
[\![\neg\varphi]\!]^{\mathcal{M}} &:= A \setminus [\![\varphi]\!]^{\mathcal{M}} & [\![\langle\pi\rangle\,\varphi]\!]^{\mathcal{M}} &:= \{a \in A \mid \exists b \in [\![\varphi]\!]^{\mathcal{M}},\ (a,b) \in [\![\pi]\!]^{\mathcal{M}}\} \\
[\![\alpha]\!]^{\mathcal{M}} &:= \alpha^{\mathcal{M}} & [\![\{\varphi\}?]\!]^{\mathcal{M}} &:= \{(a,a) \mid a \in [\![\varphi]\!]^{\mathcal{M}}\} \\
[\![\leq]\!]^{\mathcal{M}} &:= \leq & [\![\pi^{-1}]\!]^{\mathcal{M}} &:= ([\![\pi]\!]^{\mathcal{M}})^{-1} \\
[\![\pi_1 \cup \pi_2]\!]^{\mathcal{M}} &:= [\![\pi_1]\!]^{\mathcal{M}} \cup [\![\pi_2]\!]^{\mathcal{M}} & [\![\pi_1 \cap \pi_2]\!]^{\mathcal{M}} &:= [\![\pi_1]\!]^{\mathcal{M}} \cap [\![\pi_2]\!]^{\mathcal{M}} \\
[\![\pi^{\mathsf{c}}]\!]^{\mathcal{M}} &:= (A \times A) \setminus [\![\pi]\!]^{\mathcal{M}} & [\![\pi_1 \cdot \pi_2]\!]^{\mathcal{M}} &:= [\![\pi_1]\!]^{\mathcal{M}} \cdot [\![\pi_2]\!]^{\mathcal{M}}\,.
\end{aligned}$$

For simplicity, we often write $[\![\varphi]\!]$ or $[\![\pi]\!]$ instead of $[\![\varphi]\!]^{\mathcal{M}}$ and $[\![\pi]\!]^{\mathcal{M}}$. We also write $\mathcal{M}, a \models \varphi$ if $a \in [\![\varphi]\!]^{\mathcal{M}}$, and $\mathcal{M}, a, b \models \pi$ if $(a,b) \in [\![\pi]\!]^{\mathcal{M}}$.

We use the abbreviations $\mathit{true} := P \vee \neg P$, $\mathit{false} := \neg\mathit{true}$, $\geq := (\leq)^{-1}$, $< := \geq^{\mathsf{c}}$, $> := \leq^{\mathsf{c}}$ and $\langle\pi\rangle := \langle\pi\rangle\,\mathit{true}$. For all $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ formulas π, we also define a state formula $\mathsf{loop}(\pi) := \langle\pi \cap \{\mathit{true}\}?\rangle$ which holds at a if and only if $(a,a) \in [\![\pi]\!]$.

▶ **Example 4.** Suppose that $\Gamma = \{+q \mid q \in \mathbb{Q}\}$, and that we consider only models over $\mathbb{R}$ and with $[\![+q]\!] = \{(r, r+q) \mid r \in \mathbb{R}\}$. Let $q, r \in \mathbb{Q}_{\geq 0}$ and $P, Q \in \mathcal{P}$. The formula $P\,\mathsf{U}_{(q,r)}\,Q$ of metric temporal logic, which holds at time $t \in \mathbb{R}$ if there exists $t+q < t' < t+r$ such that $t' \in [\![Q]\!]$ and for all $t < t'' < t'$, $t'' \in [\![P]\!]$, can be expressed in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ as follows:

$$P\,\mathsf{U}_{(q,r)}\,Q \equiv \big\langle (+q \cdot <) \cap (+r \cdot >) \cap (< \cdot \{\neg P\}? \cdot <)^{\mathsf{c}} \big\rangle\, Q\,.$$

An interval-preserving fragment of star-free PDL. We say that a path formula $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ is *interval-preserving* if for all $\mathcal{M}$, $[\![\pi]\!]^{\mathcal{M}}$ is interval-preserving. Notice that $\leq$ and $\{\varphi\}?$ (for all φ) are interval-preserving. By Lemma 2 (and assumption on $[\![\alpha]\!]$), all $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ formulas constructed without the boolean operators $\cup$ and c are interval-preserving. However, the complement or the union of interval-preserving relations are not in general interval-preserving. We define below a fragment of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ where all path formulas are interval-preserving, and which will turn out to be as expressive as $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ (and in fact, $\mathrm{FO}[\Gamma, \leq]$) when it comes to *state* formulas. To do so, we introduce several restrictions of π^{c} which are interval-preserving, and which suffice to characterize π^{c}.

Let us first look at the different reasons for which we may have $(a,b) \in [\![\pi^{\mathsf{c}}]\!]$, assuming that π is interval-preserving. To begin with, we focus on a. One first sufficient condition for having $b \notin [\![\pi]\!](a)$ is that $[\![\pi]\!](a) = \emptyset$. Now, suppose $[\![\pi]\!](a) \neq \emptyset$. If π is interval-preserving, there are only three possible cases in which $b \notin [\![\pi]\!](a)$: $b < [\![\pi]\!](a)$, or $[\![\pi]\!](a) < b$, or $[\![\pi^{-1}]\!](b) = \emptyset$. We define formulas $\mathsf{left}\ \pi$ and $\mathsf{right}\ \pi$ corresponding respectively to the first two cases. We let

$$\begin{aligned}
\mathsf{left}\ \pi = \{\langle\pi\rangle\}? \cdot (\pi \cdot \leq)^{\mathsf{c}}, \quad \text{i.e.} \qquad & (a,b) \in [\![\mathsf{left}\ \pi]\!] \quad \text{iff} \quad b < [\![\pi]\!](a) \neq \emptyset \\
\mathsf{right}\ \pi = \{\langle\pi\rangle\}? \cdot (\pi \cdot \geq)^{\mathsf{c}}, \quad \text{i.e.} \qquad & (a,b) \in [\![\mathsf{right}\ \pi]\!] \quad \text{iff} \quad b > [\![\pi]\!](a) \neq \emptyset\,.
\end{aligned}$$

Now, if we look at $[\![\pi^{-1}]\!](b)$ instead of $[\![\pi]\!](a)$, we can make the same observations, by symmetry: we have $(a,b) \in [\![\pi^{\mathsf{c}}]\!]$ if and only if $a \notin [\![\pi^{-1}]\!](b)$, and if π is interval-preserving, there are again only four possible cases: $[\![\pi^{-1}]\!](b) = \emptyset$, or $a < [\![\pi^{-1}]\!](b)$, or $a > [\![\pi^{-1}]\!](b)$, or $[\![\pi]\!](a) = \emptyset$.

Unfortunately, the formulas $\mathsf{left}\ \pi$ and $\mathsf{right}\ \pi$ are still not interval-preserving in general. However, if we take a more symmetric restriction of π^{c}, where we look at all the possible positions of b and a relatively to $[\![\pi]\!](a)$ and $[\![\pi^{-1}]\!](b)$, we obtain four cases, illustrated in Figure 2, which we will later show correspond to interval-preserving restrictions of π^{c}.

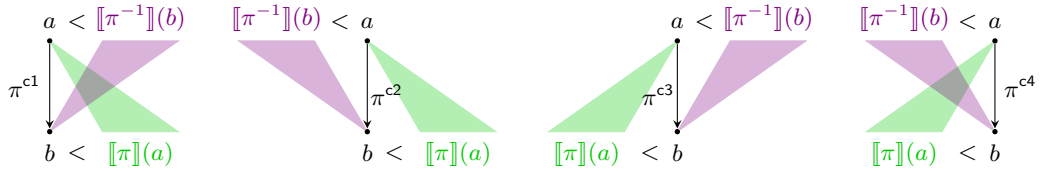

Figure 2 Definition of π^{c1}, π^{c2}, π^{c3} and π^{c4}, from left to right.

More precisely, let

$$\pi^{c1} := \mathsf{left}\ \pi \cap \left(\mathsf{left}\ \left(\pi^{-1}\right)\right)^{-1}, \text{i.e.} \qquad (a,b) \in [\![\pi^{c1}]\!] \quad \text{iff} \quad \begin{cases} b < [\![\pi]\!](a) \neq \emptyset & \text{and} \\ a < [\![\pi^{-1}]\!](b) \neq \emptyset \end{cases}$$

$$\pi^{c2} := \mathsf{left}\ \pi \cap \left(\mathsf{right}\ \left(\pi^{-1}\right)\right)^{-1}, \text{i.e.} \qquad (a,b) \in [\![\pi^{c2}]\!] \quad \text{iff} \quad \begin{cases} b < [\![\pi]\!](a) \neq \emptyset & \text{and} \\ a > [\![\pi^{-1}]\!](b) \neq \emptyset \end{cases}$$

$$\pi^{c3} := \mathsf{right}\ \pi \cap \left(\mathsf{left}\ \left(\pi^{-1}\right)\right)^{-1}, \text{i.e.} \qquad (a,b) \in [\![\pi^{c3}]\!] \quad \text{iff} \quad \begin{cases} b > [\![\pi]\!](a) \neq \emptyset & \text{and} \\ a < [\![\pi^{-1}]\!](b) \neq \emptyset \end{cases}$$

$$\pi^{c4} := \mathsf{right}\ \pi \cap \left(\mathsf{right}\ \left(\pi^{-1}\right)\right)^{-1}, \text{i.e.} \qquad (a,b) \in [\![\pi^{c4}]\!] \quad \text{iff} \quad \begin{cases} b > [\![\pi]\!](a) \neq \emptyset & \text{and} \\ a > [\![\pi^{-1}]\!](b) \neq \emptyset\,. \end{cases}$$

Notice that $\pi^{c3} \equiv ((\pi^{-1})^{c2})^{-1}$.

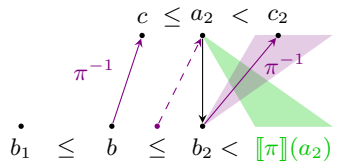
Let $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \cap, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ be the following restriction of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$:

$$\varphi ::= P \mid \varphi \vee \varphi \mid \neg\varphi \mid \langle\pi\rangle\,\varphi$$
$$\pi ::= \alpha \mid \leq \mid \{\varphi\}? \mid \pi^{-1} \mid \pi \cdot \pi \mid \pi \cap \pi \mid \pi^{c1} \mid \pi^{c2} \mid \pi^{c3} \mid \pi^{c4}\,.$$

▶ **Lemma 5.** *All* $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \cap, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ *formulas are interval-preserving.*

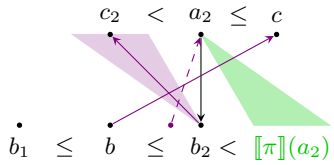
Proof. We proceed by induction on the formula. By assumption, α is interval-preserving for all $\alpha \in \Gamma$. Moreover, $\leq$ and $\{\varphi\}?$ are interval-preserving. For π^{-1}, $\pi_1 \cdot \pi_2$ and $\pi_1 \cap \pi_2$, we apply Lemma 2.

Suppose that π is interval-preserving. Let us show that π^{c1} is interval-preserving. Notice that $(\pi^{c1})^{-1} \equiv (\pi^{-1})^{c1}$. So we only need to show that for all intervals I, for all $b_1, b_2 \in [\![\pi^{c1}]\!](I)$ and $b_1 \leq b \leq b_2$ such that $[\![(\pi^{c1})^{-1}]\!](b) \neq \emptyset$, there exists $a \in I$ such that $(a,b) \in [\![\pi^{c1}]\!]$. Let $a_2 \in I$ such that $(a_2, b_2) \in [\![\pi^{c1}]\!]$. Let us show that we can in fact take $a = a_2$. The proof is illustrated in the picture below.



First, we have $b \leq b_2 < [\![\pi]\!](a_2) \neq \emptyset$. Moreover, $[\![\pi^{-1}]\!](b) \neq \emptyset$ (since $[\![(\pi^{c1})^{-1}]\!](b) \neq \emptyset$). Now, suppose towards a contradiction that $a_2 \not< [\![\pi^{-1}]\!](b)$. Let $c \in [\![\pi^{-1}]\!](b)$ such that $c \leq a_2$. Since $(a_2, b_2) \in [\![\pi^{c1}]\!]$, there exists $c_2 > a_2$ such that $(b_2, c_2) \in [\![\pi^{-1}]\!]$. We then have $c \leq a_2 < c_2$ and $[\![\pi]\!](a_2) \neq \emptyset$. Since π is interval-preserving, we obtain $a_2 \in [\![\pi^{-1}]\!]([b, b_2])$, a contradiction with the fact that $b_2 < [\![\pi]\!](a_2)$. Thus, $(a_2, b) \in [\![\pi^{c1}]\!]$.

Let us show that π^{c2} is also interval-preserving. Similarly to the previous case, we show that for all $(a_2, b_2) \in [\![\pi^{\mathsf{c2}}]\!]$ and $b \leq b_2$ such that $[\![(\pi^{\mathsf{c2}})^{-1}]\!](b) \neq \emptyset$, we have $(a_2, b) \in [\![\pi^{\mathsf{c2}}]\!]$.



First, $b \leq b_2 < [\![\pi]\!](a_2) \neq \emptyset$, and $[\![\pi^{-1}]\!](b) \neq \emptyset$. Suppose towards a contradiction that $[\![\pi^{-1}]\!](b) \not< a_2$. Let $c \in [\![\pi^{-1}]\!](b)$ such that $a_2 \leq c$, and $c_2 \in [\![\pi^{-1}]\!](b_2)$. We have $c_2 < a_2 \leq c$, and $[\![\pi]\!](a_2) \neq \emptyset$. Since π is interval-preserving, we obtain $a_2 \in [\![\pi^{-1}]\!]([b, b_2])$, a contradiction with the fact that $b_2 < [\![\pi]\!](a_2)$. Symmetrically, let J be an interval, $a_1, a_2 \in [\![(\pi^{\mathsf{c2}})^{-1}]\!](J)$, and $a_1 \leq a \leq a_2$ such that $[\![\pi^{\mathsf{c2}}]\!](a) \neq \emptyset$. Then for any $b_1 \in J$ such that $(a_1, b_1) \in [\![\pi^{\mathsf{c2}}]\!]$, we also have $(a, b_1) \in [\![\pi^{\mathsf{c2}}]\!]$, hence $a \in [\![(\pi^{\mathsf{c2}})^{-1}]\!](J)$.

Since $\pi^{\mathsf{c3}} \equiv ((\pi^{-1})^{\mathsf{c2}})^{-1}$, this also implies that π^{c3} is interval-preserving.

Finally, the case of π^{c4} is symmetric to the case of π^{c1}: for all $(a_1, b_1) \in [\![\pi^{\mathsf{c4}}]\!]$ and $b_1 \leq b$ such that $[\![(\pi^{\mathsf{c4}})^{-1}]\!](b) \neq \emptyset$, we have $(a_1, b) \in [\![\pi^{\mathsf{c4}}]\!]$. ◀

4 Star-free PDL is expressively equivalent to FO

Let φ be a state formula in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$, and $\Phi(x)$ an $\mathrm{FO}[\Gamma, \leq]$ formula with a single free variable x. We say that φ and Φ are equivalent, written $\varphi \equiv \Phi(x)$, if for all $\mathcal{M}$ and elements a in $\mathcal{M}$, we have $\mathcal{M}, a \models \varphi$ if and only if $\mathcal{M}, [x \mapsto a] \models \Phi(x)$. Similarly, for a path formula $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ and an $\mathrm{FO}[\Gamma, \leq]$ formula $\Phi(x, y)$ with exactly two free variables x and y, we write $\pi \equiv \Phi(x, y)$ if for all $\mathcal{M}$ and elements a, b in $\mathcal{M}$, we have $\mathcal{M}, a, b \models \pi$ if and only if $\mathcal{M}, [x \mapsto a, y \mapsto b] \models \Phi(x, y)$.

From $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ to $\mathrm{FO}^3[\Gamma, \leq]$. An easy induction shows that any formula in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ can be translated into an $\mathrm{FO}[\Gamma, \leq]$ formula which uses at most three distinct variables:

▶ **Lemma 6.** *For every state formula $\varphi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$, there exists a formula $\widetilde{\varphi}(x) \in \mathrm{FO}^3[\Gamma, \leq]$ such that $\varphi \equiv \widetilde{\varphi}(x)$. For every path formula $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$, there exists a formula $\widetilde{\pi}(x, y) \in \mathrm{FO}^3[\Gamma, \leq]$ such that $\pi \equiv \widetilde{\pi}(x, y)$.*

For the other direction, we will see that the fragment $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ defined below is sufficient:

$$\varphi ::= P \mid \varphi \vee \varphi \mid \neg\varphi \mid \langle\pi\rangle\, \varphi \mid \mathsf{loop}(\pi)$$
$$\pi ::= \alpha \mid \leq \mid \{\varphi\}? \mid \pi^{-1} \mid \pi \cdot \pi \mid \pi^{\mathsf{c1}} \mid \pi^{\mathsf{c2}} \mid \pi^{\mathsf{c3}} \mid \pi^{\mathsf{c4}}\,.$$

This fragment is a restriction of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \cap, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$, where the intersection is only used for $\mathsf{loop}(\pi)$ formulas.

From $\mathrm{FO}[\Gamma, \leq]$ to $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. The main result of the paper is an effective translation of $\mathrm{FO}[\Gamma, \leq]$ formulas into positive boolean combinations of formulas in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$:

▶ **Theorem 7.** *Every formula $\Phi \in \mathrm{FO}[\Gamma, \leq]$ with at least one free variable is equivalent to a positive boolean combination of formulas of the form $\widetilde{\pi}(x, y)$, where $x, y \in \mathsf{Free}(\Phi)$ and $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$.*

Note that the equivalent formula may also contain subformulas of the form $\widetilde{\pi}(x,x)$.

Before proving Theorem 7, we state some of its consequences.

▶ **Corollary 8.** *Every formula* $\Phi \in \mathrm{FO}[\Gamma,\leq]$ *with a single free variable is equivalent to some* $\mathrm{PDL}_{\mathsf{sf}}[\Gamma,\leq,\mathsf{loop},\mathsf{c1},\mathsf{c2},\mathsf{c3},\mathsf{c4}]$ *state formula. Every formula* $\Phi \in \mathrm{FO}[\Gamma,\leq]$ *with two free variables is equivalent to some* $\mathrm{PDL}_{\mathsf{sf}}[\Gamma,\leq]$ *path formula.*

Proof. If Φ has a single free variable x, it is equivalent to a positive boolean combination of formulas of the form $\widetilde{\pi}(x,x)$, which are themselves equivalent to the formulas $\mathsf{loop}(\pi)$. The combination of these $\mathsf{loop}(\pi)$ formulas is then a state formula of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma,\leq,\mathsf{loop},\mathsf{c1},\mathsf{c2},\mathsf{c3},\mathsf{c4}]$.

If Φ has two free variables x and y, we obtain an equivalent positive boolean combination of formulas of the form $\widetilde{\pi}(x,y)$, $\widetilde{\pi}(y,x)$, $\widetilde{\pi}(x,x)$, or $\widetilde{\pi}(y,y)$. We can replace any subformula $\widetilde{\pi}(y,x)$ with $\widetilde{\pi^{-1}}(x,y)$, and any subformula $\widetilde{\pi}(x,x)$ with $\widetilde{\pi_1}(x,y)\vee\widetilde{\pi_2}(x,y)$, where $\pi_1 = (\{\mathsf{loop}(\pi)\}?\cdot\leq)$ and $\pi_2 = (\{\mathsf{loop}(\pi)\}?\cdot\geq)$, and similarly for formulas $\widetilde{\pi}(y,y)$. We obtain an equivalent positive boolean combination of formulas of the form $\widetilde{\pi}(x,y)$. Since $\mathrm{PDL}_{\mathsf{sf}}[\Gamma,\leq]$ allows union and intersection of path formulas, this is equivalent to a $\mathrm{PDL}_{\mathsf{sf}}[\Gamma,\leq]$ formula. ◀

Another consequence is that $\mathrm{FO}[\Gamma,\leq]$ over linear orders with interval-preserving relations has the three-variable property. More precisely:

▶ **Theorem 9.** *Any* $\mathrm{FO}[\Gamma,\leq]$ *formula is equivalent to a boolean combination of formulas in* $\mathrm{FO}^3[\Gamma,\leq]$.

This also allows us to answer an open question from [1], namely, whether structures over the real numbers with polynomial functions have the 3-variable property. Suppose that Γ is a set of polynomials $p:\mathbb{R}\to\mathbb{R}$. Let $\mathcal{M}_\Gamma = (\mathbb{R},\leq,(p^{\mathcal{M}_\Gamma})_{p\in\Gamma})$, where $\leq$ is the usual ordering of the real numbers, and $p^{\mathcal{M}_\Gamma} = \{(x,p(x)) \mid x\in\mathbb{R}\}$ for all $p\in\Gamma$. Given an interpretation $h:\mathcal{P}\to 2^{\mathbb{R}}$ of the monadic predicates, we denote by $(\mathcal{M}_\Gamma,h)$ the structure $(\mathbb{R},\leq,(p^{\mathcal{M}_\Gamma})_{p\in\Gamma},(h(P))_{P\in\mathcal{P}})$. We say that two formulas $\Phi,\Psi\in\mathrm{FO}[\Gamma,\leq]$ are equivalent over $\mathcal{M}_\Gamma$, written $\Phi\equiv_{\mathcal{M}_\Gamma}\Psi$, if for all $h:\mathcal{P}\to 2^{\mathbb{R}}$ and $\nu:\mathsf{Free}(\Phi)\cup\mathsf{Free}(\Psi)\to\mathbb{R}$, we have $(\mathcal{M}_\Gamma,h),\nu|_{\mathsf{Free}(\Phi)}\models\Phi$ if and only if $(\mathcal{M}_\Gamma,h),\nu|_{\mathsf{Free}(\Psi)}\models\Psi$.

▶ **Theorem 10.** *For all* $\Phi\in\mathrm{FO}[\Gamma,\leq]$, *there exists a boolean combination* Ψ *of formulas in* $\mathrm{FO}^3[\Gamma,\leq]$ *such that* $\Phi\equiv_{\mathcal{M}_\Gamma}\Psi$.

Proof. Let $p\in\Gamma$, and $m_1<\cdots<m_n$ its local extrema. We denote by $p_{(-\infty,m_1)}$, $p_{[m_1,m_2)},\ldots,p_{[m_n,+\infty)}$ the (monotone) restrictions of p to intervals delimitated by its local extrema, and Δ_p the set of these partial functions. Let $\Delta=\bigcup_{p\in\Gamma}\Delta_p$. As above, we let $\mathcal{M}_\Delta = (\mathbb{R},\leq,({p_I}^{\mathcal{M}_\Delta})_{p_I\in\Delta})$, where $\leq$ is the usual ordering of the real numbers, and ${p_I}^{\mathcal{M}_\Delta} = \{(x,p(x)) \mid x\in I\}$. Note that ${p_I}^{\mathcal{M}_\Delta}$ is interval-preserving (cf. Example 1). We say that two formulas $\Phi\in\mathrm{FO}[\Gamma,\leq]$ and $\Psi\in\mathrm{FO}[\Delta,\leq]$ are equivalent, written $\Phi\equiv\Psi$, when for all $h:\mathcal{P}\to 2^{\mathbb{R}}$ and $\nu:\mathsf{Free}(\Phi)\cup\mathsf{Free}(\Psi)\to\mathbb{R}$, we have $(\mathcal{M}_\Gamma,h),\nu|_{\mathsf{Free}(\Phi)}\models\Phi$ if and only if $(\mathcal{M}_\Delta,h),\nu|_{\mathsf{Free}(\Psi)}\models\Psi$.

Let $\Phi\in\mathrm{FO}[\Gamma,\leq]$. The formula $\Psi\in\mathrm{FO}[\Delta,\leq]$ obtained by replacing each atomic formula $p(x,y)$ by $\bigvee_{p_I\in\Delta_p}p_I(x,y)$ is equivalent to Φ. Applying Theorem 9 to Ψ, we obtain another formula $\Psi'\in\mathrm{FO}[\Delta,\leq]$ such that $\Psi'\equiv\Psi$ and Ψ' is a boolean combination of formulas in $\mathrm{FO}^3[\Delta,\leq]$.

Following Example 3, one can construct for each $p_I\in\Delta$ a formula "$x\in I$" of $\mathrm{FO}^3[\Gamma,\leq]$ such that $(\mathcal{M}_\Gamma,h),\nu\models x\in I$ if and only if $\nu(x)\in I$. Consider now the formula $\Phi'\in\mathrm{FO}[\Gamma,\leq]$ obtained by replacing each atomic formula $p_I(x,y)$ in Ψ' by $x\in I\wedge p(x,y)$. Then $\Phi'\equiv\Psi'$, hence $\Phi\equiv_{\mathcal{M}_\Gamma}\Phi'$. Moreover, Φ' is a boolean combination of formulas in $\mathrm{FO}^3[\Gamma,\leq]$. ◀

The remainder of the section is devoted to the proof of Theorem 7.

Eliminating negations. The fact that all $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ path formulas are interval-preserving gives us a simple characterization of the complement of a path formula: we show below that an element b is in $[\![\pi^{\mathsf{c}}]\!](a)$ if it is to the left or to the right of all elements of $[\![\pi]\!](a)$, or if it does not satisfy $\langle \pi^{-1} \rangle$. We can then show that the complement of a path formula in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ is equivalent to a union of path formulas in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. This will allow us to deal with negation in the translation from $\mathrm{FO}[\Gamma, \leq]$ to $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$.

▶ **Lemma 11.** *For all path formulas $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$, π^{c} is equivalent to a union of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$ formulas.*

Proof. We show that

$$\begin{aligned}\pi^{\mathsf{c}} \equiv\ & (\{\neg \langle \pi \rangle\}? \cdot \leq) \cup (\{\neg \langle \pi \rangle\}? \cdot \geq) \cup \\ & (\leq \cdot \{\neg \langle \pi^{-1} \rangle\}?) \cup (\geq \cdot \{\neg \langle \pi^{-1} \rangle\}?) \cup \\ & (\pi^{\mathsf{c1}}) \cup (\pi^{\mathsf{c2}}) \cup (\pi^{\mathsf{c3}}) \cup (\pi^{\mathsf{c4}})\,.\end{aligned}$$

We denote by π' the right-hand-side formula. First, for all a, b such that $[\![\pi]\!](a) = \emptyset$ or $[\![\pi^{-1}]\!](b) = \emptyset$, we have $(a, b) \in [\![\pi^{\mathsf{c}}]\!]$ and $(a, b) \in [\![\pi']\!]$. Now, suppose that $[\![\pi]\!](a) \neq \emptyset$ and $[\![\pi^{-1}]\!](b) \neq \emptyset$. We have $(a, b) \in [\![\pi']\!]$ if and only if $(a, b) \in [\![\pi^{\mathsf{c1}} \cup \pi^{\mathsf{c2}} \cup \pi^{\mathsf{c3}} \cup \pi^{\mathsf{c4}}]\!]$. Clearly, if $(a, b) \in [\![\pi^{\mathsf{c1}} \cup \pi^{\mathsf{c2}} \cup \pi^{\mathsf{c3}} \cup \pi^{\mathsf{c4}}]\!]$, then $(a, b) \in [\![\pi^{\mathsf{c}}]\!]$. Conversely, let us show that if $(a, b) \notin [\![\pi^{\mathsf{c1}} \cup \pi^{\mathsf{c2}} \cup \pi^{\mathsf{c3}} \cup \pi^{\mathsf{c4}}]\!]$ then $(a, b) \in [\![\pi]\!]$. In that case, we have either $a_1 \leq a \leq a_2$ for some $a_1, a_2 \in [\![\pi^{-1}]\!](b)$, or $b_1 \leq b \leq b_2$ for some $b_1, b_2 \in [\![\pi]\!](a)$. Since π is interval-preserving, we obtain $(a, b) \in [\![\pi]\!]$. ◀

Existential quantification. The elimination of existential quantifiers relies on the simple lemma below:

▶ **Lemma 12.** *Let $(A, \leq)$ be a linearly ordered set, and $I_1, \ldots, I_n$ intervals of $(A, \leq)$. Then $\bigcap_{1 \leq i \leq n} I_i \neq \emptyset$ if and only if for all $1 \leq i, j \leq n$, $I_i \cap I_j \neq \emptyset$.*

Proof. We show that there exists k and ℓ such that $\bigcap_{1 \leq i \leq n} I_i = I_k \cap I_\ell$, which implies the result. We define relations $\sqsubseteq_{\text{left}}$ and $\sqsubseteq_{\text{right}}$ over $\{I_1, \ldots, I_n\}$ which, intuitively, compare respectively the left and right bounds of the intervals:

$$\begin{aligned} I \sqsubseteq_{\text{left}} J \quad & \text{if} \quad \forall a \in J, \exists b \in I, b \leq a \\ I \sqsubseteq_{\text{right}} J \quad & \text{if} \quad \forall a \in I, \exists b \in J, a \leq b\,. \end{aligned}$$

It is easy to check that $\sqsubseteq_{\text{left}}$ and $\sqsubseteq_{\text{right}}$ are transitive, an that for all I and J, we have $I \sqsubseteq_{\text{left}} J$ or $J \sqsubseteq_{\text{left}} I$ (or both), and similarly for $\sqsubseteq_{\text{right}}$. Thus, there exists k such that $I_i \sqsubseteq_{\text{left}} I_k$ for all i, and ℓ such that $I_\ell \sqsubseteq_{\text{right}} I_i$ for all i. Then for all $a \in I_k \cap I_\ell$, for all i, there exists $b, b' \in I_i$ such that $b \leq a \leq b'$. Since I_i is an interval, we obtain $a \in I_i$. Hence $I_k \cap I_\ell = \bigcap_{1 \leq i \leq n} I_i$. ◀

The next lemma follows from an application of Lemma 12 to intervals of the form $[\![\pi_i]\!](a_i)$.

▶ **Lemma 13.** *Let $n \geq 1$. For all path formulas $\pi_1, \ldots, \pi_n$ and all state formulas φ in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$, the $\mathrm{FO}[\Gamma, \leq]$ formula*

$$\Phi(x_1, \ldots, x_n) = \exists x. \left(\widetilde{\varphi}(x) \wedge \bigwedge_{1 \leq i \leq n} \widetilde{\pi_i}(x_i, x) \right) \qquad (x_i \neq x \text{ for all } i)$$

is equivalent to a positive boolean combination of formulas of the form $\widetilde{\pi}(x_j, x_k)$, with $1 \leq j, k \leq n$ and $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$.

Proof. Let $\psi = \varphi \wedge \bigwedge_{1\leq i\leq n} \langle \pi_i^{-1} \rangle$, and

$$\Psi(x_1,\dots,x_n) = \bigwedge_{1\leq i,j\leq n} (\pi_i \cdot \widetilde{\{\psi\}?} \cdot \pi_j^{-1})(x_i,x_j)\,.$$

Let us show that $\Phi(x_1,\dots,x_n) \equiv \Psi(x_1,\dots,x_n)$. Let $\mathcal{M} = (A, \leq, (\alpha^M)_{\alpha\in\Gamma}, (P^M)_{P\in\mathcal{P}})$, and $\nu : \{x_1,\dots,x_n\} \to A$. For all $1 \leq i \leq n$, let $I_i = [\![\pi_i]\!](\nu(x_i)) \cap [\![\psi]\!]$. Let us show that I_i is an interval of $([\![\psi]\!], \leq)$. First, since π_i is interval-preserving, $[\![\pi_i]\!](\nu(x_i))$ is an interval of $([\![\langle \pi_i^{-1} \rangle]\!], \leq)$. Thus, I_i is an interval of $([\![\langle \pi_i^{-1} \rangle]\!] \cap [\![\psi]\!], \leq)$. But since $[\![\langle \pi_i^{-1} \rangle]\!] \subseteq [\![\psi]\!]$, this is simply $([\![\psi]\!], \leq)$. Besides, it is easy to verify that

$$\mathcal{M}, \nu \models \Phi(x_1,\dots,x_n) \iff \bigcap_{1\leq i\leq n} I_i \neq \emptyset\,.$$

Applying Lemma 12, we obtain

$$\begin{aligned}
\mathcal{M}, \nu \models \Phi(x_1,\dots,x_n) &\iff \text{for all } 1 \leq i,j \leq n, I_i \cap I_j \neq \emptyset \\
&\iff \text{for all } 1 \leq i,j \leq n, (\nu(x_i),\nu(x_j)) \in [\![\pi_i \cdot \{\psi\}? \cdot \pi_j^{-1}]\!] \\
&\iff \mathcal{M}, \nu \models \Psi(x_1,\dots,x_n)\,.
\end{aligned}$$

◀

Translation from $\mathsf{FO}[\Gamma, \leq]$ to $\mathsf{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. We are now ready to give the proof of Theorem 7.

Proof of Theorem 7. We assume that Φ is in prenex normal form, and prove the result by induction. The translation of atomic formulas $x \leq y$ or $\alpha(x,y)$ is straightforward; moreover, $P(x) \equiv \widetilde{\{P\}?}(x,x)$, and $(x = y) \equiv \widetilde{\{true\}?}(x,y)$. Using Lemma 11 to eliminate negations, we obtain the result for all quantifier-free formulas.

The case $\Phi = \forall x.\Psi \equiv \neg\exists x.\neg\Psi$ reduces to the case of existential quantification, applying again Lemma 11 to eliminate negations.

We are left with the case $\Phi = \exists x.\Psi$. If x is not free in Ψ, then $\Phi \equiv \Psi$ (since Ψ has at least one free variable) and we are done by induction. Otherwise, assume that $\mathsf{Free}(\Psi) = \{x_1,\dots,x_n\}$ with $n > 1$ and $x = x_n$. By induction, Ψ is equivalent to a positive boolean combination of formulas of the form $\widetilde{\pi}(x_i,x_j)$ with $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. We replace $\widetilde{\pi}(x_i,x_j)$ with $\widetilde{\pi^{-1}}(x_j,x_i)$ whenever $j < i$, and bring the resulting formula into disjunctive normal form. Each conjunct is then of the form $\Upsilon = \Upsilon_1 \wedge \Upsilon_2 \wedge \Upsilon_3$, where Υ_1 uses only variables from $\{x_1,\dots,x_{n-1}\}$, $\Upsilon_2 = \bigwedge_i \widetilde{\pi}_i(y_i,x)$ with $y_i = x_j$ for some $1 \leq j < n$, and $\Upsilon_3 = \bigwedge_j \widetilde{\pi}_j(x,x)$. Note that $\Upsilon_3 \equiv \widetilde{\varphi}(x)$, where $\varphi = \bigwedge_j \mathsf{loop}(\pi_j)$. Then $\exists x.\Psi$ is equivalent to a finite disjunction of formulas

$$\exists x.\Upsilon \;\equiv\; \Upsilon_1 \wedge \exists x.\,(\Upsilon_2 \wedge \widetilde{\varphi}(x))$$

with Υ_1 and Υ_2 as above. If Υ_2 is empty, then we replace $\exists x.\widetilde{\varphi}(x)$ with the formula

$$(\leq \cdot \{\varphi\}? \cdot \geq)(x_1,x_1) \vee (\geq \cdot \{\varphi\}? \cdot \leq)(x_1,x_1)\,.$$

Otherwise, we apply Lemma 13 to $\exists x.\,(\Upsilon_2 \wedge \widetilde{\varphi}(x))$. In all cases, we obtain an equivalent formula which is a positive boolean combination of formulas $\widetilde{\pi}(x_i,x_j)$ with $1 \leq i,j < n$ and $\pi \in \mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. ◀

▶ Remark 14. Without the assumption that all atomic binary relations are interval-preserving, $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ is still equivalent to $\mathrm{FO}^3[\Gamma, \leq]$. Indeed, in the proof of Theorem 7, the assumption that all atomic binary relations are interval-preserving is only used in Lemmas 11 and 13. But if Φ uses only three variables x, y and z, this assumption is not needed in the proof of Lemma 13. Indeed, we then have $\Phi(y,z) \equiv (\pi \cdot \widetilde{\{\varphi\}?} \cdot \pi'^{-1})(y,z)$, where π is the intersection of all π_i such that $x_i = y$, and π' is the intersection of all π_i such that $x_i = z$. Moreover, Lemma 11 is no longer needed if we translate an $\mathrm{FO}^3[\Gamma, \leq]$ formula into a positive boolean combination of $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ formulas, since $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ allows to take the complement of a path formula. Note that the equivalence with $\mathrm{FO}^3[\Gamma, \leq]$ is already proven in [28] (for the calculus of relations).

5 Conclusion

We proved that every $\mathrm{FO}[\Gamma, \leq]$ formula over linear orders with interval-preserving binary relations can be translated into an equivalent positive boolean combination of path formulas in $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq, \mathsf{loop}, \mathsf{c1}, \mathsf{c2}, \mathsf{c3}, \mathsf{c4}]$. In particular, any $\mathrm{FO}[\Gamma, \leq]$ formula is equivalent to a boolean combination of formulas in $\mathrm{FO}^3[\Gamma, \leq]$, which shows that $\mathrm{FO}[\Gamma, \leq]$ has the three-variable property. This generalizes several known results.

It would be interesting to see if the equivalence between $\mathrm{FO}[\Gamma, \leq]$ and $\mathrm{PDL}_{\mathsf{sf}}[\Gamma, \leq]$ can be used as an intermediate step to prove that a temporal logic is expressively complete. It is not the case in general, since [13] provides an example of a class of structures which fits our assumptions but does not admit any expressively complete temporal logic. However, the equivalence could still be useful in more restricted settings.

A Linear Upper Bound on the Weisfeiler-Leman Dimension of Graphs of Bounded Genus

Abstract

The Weisfeiler-Leman (WL) dimension of a graph is a measure for the inherent descriptive complexity of the graph. While originally derived from a combinatorial graph isomorphism test called the Weisfeiler-Leman algorithm, the WL dimension can also be characterised in terms of the number of variables that is required to describe the graph up to isomorphism in first-order logic with counting quantifiers.

It is known that the WL dimension is upper-bounded for all graphs that exclude some fixed graph as a minor [17]. However, the bounds that can be derived from this general result are astronomic. Only recently, it was proved that the WL dimension of planar graphs is at most 3 [26].

In this paper, we prove that the WL dimension of graphs embeddable in a surface of Euler genus g is at most $4g + 3$. For the WL dimension of graphs embeddable in an orientable surface of Euler genus g, our approach yields an upper bound of $2g + 3$.

1 Introduction

The Weisfeiler-Leman (WL) algorithm is a simple combinatorial graph isomorphism test. The 1-dimensional version of the algorithm, also known as colour refinement and naive vertex classification, is known since at least the mid 1960s, and it is used as a subroutine in almost all practical graph isomorphism tools (see, for instance, [9, 25, 34, 35]), but also in machine learning (see, for instance, [1, 22, 29, 37, 40]). The 2-dimensional version can be traced back to an article by Weisfeiler and Leman that appeared 50 years ago [41]. It is closely related to the algebraic theory of coherent configurations. The generalisation to higher dimensions is due to Babai (see [6, 8]), and again it plays an important role as a subroutine in graph isomorphism algorithms, albeit more on the theoretical side. Notably, Babai uses the $(\log n)$-dimensional version in his quasipolynomial isomorphism test [6].

The connection between the WL algorithm and logic was made by Immerman and Lander [24] and Cai, Fürer, and Immerman [8]. They showed that two graphs are distinguished by the k-dimensional WL algorithm if and only if they can be distinguished in the logic C^{k+1}, the $(k + 1)$-variable fragment of first-order logic using counting quantifiers of the form $\exists^{\geq m} x$. The connection between the WL algorithm and logical definability is at the core of some of the most interesting developments in descriptive complexity theory (see, for

example, [17, 23, 39]). Only recently, it has been noted that the WL algorithm (and thus the finite-variable counting logic) has further surprising characterisations. In a breakthrough paper, Atserias and Maneva [4] showed that the dimension k of the WL algorithm required to distinguish two graphs corresponds to the level of the Sherali-Adams relaxation of the natural integer linear program for graph isomorphism testing (also see [21, 33]). This spawned a lot of work relating the WL algorithm to semidefinite programming [5, 38] and algebraic (Gröbner basis) approaches [7, 13] to graph isomorphism testing. These results can also be phrased in terms of propositional proof complexity. The latest facet of the theory is a characterisation in terms of homomorphism counts of graphs of tree width k [10]. Various aspects of the WL algorithm and its relation to logic have been studied in detail in recent years (see, for instance, [2, 3, 12, 27, 28, 31]).

Cai, Fürer, and Immerman [8] proved that for every k there are non-isomorphic (3-regular) graphs G_k, H_k of size $O(k)$ that are not distinguished by the k-dimensional WL algorithm. Thus, as an isomorphism test, the k-dimensional WL algorithm is incomplete. But, in view of the wide variety of seemingly unrelated combinatorial, logical, and algebraic characterisations of the algorithm, *we are convinced that the structural information the algorithm does detect is of fundamental importance.* The basic parameter of the algorithm is the dimension, corresponding to the number of variables in logical and the degree of polynomials in algebraic characterisations. It yields a structural invariant called the *WL dimension* of a graph G [17], defined to be the least k such that the k-dimensional WL algorithm distinguishes G from every graph H not isomorphic to G (we say that k-WL *identifies* G), or equivalently, the least k such that G can be characterised up to isomorphism (or *identified*) in the logic C^{k+1}. It is also convenient to define the *WL dimension* of a class $\mathcal{C}$ of graphs to be the maximum of the WL dimensions of all graphs in $\mathcal{C}$ if this maximum exists, and ∞ otherwise. We see the WL dimension as a measure for the inherent combinatorial or descriptive complexity of a graph or a class of graphs. We are mostly interested in the relation between the WL dimension and other graph invariants.

Work in descriptive complexity shows that the WL dimension is bounded for many natural graph classes, among them trees [24], graphs of bounded tree width [19], planar graphs [14], graphs of bounded genus [15, 16], all graph classes that exclude some fixed graph as a minor [17], interval graphs [30, 32], and graphs of bounded rank width [20]. However, most of these results do not give explicit bounds on the WL dimension, and the bounds that can be derived from the proofs are usually bad. Only recently, the second author of this paper, jointly with Ponomarenko and Schweitzer, established an almost tight bound for planar graphs [26]: the WL dimension of planar graphs is at most 3, and there are planar graphs of WL dimension 2.

In this paper, we establish bounds for graphs that can be embedded into an arbitrary surface, for example, a torus or a projective plane. By the classification theorem for surfaces (see [36, Theorem 3.1.3]), up to homeomorphism (that is, topological equivalence), all surfaces fall into only two countably infinite families, the family $(\boldsymbol{S}_k)_{k\geq 0}$ of orientable surfaces and the family $(\boldsymbol{N}_\ell)_{\ell\geq 1}$ of non-orientable surfaces. For example, the sphere $\boldsymbol{S}_0$, the torus $\boldsymbol{S}_1$, and the double torus $\boldsymbol{S}_2$ are the first three orientable surfaces, and the projective plane $\boldsymbol{N}_1$ and the Klein bottle $\boldsymbol{N}_2$ are the first two non-orientable surfaces. The *Euler genus* $\mathrm{eg}(\boldsymbol{S})$ of a surface $\boldsymbol{S}$ is $2k$ if $\boldsymbol{S}$ is homeomorphic to the orientable surface $\boldsymbol{S}_k$, and ℓ if $\boldsymbol{S}$ is homeomorphic to the non-orientable surface $\boldsymbol{N}_\ell$. We define the *Euler genus* of a graph G to be the least g such that G is embeddable (that is, can be drawn without edge crossings) in a surface of Euler genus g. Ssee Figure 1 for an example.

▶ **Theorem 1.** *The WL dimension of the class of graphs of Euler genus g is at most $4g + 3$.*

For graphs embeddable in orientable surfaces, we can improve the bound further.

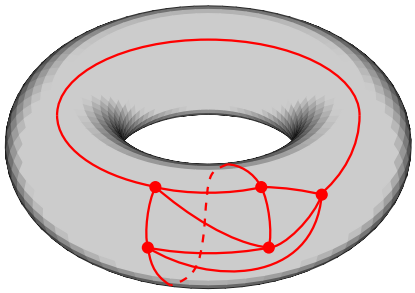

Figure 1 Embedding of K_5 into the torus.

▶ **Corollary 2.** *The WL dimension of the class of graphs embeddable in an orientable surface of Euler genus g is at most $2g + 3$.*

As mentioned above, it was first proved in [15] that the WL dimension of graphs of bounded genus is bounded. A more detailed proof of the same result can be found in the journal paper [16]. The proof of [16] only yields an asymptotically quadratic bound (in terms of the genus) on the dimension, but neither of the two papers gives an explicit bound. It seems that the proof of [15] gives a linear bound, albeit with a large constant factor of at least 80 (not all details are worked out there, so it is difficult to determine the exact bound). The proof in both of these papers is based on the fact that sufficiently large graphs of minimum degree at least 3, embedded in a surface, will have a facial cycle of length at most 6. The proof we give here is completely different. It is based on the straightforward idea of removing a non-contractible cycle to reduce the Euler genus and then using induction. The problem with this idea is that we cannot define non-contractible cycles, but rather only families of such cycles that may intersect in complicated patterns. Understanding these families leads to significant technical complications, but in the end enables us to obtain a much better bound than the simpler proofs of [15, 16]. Our proof is based on a simplified version of a construction from [17, Chapter 15], applied there to graphs "almost embeddable" in a surface.

Outline of the Paper

In Section 2, we present the conventions as well as some topological notions and facts that we use throughout the paper. In Section 3, we introduce the WL dimension and relate it to logic. In Section 4, we present the graph-theoretic machinery that we need in the proof of our main theorem. The proof is outlined in Section 5. The detailed proof is long and complicated and can be found in [18], which also contains further material with respect to all other sections.

2 Preliminaries

2.1 Graphs

We use a standard graph terminology and notation. The only slightly unusual object is our version of coloured graphs. In an *arc-coloured* graph, we colour both vertices and orientations of edges. Formally, an arc-coloured graph is a graph G together with a function $\chi\colon \{(u,u) \mid u \in V(G)\} \cup \{(u,v) \mid \{u,v\} \in E(G)\} \to \mathcal{C}$, where $\mathcal{C}$ is some set of colours. We interpret $\chi(u,u)$ as the colour of the vertex u. Whenever we refer to coloured graphs in this paper, we mean arc-coloured graphs.

2.2 Topology

We have already discussed surfaces and their Euler genus in the introduction. In our presentation and notation, we follow [17, Chapter 9]. As an important notational convention, we always use bold face letters to denote topological spaces. Many more details on surface topology can be found in [17, 36], and in [11, Appendix B].

For a topological space $\boldsymbol{X}$ and a subset $\boldsymbol{Y} \subseteq \boldsymbol{X}$, we define the *boundary* of $\boldsymbol{Y}$ in $\boldsymbol{X}$ to be the set $\boldsymbol{bd_X(Y)}$ of all points $x \in \boldsymbol{X}$ such that every neighbourhood of x has a nonempty intersection with both $\boldsymbol{Y}$ and $\boldsymbol{X} \setminus \boldsymbol{Y}$. We omit the subscript $\boldsymbol{X}$ if the space, usually a surface, is clear from the context.

A *closed disk* is a homeomorphic image of $\{x \in \mathbb{R}^2 \mid \|x\| \leq 1\}$ equipped with the usual topology, and an *open disk* is a subspace of $\mathbb{R}^2$ homeomorphic to $\mathbb{R}^2$ (viewed as a topological space). Let $\boldsymbol{g}$ be a simple closed curve in a surface $\boldsymbol{S}$. Then $\boldsymbol{g}$ is *contractible* if it is the boundary of a closed disk in $\boldsymbol{S}$, otherwise g is *non-contractible*. If $\boldsymbol{g}$ is non-contractible, we can obtain one or two surfaces of strictly smaller Euler genus by the following construction: we cut the surface along $\boldsymbol{g}$; what remains is a surface with one or two holes in it. Then we glue a disk onto each hole and obtain one or two simpler surfaces.

It will be important for us to distinguish between graphs in their standard combinatorial form – we refer to them as *abstract graphs* – and *embedded graphs*. The vertices of a graph *embedded* in a surface $\boldsymbol{S}$ are points in $\boldsymbol{S}$, and the edges are simple curves connecting the vertices in such a way that they do not cross. If G is a graph embedded in $\boldsymbol{S}$, we denote by $\boldsymbol{G}$ the subset of $\boldsymbol{S}$ consisting of all points that are either vertices of G or contained in an edge of G. The *faces* of G are the arcwise connected components of $\boldsymbol{S} \setminus \boldsymbol{G}$.

We say that an abstract graph G is *embeddable* into a surface $\boldsymbol{S}$ if it is isomorphic to (the underlying graph of) a graph embedded in $\boldsymbol{S}$. The *Euler genus* $\mathrm{eg}(G)$ of a graph G is the smallest g such that G is embeddable into a surface of Euler genus g. The graphs of Euler genus 0 are precisely the *planar graphs*, because a graph is embeddable into the 2-sphere $\boldsymbol{S}_0$ if and only if it is embeddable into the plane $\boldsymbol{R}^2$. The class of all graphs of Euler genus at most g is denoted by $\mathcal{E}_g$.

A graph G is *polyhedrally embedded* in a surface $\boldsymbol{S}$ if G is embedded in $\boldsymbol{S}$, 3-connected, and every non-contractible simple closed curve $\boldsymbol{g} \subseteq \boldsymbol{S}$ intersects $\boldsymbol{G}$ in at least three points. Just like 3-connected graphs embedded in a plane, polyhedrally embedded graphs have many nice properties that we will exploit here.

2.3 Logic

C is the extension of first-order logic FO by *counting quantifiers* $\exists^{\geq m} x$ with the obvious meaning. C is only a syntactical extension of FO, because $\exists^{\geq m} x \varphi(x)$ is equivalent to $\exists x_1 \ldots \exists x_m \Big(\bigwedge_{i \neq j} x_i \neq x_j \wedge \bigwedge_i \varphi(x_i) \Big)$. However, we are mainly interested in the fragments C^k of C consisting of all formulae with at most k variables. If $m > k$, then $\exists^{\geq m} x$ cannot be expressed in the k-variable fragment of FO, this is why we add the counting quantifiers. The logics C^k have played an important role in finite-model theory since the 1980s.

We often write $\varphi(x_1, \ldots, x_\ell)$ to indicate that the free variables of φ are among $x_1, \ldots, x_\ell$. (Not all of these variables are required to appear in φ.) Then for a graph G and vertices $u_1, \ldots, u_\ell \in V(G)$, we write $G \models \varphi(u_1, \ldots, u_\ell)$ to denote that G satisfies φ if for all i the variable x_i is interpreted by u_i. Moreover, we write $\varphi[G, u_1, \ldots, u_i, x_{i+1}, \ldots, x_\ell]$ to denote the set of all $(\ell - i)$-tuples $(u_{i+1}, \ldots, u_\ell)$ such that $G \models \varphi(u_1, \ldots, u_\ell)$.

The *width* of a formula $\varphi \in \mathsf{C}$ is the maximum number of free variables of a subformula of φ. Clearly, every formula in C^k has width at most k. An important observation that we often use is that every C-formula of width at most k is equivalent to a C^k-formula. We denote the set of all C-formulae of width at most k by $\mathsf{C}^k_{\mathsf{w}}$.

3 The WL Dimension

We start by reviewing the *k-dimensional WL algorithm* (for short: *k-WL*) for $k \geq 1$.

The *atomic type* $\mathrm{atp}(G, \bar{u})$ of a k-tuple $\bar{u} = (u_1, \dots, u_k)$ of vertices of a (possibly coloured) graph G is the set of all atomic formulae satisfied by these vertices. The exact encoding is not important for us, the relevant property is that tuples $\bar{u} = (u_1, \dots, u_k)$ and $\bar{v} = (v_1, \dots, v_k)$ of vertices of graphs G and H, respectively, have the same atomic type if and only if the mapping $u_i \mapsto v_i$ is an isomorphism from the induced subgraph $G[\{u_1, \dots, u_k\}]$ to the induced subgraph $H[\{v_1, \dots, v_k\}]$.

Now k-WL is the algorithm that, given a graph G, computes the following sequence of "colourings" C^k_i of $\big(V(G)\big)^k$ for $i \geq 0$ until it returns $C^k_\infty = C^k_i$ for the smallest i such that for all $\bar{u}, \bar{v}$ it holds that $C^k_i(\bar{u}) = C^k_i(\bar{v}) \iff C^k_{i+1}(\bar{u}) = C^k_{i+1}(\bar{v})$. The initial colouring C^k_0 assigns to each tuple its atomic type: $C^k_0(\bar{u}) \coloneqq \mathrm{atp}(G, \bar{u})$. In the $(i+1)$-st *refinement round*, the colouring C^k_{i+1} is defined by $C^k_{i+1}(\bar{u}) \coloneqq \big(C^k_i(\bar{u}), M_i(\bar{u})\big)$, where, for $\bar{u} = (u_1, \dots, u_k)$, $M_i(\bar{u})$ is the multiset

$$\Big\{\!\!\Big\{ \Big(\mathrm{atp}\big(G, (u_1, \dots, u_k, v)\big), C^k_i(u_1, \dots, u_{k-1}, v), \\ C^k_i(u_1, \dots, u_{k-2}, v, u_k), \dots, C^k_i(v, u_2, \dots, u_k)\Big) \;\Big|\; v \in V \Big\}\!\!\Big\}$$

We say that k-WL *distinguishes* two graphs G and H if there is some colour c in the range of C^k_∞ such that the number of tuples $\bar{u} \in \big(V(G)\big)^k$ with $C^k_\infty(\bar{u}) = c$ is different from the number of tuples $\bar{v} \in \big(V(H)\big)^k$ with $C^k_\infty(\bar{v}) = c$. We say that k-WL *identifies* G if it distinguishes G from all graphs H not isomorphic to G. The *WL dimension* of G is the smallest k such that k-WL identifies G.

In this paper, we reason about the WL dimension in terms of logic, using the following theorem.

▶ **Theorem 3** ([8, 24]). *Let $k \geq 1$. Let G and H be graphs, possibly coloured, and $\bar{u} = (u_1, \dots, u_k) \in \big(V(G)\big)^k$ and $\bar{v} = (v_1, \dots, v_k) \in \big(V(H)\big)^k$. Then the following are equivalent:*

1. $C^k_\infty(\bar{u}) = C^k_\infty(\bar{v})$;
2. $G \models \varphi(u_1, \dots, u_k) \iff H \models \varphi(v_1, \dots, v_k)$ *for all C^{k+1}-formulae $\varphi(x_1, \dots, x_k)$.*

We say that a graph G is *identified* by the logic C^k if there is a sentence $\mathsf{iso}_G \in \mathsf{C}^k$ such that for all graphs H we have $H \models \mathsf{iso}_G$ if and only if H is isomorphic to G.

▶ **Corollary 4.** *A graph has WL dimension k if and only if it is identified by C^{k+1}.*

The WL dimension of the class of planar graphs is at most 3 [26]. Using the previous corollary, we can re-phrase this as follows.

▶ **Theorem 5** ([26]). *For every planar graph G there is a C^4-sentence iso_G that identifies G.*

4 Shortest Path Systems, Patches and Necklaces

Here we introduce the graph-theoretic machinery necessary to prove our main theorem. Essentially, the definitions and results of this section are from [17, Chapter 15]. In fact, things are simpler here because [17, Chapter 15] deals with graphs *almost* embedded in a surface, whereas we only need to consider embedded graphs. Sometimes, we need to change the definitions in order to improve the resulting bounds on the WL dimension later. Notably, our *necklaces* play the role of the *belts* in [17], but the definition is slightly different. This also requires an adaptation of the proof that reducing necklaces exist.

▶ **Definition 6.** *Let G be a graph and $u, u' \in V(G)$. A* shortest path system (sps) from u to u' *is a family $\mathcal{Q}$ of shortest paths in G from u to u' such that every shortest path from u to u' in the subgraph $\bigcup_{Q\in\mathcal{Q}} Q$ is contained in $\mathcal{Q}$.*

We let $V(\mathcal{Q}) \coloneqq \bigcup_{Q\in\mathcal{Q}} V(Q)$ and $E(\mathcal{Q}) \coloneqq \bigcup_{Q\in\mathcal{Q}} E(Q)$ and $G(\mathcal{Q}) \coloneqq \big(V(\mathcal{Q}), E(\mathcal{Q})\big) = \bigcup_{Q\in\mathcal{Q}} Q$. We call $\mathcal{Q}$ trivial *if $|V(\mathcal{Q})| \leq 2$, that is, if $G(\mathcal{Q})$ consists of a single vertex or a single edge.*

The height $\mathrm{ht}^{\mathcal{Q}}(v)$ *of $v \in V(\mathcal{Q})$ is the distance from u to v. The vertices in $\bigcap_{Q\in\mathcal{Q}} V(Q)$ are the* articulation vertices *of $\mathcal{Q}$. An articulation vertex v is* proper *if $v \neq u$ and $v \neq u'$. We denote the set of all articulation vertices of $\mathcal{Q}$ by* $\mathrm{art}(\mathcal{Q})$.

For all $u, u' \in V(G)$ such that there is a path from u to u' in G, the canonical sps from u to u' in G *is the set $\mathcal{Q}^G(u, u')$ of all shortest paths from u to u' in G.*

While shortest paths systems are defined with respect to abstract graphs, the following notions are defined with respect to embedded graphs. For the rest of the section, we make the following assumption.

▶ **Assumption 7.** *G is a graph polyhedrally embedded in a surface $\boldsymbol{S}$ of Euler genus $g \geq 1$.*

▶ **Definition 8.** *A* patch *in G is an sps $\mathcal{Q}$ in G such that:*

(i) *$\mathcal{Q}$ has no proper articulation vertices.*

(ii) *There is a closed disk $\boldsymbol{D} \subseteq \boldsymbol{S}$ such that $\boldsymbol{G(\mathcal{Q})} \subseteq \boldsymbol{D}$.* ⌟

It can be shown that if $\mathcal{Q}$ is a non-trivial patch (i.e., a patch that does not consist of just a single vertex or a single edge), then there is a unique disk $\boldsymbol{D}(\mathcal{Q})$ such that $\boldsymbol{G(\mathcal{Q})} \subseteq \boldsymbol{D}(\mathcal{Q})$ and there is a cycle $C(\mathcal{Q}) \subseteq G(\mathcal{Q})$ such that $\boldsymbol{bd}\big(\boldsymbol{D}(\mathcal{Q})\big) = \boldsymbol{C}(\mathcal{Q})$. Furthermore, there are two paths $Q, Q' \in \mathcal{Q}$ such that $C(\mathcal{Q}) = Q \cup Q'$.

We call a subgraph $H \subseteq G$ *simplifying* if every connected component of $G \setminus H$ is contained in $\mathcal{E}_{g-1}$. Otherwise, H is *non-simplifying*.

▶ **Lemma 9** ([17], Corollary 15.3.5)**.** *For every non-simplifying subgraph $H \subseteq G$, there is exactly one connected component A^* of $G \setminus H$ with $A^* \notin \mathcal{E}_{g-1}$, and all other connected components are planar.*

A patch $\mathcal{Q}$ is *simplifying* if the graph $G(\mathcal{Q})$ is. It turns out that non-simplifying patches form the basic building blocks of our theory. Let $\mathcal{Q}$ be a non-trivial non-simplifying patch. Let A^* be the unique connected component of $G \setminus V(\mathcal{Q})$ that is not planar (the existence and uniqueness of A^* follows from Lemma 9). Then we define G/A^* to be the graph obtained from G by contracting the subgraph A^* to a single vertex a^*. By [17, Corollary 15.4.5], G/A^* is a 3-connected planar graph. Figure 2 displays a schematic view of a patch $\mathcal{Q}$ with some attached (planar) connected components as well as the non-planar component A^*, the disk $\boldsymbol{D}(\mathcal{Q})$, and the boundary cycle $\boldsymbol{C}(\mathcal{Q})$.

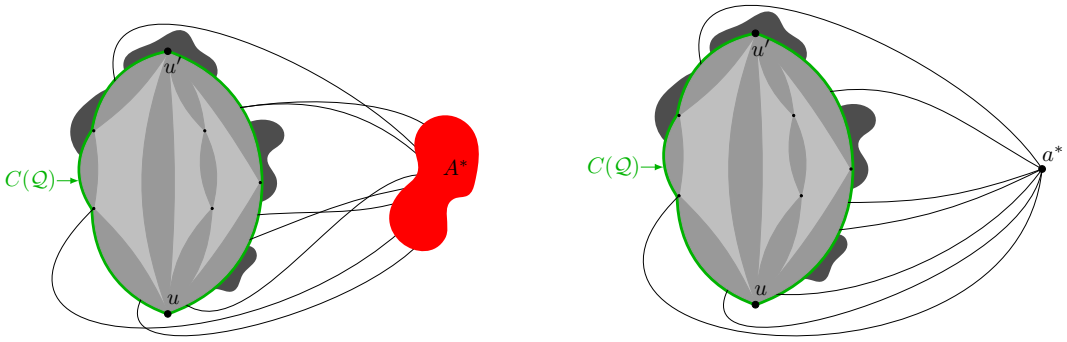

Figure 2 Left: A patch $\mathcal{Q}$ with non-planar component A^* and boundary cycle $C(\mathcal{Q})$. The curve $\boldsymbol{C}(\mathcal{Q})$ is the boundary of the disk $\boldsymbol{D}(\mathcal{Q})$, which consists of the light gray and medium gray areas. Right: the (planar) factor graph G/A^*.

We define the *internal graph* of a non-trivial non-simplifying patch $\mathcal{Q}$ to be the graph $I := I(\mathcal{Q})$ with vertex set $V(I) := V(G) \cap \boldsymbol{D}(\mathcal{Q})$ and edge set $E(I) := \{\boldsymbol{e} \in E(G) \mid \boldsymbol{e} \subseteq \boldsymbol{D}(\mathcal{Q})\}$. Note that $C(\mathcal{Q}) \subseteq I$. The definitions of the graphs $C(\mathcal{Q})$ and $I(\mathcal{Q})$ do not only depend on the abstract graph G and the sps $\mathcal{Q}$, but on the embedding of G in $\boldsymbol{S}$. However, it can be proved that actually the graphs are invariant under embeddings.

▶ **Lemma 10** ([17]). *Let $\mathcal{Q}$ be a non-trivial non-simplifying patch in G. Let G' be a graph embedded in a surface $\boldsymbol{S}'$ of Euler genus g such that G and G' are isomorphic (as abstract graphs), and let f be an isomorphism from G to G'. Then $\mathcal{Q}' := f(\mathcal{Q})$ is a non-simplifying patch in G', and it holds that $f\big(C(\mathcal{Q})\big) = C(\mathcal{Q}')$ and $f\big(I(\mathcal{Q})\big) = I(\mathcal{Q}')$.*

This follows from [17, Lemma 15.4.10]. Intuitively, the reason why this holds is that the 3-connected planar graph G/A^* has a "unique" embedding.

▶ **Corollary 11.** *Let $u, u' \in V(G)$ and $\mathcal{Q} := \mathcal{Q}^G(u, u')$ such that $\mathcal{Q}$ is a non-trivial non-simplifying patch. Let f be an automorphism of G such that $f(u) = u$ and $f(u') = u'$. Then $f\big(C(\mathcal{Q})\big) = C(\mathcal{Q})$ and $f\big(I(\mathcal{Q})\big) = I(\mathcal{Q})$.*

We remark that the analogue of Corollary 11 for simplifying patches does not hold (see [18, Figure 4]). The analysis of simplifying patches is much more involved, and we defer the reader to [18].

The final objects we define in this section are *necklaces*.

▶ **Definition 12.** *A* necklace *in G is a tuple $\mathcal{B} := (u^0, \mathcal{Q}^0, u^1, \mathcal{Q}^1, u^2, \mathcal{Q}^2)$, where $u^0, u^1, u^2 \in V(G)$ and $\mathcal{Q}^i = \mathcal{Q}^G(u^i, u^{i+1})$ (indices taken modulo 3) is the canonical sps from u^i to u^{i+1}, such that the following conditions are satisfied for every $i \in \{0, 1, 2\}$:*

- *u^0, u^1, u^2 are pairwise distinct.*
- *$V(\mathcal{Q}^i) \cap V(\mathcal{Q}^{i+1}) = \{u^{i+1}\}$ (indices modulo 3).*
- *There is a disk $\boldsymbol{D}^i \subseteq \boldsymbol{S}$ such that $\boldsymbol{G(\mathcal{Q}^i)} \subseteq \boldsymbol{D}^i$.* ⌟

For a necklace $\mathcal{B} := (u^0, \mathcal{Q}^0, u^1, \mathcal{Q}^1, u^2, \mathcal{Q}^2)$ we write $V(\mathcal{B})$ for the set $\bigcup_{i=0}^{2} \bigcup_{Q \in \mathcal{Q}^i} V(Q)$ and $E(\mathcal{B})$ for $\bigcup_{i=0}^{2} \bigcup_{Q \in \mathcal{Q}^i} E(Q)$, and we let $G(\mathcal{B}) := \big(V(\mathcal{B}), E(\mathcal{B})\big)$. Moreover, we define the set of *articulation vertices* of $\mathcal{B}$ to be $\mathrm{art}(\mathcal{B}) := \bigcup_{i=0}^{2} \mathrm{art}(\mathcal{Q}^i)$.

▶ **Definition 13.** *A necklace $\mathcal{B} := (u^0, \mathcal{Q}^1, u^1, \mathcal{Q}^2, u^2, \mathcal{Q}^3)$ is* reducing *if there are paths $Q^i \in \mathcal{Q}^i$ such that $B := Q^1 \cup Q^2 \cup Q^3$ is a non-contractible cycle.* ⌟

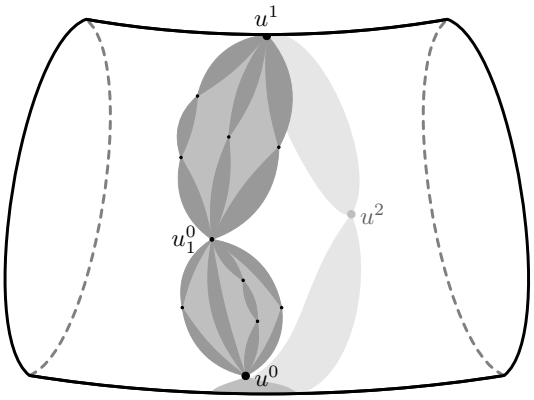

Figure 3 A necklace on a torus section.

We can think of a reducing necklace as a necklace around a handle of our surface (or a crosscap of the surface in the non-orientable case). The beads of the necklace are the disks of the patches that form the necklace. Figure 3 shows a necklace on a torus with articulation vertices u^0, u_1^0, u^1, u^2.

▶ **Lemma 14** (Necklace Lemma)**.** *G has a reducing necklace.*

Essentially, this is [17, Lemma 15.5.8], with the necklaces corresponding to the belts there. But since apart from a renaming, we have also slightly changed the content of the definition of a necklace/belt, the proof needs to be adapted, too. Again, we defer the reader to [18].

5 Upper Bound on the WL Dimension

In this section, we give an outline of the proof of our main theorem (Theorem 1). The full proof can be found in [18].

By the correspondence between k-WL and the logic C^{k+1} stated in Corollary 4, we need to prove that every graph of Euler genus at most g can be identified by a C^{4g+4}-sentence. The proof is by induction on g. The base step $g = 0$ is Theorem 5.

For the inductive step, we make the following assumption.

▶ **Assumption 15.** *$g \geq 1$, and there is a natural number $s \geq 4$ such that every graph in $\mathcal{E}_{g-1}$ can be identified by a C^s-sentence.*

We shall prove that every graph in $\mathcal{E}_g$ can be defined by a C^{s+4}-sentence. Then Theorem 1 follows by induction. After some fairly straightforward reduction steps, which include the reduction to arc-coloured 3-connected graphs from [26], we find that it suffices to prove the following lemma.

▶ **Lemma 16.** *Let G be a coloured graph polyhedrally embedded in a surface $\boldsymbol{S}$ of Euler genus g. Then there is a sentence $\mathsf{iso}_G \in \mathsf{C}^{s+3}$ that identifies G.*

For the rest of the section, we fix a positive integer n. The intended meaning of n is that it is the size of the target graph G. At this point, we have fixed three numerical parameters: the Euler genus g, the number s of variables required to identify graphs of smaller Euler genus, and the order n.

We start the proof by showing that basic objects such as shortest path systems, (pseudo-) patches and (pseudo-)necklaces are definable in the logic C^{s+3}. The following lemma illustrates the type of definability result we can expect, more of the same kind can be found in the full version [18]. Instead of definability in C^k, we actually always study definability in $\mathsf{C}^k_{\mathsf{w}}$ (see Section 2.3) and exploit the fact that every $\mathsf{C}^k_{\mathsf{w}}$-formula is equivalent to a C^k-formula.

▶ **Lemma 17.** *There are formulae* $\mathsf{csps\text{-}vert}(x,x',y) \in \mathsf{C}^3_{\mathsf{w}}$ *and* $\mathsf{csps\text{-}edge}(x,x',y_1,y_2) \in \mathsf{C}^4_{\mathsf{w}}$*, such that for all connected graphs* G *of order* $|G| \leq n$ *and all vertices* $u,u' \in V(G)$*,*

$$\mathsf{csps\text{-}vert}[G,u,u',y] = V\big(\mathcal{Q}^G(u,u')\big),$$
$$\mathsf{csps\text{-}edge}[G,u,u',y_1,y_2] = E\big(\mathcal{Q}^G(u,u')\big).$$

Recall that $\mathcal{Q}^G(u,u')$ is the canonical sps from u to u', that is, the set of all shortest paths from u to u'.

Proof. It is straightforward to define, for every $k \geq 0$, a $\mathsf{C}^3_{\mathsf{w}}$-formula $\mathrm{dist}_{=k}(x,y)$ stating that the distance between the vertices x and y is exactly k. Then we let $\mathsf{csps\text{-}vert}(x,x',y) := \bigvee_{k=0}^{n} \Big(\mathsf{dist}_{=k}(x,x') \wedge \bigvee_{i=0}^{k} \big(\mathsf{dist}_{=i}(x,y) \wedge \mathsf{dist}_{=k-i}(y,x')\big)\Big)$.
The formula $\mathsf{csps\text{-}edge}(x,x',y_1,y_2)$ can be defined similarly. ◀

With a little more effort, we can prove the following lemma.

▶ **Lemma 18.** *Let* $h < g$*. Then there is a formula* $\mathsf{csps\text{-}comp\text{-}genus}_h(x,x',y) \in \mathsf{C}^{s+2}_{\mathsf{w}}$ *such that for all connected graphs* G *of order* $|G| \leq n$ *and all* $u,u',v \in V(G)$ *the following holds. Let* $\mathcal{Q} := \mathcal{Q}^G(u,u')$*, and let* A *be the connected component of* v *in* $G \setminus G(\mathcal{Q})$ *(assuming* $v \notin V(\mathcal{Q})$*). Then*

$$G \models \mathsf{csps\text{-}comp\text{-}genus}_h(u,u',v) \iff v \notin V(\mathcal{Q}) \text{ and } \mathrm{eg}(A) \leq h.$$

Proof. It follows from Assumption 15 that for every $h < g$, there is a sentence genus_h such that for all graphs G of order $|G| \leq n$, it holds that $G \models \mathsf{genus}_h \iff \mathrm{eg}(G) \leq h$. Indeed, we can simply let genus_h be the disjunction of all sentences iso_H identifying the graphs H with $\mathrm{eg}(H) \leq h$ and $|H| \leq n$.

Using careful bookkeeping and some tricks to reduce the number of variables. we can combine genus_h with the formulae defined in Lemma 17 to obtain the desired formula. ◀

▶ **Corollary 19.** *There is a formula* $\mathsf{csps\text{-}simplifying}(x,x') \in \mathsf{C}^{s+2}_{\mathsf{w}}$ *such that for all connected graphs* $G \in \mathcal{E}_g$ *of order* $|G| \leq n$ *and all* $u,u' \in V(G)$*,*

$$G \models \mathsf{csps\text{-}simplifying}(u,u') \iff \mathcal{Q}^G(u,u') \text{ is simplifying.}$$

The formulae we have defined so far make no reference to an embedding of the input graph. However, if we want to talk about patches and necklaces, we need to take the embedding into account. For the rest of the section, we fix a specific embedded graph G.

▶ **Assumption 20.** *G is a coloured graph of order $|G| = n$ that is polyhedrally embedded in a surface $\boldsymbol{S}$ of Euler genus g.*

It is our goal to construct a $\mathsf{C}^{s+3}_{\mathsf{w}}$-sentence that identifies G. The following lemma is a key step towards this goal, and we find it worthwhile to go into some of the details of its proof.

▶ **Lemma 21.** *There are* $\mathsf{C}^7_{\mathsf{w}}$*-formulae* $\mathsf{int\text{-}vert}(x, x', y)$ *and* $\mathsf{int\text{-}edge}(x, x', y_1, y_2)$ *such that for all vertices* $u, u' \in V(G)$ *for which* $\mathcal{Q} \coloneqq \mathcal{Q}^G(u, u')$ *is a non-trivial non-simplifying patch, the following holds:*

$$\mathsf{int\text{-}vert}[G, u, u', y] = V\big(I(\mathcal{Q})\big),$$
$$\mathsf{int\text{-}edge}[G, u, u', y_1, y_2] = E\big(I(\mathcal{Q})\big).$$

Intuitively, the lemma says that even though the logical formulae only have access to the abstract graph and the disk of a patch and the internal graph depend on the embedding, we can still define the internal graph. This is non-trivial and somewhat surprising.

Proof. Let $u, u' \in V(G)$ such that $\mathcal{Q} \coloneqq \mathcal{Q}^G(u, u')$ is a non-trivial non-simplifying patch. Let $\boldsymbol{D} \coloneqq \boldsymbol{D}(\mathcal{Q})$, $C \coloneqq C(\mathcal{Q})$, and $I \coloneqq I(\mathcal{Q})$ (see Section 4).

By Lemma 9, the graph $G \setminus G(\mathcal{Q})$ has a unique non-planar connected component A^*. Since we can detect the planar connected components using the fact that we can identify all planar graphs in C^4, we can also detect A^* as the only non-planar component. This allows us to construct a $\mathsf{C}^7_{\mathsf{w}}$-formula $\mathsf{astar}(x, x', y)$ such that $\mathsf{astar}[G, u, u', y] = V(A^*)$.

Let v_1 be a vertex in $V(\mathcal{Q})$ that is adjacent to A^* and among all such vertices has minimal height in the sps $\mathcal{Q}$, and let h be this height. Since A^* is embedded outside of the disk $\boldsymbol{D}$, the vertex v_1 must be on the boundary cycle C of $\boldsymbol{D}$. There is at most one other vertex of height h on this cycle. Thus, even though v_1 is not unique, there are at most two choices. If there is a second vertex of height h adjacent to A^*, let us call it v_1'. Using the formula $\mathsf{astar}(x, x', y)$ and the fact that vertices of a certain height are definable in $\mathsf{C}^3_{\mathsf{w}}$, we can construct a $\mathsf{C}^7_{\mathsf{w}}$-formula $\varphi_1(x, x', y_1)$ such that v_1 and possibly v_1' are the only vertices in $\varphi_1[G, u, u', y_1]$.

Recall that G/A^* denotes the graph obtained from G by contracting the connected subgraph A^* to a single vertex, which we call a^*, and that the graph G/A^* is a 3-connected planar graph. By Whitney's Theorem, the facial subgraphs (i.e., the subgraphs induced by the boundaries of the faces of an embedding) of a 3-connected plane graph are precisely the chordless non-separating cycles. In particular, they are independent of the embedding. Furthermore, every edge is contained in exactly two of these facial cycles. Let us consider the edge v_1a^* in the graph G/A^*. Let F and F' be the two facial cycles that contain this edge. Both F and F' contain exactly one neighbour of a^* distinct from v_1. Let v_2, v_2' be these neighbours.

By [26, Lemma 22], if we have a 3-connected planar graph H and three vertices w_1, w_2, w_3 on a common facial cycle, then after individualising these three vertices, the 1-dimensional WL algorithm computes a discrete colouring, i.e., a colouring in which every vertex has its own unique colour. By Theorem 3, this implies that for every vertex w of H there is a formula $\psi_{H,w}(z_1, z_2, z_3, y) \in \mathsf{C}^5_{\mathsf{w}}$ such that $\psi_{H,w}[H, w_1, w_2, w_3, y] = \{w\}$. We apply this to the graph G/A^* and the three vertices a^*, v_1, v_2 and obtain, for every vertex $w \in V(G/A^*) = (V(G) \setminus V(A^*)) \cup \{a^*\}$, a formula $\psi_w(z^*, y_1, y_2, y) \in \mathsf{C}^5_{\mathsf{w}}$ such that $\psi_w[G/A^*, a^*, v_1, v_2, y] = \{w\}$. From this formula and the formula $\mathsf{astar}(x, x', y)$ we can construct a $\mathsf{C}^7_{\mathsf{w}}$-formula $\widetilde{\psi}_w(x, x', y_1, y_2, z)$ such that $\widetilde{\psi}_w[G, u, u', v_1, v_2, z] = \{w\}$. (Unfortunately, this construction is quite tedious; details can be found in [18].)

Since $A^* \cap \boldsymbol{D} = \emptyset$, we have $V(I) = V(G) \cap \boldsymbol{D} \subseteq V(G \setminus A^*)$. We let

$$\delta(x, x', y_1, y_2, z) \coloneqq \bigvee_{w \in V(I)} \widetilde{\psi}_w(x, x', y_1, y_2, z).$$

Then $\delta[G, u, u', v_1, v_2, z] = V(I)$. Thus $\delta(x, x', y_1, y_2, z)$ is almost the formula $\mathsf{int\text{-}vert}(x, x', y)$ we want, except that it has two additional parameters v_1, v_2, which we have to get rid of.

We apply [26, Corollary 27], which says that the 3-dimensional WL algorithm *determines orbits* in coloured 3-connected graphs. This means that it distinguishes two vertices if and only if they belong to different orbits of the automorphism group of the given graph. It follows that for every 3-connected planar graph H and for every orbit O of the automorphism group of H, there is a formula $\xi_{H,O}(y_2) \in \mathsf{C}^4_{\mathsf{w}}$ such that $\xi_{H,O}[H, y_2] = O$.

To eliminate the parameter v_2, we apply the corollary to the graph G/A^*, but only after individualising the vertices a^* and v_1. That is, we modify the colouring such that each of the two vertices gets its own colour and is thus fixed by all automorphisms. Let O_2 be the orbit of v_2 in this coloured graph. By the definition of v_2, either $O_2 = \{v_2, v_2'\}$ or $O_2 = \{v_2\}$. Since the graph G/A^* is 3-connected, by eliminating the colour relations for a^* and v_1 at the cost of new free variables z^* and y_1, we obtain a new formula $\psi_2(z^*, y_1, y_2) \in \mathsf{C}^6_{\mathsf{w}}$ such that $\psi_2[G/A^*, a^*, v_1, y_2] = O_2$. We can transform this formula ψ_2 into a $\mathsf{C}^7_{\mathsf{w}}$-formula $\widetilde{\psi}_2(x, x', y_1, y_2)$ such that $\widetilde{\psi}_2[G, u, u', v_1, y_2] = O_2$. We let

$$\delta'(x, x', y_1, z) \coloneqq \exists y_2 \big(\widetilde{\psi}_2(x, x', y_1, y_2) \wedge \delta(x, x', y_1, y_2, z)\big).$$

If $O_2 = \{v_2\}$, then clearly $\delta'[G, u, u', v_1, z] = \delta[G, u, u', v_1, v_2, z] = V(I)$. So suppose that $O_2 = \{v_2, v_2'\}$, and let f be an automorphism of G with $f(u) = u, f(u') = u', f(v_1) = v_1$, and $f(v_2) = v_2'$. By Corollary 11, we have $f\big(V(I)\big) = V(I)$ and thus

$$\begin{aligned}\delta[G, u, u', v_1, v_2', z] &= \delta[f(G), f(u), f(u'), f(v_1), f(v_2), z] \\ &= f\big(\delta[G, u, u', v_1, v_2, z]\big) \\ &= f\big(V(I)\big) = V(I).\end{aligned}$$

It follows that

$$\delta'[G, u, u', v_1, z] = \delta[G, u, u', v_1, v_2, z] \cup \delta[G, u, u', v_1, v_2', z] = V(I).$$

So we have eliminated the parameter v_2. To eliminate v_1, we use a similar argument, which gives us the formula $\mathsf{int\text{-}vert}(x, x', y)$. The formula $\mathsf{int\text{-}edge}(x, x', y_1, y_2)$ can be constructed similarly. ◀

At this point, the proof of Lemma 16 branches into two cases.

Case 1: G does not contain any simplifying patches

By Lemma 14, the graph G contains a reducing necklace. We fix such a necklace $\mathcal{B} = (u^0, \mathcal{Q}^1, u^1, \mathcal{Q}^2, u^2, \mathcal{Q}^3)$. For this, it is sufficient to fix the three vertices u^0, u^1, u^2, because the $\mathcal{Q}^i$ are canonical shortest path systems. We are going to define a subgraph $\mathrm{Cut}(\mathcal{B})$ of G obtained from G by "cutting through the beads". Since the necklace is reducing, the Euler genus of every connected component of $\mathrm{Cut}(\mathcal{B})$ is at most $g - 1$ and we can identify it via a C^s-sentence using Assumption 15. We colour $\mathrm{Cut}(\mathcal{B})$ in such a way that we can reconstruct G and identify it.

Since in this case, there are no simplifying patches, we can define the internal graphs of all patches that form the necklace using Lemma 21. The cut graph $\mathrm{Cut}(\mathcal{B})$ is obtained from G by removing all trivial patches contained in $\mathcal{B}$, all articulation vertices and the internal graphs of all non-trivial patches contained in $\mathcal{B}$. Since the necklace is reducing, there is a non-contractible simple closed curve through the necklace, and we can choose this curve such that it is disjoint from the cut graph. Thus, the cut graph is embeddable in the surface obtained by cutting $\boldsymbol{S}$ along this non-contractible closed curve and therefore has smaller Euler genus.

To prove that G is identified in the logic $\mathsf{C}^{s+3}_{\mathsf{w}}$, we need to show that for every graph $\widehat{G}$ that is not isomorphic to G, there is a $\mathsf{C}^{s+3}_{\mathsf{w}}$-sentence that distinguishes G and $\widehat{G}$. To prove

this, we show that if G and $\widehat{G}$ satisfy the same $\mathsf{C}_{\mathsf{w}}^{s+3}$-sentences, then they are isomorphic. We use the fact that the necklace $\mathcal{B}$ is definable in G by $\mathsf{C}_{\mathsf{w}}^{7}$-formulae using the three parameters u^0, u^1, u^2. The same formulae define some object $\widehat{B}$ in $\widehat{G}$. We call $\widehat{B}$ a "pseudo-necklace". It is not necessarily a necklace, because $\widehat{G}$ is not necessarily an embedded graph and objects like patches and necklaces, which depend on an embedding, do not exist in $\widehat{G}$. Nevertheless, from the pseudo-necklace we can define a pseudo-cut graph $\mathrm{Cut}(\widehat{\mathcal{B}})$. Since $\mathrm{Cut}(\mathcal{B})$ is identified in the logic $\mathsf{C}_{\mathsf{w}}^{s}$, we can show that $\mathrm{Cut}(\mathcal{B})$ and $\mathrm{Cut}(\widehat{\mathcal{B}})$ are isomorphic. Since we can reconstruct G and $\widehat{G}$ from the respective (pseudo-)cut graphs, we conclude that G and $\widehat{G}$ are isomorphic.

Case 2: G contains a simplifying patch

This case sounds simpler than the first one: instead of a complicated necklace, here we only need to remove a simplifying patch from our graph. The remaining pieces have smaller Euler genus and thus can be identified in the logic $\mathsf{C}_{\mathsf{w}}^{s}$. Hence, all we need to do is colour the pieces in such a way that we can reconstruct the original graph. The problem with this line of reasoning is that simplifying patches have a much more complicated structure than non-simplifying patches. For example, we cannot define the interior of a simplifying patch in the same way as we did for non-simplifying patches in Lemma 21 since there is not necessarily a non-planar connected component which marks the "outside region" of the patch. Therefore, the idea of the proof is to remove the canonical sps and some interior parts of the corresponding patch, which are actually interiors of non-simplifying subpatches and thus definable by Lemma 21.

More precisely, we fix two vertices u and u' such that $\mathcal{Q} \coloneqq \mathcal{Q}^G(u, u')$ is a minimal simplifying canonical patch in G, that is, a simplifying canonical patch all of whose proper canonical subpatches are non-simplifying. We extend $\mathcal{Q}$ by the internal graphs of all proper subpatches and obtain a graph J, which is actually embedded in the disk of $\mathcal{Q}$ and therefore planar.

Now we distinguish between two cases. If $J \setminus \{u, u'\}$ is connected, the patch $\mathcal{Q}$ behaves almost like a non-simplifying patch, and we can argue similarly as in Case 1. If $J \setminus \{u, u'\}$ is disconnected, the patch $\mathcal{Q}$ can be split into several so-called *fibres*. The subgraph J contained in the fibres is definable in our logic when we fix one more particular vertex. In fact, the subgraph contained in every single fibre is definable. We exploit this in order to encode in the boundary vertices of the fibres the way in which the remainder of the graph is attached to them, similarly as in Case 1, but due to the possibly complex structure of J a lot more involved.

An improved bound in case the surface is orientable

The combination of Case 1 and Case 2 yields Theorem 1. Exploiting our inductive approach further, we can deduce a better bound in case we know that the given graph is embeddable in an *orientable* surface of Euler genus at most g, as stated in Corollary 2.

Proof of Corollary 2. The Euler genus of an orientable surface is always even. Suppose G is a graph embeddable in an orientable surface of Euler genus g. Since the subgraphs obtained by cutting through the beads are also embeddable in orientable surfaces of smaller Euler genus, their Euler genus is at least 2 smaller than the Euler genus of G. Therefore, proceeding inductively and redefining s to be the number of variables needed for graphs embeddable in orientable surfaces of Euler genus at most $g - 2$, we can improve our bound from Theorem 1 to $2g + 3$. ◀

6 Concluding Remarks

The WL dimension is a measure for the combinatorial and descriptive complexity of a graph. In view of its numerous, seemingly unrelated characterisations in terms of logic, algebra, mathematical programming, and homomorphisms, we can arguably regard the WL dimension as a natural and robust graph invariant.

We have proved an upper bound of $4g + 3$ for the WL dimension of graphs of Euler genus g and showed that if G is known to be embeddable in an orientable surface of Euler genus g, the bound improves to $2g + 3$. The immediate remaining question is how tight our bound is.

We believe that by refining our arguments in some places it might be possible to reduce the bound from Theorem 1 to $3g + 3$ or even $2g + 3$; any further improvement seems to require substantial additional ideas. It is conceivable that the WL dimension of planar graphs is 2. If this is the case, the additive term in our bound would automatically drop to 2.

In terms of lower bounds, using the so-called CFI construction [8], it is easy to prove a linear lower bound of $\epsilon \cdot g$ for the WL dimension of graphs of Euler genus g, albeit with a rather small constant $\epsilon > 0$. To close the gap between upper and lower bound, it may be worthwhile to spend some effort on improving the lower bound.

Beyond graphs of bounded genus, we can try to determine the WL dimension of other graph classes and tie the WL dimension to other graph invariants. A natural target would be the class of all graphs that exclude the complete graph K_ℓ as a minor. We know that the WL dimension of this class is bounded [17]. But even an exponential bound on the WL dimension in terms of ℓ would be major progress.

Abstract

We consider the problem of deciding termination of single-path while loops with integer variables, affine updates, and affine guard conditions. The question is whether such a loop terminates on all integer initial values. This problem is known to be decidable for the subclass of loops whose update matrices are diagonalisable, but the general case has remained open since being conjectured decidable by Tiwari in 2004. In this paper we show decidability of determining termination for arbitrary update matrices, confirming Tiwari's conjecture. For the class of loops considered in this paper, the question of deciding termination on a specific initial value is a longstanding open problem in number theory. The key to our decision procedure is in showing how to circumvent the difficulties inherent in deciding termination on a fixed initial value.

1 Introduction

Termination is a central problem in program verification. In this paper we study termination of *single-path linear loops*, i.e., programs of the form

$$\textit{while } (g_1(\boldsymbol{x}) > 0 \wedge \ldots \wedge g_m(\boldsymbol{x}) > 0) \textit{ do } \boldsymbol{x} := f(\boldsymbol{x})\,,$$

where $g_1, \ldots, g_m : \mathbb{R}^d \to \mathbb{R}$ and $f : \mathbb{R}^d \to \mathbb{R}^d$ are affine maps with integer coefficients. Here the loop body has a single control path that performs a simultaneous affine update of the program variables. Analysis of loops of this form, including acceleration and termination, is an important part of analysing more complex programs (see, e.g., [7, 14, 16]).

For a set $S \subseteq \mathbb{R}^d$, we say that the above loop *terminates on* S if it terminates on all initial vectors $\boldsymbol{x} \in S$. Despite the simplicity of single-path linear loops, the question of deciding termination has proven challenging (and termination already becomes undecidable if the loop

body consists of a nondeterministic choice between two different linear updates). Tiwari [25] showed that termination of single-path linear loops is decidable over $\mathbb{R}^d$. Subsequently, Braverman [9], using a more refined analysis of the loop components, showed that termination is decidable over $\mathbb{Q}^d$ and noted that termination on $\mathbb{Z}^d$ can be reduced to termination on $\mathbb{Q}^d$ in the homogeneous case, i.e., when the update map f and guards $g_1, \ldots, g_m$ are linear. More recently, Ouaknine, Sousa-Pinto, and Worrell [18] have proven that termination over $\mathbb{Z}^d$ is decidable in the non-homogeneous case under the assumption that the update function f has the form $f(\boldsymbol{x}) = A\boldsymbol{x} + \boldsymbol{a}$ for A a diagonalisable integer matrix. Decidability of termination for non-homogeneous linear loops over $\mathbb{Z}^d$ was conjectured by Tiwari [25, Conjecture 1], but has remained open until now.

In this paper we give a procedure for deciding termination of the general class of single-path linear loops over the integers, i.e., we generalise the result of [18] by lifting the assumption of diagonalisability. Note that for this class of programs, the question of termination on a *given initial value* in $\mathbb{Z}^d$ (as opposed to termination over all of $\mathbb{Z}^d$) is equivalent to the *Positivity Problem* for linear recurrence sequences, i.e., the problem of whether all terms in a given integer linear recurrence sequence are positive. Decidability of the Positivity Problem is a longstanding open problem (going back at least as far as the 1970s [22, 24]), and results in [19] suggest that a solution to the problem will require significant breakthroughs in number theory. However, in considering termination over $\mathbb{Z}^d$ one can benefit from the freedom to choose the initial values of the loop variables. In the present paper we exploit this freedom in order to circumvent the need to solve "hard instances" of the Positivity Problem when deciding termination of linear loops. In particular, we avoid the use of sophisticated Diophantine-approximation techniques, such as the S-units theorem, that were employed in [19]. By eschewing such tools we lose all hope of obtaining an effective characterisation of the set of non-terminating points, as was done in the diagonalisable case in [19], but our methods nevertheless manage to solve the decision problem in the general case.

Among the tools we use are a circle of closely related results in the geometry of numbers, including Khinchine's flatness theorem, Kronecker's theorem on simultaneous Diophantine approximation, and the result of Khachiyan and Porkolab that it is decidable whether a convex semi-algebraic set contains an integer point. In tandem with these, from algebraic number theory, we use a result of Masser that allows to compute all algebraic relations among the eigenvalues of the update matrix of a given loop. Using this last result, we define a semi-algebraic subset of "non-termination candidates" such that the loop is non-terminating if and only if this set contains an integer point.

In this paper we focus on the foundational problem of providing complete methods to solve termination. Much effort has been devoted to scalable and pragmatic methods to prove termination for classes of programs that subsume linear loops. In particular, techniques to prove termination via synthesis of linear ranking functions [4, 5, 8, 10, 11, 20, 21] and their extension, multiphase linear ranking functions [6, 3], have been developed. Many of these techniques have been implemented in software verification tools, such as Microsoft's Terminator [12]. Although these methods are capable of handling non-deterministic linear loops, they can only guarantee termination whenever ranking functions of a certain form exist.

2 Background

2.1 Convexity

The *affine hull* of $S \subseteq \mathbb{R}^d$ is the smallest affine set that contains S, where an affine set is the translation of a vector subspace of $\mathbb{R}^d$. The affine hull of S can be characterised as follows:

$$\mathrm{aff}(S) := \left\{ \sum_{i=1}^{k} \alpha_i \boldsymbol{x}_i \mid k > 0, \boldsymbol{x}_i \in S, \alpha_i \in \mathbb{R}, \sum_{i=1}^{k} \alpha_i = 1 \right\}.$$

The *convex hull* of $S \subseteq \mathbb{R}^d$ is the smallest convex set that contains S. The convex hull of S can be characterised as follows:

$$\mathrm{conv}(S) := \left\{ \sum_{i=1}^{k} \alpha_i \boldsymbol{x}_i \mid k > 0, \boldsymbol{x}_i \in S, \alpha_i \in \mathbb{R}_{\geq 0}, \sum_{i=1}^{k} \alpha_i = 1 \right\}.$$

Clearly $\mathrm{conv}(S) \subseteq \mathrm{aff}(S)$. The *relative interior* of a convex set $S \subseteq \mathbb{R}^d$ is its interior with respect to the restriction of the Euclidean topology to $\mathrm{aff}(S)$. We have the following easy proposition, characterising the relative interior.

▶ **Proposition 1.** *Let $S = \{\boldsymbol{a}_1, \ldots, \boldsymbol{a}_n\} \subseteq \mathbb{R}^d$. If $\boldsymbol{u}$ lies in the relative interior of $\mathrm{conv}(S)$ then there exist $\alpha_1, \ldots, \alpha_n > 0$ such that $u = \sum_{i=1}^{n} \alpha_i \boldsymbol{a}_i$ and $\sum_{i=1}^{n} \alpha_i = 1$.*

Proof. Since $\boldsymbol{u}$ lies in the relative interior of $\mathrm{conv}(S)$, for $\varepsilon > 0$ sufficiently small we have that

$$(1 + n\varepsilon)u - \sum_{i=1}^{n} \varepsilon \boldsymbol{a}_i \in \mathrm{conv}(S).$$

For such an ε there exist $\beta_1, \ldots, \beta_n \geq 0$ such that $(1 + n\varepsilon)u - \sum_{i=1}^{n} \varepsilon \boldsymbol{a}_i = \sum_{i=1}^{n} \beta_i \boldsymbol{a}_i$ and $\sum_{i=1}^{n} \beta_i = 1$. But then $\boldsymbol{u} = \sum_{i=1}^{n} \frac{\beta_i + \varepsilon}{1 + n\varepsilon} \boldsymbol{a}_i$. Defining $\alpha_i := \frac{\beta_i + \varepsilon}{1 + n\varepsilon}$ for $i \in \{1, \ldots, n\}$, the proposition is proved. ◀

A *lattice of rank r* in $\mathbb{R}^d$ is a set

$$\Lambda := \{z_1 \boldsymbol{v}_1 + \cdots + z_r \boldsymbol{v}_r \colon z_1, \ldots, z_r \in \mathbb{Z}\},$$

where $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_r$ are linearly independent vectors in $\mathbb{R}^d$. Given a convex set $C \subseteq \mathbb{R}^d$, define the *width* of C along a vector $\boldsymbol{u} \in \mathbb{R}^d$ to be

$$\sup\{\boldsymbol{u}^\top (\boldsymbol{x} - \boldsymbol{y}) : \boldsymbol{x}, \boldsymbol{y} \in C\}.$$

Furthermore the *lattice width* of C is the infimum over all non-zero vectors $\boldsymbol{u} \in \Lambda$ of the width of C along $\boldsymbol{u}$.

The following result (see [2, Theorem 7.2.1]) captures the intuition that a convex set that contains no lattice point in its interior must be "thin" in some direction.

▶ **Theorem 2** (Flatness Theorem). *Given a full-rank lattice Λ in $\mathbb{R}^d$ there exists W such that any convex set $C \subseteq \mathbb{R}^d$ of lattice width at least W contains a lattice point.*

Recall that $C \subseteq \mathbb{R}^d$ is said to be *semi-algebraic* if it is definable by a boolean combination of polynomial constraints $p(x_1, \ldots, x_d) > 0$, where $p \in \mathbb{Z}[x_1, \ldots, x_d]$.

▶ **Theorem 3** (Khachiyan and Porkolab [15]). *It is decidable whether a given convex semi-algebraic set $C \subseteq \mathbb{R}^d$ contains an integer point, that is, whether $C \cap \mathbb{Z}^d \neq \emptyset$.*

2.2 Groups of Multiplicative Relations

In this subsection we will introduce some concepts concerning groups of multiplicative relations among algebraic numbers.

Let $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$. We define the s-dimensional torus to be $\mathbb{T}^s$, considered as a group under component-wise multiplication. Given a tuple of algebraic numbers $\boldsymbol{\gamma} = (\gamma_1, \cdots, \gamma_s) \in \mathbb{T}^s$, the orbit $\{\boldsymbol{\gamma}^n : n \in \mathbb{N}\}$ is a subset of $\mathbb{T}^s$. In the following we characterise the topological closure of the orbit as an algebraic subset of $\mathbb{T}^s$.

The *group of multiplicative relations* of $\boldsymbol{\gamma} \in \mathbb{T}^s$ is defined as the following additive subgroup of $\mathbb{Z}^s$:

$$L(\boldsymbol{\gamma}) = \{\boldsymbol{v} \in \mathbb{Z}^s : \boldsymbol{\gamma}^{\boldsymbol{v}} = 1\},$$

where $\boldsymbol{\gamma}^{\boldsymbol{v}}$ is defined to be $\gamma_1^{v_1} \cdots \gamma_s^{v_s}$ for $\boldsymbol{v} \in \mathbb{Z}^s$, that is, exponentiation acts coordinate-wise. Since $L(\boldsymbol{\gamma})$ is a subgroup of $\mathbb{Z}^s$, it is a free Abelian group and hence has a finite basis. The following powerful theorem of Masser [17] gives bounds on the magnitude of the components of such a basis.

▶ **Theorem 4** (Masser). *The free Abelian group $L(\boldsymbol{\gamma})$ has a basis $\boldsymbol{v}_1, \cdots, \boldsymbol{v}_l \in \mathbb{Z}^s$ for which*

$$\max_{1 \le i \le l, 1 \le j \le s} |v_{i,j}| \le (D \log H)^{O(s^2)},$$

where H and D bound respectively the heights and degrees of all the γ_i.

Membership of a tuple $\boldsymbol{v} \in \mathbb{Z}^s$ in $L(\boldsymbol{\gamma})$ can be computed in polynomial space, using a decision procedure for the existential theory of the reals. In combination with Theorem 4, it follows that we can compute a basis for $L(\boldsymbol{\gamma})$ in polynomial space by brute-force search.

Corresponding to $L(\boldsymbol{\gamma})$, we consider the following multiplicative subgroup of $\mathbb{T}^s$:

$$T(\boldsymbol{\gamma}) = \{\boldsymbol{\mu} \in \mathbb{T}^s : \forall \boldsymbol{v} \in L(\boldsymbol{\gamma}), \boldsymbol{\mu}^{\boldsymbol{v}} = 1\}.$$

If $\mathcal{B}$ is a basis of $L(\boldsymbol{\gamma})$, we can equivalently characterise $T(\boldsymbol{\gamma})$ as $\{\boldsymbol{\mu} \in \mathbb{T}^s : \forall \boldsymbol{v} \in \mathcal{B}, \boldsymbol{\mu}^{\boldsymbol{v}} = 1\}$. Crucially, this finitary characterisation allows us to represent $T(\boldsymbol{\gamma})$ as an algebraic set in $\mathbb{T}^s$.

We will use the following classical lemma of Kronecker on simultaneous Diophantine approximation to show that the orbit $\{\boldsymbol{\gamma}^n : n \in \mathbb{N}\}$ is a dense subset of $T(\boldsymbol{\gamma})$.

▶ **Lemma 5.** *Let $\boldsymbol{\theta}, \boldsymbol{\psi} \in \mathbb{R}^s$. Suppose that for all $\boldsymbol{v} \in \mathbb{Z}^s$, if $\boldsymbol{v}^T\boldsymbol{\theta} \in \mathbb{Z}$ then also $\boldsymbol{v}^T\boldsymbol{\psi} \in \mathbb{Z}$, i.e., all integer relations among the coordinates of $\boldsymbol{\theta}$ also hold among those of $\boldsymbol{\psi}$ (modulo $\mathbb{Z}$). Then, for each $\varepsilon > 0$, there exist $\boldsymbol{p} \in \mathbb{Z}^s$ and a non-negative integer n such that*

$$\|n\boldsymbol{\theta} - \boldsymbol{p} - \boldsymbol{\psi}\|_\infty \le \varepsilon.$$

We now arrive at the main result of the section:

▶ **Theorem 6.** *Let $\boldsymbol{\gamma} \in \mathbb{T}^s$. Then the orbit $\{\boldsymbol{\gamma}^k : k \in \mathbb{N}\}$ is a dense subset of $T(\boldsymbol{\gamma})$.*

Proof. Let $\boldsymbol{\theta} \in \mathbb{R}^s$ be such that $\boldsymbol{\gamma} = e^{2\pi i\boldsymbol{\theta}}$ (with exponentiation operating coordinate-wise). Notice that $\boldsymbol{\gamma}^{\boldsymbol{v}} = 1$ if and only if $\boldsymbol{v}^T\boldsymbol{\theta} \in \mathbb{Z}$. If $\boldsymbol{\mu} \in T(\boldsymbol{\gamma})$, we can likewise define $\boldsymbol{\psi} \in \mathbb{R}^s$ to be such that $\boldsymbol{\mu} = e^{2\pi i\boldsymbol{\psi}}$. Then the premises of Kronecker's lemma apply to $\boldsymbol{\theta}$ and $\boldsymbol{\psi}$. Thus, given $\varepsilon > 0$, there exist a non-negative integer k and $\boldsymbol{p} \in \mathbb{Z}^s$ such that $\|k\boldsymbol{\theta} - \boldsymbol{p} - \boldsymbol{\psi}\|_\infty \le \varepsilon$. Whence

$$\|\boldsymbol{\gamma}^k - \boldsymbol{\mu}\|_\infty = \|e^{2\pi i(k\boldsymbol{\theta} - \boldsymbol{p})} - e^{2\pi i\boldsymbol{\psi}}\|_\infty \le \|2\pi(k\boldsymbol{\theta} - \boldsymbol{p} - \boldsymbol{\psi})\|_\infty \le 2\pi\varepsilon. \qquad \blacktriangleleft$$

3 Termination Analysis via Spectral Theory

The general form of a simple linear loop in dimension d is as follows:

$$\textit{while } (g_1(\boldsymbol{x}) > 0 \wedge \ldots \wedge g_m(\boldsymbol{x}) > 0) \textit{ do } \boldsymbol{x} := f(\boldsymbol{x}) \,,$$

where $g_1, \ldots, g_m : \mathbb{R}^d \to \mathbb{R}$ and $f : \mathbb{R}^d \to \mathbb{R}^d$ are affine functions. We assume that f and $g_1, \ldots, g_m$ have integer coefficients, that is, $f(\boldsymbol{x}) = A\boldsymbol{x} + \boldsymbol{a}$ for $A \in \mathbb{Z}^{d\times d}$ and $\boldsymbol{a} \in \mathbb{Z}^d$, and $g_i(\boldsymbol{x}) = \boldsymbol{b}_i^\top \boldsymbol{x} + c_i$ for $\boldsymbol{b}_i \in \mathbb{Z}^d$, $c_i \in \mathbb{Z}$ and $i = 1, \ldots, m$.

Note that

$$\begin{pmatrix} f(\boldsymbol{x}) \\ 1 \end{pmatrix} = \begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} \text{ and } g_i(\boldsymbol{x}) = \begin{pmatrix} \boldsymbol{b}_i^\top & c_i \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} . \tag{1}$$

for all $\boldsymbol{x} \in \mathbb{R}^d$. We say that f is *non-degenerate* if no quotient of two distinct eigenvalues of the update matrix $\begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}$ is a root of unity.

▶ **Proposition 7.** *The termination problem for simple linear loops on integers is reducible to the special case of the problem for non-degenerate update functions.*

Proof. Consider a simple linear loop, as described above, whose update matrix has distinct eigenvalues $\lambda_1, \ldots, \lambda_s$. Let L be the least common multiple of the orders of the roots of unity appearing among the quotients λ_i/λ_j for $i \neq j$. It is known that $L = 2^{O(d\sqrt{\log d})}$ [13, Subsection 1.1.9]. The update matrix corresponding to the affine map $f^L = \underbrace{f \circ \cdots \circ f}_{L}$ has eigenvalues $\lambda_1^L, \ldots, \lambda_s^L$ and hence is non-degenerate. Moreover the original loop terminates if and only if the following loop terminates:

$$\textit{while } \bigwedge_{i=0}^{L-1} \left(g_1(f^i(\boldsymbol{x})) > 0 \wedge \ldots \wedge g_m(f^i(\boldsymbol{x})) > 0\right) \textit{ do } \boldsymbol{x} := f^L(\boldsymbol{x}) \,,$$

This concludes the proof. ◀

In the rest of this section and in the next section we focus on the case of a loop

$$\mathsf{P}: \textit{ while } (g(\boldsymbol{x}) > 0) \textit{ do } x \leftarrow f(\boldsymbol{x}) \textit{ end} \tag{2}$$

with a single guard function $g(\boldsymbol{x}) = \boldsymbol{b}^\top \boldsymbol{x} + c$ and with non-degenerate update function $f(\boldsymbol{x}) = A\boldsymbol{x} + \boldsymbol{a}$, with both maps having integer coefficients. We show that a spectral analysis of the matrix underlying the loop update function suffices to classify almost all initial values of the loop as either terminating or eventually non-terminating. Towards the end of the section we isolate a class of so-called *critical* initial values that are not amenable to this analysis. We show how to deal with such points in Section 4.

With respect to the loop P we say that $\boldsymbol{x} \in \mathbb{R}^d$ is *terminating* if there exists n such that $g(f^n(\boldsymbol{x})) \leq 0$. We say that $\boldsymbol{x}$ is *eventually non-terminating* if the sequence $\langle g(f^n(\boldsymbol{x})) : n \in \mathbb{N}\rangle$ is *ultimately positive*, i.e., there exists N such that for all $n \geq N$ $g(f^n(\boldsymbol{x})) > 0$. Clearly there exists $\boldsymbol{z} \in \mathbb{Z}^d$ that is non-terminating if and only if there exists $\boldsymbol{z} \in \mathbb{Z}^d$ that is eventually non-terminating. Thus we can regard the problem of deciding termination on $\mathbb{Z}^d$ as that of searching for an eventually non-terminating point.

Let $\lambda_1, \ldots, \lambda_s$ be the non-zero eigenvalues of $\begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}$ and let $k_{\max}$ be the maximum multiplicity over all these eigenvalues.

Define a linear preorder on $I := \{0, \dots, k_{\max} - 1\} \times \{1, \dots, s\}$ by $(i_1, j_1) \preccurlyeq (i_2, j_2)$ if either (i) $|\lambda_{j_1}| < |\lambda_{j_2}|$ or (ii) $|\lambda_{j_1}| = |\lambda_{j_2}|$ and $i_1 \leq i_2$. Write $(i_1, j_1) \prec (i_2, j_2)$ if $(i_1, j_1) \preccurlyeq (i_2, j_2)$ and $(i_2, j_2) \not\preccurlyeq (i_1, j_1)$. Then we have

$$(i_1, j_1) \prec (i_2, j_2) \text{ iff } \lim_{n\to\infty} \frac{\binom{n}{i_1}|\lambda_{j_1}|^n}{\binom{n}{i_2}|\lambda_{j_2}|^n} = 0\,,$$

that is, the preorder $\preccurlyeq$ characterises the asymptotic order of growth in absolute value of the terms $\binom{n}{i}\lambda_j^n$ for $(i, j) \in I$. This preorder moreover induces an equivalence relation $\approx$ on I where $(i_1, j_1) \approx (i_2, j_2)$ iff $(i_1, i_1) \preccurlyeq (i_2, j_2)$ and $(i_2, i_2) \preccurlyeq (i_1, j_1)$.

The following closed-form expression for $g(f^n(\boldsymbol{x}))$ will be the focus of the subsequent development.

▶ **Proposition 8.** *There is a set of affine functions $h_{i,j} : \mathbb{R}^d \to \mathbb{C}$ such that for all $\boldsymbol{x} \in \mathbb{R}^d$ and all $n \geq d$ we have*

$$\boldsymbol{g}(f^n(\boldsymbol{x})) = \sum_{(i,j)\in I} \binom{n}{i} \lambda_j^n \, h_{i,j}(\boldsymbol{x})\,.$$

Proof. By the Jordan-Chevalley decomposition we can write $\begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix} = P^{-1}DP + N$, where D is diagonal, N is nilpotent, P is invertible, $P^{-1}DP$ and N commute, and all matrices have algebraic coefficients. Moreover we can write $D = \lambda_1 D_1 + \cdots + \lambda_s D_s$ for appropriate idempotent diagonal matrices $D_1, \dots, D_s$. Then for all $n \in \mathbb{N}$ with $n \geq d$ we have

$$\begin{aligned}
g(f^n(\boldsymbol{x})) &= (\boldsymbol{b}^\top \; c) \begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}^n \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} \\
&= (\boldsymbol{b}^\top \; c)(P^{-1}DP + N)^n \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} \\
&= (\boldsymbol{b}^\top \; c) \sum_{i=0}^{n} \binom{n}{i} P^{-1} D^{n-i} P N^i \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} \\
&= (\boldsymbol{b}^\top \; c) \sum_{i=0}^{d} \binom{n}{i} P^{-1} (\lambda_1^{n-i} D_1 + \cdots + \lambda_s^{n-i} D_s) P N^i \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} \quad (\text{since } N^{d+1} = 0) \\
&= \sum_{j=1}^{s} \lambda_j^n \sum_{i=0}^{d} \binom{n}{i} \underbrace{\lambda_j^{-i} (\boldsymbol{b}^\top \; c) P^{-1} D_j P N^i \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix}}_{h_{i,j}(\boldsymbol{x})} \qquad (3) \\
&= \sum_{j=1}^{s} \sum_{i=0}^{d} \binom{n}{i} \lambda_j^n h_{i,j}(\boldsymbol{x})\,,
\end{aligned}$$

where for $(i, j) \in I$ the affine function $h_{i,j}$ is defined in Line (3). Clearly each function $h_{i,j}$ is a complex-valued affine function on $\mathbb{R}^d$ with algebraic coefficients. ◀

Define $\gamma_i = \frac{\lambda_i}{|\lambda_i|}$ for $i = 1, \dots, s$, that is, we obtain the γ_i by normalising the eigenvalues to have length 1. Recall from Section 2.2 the definition of the group $L(\boldsymbol{\gamma})$ of multiplicative relations that hold among $\gamma_1, \dots, \gamma_s$, *viz.*,

$$L(\boldsymbol{\gamma}) = \{(n_1, \dots, n_s) \in \mathbb{Z}^s : \gamma_1^{n_1} \cdots \gamma_s^{n_s} = 1\}\,.$$

Recall also that we have $T(\boldsymbol{\gamma}) \subseteq \mathbb{T}^s$, given by

$$T(\boldsymbol{\gamma}) = \{(\mu_1, \ldots, \mu_s) \in \mathbb{T}^s : \mu_1^{n_1} \cdots \mu_s^{n_s} = 1 \text{ for all } (n_1, \ldots, n_s) \in L(\boldsymbol{\gamma})\}\,.$$

Given an $\approx$-equivalence class $E \subseteq I$, note that for all $(i_1, j_1), (i_2, j_2) \in E$ we have $i_1 = i_2$ and $|\lambda_{j_1}| = |\lambda_{j_2}|$. Thus E is determines a common multiplicity, which we denote i_E, and a set of eigenvalues that all have the same absolute value, which we denote ρ_E.

Given an $\approx$-equivalence class E, define $\Phi_E : \mathbb{R}^d \times T(\boldsymbol{\gamma}) \to \mathbb{R}$ by[1]

$$\Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) = \sum_{(i,j)\in E} h_{i,j}(\boldsymbol{x})\mu_j\,. \tag{4}$$

From the above definition of Φ_E we have

$$\sum_{(i,j)\in E} \binom{n}{i} \lambda_j^n h_{i,j}(\boldsymbol{x}) = \binom{n}{i_E} \rho_E^n \Phi_E(\boldsymbol{x}, \boldsymbol{\gamma}^n)\,. \tag{5}$$

for all $\boldsymbol{x} \in \mathbb{R}^d$ and all $n \in \mathbb{N}$.

We say that an equivalence class E of I is *dominant* for $\boldsymbol{x} \in \mathbb{R}^d$ if E is the equivalence class of the maximal indices (i, j) for which $h_{i,j}(\boldsymbol{x})$ is non-zero. Equivalently, E is dominant for $\boldsymbol{x}$ if E is the maximal equivalence class such that $\Phi_E(\boldsymbol{x}, \cdot)$ is not identically zero on $T(\boldsymbol{\gamma})$. (The equivalence of these two characterisations follows from the linear independence of the functions $\binom{n}{i}\lambda_j^n$ for $(i, j) \in E$.)

The following proposition shows how information about termination of the loop P on an initial value $\boldsymbol{x} \in \mathbb{R}^d$ can be derived from properties of $\Phi_E(\boldsymbol{x}, \cdot)$.

▶ **Proposition 9.** *Consider the loop P in (2). Let $\boldsymbol{x} \in \mathbb{R}^d$ and let E be an $\approx$-equivalence class that is dominant for $\boldsymbol{x}$. Then*

1. *If $\inf_{\boldsymbol{\mu}\in T(\boldsymbol{\gamma})} \Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) > 0$ then $\boldsymbol{x}$ is eventually non-terminating for P.*
2. *If $\inf_{\boldsymbol{\mu}\in T(\boldsymbol{\gamma})} \Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) < 0$ then $\boldsymbol{x}$ is terminating for P.*

Proof. By Proposition 8 and Equation (5) we have that for all $n \geq d$,

$$\begin{aligned} g(f^n(\boldsymbol{x})) &= \sum_{(i,j)\in I} \binom{n}{i} \lambda_j^n h_{i,j}(\boldsymbol{x}) \\ &= \binom{n}{i_E} \rho_E^n \Phi_E(\boldsymbol{x}, \boldsymbol{\gamma}^n) + \sum_{(i,j)\in I\setminus E} \binom{n}{i} \lambda_j^n h_{i,j}(\boldsymbol{x})\,. \end{aligned} \tag{6}$$

Moreover by the dominance of E we have that

$$\lim_{n\to\infty} \frac{\binom{n}{i}|\lambda_j|^n}{\binom{n}{i_E}\rho_E^n} = 0 \tag{7}$$

for all $(i, j) \in I \setminus E$ such that $h_{i,j}(\boldsymbol{x}) \neq 0$.

We first prove Item 1. By assumption, in this case there exists $\varepsilon > 0$ such that $\Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) \geq \varepsilon$ for all $\boldsymbol{\mu} \in T(\boldsymbol{\gamma})$. Together with Equation (7), this shows that the asymptotically dominant term in Equation (6) has positive sign. It follows that $g(f^n(\boldsymbol{x}))$ is positive for n sufficiently large and hence $\boldsymbol{x}$ is eventually non-terminating.

[1] That the function Φ_E is real-valued follows from the fact that if eigenvalues λ_{j_1} and λ_{j_2} are complex conjugates then γ_{j_1} and γ_{j_2} are also complex conjugates, as are $h_{i,j_1}(\boldsymbol{z})$ and $h_{i,j_2}(\boldsymbol{z})$ (see the proof of Proposition 8).

We turn now to Item 2. By assumption there exists $\varepsilon > 0$ and an open subset U of $T(\boldsymbol{\gamma})$ such that $\Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) < -\varepsilon$ for all $\boldsymbol{\mu} \in U$. Moreover by density of $\{\boldsymbol{\gamma}^n : n \in \mathbb{N}\}$ in $T(\boldsymbol{\gamma})$ there exist infinitely many n such that $\boldsymbol{\gamma}^n \in U$. Exactly as in Case 1 we can now use the dominance of E to conclude that $g(f^n(\boldsymbol{x})) < 0$ for sufficiently large n such that $\boldsymbol{\gamma}^n \in U$ and hence $\boldsymbol{x}$ is terminating. ◀

Given $\boldsymbol{z} \in \mathbb{Z}^d$, since $T(\boldsymbol{\gamma})$ is an algebraic subset of $\mathbb{T}^s$, the number $\inf_{\boldsymbol{\mu} \in T(\boldsymbol{\gamma})} \Phi_E(\boldsymbol{z}, \boldsymbol{\mu})$ is algebraic and its sign can be decided. Note however that Proposition 9 does not completely resolve the question of termination with respect to guard g from a given initial value $\boldsymbol{z}$. Indeed, let us define $\boldsymbol{z} \in \mathbb{R}^d$ to be *critical* if $\inf_{\boldsymbol{\mu} \in E} \Phi_E(\boldsymbol{z}, \boldsymbol{\mu}) = 0$, where E is the dominant equivalence class for $\boldsymbol{z}$. Then neither clause in the above proposition suffices to resolve termination of the loop P in (2) on such a $\boldsymbol{z}$. Indeed the question of whether such a point is eventually non-terminating is equivalent to the *Ultimate Positivity Problem* for linear recurrence sequences: a longstanding and notoriously difficult open problem in number theory, only known to be decidable up to order 4 [1, 19]. Fortunately in the setting of deciding loop termination we can sidestep such difficult questions. The following section is devoted to handling critical points. The idea is to show that if there is a critical initial value then there is another initial value that is eventually non-terminating and moreover whose eventual non-termination can be established by Proposition 9.

4 Analysis of Critical Points

In this section we continue to analyse termination of the loop P, as given in (2) in the previous section, and refer to the notation established therein.

4.1 Transition Invariance of Critical Points

Intuitively critical points are those for which it is difficult to determine eventual non-termination. One should therefore expect that if $\boldsymbol{x} \in \mathbb{R}^d$ is critical then $f(\boldsymbol{x})$ should also be critical. This, and more, follows from the following proposition.

▶ **Proposition 10.** *Let $\boldsymbol{x} \in \mathbb{R}^d$ and let $E \subseteq I$ be an equivalence class that is dominant for $\boldsymbol{x}$. Then E is also dominant for $f(\boldsymbol{x})$ and for all $\boldsymbol{\mu} \in T(\boldsymbol{\gamma})$ we have $\Phi_E(f(\boldsymbol{x}), \boldsymbol{\mu}) = \rho_E \, \Phi_E(\boldsymbol{x}, \boldsymbol{\gamma}\boldsymbol{\mu})$, where the product $\boldsymbol{\gamma}\boldsymbol{\mu}$ is defined pointwise.*

Proof. By definition we have $\Phi_E(\boldsymbol{x}, \boldsymbol{\mu}) = \sum_{(i,j) \in E} h_{i,j}(\boldsymbol{x}) \mu_j$, where the $h_{i,j}$ satisfy

$$(\boldsymbol{b}^\top \; c) \begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}^n \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} = \sum_{(i,j) \in I} h_{i,j}(\boldsymbol{x}) \binom{n}{i} \lambda_j^n \tag{8}$$

for all $n \geq d$. Likewise we have $\Phi_E(f(\boldsymbol{x}), \boldsymbol{\mu}) = \sum_{(i,j) \in S} \widetilde{h}_{i,j}(\boldsymbol{x}) \mu_j$, where the $\widetilde{h}_{i,j}$ satisfy

$$(\boldsymbol{b}^\top \; c) \begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}^{n+1} \begin{pmatrix} \boldsymbol{x} \\ 1 \end{pmatrix} = \sum_{(i,j) \in I} \widetilde{h}_{i,j}(\boldsymbol{x}) \binom{n}{i} \lambda_j^n \,. \tag{9}$$

Combining Equations (8) and (9) we have the for all $n \geq d$,

$$\begin{aligned} \sum_{(i,j) \in I} \widetilde{h}_{i,j}(\boldsymbol{x}) \binom{n}{i} \lambda_j^n &= \sum_{(i,j) \in I} h_{i,j}(\boldsymbol{x}) \binom{n+1}{i} \lambda_j^{n+1} \\ &= \sum_{(i,j) \in I} h_{i,j}(\boldsymbol{x}) \left[\binom{n}{i} + \binom{n}{i-1} \right] \lambda_j \lambda_j^n \,. \end{aligned}$$

Now the collection of functions $n \mapsto \binom{n}{i}\lambda_j^n$ for $(i,j) \in I$ is linearly independent in the vector space $\mathbb{C}^{\mathbb{N}}$ (see, e.g., [23, Lemma 9.6]). Equating the coefficients of the functions $\binom{n}{i}\lambda_j^n$ for $(i,j) \in E$ in the above equation we have $\widetilde{h}_{i,j} = \lambda_j h_{i,j} = \rho_E \gamma_j h_{i,j}$ for all $(i,j) \in E$; likewise we have that E is dominant for $f(\boldsymbol{x})$. The proposition follows. ◀

The next lemma shows that the existence of a critical point entails the existence of an eventually non-terminating point.

▶ **Lemma 11.** *If $\boldsymbol{z} \in \mathbb{R}^d$ is critical then there exists a positive integer M such that for all $n \geq M$, all points in the relative interior of* $\mathrm{conv}(\{f^d(\boldsymbol{z}), f^{d+1}(\boldsymbol{z}), \ldots, f^n(\boldsymbol{z})\})$ *are eventually non-terminating.*

Proof. Given an arbitrary $\boldsymbol{\mu} \in T(\boldsymbol{\gamma})$ we claim that there exists $n \geq d$ for which we have $\Phi_E(f^n(\boldsymbol{z}), \boldsymbol{\mu}) > 0$. If this were not the case then for all $n \geq d$ we would have $\Phi_E(f^n(\boldsymbol{z}), \boldsymbol{\mu}) = \Phi_E(\boldsymbol{z}, \boldsymbol{\xi}^n \boldsymbol{\mu}) = 0$. But by Theorem 6, the set $\{\boldsymbol{\xi}^n \boldsymbol{\mu} : n \geq d\}$ is dense in $T(\boldsymbol{\gamma})$ and hence we would have that $\Phi_E(\boldsymbol{z}, \cdot)$ is identically 0 on $T(\boldsymbol{\gamma})$, contradicting the dominance of E.

For each $n \in \mathbb{N}$, the set $C_n = \{\boldsymbol{\mu} \in T(\boldsymbol{\gamma}) : \Phi_E(f^n(\boldsymbol{z}), \boldsymbol{\mu}) > 0\}$ is an open subset of $T(\boldsymbol{\gamma})$. Moreover, by the analysis above, the collection $\{C_n : n \geq d\}$ is an open cover of $T(\boldsymbol{\gamma})$. Thus by compactness of $T(\boldsymbol{\gamma})$ there exists $M \in \mathbb{N}$ such that $C_d, C_{d+1}, \cdots, C_M$ is a finite cover of $T(\boldsymbol{\gamma})$.

By Proposition 1, for all $n \geq M$ and all points $\boldsymbol{x}$ lying in the relative interior of $\mathrm{conv}(\{f^d(\boldsymbol{z}), f^{d+1}(\boldsymbol{z}), \ldots, f^n(\boldsymbol{z})\})$, there exist $\alpha_d, \ldots, \alpha_n > 0$ such that $\sum_{i=d}^n \alpha_i = 1$ and $\boldsymbol{x} = \sum_{i=d}^n \alpha_i f^i(\boldsymbol{z})$. Since Φ_E is an affine map in its first variable, it follows that $\Phi_E(\boldsymbol{x}, \cdot) = \sum_{i=d}^n \alpha_i \Phi_E(f^i(\boldsymbol{z}), \cdot)$ is strictly positive on $T(\boldsymbol{\gamma})$. Hence $\boldsymbol{x}$ is eventually non-terminating by Proposition 9. ◀

4.2 Integer Non-Terminating Points from Critical Points

Lemma 11 shows how to derive the existence of non-terminating points from the existence of a critical point. In this subsection we refine this analysis to derive the existence of *integer* non-terminating points. In particular, fixing an initial value $\boldsymbol{z}_* \in \mathbb{Z}^d$, we show that for n sufficiently large, the set

$$\mathrm{conv}(\{f^d(\boldsymbol{z}_*), f^{d+1}(\boldsymbol{z}_*), \ldots, f^n(\boldsymbol{z}_*)\})$$

contains an integer point in its relative interior.

Define $V := \mathrm{Aff}(\{f^n(\boldsymbol{z}_*) : n \geq d\})$ and let the vector subspace $V_0 \subseteq \mathbb{R}^d$ be the unique translate of V containing the origin. Write d_0 for the dimension of V_0 (equivalently the dimension of V).

▶ **Proposition 12.** *For all non-zero integer vectors $\boldsymbol{v} \in V_0$ the set $\{|\boldsymbol{v}^\top f^n(\boldsymbol{z}_*)| : n \geq d\}$ is unbounded.*

Proof. Consider the sequence $x_n := \boldsymbol{v}^\top f^n(\boldsymbol{z}_*) = \begin{pmatrix} A & \boldsymbol{a} \\ 0 & 1 \end{pmatrix}^n \begin{pmatrix} \boldsymbol{z}_* \\ 1 \end{pmatrix}$. If this sequence were constant then $\boldsymbol{v}$ would be orthogonal to V_0, contradicting the fact that $\boldsymbol{v}$ is non-zero. Since the sequence is non-constant, integer-valued, and satisfies a non-degenerate linear recurrence of order at most $d+1$ (see, e.g., [13, Subsection 1.1.12]), by the Skolem-Mahler-Lech Theorem

we have that $\{|\boldsymbol{v}^\top f^n(\boldsymbol{z}_*)| : n \geq d\}$ is unbounded (see the discussion of growth of linear recurrence in [13, Section 2.2]).[2] ◀

▶ **Proposition 13.** *There exists M such that for all $n \geq M$ the set*

$$\mathrm{conv}(\{f^d(\boldsymbol{z}_*), f^{d+1}(\boldsymbol{z}_*), \ldots, f^n(\boldsymbol{z}_*)\})$$

contains an integer point in its relative interior.

Proof. Since V_0 is spanned by integer vectors, $\Lambda := V_0 \cap \mathbb{Z}^d$ is a lattice of rank d_0 in $\mathbb{R}^d$. Define $C := \mathrm{conv}(\{f^n(\boldsymbol{z}_*) : n \geq d\}) \subseteq V$ and $C_0 := C - f^d(\boldsymbol{z}_*) \subseteq V_0$.

Let $\theta : \mathbb{R}^d \to \mathbb{R}^{d_0}$ be a linear map that takes V_0 bijectively onto $\mathbb{R}^{d_0}$ and whose kernel is the orthogonal complement of V_0. Then $\theta(\Lambda)$ is a lattice in $\mathbb{R}^{d_0}$ of full rank. We claim that the lattice width of $\theta(C_0)$ with respect to $\theta(\Lambda)$ is infinite. Indeed for any non-zero vector $\boldsymbol{v} \in \theta(\Lambda)$ we have

$$\boldsymbol{v}^\top(\theta(f^n(\boldsymbol{z}_*)) - \theta(f^d(\boldsymbol{z}_*))) = (\theta^*\boldsymbol{v})^\top(f^n(\boldsymbol{z}_*) - f^d(\boldsymbol{z}_*))\,, \tag{10}$$

where $\theta^* : \mathbb{R}^{d_0} \to \mathbb{R}^d$ is the adjoint map of θ. But $\theta^*\boldsymbol{v}$ is a non-zero rational vector in V_0 and hence Proposition 12 entails that the absolute value of (10) is unbounded as n runs over $\mathbb{N}$. This proves the claim.

By Theorem 2 we have that $\theta(C_0)$ contains a point of $\theta(\Lambda)$ in its relative interior and hence C_0 contains a point of Λ (necessarily an integer point) in its relative interior. We conclude that C also contains an integer point in its relative interior. ◀

We summarise Sections 3 and 4 with a theorem characterising when a loop with a single guard is terminating.

▶ **Theorem 14.** *The loop P, given in* (2)*, is non-terminating on $\mathbb{Z}^d$ if and only if there exists $\boldsymbol{z} \in \mathbb{Z}^d$ and an $\approx$-equivalence class E such that (i) E is dominating for $\boldsymbol{z}$ and (ii) $\inf_{\boldsymbol{\mu} \in T(\boldsymbol{\gamma})} \Phi_E(\boldsymbol{z}, \boldsymbol{\mu}) \geq 0$.*

Proof. If no such $\boldsymbol{z}$ exists then the loop is terminating by Proposition 9(2). Conversely, if such a $\boldsymbol{z}$ exists then by Lemma 11 and Proposition 13 there exists $\boldsymbol{z}' \in \mathbb{Z}^d$ such that $\inf_{\boldsymbol{\mu} \in T(\boldsymbol{\gamma})} \Phi_E(\boldsymbol{z}', \boldsymbol{\mu}) > 0$ (and with E still dominating for $\boldsymbol{z}'$.) Such a point is eventually non-terminating by Proposition 9(1). ◀

We postpone the question of the effectiveness of the above characterisation until we handle loops with multiple guards, in Section 5.

---

[2] The above argument actually establishes that $\langle x_n : n \in \mathbb{N}\rangle$ diverges to infinity in absolute value. We briefly sketch a more elementary proof of mere unboundedness. If the sequence $\langle x_n : n \in \mathbb{N}\rangle$ were bounded then by van der Waerden's Theorem, for all m it would contain a constant subsequence of the form $x_\ell, x_{\ell+p}, \ldots, x_{\ell+mp}$ for some $\ell, p \geq 1$. In particular, if $m = d$ then since every infinite subsequence $y_n := x_{\ell+pn}$ satisfies a linear recurrence of order at most $d+1$, $\langle x_n : n \in \mathbb{N}\rangle$ would have an infinite constant subsequence $\langle x_{\ell+pn} : n \in \mathbb{N}\rangle$. If $p = 1$ then $\langle x_n : n \in \mathbb{N}\rangle$ is constant and if $p > 1$ then by [23, Lemma 9.11] $\langle x_n : n \in \mathbb{N}\rangle$ is degenerate.

5 Multiple Guards

Now we are ready to present our decision procedure for a general linear loop program

$$\mathsf{Q} : \textit{while } (g_1(\boldsymbol{x}) > 0 \wedge \ldots \wedge g_m(\boldsymbol{x}) > 0) \textit{ do } \boldsymbol{x} := f(\boldsymbol{x}), \tag{11}$$

with multiple guards. Associated to the loop Q we consider m single-guard loops with a common update function:

$$\mathsf{Q}_i : \textit{while } (g_i(\boldsymbol{x}) > 0) \textit{ do } \boldsymbol{x} := f(\boldsymbol{x}),$$

for $i = 1, \ldots, m$. Clearly Q is non-terminating if and only if there exists $\boldsymbol{z} \in \mathbb{Z}^d$ such that each loop Q_i is non-terminating on $\boldsymbol{z}$. As we now explain, we can decide the existence of such a point following the proof of Theorem 14.

Let $\lambda_1, \ldots, \lambda_s$ be the distinct non-zero eigenvalues of the matrix corresponding to the update function f in the loop Q. As before, write $\gamma_j = \frac{\lambda_j}{|\lambda_j|}$ for $j = 1, \ldots, s$. For $i = 1, \ldots, m$, denote by $\Phi_E^{(i)} : \mathbb{R}^d \times T(\boldsymbol{\gamma}) \to \mathbb{R}$ the function associated to loop Q_i and $\approx$-equivalence class E as defined by (4). Given $\approx$-equivalence classes $E_1, \ldots, E_m$, we define $W_{E_1,\ldots,E_m} \subseteq \mathbb{R}^d$ to be the set of $\boldsymbol{\gamma} \in \mathbb{R}^d$ such that the following hold for $i = 1, \ldots, m$:

- E_i is dominant for $\boldsymbol{x}$ in loop Q_i, that is, $\Phi_{E_i}^{(i)}(\boldsymbol{x}, \cdot) \not\equiv 0$ and $\Phi_E^{(i)}(\boldsymbol{x}, \cdot) \equiv 0$ for all $E_i \prec E$.
- $\inf_{\boldsymbol{\mu} \in T(\boldsymbol{\gamma})} \Phi_{E_i}^{(i)}(\boldsymbol{x}, \boldsymbol{\mu}) \geq 0$.

▶ **Proposition 15.** *Loop Q is non-terminating if and only if there exist $\approx$-equivalence classes $E_1, \ldots, E_m$ such that $W_{E_1,\ldots,E_m}$ contains an integer point.*

Proof. Suppose that Q fails to terminate on $\boldsymbol{z} \in \mathbb{Z}^d$. Then each loop Q_i also fails to terminate on $\boldsymbol{z} \in \mathbb{Z}^d$. Thus if E_i is the dominant equivalence class for $\boldsymbol{z}$ in program Q_i, for $i = 1, \ldots, m$, applying Proposition 9(2) we get that $\boldsymbol{z} \in W_{E_1,\ldots,E_m}$.

Conversely, suppose $\boldsymbol{z} \in W_{E_1,\ldots,E_m}$ for some $\approx$-equivalence classes $E_1, \ldots, E_m$. Then, by Lemma 11 and Proposition 13, there is an integer point $\boldsymbol{z}' \in \mathrm{conv}(\{f^n(\boldsymbol{z}) : n \geq d\})$ such that $\inf_{\boldsymbol{\mu} \in T(\boldsymbol{\gamma})} \Phi_{E_i}^{(i)}(\boldsymbol{z}', \boldsymbol{\mu}) > 0$ for $i = 1, \ldots, m$. By Proposition 9(1), each loop Q_i fails to terminate on $\boldsymbol{z}'$ and hence also Q is non-terminating on $\boldsymbol{z}'$. ◀

Proposition 15 leads to the following procedure for deciding termination of a given linear loop Q, as shown in (11).

1. Compute the eigenvalues of the matrix corresponding to the loop update function, as given in (1).
2. Compute the dominance preorder $\preccurlyeq$ among eigenvalues.
3. Compute a basis of the group of multiplicative relations $L(\boldsymbol{\gamma})$.
4. Return "non-terminating" if some set $W_{E_1,\ldots,E_m}$ contains an integer point and otherwise return "terminating".

In terms of effectiveness, Steps 1 and 2 can be accomplished via standard symbolic computations with algebraic numbers. (We refer to [18] for a detailed treatment in a very similar setting.) By Theorem 4, computing a basis of $L(\boldsymbol{\gamma})$ reduces to checking a finite collection of multiplicative relations among algebraic numbers. Given a basis of $L(\boldsymbol{\gamma})$ we can directly obtain representations of each set $W_{E_1,\ldots,E_m}$ as semi-algebraic subsets of $\mathbb{R}^d$. Finally, since $W_{E_1,\ldots,E_m}$ is convex, we can decide the existence of an integer point in each set $W_{E_1,\ldots,E_m}$ using Theorem 3.

We have thus established the main result of the paper:

▶ **Theorem 16.** *There is a procedure to decide termination of single-path linear loops (of the form specified in* (11)*) over the integers.*

Abstract

We study countably infinite Markov decision processes with Büchi objectives, which ask to visit a given subset F of states infinitely often. A question left open by T.P. Hill in 1979 [10] is whether there always exist ε-optimal Markov strategies, i.e., strategies that base decisions only on the current state and the number of steps taken so far. We provide a negative answer to this question by constructing a non-trivial counterexample. On the other hand, we show that Markov strategies with only 1 bit of extra memory are sufficient.

1 Introduction

Background. Markov decision processes (MDPs) are a standard model for dynamic systems that exhibit both stochastic and controlled behavior [16]. MDPs play a prominent role in numerous domains, including artificial intelligence and machine learning [19, 18], control theory [4, 1], operations research and finance [5, 17], and formal verification [9, 2]. In an MDP, the system starts in the initial state and makes a sequence of transitions between states. Depending on the type of the current state, either the controller gets to choose an enabled transition (or a distribution over transitions), or the next transition is chosen randomly according to a defined distribution. By fixing a strategy for the controller, one obtains a probability space of runs of the MDP. The goal of the controller is to optimize the expected value of some objective function on the runs.

The type of strategy needed for an optimal (resp. ε-optimal) strategy for some objective is also called the *strategy complexity* of the objective. There are different types of strategies, depending on whether one can take the whole history of the run into account (history-dependent; (H)), or whether one is limited to a finite amount of memory (finite memory;

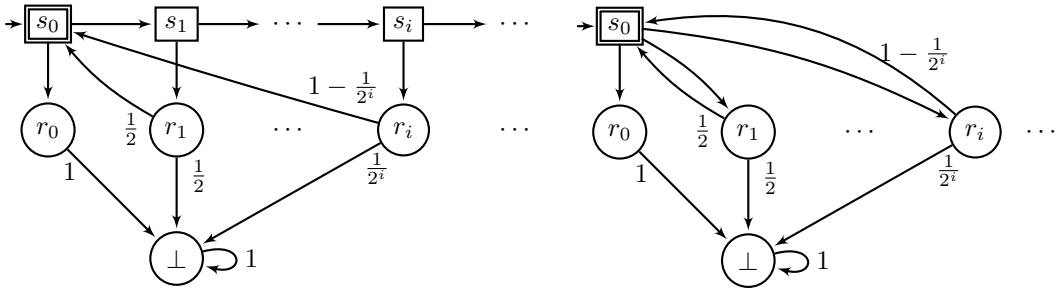
(F)) or whether decisions are based only on the current state (memoryless; (M)). Moreover, the strategy type depends on whether the controller can randomize (R) or is limited to deterministic choices (D). The simplest type MD refers to memoryless deterministic strategies. *Markov strategies* are strategies that base their decisions only on the current state and the number of steps in the history or the run. Thus they do use infinite memory, but only in a very restricted form by maintaining an unbounded step-counter. For finite MDPs, there exist optimal MD-strategies for many (but not all) objectives [6, 7, 8, 16], but the picture is more complex for countably infinite MDPs [13, 15, 16].

We study here so-called *Goal* objectives defined via a subset of goal states F: In the basic Goal objective (also called the *Reachability* objective) one simply wants to reach the set F. In the *Büchi* objective one wants to visit the set F infinitely often. For finite MDPs there exist optimal MD-strategies for both these objectives [7, 16]. For countably infinite MDPs, optimal strategies (where they exist) and ε-optimal strategies for Reachability can be chosen MD [15, 16]. Similarly, optimal strategies for Büchi (where they exist) can be chosen MD [13]. However, ε-optimal strategies for Büchi require infinite memory (cannot be chosen FR); cf. [13, 14].



(a) Finitely branching, but infinitely many controlled states.

(b) Infinitely branching, but just one controlled state.

Figure 1 Two MDPs where ε-optimal strategies for Büchi require infinite memory. Let $F = \{s_0\}$ be the set of goal states. Here and throughout the paper we indicate goal states by double borders, and controlled states as rectangles.

▶ **Example 1.** Consider the MDPs in Figure 1. Every finite memory (FR) strategy will only attain probability 0 for Büchi in these examples [13]. However, there exists an ε-optimal Markov strategy for every $\varepsilon > 0$: At the i-th time that state s_0 is visited, pick the successor state r_{i+k} where k is some sufficiently large number depending on ε, e.g., $k = \lceil \log_2(1/\varepsilon) \rceil$. For example (b) this can easily be done with a step-counter since s_0 is visited for the i-th time in step $2(i-1)$ unless the system has reached the state $\perp$. For example (a), under this strategy, state s_0 is visited for the i-th time in step $\sum_{j=1}^{i-1}(k+j+1)$ unless the system has reached the state $\perp$. ◀

▶ **Example 2.** Consider the MDP from Figure 2, taken from [11, Example 4.2]. Every FR-strategy attains only probability 0 of Büchi. Moreover, the strategy that, in state s_0, subsequently picks $r_1, r_2, \ldots$ also attains probability 0, unlike in Example 1. But a different infinite-memory strategy achieves a positive probability. Indeed, let σ be the strategy that, in s_0, picks 2^1 times r_1 and then 2^2 times r_2 and $\ldots 2^i$ times r_i etc. This strategy σ achieves a positive probability of Büchi. (In more detail, σ achieves a positive probability of not falling in a losing sink $\perp$, and in almost all of the remaining runs it visits a goal state infinitely often.) Note that σ is a Markov strategy. ◀

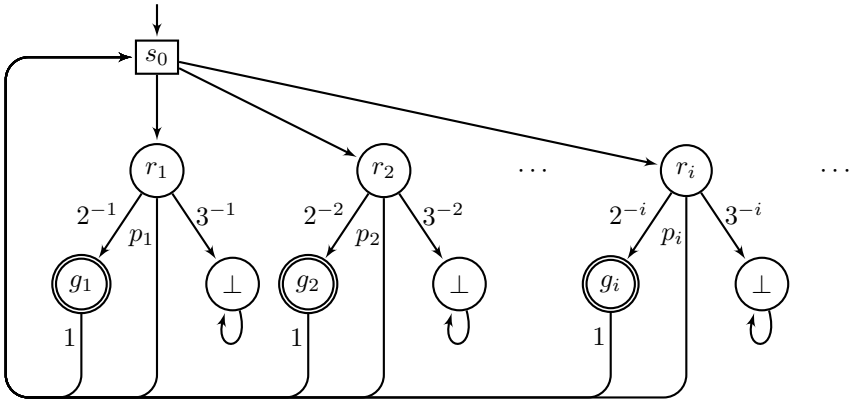


Figure 2 An MDP where ε-optimal strategies for Büchi require infinite memory. The transition probability p_i stands for $1 - 2^{-i} - 3^{-i}$. The state s_0 is the only controlled state.

The open problem. While the MDPs in Examples 1 and 2 require infinite memory, Markov strategies suffice for them. Such examples led to the question whether there always exists a family of ε-optimal Markov strategies for Büchi in all countably infinite MDPs.

A partial answer was given by Hill [10] (Proposition 5.1), who showed that ε-optimal Markov strategies for Büchi exist in the special case where the MDP contains only a *finite* number of controlled states. This result applies to the MDPs from Example 2 and Figure 1b), but not directly to the one in Figure 1a).

The question for general MDPs was stated as an open problem in [10] (p.158, l.4) and mentioned again in [11] (Q1 in Section 5).

Our contributions. We provide a negative answer to the open problem. We construct a non-trivial example of a countable acyclic and finitely branching MDP and prove that no ε-optimal Markov strategies for Büchi exist for it (for any $\varepsilon < 1$). In combination with the example from Figure 1, this shows that for general MDPs neither finite memory (FR) nor Markov strategies are sufficient.

Secondly, we provide an upper bound on the strategy complexity of Büchi. We show that for *acyclic* countable MDPs there always exist ε-optimal strategies that are deterministic and use only one bit of memory. Since every MDP can be transformed into an acyclic one by encoding a step-counter into the states, it follows that general countable MDPs have ε-optimal strategies for Büchi that are deterministic and use only a step-counter plus one extra bit of memory. Thus Markov strategies are almost, but not quite, sufficient. Table 1 summarizes these results.

Table 1 Existence of various types of ε-optimal strategies for the Büchi objective, for several classes of MDPs. New results are in boldface.

General MDP	×	×	×	**×**	**✓**

2 Preliminaries

A *probability distribution* over a countable set S is a function $f : S \to [0,1]$ with $\sum_{s \in S} f(s) = 1$. We write $\mathcal{D}(S)$ for the set of all probability distributions over S.

For a set S we write S^* (resp. S^ω) for the set of all finite (resp. infinite) sequences of elements in S. We use slightly generalized regular expressions for sets of sequences, e.g., if $s_0 \in S$ we may write $s_0 S^\omega$ for the set of infinite sequences starting with s_0.

Markov decision processes. A *Markov decision process* (MDP) $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ consists of a countable set S of *states*, which is partitioned into a set $S_\Box$ of *controlled states* and a set $S_\bigcirc$ of *random states*, a *transition relation* $\longrightarrow \subseteq S \times S$, and a *probability function* $P : S_\bigcirc \to \mathcal{D}(S)$. We write $s \longrightarrow s'$ if $(s, s') \in \longrightarrow$, and refer to s' as a *successor* of s. We assume that every state has at least one successor. The probability function P assigns to each random state $s \in S_\bigcirc$ a probability distribution $P(s)$ over its (non-empty) set of successor states. A *sink in* $\mathcal{M}$ is a subset $T \subseteq S$ closed under the $\longrightarrow$ relation, that is, $s \in T$ and $s \longrightarrow s'$ implies that $s' \in T$.

An MDP is *acyclic* if the underlying directed graph $(S, \longrightarrow)$ is acyclic, i.e., there is no directed cycle. It is *finitely branching* if every state has finitely many successors and *infinitely branching* otherwise. An MDP without controlled states ($S_\Box = \emptyset$) is called a *Markov chain*.

Strategies and Probability Measures. A *run* ρ is an infinite sequence $s_0 s_1 \cdots$ of states such that $s_i \longrightarrow s_{i+1}$ for all $i \in \mathbb{N}$; write $\rho(i) \stackrel{\text{def}}{=} s_i$ for the i-th state along ρ. A *partial run* is a finite prefix of a run. We say that (partial) run ρ *visits* s if $s = \rho(i)$ for some i, and that ρ starts in s if $s = \rho(0)$.

A *strategy* is a function $\sigma : S^* S_\Box \to \mathcal{D}(S)$ that assigns to partial runs $\rho s \in S^* S_\Box$ a distribution over the successors $\{s' \in S \mid s \longrightarrow s'\}$. The set of all strategies in $\mathcal{M}$ is denoted by $\Sigma_\mathcal{M}$ (we omit the subscript and write Σ if $\mathcal{M}$ is clear from the context). A (partial) run $s_0 s_1 \cdots$ is induced by strategy σ if for all i either $s_i \in S_\Box$ and $\sigma(s_0 s_1 \cdots s_i)(s_{i+1}) > 0$, or $s_i \in S_\bigcirc$ and $P(s_i)(s_{i+1}) > 0$.

An MDP $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$, an initial state $s_0 \in S$, and a strategy σ induce a probability space in which the outcomes are runs starting in s_0 and with measure $\mathcal{P}_{\mathcal{M},s_0,\sigma}$ defined as follows. It is first defined on *cylinders* $s_0 s_1 \dots s_n S^\omega$, where $s_1, \dots, s_n \in S$: if $s_0 s_1 \dots s_n$ is not a partial run induced by σ then $\mathcal{P}_{\mathcal{M},s_0,\sigma}(s_0 s_1 \dots s_n S^\omega) \stackrel{\text{def}}{=} 0$. Otherwise, $\mathcal{P}_{\mathcal{M},s_0,\sigma}(s_0 s_1 \dots s_n S^\omega) \stackrel{\text{def}}{=} \prod_{i=0}^{n-1} \bar{\sigma}(s_0 s_1 \dots s_i)(s_{i+1})$, where $\bar{\sigma}$ is the map that extends σ by $\bar{\sigma}(ws) = P(s)$ for all $ws \in S^* S_\bigcirc$. By Carathéodory's theorem [3], this extends uniquely to a probability measure $\mathcal{P}_{\mathcal{M},s_0,\sigma}$ on the Borel σ-algebra $\mathcal{F}$ of subsets of $s_0 S^\omega$. Elements of $\mathcal{F}$, i.e., measurable sets of runs, are called *events* or *objectives* here. For $X \in \mathcal{F}$ we will write $\overline{X} \stackrel{\text{def}}{=} s_0 S^\omega \setminus X \in \mathcal{F}$ for its complement and $\mathcal{E}_{\mathcal{M},s_0,\sigma}$ for the expectation w.r.t. $\mathcal{P}_{\mathcal{M},s_0,\sigma}$. We drop the indices wherever possible without introducing ambiguity.

Strategy Classes. Strategies are in general *randomized* (R) in the sense that they take values in $\mathcal{D}(S)$. A strategy σ is *deterministic* (D) if $\sigma(\rho)$ is a Dirac distribution for all runs $\rho \in S^* S_\Box$.

We formalize the amount of *memory* needed to implement strategies. Let M be a countable set of memory modes, and let $\tau : \mathsf{M} \times S \to \mathcal{D}(\mathsf{M} \times S)$ be a function that meets the following two conditions: for all modes $\mathsf{m} \in \mathsf{M}$,

- for all controlled states $s \in S_\Box$, the distribution $\tau(\mathsf{m}, s)$ is over $\mathsf{M} \times \{s' \mid s \longrightarrow s'\}$.
- for all random states $s \in S_\bigcirc$, we have $\sum_{\mathsf{m}' \in \mathsf{M}} \tau(\mathsf{m}, s)(\mathsf{m}', s') = P(s)(s')$.

The function τ together with an initial memory mode m_0 induce a strategy $\sigma_\tau : S^*S_\Box \to \mathcal{D}(S)$ as follows. Consider the Markov chain with the set $\mathsf{M} \times S$ of states and the probability function τ. A sequence $\rho = s_0 \cdots s_i$ corresponds to a set $H(\rho) = \{(\mathsf{m}_0, s_0) \cdots (\mathsf{m}_i, s_i) \mid \mathsf{m}_0, \ldots, \mathsf{m}_i \in \mathsf{M}\}$ of runs in this Markov chain. Each $\rho s \in s_0 S^* S_\Box$ induces a probability distribution $\mu_{\rho s} \in \mathcal{D}(\mathsf{M})$, the probability of being in state (m, s) conditioned on having taken some partial run from $H(\rho s)$. We define σ_τ such that $\sigma_\tau(\rho s)(s') = \sum_{\mathsf{m},\mathsf{m}' \in \mathsf{M}} \mu_{\rho s}(\mathsf{m}) \tau(\mathsf{m}, s)(\mathsf{m}', s')$ for all $\rho s \in S^* S_\Box$ and all $s' \in S$.

We say that a strategy σ can be *implemented* with memory M if there exist $\mathsf{m}_0 \in \mathsf{M}$ and τ such that $\sigma_\tau = \sigma$. We define certain classes of strategies:

- A strategy σ is *finite memory* (F) if there exists a finite memory M implementing σ.
- A strategy σ is *memoryless* (M) (also called *positional*) if it can be implemented with a memory of size 1. We may view M-strategies as functions $\sigma : S_\Box \to \mathcal{D}(S)$.
- A strategy σ is *1-bit* if it can be implemented with a memory of size 2. Such a strategy is then determined by a function $\tau : \{0,1\} \times S \to \mathcal{D}(\{0,1\} \times S)$. Intuitively τ uses one bit of memory to capture two different modes.
- A strategy σ is *Markov* if it can be implemented with the natural numbers $\mathbb{N}$ as the memory, and a function τ such that the distribution $\tau(\mathsf{m}, s)$ is over $\{\mathsf{m}+1\} \times S$ for all $\mathsf{m} \in \mathsf{M}$ and $s \in S$. Intuitively, such a strategy depends only on the the current state and the number of steps taken so far, i.e., it has access to a step-counter. We view Markov strategies as functions $\sigma : \mathbb{N} \times S_\Box \to \mathcal{D}(S)$. Note that such a strategy is generally not finite memory.
- A strategy σ is *1-bit Markov* if it can be implemented with $\mathbb{N} \times \{0,1\}$ as the memory, and a function τ such that the distribution $\tau(n, b, s)$ is over $\{n+1\} \times \{0,1\} \times S$ for all $(n, b) \in \mathsf{M}$ and $s \in S$. We view such strategies as functions $\sigma : \mathbb{N} \times \{0,1\} \times S_\Box \to \mathcal{D}(\{0,1\} \times S)$.

Payoffs, Values, Optimality. We are interested in strategies to maximize the expectation of a given measurable *payoff* function $f : S^\omega \to \mathbb{R}$, a random variable that assigns a real value to every run. The *value* of state s (w.r.t. f) is the supremum of expected values of f over all strategies:

$$\mathtt{val}_{\mathcal{M},f}(s) \stackrel{\text{def}}{=} \sup_{\sigma \in \Sigma} \mathcal{E}_{\mathcal{M},s,\sigma}(f),$$

For $\varepsilon \geq 0$ and $s \in S$, we say that a strategy σ is *ε-optimal* iff $\mathcal{E}_{\mathcal{M},s,\sigma}(f) \geq \mathtt{val}_{\mathcal{M},f}(s) - \varepsilon$ and *uniformly* ε-optimal iff this holds for every $s \in S$. A (uniformly) 0-optimal strategy is simply called (uniformly) *optimal*.

In this paper, we will need two types of payoff functions. The first is the *total reward*, a random variable given as $f(\rho) \stackrel{\text{def}}{=} \sum_{t=0}^{\infty} r(\rho(t))$, where $r : S \to \mathbb{R}$ is some given *reward* function. A useful fact [16, Theorem 7.1.9] is that if S is finite and the range of r is bounded then there exist optimal strategies (for total reward) which are memoryless and deterministic.

The second type of payoff functions we consider are those with range $\{0,1\}$. Each such payoff function f uniquely identifies an objective (set of runs) φ by viewing f as the characteristic function of φ, i.e., $f(\rho) = 1$ if $\rho \in \varphi$ and 0 otherwise. Then $\mathcal{E}_{\mathcal{M},s,\sigma}(f) = \mathcal{P}_{\mathcal{M},s,\sigma}(\varphi)$. We call this the *probability of achieving* φ (using strategy σ starting from the state s) and simply write $\mathtt{val}_{\mathcal{M},\varphi}(s) = \mathtt{val}_{\mathcal{M},f}(s) = \sup_{\sigma \in \Sigma} \mathcal{P}_{\mathcal{M},s,\sigma}(\varphi)$.

Our main focus are *reachability* (sometimes also called *goal*) and *Büchi* objectives, which are determined by a set of states $F \subseteq S$ and defined as follows. Let us slightly abuse notation and identify F with its characteristic function, i.e., $F(s) = 1$ if $s \in F$.

- The *reachability* objective is to visit F at least once during a run. The corresponding payoff is $f(\rho) \stackrel{\text{def}}{=} \max_{t \in \mathbb{N}} \rho(t)$, and we define $\mathtt{Goal}(F) \stackrel{\text{def}}{=} \{\rho \in S^\omega \mid \max_{t \in \mathbb{N}} F(\rho(t)) = 1\}$;
- The *Büchi* objective is to visit F infinitely often. The corresponding payoff function is $f(\rho) \stackrel{\text{def}}{=} \limsup_{t \to \infty} F(\rho(t))$, and we let $\mathtt{Büchi}(F) \stackrel{\text{def}}{=} \{\rho \in S^\omega \mid \limsup_{t \to \infty} F(\rho(t)) = 1\}$.

3 The Lower Bound

In this section we solve Hill's problem ([10] and [11, Q1]) by exhibiting an MDP where the initial state has value 1 w.r.t. the Büchi objective, but every Markov strategy achieves this objective with probability 0. As explained in the introduction, it follows that in acyclic MDPs, ε-optimal MR-strategies are not guaranteed to exist. In fact, in the following theorem we prove the latter fact first, and subsequently generalize it to solve Hill's problem.

▶ **Theorem 3.** *There exists an acyclic MDP $\mathcal{M}$, a state s_0 and a set of states F such that*

1. *for every Markov strategy σ, we have $\mathcal{P}_{\mathcal{M},s_0,\sigma}(\texttt{Büchi}(F)) = 0$, and*
2. $\texttt{val}_{\texttt{Büchi}(F)}(s_0) = 1$ *and for every $\varepsilon > 0$ there exists a deterministic 1-bit strategy σ_ε s.t. $\mathcal{P}_{\mathcal{M},s_0,\sigma_\varepsilon}(\texttt{Büchi}(F)) \geq 1 - \varepsilon$.*

In the remainder of this section we provide a proof sketch. The full proof is in [12].

Proof sketch for Theorem 3. Our construction is based on an infinite MDP $\mathcal{M}$ that consists of a chain of height-n trees, T^n, for $n \in \mathbb{N} = \{1, 2, \ldots\}$. Figure 3 depicts its initial segment T^1, T^2, T^3. Each such tree is "rooted" at a brown state on the top level, with a transition incoming from a blue state. We make use of some conventions that simplify the presentation and the analysis. In Figure 3, the different colors of the states highlight the structure of the MDP; the colors are also indicated by letters in the states: blue (L), brown (B), yellow (Y), red (R), green (G), white (W). The start state, s_0, is the blue state in the top-left corner. The controlled states are exactly the yellow states. The goal set F consists of the green states at the bottom. Two transitions emanate from each red state: a black (right) transition and a red (left) transition, both leading to the same (brown or green) state.

We consider the strengthened Büchi objective that asks to see F infinitely often and moreover that *no red transition* is taken. This corresponds exactly to the normal Büchi objective if we redirect every red transition to an infinite (losing) chain of non-green states (not depicted in Figure 3).

We first argue that no MR-strategy achieves a positive probability of that objective. Then we show that the MDP $\mathcal{M}$ can be modified so that no Markov strategy achieves a positive probability.

Intuition behind the construction of $\mathcal{M}$. The objective, say φ, of visiting infinitely many green states and no red transition creates tension between trying to visit green states and avoiding too many red states (the latter states incur a risk of taking a red transition). In the proof we need to show that no memoryless strategy strikes a good balance between these competing goals. On the one end of the spectrum, an MR-strategy might always choose the upward transition in the yellow states (which are the only controlled states). But such a strategy never visits any green state, thus clearly violates φ. On the other end of the spectrum lies the "greedy" MR-strategy, which always chooses the downward transition in the yellow states, in order to visit as many green states as possible. Indeed, under this strategy, let u_n denote the probability that, starting in the top-left brown state of T^n, no green state is visited in T^n. By induction (given in [12]) one can show that there is $u < 1$ such that $u_n \leq u$ holds for all n. Considering the probability of the transitions emanating from the blue states (at the top), the expected overall number of visited green states is at least $\sum_{n=1}^{\infty} \frac{1}{n}(1 - u_n) \geq (1 - u) \sum_{n=1}^{\infty} \frac{1}{n} = \infty$. It is not hard to strengthen this statement so that the greedy strategy almost surely visits infinitely many green states. So the greedy strategy satisfies one part of φ, but it does so at the expense of visiting many red states. Red states though are associated with a risk of taking a red transition, and it follows from the proof in [12] that the greedy strategy almost surely ends up taking at least one (and indeed infinitely many) red transition(s).

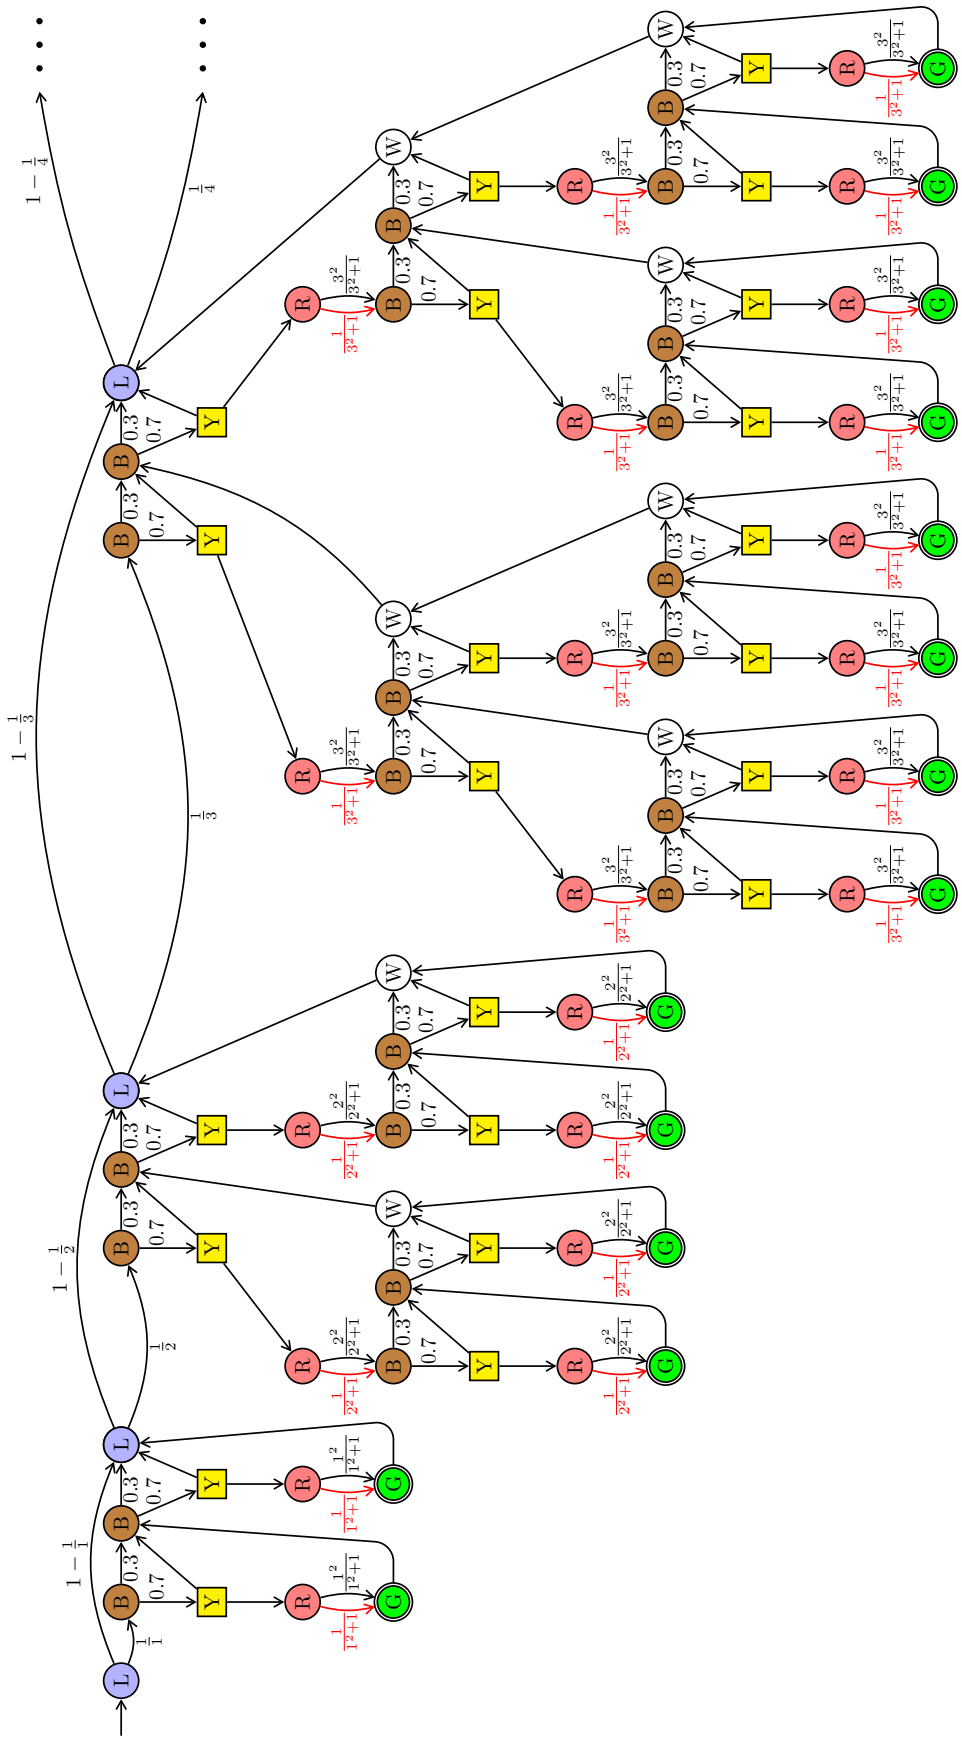

Figure 3 For this acyclic MDP $\mathcal{M}$ there are ε-optimal deterministic 1-bit strategies for the Büchi objective $\texttt{Büchi}(T)$ where T contains exactly all green states. No MR-strategy achieves even a positive probability.

Good 1-bit strategies. The two competing goals discussed in the previous paragraph can be balanced using a deterministic 1-bit strategy, which we describe in the following. This strategy, σ_1, sets its bit to 0 whenever a blue state (at the top) is entered. While the bit is 0, in each tree T^n it maximizes the probability of visiting a green state by choosing the downward transition in the yellow states, thus accepting a certain risk of taking a red transition. However, if and when a green state in T^n is visited, the bit is set to 1, and for the remaining sojourn in T^n the strategy σ_1 chooses the upward transitions in the yellow states, thus avoiding any risk of a red transition in the remainder of T^n. Although σ_1 appears to visit fewer green states than the aforementioned "greedy" MR-strategy, σ_1 still visits infinitely many green states almost surely. This is because for each tree T^n, the two strategies have the same probability of visiting at least one green state in T^n. The strategy σ_1 can be improved, for each $\varepsilon > 0$, to achieve φ with probability at least $1 - \varepsilon$, by fixing the bit to 1 in the first k trees $T^1, \ldots, T^k$, for a k that depends on ε. Thus the first k trees are virtually skipped, eliminating the risk of taking any red transition there. In this way one can make the risk of taking a red transition arbitrarily small, while still visiting infinitely many green states with probability 1.

No good MR-strategies. We need to show that not only the extreme MR-strategies described above are inadequate but that every MR-strategy achieves φ with probability 0. To this end, for each tree T^n, define two probabilities:

- t_n (for "total success"): the probability that, starting in the top-left brown state of T^n, at least one green state but no red transition is visited in T^n;
- d_n (for "death"): the probability that, starting in the top-left brown state of T^n, a red transition is visited in T^n.

A very technical proof shows that $d_n \geq 0.008 \cdot t_n$ holds for all n, and this key inequality captures the inability of *any* MR-strategy to strike an adequate balance between the mentioned competing goals. Indeed, one can show that for an MR-strategy to have a positive probability of not visiting any red transition, the series $\sum_{n=1}^{\infty} \frac{1}{n} \cdot d_n$ needs to converge; but to have a positive probability of visiting infinitely many green states, the series $\sum_{n=1}^{\infty} \frac{1}{n} \cdot t_n$ needs to diverge (in both cases, the factor $\frac{1}{n}$ is the probability of visiting the top-left brown node of T^n). By the inequality above, this is impossible.

No good Markov strategies. For the proof of Theorem 3, we also need to show that all Markov strategies achieve probability 0. To this end, we modify the MDP $\mathcal{M}$ so that for each state, all paths from the initial state s_0 to s have the same length. This can be achieved by replacing some transitions in $\mathcal{M}$ by longer chains consisting of non-green states. This modification does not change the fact that MR-strategies achieve probability 0. But since in the new MDP each state can only be visited at a certain time, which is known a priori, a step-counter does not help. Hence all Markov strategies, like MR-strategies, achieve φ with probability 0. ◀

Theorem 3 answers Hill's question negatively. By combining the MDP from Theorem 3 with one of the MDPs from Figure 1 (by adding a new initial random state that branches to the MDPs with probability $\frac{1}{2}$ each), one can even construct a single MDP whose value w.r.t. $\texttt{Büchi}(F)$ is 1, but every FR- and every Markov strategy achieves probability 0.

A slight modification of the example above yields a lower bound on the memory requirements for the almost-sure parity objective. Recall that the parity objective is defined on systems whose states are labeled by a finite set of colors $C \stackrel{\text{def}}{=} \{1, 2, \ldots, max\} \subseteq \mathbb{N}$, where a run is in $\texttt{Parity}(C)$ iff the highest color that is seen infinitely often in the run is even.

▶ **Corollary 4.** *There exist an acyclic MDP $\mathcal{M}'$ with colors $\{1,2,3\}$ and a state s_0 such that*
1. *for every Markov strategy σ, we have $\mathcal{P}_{\mathcal{M}',s_0,\sigma}(\texttt{Parity}(\{1,2,3\})) = 0$, and*
2. *there exists a deterministic 1-bit strategy σ' such that $\mathcal{P}_{\mathcal{M}',s_0,\sigma'}(\texttt{Parity}(\{1,2,3\})) = 1$.*

Proof. We obtain $\mathcal{M}'$ by modifying the MDP $\mathcal{M}$ from Theorem 3 as follows. Label all green states in F by color 2 and the rest by color 1. Then modify each red transition to go to its target via a fresh state labeled by color 3. Clearly $\mathcal{M}'$ is still acyclic and labeled by colors $\{1,2,3\}$.

From the proof of Theorem 3 (1), under every Markov strategy in $\mathcal{M}$ a.s. seeing infinitely many green states (in F) implies seeing infinitely many red transitions. So in $\mathcal{M}'$ every Markov strategy σ a.s. either sees color 2 only finitely often or color 3 infinitely often, thus $\mathcal{P}_{\mathcal{M}',s_0,\sigma}(\texttt{Parity}(\{1,2,3\})) = 0$.

From the proof of Theorem 3 (2), there is a deterministic 1-bit strategy σ in $\mathcal{M}$ that attains probability $\geq 1/2$ for $\texttt{Büchi}(F)$ without taking any red transition and otherwise a.s. takes a red transition. This property of σ holds not only when starting from s_0 but from every other state as well. We obtain σ' in $\mathcal{M}'$ by continuing to play σ even after red transitions have been taken. Under σ' the probability of going through infinitely many red transitions (and seeing color 3) is $\leq (1/2)^\infty = 0$, and the probability of seeing infinitely many states in F (with color 2) is 1. Thus $\mathcal{P}_{\mathcal{M}',s_0,\sigma'}(\texttt{Parity}(\{1,2,3\})) = 1$. ◀

4 The Upper Bound

We show that acyclic MDPs admit ε-optimal deterministic 1-bit strategies for Büchi.

We start by giving some intuition why 1 bit of memory is needed and how it is used. A step $s' \longrightarrow s''$ from some controlled state s' is *value-decreasing* iff $\texttt{val}(s'') < \texttt{val}(s')$. While an optimal strategy can never tolerate any value-decreasing step, an ε-optimal strategy might have to take value-decreasing steps infinitely often. The trick is to keep the collective value-loss sufficiently small ($\leq \varepsilon$), while satisfying the other requirements of the objective. So the strategy needs to play "ever better" (i.e., tolerate only smaller and smaller value decreases) along a run. In general this requires infinite memory, since one might re-visit the same state infinitely often and needs to choose a different transition from it every time; cf. Figure 1. However, in an acyclic MDP, with high probability, the distance to the initial state increases with the number of steps taken. Thus one can partition the state space into separate regions, depending on the distance from the initial state, and fix an acceptable rate of value-decrease for each region. Just limiting the collective value-loss is not sufficient for Büchi, one also needs to make progress and visit the set of goal states F at least once in each region. The problem is that some runs might linger in some region too long, and visit F *many times*, but see too many value-decreasing steps at the rate of this region. Therefore, as soon as one has visited F in some region, one should try to get to the next outer region (further away from the initial state) where the rate of value-loss is smaller. Thus one needs 1 bit of memory to record whether one has already seen F in this region. (Remember that the same state can be reached by different runs with different histories.) Just 1 bit suffices, because the probability of returning to a previous inner region (and misinterpreting the bit) can be made arbitrarily small, since the MDP is acyclic.

▶ **Theorem 5.** *For every acyclic countable MDP $\mathcal{M}$, finite set of initial states I, set of states F and $\varepsilon > 0$, there exists a deterministic 1-bit strategy for $\texttt{Büchi}(F)$ that is ε-optimal from every $s \in I$.*

Proof. Let $\mathcal{M} = (S, S_\Box, S_\bigcirc, \longrightarrow, P)$ be an acyclic MDP, $I \subseteq S$ a finite set of initial states and $F \subseteq S$ a set of goal states and $\varphi \stackrel{\text{def}}{=} \texttt{Büchi}(F)$ denote the Büchi objective w.r.t. F. We prove the claim for finitely branching $\mathcal{M}$ first and transfer the result to general MDPs at the end. For every $\varepsilon > 0$ and every $s \in I$ there exists an ε-optimal strategy σ_s such that

$$\mathcal{P}_{\mathcal{M},s,\sigma_s}(\varphi) \geq \texttt{val}_{\mathcal{M},\varphi}(s) - \varepsilon. \tag{1}$$

However, the strategies σ_s might differ from each other and might use randomization and a large (or even infinite) amount of memory. We will construct a single deterministic strategy σ' that uses only 1 bit of memory such that $\forall_{s\in I}\, \mathcal{P}_{\mathcal{M},s,\sigma'}(\varphi) \geq \texttt{val}_{\mathcal{M},\varphi}(s) - 2\varepsilon$. This proves the claim as ε can be chosen arbitrarily small.

In order to construct σ', we first observe the behavior of the finitely many σ_s for $s \in I$ on an infinite, increasing sequence of finite subsets of S. Based on this, we define a second stronger objective φ' with

$$\varphi' \subseteq \varphi, \tag{2}$$

and show that all σ_s attain at least $\texttt{val}_{\mathcal{M},\varphi}(s) - 2\varepsilon$ w.r.t. φ', i.e.,

$$\forall_{s\in I}\, \mathcal{P}_{\mathcal{M},s,\sigma_s}(\varphi') \geq \texttt{val}_{\mathcal{M},\varphi}(s) - 2\varepsilon. \tag{3}$$

We construct σ' as a deterministic 1-bit *optimal* strategy w.r.t. φ' from all $s \in I$ and obtain

$$\begin{aligned}
\mathcal{P}_{\mathcal{M},s,\sigma'}(\varphi) &\geq \mathcal{P}_{\mathcal{M},s,\sigma'}(\varphi') && \text{by (2)} \\
&\geq \mathcal{P}_{\mathcal{M},s,\sigma_s}(\varphi') && \text{by optimality of } \sigma' \text{ for } \varphi' \\
&\geq \texttt{val}_{\mathcal{M},\varphi}(s) - 2\varepsilon && \text{by (3).}
\end{aligned}$$

Informal outline: Behavior of σ_s, objective φ' and properties (2) and (3). For the formal proof see [12].

Let $\mathsf{bubble}_k(I)$ be the set of states that can be reached from some initial state in I within at most k steps. Since I is finite and $\mathcal{M}$ is finitely branching, $\mathsf{bubble}_k(I)$ is finite for every k.

We define a sequence of sufficiently large and increasing numbers k_i and l_i with $k_i < l_i < k_{i+1}$ for $i \in \mathbb{N}$ and finite sets $K_i \stackrel{\text{def}}{=} \mathsf{bubble}_{k_i}(I)$ and $L_i \stackrel{\text{def}}{=} \mathsf{bubble}_{l_i}(I)$. Every run from a $s \in I$ according to σ_s must eventually leave each of these finite sets, because $\mathcal{M}$ is acyclic. Moreover, we choose these numbers so that once a run has left L_i it is very unlikely to return to K_i. Let $F_i \stackrel{\text{def}}{=} F \cap K_i \setminus L_{i-1}$. Runs according to σ_s are very likely to follow a particular pattern. Let $R_1 \stackrel{\text{def}}{=} (K_1 \setminus F_1)^* F_1$, $R_2 \stackrel{\text{def}}{=} (K_2 \setminus F_2)^* F_2$ and $R_{i+1} \stackrel{\text{def}}{=} (K_{i+1} \setminus (F_{i+1} \cup K_{i-1}))^* F_{i+1}$ for $i \geq 2$. We show that

$$\forall_{s\in I}\, \mathcal{P}_{\mathcal{M},s,\sigma_s}(\varphi \cap \overline{R_1 R_2 \dots R_{i+1}(S \setminus K_i)^\omega}) \quad \leq \quad \varepsilon \tag{4}$$

We now define the Borel objectives $R_{\leq i} \stackrel{\text{def}}{=} R_1 R_2 \dots R_i S^\omega$ and $\varphi' \stackrel{\text{def}}{=} \bigcap_{i\in\mathbb{N}} R_{\leq i}$. Since $F_i \cap F_k = \emptyset$ for $i \neq k$ and φ' implies a visit to the set F_i for all $i \in \mathbb{N}$, we have $\varphi' \subseteq \varphi$ and obtain (2). Using (4), we show that $\forall_{s\in I}\, \mathcal{P}_{\mathcal{M},s,\sigma_s}(\varphi') \geq \texttt{val}_{\mathcal{M},\varphi}(s) - 2\varepsilon$ and thus obtain (3).

Definition of the 1-bit strategy σ'. We now define a deterministic 1-bit strategy σ' that is optimal for objective φ' from every $s \in I$. First we define certain "suffix" objectives of φ'. Recall that $R_i = (K_i \setminus (F_i \cup K_{i-2}))^* F_i$. Let $R_{i,j} \stackrel{\text{def}}{=} R_i R_{i+1} \dots R_j S^\omega$ and $R_{\geq i} \stackrel{\text{def}}{=} \bigcap_{j\geq i} R_{i,j}$. Consider the objectives $R_{\geq i+1}$ for runs that start in states $s' \in F_i$. For every state $s' \in F_i$ we consider its value w.r.t. the objective $R_{\geq i+1}$, i.e., $\texttt{val}_{\mathcal{M},R_{\geq i+1}}(s') \stackrel{\text{def}}{=} \sup_{\hat{\sigma}} \mathcal{P}_{\mathcal{M},s',\hat{\sigma}}(R_{\geq i+1})$.

For every $i \geq 1$ we consider the finite subspace $K_i \setminus K_{i-2}$. In particular, it contains the sets F_{i-1} and F_i. We define a bounded total reward objective B_i for runs starting in F_{i-1} as follows. Runs that exit the subspace (either by leaving K_i or by visiting K_{i-2}) before visiting F_i get reward 0. All other runs must visit F_i eventually (since $\mathcal{M}$ is acyclic and the subspace is finite). When some run reaches the set F_i *for the first time* in some state s' then this run gets the reward of $\mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s')$. Using [16, Theorem 7.1.9], we show that there exists a uniform optimal MD-strategy σ_i for B_i on $K_i \setminus K_{i-2}$ in $\mathcal{M}$.

We now define σ' by combining different MD-strategies σ_i, depending on the current state and on the value of the 1-bit memory. The intuition is that the strategy σ' has two modes: normal-mode and next-mode. In a state $s' \in K_i \setminus K_{i-1}$, if the memory is $i \pmod 2$ then the strategy is in normal-mode and plays towards reaching F_i. Otherwise, the strategy is in next-mode and plays towards reaching F_{i+1}.

Initially σ' starts in a state $s \in I$ with the 1-bit memory set to 1. We define the behavior of σ' in a state $s' \in K_i \setminus K_{i-1}$ for every $i \geq 1$. If the 1-bit memory is $i \pmod 2$ and $s' \notin F_i$ then σ' plays like σ_i. (Intuitively, one plays towards F_i, since one has not yet visited it.) If the 1-bit memory is $i \pmod 2$ and $s' \in F_i$ then the 1-bit memory is set to $(i+1) \pmod 2$, and σ' plays like σ_{i+1}. (Intuitively, one records the fact that one has already seen F_i and then targets the next set F_{i+1}.) If the 1-bit memory is $(i+1) \pmod 2$ then σ' plays like σ_{i+1}. (Intuitively, one plays towards F_{i+1}, since one has already visited F_i.)

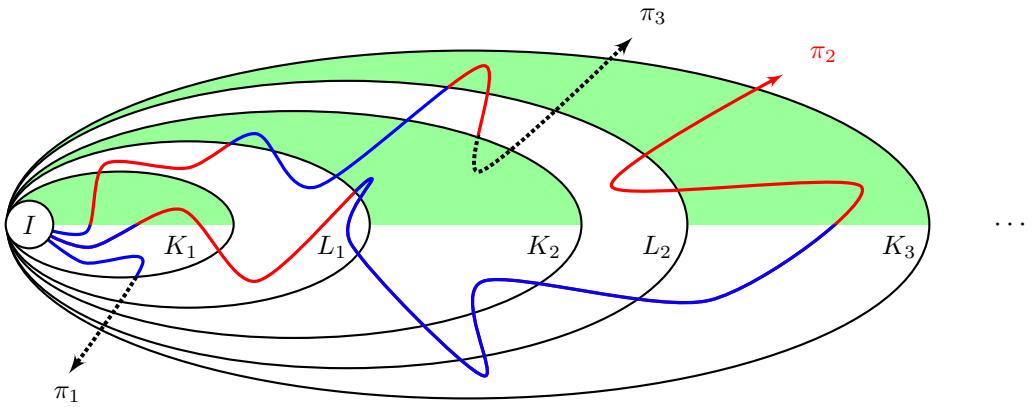

Figure 4 Memory updates along runs π_1, π_2, π_3, drawn in blue while the memory-bit is one and in red while the bit is zero. The green region in K_1 is F_1, and for all $i \geq 2$, the green region in $K_i \setminus L_{i-1}$ is F_i. Both π_1 and π_3 violate φ' and are drawn as dotted lines once they do.

Observe that if a run according to σ' exits some set K_i (and thus enters $K_{i+1} \setminus K_i$) with the bit still set to $i \pmod 2$ (normal-mode) then this run has not visited F_i and thus does not satisfy the objective φ'. (Or the same has happened earlier for some $j < i$, in which case also the objective φ' is violated.) An example is the run π_1 in Figure 4. However, if a run according to σ' exits some set K_i (and thus enters $K_{i+1} \setminus K_i$) with the bit set to $(i+1) \pmod 2$ (thus σ_{i+1} in next-mode) then in the new set $K_{i'} \setminus K_{i'-1}$ with $i' = i+1$ the bit is set to $i' \pmod 2$ and σ' continues to play like σ_{i+1} in normal-mode. Even if this run returns (temporarily) to K_i (but not to K_{i-1}) the strategy σ' continues to play like σ_{i+1} in next-mode. An example is the run π_2 in Figure 4. Finally, if a run returns to K_{i-1} after having visited F_i then it fails the objective φ', e.g., run π_3 in Figure 4.

The 1-bit strategy σ' is optimal for φ' from every $s \in I$. Let $s \in I$ be arbitrary. For a given run from s, let $\mathsf{firstin}(F_i)$ be the first state s' in F_i that is visited (if any). We define a bounded reward objective B'_i for runs starting at s as follows. Every run that does not satisfy the objective $R_{\leq i}$ gets assigned reward 0. Otherwise, consider a run from s that satisfies $R_{\leq i}$. When this run reaches the set F_i for the first time in some state s' then this run gets a reward of $\mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s')$. Note that this reward is ≤ 1.

We show that for all $i \in \mathbb{N}$

$$\mathtt{val}_{\mathcal{M},\varphi'}(s) = \mathtt{val}_{\mathcal{M},B'_i}(s) \tag{5}$$

Towards the $\geq$ inequality, let $\hat{\sigma}$ be an $\hat{\varepsilon}$-optimal strategy for B'_i from s. We define the strategy $\hat{\sigma}'$ to play like $\hat{\sigma}$ until a state $s' \in F_i$ is reached and then to switch to some $\hat{\varepsilon}$-optimal strategy for objective $R_{\geq i+1}$ from s'. Every run from s that satisfies φ' can be split into parts, before and after the first visit to the set F_i, i.e., $\varphi' = \{w_1 s' w_2 \mid w_1 s' \in R_{\leq i}, s' \in F_i, s' w_2 \in R_{\geq i+1}\}$. Therefore we obtain that $\mathcal{P}_{\mathcal{M},s,\hat{\sigma}'}(\varphi') \geq \mathcal{E}_{\mathcal{M},s,\hat{\sigma}}(B'_i) - \hat{\varepsilon} \geq \mathtt{val}_{\mathcal{M},B'_i}(s) - 2\hat{\varepsilon}$. Since this holds for every $\hat{\varepsilon} > 0$, we obtain $\mathtt{val}_{\mathcal{M},\varphi'}(s) \geq \mathtt{val}_{\mathcal{M},B'_i}(s)$.

Towards the $\leq$ inequality, let $\hat{\sigma}$ be any strategy for φ' from s. We have $\mathcal{P}_{\mathcal{M},s,\hat{\sigma}}(\varphi') \leq \sum_{s' \in F_i} \mathcal{P}_{\mathcal{M},s,\hat{\sigma}}(R_{\leq i} \cap \mathsf{firstin}(F_i) = s') \cdot \mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s') = \mathcal{E}_{\mathcal{M},s,\hat{\sigma}}(B'_i)$. Thus $\mathtt{val}_{\mathcal{M},\varphi'}(s) \leq \mathtt{val}_{\mathcal{M},B'_i}(s)$. Together we obtain (5).

For all $i \in \mathbb{N}$ and every state $s' \in F_i$ we show that

$$\mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s') = \mathtt{val}_{\mathcal{M},B_{i+1}}(s') \tag{6}$$

Towards the $\geq$ inequality, let $\hat{\sigma}$ be an $\hat{\varepsilon}$-optimal strategy for B_{i+1} from $s' \in F_i$. We define the strategy $\hat{\sigma}'$ to play like $\hat{\sigma}$ until a state $s'' \in F_{i+1}$ is reached and then to switch to some $\hat{\varepsilon}$-optimal strategy for objective $R_{\geq i+2}$ from s''. We have that $\mathcal{P}_{\mathcal{M},s',\hat{\sigma}'}(R_{\geq i+1}) \geq \mathcal{E}_{\mathcal{M},s',\hat{\sigma}}(B_{i+1}) - \hat{\varepsilon} \geq \mathtt{val}_{\mathcal{M},B_{i+1}}(s) - 2\hat{\varepsilon}$. Since this holds for every $\hat{\varepsilon} > 0$, we obtain $\mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s') \geq \mathtt{val}_{\mathcal{M},B_{i+1}}(s')$.

Towards the $\leq$ inequality, let $\hat{\sigma}$ be any strategy for $R_{\geq i+1}$ from $s' \in F_i$. We have

$$\begin{aligned}\mathcal{P}_{\mathcal{M},s',\hat{\sigma}}(R_{\geq i+1}) &\leq \sum_{s'' \in F_{i+1}} \mathcal{P}_{\mathcal{M},s',\hat{\sigma}}(R_{i+1} S^\omega \cap \mathsf{firstin}(F_{i+1}) = s'') \cdot \mathtt{val}_{\mathcal{M},R_{\geq i+2}}(s'') \\ &= \mathcal{E}_{\mathcal{M},s',\hat{\sigma}}(B_{i+1}).\end{aligned}$$

Thus $\mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s') \leq \mathtt{val}_{\mathcal{M},B_{i+1}}(s')$. Together we obtain (6).

We show, by induction on i, that σ' is optimal for B'_i for all $i \in \mathbb{N}$ from start state s, i.e.,

$$\mathcal{E}_{\mathcal{M},s,\sigma'}(B'_i) = \mathtt{val}_{\mathcal{M},B'_i}(s) \tag{7}$$

In the base case of $i = 1$ we have that $B'_1 = B_1$. The strategy σ' plays σ_1 until reaching F_1, which is optimal for objective B_1 and thus optimal for B'_1. For the induction step we assume (IH) that σ' is optimal for B'_i.

$$\begin{aligned}
\mathtt{val}_{\mathcal{M},B'_{i+1}}(s) &= \mathtt{val}_{\mathcal{M},B'_i}(s) && \text{by (5)} \\
&= \mathcal{E}_{\mathcal{M},s,\sigma'}(B'_i) && \text{by (IH)} \\
&= \sum_{s' \in F_i} \mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i} \cap \mathsf{firstin}(F_i) = s') \cdot \mathtt{val}_{\mathcal{M},R_{\geq i+1}}(s') && \text{by def. of } B'_i \\
&= \sum_{s' \in F_i} \mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i} \cap \mathsf{firstin}(F_i) = s') \cdot \mathtt{val}_{\mathcal{M},B_{i+1}}(s') && \text{by (6)} \\
&= \sum_{s' \in F_i} \mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i} \cap \mathsf{firstin}(F_i) = s') \cdot \mathcal{E}_{\mathcal{M},s',\sigma_{i+1}}(B_{i+1}) && \text{opt. of } \sigma_{i+1} \text{ for } B_{i+1} \\
&= \mathcal{E}_{\mathcal{M},s,\sigma'}(B'_{i+1}) && \text{by def. of } \sigma' \text{ and } B'_{i+1}
\end{aligned}$$

So σ' attains the value $\mathtt{val}_{\mathcal{M},B'_{i+1}}(s)$ of the objective B'_{i+1} from s and is optimal. Thus (7).

Now we show that σ' performs well on the objectives $R_{\leq i}$ for all $i \in \mathbb{N}$.

$$\mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i}) \geq \mathtt{val}_{\mathcal{M},\varphi'}(s) \tag{8}$$

We have

$$\begin{aligned}
\mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i}) &\geq \mathcal{E}_{\mathcal{M},s,\sigma'}(B'_i) && \text{since } B'_i \text{ gives rewards 0 for runs} \notin R_{\leq i} \text{ and} \leq 1 \text{ otherwise}\\
&= \mathtt{val}_{\mathcal{M},B'_i}(s) && \text{by (7)}\\
&= \mathtt{val}_{\mathcal{M},\varphi'}(s) && \text{by (5)}
\end{aligned}$$

So we get (8). Now we are ready to prove the optimality of σ' for φ' from s.

$$\begin{aligned}
\mathcal{P}_{\mathcal{M},s,\sigma'}(\varphi') &= \mathcal{P}_{\mathcal{M},s,\sigma'}(\cap_{i\in\mathbb{N}} R_{\leq i}) && \text{by def. of } \varphi'\\
&= \lim_{i\to\infty} \mathcal{P}_{\mathcal{M},s,\sigma'}(R_{\leq i}) && \text{by continuity of measures from above}\\
&\geq \lim_{i\to\infty} \mathtt{val}_{\mathcal{M},\varphi'}(s) && \text{by (8)}\\
&= \mathtt{val}_{\mathcal{M},\varphi'}(s)
\end{aligned}$$

From finitely to infinitely branching MDPs. Encode infinite branching into finite branching like in Figure 1, apply the above result to obtain a 1-bit strategy for the finitely branching version, and then transform this strategy back into a 1-bit strategy for the original MDP. ◀

Now we show our upper bound on the strategy complexity of Büchi for general MDPs.

▶ **Theorem 6.** *For every countable MDP $\mathcal{M}$, finite set of initial states I, set of states F and $\varepsilon > 0$, there exists a deterministic 1-bit Markov strategy for* $\mathtt{Büchi}(F)$ *that is ε-optimal from every $s \in I$.*

Proof. Encode a step-counter into the states to obtain an acyclic MDP, apply Theorem 5 to obtain an ε-optimal deterministic 1-bit strategy for it, and then transform this strategy back into an ε-optimal deterministic 1-bit Markov strategy in the original MDP. ◀

Abstract

Determinization of Büchi automata is a long-known difficult problem, and after the seminal result of Safra, who developed the first asymptotically optimal construction from Büchi into Rabin automata, much work went into improving, simplifying, or avoiding Safra's construction. A different, less known determinization construction was proposed by Muller and Schupp. The two types of constructions share some similarities but their precise relationship was still unclear. In this paper, we shed some light on this relationship by proposing a construction from nondeterministic Büchi to deterministic parity automata that subsumes both constructions: Our construction leaves some freedom in the choice of the successor states of the deterministic automaton, and by instantiating these choices in different ways, one obtains as particular cases the construction of Safra and the construction of Muller and Schupp. The basis is a correspondence between structures that are encoded in the macrostates of the determinization procedures – Safra trees on one hand, and levels of the split-tree, which underlies the Muller and Schupp construction, on the other hand. Our construction also allows for mixing the mentioned constructions, and opens up new directions for the development of heuristics.

1 Introduction

Büchi automata are finite automata for infinite words, and were initially introduced to show decidability of the logic S1S [2]. Infinite words can be used to model infinite execution traces of reactive, non-terminating systems, and serve as a translation target from logics like LTL (see, e.g., [15, 5]), which is a popular and well-understood specification formalism. For this reason, Büchi automata nowadays play a central role in formal methods like model-checking [1] and runtime-verification [6], because they can represent all ω-regular languages and are suitable for efficient algorithmic treatment. Unfortunately, the simplicity of the Büchi acceptance condition makes it crucially dependent on nondeterminism, i.e., not every ω-regular language (or LTL formula) can be accepted by a deterministic Büchi automaton (see, e.g., [16]). In some settings, this nondeterminism causes difficulties, such that algorithms require a representation of the property by a deterministic automaton, like in probabilistic model-checking (see, e.g., [1, Section 10.3]), or in synthesis (see [17] for an overview of the theory, and [9] for recent developments in practice).

A first determinization procedure that translates nondeterministic Büchi automata into deterministic automata was presented in [8]. The first asymptotically optimal and most well-known determinization construction for Büchi automata is the construction of Safra [13]. It translates a nondeterministic Büchi automaton with n states into a deterministic Rabin automaton with at most $2^{\mathcal{O}(n \log n)}$ states and $\mathcal{O}(n)$ sets in the acceptance condition. In applications like synthesis, the deterministic automaton is used to build a game that inherits as winning condition the acceptance condition of the automaton. In the theory of infinite duration games, the parity condition plays a central role (see, e.g., the survey [18]). For this reason, Piterman modified Safra's construction in order to directly obtain a parity automaton [11]. This construction was reformulated in [14], where also a tighter analysis of its state complexity is given with an upper bound of $\mathcal{O}(n!^2)$ for the number of states. A similar construction is presented in [12], adapted to the translation of ω-regular expressions directly into parity automata.

It is known that the Safra construction is essentially optimal [3], so there is no hope of significantly improving the worst-case upper bounds of the known constructions. However, the data structure of Safra trees (or history trees) that is used for the states of the deterministic automata, is challenging to deal with in implementations. Therefore, alternative approaches for determinization have been studied, leading to a family of constructions that are based on a construction by Muller and Schupp, which appeared in [10] as a by-product of a translation from alternating to non-deterministic tree automata. An explicit description of the construction specifically for determinization of Büchi automata is presented in [7]. A refinement of that construction is presented in [4], in which the states of the deterministic automaton are no longer represented as trees but as ordered and labelled tuples of sets.

The two approaches of Safra and Muller-Schupp show some similarities, as pointed out in the conclusion of [4], but from the existing formulations of the constructions, their precise relationship is not clear.

In this paper, we provide a construction for transforming nondeterministic Büchi automata into deterministic parity automata that cleanly explains the connections between the approaches of Safra and Muller-Schupp. It turns out that both types of constructions can be formulated on the same data structure, which can either be understood as ordered tuples of sets in which each set has an additional rank (a natural number), or as Safra trees in which each node has an additional rank (the same structure is essentially used in the constructions from [11] and [14]). The transitions are defined in terms of a sequence of simple operations, and it turns out that the two constructions only differ in one of these operations. In summary, our contributions are the following:

- We provide a new and relatively simple formulation of a Muller-Schupp style determinization construction that yields deterministic parity automata. Compared to previous constructions from [7] and [4], we encode less information in the states, and obtain a construction that has the same worst-case upper bound as the Safra style constructions.
- We extend our Muller-Schupp style construction by introducing a degree of freedom in the choice of the successor states. This freedom can be used to make the construction correspond to Safra's construction as presented in [11] and [14]. We therefore obtain a construction that unifies the approaches of Safra and Muller-Schupp in one general construction. Furthermore, the freedom in the choice of the successors of transitions also yields new ways of obtaining deterministic parity automata, and can be used in implementations as a heuristic to reduce the state space of the resulting automaton.

This work is organized as follows. After introducing the basic notations in Section 2, we present the new variant of the Muller-Schupp construction in Section 3, and then briefly review Safra's construction in Section 4. We explain the structural relationship between

those two constructions in Section 5, and finally introduce our generalized construction as a simple extension of the presented Muller-Schupp construction in Section 6. In Section 7 we discuss and conclude.

2 Preliminaries

First we briefly review basic definitions concerning ω-automata and ω-languages. If Σ is a finite alphabet, then Σ^ω is the set of all infinite *words* $w = w_0 w_1 \dots$ with $w_i \in \Sigma$. For $w \in \Sigma^\omega$ we denote by $w(i)$ the i-th symbol w_i. For convenience, we write $[n]$ for the set of natural numbers $\{1, \dots, n\}$. A *Büchi automaton* $\mathcal{A}$ is a tuple $(Q, \Sigma, \Delta, Q_0, F)$, where Q is a finite set of states, Σ a finite alphabet, $\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation and $Q_0, F \subseteq Q$ are the sets of initial and accepting states, respectively. When Q is understood and $X \subseteq Q$, then $\overline{X} := Q \setminus X$. We write $\Delta(p, x) := \{q \mid (p, x, q) \in \Delta\}$ to denote the set of *successors* of p on symbol x and $\Delta(P, x)$ for $\bigcup_{p \in P} \Delta(p, x)$. A *run* of an automaton on a word $w \in \Sigma^\omega$ is an infinite sequence of states $q_0, q_1, \dots$ starting in some $q_0 \in Q_0$ such that $(q_i, w(i), q_{i+1}) \in \Delta$ for all $i \geq 0$. An automaton is *deterministic* if $|Q_0| = 1$ and $|\Delta(p, x)| \leq 1$ for all $p \in Q, x \in \Sigma$, and *non-deterministic* otherwise. In this work, we assume Büchi automata to be non-deterministic and refer to them as NBA. A *transition-based deterministic parity automaton* (TDPA) is a deterministic automaton $(Q, \Sigma, \Delta, Q_0, c)$ where instead of $F \subseteq Q$ there is a *priority function* $c : \Delta \to \mathbb{N}$ assigning a natural number to each transition.

A run of an NBA is *accepting* if it contains infinitely many accepting states. A run of a TDPA is accepting if the smallest priority that appears infinitely often on transitions along the run is even. An automaton $\mathcal{A}$ *accepts* $w \in \Sigma^\omega$ if there exists an accepting run on w, and the language $L(\mathcal{A}) \subseteq \Sigma^\omega$ *recognized* by $\mathcal{A}$ is the set of all accepted words. To avoid confusion, we sometimes refer to states of TDPA that we construct as *macrostates* to distinguish them from the states of the underlying Büchi automaton.

3 A Simplified Muller-Schupp Construction

The essential idea for determinization using the Muller-Schupp construction is the following: given some Büchi automaton $\mathcal{A}$ and input word w, the resulting deterministic automaton conceptually traverses a specific run-tree of $\mathcal{A}$ on w, called reduced split-tree in [7], and tracks enough information to decide whether an infinite path with a specific shape exists in this tree. Such a path is known to exist if and only if w is accepted by $\mathcal{A}$. The construction presented in [7] uses a structure called contraction trees in order to track the relevant information. This has been simplified in [4] to macrostates that consist of an ordered tuple of disjoint sets of Büchi states, and two preorders over the states appearing in the tuple.

In this section, we further simplify the structure of the macrostates for the deterministic automaton to ordered tuples of disjoint sets of Büchi states, and a single additional linear order on these sets (formally expressed as a ranking function that assigns to each set a natural number). This also results in a relatively simple transition function on the macrostates.

The *reduced split-tree* $t^{rs}(\mathcal{A}, w)$ for NBA $\mathcal{A}$ and word $w \in \Sigma^\omega$ is an ordered infinite tree in which the nodes are labelled by state-sets, and each node has at most two successors. Formally, it is constructed as follows. The first level of the tree consists of the root node labelled by the initial states Q_0. To construct level $i + 1$ from level i, for each node at level i labelled by set S of states, let the *left child* of S be labelled by $\Delta(S, w(i)) \cap F$ and the *right child* by $\Delta(S, w(i)) \cap \overline{F}$, i.e., accepting and non-accepting successor states are separated. Then keep only the leftmost (wrt. the natural ordering of neighbors) occurrence of each state

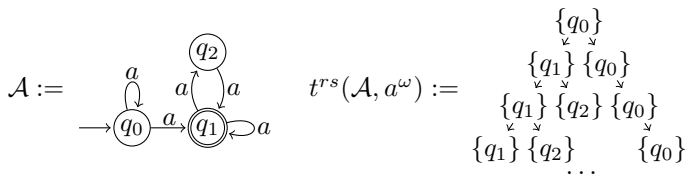

Figure 1 Example of a reduced split-tree $t^{rs}(\mathcal{A}, a^\omega)$ of an NBA $\mathcal{A}$. It has an infinite path representing the run q_0^ω and a left-path representing the run $q_0 q_1^\omega$, from which finite paths $q_0 q_1^* q_2$ branch off.

in the level and finally remove nodes labelled by $\emptyset$. Clearly, because of the normalization, the number of nodes on each level can be at most $|Q|$. An example of a reduced split-tree is shown in Figure 1. We call an infinite path in the tree that takes the left branch infinitely often a *left-path*. Reduced split-trees have the following useful property:

▶ **Lemma 1** ([7], Lemma 2). *$\mathcal{A}$ accepts $w \iff t^{rs}(\mathcal{A}, w)$ has a left-path.*
