In the following, we identify nodes in the same level with their label sets. To obtain a deterministic automaton, we augment the nodes of the reduced split-tree with number tokens that we call *(age-)ranks*, which are used to infer a left-path.

The new macrostates in the deterministic automaton represent levels of reduced split-trees and consist of a tuple of disjoint non-empty sets $t := (S_1, S_2, \ldots, S_n)$ equipped with a bijection $\alpha : [n] \to [n]$ satisfying $\alpha(n) = 1$, which assigns to each set S_i the rank $\alpha(i)$. We call a pair (α, t) that satisfies these constraints *ranked slice* and we call it *pre-slice*, if t contains empty sets or α is not a bijection. Notice that all macrostates are ranked slices, whereas pre-slices occur only during intermediate steps. We introduce the following useful notations to work with ranked slices. Let $|t| := n$ and $Q_t := \bigcup_{i=1}^{|t|} S_i$. The function $\mathsf{idx} : Q_t \to [|t|]$ maps each state $q \in Q_t$ to the tuple index i such that $q \in S_i$, and by $\alpha(q)$ we denote $\alpha(\mathsf{idx}(q))$ for $q \in Q_t$.

When reading symbol $x \in \Sigma$ in macrostate (α, t), the successor macrostate (α', t') is obtained by a sequence of successive operations step, prune and normalize, where, roughly,

- step interprets t as nodes on a reduced split-tree level and calculates the next level sets,
- prune removes the empty sets produced by step, reassigning ranks in a specific way, and
- normalize just turns the ranking function obtained after prune into a bijection again.

Below, we formally define these operations (step and prune are illustrated in Figure 2).

First we describe step, which constructs the next level of the reduced split-tree and passes each existing rank on to the respective right child. Let

$$\Delta_t(q, x) := \Delta(q, x) \setminus \Delta\Big(\bigcup_{i=1}^{\mathsf{idx}(q)-1} S_i, x\Big),$$

restricting for each state $q \in Q_t$ the successors to only those which are not reached by some other state located in a set to the left of q. Then, for each node S_i let $\hat{S}_{2i-1} := \Delta_t(S_i, x) \cap F$ be the *left child* and $\hat{S}_{2i} := \Delta_t(S_i, x) \cap \overline{F}$ the *right child*, containing the accepting and non-accepting normalized successors, respectively. Let $\hat{\alpha}(2i) := \alpha(i)$ and $\hat{\alpha}(2i-1) := n+1$, i.e., the right children inherit the rank of the parent and the left children all get the same new maximal rank $n+1$, resulting in a pre-slice $(\hat{\alpha}, \hat{t})$.

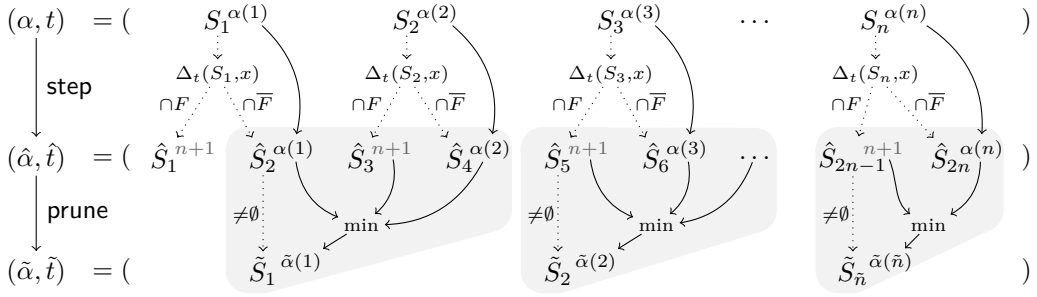

Figure 2 Abstract illustration of step and prune in a Muller-Schupp transition on some $x \in \Sigma$. The superscripts represent the assigned ranks. First, step calculates the normalized successors, separating accepting from non-accepting states and passing the parent rank on to the right child. In the illustration, we assume that the sets $\hat{S}_i \neq \emptyset$ for $i \in \{2, 5, 2n-1\}$, i.e., $x_1 = 2, x_2 = 5, x_{\tilde{n}} = x_3 = 2n-1$. Then prune keeps sets at these positions for the resulting tuple $\tilde{t}$, and $\tilde{\alpha}$ is obtained by taking the minimum of the ranks given by $\hat{\alpha}$ in the ranges spanning from one x_i up to the position before x_{i+1}. Finally $t' := \tilde{t}$ and $\tilde{\alpha}$ is normalized to α', while preserving strict ordering between positions wrt. $\tilde{\alpha}$. The dotted edges connect parent sets (in the top row) and resulting left/right children sets (bottom row) in the conceptual reduced split-tree, the solid edges show the movements of the rank values assigned to the sets.

Intuitively, in the prune operation, all ranks that mark empty sets after step are relocated onto the closest non-empty set to the left (or removed, if no such set exists). When multiple ranks occupy the same set, then the smallest one is preserved. Ranks that moved to the left in this way and are not removed, indicate a good (green) event, whereas ranks which were removed indicate a bad (red) event.

Formally, let $x_1 < x_2 < \ldots < x_{\tilde{n}}$ be the increasing sequence of all indices such that $\hat{S}_{x_j} \neq \emptyset$. Then prune returns $(\tilde{\alpha}, \tilde{t})$ with the tuple $\tilde{t} := (\hat{S}_{x_1}, \ldots, \hat{S}_{x_{\tilde{n}}})$ without empty sets, where $\tilde{\alpha}$ is defined as $\tilde{\alpha}(i) := \min\{\hat{\alpha}(j) \mid x_i \leq j < x_{i+1}\}$ with $x_{\tilde{n}+1} := |\hat{t}| + 1$.

The set of *green* ranks is given by $G := \mathsf{img}(\tilde{\alpha}) \cap \{\hat{\alpha}(j) \mid \hat{S}_j = \emptyset\}$, where $\mathsf{img}(\tilde{\alpha})$ denotes the image of $\tilde{\alpha}$. These are the ranks that mark empty sets after step and are not removed by prune. The set of *red* ranks given by $R := \mathsf{img}(\hat{\alpha}) \setminus \mathsf{img}(\tilde{\alpha})$ contains the ranks that were not preserved during prune. The set of *active ranks* is $A := G \uplus R$. Let $k := \min A$ (or $k := |Q| + 1$ if $A = \emptyset$) denote the *dominating* rank of the transition, i.e., the smallest active rank. We define the priority p of the transition as $2k$ if $k \in G$ and $2k - 1$ otherwise.

The function $\tilde{\alpha}$ might assign the same rank to several sets, and it might have gaps (unused rank values between used ones). So finally, normalize returns (α', t') with $t' := \tilde{t}$ and a final bijective ranking function $\alpha' : [|t'|] \to [|t'|]$ such that $\tilde{\alpha}(j) < \tilde{\alpha}(k) \Rightarrow \alpha'(j) < \alpha'(k)$ for all $j, k \in \{1, \ldots, |t'|\}$, i.e., a total order which is compatible with the preorder induced by $\tilde{\alpha}$. If there are several such ranking functions α', then any of these works.

A TDPA $\mathcal{B}$ is obtained by taking the initial state (α_0, t_0) with $t_0 := (Q_0), \alpha_0(1) := 1$ and a transition function that picks for each state a valid successor that satisfies the description above, and assigns the corresponding priority p to the edge. Observe that by construction, the sequence of states visited along some word $w \in \Sigma^\omega$ from the initial state represents exactly the levels of $t^{rs}(\mathcal{A}, w)$, marked with ranks.

▶ **Theorem 2.** *For a given NBA with n states, the TDPA obtained by the Muller-Schupp construction accepts the same language as the NBA, and its number of states is in $\mathcal{O}(n!^2)$.*

The correctness follows from the correctness of the generalized construction presented in Section 6. The claim on the state complexity directly follows from the upper bound given in [14, Proposition 2], and the bijection between the set of ranked slices and the set of ranked Safra trees presented in Section 5.

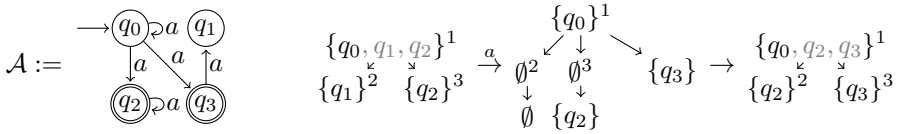

Figure 3 Example of a Safra-tree transition on letter a, based on NBA $\mathcal{A}$. The LIR position of nodes is depicted as superscript of the sets. The "redundant" states that are implicit in our definition are depicted in gray in the initial and resulting tree. In the intermediate step, the tree is depicted after calculating and pruning successor state sets. In the final tree the remaining actions are performed and LIR positions are updated. The transition has a red event for LIR position 2 and a green event for position 3. Because of the removal of the node at position 2 in the LIR, the node that originally was at position 3 moved up, whereas the fresh node labelled by $\{q_3\}$ comes last.

4 Sketch of the Safra Construction

In this section, we roughly illustrate the used structures and operations of the Safra construction along the lines of [11, 14], so that we can demonstrate its relationship with the Muller-Schupp construction in the next section. As before, $\mathcal{A}$ is an NBA with the usual components.

A *Safra tree* is a finite ordered tree with non-empty state-sets as labels. Usually, it is required that a parent is labelled by a strict superset of all states in its subtree and siblings are labelled by pairwise disjoint sets. We use the equivalent requirement that *all* labels in the tree are pairwise disjoint, i.e., refrain from listing states in the parent label which are already present in some descendant. One can easily reconstruct the "full" label set of a node wrt. the classical definition by taking the union of all the labels in its subtree. To obtain parity automata, each node of the Safra tree is associated with a number from $\{1, \ldots, n\}$, where n is the number of nodes in the Safra tree [11]. These numbers satisfy the property that parent nodes have smaller numbers than their children, and a node has a smaller number than its right sibling. The numbers correspond to the ranks that we use in Section 3, and we therefore refer to Safra trees in combination with these numbers as *ranked Safra trees*. Two ranked Safra trees are shown in Figure 3 (and an intermediate tree in the middle).

In [14], a slightly different representation is used based on a *later introduction record* (LIR), which just lists the tree nodes in their introduction order, i.e., nodes appear in this list after parents and older siblings (in this representation, nodes have canonical names depending only on their position in the tree). Safra trees with LIR directly correspond to ranked Safra trees by annotating each tree node with its position in the LIR.

A transition on symbol $x \in \Sigma$ is constructed as follows (see Figure 3 for an example). First, for each label set S, the set $S' := \Delta(S, x)$ of successor states is calculated. After this, each node gets a fresh right-most child, and the accepting states in S', that is $S' \cap F$, are moved into the label of this child. Then, disjointness is ensured by keeping of each state only the copy which is located at the deepest node along the leftmost branch where that state occurs (this stage is represented by the middle tree in Figure 3). If now some internal node has an empty label, but a non-empty subtree (a good event for the node), its subtree is collapsed into a single node by removing all descendants and moving the states in their labels into the parent label. Finally, all remaining sets that are labelled by $\emptyset$ are removed (being removed is a bad event for a node). In the following, we refer to good and bad events as *green* and *red*, respectively. The priority for the transition is derived from the green and red events, which are associated with the relative position of the corresponding nodes in the LIR. The LIR for the new tree is obtained by deleting removed nodes from the LIR and appending fresh nodes that remain in the resulting tree in arbitrary order.

5 From Safra-trees to ranked slices and back

In this section we state the key observation that was the starting point of this work: there is a bijection between the set of ranked slices and the set of ranked Safra trees. From a ranked Safra tree, one obtains the ranked slice by simply listing the nodes of the Safra tree by a depth-first post-order traversal (i.e., a parent processed after all its children). We formalize this relationship below, and then explain that the transitions defined in the Muller-Schupp construction and in the Safra construction are very similar, which then leads to the unified construction.

Let (α, t) be a ranked slice with $t = (S_1, \ldots, S_n)$. The tuple index of the *parent* of S_i is the closest index to the right of i that has a smaller rank and is formally defined as $\uparrow(i) := \min_{i<k\leq n}\{k \mid \alpha(k) < \alpha(i)\}$. As we require by definition of ranked slices that the rightmost position in the tuple always has rank 1, this is the only position in the tuple for which the parent is undefined. The ordered tree induced by $\uparrow$, with siblings in tuple index order, is called the *rank tree* of (α, t). The tuple index of the *left subtree boundary* of S_i is the closest index to the left with a smaller rank, and is denoted by $\leftarrow(i) := \max_{1\leq k<i}\{k \mid \alpha(k) < \alpha(i)\}$ or 0 if no such index exists. It points to either the direct left sibling of i, or the left sibling of the closest ancestor, if one exists. Effectively, $\leftarrow(i)$ is the closest neighbor to the left which is not a descendant of i. As children by definition are always to the left of their parents, every node at indices $\leftarrow(i)+1, \ldots, i$ is in the subtree of i.

For an example, consider the tuple $(\{q_3\}^4, \{q_1\}^2, \{q_2\}^3, \{q_0\}^1)$, where the superscripts denote the assigned rank (e.g., $\alpha(1) = 4$). The rightmost position 4 of the tuple is the root of the tree. For the positions 2 and 3, which have rank 2 and 3 respectively, the next position to the right with a smaller rank is in both cases position 4, i.e., $\uparrow(2) = \uparrow(3) = 4$. Finally, position 1 in the tuple has position 2 as parent, i.e., $\uparrow(1) = 2$. The discussed tuple is depicted with the parent edges at the bottom right of Figure 4. There is also one non-trivial left subtree boundary in this tuple, assigned by $\leftarrow(3) = 2$, i.e. index 2 is not in the subtree of index 3, and in this case is an actual left sibling of index 3.

We use the notation $\uparrow_\alpha := \alpha \circ \uparrow \circ \alpha^{-1}$ to denote the parent rank of another rank directly, without mentioning the indices in the tuple. In the previous example, we have $\uparrow_\alpha(4) = 2$, and $\uparrow_\alpha(2) = \uparrow_\alpha(3) = 1$. We identify the age-ranks $\alpha(i)$ as nodes of the tree, while each set S_i determines the label of the node $\alpha(i)$, called *hosted set*. We write $S_i^{\downarrow} := \bigcup_{k=\leftarrow(i)+1}^{i} S_k$ for the *subtree set* of node $\alpha(i)$.

▶ **Definition 3.** *Let* safra2slice *be the mapping which takes a ranked Safra tree and returns* (α, t)*, with* $t := (S_1, \ldots, S_n)$ *being the label sets of the nodes in depth-first post-order (i.e., a parent processed after all its children) traversal order and ranking* α *defined by the ranks of the corresponding Safra tree nodes.*

Let slice2safra *be the mapping which takes a ranked slice* (α, t) *and returns the ranked Safra tree given by the rank tree of* (α, t)*, i.e. the tree structure defined by* $\uparrow$ *and the ordering of siblings given by the order of the corresponding sets in* t*.*

It is easy to see from the definitions that safra2slice and slice2safra are injective and return a valid ranked slice and ranked Safra tree, respectively. This implies that there exists a bijection between the sets of ranked Safra trees and ranked slices. It is also not very hard to see that the following holds:

▶ **Lemma 4.** safra2slice *and* slice2safra *are inverses of each other and provide a bijection between ranked Safra trees and ranked slices.*

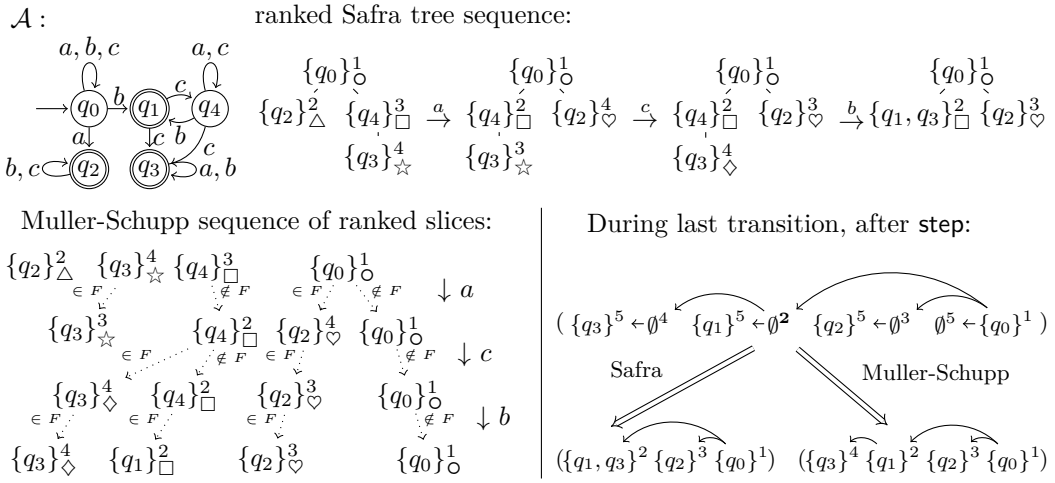

Figure 4 Transitions based on NBA $\mathcal{A}$ using both constructions. The superscripts denote the ranks of tree nodes / sets in the slice tuple. The subscripts are added for illustration purposes and conceptually track nodes throughout time, i.e., the same symbol marks the "same" node at different times. The algorithms agree on all but the last transition, where they differ due to different handling of green nodes/ranks, in this case rank 2 that marks an empty set after calculating and splitting the successors (illustrated on the bottom right). In the Muller-Schupp case, the rank is moved left during prune, resulting in a child being pulled into the parent in the rank tree, whereas in the Safra construction the whole subtree is collapsed. The solid edges between sets depict the rank tree induced by $\uparrow$, dotted edges depict the edges in the conceptual split-tree. In the bottom right the slices are shown together with their tree interpretation.

As we have established that both constructions, Muller-Schupp and Safra, operate on essentially the same structures, from now on we talk about ranked slices and trees interchangeably. Using this relationship, one can take the same tree/slice and apply both the successor calculation of the Safra construction and of the Muller-Schupp construction to it. What one first notices, is that the resulting tree/slice is very similar or equal in many cases. This is owed to the fact that most operations in one construction have an equivalent operation in the other, just formulated for the other representation.

For example, moving accepting successor states into a fresh child node in Safra's construction corresponds to splitting accepting successors from non-accepting ones during step in the Muller-Schupp construction, as in the successor tuple the new child (in the conceptual split-tree) gets a fresh, larger rank and by definition becomes the rightmost child in the rank tree of the resulting new slice. The normalization steps that make the successor sets pairwise disjoint also yield the same results. The ranks of nodes with green events in the Safra construction coincide with ranks of sets that signal green in the ranked slices, and ranks of Safra nodes with red events with ranks of sets that signal red. The removal of empty sets by prune and renumbering the ranks with normalize is the same as the removal of the corresponding nodes in the Safra tree and updating the LIR, i.e., the ranks of Safra nodes.

In fact, *the only difference* between the constructions is what happens with a tree node in case of a green event. Recall that in Safra's construction, the whole subtree of a green node is collapsed to a single node. In the Muller-Schupp construction, the green ranks are those that end up on an empty set after step, and that survive the prune operation, in which the ranks are moved to the next non-empty set to the left, and only the minimal ones are kept on each non-empty set. In the view of ranked trees, this corresponds to a green node absorbing its rightmost, uppermost child node into it, while keeping the rest of the subtree unchanged. See Figure 4 for an illustration.

After observing that both constructions differ in only a minor step and noticing that both yield correct (but possibly different) automata, it becomes apparent that the exact step performed for green events is not essential and there must be a more general mechanism to uncover. The construction we present in Section 6 results from this line of thought.

On the practical side, it is worth mentioning that the cost of switching between the representations using the presented bijection is negligible – the traversal of a ranked Safra tree to obtain a ranked slice is obviously possible in linear time. For the other direction there also exists a simple linear time algorithm that calculates the parent and left subtree boundary relation from the ranking α.

6 The unified construction

In this section, we present a construction that builds on the Muller-Schupp construction from Section 3, and unifies it with Safra's construction by adding another operation, called merge, between prune and normalize: $(\alpha, t) \xrightarrow{\text{step}} (\hat{\alpha}, \hat{t}) \xrightarrow{\text{prune}} (\tilde{\alpha}, \tilde{t}) \xrightarrow{\text{merge}} (\check{\alpha}, \check{t}) \xrightarrow{\text{normalize}} (\alpha', t')$.

This new operation is nondeterministic, and can be instantiated in different ways. In particular, it can be instantiated trivially and thus corresponds to the Muller-Schupp construction, and it can be used to emulate the Safra construction.

We first describe the idea of merge, and then give a formal definition. Assume that, after step and prune have been applied to some ranked slice (α, t), we have the pre-slice $(\tilde{\alpha}, \tilde{t})$, and the dominating (minimal active) rank k (determined by prune, see Section 3). Then merge can collapse groups of neighbouring sets in the tuple, and preserves the minimum rank from each collapsed range, similar to prune. In contrast to prune, which "merges" one non-empty set with multiple empty sets in a deterministic manner, merge may actually take the union of multiple adjacent non-empty sets, depending on the ranks currently assigned to them.

The non-overlapping intervals of sets that are collapsed together are not uniquely determined in general. They only have to satisfy the constraints that no sets with rank smaller than the dominating rank k are merged with anything else, and that the set with rank k is not merged with anything to the right of it. These constraints are important for the correctness, and ensure that in the ranked Safra tree perspective, the nodes with rank smaller than k do not change, and that the node with the dominating rank k is not merged with sets outside of its subtree.

Formally, merge returns a pre-slice $(\check{\alpha}, \check{t})$ obtained in the following way (see Figure 5 for an illustration). Let $I_1, I_2, \ldots, I_{n'}$ be a sequence of sets partitioning the set of indices $\{1, \ldots, \tilde{n}\}$ in $\tilde{t}$ into adjacent groups, i.e., $\min I_1 = 1$, $\max I_{n'} = \tilde{n}$ and for all $j > 1$ we have $\min I_j = \max I_{j-1} + 1$. This grouping should satisfy the following property for all $1 \leq j \leq n'$ and $l \in I_j$: if $\tilde{\alpha}(l) < k$, then $|I_j| = 1$, and if $\tilde{\alpha}(l) = k$, then $\max I_j = l$. Then the pre-slice $(\check{\alpha}, \check{t})$ is defined by the sets $\check{S}_i := \bigcup_{j \in I_i} \tilde{S}_j$ and the ranking function $\check{\alpha}(i) := \min\{\tilde{\alpha}(j) \mid j \in I_i\}$ for all $i \in \{1, \ldots, n'\}$, i.e., for each interval, the union of the sets and the smallest rank is taken.

As in the Muller-Schupp construction, normalize is applied to $(\check{\alpha}, \check{t})$ to obtain the successor macrostate (α', t'). This extended transition relation is used to obtain the transition-based deterministic parity automaton, as before.

An example showing how the choice of different merge strategies leads to different successor states is illustrated in Figure 6. Observe that we can recover the Muller-Schupp construction by using the identity function for merge, or in other words, putting each index into its own interval, which is the finest partitioning of indices that satisfies the requirements on merge. On the other hand, we can also take the coarsest compatible partitioning, i.e., minimize the number of intervals. We call this kind of update *maximal collapse*.

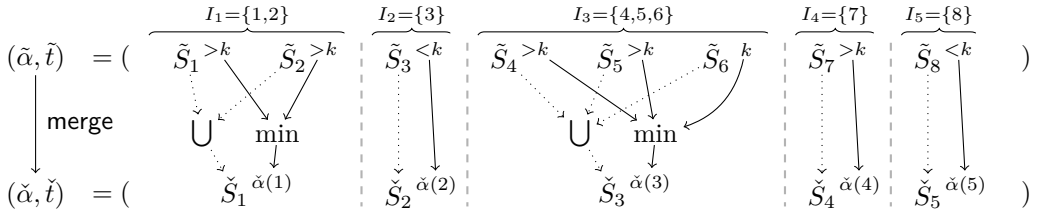

Figure 5 Illustration of the general merge operation that comes after prune and before normalize, with the minimal active rank k and ranks depicted as set superscripts. The illustrated intervals are the coarsest partitioning of indices in $\tilde{t}$ satisfying the constraints.

We can emulate a Safra-update by imposing some additional constraints on the intervals, ensuring that only the complete subtrees of nodes with green ranks are merged. More concretely, we require that intervals that are not singletons span exactly the nodes of the complete subtree that is rooted in a green rank in the view of the slice as ranked Safra tree. Note that for an index ℓ in the tuple, the subtree of the corresponding node in the ranked Safra tree corresponds to the interval that starts one step right of the left subtree boundary of ℓ, and ends in ℓ, that is, the interval $\leftarrow(l)+1, \ldots, \ell$. Thus, for imitating the Safra merge rule, the intervals $I_1, I_2, \ldots, I_{n'}$ from merge are the unique smallest intervals satisfying

$$\forall i \in [n'], l \in I_i : \quad \tilde{\alpha}(l) \in G \implies \leftarrow(l)+1 \in I_i \quad \text{(complete subtrees collapsed)}.$$

▶ **Proposition 5.** *The operation* merge *can be instantiated such that the transitions of the constructed TDPA correspond to the transitions of the Muller-Schupp construction or to the transitions of the Safra construction.*

Notice that for all merge rules except for the Muller-Schupp update, the relationship of ranked slices and consecutive levels of the reduced split-tree (see Section 3) breaks down. One can, however, reflect the merges also in the reduced split-tree by doing the merges of the corresponding sets on each level, which leads to an acyclic graph instead of a tree. This view is helpful in the correctness proof of the construction.

▶ **Theorem 6.** *Let $\mathcal{A}$ be an NBA. Then a deterministic parity automaton $\mathcal{B}$, obtained by the described determinization construction, has at most $\mathcal{O}(n!^2)$ states and recognizes the same language as $\mathcal{A}$.*

The upper bound holds because the same macrostates are used as in the presented Muller-Schupp construction in Section 3. The correctness can be shown by a refinement of the original correctness proof of the Safra construction [13].

7 Discussion and Conclusion

We have presented a new variant of the Muller-Schupp construction for determinization of Büchi automata into parity automata, reducing the information stored in the macrostates to ordered tuples of disjoint sets annotated with ranks. These ranked slices are in bijection with ranked Safra trees, which leads to a general construction that can emulate the Muller-Schupp construction and the Safra-construction. This answers, in some sense, the question from [4] on the relation between the two types of constructions.

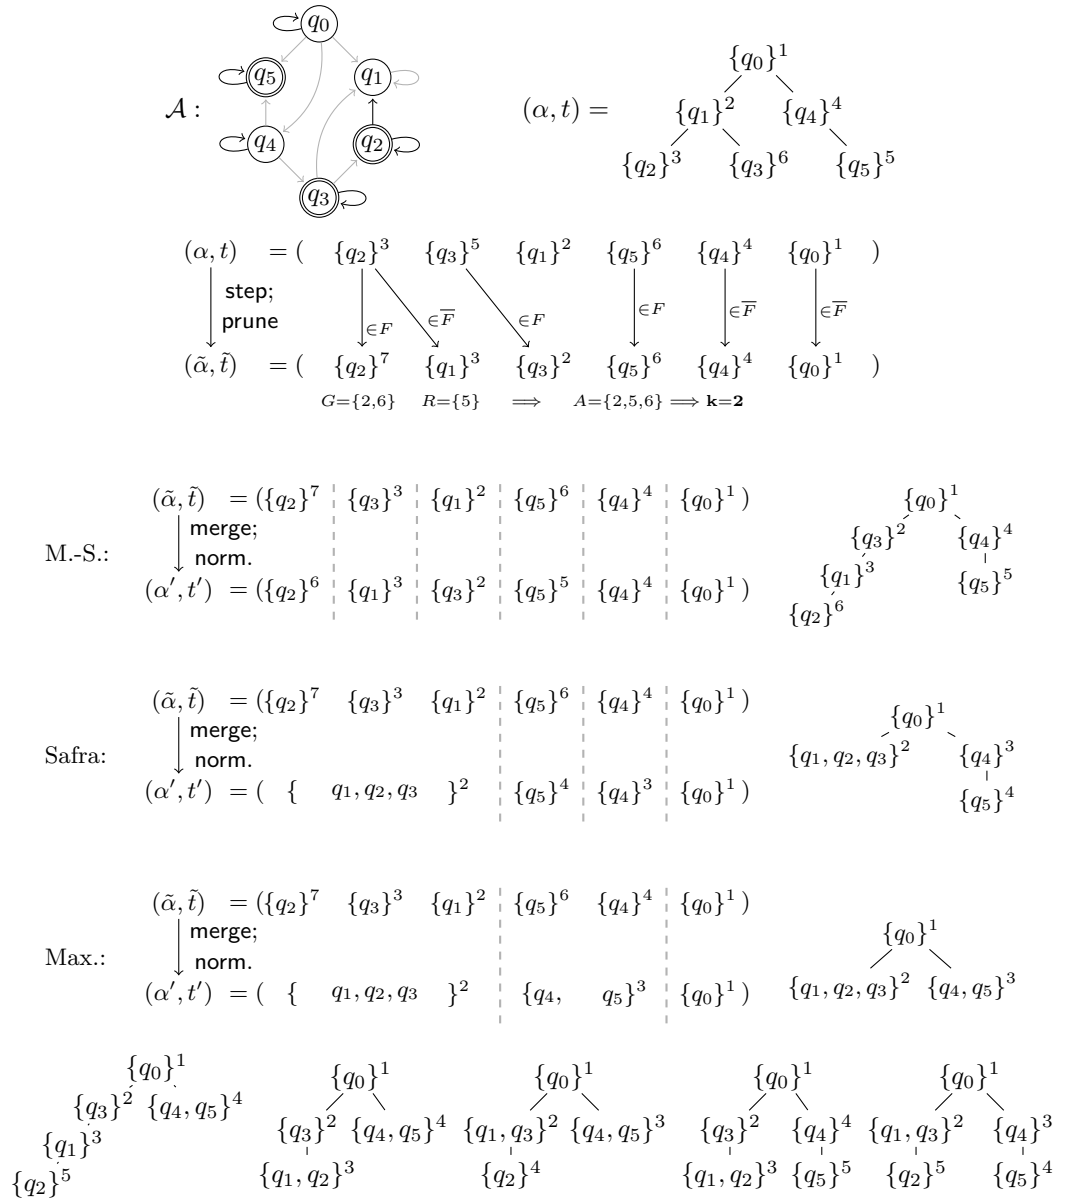

Figure 6 $\mathcal{A}$ illustrates the relevant part of an NBA during a transition on some symbol $x \in \Sigma$, that is, the arrows correspond to the x-transitions of $\mathcal{A}$. The gray edges are the ones pruned in the reduced transition relation Δ_t. The current macrostate (α, t) is represented as the rank tree to the right of $\mathcal{A}$, and as ranked slice below $\mathcal{A}$. The step and prune operations (see Fig. 2 for details) result in ranks 1,3 and 4 being passed down along the right child. Ranks 2 and 6 are moved to the left and hence are green. Rank 5 is overwritten by 2 and hence is red. Rank 7 is a fresh rank which is larger than the others. The dominating rank k is 2. The choice of different merge intervals (as shown in Fig. 5) results in different successors. The successors for the three discussed variants, Muller-Schupp, Safra, and maximal collapse, are shown as rank trees on the right. The 5 other permitted successors are depicted at the bottom.

In general, one can obtain many different valid deterministic automata by choosing different deterministic transition functions that are compatible with the described successor relation. One can also imagine this as constructing a non-deterministic automaton with *all* permitted successors, and then pruning the edges arbitrarily, while preserving for each state only one outgoing transition for each symbol, to "carve" out a valid deterministic automaton.

This non-determinism comes from two sources. One degree of freedom in our construction comes from the different ways of assigning ranks (to new nodes, and when closing gaps resulting from deleted ranks). This freedom is already mentioned in [14]. But here the flexibility is just in the choice of the specific permutation, which still describes structurally the same tree in any case. The novel and in our opinion powerful degree of freedom in our construction is the possibility for different valid merge operations, which allows for a vastly larger pool of possible successors, as the results may describe structurally different trees. Furthermore, the smaller the smallest active rank, the more different a permitted successor may look like.

We have explicitly mentioned the merge strategies that lead to the Muller-Schupp and Safra constructions, and also have mentioned a third strategy, the maximal collapse rule that merges as many sets as possible (as shown in e.g. Figure 6). We also want to point out that, while fixing one such merge-rule for the whole construction is the simplest implementation, the construction permits using *any* valid successor without the need to disambiguate the merge operation beforehand, i.e., picking the successor of a state from the set of permitted ones is a *local* choice. One may think of schemes where the successor is chosen dynamically, depending on the input or already computed information. For example, one can check whether a valid successor has already been constructed, and only add a new state according to a fixed policy if this is not the case. We have already implemented a prototype making use of such an optimization (among others) with encouraging results.

We also want to point out that the presented construction works equally well with transition-based Büchi automata as input, in which case the step operation separates states which are reached by at least one accepting transition from those that are not. One can easily verify that this does not impact the reasoning in the proofs.

It is also possible to adapt the construction to yield Rabin automata, such that the corresponding Safra construction as presented in [14] is subsumed. In this setting, however, the presentation of macrostates as ordered tuples of sets is less natural. Furthermore, in this setting the merges of sets needs to be restricted to subtrees of green nodes, because there is no total order of importance of nodes as provided by the ranks.

Abstract

The permutation language P_n consists of all words that are permutations of a fixed alphabet of size n. Using divide-and-conquer, we construct a regular expression R_n that specifies P_n. We then give explicit bounds for the length of R_n, which we find to be $4^n n^{-(\lg n)/4+\Theta(1)}$, and use these bounds to show that R_n has minimum size over all regular expressions specifying P_n.

1 Introduction

Given a regular language L defined in some way, it is a challenging problem to find good upper and lower bounds on the size of the smallest regular expression specifying L. (In this paper, by a regular expression, we always mean one using the operations of union, concatenation, and Kleene closure only.) Indeed, as a computational problem, it is known that determining the shortest regular expression corresponding to an NFA is PSPACE-hard [12]. Jiang and Ravikumar proved the analogous result for DFAs [11]. For more recent results on inapproximability, see [9].

For nontrivial families of languages, only a handful of results are already known. For example, Ellul et al. [7] showed that the shortest regular expression for the language $\{w \in \{0,1\}^n : |w|_1 \text{ is even}\}$ is of length $\Omega(n^2)$. Here $|w|_1$ denotes the number of occurrences of the symbol 1 in the word w. (A simple divide-and-conquer strategy provides a matching upper bound.) Chistikov et al. [4] showed that the regular language

$$\{ij : 1 \leq i < j \leq n\}$$

can be specified by a regular expression of size exactly $n(\lfloor \log_2 n \rfloor + 2) - 2^{\lfloor \log_2 n \rfloor + 1}$, and furthermore this bound is optimal. Mousavi [13] developed a general program for computing lower bounds on regular expression size for the binomial languages

$$B(n,k) = \{w \in \{0,1\}^n : |w|_1 = k\}.$$

Let n be a positive integer, and define $\Sigma_n = \{1, 2, \ldots, n\}$. In this paper we study the finite language P_n consisting of all permutations of Σ_n. Thus, for example,

$$P_3 = \{123, 132, 213, 231, 312, 321\}.$$

We are interested in regular expressions that specify P_n. In counting the length of regular expressions, we adopt the conventional measure of *alphabetic length* (see, for example, [6]): the length of a regular expression is the number of occurrences of symbols of the alphabet Σ_n. Thus, other symbols, such as parentheses and `+`, are ignored.

A brute-force solution, which consists of listing all the members of P_n and separating them by the union symbol `+`, evidently gives a regular expression for P_n of alphabetic length $n \cdot n!$. This can be improved to $n! \sum_{0 \le i < n} 1/i! \sim e \cdot n!$ by tail recursion, where $E(S)$ represents a regular expression for all permutations of the symbols of S:

$$E(S) = \sum_{i \in S} i(E(S - \{i\})); \quad E(i) = i.$$

For example, for P_4 this gives

```
1(2(34+43)+3(24+42)+4(23+32))+2(1(34+43)+3(14+41)+4(13+31))+
 3(1(24+42)+2(14+41)+4(12+21))+4(1(23+32)+2(13+31)+3(12+21)).
```

Can we do better?

Ellul et al. [7] proved the following weak lower bound: every regular expression for P_n has alphabetic length at least 2^{n-1}. A slightly stronger bound of $n2^{n-1}$ was also shown by Agrawal et al. [1]. In this note we derive an upper bound through divide-and-conquer. We then show that the regular expression this strategy produces is, in fact, actually optimal. This improves the results from [7, 1].

The language P_n is of particular interest because its complement has short regular expressions, as shown in [7]. For other results concerning context-free grammars for P_n, see [7, 2, 3, 8]. Cho et al. [5] considered the related problem of determining the size of the minimal DFA recognizing all permutations of a given finite language.

2 Divide-and-conquer

Consider the following divide-and-conquer strategy, as given by Agrawal et al. [1]. Let S be an alphabet of cardinality n. We consider all subsets $T \subseteq S$ of cardinality $\lfloor n/2 \rfloor$. For each subset we recursively determine a regular expression for the permutations of T, a regular expression for the permutations of $S - T$, and concatenate them together. This gives

$$E(S) = \sum_{\substack{T \subseteq S \\ |T| = \lfloor n/2 \rfloor}} (E(T))(E(S - T)); \quad E(i) = i. \tag{1}$$

Finally, we define $R_n = E(\Sigma_n)$.

Thus, for example, we get

```
R4 = (12+21)(34+43)+(13+31)(24+42)+(23+32)(14+41)+
     (14+41)(23+32)+(24+42)(13+31)+(34+43)(12+21)
```

for P_4.

The alphabetic length of the resulting regular expression R_n for all permutations of Σ_n is then $f(n)$, where

$$f(n) = \begin{cases} 1, & \text{if } n = 1; \\ \binom{n}{\lfloor n/2 \rfloor} \big(f(\lfloor n/2 \rfloor) + f(\lceil n/2 \rceil)\big), & \text{if } n > 1. \end{cases}$$

The first few values of $f(n)$ are given in the table below.

n	$f(n)$
1	1
2	4
3	15
4	48
5	190
6	600
7	2205
8	6720
9	29988
10	95760

It is sequence A320460 in the *On-Line Encyclopedia of Integer Sequences* [15].

It seems hard to determine a simple closed-form expression for $f(n)$. Agrawal et al. [1] show that $f(n) \leq 8 \cdot 4^n$. We can roughly estimate $f(n)$ as follows, at least when $n = 2^m$ is a power of 2:

$$\begin{aligned} f(2^m) &= 2\binom{2^m}{2^{m-1}} f(2^{m-1}) \\ &= 2^m \binom{2^m}{2^{m-1}} \binom{2^{m-1}}{2^{m-2}} \cdots \binom{2}{1} \\ &= 2^m \frac{(2^m)!}{(2^{m-1})!\,(2^{m-2})! \cdots 2!\,1!}. \end{aligned}$$

Substituting the Stirling approximation $n! \sim \sqrt{2\pi n}(n/e)^n$ and simplifying, we get that $f(2^m)$ is roughly equal to

$$4^{2^m} e^{-1} \pi^{(1-m)/2} 2^{-(m^2-5m+6)/4}.$$

To make this precise, and make it work when n is not a power of 2, however, takes more work.

The rest of the paper is organized as follows: in Section 3, we prove that our regular expression is in fact optimal, assuming one result that is proven at the end of the paper. In Section 4, we establish some inequalities related to Stirling's formula. In Section 5, we connect these inequalities to $f(n)$ and obtain the estimate mentioned in the abstract. Finally, in Section 6 we use our obtained bounds on $f(n)$ to provide the missing piece in our optimality proof.

3 Optimality

In order to show that our regular expression has minimum possible length, we use the following property of $f(n)$ that we prove in Section 6:

▶ **Lemma 1.** *If $n \geq 1$, then every integer $0 < k < n$ satisfies $\binom{n}{k}(f(k) + f(n-k)) \geq f(n)$. Equality occurs if and only if $k = \lfloor n/2 \rfloor$ or $k = \lceil n/2 \rceil$.*

For $n \geq 1$ and $1 \leq k \leq n!$, define $\ell(n, k)$ to be the minimum alphabetic length of a regular expression specifying a subset of P_n, where the subset has cardinality at least k.

▶ **Lemma 2.** *If $n \geq 1$ and $1 \leq k \leq n!$, then $\ell(n, k)/k \geq \ell(n, n!)/n! \geq f(n)/n!$.*

Proof. We prove this by induction over the lexicographical ordering of pairs (n, k). This is easy for our base case $n = k = 1$, as the best regular expression is a single character. We thus suppose $n \geq 2$.

Consider a regular expression for a subset of P_n of cardinality at least $k \geq 1$ that has minimum alphabetic length. Clearly no such expression will involve ϵ or $\emptyset$. We now consider the possibilities for the last (outermost) operation in the regular expression. Clearly the only relevant possibilities are union and concatenation.

If the last operation is a union, then it is the union of two subsets of P_n of cardinalities $k_1, k_2 \geq 1$ where $k_1 + k_2 \geq k$, and $k_1, k_2 < k$ by minimality. Then we get

$$\begin{aligned}\frac{\ell(n,k)}{k} &\geq \frac{\ell(n,k_1)+\ell(n,k_2)}{k_1+k_2} \\ &\geq \min\left\{\frac{\ell(n,k_1)}{k_1}, \frac{\ell(n,k_2)}{k_2}\right\} \\ &\geq \frac{\ell(n,n!)}{n!} \geq \frac{f(n)}{n!}.\end{aligned}$$

If the last operation is a concatenation, then it is the concatenation of two regular expressions for subsets of P_{n_1} and P_{n_2} of cardinalities k_1 and k_2 respectively (possibly after changing alphabets) where $n_1 + n_2 = n$ and $k_1 k_2 \geq k$. By minimality, we have n_1, n_2, k_1, k_2 all positive, so $n_1, n_2 < n$. We now obtain

$$\begin{aligned}\frac{\ell(n,k)}{k} &\geq \frac{\ell(n_1,k_1)+\ell(n_2,k_2)}{k_1 k_2} \\ &\geq \frac{\ell(n_1,n_1!)+\ell(n_2,k_2)}{n_1!\; k_2} \\ &\geq \frac{\ell(n_1,n_1!)+\ell(n_2,n_2!)}{n_1!\; n_2!} \\ &\geq \frac{f(n_1)+f(n_2)}{n_1!\; n_2!} \\ &= \frac{1}{n!}\binom{n}{n_1}(f(n_1)+f(n-n_1)) \\ &\geq \frac{1}{n!}\binom{n}{\lfloor n/2\rfloor}(f(\lfloor n/2\rfloor)+f(\lceil n/2\rceil)) \qquad \text{(by Lemma 1)} \\ &= \frac{f(n)}{n!}.\end{aligned}$$

In both cases, we get the desired inequalities for these choices of n and k, completing our induction. ◀

▶ **Theorem 3.** *Let $n \geq 1$. Over all regular expressions for the permutation language P_n, the regular expression R_n given by our divide-and-conquer strategy achieves the minimum alphabetic length.*

Proof. By our construction from Section 2, the regular expression R_n specifies the entirety of P_n and has alphabetic length $f(n)$. We thus get the upper bound $\ell(n, n!) \leq f(n)$. By Lemma 2, we have the matching lower bound $\ell(n, n!) \geq f(n)$. Thus, R_n has minimum possible alphabetic length for a regular expression specifying P_n. ◀

4 Analysis

In what follows we use ln to denote the natural logarithm, and lg to denote logarithms to the base 2.

Define $S : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ to be the usual Stirling approximation [14]:

$$S(x) = \sqrt{2\pi x}(x/e)^x.$$

▶ **Lemma 4.** *For every $x \geq 1$, we have the bounds*

$$S\big(x+\frac{1}{2}\big)^2 \leq S(x)S(x+1) \leq e^{1/(2x)}S\big(x+\frac{1}{2}\big)^2.$$

Proof. The first two derivatives of $\ln S(x)$ are

$$\frac{d}{dx}\ln S(x) = \frac{1}{2x} + \ln x$$

$$\frac{d^2}{dx^2}\ln S(x) = -\frac{1}{2x^2} + \frac{1}{x},$$

and so we see that $\ln S(x)$ is convex (that is, its derivative is increasing) for all $x > 1/2$. Thus, by Jensen's inequality [10] and exponentiating, we obtain the lower bound

$$S(x)S(x+1) \geq S\big(x+\frac{1}{2}\big)^2$$

for all $x \geq 1$.

Now, using the mean value theorem twice, we get that

$$(\ln S(x)) + \frac{1}{2}\mu \leq \ln S(x+\frac{1}{2}) \tag{2}$$

$$\ln S(x+1) \leq (\ln S(x+\frac{1}{2})) + \frac{1}{2}M, \tag{3}$$

where

$$\mu = \inf_{z\in[x,x+\frac{1}{2}]} (\ln S(z))' = \frac{1}{2x} + \ln x$$

$$M = \sup_{z\in[x+\frac{1}{2},x+1]} (\ln S(z))' = \frac{1}{2(x+1)} + \ln(x+1).$$

Adding the inequalities (2) and (3), we get

$$\begin{aligned}(\ln S(x)) + (\ln S(x+1)) &\leq (2\ln S(x+1/2)) - \mu/2 + M/2\\ &\leq (2\ln S(x+1/2)) + \frac{1}{2}\ln(\frac{x+1}{x})\\ &\leq (2\ln S(x+1/2)) + \frac{1}{2x}.\end{aligned}$$

This gives us the inequality

$$S(x)S(x+1) \leq e^{1/(2x)}S(x+1/2)^2$$

for all $x \geq 1$. ◀

Next, for $\alpha \in \mathbb{R}$, define the function $g_\alpha : \mathbb{R}_{>0} \to \mathbb{R}_{>0}$ by

$$g_\alpha(x) = \frac{4^x}{x^{(\lg x)/4}} x^\alpha.$$

Our goal is to show that f can be approximated by g_α for some choice of α.

▶ **Lemma 5.** *Let $\alpha > 0$. Then for every $x \geq 4^\alpha$ we have*

$$e^{-1/(2\sqrt{x})} \frac{5}{2} g_\alpha(x + \frac{1}{2}) \leq g_\alpha(x) + g_\alpha(x+1) \leq e^{1/(2\sqrt{x})} \frac{5}{2} g_\alpha(x + \frac{1}{2}).$$

Proof. We again compute the logarithmic derivative:

$$\frac{d}{dx} \ln g_\alpha(x) = \frac{\alpha - (\lg x)/2}{x} + \ln 4.$$

For $x \geq 4^\alpha$, this derivative is at most $\ln 4$, so by the mean value theorem,

$$\ln g_\alpha(x+1) - \ln 2 \leq \ln g_\alpha(x + \frac{1}{2}) \leq \ln g_\alpha(x) + \ln 2.$$

Exponentiating, we get

$$\frac{1}{2} g_\alpha(x+1) \leq g_\alpha(x + \frac{1}{2}) \leq 2 g_\alpha(x). \tag{4}$$

Next, we note that the derivative of $\ln x$ exceeds that of $\sqrt{x}$ for $0 < x < 4$ and is less for $x > 4$. So, since $\ln 4 < \sqrt{4}$, we have $\ln x < \sqrt{x}$ for all $x > 0$. Hence

$$\begin{aligned} \frac{d}{dx} \ln g_\alpha(x) &= \frac{\alpha}{x} - \frac{\ln x}{2x \ln 2} + \ln 4 \\ &\geq \ln 4 - \frac{\sqrt{x}}{(2 \ln 2) x} \\ &\geq \ln 4 - 1/\sqrt{x} \end{aligned}$$

for all $x > 0$. Thus, by the mean value theorem and exponentiating again, we get

$$\frac{1}{2} e^{1/(2\sqrt{x})} g_\alpha(x+1) \geq g_\alpha(x + \frac{1}{2}) \geq 2 e^{-1/(2\sqrt{x})} g_\alpha(x). \tag{5}$$

We can now combine the inequalities (4) and (5) for $x \geq 4^\alpha$ to get

$$\begin{aligned} e^{-1/(2\sqrt{x})} \frac{5}{2} g_\alpha(x + \frac{1}{2}) &\leq \frac{1}{2} g_\alpha(x + \frac{1}{2}) + 2 e^{-1/(2\sqrt{x})} g_\alpha(x + \frac{1}{2}) \\ &\leq g_\alpha(x) + g_\alpha(x+1) \\ &\leq \frac{1}{2} e^{1/(2\sqrt{x})} g_\alpha(x + \frac{1}{2}) + 2 g_\alpha(x + \frac{1}{2}) \\ &\leq e^{1/(2\sqrt{x})} \frac{5}{2} g_\alpha(x + \frac{1}{2}), \end{aligned}$$

which gives us both desired bounds. ◀

We now show an identity relating g_α and S.

▶ **Lemma 6.** *Suppose $x > 0$ and $\beta > 0$. If $\alpha = \lg \beta + 1/4 - (\lg \pi)/2$, then*

$$\beta \frac{S(2x)}{S(x)^2} g_\alpha(x) = g_\alpha(2x).$$

Proof. We have

$$\begin{aligned}
\beta\frac{S(2x)}{S(x)^2}g_\alpha(x) &= \beta\frac{\sqrt{4\pi x}(2x/e)^{2x}}{(\sqrt{2\pi x}(x/e)^x)^2}\frac{4^x}{x^{\lg x/4}}x^\alpha \\
&= \beta\frac{4^x}{\sqrt{\pi x}}\frac{4^x}{x^{\lg x/4}}x^\alpha \\
&= \frac{2^{\lg\beta+1/4}}{\pi^{1/2}x^{1/4}x^{1/4}2^{1/4}}\frac{4^{2x}}{x^{\lg x/4}}x^\alpha \\
&= 2^{\lg\beta+1/4-\lg\pi/2}\frac{4^{2x}}{2^{(1+\lg x)/4}x^{(1+\lg x)/4}}x^\alpha \\
&= \frac{4^{2x}}{(2x)^{(\lg 2x)/4}}(2x)^\alpha \\
&= g_\alpha(2x).
\end{aligned}$$

◀

5 Bounds on $f(n)$

In this section we obtain an estimate for $f(n)$, the size of the optimal regular expression for P_n.

▶ **Theorem 7.** *For all $n \geq 1$ we have*

$$0.195\frac{4^n}{n^{(\lg n)/4}}n^{5/4-(\lg\pi)/2} \leq f(n) \leq \frac{1}{4}\frac{4^n}{n^{(\lg n)/4}}n^{(\lg 5)-3/4-(\lg\pi)/2}.$$

Further, when n is a power of two, we get the following upper bound, matching the general lower bound.

$$f(n) \leq \frac{1}{4}\frac{4^n}{n^{\lg n/4}}n^{5/4-(\lg\pi)/2}.$$

Proof. Recall the Stirling approximation

$$e^{1/(12n+1)}S(n) \leq n! \leq e^{1/12n}S(n); \tag{6}$$

see [14]. Now suppose that $f(n) \leq r_n g_\alpha(n)$ and $f(n+1) \leq r_{n+1}g_\alpha(n+1)$, where $n \geq \max\{1, 4^\alpha\}$, for some non-decreasing function $r : \mathbb{N} \to \mathbb{R}_{>0}$. Then by combining Lemma 4, Lemma 5, and equation (6), we get

$$\begin{aligned}
f(2n+1) &= \binom{2n+1}{n}(f(n)+f(n+1)) \\
&\leq e^{\frac{1}{12(2n+1)}-\frac{1}{12n+1}-\frac{1}{12(n+1)+1}}\frac{S(2n+1)}{S(n)S(n+1)}(r_n g_\alpha(n)+r_{n+1}g_\alpha(n+1)) \\
&\leq \frac{5}{2}r_{n+1}e^{1/(2\sqrt{n})}\frac{S(2n+1)}{S(n+1/2)^2}g_\alpha(n+1/2)
\end{aligned}$$

and

$$\begin{aligned}
f(2n) &= \binom{2n}{n}(f(n)+f(n)) \\
&\leq 2r_n e^{\frac{1}{12(2n)}-2\frac{1}{12n+1}}\frac{S(2n)}{S(n)^2}g_\alpha(n) \\
&\leq 2r_n\frac{S(2n)}{S(n)^2}g_\alpha(n).
\end{aligned}$$

For the case where n is a power of two only, we use $\beta = 2$ and $r_n = C$, we set

$$\alpha = \lg\beta + 1/4 - (\lg\pi)/2 = 5/4 - (\lg\pi)/2,$$

so $\alpha > 0$ and $4^\alpha < 2$. Now Lemma 6 gives us the identity $2\frac{S(2x)}{S(x)^2} g_\alpha(x) = g_\alpha(2x)$. Then by induction we have $f(n) \le C g_\alpha(n)$ for all $n \ge 1$, where C is any constant that satisfies this bound for $n < 4$. In particular, $C = \frac{1}{4}$ works, so we have $f(n) \le \frac{1}{4} g_{5/4-\lg\pi/2}(n)$ for all $n \ge 1$ that are powers of two.

Next, for general n, we use $\beta = 5/2$ and $r_n = Ce^{-\frac{\sqrt{5}}{(4-\sqrt{10})\sqrt{n}}}$, we set

$$\alpha = \lg\beta + 1/4 - \lg\pi/2 = \lg 5 - 3/4 - \lg\pi/2,$$

so $\alpha > 0$ and $4^\alpha < 4$. Now Lemma 6 gives us the identity $\frac{5}{2}\frac{S(2x)}{S(x)^2} g_\alpha(x) = g_\alpha(2x)$. For $n \ge 4$, we get

$$\begin{aligned}
r_{n+1} e^{1/(2\sqrt{n})} &= Ce^{\frac{1}{2\sqrt{n}} - \frac{\sqrt{5}}{(4-\sqrt{10})\sqrt{n+1}}} \\
&\le C(e^{\frac{1}{\sqrt{n}}})^{\frac{1}{2} - \frac{\sqrt{5}}{4-\sqrt{10}}\frac{\sqrt{4}}{\sqrt{5}}} \\
&= C(e^{\frac{1}{\sqrt{n}}})^{-\frac{\sqrt{10}}{2(4-\sqrt{10})}} \\
&= Ce^{-\frac{\sqrt{5}}{(4-\sqrt{10})\sqrt{2n}}} \\
&\le r_{2n+1}.
\end{aligned}$$

Easily, we also get $2r_n \le \frac{5}{2} r_{2n}$. Thus, by induction we have $f(n) \le r_n g_\alpha(n)$ for all $n \ge 12$, where C is chosen to make this work for $12 \le n < 24$. In particular, $C = \frac{1}{4}$ works again. Further, since we have $r_n < C$ for all $n \ge 1$, we also have $f(n) \le \frac{1}{4} g_{\lg 5 - 3/4 - \lg\pi/2}(n)$ for all $n \ge 12$. Finally, we check manually that this last inequality holds for $1 \le n < 12$ too, and thus for all $n \ge 1$.

All that remains is the lower bound. We get similar recurrences, supposing $f(n) \ge r_n g_\alpha(n)$ and $f(n+1) \ge r_{n+1} g_\alpha(n+1)$, where $n \ge \max\{1, 4^\alpha\}$ for some non-increasing $r : \mathbb{N} \to \mathbb{R}_{>0}$. Then by a similar argument as for the upper bounds, we have

$$\begin{aligned}
f(2n+1) &= \binom{2n+1}{n}(f(n) + f(n+1)) \\
&\ge \frac{5}{2} r_{n+1} e^{\frac{1}{12(2n+1)+1} - \frac{1}{12n} - \frac{1}{12(n+1)}} e^{-1/(2\sqrt{n})} e^{-1/(2n)} \frac{S(2n+1)}{S(n+1/2)^2} g_\alpha(n+1/2) \\
&\ge \frac{5}{2} r_{n+1} e^{-1/(2\sqrt{n}) - 2/(3n)} \frac{S(2n+1)}{S(n+1/2)^2} g_\alpha(n+1/2)
\end{aligned}$$

and

$$\begin{aligned}
f(2n) &= \binom{2n}{n}(f(n) + f(n)) \\
&\ge 2 r_n e^{\frac{1}{24n+1} - \frac{2}{12n}} \frac{S(2n)}{S(n)^2} g_\alpha(n) \\
&\ge 2 r_n e^{-1/(6n)} \frac{S(2n)}{S(n)^2} g_\alpha(n).
\end{aligned}$$

This time, we set $\beta = 2$ with $r_n = Ce^{1/3n}$ (indeed non-increasing), and $\alpha = 5/4 - \lg\pi/2$, noting $4^\alpha < 4$. Now for $n = 16$, we have $\ln\frac{5}{4} \ge \frac{17}{96} = \frac{1}{2\sqrt{n}} + \frac{5}{6n}$. Since this right-hand side is non-increasing in n, we in fact have $\ln\frac{5}{4} \ge \frac{1}{2\sqrt{n}} + \frac{5}{6n}$ for all $n \ge 17$ too. This implies

$$\begin{aligned}
\frac{5}{2} r_{n+1} e^{-1/(2\sqrt{n}) - 2/(3n)} &= 2Ce^{\ln\frac{5}{4} + \frac{1}{3(n+1)} - \frac{1}{2\sqrt{n}} - \frac{5}{6n} + \frac{1}{6n}} \\
&\ge 2Ce^{\frac{1}{3(n+1)} + \frac{1}{6n}} \\
&\ge 2r_{2n+1}.
\end{aligned}$$

Further, $2r_n e^{-1/6n} = 2r_{2n}$, so by induction we have $f(n) \geq r_n g_\alpha(n)$ for all $n \geq 17$, where C is chosen to satisfy this bound for $17 \leq n < 34$. In particular, $C = 0.195$ works. Since $r_n > C$ for all $n \geq 17$, we also have $f(n) \geq 0.195 g_{5/4-\lg \pi/2}(n)$ for all $n \geq 17$. Finally, we check manually that this works for all $1 \leq n < 17$ too, and thus for all $n \geq 1$. ◀

6 Optimality revisited

We now give a simple lower bound on the growth of f.

▶ **Lemma 8.** *We have $f(n+1) \geq 3f(n)$ for all $n \geq 1$.*

Proof. We prove this by induction on n. It is easy to verify the base case $f(2) = 4 \geq 3 = 3f(1)$. Otherwise $n > 1$. Suppose the desired inequality holds for all smaller values of n. If $n \geq 2$ is odd, then let $1 \leq m < n$ satisfy $2m + 1 = n$. Then

$$\begin{aligned}
f(n+1) &= f(2m+2) \\
&= 2\binom{2m+2}{m+1} f(m+1) \\
&= 2\frac{2m+2}{m+1}\binom{2m+1}{m} f(m+1) \\
&= \binom{2m+1}{m}(f(m+1) + 3f(m+1)) \\
&\geq \binom{2m+1}{m}(3f(m) + 3f(m+1)) \\
&= 3f(2m+1) \\
&= 3f(n).
\end{aligned}$$

Otherwise, if $n \geq 2$ is even, then let $1 \leq m < n$ satisfy $2m = n$. We note that $4m+2 \geq 3m+3$, so $2\frac{2m+1}{m+1} \geq 3$. We then have

$$\begin{aligned}
f(n+1) &= f(2m+1) \\
&= \binom{2m+1}{m}(f(m) + f(m+1)) \\
&= \frac{2m+1}{m+1}\binom{2m}{m}(f(m) + f(m+1)) \\
&\geq \frac{2m+1}{m+1}\binom{2m}{m}(f(m) + 3f(m)) \\
&= 2\frac{2m+1}{m+1} f(2m) \\
&\geq 3f(2m) \\
&= 3f(n).
\end{aligned}$$

◀

Armed with this inequality and the bounds given by Theorem 7 of Section 5, we are ready to complete our proof of the optimality of R_n. We recall Lemma 1, which is what we have left to show:

▶ **Lemma 1.** *If $n \geq 1$, then every integer $0 < k < n$ satisfies $\binom{n}{k}(f(k) + f(n-k)) \geq f(n)$. Equality occurs if and only if $k = \lfloor n/2 \rfloor$ or $k = \lceil n/2 \rceil$.*

Proof. We easily check the cases $n < 12$ by hand. Let $n \geq 12$ be arbitrary. It suffices to consider the cases where $k \leq \lfloor n/2 \rfloor$, as those where $k \geq \lceil n/2 \rceil$ are symmetric. Equality for the case $k = \lfloor n/2 \rfloor$ is given by the definition of $f(n)$.

Suppose that $n/6 \leq k < \lfloor n/2 \rfloor$. Then $n > 9$, so $3n - 3 > 2n + 6$. Hence we get

$$\frac{n/2 - 1/2}{n/2 + 3/2} > 2/3$$

and so

$$\frac{\lfloor n/2 \rfloor}{\lceil n/2 \rceil + 1} > 2/3. \tag{7}$$

Also, from $k \geq n/6$ we get $3k + 3 \geq \lceil n/2 \rceil + 2$, and so

$$\frac{k+1}{\lceil n/2 \rceil + 2} \geq 1/3. \tag{8}$$

Then

$$\begin{aligned}
&\binom{n}{k}(f(k) + f(n-k)) \\
&\geq \binom{n}{k} f(n-k) \\
&\geq \binom{n}{k} 3^{\lfloor n/2 \rfloor - k} f(\lceil n/2 \rceil) && \text{(by Lemma 8)} \\
&\geq 3^{\lfloor n/2 \rfloor - k} \binom{n}{k} \frac{f(\lfloor n/2 \rfloor) + f(\lceil n/2 \rceil)}{2} \\
&= \frac{3^{\lfloor n/2 \rfloor - k}}{2} \prod_{k \leq j < \lfloor n/2 \rfloor} \frac{j+1}{n-j} \binom{n}{\lfloor n/2 \rfloor} (f(\lfloor n/2 \rfloor) + f(\lceil n/2 \rceil)) \\
&= \frac{3^{\lfloor n/2 \rfloor - k}}{2} \frac{\prod_{k < j \leq \lfloor n/2 \rfloor} j}{\prod_{\lceil n/2 \rceil < j \leq n-k} j} f(n) \\
&= \frac{3^{\lfloor n/2 \rfloor - k}}{2} \frac{\lfloor n/2 \rfloor}{\lceil n/2 \rceil + 1} \frac{\prod_{k+1 \leq j \leq \lfloor n/2 \rfloor - 1} j}{\prod_{\lceil n/2 \rceil + 2 \leq j \leq n-k} j} f(n) \\
&> \frac{3^{\lfloor n/2 \rfloor - k}}{2} (2/3) \prod_{1 \leq j \leq \lfloor n/2 \rfloor - k - 1} \frac{k+j}{\lceil n/2 \rceil + 1 + j} f(n) && \text{(by (7))} \\
&\geq 3^{\lfloor n/2 \rfloor - k - 1} \left(\frac{k+1}{\lceil n/2 \rceil + 2} \right)^{\lfloor n/2 \rfloor - k - 1} f(n) \\
&\geq 3^{\lfloor n/2 \rfloor - k - 1} (1/3)^{\lfloor n/2 \rfloor - k - 1} f(n) && \text{(by (8))} \\
&= f(n).
\end{aligned}$$

Next, suppose $1 \leq k < n/6$. Then $4k < n - n/3$ and so $4 < \frac{n-1}{k}$. Then if $k > 1$,

$$\begin{aligned}
\binom{n}{k} &= n \prod_{2 \leq j \leq k} \frac{n - 1 - k + j}{j} \\
&\geq n \left(\frac{n-1}{k} \right)^{k-1} \\
&\geq n 4^{k-1}.
\end{aligned}$$

We note also that $\binom{n}{1} = n4^0$, so we have $\binom{n}{k} \geq n4^{k-1}$ for all $1 \leq k < n/6$. We note from our proof of Lemma 5 that the derivative of $\ln g_\alpha(x)$ is at most $\ln 4$ for $x \geq 4^\alpha$. In particular, for $\alpha = 5/4 - \lg \pi/2$, this derivative is at most $\ln 4$ for all $x \geq 2$, and so $4^k g_\alpha(n-k) \geq g_\alpha(n)$ here (as $n - k > 5n/6 \geq 10$). Thus

$$\begin{aligned}
&\binom{n}{k}(f(k) + f(n-k)) \\
&\geq \binom{n}{k} f(n-k) \\
&\geq n4^{k-1}\left(0.195 g_{5/4-\lg\pi/2}(n-k)\right) && \text{(by Theorem 7)} \\
&\geq n4^{k-1}\left(0.195 \frac{g_{5/4-\lg\pi/2}(n)}{4^k}\right) \\
&= 0.195 n \frac{1}{4} g_{5/4-\lg\pi/2}(n) \\
&= 0.195 n \frac{1}{4} n^{2-\lg 5} g_{\lg 5 - 3/4 - \lg\pi/2}(n) \\
&\geq 0.195 n^{3-\lg 5} f(n) && \text{(by Theorem 7)} \\
&> f(n) && \text{(since } n \geq 12 > 0.195^{-\frac{1}{3-\lg 5}}\text{).}
\end{aligned}$$

Abstract

In this paper we provide a positive answer to a question left open by Alur and and Deshmukh in 2011 by showing that equivalence of finite-valued copyless streaming string transducers is decidable.

1 Introduction

Finite transducers are simple devices that allow to reason about data transformations in an effective, and even efficient way. In their most basic form they transform strings using finite control. Unlike automata, their power heavily depends on various parameters, like non-determinism, the capability of scanning the input several times, or the kind of storage they may use. The oldest transducer model, known as generalized sequential machine, extends finite automata by outputs. Inspired by an approach that applies to arbitrary relational structures [9], logic-based transformations (also called transductions) were considered by Engelfriet and Hoogeboom [12]. They showed that two-way transducers and monadic-second order (MSO) definable transductions are equivalent in the deterministic case (and even if the transduction is single-valued, which is more general than determinism). This equivalence supports thus the notion of "regular" functions, in the spirit of classical results on regular word languages from automata theory and logics due to Büchi, Elgot, Trakhtenbrot, Rabin, and others. A one-way transducer model that uses write-only registers as additional storage was proposed a few years ago by Alur and Cerný [2], and called streaming string transducer (SST). SST were shown equivalent to two-way transducers and MSO definable transductions in the deterministic setting, and again, even in the single-valued case.

In the relational case the picture is less satisfactory, as expressive equivalence is only preserved for SST and non-deterministic MSO transductions [5], which extend the original MSO transductions by existentially quantified monadic parameters. On the other hand, two-way transducers and SST are incomparable in the relational case. Between functions and relations there is however one class of transductions that exhibits a better behavior, and this is the class of finite-valued transductions. Being finite-valued means that there exists some constant k such that every input belonging to the domain has at most k outputs.

Finite-valued transductions were intensively studied in the setting of one-way and two-way transducers. For one-way transducers, k-valuedness can be checked in PTIME [17]. In addition, every k-valued one-way transducer can be effectively decomposed into a union of k

unambiguous one-way transducers of exponential size [24, 23]. For both two-way transducers and SST, checking k-valuedness is in PSPACE.

Besides expressiveness, another fundamental question concerning transducers is the equivalence problem, that is, the problem of deciding whether two transducers define the same relation (or the same partial function if we consider the single-valued case). The equivalence problem turns out to be PSPACE-complete for deterministic two-way transducers [16], single-valued two-way transducers, as well as for single-valued SST [5]. For deterministic SST, equivalence is in PSPACE [3], but it is open whether this complexity upper bound is optimal. For arbitrary SST, and in fact even for non-deterministic one-way transducers over a unary output alphabet, equivalence is undecidable [13, 18]. The equivalence problem for k-valued one-way transducers was shown to be decidable by Culik and Karhumäki using an elegant argument based on Ehrenfeucht's conjecture [10], and the authors noted that the same proof goes through for two-way transducers as well. The decidability status for the equivalence problem for k-valued SST was first stated as an open problem in [5]. Another open problem is whether SST and two-way transducers are equivalent in the finite-valued case, like in the single-valued case. It is worth noting, however, that in the full relational case SST and two-way transducers are incomparable. Concerning this last open question, a partial positive answer was given in [14], by decomposing any finite-valued SST with only one register into a finite union of unambiguous SST. This decomposition result also entails the decidability of the equivalence problem for the considered class.

The main result of this paper is a positive answer to the first question left open in [5]:

▶ **Theorem 1.** *The equivalence problem for finite-valued SST is decidable.*

We show the above result with a proof idea due to Culik and Karhumäki [10], based on the Ehrenfeucht conjecture. Our proof is much more involved, because SST produce their outputs piece-wise, in contrast to one-way and two-way transducers, that produce output linearly while reading the input. We manage to overcome this obstacle using some (mild) word combinatorics and word equations, by introducing a suitable normalization procedure for SST. We believe that our technique will also allow to solve the second problem left open in [5], which is the expressive equivalence between finite-valued SST and two-way transducers.

Related work

The equivalence problem for transducers has recently raised interest for more complex types of transducers in the single-valued case: Filiot and Reynier showed that equivalence of copyful, deterministic SST is decidable by showing them equivalent to HDT0L systems and applying [10], which contains the above-mentioned result as a special case. Subsequently, Benedikt et al. showed that equivalence of copyful, deterministic SST has Ackerman complexity, with a proof based on polynomial automata and ultimately on Hilbert's basis theorem [6]. Interestingly, the use of Hilbert's basis theorem goes back to the proof of Ehrenfeucht's conjecture [1, 15]. A similar approach was used by Boiret et al. in [7] to show that bottom-up register automata over unordered forests have a decidable equivalence problem, see also the nice survey [8].

Overview

Section 2 introduces the transducer model, then Section 3 sets up the technical machinery that allows to normalize finite-valued SST. Section 4 shows the major normalization result, which holds for left quotients of SST. Finally Section 5 recalls the Ehrenfeucht-based proof for equivalence and the application to finite-valued SST. A full version of the paper is available at `https://arxiv.org/abs/1902.06973`.

2 Streaming string transducers

A *streaming string transducer* (*SST*) is a tuple $T = (\Sigma, \Gamma, X, Q, U, I, E, F, x_{\text{out}})$, where Σ and Γ are finite input and output alphabets, X is a finite set of registers (usually denoted x, x', x_1, x_2, etc.), Q is a finite set of states, U is a finite set of register updates, that is, functions from X to $(X \uplus \Gamma)^*$, $I, F \subseteq Q$ are subsets of states, defining the initial and final states, $E \subseteq Q \times \Sigma \times U \times Q$ is a transition relation, describing, for each state and input symbol, the possible register updates and target states, and finally $x_{\text{out}} \in X$ is a register for the output. Note that, compared to the original definition from [2], here we forbid for simplicity the use of final production rules, that perform ad additional register update after the end of the input. This simplification is immaterial with respect to the decidability of the equivalence problem. For example, it can be enforced, without loss of generality, by assuming that all well-formed inputs are terminated by a special marker, say $\dashv$, on which the transducer can apply a specific transition. We assume here that *all inputs of a transducer are non-empty and of the form $u \dashv$, with $\dashv$ not occurring in u.*

Copyless restriction and capacity

An SST as above is *copyless* if for all register updates $f \in U$, every register $x \in X$ appears at most once in the word $f(x_1) \dots f(x_m)$, where $X = \{x_1, \dots, x_m\}$. For a copyless SST, every output has length at most linear in the length of the input. More precisely, every output associated with an input u has length at most $c|u|$, where $c = \max_{f \in U} \sum_{x \in X} |f(x)|_\Gamma$ is the maximum number of letters that the SST can add to its registers along a single transition (this number c is called *capacity* of the SST).

Hereafter, we assume that all SST are copyless.

Register updates and flows

Every register update, and in general every function $f : X \to (X \uplus \Gamma)^*$ is naturally extended to a morphism on $(X \uplus \Gamma)^*$, by defining it as identity over Γ. When reasoning with register updates, it is sometimes possible to abstract away the specific words over Γ, and only consider how the contents of the registers flows into other registers. Formally, the *flow* of an update $f : X \to (X \uplus \Gamma)^*$ is the bipartite graph that consists of two ordered sequences of nodes, one on the left and one on the right, with each node in a sequence corresponding to a specific register, and arrows that go from the node corresponding to register x to a right node corresponding to register x whenever x occurs in $f(x)$. For example, the flow of the update f defined by $f(x_1) = a\, x_1\, aa\, x_3$, $f(x_2) = b\, a$, and $f(x_3) = x_2\, b$ is the second bipartite graph in the figure on page 5.

Note that there are finitely many flows on a fixed number of registers. Moreover, flows can be equipped with a natural composition operation: given two flows F_1 and F_2, $F_1 \cdot F_2$ is the bipartite graph obtained by glueing the right nodes of F_1 with the left nodes of F_2, and by shortcutting pairs of consecutive arrows. We call *flow monoid* of an SST T the monoid of flows generated by the updates of T, with the composition operation as associative product.

Transitions, runs, and loops

A transition (q, a, f, q') of an SST T is conveniently denoted by the arrow $q \xrightarrow[T]{a/f} q'$, and the subscript T is often omitted when clear from the context. A *run* on $w = a_1 \dots a_n$ is a sequence of transitions of the form $q_0 \xrightarrow{a_1/f_1} q_1 \xrightarrow{a_2/f_2} \dots \xrightarrow{a_n/f_n} q_n$. Sometimes, a run as

above is equally denoted by $q_0 \xrightarrow{w/f} q_n$, so as to highlight the underlying input w and the induced register update $f = f_1 \circ \cdots \circ f_n$. A run is *initial* (resp. *final*) if it begins with an initial (resp. final) state; it is *successful* if it is both initial and final.

Given two registers x, x' and a run $\rho : q \xrightarrow{w/f} q'$, we say that x *flows into* x' *along* ρ if x occurs in $f(x')$. Note that this property depends only on the flow of the induced update f.

An SST is said to be *trimmed* is every state occurs in at least one successful run, so every state is reachable from the initial states and co-reachable from the final states. This property can be easily enforced with a polynomial-time preprocessing.

When reasoning with automata, it is common practice to use pumping arguments. Pumping will also be used here, but the notion of loop needs to be refined as to take into account the effect of register updates. Formally, a *loop* of a run ρ of an SST is any non-empty factor of ρ of the form $\gamma : q \xrightarrow{w/f} q$, that starts and ends in the same state q, and induces a *flow-idempotent* update, namely, an update f such that f and $f \circ f$ have the same flow.

Outputs and finite-valuedness

The *output* of a successful run $\rho : q_0 \xrightarrow{w/f} q_n$ is defined as $\mathrm{out}(\rho) = (f_0 \circ f)(x_{\mathrm{out}})$, where $f_0(x) = \varepsilon$ for all $x \in X$. Sometimes, we write $\mathrm{out}(f)$ in place of $\mathrm{out}(\rho)$. The *relation realized by an SST* is the set of pairs $(u, v) \in \Sigma^* \times \Gamma^*$, where u is a well-formed input (namely, terminating with $\dashv$) and v is the output associated with some successful run on u. An SST is *k-valued* if for every input u, there are at most k different outputs associated with u. It is *single-valued* (resp. *finite-valued*) if it is k-valued for $k = 1$ (resp. for some $k \in \mathbb{N}$). The domain an SST T, denoted $\mathrm{Dom}(T)$, is the set of input words that have some successful run in T. Two SST T_1, T_2 are *equivalent*, denoted as $T_1 \equiv T_2$, if they realize the same relation over $\Sigma^* \times \Gamma^*$.

Register valuations

A *register valuation* is a function from X to Γ^*. Given a successful run $\rho : q_0 \xrightarrow{a_1/f_1} q_1 \xrightarrow{a_2/f_2} \ldots \xrightarrow{a_n/f_n} q_n$ and a position $i \in \{0, \ldots, n\}$ in it, *the register valuation at position i in ρ* is the function $\mathrm{val}_{\rho,i}$ that is defined inductively on i as follows: $\mathrm{val}_{\rho,0}(x) = \varepsilon$, for all $x \in X$, and $\mathrm{val}_{\rho,i+1} = \mathrm{val}_{\rho,i} \circ f_i$. Note that $\mathrm{val}_{\rho,n}(x_{\mathrm{out}})$ coincides with the final output $\mathrm{out}(f_1 \circ \cdots \circ f_n)$ produced by ρ.

3 Normalizations

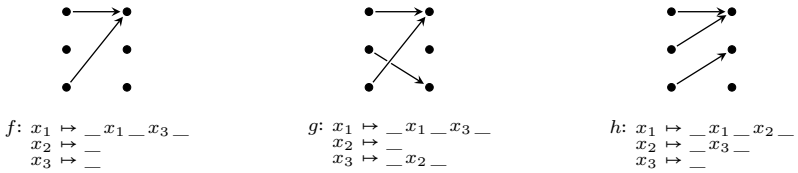
A major stumbling block in deciding equivalence of SST, as well as other crucial problems, lies in the fact that the same output can be produced by very different runs. This phenomenon already appears with much simpler transducers, e.g. with one-way transducers, where runs may produce the same output, but at different speeds. However, the phenomenon is more subtle for SST, as the output is produced piece-wise, and not sequentially: runs with same output may appear to be different in many ways, e.g. in terms of the flows of the register updates, or in terms of shifts of portions of the output. The goal of this section is to provide suitable normalization steps that remove, one at a time, the above mentioned degrees of freedom in producing the same output.

Another issue that we will be concerned with is the compatibility of the normalization steps with constructions on transducers that shortcut arbitrary long runs into a single transition. Essentially, we aim at having an effective notion of equivalence w.r.t. final outputs that works not only for transitions but also for runs.

Normalization of flows

In this section, *m will always denote the number of registers of an SST and $X = \{x_1, \dots, x_m\}$ the set of registers.* It is convenient to equip X with a total order, say $x_1 < \cdots < x_m$. Accordingly, we let $\chi = x_1 \dots x_m$ be the juxtaposition of all register names, and $f(\chi) = f(x_1) \dots f(x_m)$ for every register update f.

We say that a register update f is *non-erasing* if for every register x, $f(\chi)$ contains at least an occurrence of x (in fact, exactly one, since T is copyless). This can be rephrased as a property of the flow of f, where every node on the left must have an outgoing arrow. In a similar way, we say that f is *non-permuting* if registers appear in $f(\chi)$ with their natural order and without jumps, that is, $f(\chi) \in \Gamma^* x_1 \Gamma^* \dots \Gamma^* x_k \Gamma^*$, for some $k \le m$. As before, this can be rephrased by saying that the arrows in the flow of f must not be crossing, and the target nodes to the right must form a prefix of χ. Below are some examples of updates with their flows: the first update f is erasing, the second update g is non-erasing but permuting, and the third update h is non-erasing and non-permuting.



We say that T is *flow-normalized* if all its register updates are non-erasing and non-permuting. Note that a flow-normalized SST with m registers can have at most 2^m different flows.

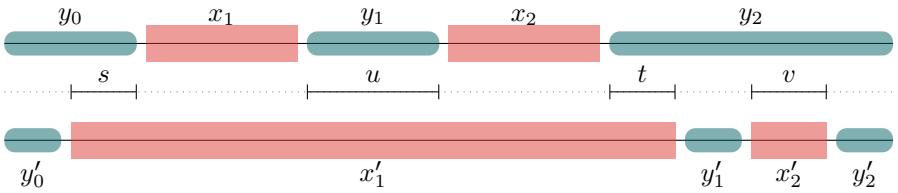
▶ **Proposition 2.** *One can transform any SST into an equivalent flow-normalized one.*

Recall that a register valuation is a function from X to Γ^*. With a flow-normalized SST, one can also define a dual notion of valuation, representing "gaps" between registers that shrink along the run. For this we introduce $m+1$ fresh variables $y_0, y_1, \dots, y_m$, called *gaps*. Hereafter, *$Y = \{y_0, y_1, \dots, y_m\}$ will always denote the set of gaps.* We use the term *valuation* to generically denote a register/gap valuation, that is, a function from $X \uplus Y$ to Γ^*.

The idea is that a gap y_j represents a word that is inserted between register x_j (if $j > 0$) and register x_{j+1} (if $j < n$) so as to form the final output. Formally, given a word $w \in \Gamma^* x_1 \Gamma^* \dots \Gamma^* x_k \Gamma^*$, with $k \le m$, and given two registers x_i, x_j, with $i < j$, we denote by $w\langle x_i, x_j\rangle$ the maximal factor of w strictly between the unique occurrence of x_i and the unique occurrence of x_j, using the following conventions for the degenerate cases: if $i = 0$, then $w\langle x_i, x_j\rangle$ is a maximal prefix of w; if $i > 0$ but there is no occurrence of x_i, then $w\langle x_i, x_j\rangle = \varepsilon$; finally, if there is an occurrence of x_i but no occurrence of x_j in w, then $w\langle x_i, x_j\rangle$ is a maximal suffix. Given a run $\rho : q_0 \xrightarrow{a_1/f_1} q_1 \xrightarrow{a_2/f_2} \dots \xrightarrow{a_n/f_n} q_n$ and a position i in it, *the valuation at position i of ρ* is the function $\mathrm{val}_{\rho,i} : X \uplus Y \to \Gamma^*$ such that

- $\mathrm{val}_{\rho,i}$ restricted to X is the register valuation at position i of ρ,
- $\mathrm{val}_{\rho,i}$ maps every gap y_j to the word $(f_{i+1} \circ \cdots \circ f_n)(\chi)\langle x_j, x_{j+1}\rangle$.

By definition, the image of the word $\zeta = y_0\, x_1\, y_1 \dots x_m\, y_m$ via the valuation $\mathrm{val}_{\rho,i}$ is always equal to the final output $\mathrm{out}(\rho)$, for all positions i. In this sense, the sequence of valuations $\mathrm{val}_{\rho,0}, \mathrm{val}_{\rho,1}, \dots, \mathrm{val}_{\rho,n}$ can be identified with a sequence of factorizations of $\mathrm{out}(\rho)$. For example, below are the factorizations of the output before and after a transition with register update f such that $f(x_1) = s\, x_1\, u\, x_2\, t$ and $f(x_2) = v$, for $s, u, t, v \in \Gamma^*$:



This also suggests the principle that gaps, like registers, are updated along transitions via suitable morphisms, but in a symmetric way, that is, from right to left. For instance, in the above picture, the gaps y_0, y_1, y_2 are updated by the function $f^\star$ such that $f^\star(y_0) = y_0\, s$, $f^\star(y_1) = u$, and $f^\star(y_2) = t\, y_1\, v\, y_2$. In general, the function $f^\star$, called *gap update*, is uniquely determined by the register update f, and vice versa, f is uniquely determined by the gap update $f^\star$. Another perhaps interesting phenomenon is that the gap update $f^\star$ is also non-erasing and non-permuting (the notion of non-permuting gap assignment is defined w.r.t. the reverse order $y_m < \cdots < y_0$).

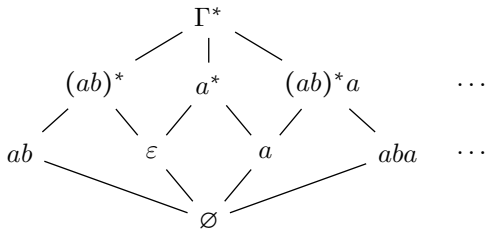
Normalization of states

The next normalization step splits the states of an SST in such a way that it becomes possible to associate with each state an over-approximation of the possible register/gap valuations witnessed when the state is visited along a successful run. These over-approximations are very simple languages over the output alphabet Γ, e.g. singleton languages like $\{aba\}$ and periodic languages like $\{ab\}^*\{a\}$ (often denoted $(ab)^*a$ to improve readability). Basically our over-approximations refer to length and period constraints. The *period* of a word w is the least number $0 < p \leq |w|$ such that w is a prefix of $(w[1,p])^\omega$. For example, the period of $w = abcab$ is 3.

For a given parameter $\alpha \in \mathbb{N}$ we define the family $\mathcal{L}_\alpha$ that contains:

- the empty language $\varnothing$,
- the singleton languages $\{u\}$, with $u \in \Gamma^*$ and $|u| \leq \alpha$,
- the periodic languages u^*v, with $u \in \Gamma^+$ *primitive* (i.e. $u = w^k$ only if $k = 1$), $|u| \leq \alpha$, and $v \in \Gamma^*$ strict prefix of u,
- the universal language Γ^*.

The languages in $\mathcal{L}_\alpha$, partially ordered by containment, form a finite meet semi-lattice, where the meet is the intersection $\cap$. We depict here part of the lattice $\mathcal{L}_\alpha$ for a parameter $\alpha \geq 3$:



The semi-lattice structure allows to derive a best over-approximation in $\mathcal{L}_\alpha$ of any language $L \subseteq \Gamma^*$, that is: $L^{\uparrow\alpha} = \bigcap\{L' \in \mathcal{L}_\alpha : L' \supseteq L\}$. We will mostly use the approximation operator $^{\uparrow\alpha}$ on singleton languages. For example, for $\alpha = 3$, we have $\{aba\}^{\uparrow\alpha} = \{aba\}$, $\{ababa\}^{\uparrow\alpha} = (ab)^*a$, and $\{abbb\}^{\uparrow\alpha} = \Gamma^*$. Note also that if $|w| \leq \alpha$ then $w^{\uparrow\alpha} = \{w\}$. A useful property is the compatibility of $^{\uparrow\alpha}$ with concatenation, which immediately extends to compatibility with word morphisms:

▶ **Lemma 3.** $(L_1 \cdot L_2)^{\uparrow\alpha} = (L_1{}^{\uparrow\alpha} \cdot L_2{}^{\uparrow\alpha})^{\uparrow\alpha}$ *for every* $\alpha \in \mathbb{N}$ *and* $L_1, L_2 \subseteq \Gamma^*$.

Recall that X, Y denote, respectively, the sets of registers and gaps of a flow-normalized SST. Given a valuation $\nu : X \uplus Y \to \Gamma^*$, its *$\alpha$-approximant* is the function $\nu^{\uparrow\alpha} : X \uplus Y \to \mathcal{L}_\alpha$ that maps any $z \in X \uplus Y$ to the language $\{\nu(z)\}^{\uparrow\alpha}$. The set of α-approximants is denoted $\mathcal{L}_\alpha^{X \uplus Y}$, and consists of all maps from $X \uplus Y$ to $\mathcal{L}_\alpha$. Further let

$$\mathrm{Val}_q = \{\mathrm{val}_{\rho,i} \,:\, \rho \text{ successful run visiting } q \text{ at any position } i\}$$

be the set of possible valuations induced by an arbitrary successful run when visiting state q.

A first desirable property is that all valuations in Val_q have the *same* α-approximant, which is thus determined by the state q. Formally, given a flow-normalized SST T with trimmed state space Q, we say that T *admits α-approximants* if every state $q \in Q$ can be effectively annotated with an α-approximant $A_q \in \mathcal{L}_\alpha^{X \uplus Y}$ in such a way that

$$\forall \nu \in \mathrm{Val}_q : \qquad \nu^{\uparrow\alpha} = A_q. \tag{1}$$

This condition is best understood as an invariant on lengths and periods that can be enforced on valuations of registers and gaps when visiting a particular state. For instance, when the approximant A_q guarantees a certain period, then this period will be the same for all valuations occurring at q, independently of the specific initial run that may lead to q (for registers), and of the run that may lead from q to an accepting state (for gaps).

The proposition below shows that it is always possible to refine any SST T so as to admit α-approximants, for any parameter α. The proof for α-approximants that concern only registers could be understood as unfolding the SST T, and merging nodes corresponding to any two inputs u and v, with u prefix of v, whenever the induced α-approximants at u and v are the same for every register x. In general, the resulting SST can be seen a covering of the original SST T, in the sense formalized by Sakarovitch and de Souza in [22]: T' is a *covering* of T if the states of T' can be mapped homomorphically to states of T, while preserving transitions and the distinction into initial and final states, and, moreover, the outgoing transitions of every state of T' map one-to-one to outgoing transitions of a corresponding state of T. This implies that the successful runs of T and those of T' are in one-to-one correspondence.

▶ **Proposition 4.** *Let T be a flow-normalized SST, and let $\alpha \in \mathbb{N}$. One can construct an equivalent flow-normalized SST T' that admits α-approximants and that is a covering of T.*

Notation. Whenever an SST admits α-approximants A_q as above, it is convenient to denote its states by triples of the form (q, A_X, A_Y), where A_X (resp. A_Y) is the restriction of the α-approximant A_q of state q to registers (resp. gaps).

Note that the smaller the parameter α, the weaker is the property required for α-approximants (in particular, for $\alpha = 0$ the lattice $\mathcal{L}_\alpha$ collapses to $\varnothing$ and Γ^*). Choosing α to be at least the capacity of the SST is already a reasonable choice, as it gives a nice characterization of equivalence of transitions w.r.t. the produced outputs (cf. Lemma 5 below). However, we will see that it is desirable to have even finer approximants, in such a way that our results will be compatible with left quotients of SST, that shortcut arbitrary long runs into single transitions. We postpone the technical details to Section 4, and only provide a rough intuition underlying the choice of the appropriate parameter α. We will choose α much larger than the capacity of the SST, so that, by pumping arguments, one can show that, for every state q and every parameter $\beta \geq \alpha$, the β-approximant cannot be strictly smaller than the α-approximant on *all* valuations from Val_q.

Normalization of transitions

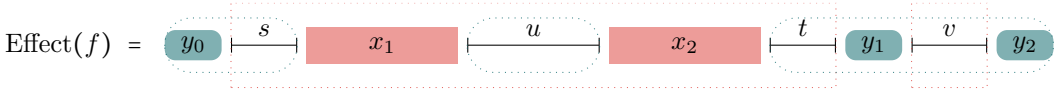
We finally turn to studying a notion of equivalence on transitions that is similar to the two-sided Myhill-Nerode equivalence on words. We will only compare transitions that consume the same input letter and link the same pair of states. Instead of using words as two-sided contexts, we will use initial and final runs that can be attached to the considered transitions in order to form successful runs, and instead of comparing membership in a language, we will compare the effect on the produced outputs.

Consider two transitions $\tau_1 : q \xrightarrow{a/f_1} q'$ and $\tau_2 : q \xrightarrow{a/f_2} q'$. We say that τ_1 and τ_2 are *equivalent* if for every initial run ρ leading to q and every final run σ starting in q', the outputs $\mathrm{out}(\rho\,\tau_1\,\sigma)$ and $\mathrm{out}(\rho\,\tau_2\,\sigma)$ are equal. We often refer to (ρ, σ) as a *context* for τ_1, τ_2.

In general, two transitions of an SST having the same source, target and Σ-label might turn out to be non-equivalent, and still produce the same output within specific contexts. However, Lemma 5 below shows that this is not the case with α-approximants at hand, provided that α is at least the capacity of the SST. More precisely, we will show that the equivalence of two transitions $\tau_1 : (q, A_X, A_Y) \xrightarrow{a/f_1} (q', A'_X, A'_Y)$ and $\tau_2 : (q, A_X, A_Y) \xrightarrow{a/f_2} (q', A'_X, A'_Y)$, where f_1, f_2 have the same flow, only depends on the α-approximants A_X, A'_Y that annotate the source and target states. This will imply that τ_1, τ_2 either always produce the same output or always produce different outputs, independently of the surrounding contexts. To prove the statement, we have to consider register valuations induced by initial runs, and symmetrically gap valuations induced by final runs. It helps to introduce the following:

Notation. Given an initial run ρ, $\mathrm{val}_{\rho\bullet}$ is the register valuation induced at the end of ρ; symmetrically, $\mathrm{val}_{\bullet\sigma}$ is the gap valuation induced at the beginning of a final run σ.

We also recall a consequence of the flow normalization: the effect on the final output of an update f that occurs in a successful run can be described by a word $\mathrm{Effect}(f)$ over the alphabet $X \uplus Y \uplus \Gamma$, defined as $\mathrm{Effect}(f) = y_0\, f(x_1)\, y_1 \dots f(x_m)\, y_{m+1}$. Note that in $\mathrm{Effect}(f)$ each register (resp. gap) occurs exactly once, according to the order $x_1 < \dots < x_m$ (resp. $y_0 < \dots < y_m$) – the occurrences of registers and gaps, however, may not be strictly interleaved. In $\mathrm{Effect}(f)$, an occurrence of $x_i \in X$ represents an abstract valuation for register x_i *before* applying the update f, while an occurrence of $y_j \in Y$ represents an abstract valuation for the gap y_j *after* applying f. In particular, note that the x's and the y's refer to valuations induced at different positions of a run. The maximal factors of $\mathrm{Effect}(f)$ that are entirely over Γ represent the words that need to be added in order to get the register valuation *after* f, or equally the gap valuation *before* f. For instance, by reusing the example update f from page 5, where $f(x_1) = s\,x_1\,u\,x_2\,t$ and $f(x_2) = v$, the effect of f is described by the word $\mathrm{Effect}(f) = y_0\,s\,x_1\,u\,x_2\,t\,y_1\,v\,y_2$, suggestively depicted as



(here the lengths of the blocks labeled with variables are immaterial). Note that the y_j above are in fact the y'_j from the picture at page 5. In the above figure we have also highlighted with dotted rectangles the factors that represent gap valuations before the update (e.g. $y_0\,s$), and register valuations after the update (e.g. $s\,x_1\,u\,x_2\,t$).

Given a valuation ν and two approximants $A \in \mathcal{L}^X_\alpha$ and $A' \in \mathcal{L}^Y_\alpha$, one for register valuations and the other for gap valuations, we write $\nu \in A \uplus A'$ to mean that $\nu(x) \in A(x)$ and $\nu(y) \in A'(y)$ for all $x \in X$ and $y \in Y$.

▶ **Lemma 5.** *Let T be a trimmed flow-normalized SST. Given two transitions $\tau_i : q \xrightarrow{a/f_i} q'$, with $i \in \{1,2\}$, a context (ρ,σ) for them, and the α-approximants $A = ((val_{\rho\bullet})^{\uparrow\alpha})|_X$ and $A' = ((val_{\bullet\sigma})^{\uparrow\alpha})|_Y$, with $\alpha \in \mathbb{N}$, the following holds:*

1. *If $Effect(f_1) = Effect(f_2)$ holds on all valuations $\nu \in A \uplus A'$, then $out(\rho\,\tau_1\,\sigma) = out(\rho\,\tau_2\,\sigma)$.*
2. *If τ_1, τ_2 have the same flow, $out(\rho\,\tau_1\,\sigma) = out(\rho\,\tau_2\,\sigma)$, and $\alpha \geq c$, where c is the capacity of T, then $Effect(f_1) = Effect(f_2)$ holds on all valuations $\nu \in A \uplus A'$.*

Recall that in an SST that admits α-approximants, states are of the form (q, A_X, A_Y), and we have $((\mathrm{val}_{\rho\bullet})^{\uparrow\alpha})|_X = A_X$ (resp. $((\mathrm{val}_{\bullet\sigma})^{\uparrow\alpha})|_Y = A_Y$) for every initial run ρ that ends in (q, A_X, A_Y) (resp. for every final run σ that starts in (q, A_X, A_Y)). By pairing this with Lemma 5, we immediately obtain the following corollary:

▶ **Corollary 6.** *Let T be a trimmed flow-normalized SST. One can decide in polynomial time whether two given transitions τ_1, τ_2 of T with the same flow are equivalent. Moreover, if T has capacity c and admits α-approximants for some $\alpha \geq c$, then only two cases can happen:*

1. *either $out(\rho\,\tau_1\,\sigma) = out(\rho\,\tau_2\,\sigma)$ for every context (ρ,σ) (so τ_1, τ_2 are equivalent),*
2. *or $out(\rho\,\tau_1\,\sigma) \neq out(\rho\,\tau_2\,\sigma)$ for* every *context (ρ,σ) (so τ_1, τ_2 are not equivalent).*

Another important consequence is the following theorem, that normalizes finite-valued SST in order to bound the maximum number of transitions linking the same pair of states and consuming the same input letter. This number is called *edge ambiguity* for short.

▶ **Theorem 7.** *Let T be a k-valued, flow-normalized SST that has m registers, capacity c, and that admits α-approximants, for some $\alpha \geq c$. One can construct an equivalent SST T', with the same states and the same registers as T, that has edge ambiguity at most $k \cdot 2^m$.*

Proof. By Corollary 6, T has at most k pairwise non-equivalent transitions with the same input letter, the same source and target states, and the same flow. Moreover equivalence of such transitions can be decided. We can then normalize T by removing in each equivalence class all but one transitions with the same flow. Since T has at most 2^m flows, the normalization results in an equivalent SST T' with edge ambiguity at most $k \cdot 2^m$. ◀

The next section is devoted to prove a very similar result as above, but for all SST that can be obtained by shortcutting runs into single transitions, and that thus have arbitrary large capacity. This will be the main technical ingredient for establishing the decidability of the equivalence problem for k-valued SST.

4 Shortcut construction

Here we focus on a transformation of relations that absorbs the first input letter when this is equal to a specific element, say $a \in \Sigma \setminus \{\dashv\}$. Such a transformation maps any relation R to the relation $R_a = \{(u,v) : (au,v) \in R\}$. Observe that $R = R_\varepsilon \cup \bigcup_{a\in\Sigma} R_a$, where $R_\varepsilon = R \cap (\{\dashv\} \times \Gamma^*)$.

It is easy to see that the class of relations realized by SST is effectively closed under the transformation $R \mapsto R_a$. To prove this closure property, it is convenient to restrict, without loss of generality, to SST with *transient initial states*, namely, SST where no transition reaches an initial state. Under this assumption, the closure property also preserves the state space (though some states may become useless), the set of registers, the property of being k-valued, as well as the α-approximants, if they are admitted by the original SST. However, the transformation does not preserves the capacity, which may increase.

▶ **Lemma 8.** *Given a flow-normalized SST T with transient initial states, and given a letter $a \in \Sigma \setminus \{\dashv\}$, one can construct an SST T_a with transient initial states such that*

- *$Dom(T_a) = \{u \in \Sigma^* : au \in Dom(T)\}$,*
- *T_a on input u produces the same outputs as T on input au.*

Moreover, T_a has the same states and the same registers as T; if T has capacity c, then T_a has capacity $2c$; if T admits α-approximants, then so does T_a (via the same annotation).

The above construction can be applied inductively to compute an SST for any *left quotient* $R_u = \{(v, w) : (u\,v, w) \in R\}$ of R. For $u = a_1 \dots a_n \in (\Sigma \setminus \{\dashv\})^*$, we let $T_u = (\dots (T_{a_1})_{a_2} \dots)_{a_n}$.

The last and most technical step consists in proving that edge ambiguity can be uniformly bounded in every SST T_u, provided that the initial SST T is finite-valued, flow-normalized, and admits α-approximants for a large enough α. More precisely, we aim at establishing that, for α much larger than the capacity of T, the notion of α-approximant, besides satisfying Equation (1), also satisfies the following property:

$$\begin{aligned} \forall \beta \geq \alpha \quad \exists \rho \ : \qquad (\mathrm{val}_{\rho\bullet})^{\uparrow\beta} &= (\mathrm{val}_{\rho\bullet})^{\uparrow\alpha} \\ \forall \beta \geq \alpha \quad \exists \sigma \ : \qquad (\mathrm{val}_{\bullet\sigma})^{\uparrow\beta} &= (\mathrm{val}_{\bullet\sigma})^{\uparrow\alpha}. \end{aligned} \tag{2}$$

In this case we say that the α-approximants are *tight*.

Intuitively, the above property can be explained as follows. When considering an SST with states annotated with α-approximants, it may happen that for some larger parameter β some initial runs induce register valuations at a state (q, A_X, A_Y) whose β-approximants are strictly included in A_X (e.g. possibly entailing new periodicities). These runs should be thought of as exceptional cases, and there is a way of pumping them so as to restore the equality between A_X and the induced β-approximant.

Let us first see how tight approximants are used. The theorem below assumes that there is an SST T' with tight approximants (later we will show how to compute such an SST), and bounds the edge ambiguity of the SST T'_u that realizes a left quotient of T'.

▶ **Theorem 9.** *Let T' be a k-valued, flow-normalized SST realizing R, with transient initial states and tight α-approximants. For every $u \in \Sigma^*$, one can construct an SST T'_u realizing R_u, with the same states and the same registers as T', and with edge ambiguity at most $k \cdot 2^m$.*

Proof. The crux is to show that the SST T'_u obtained from Lemma 8 has at most k pairwise non-equivalent transitions with the same flow (for any given source/target state and label). Once this is proven, one can proceed as in the proof of Theorem 7, by removing all but one transition with the same flow in each equivalence class. By way of contradiction, assume that T'_u has $k+1$ pairwise non-equivalent transitions $\tau_1, \dots, \tau_{k+1}$ with the same flow. Since T' admits tight α-approximants, by Lemma 8 we know that the source and target state, respectively, of the previous transitions are annotated with tight α-approximants, say (A_X, A_Y) and (A'_X, A'_Y), respectively.

We begin by applying the first claim of Lemma 5, implying that the equation $\mathrm{Effect}(f_i) = \mathrm{Effect}(f_j)$ is violated for some valuation $\nu \in A_X \uplus A'_Y$. Then, we let $\beta = \max(\alpha, |u|c)$ and use Equations (1) and (2) to get a context (ρ, σ) such that $(\mathrm{val}_{\rho\bullet})^{\uparrow\beta} = A_X$ and $(\mathrm{val}_{\bullet\sigma})^{\uparrow\beta} = A'_Y$. Finally, knowing that β is at least the capacity of T'_u, we apply the second claim of Lemma 5 to get $\mathrm{out}(\rho\,\tau_i\,\sigma) \neq \mathrm{out}(\rho\,\tau_j\,\sigma)$, thus witnessing non-equivalence of all pairs of transitions τ_i, τ_j at the same time. This contradicts the assumption that T'_u (and hence T') is k-valued. ◀

Now, let T be a flow-normalized SST with m registers, capacity c, and trimmed state space Q. Below, we show how to compute, with the help of Proposition 4, an SST T' equivalent to T that admits tight approximants. For simplicity, we will mostly focus on

register valuations induced by initial runs, even though similar results can be also stated for gap valuations induced by final runs. We begin by giving a few technical results based on pumping arguments. We say that register x is *productive* along ρ if the update induced by ρ maps x to a word that contains at least one letter from Γ. We also recall that a loop of a run needs to induce a flow-idempotent update.

▶ **Lemma 10.** *If $\rho = \rho_1 \gamma \rho_2$ is an initial run of T, with γ loop, then for every $n > 0$ the pumped run $\rho^{(n)} = \rho_1 \gamma^n \rho_2$ induces valuations $val_{\rho^{(n)}\bullet}$ mapping any register x to a word of the form $u_0 v_1^{n-1} u_1 \dots v_{2m}^{n-1} u_{2m}$, where $u_0, \dots, u_{2m}, v_1, \dots, v_{2m} \in \Gamma^*$ depend on ρ and x, but not on n. Moreover, we have $v_i \neq \varepsilon$ for some i if there is a register x' that is productive along γ and that flows into x along ρ_2.*

Given a tuple of pairwise disjoint loops $\overline{\gamma} = \gamma_1, \dots, \gamma_\ell$ in a run ρ, we write $\rho' \trianglerighteq_{\overline{\gamma}} \rho$ when ρ' is obtained from ρ by *simultaneously* pumping n times every loop γ_i, for some $n > 0$. When using this notation, we often omit the subscript $\overline{\gamma}$; in this case we tacitly assume that $\overline{\gamma}$ is *uniquely determined* from ρ. In this way, when writing, for instance, $\rho', \rho'' \trianglerighteq \rho$, we will know that ρ', ρ'' are obtained by pumping the same loops of ρ. We also say that a property on runs holds *for all but finitely many* $\rho' \trianglerighteq \rho$ if it holds on runs ρ' that are obtained from ρ by pumping n times the loops in a fixed tuple $\overline{\gamma}$, for all $n > n_0$ and for a sufficiently large n_0.

▶ **Lemma 11.** *Let ρ be an initial run and x a register. If $val_{\rho\bullet}(x)$ has length (resp. period) larger than $\alpha = m\, c\, |Q|\, 2^{3 \cdot 2^m}$, then for every $\beta \geq \alpha$ and for all but finitely many $\rho' \trianglerighteq \rho$, $val_{\rho'\bullet}(x)$ has length (resp. period) larger than β.*

Using the previous lemmas and the fact that the type of quantification "for all but finitely many runs" commutes with conjunctions (e.g. those used to enforce properties on each register $x \in X$), we obtain that α-approximants are tight for sufficiently large α:

▶ **Proposition 12.** *Let T' be the SST admitting α-approximants that is obtained from T using Proposition 4, for any $\alpha \geq m\, c\, |Q|\, 2^{3 \cdot 2^m}$, where Q is the set of states of T. The α-approximants of T' are tight.*

5 Equivalence algorithm

The equivalence algorithm for k-valued SST follows a classical approach of Culik and Karhumäki [10] that is based on so-called *test sets*. A test set for two SST T_1, T_2 over input alphabet Σ is a set $F \subseteq \Sigma^*$ such that T_1, T_2 are equivalent if and only if they are equivalent over F. The main contribution of [10] is to show that *finite* test sets exist and be computed effectively for k-valued one-way transducers.The key ingredient of their proof is to show the existence of a test set that works for *all* transducers with fixed number of states. An essential observation is that for k-valued one-way, or even two-way, transducers one can assume that the edge ambiguity is at most k. The reason for this is simply that the output is generated sequentially. For SST the situation is far more complex because the output is generated piecewise. The purpose of the normalizations performed in Section 3 was precisely to restore the property of bounded edge ambiguity.

In a nutshell, the existence of a test set for transducers is a consequence of Ehrenfeucht's conjecture, whereas the effectiveness is based on the resolution of word equations due to Makanin (see e.g. the survey [11]).

Ehrenfeucht's conjecture was originally stated as a conjecture about formal languages: for every language $L \subseteq \Sigma^*$, there is a finite subset $F \subseteq L$ such that for all morphisms $f, g : \Sigma^* \to \Delta^*$, $f(w) = g(w)$ for every $w \in L$ if and only if $f(w) = g(w)$ for every $w \in F$. Such a set F is called a *test set* for L.

There is an equivalent formulation of Ehrenfeucht's conjecture in terms of a compactness property of word equations [20]. Let Σ and Ω be two alphabets, where the elements in Ω are called unknowns. A word equation is a pair $(u, v) \in \Omega^* \times \Omega^*$, and a solution is a morphism $\sigma : \Omega^* \to \Sigma^*$ such that $\sigma(u) = \sigma(v)$. Ehrenfeucht's conjecture is equivalent to saying that any system of equations over a finite set Ω of unknowns has a finite, equivalent subsystem, where equivalence means that the solution sets are the same. The latter compactness property was proved in [1, 15] by encoding words by polynomials and using Hilbert's basis theorem.

In view of Propositions 2, 4, and 12, we can restrict without loss of generality to SST that are flow-normalized and that admit tight approximants. Hereafter, we shall tacitly assume that all transducers are of this form. Given some integers k, n, m, and e, let $\mathcal{C}_k(n, m, e)$ be the class of k-valued SST with at most n states, m registers, and edge-ambiguity at most e. Note that if T is k-valued, then by Theorem 7 it belongs to $\mathcal{C}_k(n, m, e)$, where n, m are the number of states and registers of T and $e = k \cdot 2^m$. Similarly, by Lemma 8 and Theorem 9, every left quotient T_u also belongs to $\mathcal{C}_k(n, m, e)$.

Now, let us fix k, n, m, e and consider an arbitrary SST T from $\mathcal{C}_k(n, m, e)$. Following [10] we first build an abstraction of T by replacing each maximal factor from Γ^* occurring in some update function of T, by a distinct unknown from Ω. The SST $\Delta(T)$ obtained in this way is called a *schema*; its outputs are words over Ω. Note that the assumption of bounded edge ambiguity is essential here to get a uniform bound on the number of unknowns required for a schema. Clearly, there are only finitely many schemas of SST in $\mathcal{C}_k(n, m, e)$. We denote by $\phi_T : \Omega \rightharpoonup \Gamma^*$ the partial mapping (concretization) that associates with each unknown the corresponding word from Γ^* as specified by the updates of T.

We can rephrase the equivalence $T_1 \equiv T_2$ of two arbitrary SST from $\mathcal{C}_k(n, m, e)$ as an infinite "system" of word equations[1] $\mathcal{S} = \bigwedge_{u \in \Sigma^*} \bigvee_\pi S_\pi$ over set of unknowns $\Omega \uplus \Omega'$. The unknowns from Ω are used for the schema $\Delta(T_1)$, whereas those from Ω' are used for $\Delta(T_2)$; in particular, $\phi_{T_1} : \Omega \to \Gamma^*$ and $\phi_{T_2} : \Omega' \to \Gamma^*$. The disjunctions in $\mathcal{S}$ are finite, with π ranging over the possible schemas Δ_1, Δ_2 (for T_1 and T_2, respectively) and the possible partitions of the set of runs of Δ_1 and Δ_2 over the input u, into at most k groups (one for each possible output). Finally, S_π is a (finite) system of word equations, stating the equality of the words from $\Omega^* \cup \Omega'^*$ that belong to the same group according to π.

The following lemma was stated in [10] for k-valued one-way transducers, but it holds as well for two-way transducers and for SST (even copyful, with a proper definition for $\mathcal{C}_k(n, m, e)$):

▶ **Lemma 13.** *Given two SST T_1, T_2 from $\mathcal{C}_k(n, m, e)$, the system $\mathcal{S} = \bigwedge_{u \in \Sigma^*} \bigvee_\pi S_\pi$ has $\phi_{T_1} \uplus \phi_{T_2}$ as solution if and only if $T_1 \equiv T_2$.*

As shown in [10], the Ehrenfeucht conjecture can be used to show that any infinite system $\mathcal{S}$ as in Lemma 13 is equivalent to some *finite* sub-system $\mathcal{S}_N = \bigwedge_{u \in \Sigma^{\leq N}} \bigvee_\pi S_\pi$. This gives:

▶ **Lemma 14.** *Given $n, m, e \in \mathbb{N}$, there is $N \in \mathbb{N}$ such that $\Sigma^{\leq N}$ is a test set for every pair of SST T_1, T_2 from $\mathcal{C}_k(n, m, e)$.*

Using Theorem 7 and Lemma 14 we can derive immediately the existence of a finite test set for any two k-valued SST. The last question is how to compute such a test set effectively. For this we will use the shortcut construction provided in Section 4.

[1] Formally, $\mathcal{S}$ depends on n and k, but for simplicity we leave out the indices.

▶ **Lemma 15.** *Assume that the formulas $\mathcal{S}_N$ and $\mathcal{S}_{N+1}$ are equivalent, i.e., they have the same solutions. Then $\Sigma^{\leq N}$ is a test set for any pair of SST from $\mathcal{C}_k(n,m,e)$.*

Proof. Let $T_1 \equiv_r T_2$ denote equivalence of T_1 and T_2 relativized to $\Sigma^{\leq r}$. The goal is to prove that $\Sigma^{\leq N}$ is a test set, namely, for all $r > N$ and all $T_1, T_2 \in \mathcal{C}_k(n,m,e)$, $T_1 \equiv_r T_2$ holds if and only if $T_1 \equiv_N T_2$. Clearly, for any $r \geq 0$, $T_1 \equiv_{r+1} T_2$ is equivalent to $T_{1,a} \equiv_r T_{2,a}$ for every $a \in \Sigma$, and $T_1 \equiv_0 T_2$ (the latter being abbreviated as $(*)$ below). Moreover, by Theorem 9, we have $T_{1,a}, T_{2,a} \in \mathcal{C}_k(n,m,e)$. This enables the following proof by induction on r:

$$\begin{array}{ccccc} T_1 \equiv_{r+1} T_2 & \Leftrightarrow & T_{1,a} \equiv_r T_{2,a}\ (\forall a \in \Sigma) \text{ and } (*) & & T_1 \equiv_N T_2. \\ & & \Updownarrow \text{(ind. hyp.)} & & \Updownarrow \\ & & T_{1,a} \equiv_N T_{2,a}\ (\forall a \in \Sigma) \text{ and } (*) & \Leftrightarrow & T_1 \equiv_{N+1} T_2 \end{array}$$ ◀

Using Makanin's algorithm for solving word equations (and even for deciding the existential theory of word equations, see e.g. [11] for a modern presentation) we obtain:

▶ **Proposition 16.** *Given $n,m,e \in \mathbb{N}$, there is $N \in \mathbb{N}$ such that $\Sigma^{\leq N}$ is a test set for every pair of SST from $\mathcal{C}_k(n,m,e)$, and such an N can be effectively computed.*

Proof. By Lemma 14 we know that N exists, and Makanin's algorithm allows to determine whether $\mathcal{S}_N, \mathcal{S}_{N+1}$ are equivalent, so to determine N by Lemma 15. ◀

We finally obtain the main result:

▶ **Theorem 1.** *The equivalence problem for finite-valued SST is decidable.*

Of course, Theorem 1 does not come with any complexity upper bound, mainly because of the Ehrenfeucht conjecture. The only known lower bound is PSPACE-hardness, which holds even for single-valued SST over unary output alphabets, and follows from a simple reduction from universality of NFA.

Quite surprisingly, the exact complexity of equivalence is not known even for *deterministic* SST, where the problem is known to be between NLOGSPACE and PSPACE [3]. We also recall that equivalence of deterministic SST with *unary output* can be checked in PTIME using invariants [4]. Finally, we recall that the currently best upper bound for solving word equations is PSPACE [21] (with even linear space requirement, as shown in [19]).

6 Conclusions

Our paper answers to a question left open in [5], showing that the equivalence problem for finite-valued SST is decidable. We followed a proof for one-way transducers due to Culik and Karhumäki [10], that is based on the Ehrenfeucht conjecture. The main contribution of the paper is to provide the technical development that allows to follow the proof scheme of [10]. We believe that this development will also allow to obtain stronger results. We conjecture that finite-valued SST can be effectively decomposed into finite unions of unambiguous SST. This would entail that in the finite-valued setting, two-way transducers and SST have the same expressive power, as is it the case for single-valued transducers. If this holds with elementary complexity, then the equivalence of single-valued SST (or two-way transducers) could also be solved with elementary complexity. We believe that the complexity is indeed elementary, and leave this for future work.

Abstract

We introduce a new approach to implicit complexity in linear logic, inspired by functional database query languages and using recent developments in effective denotational semantics of polymorphism. We give the first sub-polynomial upper bound in a type system with impredicative polymorphism; adding restrictions on quantifiers yields a characterization of logarithmic space, for which extensional completeness is established via descriptive complexity.

1 Introduction

Machine-free complexity. We pursue here a research theme advocated by Leivant [26]: using type systems and the proofs-as-programs correspondence to define functional languages whose expressible functions are exactly those of a given complexity. This usually consists of two independent parts: *soundness* – all those functions admit such complexity bounds – and *extensional completeness* – for every algorithm with this complexity, there is an expressible program computing the same function. This is part of the general area of *implicit computational complexity* (ICC), whose goal is to obtain characterizations of complexity classes by programming languages, without explicit resource bounds on a machine model (other methods in ICC include, for instance, recursive function algebras).

On the other hand, *descriptive complexity* is closer to a declarative programming paradigm: it consists in characterizing complexity classes as sets of *queries* – predicates over finite first-order relational structures – written in some logic. (Such structures often go by the

name of *finite models*; see Definition 3.) The field was launched by Fagin's result that NP queries correspond to existential second-order logic [11]. For our purposes, an useful example is Immerman's characterization of *deterministic logarithmic space* (L) (Theorem 13).

This idea of representing inputs as finite first-order structures also appeared in the early history of ICC: Gurevich [17] showed in 1983 that in this setting, a form of primitive recursion captures L. But unlike in descriptive complexity, Gurevich considers endofunctions instead of relations and queries.

Queries in the λ-calculus. Hillebrand's PhD thesis [18] is a junction point between implicit and descriptive complexity. The idea was to represent finite models inside the simply typed λ-calculus (STλ), using them to represent the inputs to programs. By doing so, Hillebrand et al. managed to characterize P [19], PSPACE [1] and k-EXPTIME/k-EXPSPACE[1] [20] – the extensional completeness for the first two being established through descriptive complexity.

Keeping in mind the connections between finite model theory and relational databases, this can also be seen as using STλ as a functional language for database queries, expressive enough to admit translations from other languages such as Datalog, as is done in [21].

The present paper could then be motivated as looking for a *sub-polynomial*[2] functional query language, filling a gap in the aforementioned work.

Linear logic for ICC. Here it is natural to turn to *linear logic*, a constructive logic born from the proofs-as-programs correspondence, in which several characterizations of sub-polynomial complexity classes have already been devised [38, 36, 7, 28, 29]. From its inception, linear logic has indeed had the ambition to "help us improve the efficiency of programs" [13, p. 3], and a landmark result in that direction was characterizing P through Light Linear Logic [16].

In this paper, we will use Elementary Linear Logic (ELL) [16, 8], which was originally introduced to capture the class ELEMENTARY[3]. A recent line of work by Baillot et al. [2, 3, 4] shows that one can define, inside variants of ELL, types of programs which compute smaller complexity classes, such as P. We follow this approach, by introducing a type `Inp` which is essentially an abstract data type[4] for finite models. Our main result is (writing $\mathtt{Bool} = 1 \oplus 1$):

▶ **Theorem 1.** *The class of queries computed by the proofs of* $\mathtt{Inp} \multimap !!\mathtt{Bool}$ *in second-order Elementary Linear Logic* (ELL_2) *is* between L and NL. *Furthermore, a suitable restriction on the existential witnesses in the proof gives an* exact characterization of L.

Here NL stands for *non-deterministic logarithmic space*. Actually, we obtain a better upper bound than NL in the unrestricted case, namely the class L^{UL} which will be defined later. But we believe that this is still not optimal:

▶ **Conjecture 1.** *Even without the restriction, the class of queries obtained is* exactly L.

---

[1] k-EXPTIME(resp. k-EXPSPACE) is the class of functions which can be computed in time (resp. space) $2 \uparrow^k (p(n))$, where p is a polynomial and n is the size of the input. (We use Knuth's up-arrow notation [24] for iterated exponentials: $2 \uparrow^{k+1} (n) = 2^{2\uparrow^k(n)}$, and $2 \uparrow^0 (n) = n$.)

[2] That is, capturing a complexity class below P. To be fair, Hillebrand's thesis does define a characterization of the sub-polynomial class of *first-order queries* (FO) in STλ, but this class has very little expressivity, and our work captures a class still well above FO.

[3] This is the class of elementary recursive functions, i.e. the union over $k \in \mathbb{N}$ of the classes k-EXPTIME.

[4] This term is the programming language counterpart of existential formulas in logic, cf. infra.

Our characterization has a few distinctive features with respect to the previous variants of linear logic capturing logarithmic space [36, 7, 28]: it takes place in a simple pre-existing logical system, which contains only usual logical connectives, and no primitive datatypes[5]; at the price of a more involved encoding of inputs, the `Inp` type. But a main novelty, in our opinion, is the unrestricted case: to our knowledge, it is the first[6] sub-polynomial bound in a type system with *impredicative polymorphism*.

This forces our approach to be significantly different to these previous works: they all exploit some form of the Geometry of Interaction (GoI) [14, 9] as a space-efficient evaluator, whereas in our case this does not work[7] because of impredicative quantication. In the predicative case, there is still an obstruction to the GoI: the *additive* connectives of linear logic. Instead, our tool of choice will be *denotational semantics*.

Semantic evaluation and polymorphism. This is indeed the sequel to a previous paper [32] which studied the semantics of second-order Multiplicative-Additive Linear Logic (MALL_2) with applications in mind; in particular it proved that Girard's model of MALL_2 in *coherence spaces* [12, 13] is finite and effective. In order to establish our upper complexity bounds, we will compute the denotation of a program applied to its input in the coherence space model.

This *semantic evaluation* technique has been very successful before for establishing complexity bounds in STλ: it is how soundness is established in the aforementioned works of Hillebrand et al., and also underlies Terui's more recent result on the complexity of β-reduction in STλ at fixed order [39]. Beyond STλ, it has been applied to System T and PCF, see [25] and references therein. However, these applications had been confined to monomorphic type systems[8] until the prequel showed:

▶ **Theorem 2** ([32]). *The languages decided by proofs of* $!\texttt{Str} \multimap !!\texttt{Bool}$ *in* ELL_2*, where* `Str` *is the type of* ELL *Church encodings of strings, are exactly the* regular languages.

An analysis of the proof also suggested that to increase the expressivity[9] while keeping $!!\texttt{Bool}$ as output, one should replace `Str` by an *existential* input type. Hence the `Inp` type.

To perform semantic evaluation in a polymorphic language, one needs an effective model of polymorphism, and such models are not easy to build. First, one must first restrict to a purely linear language[10] such as MALL_2 to make a non-trivial finitary semantics possible. Even then, obstacles remain: for instance, the prequel [32] proved that no degenerate model of MALL_2 (in which $\otimes$ and $\parr$ are identified) can satisfy a desirable "constancy property", so this excludes the Scott model of linear logic used by [39]. Girard managed to build a

[5] Given the special status granted to unary Church integers by the "skewed iteration" rule in Schöpp's SBAL [36], it is fair to consider them to be primitive datatypes.

[6] Excluding the characterization of regular languages in ELL_2, cf. infra, but regular languages do not form a well-behaved complexity class (for instance they are not closed under uniform AC^0 reductions).

[7] We will not enter into details here, but essentially, the GoI works by "following paths" inside a proof, and in our case, the length of these paths would be super-polynomial.

[8] That said, there have been some uses of rather different semantic techniques for implicit complexity in presence of polymorphism, e.g. realizability [6].

[9] This was also a major motivation in the work of Hillebrand et al.: they wanted to overcome limits in STλ such as Statman's classical result that equality cannot be defined on STλ Church integers (see the introduction to [21]). Hillebrand and Kanellakis [20] later proved that the languages decided by STλ predicates over Church-encoded strings are regular (this inspired the analogous result on ELL_2). Such restrictions seem drastic since the β-equivalence problem for STλ is not in ELEMENTARY [37, 27], hinting that its computational power should be much greater. By using finite models as inputs, Hillebrand, Kanellakis and Mairson [21] manage to express all ELEMENTARY queries.

[10] The type $\forall X.\ X \to (X \to X) \to X$ of polymorphic Church integers – more generally, any infinite data type whose destructors are definable – has an inifinite denotation in any semantics of System F.

semantics for System F [12] which later turned out to be finite and effective for MALL_2 by representing types depending on type parameters as *normal functors*[11]. Although we will not have to study the properties of normal functors here – the semantic groundwork has been laid in the prequel – we consider that this ingredient is crucial enough to deserve inclusion in the title.

New complexity phenomena in MALL. The bottleneck for this L^{UL} bound is the complexity of an iterated composition problem: given a MALL_2 type A and k proofs $f_1, \ldots, f_k$ of $A \vdash A$, compute their composition $f_1 \circ \ldots \circ f_k$. To illustrate the kind of complexity constraint induced by the linearity of the f_i, consider the types $\mathtt{Bool} \otimes \ldots \otimes \mathtt{Bool}$ (n times) and $\mathtt{Bool} \,\&\, \ldots \,\&\, \mathtt{Bool}$ (n times). A non-linear function does not distinguish them, whereas for linear functions:

- an iteration over $\mathtt{Bool} \otimes \ldots \otimes \mathtt{Bool}$ can simulate a Turing machine running in space n (minus $O(1)$ bits for the control state);
- an iteration over $\mathtt{Bool} \,\&\, \ldots \,\&\, \mathtt{Bool}$ can be computed in space $O(\log(nk))$.

This kind of phenomenon surfaced when we tried to obtain bounds on our ELL_2 queries; we are not aware of a previous mention in the literature. Coherence spaces are sensitive to this (e.g. the interpretation of $\otimes$ and & bit vectors have respective sizes 2^n and $2n$) and thus manage to give a systematic sub-polynomial (but not L) bound on iterations.

For now, we have only managed to find a logarithmic space algorithm for those iterations in very specific cases of A, subsuming the above example. These cases still leave enough room for an extensional completeness result, leading to our exact characterization of L. But even in propositional MALL, the complexity of iterations remains mysterious.

Plan of the paper. In Section 2 we introduce the necessary definitions and state the main theorems. The lower bound on expressivity is established using descriptive complexity in Section 3, while our upper bounds are both proved in Section 4 via semantic evaluation.

2 Elementary Linear Logic as a query language

2.1 Linear Logic

In this paper, we assume some familiarity with the basic ideas of the proofs-as-programs paradigm and more specifically of linear logic. The formulas and the sequent calculus of second-order Multiplicative-Additive Linear Logic (MALL_2) are recalled in the full paper, in Appendix A. Recall that MALL_2 forbids using the structural rules of contraction and weakening, enforcing *linearity* whose computational meaning is that data cannot be duplicated or erased.

In order to allow the use of the structural rules in a controlled manner, the grammar of full Linear Logic extends the syntax of MALL_2 with *exponential modalities* $!F$ and $?F$ which allow to tag duplicable assumptions and conclusions. (Second-order) *Elementary Linear Logic* (ELL_2) corresponds to the subsystem whose rules governing the exponential connectives are given in Figure 1; this makes the principles of digging ($!A \multimap !!A$) and dereliction ($!A \multimap A$) invalid in ELL_2 while they are provable in full Linear Logic.

[11] A remark: the fact that our L^{UL} upper bound involves *unambiguous* nondeterminism, as we shall see, is related to the *stability* of linear maps in coherence spaces; stable maps are the "lower-dimensional analogue" of normal functors, and interestingly, it seems that stability is required for the construction of models of polymorphism based on normal functors.

$$\text{(functorial promotion)}\frac{\vdash \Gamma, A}{\vdash ?\Gamma, !A} \qquad \text{(weakening)}\frac{\vdash \Gamma}{\vdash \Gamma, ?A} \qquad \text{(contraction)}\frac{\vdash \Gamma, ?A, ?A}{\vdash \Gamma, ?A}$$

Figure 1 Exponential rules for the ELL_2 sequent calculus. In the functorial promotion rule, when $\Gamma = B_1, \dots, B_k$, $?\Gamma$ stands for $?B_1, \dots, ?B_k$.

ELL_2 thus satisfies a *stratification* property: the *depth* of a given connective – i.e. the number of !/? modalities it is in the scope of – does not change during cut-elimination (key cut-elimination rules are also recalled in Appendix A). As a consequence, this notion of depth is of the utmost relevance for the computational complexity properties of ELL_2.

LL notations. When π and ρ have respective conclusions $\vdash \Gamma, A$ and $\vdash A^\perp, \Delta$, we write $\mathbf{cut}(\pi, \rho)$ for the proof of $\vdash \Gamma, \Delta$ consisting of a cut-rule with premises π and ρ. Given a proof $\pi : A$, $!\pi$ denotes the proof of $!A$ obtained by applying the promotion rule to π. As we formally use one-sided sequents, $A_1, \dots, A_n \vdash B$ is a notation for $\vdash A_1^\perp, \dots, A_n^\perp, B$.

2.2 Finite models

▶ **Definition 3.** *Let Σ be a first-order relational signature, i.e. a list of relation symbols $\{\mathcal{R}_0, \dots, \mathcal{R}_k\}$ with their respective arities $r_0, \dots, r_k$.*

A finite model $\mathfrak{D}$ *over Σ consists of a finite set D and an interpretation $\mathcal{R}_i^{\mathfrak{D}} \subseteq D^{r_i}$ for each relation symbol. It is* totally ordered *when $\mathcal{R}_0 = \leq$, $r_0 = 2$ and $\mathcal{R}_0^{\mathfrak{D}}$ is a total order.*

We write $\mathrm{FinMod}(\Sigma)$ *for the set of totally ordered finite models over Σ.*

As an example, a possible signature for binary strings is $\{\leq, S\}$ with arities 2 and 1. Finite models consist of a totally ordered set $(D, \leq^{\mathfrak{D}})$ with a unary predicate $S^{\mathfrak{D}}$; we interpret $(D, \leq^{\mathfrak{D}})$ as the indices of the string, and $S^{\mathfrak{D}}(d)$ as "the dth bit is set to 1".

▶ Remark 4. The "totally ordered" assumption is common in descriptive complexity (see e.g. Theorem 13) and will be often kept implicit in the paper. Indeed, there are order-independent queries requiring a total order to be expressed.

To use finite models as inputs for ELL_2 programs, we represent the elements of $\mathrm{FinMod}(\Sigma)$ as proofs of an ELL_2 formula $\mathtt{Inp}_\Sigma$.

▶ **Definition 5.** *We define the types with a free variable δ:*

$$\mathtt{List}[\delta] = \forall X.\, !(\delta \multimap X \multimap X) \multimap !(X \multimap X) \qquad \mathtt{C}[\delta] = \delta \multimap \delta \otimes \delta \qquad \mathtt{W}[\delta] = \delta \multimap 1$$

$$\mathtt{Ctx}[\delta] = !\mathtt{List}[\delta] \otimes !!\mathtt{C}[\delta] \otimes !!\mathtt{W}[\delta] \qquad \mathtt{Bool} = 1 \oplus 1 \qquad \mathtt{Rel}_r[\delta] = \delta^r \multimap \mathtt{Bool}$$

Given a signature $\Sigma = \{\leq, \mathcal{R}_1, \dots, \mathcal{R}_k\}$ with arities $r_0 = 2, r_1, \dots, r_k$, we also define:

$$\mathtt{Inp}_\Sigma[\delta] = \mathtt{Ctx}[\delta] \otimes \bigotimes_{0 \leq i \leq k} !!\mathtt{Rel}_{r_i}[\delta] \qquad \mathtt{Inp}_\Sigma = \exists \delta.\, \mathtt{Inp}_\Sigma[\delta]$$

We now define the encoding $\overline{\mathfrak{D}}$ of any totally ordered finite model $\mathfrak{D}$ over Σ as a proof of $\mathtt{Inp}_\Sigma[\mathtt{Fin}(n)]$, where $\mathtt{Fin}(n) = 1 \oplus \dots \oplus 1$ with n summands, n being the domain size.

Let $\mathfrak{D} = (D, \leq^{\mathfrak{D}}, \mathcal{R}_1^{\mathfrak{D}}, \dots, \mathcal{R}_k^{\mathfrak{D}}) \in \mathrm{FinMod}(\Sigma)$ with $\mathrm{Card}(D) = n$. Choose a bijection between D and the n proofs of $\mathtt{Fin}(n)$.

- *We represent D as a Church-encoded list of type* $\mathtt{List}[\mathtt{Fin}(n)]$ *enumerating the n elements of* $\mathtt{Fin}(n)$.
- *Each relation* $\mathcal{R}_i^{\mathfrak{D}}$ *can be represented by an element of* $\mathtt{Rel}_{r_i}[\mathtt{Fin}(n)]$.
- *Finally, since* $\mathtt{Fin}(n)$ *is a positive type, there are canonical elements of type* $\mathtt{C}[\mathtt{Fin}(n)]$ *and* $\mathtt{W}[\mathtt{Fin}(n)]$ *implementing the structural rules.*

▶ **Definition 6.** *A proof* π *of* $\mathtt{Inp}_\Sigma \multimap \mathtt{!!Bool}$ *defines the query which evaluates to true on* $\mathfrak{D} \in \mathrm{FinMod}(\Sigma)$ *iff the application of* π *to the encoding* $\overline{\mathfrak{D}}$ *reduces to* $\mathtt{!!true}$ *(where* $\mathtt{true}$ *is the proof of* $\mathtt{Bool} = 1 \oplus 1$ *proving the left occurrence of* 1*).*

2.3 Complexity classes and the main theorems

For the rest of the paper, we fix a signature $\Sigma = \{\mathcal{R}_0 = \leq, \mathcal{R}_1, \dots, \mathcal{R}_N\}$ with arities $r_0 = 2, r_1 \dots, r_N$.

As we said in the introduction, we write L (resp. NL) for the class of decision problems solvable in deterministic (resp. non-deterministic) logarithmic space. The *unambiguous* logarithmic space class UL [33] consists of the problems which can be solved by a NL Turing machine whose accepting runs are guaranteed to be *unique*: for each input, if the machine accepts, there is a single sequence of non-deterministic choices leading to the accepting state. (So $\mathsf{UL} \subseteq \mathsf{NL}$.) L^{UL} denotes L with an UL oracle; as usual we use the Ruzzo–Simon–Tompa definition[12] of space-bounded oracle machines [35, §4].

We can now state our result in the unrestricted case.

▶ **Theorem 7.** *The class of queries computed by the proofs of* $\mathtt{Inp}_\Sigma \multimap \mathtt{!!Bool}$ *in* ELL_2 *is between* L *and* L^{UL}.

It is known that $\mathsf{NL}^{\mathsf{NL}} = \mathsf{NL}$ (as noted in [23, Corollary 2], it follows from $\mathsf{NL} = \mathsf{coNL}$), so $\mathsf{L}^{\mathsf{UL}} \subseteq \mathsf{NL}$, hence the statement in the introduction. Furthermore, while $\mathsf{NL} \subset \mathsf{P}$, it is commonly believed that $\mathsf{NL} \neq \mathsf{P}$, so our class of queries is presumably strictly sub-polynomial.

To state the second main theorem, we now introduce a fragment of ELL_2 with an ad-hoc restriction on existential witnesses.

▶ **Definition 8.** *The set of* positive polynomial formulas PP *is the subset of* MALL_2 *formulas generated by the grammar* $P, Q, \dots ::= 0 \mid 1 \mid X \mid P \otimes Q \mid P \oplus Q$.

We define PP3 *to be the set of formulas of the form* $P \otimes (Q \multimap R)$*, where* $P, Q, R \in \mathrm{PP}$.

The logic $\mathrm{ELL}_2^{\mathrm{PP3}}$ *is defined by the same rules as* ELL_2 *except that we exclude the cut rule, and restrict the* $\exists$*-rule as follows: the witness must belong to* PP3.

The "cut-free" part is necessary because *a cut between two* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *proofs does not necessarily normalize into a* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *proof.* However, we do have:

▶ **Proposition 9.** *Let* π *and* ρ *be* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *proofs with respective conclusions* $\vdash \Gamma, A$ *and* $\vdash A^\perp, \Delta$*. If* A *is* quantifier-free*, then* $\mathbf{cut}(\pi, \rho)$ *is in* $\mathrm{ELL}_2^{\mathrm{PP3}}$.

With $\mathrm{ELL}_2^{\mathrm{PP3}}$, we obtain an exact characterization of L:

▶ **Theorem 10.** *The class of queries computed by proofs of* $\mathtt{Inp}_\Sigma \multimap \mathtt{!!Bool}$ *in* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *is* L.

[12] A remark on notation: they would write $\mathsf{L}^{\langle \mathsf{UL} \rangle}$ instead of L^{UL} and use the latter to denote a naive notion of oracle machine. See [35, Example 1] for an example of the subtleties involved: without a careful definition, $\mathsf{NL}^{\mathsf{NL}}$ would include NP.

3 The lower bound: encoding logarithmic space queries

In this section, we use descriptive complexity to get the lower bound in both theorems above (so, for the second one, this is an extensional completeness proof).

3.1 Reminder: Immerman's characterization of L

Descriptive complexity considers queries given by formulas in extensions of classical first-order logic. The first-order formulas over Σ are generated by the grammar $\phi, \psi, \ldots ::= \mathcal{R}_i(x_1, \ldots, x_{r_i}) \mid \neg\phi \mid \phi \vee \psi \mid \exists x.\phi$, where the x_j are variables.

As usual, the semantics of these formulas is specified by a "satisfaction" relation $\mathfrak{D} \models \phi[\sigma]$ for $\mathfrak{D} \in \mathrm{FinMod}(\Sigma)$, defined by induction over ϕ, where σ assigns elements of the domain D of $\mathfrak{D}$ to the free variables of ϕ: e.g. $\mathfrak{D} \models (\exists x.\phi)[\sigma]$ iff $\mathfrak{D} \models \phi[\sigma + (x \mapsto d)]$ for some $d \in D$. Thus, when such a formula ϕ is closed, it defines the query $\mathfrak{D} \mapsto (\mathfrak{D} \models \phi)$.

To express all logarithmic space queries, we need to extend our language of formulas with a *deterministic transitive closure* operator.

▶ **Definition 11.** *The formulas of* first-order logic with deterministic transitive closure (FO+DTC) *are generated by the above grammar extended with a new clause:*

$$\phi, \psi, \ldots ::= \ldots \mid \mathrm{DTC}_{\vec{x},\vec{y}}(\phi) \quad (\vec{x} \text{ and } \vec{y} \text{ are lists of variables of same length})$$

The definition of the satisfaction relation is extended with the following induction case: $\mathfrak{D} \models \mathrm{DTC}_{\vec{x},\vec{y}}(\phi)[\sigma] \iff \sigma(\vec{x})\ R^*\ \sigma(\vec{y})$ *where*

- R^* *is the reflexive transitive closure of the binary relation* $R \subseteq D^k \times D^k$*;*
- D *is the domain of* $\mathfrak{D}$ *and* $\vec{x}, \vec{y}$ *have length* k*;*
- $\vec{a}\ R\ \vec{b} \iff \mathfrak{D} \models \phi_d[\sigma + (\vec{x} \mapsto \vec{a}) + (\vec{y} \mapsto \vec{b})]$[13] *with* ϕ_d *defined as* $\phi \wedge (\forall \vec{z}.\, \phi[\vec{z}/\vec{y}] \Rightarrow \vec{z} = \vec{y})$.

▶ Remark 12. In the above definition, the relation R defined by ϕ_d is *deterministic*, i.e. it is the graph of a partial function $D^k \rightharpoonup D^k$, hence the name. Indeed, it is a "determinization" of the relation defined by ϕ.

▶ **Theorem 13** (Immerman [22])**.** *The* L *queries over totally ordered finite models are exactly those expressible in* FO+DTC*.*

3.2 An encoding of FO+DTC

Thus, it suffices to compile FO+DTC formulas, by induction, to $\mathrm{ELL}_2^{\mathrm{PP3}}$ proofs. For this purpose, it is convenient to interpret formulas with free variables as relation-valued queries:

▶ **Theorem 14.** *Let* $\phi(\vec{x})$ *be an* FO+DTC *formula with* k *free variables. Then there exists an* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *proof* π_ϕ *of* $\mathtt{Inp}[\delta] \vdash !!\mathtt{Rel}_k[\delta]$ *such that, for all* $\mathfrak{D} \in \mathrm{FinMod}(\Sigma)$ *with a domain* D *of size* n*,* $\mathbf{cut}(\overline{\mathfrak{D}}, \pi_\phi[\mathtt{Fin}(n)/\delta])$ *reduces to the encoding of* $\{\vec{a} \in D^k \mid \mathfrak{D} \models \phi[\vec{x} \mapsto \vec{a}]\}$*.*

▶ **Corollary 15** (Lower bound for Theorem 7 and Theorem 10)**.** *All* FO+DTC *queries – and therefore all* L *queries – over* $\mathrm{FinMod}(\Sigma)$ *can be computed by* $\mathrm{ELL}_2^{\mathrm{PP3}}$ *proofs of* $\mathtt{Inp}_\Sigma \multimap \mathtt{Bool}$*.*

Proof. Note that $\mathtt{Rel}_0[\delta] \cong \mathtt{Bool}$, and apply a $\parr$-rule and a $\forall$-rule to the $\mathrm{ELL}_2^{\mathrm{PP3}}$ proof given by the previous theorem. ◀

[13] The new assignments for $\vec{x}$ and $\vec{y}$ override the pre-existing ones in σ.

The detailed proof of Theorem 14 is given in the full paper, in Appendix B. As stated before, it works by induction on the FO+DTC formula, the bulk of the work for the induction being the case $\phi = \mathrm{DTC}_{\vec{x},\vec{y}}(\psi)$. The remainder of the section gives a rough summary of the ideas involved.

Let $R \subseteq D^k \times D^k$, and define $\psi_R : Q \mapsto \{(x,z) \mid x = z \vee (\exists y : x\, R\, y \wedge y\, Q\, z)\}$. Then ψ_R is a monotone function over $\mathcal{P}(D^k \times D^k)$, a lattice of height $n^{2k}+1$ ($n = \mathrm{Card}(D)$). Its least fixpoint $\psi_R^{n^{2k}+1}(\emptyset)$ is exactly the reflexive transitive closure of R. To compute $\psi_R^{n^{2k}+1}$, we use an iterator of type $\mathtt{Nat} = \forall X.!(X \multimap X) \multimap !(X \multimap X)$ derived from the $\mathtt{List}[\delta]$.

But this only allows us to iterate *linear* functions. This is where we use the assumption that R is *deterministic*: if $f_R : D^k \rightharpoonup D^k$ is the partial function associated to R, then $\psi_R(Q) = \{(x,z) \mid x = z \vee (f_R(x) \text{ defined} \wedge f_R(x)\, Q\, z)\}$. In this reformulation, the existential quantifier, which was a source of non-linearity, has disappeared: now, for each (x,z), the evaluation of $(x,z) \in \psi_R(Q)$ uses Q at most once, on $(f_R(x), z)$. In the end, we manage to write a function of type $\mathtt{Rel}_{2k}[\delta] \multimap \mathtt{Rel}_{2k}[\delta]$ representing ψ_R, which we feed to the $\mathtt{Nat}$.

A not-quite-trivial step is to define a proof of $\mathtt{Ctx}[\delta], !!\mathtt{Rel}_{2k}[\delta] \vdash !!(\delta^k \multimap 1 \oplus \delta^k)$ sending a relation ϕ to the partial function associated to its determinization ϕ_d. To do so, at one point, we need to instantiate the input $\mathtt{List}[\delta]$ at the type $\delta^{k-1} \otimes (\delta^k \multimap 1 \oplus \delta^k \oplus 1)$; this is our most complicated existential witness, and it is in PP3. We refer the reader to Appendix B of the full paper again for details.

4 The upper bounds: semantic evaluation

We now give space-efficient algorithms for queries defined by proofs of $\mathtt{Inp}_\Sigma \multimap !!\mathtt{Bool}$ in ELL_2 (resp. $\mathrm{ELL}_2^{\mathrm{PP3}}$). First, we analyse the shape of such a proof, to obtain alternative definitions of the same predicates involving only MALL_2 types and proofs. This puts us in a position to evaluate our queries in a finite, effective semantics of MALL_2: the model of coherence spaces and normal functors which we recall next. Then, we quickly derive the unrestricted L^{UL} bound for Theorem 7, and finally prove L soundness for Theorem 10 thanks to a tricky combinatorial algorithm on coherence spaces.

4.1 Syntactic analysis

Purely syntactic arguments suffice to show that our ELL_2 queries can be captured by a kind of function algebra, defined below. Though it bears some similarities with Gurevich's characterization of L [17] by primitive recursion on finite models, a major difference is that our functions may take arguments which are not just domain elements (that can be coded on $O(\log n)$ bits) but also higher-order data of polynomial size in n, such as relations. Indeed, linearity serves mainly to tame the complexity in presence of higher-order features, while it is mostly meaningless on first-order data.

▶ **Definition 16.** *We define inductively, simultaneously for all $(k+1)$-tuples $(A_1, \ldots, A_k, B)$ of MALL_2 types with at most one free type variable δ, the classes of functions $\mathcal{C}(A_1, \ldots, A_k; B)$ taking as input:*

- *a closed MALL_2 type T (i.e. without free variables)*
- *a list $L = [\tau_1, \ldots, \tau_n]$ of proofs of T*
- *a k-tuple of proofs $(\rho_1, \ldots, \rho_k)$ with $\rho_i : A_i[T/\delta]$*

and returning a proof of $B[T/\delta]$ as follows:

- *if π is a proof of $A_1, \ldots, A_k \vdash B$, then*
  $[(T; L; \rho_1, \ldots, \rho_k) \mapsto \mathbf{cut}(\rho_1, \ldots \mathbf{cut}(\rho_k, \pi[T/\delta]) \ldots)] \in \mathcal{C}(A_1, \ldots, A_k; B)$

- (projection) $\Pi_i^k = [(T; L; \rho_1, \dots, \rho_k) \mapsto \rho_i] \in \mathcal{C}(A_1, \dots, A_k; A_i)$
- (composition) *if* $f_i \in \mathcal{C}(A_1, \dots, A_k; B_i)$ *for* $i \in \{1, \dots, l\}$ *and* $g \in \mathcal{C}(B_1, \dots, B_l; C)$*, then* $[(T; L; \vec{\rho}) \mapsto g(T; L; f_1(T; L; \vec{\rho}), \dots, f_l(T; L; \vec{\rho}))] \in \mathcal{C}(A_1, \dots, A_k; C)$
- (iteration) *if* $f \in \mathcal{C}(A_1, \dots, A_k; \delta \multimap B \multimap B)$*, then* $[(T; L = [\tau_1, \dots, \tau_n]; \vec{\rho}) \mapsto f(T; L; \vec{\rho})\langle\tau_1\rangle \circ \dots \circ f(T; L; \vec{\rho})\langle\tau_n\rangle] \in \mathcal{C}(A_1, \dots, A_k; B \multimap B)$ *where*
  - $\pi\langle\tau\rangle$ *is the partial application of* $\pi : T \multimap B[T/\delta] \multimap B[T/\delta]$ *to* $\tau : T$*, to produce a proof of* $B[T/\delta] \multimap B[T/\delta]$*;*
  - $\circ$ *is the composition of proofs of* $B[T/\delta] \multimap B[T/\delta]$ *seen as endomorphisms of* $B[T/\delta]$*.*

▶ **Proposition 17.** *Let* $(A_1, \dots, A_k, B)$ *be a* $(k+1)$*-tuple of* MALL_2 *types and* π *be an* ELL_2 *proof of* $\forall\delta.((!\mathtt{List}[\delta] \otimes !!A_1 \otimes \dots \otimes !!A_k) \multimap !!B)$*. Then there exists a function* $f \in \mathcal{C}(A_1, \dots, A_k; B)$ *such that for all* $\rho_i : A_i[T/\delta]$ *(*$i \in \{1, \dots, m\}$*) and* $\tau_1, \dots, \tau_n : T$*,* $\mathbf{cut}(![\tau_1, \dots, \tau_n] \otimes !!\rho_1 \otimes \dots \otimes !!\rho_k, \pi) = !!f(T; [\tau_1, \dots, \tau_n]; \rho_1, \dots, \rho_k)$ *(where the* $[\tau_1, \dots, \tau_n]$ *on the left is a Church-encoded list in* ELL_2 *of type* $\mathtt{List}[T]$*).*

Moreover, if π *is in* $\mathrm{ELL}_2^{\mathrm{PP3}}$*, then there is an inductive derivation for* f *in which all instances of the iteration scheme use a type of accumulators in* PP3*: that is, they are applied to functions in* $\mathcal{C}(\dots; \delta \multimap P \multimap P)$ *with* $P \in \mathrm{PP3}$*.*

Though the proof of this proposition presents no conceptual difficulty, it is cumbersome and so is relegated to the full paper, in Appendix C. Importantly, it is thanks to the stratification property of ELL_2 that the types involved in the function algebra can be taken in MALL_2: the argument uses the "truncation at depth 2" operation introduced in the prequel to prove Theorem 2. Note that they may still contain impredicative quantifications, making its finite interpretation essential to our approach.

▶ Remark 18. The converse also holds: one can map functions in our algebra to ELL_2 proofs.

This can now be specialized to the case $\pi : \mathtt{Inp}_\Sigma \multimap !!\mathtt{Bool}$; indeed,

$$\mathtt{Inp}_\Sigma \multimap !!\mathtt{Bool} \cong \forall\delta.\ !\mathtt{List}[\delta] \otimes !!\mathtt{C}[\delta] \otimes !!\mathtt{W}[\delta] \otimes \bigotimes_{0 \le i \le N} !!\mathtt{Rel}_{r_i}[\delta] \multimap !!\mathtt{Bool}$$

Our ELL_2-definable (resp. $\mathrm{ELL}_2^{\mathrm{PP3}}$-definable) queries can therefore be specified, equivalently, by functions in $\mathcal{C}(\mathtt{C}[\delta], \mathtt{W}[\delta], \mathtt{Rel}_{r_0}[\delta], \dots, \mathtt{Rel}_{r_N}[\delta]; \mathtt{Bool})$. The next step is to evaluate these functions in the coherence space model.

4.2 The finite semantics of second-order MALL in coherence spaces

We recall key facts about the denotational model of MALL_2 in which we will carry out our semantic evaluation. A comprehensive introduction to this model for propositional MALL may be found in [15], and the extension to MALL_2 is taken from the prequel [32].

In this semantics, a formula/type is interpreted as a *coherence space*: an undirected reflexive graph, i.e. a pair $X = (|X|, \frown_X)$ of a set $|X|$ – customarily called the *web* of X – and a symmetric and reflexive relation $\frown_X \subseteq |X| \times |X|$ – its *coherence relation*. Elements $x, y \in |X|$ are called *coherent* when $x \frown_X y$. A *clique* is a subset of pairwise coherent elements of $|X|$; we write $c \sqsubset X$ when c is a clique of X. The denotation of a closed type A is a coherence space, and a proof/program $\pi : A$ is interpreted as a clique $[\![\pi]\!] \sqsubset [\![A]\!]$.

$[\![A]\!]$ is defined by induction on A, the connectives $\otimes, \parr, \&, \oplus, (-)^\perp$ being mapped to operations on coherence spaces. The base case depends on an assignment of type variables. So, if A has n type variables, $[\![A]\!]$ is actually a map from n-tuples of coherence spaces to coherence spaces. Similarly, $[\![\pi]\!]$ also depends on such an assignment, and one should

write $[\![\pi]\!](X_1, \ldots, X_n) \sqsubset [\![A]\!](X_1, \ldots, X_n)$. To extend the semantics to MALL_2, we interpret quantifiers as sending such "$(n+1)$-parameter spaces" to "n-parameter spaces". The following proposition sums up the properties that will be necessary for our purposes.

▶ **Proposition 19** ([32]). *Let A be a MALL_2 type with a single free type variable.*
- *$[\![A]\!](X)$ is* finite*, with size polynomial in the size of X when A is fixed.*
- *$[\![\pi]\!](X)$ can be computed in logarithmic space when $\pi : A$ is fixed.*

Finally, we need to recall the semantic counterpart of cut-elimination, that is, composition of morphisms. A first remark is that $|X \multimap Y| = |X| \times |Y|$. So a clique $c \sqsubset X \multimap Y$ can in fact be seen as a *binary relation* $c \subseteq |X| \times |Y|$. The composition of c with some $c' \sqsubset Y \multimap Z$, seen as morphisms of coherence spaces, is then none other than their *relational composition*. Additionally, the coherence relation ensures the well-known fact that:

▶ **Proposition 20.** *Let $c \sqsubset X \multimap Y$, $c' \sqsubset Y \multimap Z$, $x \in |X|$ and $z \in |Z|$. Then there exists* at most one *$y \in |Y|$ such that $(x, y) \in c$ and $(y, z) \in c'$.*

4.3 The unrestricted case: an unambiguous logarithmic space bound

In this subsection and in the next one, we abbreviate for convenience $[\![\mathtt{Fin}(n)]\!]$, i.e. the n-vertex coherence space with no edges, as $\mathtt{Fin}(n)$. So, if A is a MALL_2 type with a single variable δ, then $[\![A[\mathtt{Fin}(n)/\delta]]\!] = [\![A]\!](\mathtt{Fin}(n))$. Our main theorem here is:

▶ **Theorem 21.** *Let $f \in \mathcal{C}(A_1, \ldots, A_k; B)$. Then $[\![f(T; L; \rho_1, \ldots, \rho_k)]\!]$ is determined by $[\![T]\!]$, $[\![L]\!] = [[\![\tau_1]\!], \ldots, [\![\tau_n]\!]]$ (where $L = [\tau_1, \ldots, \tau_n]$) and $[\![\rho_1]\!], \ldots, [\![\rho_k]\!]$. Furthermore, when f is fixed, $[\![f(T; L; \rho_1, \ldots, \rho_k)]\!]$ can be computed from these denotations in L^{UL}.*

Proof. By structural induction on Definition 16; the first part is an immediate consequence of the functoriality/compositionality of $[\![-]\!]$, so we focus on the complexity. We take care of the base case, where the function comes from a proof $\pi : (A_1, \ldots, A_k \vdash B)$, with Proposition 19 and the fact that relational composition is in L. For the composition scheme, we use the closure of[14] L^{UL} under composition. The iteration scheme is handled by Lemma 22 below. ◀

▶ **Lemma 22.** *Let A be a MALL_2 type with a single type variable. Given $n, k \in \mathbb{N}$, $f_1, \ldots, f_k \sqsubset [\![A \multimap A]\!](\mathtt{Fin}(n))$ and $(u, v) \in |[\![A]\!](\mathtt{Fin}(n))|^2$, whether $(u, v) \in (f_k \circ \ldots \circ f_1)$ can be decided in UL (in the size of the input, which is polynomial[15] in n and k).*

Proof. Thanks to Proposition 20, if $v \in (f_k \circ \ldots \circ f_1)(\{u\})$ then there is a *unique* sequence $u_0 = u, u_1, \ldots u_k = v$ such that $u_{i+1} \in f(\{u_i\})$. We successively guess the u_i; at each point, we need only store (u_i, u_{i+1}) to check its presence in f_i. This can be done by a UL Turing machine because each u_i can be stored in space $O(\log n)$: indeed, $|[\![A]\!](\mathtt{Fin}(n))|$ has cardinality polynomial in n (Proposition 19) and there is a natural representation of its points of using $O(1)$ variables in $|\mathtt{Fin}(n)| = \{1, \ldots, n\}$, see [32, Section IV.D]. (Notice that we do not even make use of the coherence relation of $[\![A]\!](\mathtt{Fin}(n))$; its mere existence ensures that the naive NL algorithm is actually UL.) ◀

The upper bound of Theorem 7 follows immediately from Theorem 21 together with:

[14] Strictly speaking, L^{UL} denotes a class of decision problems, and it is the associated class of function problems $\mathsf{FL}^{\mathsf{UL}}$ which is closed under composition (the usual proof for FL relativizes).

[15] The f_i are cliques in the graph $[\![A \multimap A]\!](\mathtt{Fin}(n))$, which has a polynomial size in n by virtue of Proposition 19. Note that we always have $k \geq 1$.

▶ **Lemma 23.** *Let* $\mathfrak{D} \in \mathrm{FinMod}(\Sigma)$*. Its* ELL_2 *encoding* $\overline{\mathfrak{D}} : \mathtt{Inp}_\Sigma[\mathtt{Fin}(n)]$ *(*n *is the domain size of* $\mathfrak{D}$*) contains* MALL_2 *proofs of* $\mathtt{C}[\mathtt{Fin}(n)]$*,* $\mathtt{W}[\mathtt{Fin}(n)]$ *and* $\mathtt{Rel}_{r_i}[\mathtt{Fin}(n)]$ *(*$i \in \{1, \dots, N\}$*).*

The denotations of these proofs in the coherence space model can all be computed in L*.*

4.4 Iterations in deterministic log space for low-complexity types

As can be seen in the proof of Theorem 21, the single crucial point where the complexity of evaluating a query does not seem to fall squarely in L is Lemma 22. By putting the complexity of this iterated composition problem in L when $A \in \mathrm{PP3}$, we will get the L soundness result for Theorem 10.

A first remark is that for $A \in \mathrm{PP3}$, $A[\mathtt{Fin}(n)/\delta] \cong \mathtt{Fin}(P(n)) \otimes (\mathtt{Fin}(Q(n)) \multimap \mathtt{Fin}(R(n)))$ where P, Q, R are polynomials with integer coefficients. The goal becomes to show:

▶ **Theorem 24.** *Let* $A \cong \mathtt{Fin}(m) \otimes (\mathtt{Fin}(n) \multimap \mathtt{Fin}(p))$ *for some* $m, n, p \in \mathbb{N}$*. Given* $f_1, \dots, f_k \sqsubset [\![A \multimap A]\!]$ *and* $(u, v) \in |[\![A]\!]|^2$*, whether* $(u, v) \in (f_k \circ \dots \circ f_1)$ *can be decided in* L*.*

At this point, the proofs start to involve tricky combinatorics on coherence spaces, so this final section of the paper is written for readers familiar with the coherence space model of MALL (but not necessarily its extension to MALL_2). For instance we will often identify cliques $f \sqsubset A \multimap B$ with linear maps from the cliques of A to the cliques of B.

We start with a lemma solving the case $m = 1$, generalizing the example given at the end of the introduction.

▶ **Lemma 25.** *Let* $A = \mathtt{Fin}(n) \multimap \mathtt{Fin}(p)$*,* $f_1, \dots, f_k \sqsubset A \multimap A$*,* $\nu, \nu' \in |\mathtt{Fin}(n)|$ *and* $\pi \in |\mathtt{Fin}(p)|$*. There exists* at most one π' *such that* $(\nu', \pi') \in (f_k \circ \dots \circ f_1)(\{(\nu, \pi)\})$*.*

Furthermore, there is a logarithmic space algorithm taking $n, p, f_1, \dots, f_k, \nu, \nu', \pi$ *as inputs which decides whether* π' *exists and, if so, finds it.*

Proof. Consider the adjoint maps $f_i^\perp \sqsubset (\mathtt{Fin}(n) \otimes \mathtt{Fin}(p)^\perp \multimap \mathtt{Fin}(n) \otimes \mathtt{Fin}(p)^\perp)$. The graph $\mathtt{Fin}(n) \otimes \mathtt{Fin}(p)^\perp$ has n connected components, which are all cliques (of size p). These $f_i^\perp$ send cliques to (possibly empty) cliques, so for $j \in |\mathtt{Fin}(n)|$, $f_i^\perp(\{j\} \times |\mathtt{Fin}(p)|)$ is either (1) empty or (2) included in some $\{l\} \times |\mathtt{Fin}(p)|$, for l uniquely determined by j. This defines partial maps $\widehat{f_i^\perp} : |\mathtt{Fin}(n)| \rightharpoonup |\mathtt{Fin}(n)|$: in case (1) $\widehat{f_i^\perp}(j)$ is undefined, in case (2) $\widehat{f_i^\perp}(j) = l$.

This allows us to perform a backwards iteration: we define $\nu_k = \nu'$ and, for $i = k, \dots, 1$, $\nu_{i-1} = \widehat{f_i^\perp}(\nu_i)$; ν_0 can be computed in logarithmic space. If ν_0 is undefined or $\nu_0 \neq \nu$, then π' does not exist: we return false.

Otherwise, let us restrict each i-th intermediate $\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)$ to the connected component corresponding to ν_i, and take the corresponding sub-cliques: for $i = 1, \dots, k$, $f_i' = f_i \cap ((\{\nu_{i-1}\} \times |\mathtt{Fin}(p)|) \times (\{\nu_i\} \times |\mathtt{Fin}(p)|))$. Then either $(f_k' \circ \dots \circ f_1')(\{\pi\})$ is empty, and π' does not exist; or it contains a single element, which is then π'.

Each ν_i is computable in logarithmic space, so $(f_1', \dots, f_k')$ also is; additionally, the computation of $(f_k' \circ \dots \circ f_1')(\{\pi\})$ from $(f_1', \dots, f_k')$ and π only needs to store a single point of $\mathtt{Fin}(p)$ in working memory, because the cliques of the latter are subsingletons. Since L is closed under L-reductions, we are done. (Making the interactive composition explicit results in a quadratic time algorithm.) ◀

We would like to L-reduce the problem to the case $m = 1$, by determining the projection to $|\mathtt{Fin}(m)|$ of the unique "path" of $k + 1$ points corresponding to a point of the clique $f_k \circ \dots \circ f_1$. This would involve an iteration analogous to the previous proof, but forwards instead of backwards.

But the image $f_i(\{j\} \times |\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)|)$ is *not necessarily connected*, because $\{j\} \times |\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)|$ is not a clique (though $\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)$ is a connected graph, it is not complete). So one cannot guarantee that this image is included in some $\{l\} \times |\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)|$. An explicit counter-example is the interpretation of the term $\lambda(x \otimes g).\,((g\,x) \otimes \ldots)$ when $m = n$: in some sense, the first component of the output depends on *both x and g being known*, not only x. However, knowing x is enough to determine what argument will be fed to g (x itself, in this example). The intuitive idea is to propagate this backwards.

The following lemma ensures that we can always either carry on with the forwards iteration or start the backwards propagation (Π_1 (resp. Π_2) is the projection on the first (resp. second) component):

▶ **Lemma 26.** *Let $c \sqsubset A \parr B$ be a non-empty clique. Then $\Pi_1(c)$ is included in a connected component of A, or (non-exclusively) $\Pi_2(c)$ is included in a connected component of B.*

Proof sketch. If $\Pi_1(u)$ and $\Pi_1(v)$ are in different connected components for $u, v \in c$, then $\Pi_2(u)$ and $\Pi_2(v)$ are coherent or equal, and all other $\Pi_2(w)$ are coherent or equal to at least one of them: $\Pi_2(c)$ is connected with diameter ≤ 3. ◀

Proof of Theorem 24. We write $A = \mathtt{Fin}(m) \otimes B$ and $B = \mathtt{Fin}(n) \multimap \mathtt{Fin}(p)$. If $n = 0$, $A \cong 0$ and the problem is trivial and if $n = 1$, $A \cong \mathtt{Fin}(m) \otimes \mathtt{Fin}(p)$, so a simple forward propagation solves the problem. From now on, we thus assume that $n > 1$, which makes B connected. Let $f_1, \ldots, f_k \sqsubset A \multimap A$, $(\mu, (\nu, \pi)) \in |A|$ and $(\mu', (\nu', \pi')) \in |A|$. The goal is to decide, in logarithmic space, whether $(\mu', (\nu', \pi')) \in (f_k \circ \ldots \circ f_1)(\{(\mu, (\nu, \pi))\})$.

Let $\mu_0 = \mu$. If the clique $f_1(\{(\mu, (\nu, \pi))\})$ is empty, then the answer is negative; else, let $\{\mu_1\} \times |B|$ be the connected component containing it. For $1 \leq i < k$, assuming that μ_i is defined, then $f_{i+1}(\{\mu_i\} \times |B|)$ is either:

- empty, and the answer is negative;
- non-empty and contained in some $\{\mu_{i+1}\} \times |B|$ – this defines $\mu_{i+1} \in |\mathtt{Fin}(m)|$ uniquely;
- non-empty and disconnected.

Let $f_i^{\ddagger} = f_i \cap ((\{\mu_{i-1}\} \times |B|) \times (\{\mu_i\} \times |B|))$ for all $i \geq 1$ for which μ_i is defined. If the iteration reaches $i = k$, this means that $(f_1^{\ddagger}, \ldots, f_k^{\ddagger})$ can be computed in logarithmic space, and as in Lemma 25 we can use this to L-reduce the problem to the case $m = 1$, so we are done. If it aborts because of emptiness, then the algorithm can immediately return false.

The remaining case is the last item above. Suppose that μ_{i+1} is undefined because of disconnectedness. Let $f_{i+1}^{\dagger} = f_{i+1} \cap ((\{\mu_i\} \times |B|) \times |A|)$; it can be seen as a clique $f_{i+1}^{\dagger} \sqsubset B \multimap A = B^{\perp} \parr A$, with $B^{\perp} = \mathtt{Fin}(n) \otimes \mathtt{Fin}(p)^{\perp}$. The assumption that $\Pi_2(f_{i+1}^{\dagger}) = f_{i+1}(\{\mu_i\} \times |B|)$ is non-empty and disconnected entails, by Lemma 26, that $\Pi_1(f_{i+1}^{\dagger})$ is connected. In other words $\Pi_1(f_{i+1}^{\dagger}) \subseteq \{\nu''\} \times |\mathtt{Fin}(p)|$ for some ν''.

Let us apply the algorithm of Lemma 25 to the inputs $n, p, f_1^{\ddagger}, \ldots, f_i^{\ddagger}, \nu, \nu'', \pi$. This can be done in logarithmic space, and the subroutine either raises a failure or gives us some $\pi'' \in |\mathtt{Fin}(p)|$. In the former case, we can return false; in the latter, we know that $(f_k \circ \ldots \circ f_1)(\{(\mu, (\nu, \pi))\}) = (f_k \circ \ldots \circ f_{i+1})(\{(\mu_i, (\nu'', \pi''))\})$. So all we have to do is to tail-recurse on a suffix of the original input; to implement this in L, it suffices to keep a counter indicating what the current suffix is. This is a strict suffix, because μ_1 is always defined by construction (see above); therefore, our algorithm terminates, while maintaining a logarithmic working space. ◀

▶ Remark 27. $\mathtt{Fin}(m) \otimes (\mathtt{Fin}(n) \multimap \mathtt{Fin}(p)) \cong \bigoplus_{i=1}^{m} \&_{j=1}^{n} \bigoplus_{k=1}^{p} 1$, and such a bicartesian MALL formula can be seen as a game where Player and Opponents alternate choices of branches. Linear implication consists in playing two games in parallel. Morally, Lemma 26 says: if it is your turn to play on both boards, then you must make a choice; and our L algorithm is mostly about scheduling a set of strategies interacting together.

5 Perspective: unrestricted L upper bound through game semantics?

In the extensional completeness proof, strikingly, the *determinism* of a relation corresponds exactly to the *linearity* of its pre-composition operator. This is one reason for which we believe that our class of queries in ELL_2 is exactly L (Conjecture 1) – or at least, that it is strictly containted in NL which corresponds to first-order logic with general transitive closure [22]. Thus, our L^{UL} bound is likely not optimal: it is widely believed that $\mathsf{UL} = \mathsf{NL}$ [34, 33].

To bring down the complexity of the bottleneck – namely the iterated composition – from UL to L, bridging the intuitions of Remark 27 with a proper game semantics of full MALL_2 might be key. In this direction, it is known that the points of the web of a (hyper)coherence space can be seen as external positions of a game [10, 5, 30, 31]. With this point of view, the uniqueness of the intermediate points in the iteration of Lemma 22 reflects the determinism of an underlying interaction which reaches those final positions.

Automatic Semigroups vs Automaton Semigroups

Matthieu Picantin

picantin@irif.fr

Abstract

We develop an effective and natural approach to interpret any semigroup admitting a special language of greedy normal forms as an automaton semigroup, namely the semigroup generated by a Mealy automaton encoding the behaviour of such a language of greedy normal forms under one-sided multiplication. The framework embraces many of the well-known classes of (automatic) semigroups: free semigroups, free commutative semigroups, trace or divisibility monoids, braid or Artin–Tits or Krammer or Garside monoids, Baumslag–Solitar semigroups, etc. Like plactic monoids or Chinese monoids, some neither left- nor right-cancellative automatic semigroups are also investigated, as well as some residually finite variations of the bicyclic monoid. It provides what appears to be the first known connection from a class of automatic semigroups to a class of automaton semigroups. It is worthwhile noting that, "being an automatic semigroup" and "being an automaton semigroup" become dual properties in a very automata-theoretical sense. Quadratic rewriting systems and associated tilings appear as the cornerstone of our construction.

2012 ACM Subject Classification Theory of computation → Automata over infinite objects; Theory of computation → Rewrite systems

Keywords and phrases Mealy machine, semigroup, rewriting system, automaticity, self-similarity

1 Introduction

The half century long history of the interactions between (semi)group theory and automata theory went through a pivotal decade from the mid-eighties to the mid-nineties. Contemporaneously but independently, two new theories truly started to develop and thrive: automaton (semi)groups on the one hand with the works of Aleshin [2, 3] and Grigorchuk [27, 28] and the book [47], and automatic (semi)groups on the other hand with the work of Cannon and Thurston and the book [24]. We refer to [55] for a clear and short survey on the known interactions between groups and automata. A deeper and more extended survey by Bartholdi and Silva can be found out in two chapters [7, 8] of the forthcoming AutoMathA handbook. We can refer to [14, 45] for automaton semigroups and to [17, 33] for automatic semigroups.

Remote siblings. As their very name indicates, automaton (semi)groups and automatic (semi)groups share a same defining object: the *automaton* or the letter-to-letter transducer in this case. Beyond this common origin, these two topics until now happened to remain largely distant both in terms of community and in terms of tools or results. Typically, any paper on one or the other topic used to contain a sentence like "it should be emphasised that, despite their similar names, the notions of automaton (semi)groups are entirely separate from

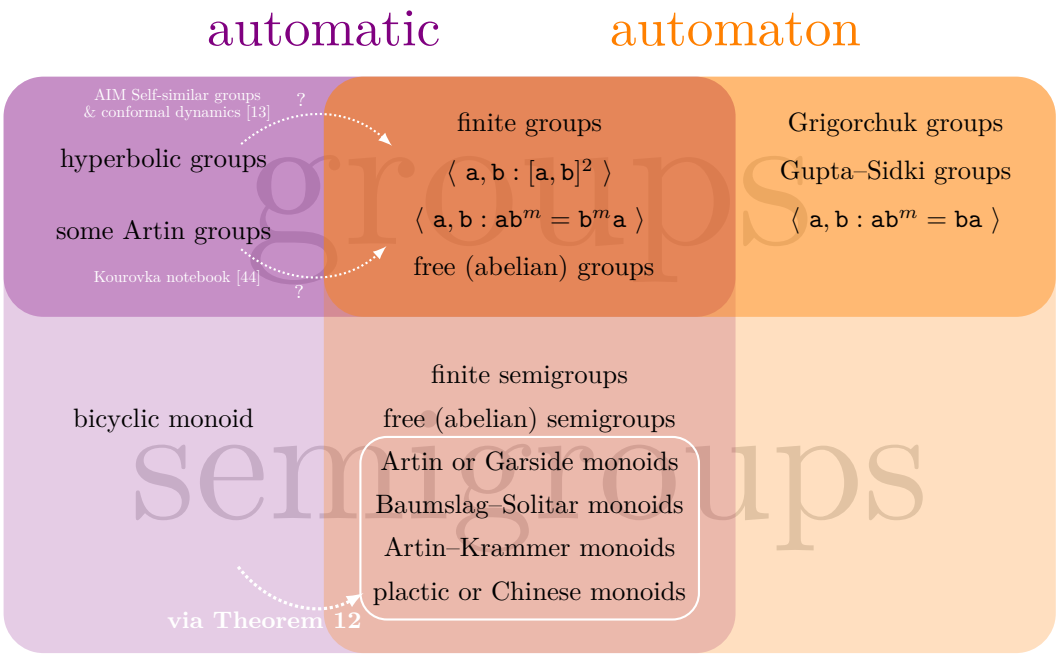

Figure 1 The big picture: comparing the classes of automatic *vs* automaton (semi)groups.

the notions of automatic (semi)groups". This was best evidenced by the above-mentioned valuable handbook chapter [7] which splits into exactly two sections (automatic groups and automaton groups) without any reference between one and the other appearing explicitly.

Related open problems. A significant problem is to recognise whether a given (semi)group is self-similar, that is, an automaton (semi)group, see Figure 1. Amongst the thirty-odd listed problems from [13], we can pick the one with the number 1.1:

> **Problem A.** It seems quite difficult to show whether a given group is self-similar. Are Gromov hyperbolic groups self-similar? Find obstructions to self-similarity.

Amongst the unsolved problems in group theory from the Kourovka Notebook [44], the one (with number 16.84) asked by Sushchanskii (see also [40, 51]) can be formulated as follows:

> **Problem B.** Is the n-strand braid group $\mathbf{B}_n$ a subgroup of some automaton group?

All these questions can be meaningfully rephrased in terms of semigroups or monoids.

Our contributions. The aim here is to establish a possible connection between being an automatic semigroup and being an automaton semigroup. Preliminary observations are that these classes intersect non trivially and that neither is included in the other (see Figure 1). Like the Grigorchuk group for instance, many automaton groups are infinite torsion groups, hence cannot be automatic groups. By contrast, it is an open question whether every automatic group is an automaton group. The latter is related to the question whether every automatic group is residually finite, which remains open despite the works by Wise [58] and Elder [23]. Like the bicyclic monoid, some automatic semigroups are not residually finite, hence cannot be automaton semigroups (see [14] for instance). As for the intersection, we know that at least finite semigroups, free semigroups (of rank at least 2, see [11, 12]), free abelian semigroups happen to be both automatic semigroups and automaton semigroups.

We propose here a new and natural way to interpret algorithmically each semigroup from a wide class of automatic semigroups – encompassing all the above-mentioned classes – as an automaton semigroup (Theorem 12). Furthermore, it is worthwhile noting that, in all these cases, "being an automatic semigroup" and "being an automaton semigroup" become dual properties in a very automata-theoretical sense (Corollary 15).

Occurring as the very first bridge between two hitherto irreconcilable research areas, Theorem 12 allows us to also provide a (more than) positive answer to the monoidal version of Problem **B**. While the n-strand braid monoid $\mathbf{B}^1_{n+}$ is the paradigmatic example of an automatic monoid from [24, Chapter 9], Theorem 12 implies that $\mathbf{B}^1_{n+}$ is (not only a submonoid of) an automaton monoid as well, see Example 23. From this significant milestone arise various new questions and perspectives, that will hopefully pervade both research fields.

Organisation. The structure of the paper is as follows. As a simple preliminary, Section 2 illustrates in a deliberately informal manner how a single Mealy automaton can be used in order to define both self-similar structures and automatic structures (via a principle of duality). In Section 3, we set up the notations for Mealy automata and recall necessary notions of dual automata, cross-diagrams, and self-similar structures. In Section 4, we recall basics about normal forms and automatic structures, and we give necessary notions of quadratic normalisations and square-diagrams. Section 5 is devoted to our main results (Theorem 12 and Corollary 15), while Section 6 finally gathers several carefully selected examples, counterexamples, and open problems.

2 A preliminary example

As their very name indicates, automaton (semi)groups and automatic (semi)groups share a same defining object. In both cases, a *Mealy automaton* (see Definition 1) basically transforms words into words.

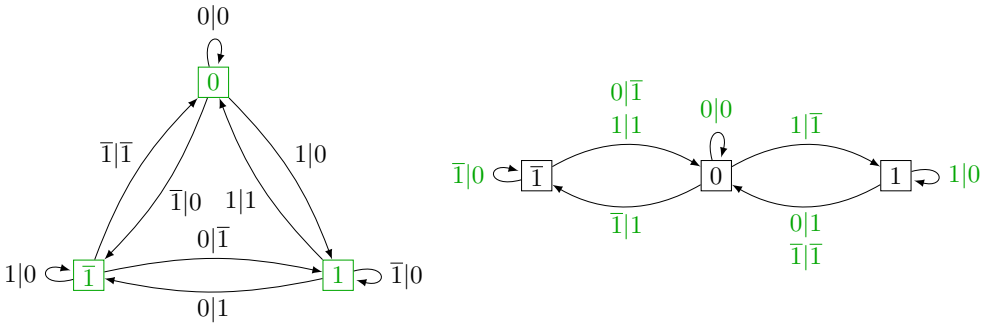

Figure 2 Two (dual) Mealy automata: the left-hand one computing the division by 3 in base 2 (most significant digit first) *vs* the right-hand one computing the multiplication by 2 in base 3 (least significant digit first).

The Mealy automaton displayed on Figure 2 (left) is some signed-digit version of one of the most classical examples of a transducer (see [53, Prologue] for a delightfully alternate history). Signed-digit numeration systems [4, 18] are not the topic, now they provide a special opportunity to illustrate our purpose. When starting from the state 0 and reading any binary word or any $\{\overline{1}, 0, 1\}$-word $\mathbf{u}$ (most significant digit first), it computes the division by 3 in base 2 by outputting the (quotient) $\{\overline{1}, 0, 1\}$-word $\mathbf{v}$ (most significant digit first) satisfying

$$(\mathbf{u})_2 = 3 \times (\mathbf{v})_2 + f \qquad (\%)$$

where the (remainder) $f \in \{\overline{1}, 0, 1\}$ corresponds to the arrival state of the run, and where $(\mathbf{w})_b$ denotes by convention the number that is represented by $\mathbf{w}$ in base b.

For the current preliminary section, let us now focus on this basic example and consider the two different viewpoints described as follows.

On the one hand, it seems natural to consider the set of those functions (from $\{\overline{1}, 0, 1\}$-words to $\{\overline{1}, 0, 1\}$-words) thus associated with each state, then to compose them with each other, and finally to study the (semi)group which is generated by such functions.

For instance, the function $\mathbf{u} \mapsto \mathbf{v}$ associated with the state 0 (satisfying Equation (%)) can be squared, cubed, and so on, to obtain functions, which can be again interpreted as the division by $9, 27, \ldots$ (in base 2 with most significant digit first), or can be composed with the functions induced by the other two states. The generated semigroup happens to be the rank 3 free semigroup $\{\overline{1}, 0, 1\}^+$ (provided that the three states and their induced functions are identified). This simple idea coincides with the notion of automaton (semi)groups or self-similar structures (see Definition 2). With this crucial standpoint, we can compute (semi)group operations by manipulating the corresponding Mealy automaton (see [5, 7, 35, 46]), and hopefully foresee some combinatorial and dynamical properties by examining its shape (see [6, 9, 10, 19, 25, 26, 34, 36, 37, 38, 51, 56] for instance).

On the other hand, it may be also natural to simply iterate the runs. The starting language is again over the (input/output) alphabet, now the images of the transformations are some languages over the stateset.

For instance, restarting again from the state 0, the previously output word $\mathbf{v}$ (satisfying Equation (%)) can be read in turn, and so on. The successive arrival states can be then collected and concatenated in order to obtain here the decomposition of $(\mathbf{u})_2$ in base 3 (least significant digit first). The whole process has thus inherently a quadratic time complexity.

This second idea coincides with the fundamental notion of automatic (semi)groups (see Definition 3 and [7, 17, 24, 33, 51]), for which Mealy automata can compute normal forms.

To conclude this preliminary section, let us mention that states and letters of any Mealy automaton play a symmetric role, and that several properties can be beneficially derived from the so-called *dual (Mealy) automaton*, obtained by exchanging the stateset and the alphabet (see [36] for an overview).

For instance, Figure 2 displays a pair of dual automata. While the left-hand automaton allows to compute the division by 3 in base 2 (most significant digit first) as we have seen just above, its dual automaton (right) essentially computes the multiplication by 2 in base 3 (least significant digit first). More precisely, its state 0 induces the function $x \mapsto 2 \times x$ on $\mathbb{Z}$, while its states $\overline{1}$ and 1 induce the functions $x \mapsto 2 \times x - 1$ and $x \mapsto 2 \times x + 1$ respectively: they together generate the semigroup $\langle\ \overline{1}, 0, 1 : 01 = 1\overline{1}, 0\overline{1} = \overline{1}1\ \rangle_+$. Let us also mention that the induced functions happen to be invertible and to generate a group which is isomorphic with the so-called Baumslag–Solitar group $\mathbf{BS}(2, 1) = \langle\ \mathtt{a}, \mathtt{b} : \mathtt{ab}^2 = \mathtt{ba}\ \rangle$ (see Figure 1, Example 20, and [51]).

Besides, such a Mealy automaton (right) can be used to compute the base 2 from the base 3 representation of the fractional part of any rational number, by iterating runs as explained above. For instance, finitely iterated runs from the state 0 and the initial word $0001\overline{1}$ produce the infinite word $(0\overline{1}0010)^\omega$, both words representing (the fractional part of) the rational $-\frac{2}{9}$ in base 3 (least significant digit first) and in base 2 (most significant digit first) respectively.

This innocuous example allows to illustrate the quite simple machineries associated both with automaton semigroups and with automatic semigroups. It also aims to give an informal glimpse of their behaviours through the duality principle: for instance, division *vs* multiplication, factor *vs* base, least *vs* most significant digit first, integer part *vs* fractional part.

3 Mealy automata and self-similar structures

We first recall the formal definition of an automaton. Possible references are [7, 14, 45, 47].

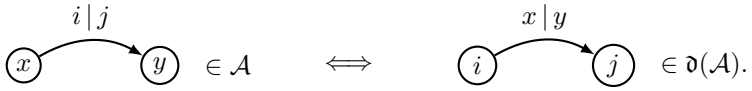
▶ **Definition 1.** *A* (finite, deterministic, and complete) automaton *is a triple* $\big(Q, \Sigma, \tau = (\tau_i \colon Q \to Q)_{i\in\Sigma}\big)$*, where the* stateset Q *and the* alphabet Σ *are non-empty finite sets, and where the* τ_i*'s are functions.*

A Mealy automaton *is a quadruple* $\big(Q, \Sigma, \tau = (\tau_i \colon Q \to Q)_{i\in\Sigma}, \sigma = (\sigma_x \colon \Sigma \to \Sigma)_{x\in Q}\big)$ *such that both* (Q, Σ, τ) *and* (Σ, Q, σ) *are automata.*

In other terms, a Mealy automaton is a complete, deterministic, letter-to-letter transducer with the same input and output alphabet.

The graphical representation of a Mealy automaton is standard, see Figures 2 and 7.

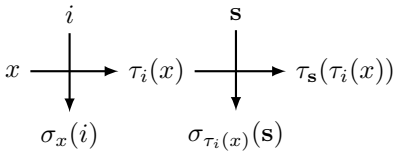
In a Mealy automaton $\mathcal{A} = (Q, \Sigma, \tau, \sigma)$, the sets Q and Σ play dual roles. So we may consider the *dual (Mealy) automaton* defined by $\mathfrak{d}(\mathcal{A}) = (\Sigma, Q, \sigma, \tau)$:



We view $\mathcal{A} = (Q, \Sigma, \tau, \sigma)$ as an automaton with an input and an output tape, thus defining mappings from input words over Σ to output words over Σ. Formally, for $x \in Q$, the map $\sigma_x \colon \Sigma^* \to \Sigma^*$, extending $\sigma_x \colon \Sigma \to \Sigma$, is defined recursively by:

$$\forall i \in \Sigma,\ \forall \mathbf{s} \in \Sigma^*, \qquad \sigma_x(i\mathbf{s}) = \sigma_x(i)\sigma_{\tau_i(x)}(\mathbf{s})\,.$$

The above equation can be easier to understood when depicted by a *cross-diagram* (see [1]):



By convention, the image of the empty word is itself. The mapping σ_x for each $x \in Q$ is length-preserving and prefix-preserving. We say that σ_x is the *production function* associated with $(\mathcal{A}, x)$. For $\mathbf{x} = x_1 \cdots x_n \in Q^n$ with $n > 0$, set $\sigma_{\mathbf{x}} \colon \Sigma^* \to \Sigma^*, \sigma_{\mathbf{x}} = \sigma_{x_n} \circ \cdots \circ \sigma_{x_1}$. Denote dually by $\tau_i \colon Q^* \to Q^*, i \in \Sigma$, the production functions associated with the dual automaton $\mathfrak{d}(\mathcal{A})$. For $\mathbf{s} = s_1 \cdots s_n \in \Sigma^n$ with $n > 0$, set $\tau_{\mathbf{s}} \colon Q^* \to Q^*,\ \tau_{\mathbf{s}} = \tau_{s_n} \circ \cdots \circ \tau_{s_1}$.

▶ **Definition 2.** *The semigroup of mappings from* Σ^* *to* Σ^* *generated by* $\{\sigma_x, x \in Q\}$ *is called the* semigroup generated by $\mathcal{A}$ *and is denoted by* $\langle\ \mathcal{A}\ \rangle_+$*. When* $\mathcal{A}$ *is invertible, its production functions are permutations on words of the same length and thus we may consider the corresponding group instead; this group is the* group generated by $\mathcal{A}$ *and is denoted by* $\langle\ \mathcal{A}\ \rangle$*. A (semi)group is called an* automaton (semi)group *whenever it can be generated by some Mealy automaton. The term* self-similar *is used as a synonym.*

4 Quadratic normalisations and automatic structures

This section gathers the definitions of some classical notions like normal form or automatic structure (see [24, 17, 33]), together with the slighly more specific notion of a quadratic normalisation (see [20, 22]).

For any set $\mathcal{Q}$, we denote by $\mathcal{Q}^+$ the free semigroup over $\mathcal{Q}$ (*resp.* by $\mathcal{Q}^*$ the free monoid and by $\mathtt{1}$ its unit element) and call its elements $\mathcal{Q}$-*words*. We write $|\mathbf{w}|$ for the length of a $\mathcal{Q}$-word $\mathbf{w}$, and $\mathbf{ww'}$ for the product of two $\mathcal{Q}$-words $\mathbf{w}$ and $\mathbf{w'}$.

▶ **Definition 3.** *Let S be a semigroup with a generating set $\mathcal{Q}$. A* normal form *for $(S, \mathcal{Q})$ is a (set-theoretic) section of the canonical projection* EV *from the language of $\mathcal{Q}$-words onto S, that is, a map* NF *that assigns to each element of S a distinguished representative $\mathcal{Q}$-word with* $\mathrm{EV} \circ \mathrm{NF} = \mathrm{Id}_S$*:*

$$\mathrm{EV} : \mathcal{Q}^+ \longrightarrow S \qquad \mathrm{NF}$$

Whenever $\mathrm{NF}(S)$ *is regular, it provides a* right-automatic structure *for S if the language* $\mathcal{L}_q = \{ \ (\ \mathrm{NF}(a)\#^{|\mathrm{NF}(aq)|},\ \mathrm{NF}(aq)\#^{|\mathrm{NF}(a)|}\ ) : a \in S \ \}$ *over the alphabet* $(\mathcal{Q} \sqcup \{\#\})^2$ *is regular for each $q \in \mathcal{Q}$, where the normal forms of a pair are right-padded with an extra symbol $\# \notin \mathcal{Q}$ to equalise the lengths. The semigroup S can then be called a* (right-)automatic semigroup*.*

We mention here the thorough and precious study in [32] of the different notions (right- or left-reading-padding *vs* right- or left-multiplication) of automaticity for semigroups.

▶ Remark 4. In his seminal work [24, Chapter 9], Thurston shows how the whole set of these different automata recognizing the multiplication – that is, recognizing the languages $\mathcal{L}_q$ – in Definition 3 can be replaced with advantage by a single letter-to-letter transducer over the alphabet $\mathcal{Q}$ (see Definition 14) that computes the normal forms via iterated runs: each run both provides one symbol of the final normal form and outputs a word still to be normalised.

One will often consider the associated normalisation $\mathrm{N} = \mathrm{NF} \circ \mathrm{EV}$ over $\mathcal{Q}$.

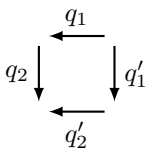
▶ **Definition 5.** *A* normalisation *is a pair $(\mathcal{Q}, \mathrm{N})$, where $\mathcal{Q}$ is a set and* N *is a map from $\mathcal{Q}^+$ to itself satisfying, for all $\mathcal{Q}$-words $\mathbf{u}, \mathbf{v}, \mathbf{w}$:*

- $|\mathrm{N}(\mathbf{w})| = |\mathbf{w}|$,
- $|\mathbf{w}| = 1 \Rightarrow \mathrm{N}(\mathbf{w}) = \mathbf{w}$,
- $\mathrm{N}(\mathbf{u}\,\mathrm{N}(\mathbf{w})\,\mathbf{v}) = \mathrm{N}(\mathbf{uwv})$.

A $\mathcal{Q}$-word $\mathbf{w}$ satisfying $\mathrm{N}(\mathbf{w}) = \mathbf{w}$ is called N-normal*. If S is a semigroup, we say that $(\mathcal{Q}, \mathrm{N})$ is a* normalisation for *S if S admits the presentation*

$$\langle\ \mathcal{Q} : \{\, \mathbf{w} = \mathrm{N}(\mathbf{w}) \mid \mathbf{w} \in \mathcal{Q}^+ \,\}\ \rangle_+.$$

We associate with every element $q \in \mathcal{Q}$ a q-labeled edge and with a product the concatenation of the associated edges, and represent equalities in the ambient semigroup using commutative diagrams, that we shall often organise as tilings and that we call here *square-diagram*. For instance, the following square illustrates an equality $q_1 q_2 = q_1' q_2'$.



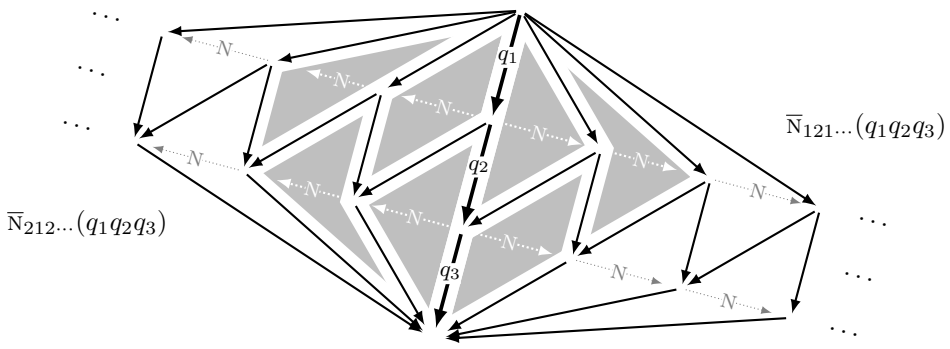


Figure 3 From an initial $\mathcal{Q}$-word $q_1q_2q_3$, one applies normalisations on the first and the second 2-factors alternatively up to stabilisation, beginning either on the first 2-factor q_1q_2 (right-hand side here) or on the second q_2q_3. The gray zone corresponds to Condition ( ) as defined in Definition 7.

For a normalisation $(\mathcal{Q}, \mathrm{N})$, we denote by $\overline{\mathrm{N}}$ the restriction of N to $\mathcal{Q}^2$ and, for $i \geq 1$, by $\overline{\mathrm{N}}_i$ the (partial) map from $\mathcal{Q}^+$ to itself that consists in applying $\overline{\mathrm{N}}$ to the entries in position i and $i+1$. For any finite sequence $\mathbf{i} = i_1 \cdots i_n$ of positive integers, we write $\overline{\mathrm{N}}_{\mathbf{i}}$ for the composite map $\overline{\mathrm{N}}_{i_n} \circ \cdots \circ \overline{\mathrm{N}}_{i_1}$ (so $\overline{\mathrm{N}}_{i_1}$ is applied first).

▶ **Definition 6.** *A normalisation* $(\mathcal{Q}, \mathrm{N})$ *is* quadratic *if the two following conditions hold:*

- *a* $\mathcal{Q}$*-word* $\mathbf{w}$ *is* N*-normal if, and only if, every length-two factor of* $\mathbf{w}$ *is;*
- *for every* $\mathcal{Q}$*-word* $\mathbf{w}$*, there exists a finite sequence* $\mathbf{i}$ *of positions, depending on* $\mathbf{w}$*, such that* $\mathrm{N}(\mathbf{w})$ *is equal to* $\overline{\mathrm{N}}_{\mathbf{i}}(\mathbf{w})$*.*

▶ **Definition 7.** *As illustrated in Figure 3, with any quadratic normalisation* $(\mathcal{Q}, \mathrm{N})$ *is associated its* breadth (d, p) *(called minimal left and right classes in [20, 22]) defined as:*

$$d = \max_{(q_1,q_2,q_3)\in\mathcal{Q}^3} \min\{\,\ell : \mathrm{N}(q_1q_2q_3) = \overline{\mathrm{N}}\underbrace{_{212\cdots}}_{\text{length } \ell}(q_1q_2q_3)\},\ \textit{and}$$

$$p = \max_{(q_1,q_2,q_3)\in\mathcal{Q}^3} \min\{\,\ell : \mathrm{N}(q_1q_2q_3) = \overline{\mathrm{N}}\underbrace{_{121\cdots}}_{\text{length } \ell}(q_1q_2q_3)\}.$$

Such a breadth need to be finite provided that $\mathcal{Q}$ *is finite, and then satisfies* $|d-p| \leq 1$*. For* $p \leq 3$ *(and* $d \leq 4$*), the quadratic normalisation* $(\mathcal{Q}, \mathrm{N})$ *is said to satisfy Condition* ( ) *(its corresponds with the so-called* domino rule *in [21] but with a different reading direction).*

The first main result of [22] is an axiomatisation of these quadratic normalisations satisfying Condition ( ) in terms of their restrictions to length-two words: any idempotent map $\overline{\mathrm{N}}$ on $\mathcal{Q}^2$ that satisfies $\overline{\mathrm{N}}_{2121} = \overline{\mathrm{N}}_{121} = \overline{\mathrm{N}}_{1212}$ extends into a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ satisfying Condition ( ). For larger breadths, a map on length-two words normalising length-three words needs not normalise words of greater length.

The second main result of [22] involves termination. Every quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ gives rise to a quadratic rewriting system, namely the one with rules $\mathbf{w} \longrightarrow \overline{\mathrm{N}}(\mathbf{w})$ for $\mathbf{w} \in \mathcal{Q}^2$. By Definition 6, such a rewriting system is confluent and normalising, meaning that, for every initial word, there exists a finite sequence of rewriting steps leading to a unique N-normal word, but its convergence, meaning that *any* sequence of rewriting steps is finite, is a quite different problem.

▶ **Theorem 8** ([22])**.** *If* $(\mathcal{Q}, \mathrm{N})$ *is a quadratic normalisation satisfying Condition* ( )*, then the associated rewriting system is convergent.*

More precisely, every rewriting sequence starting from a word of $\mathcal{Q}^p$ has length at most $\frac{p(p-1)}{2}$ (*resp.* $2^p - p - 1$) in the case of a breadth $(3,3)$ (*resp.* either $(3,4)$ or $(4,3)$). Theorem 8 is essentially optimal since there exist nonconvergent rewriting systems with breadth $(4,4)$.

The results of Section 5 rely on the special Condition ( ). As mentioned, this condition was already outlined by Dehornoy and Guiraud (see [22]). However, none of their results (in particular Theorem 8 given above for the sake of completeness) is either applied or needed to establish ours. The current work and its exposition are thus self-contained and our constructions never require any of their stronger hypotheses (neither cancellativity nor absence of nontrivial invertible elements). We want here to emphasise that Condition ( ) happens to appear as a common denominator from different approaches (see also [29]).

5 From an automatic structure to a self-similar structure

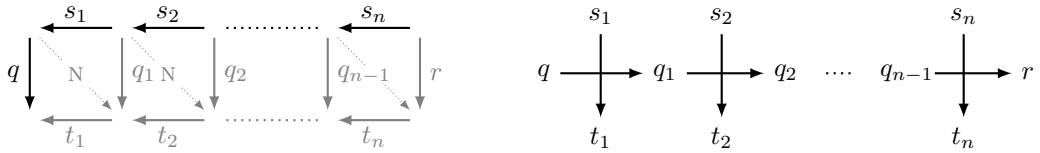
All the ingredients are now in place to effectively and naturally interpret as an automaton monoid any automatic monoid admitting a special language of normal forms – namely, a quadratic normalisation satisfying Condition ( ). The point is to construct a Mealy automaton encoding the behaviour of its language of normal forms under one-sided multiplication.

▶ **Definition 9.** *Assume that S is a semigroup admitting a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$. We define the Mealy automaton $\mathcal{M}_{\mathcal{Q},\mathrm{N}} = (\mathcal{Q}, \mathcal{Q}, \tau, \sigma)$ such that, for every $(a,b) \in \mathcal{Q}^2$, $\sigma_b(a)$ is the rightmost element of $\mathcal{Q}$ in the normal form $\mathrm{N}(ab)$ of ab and $\tau_a(b)$ is the left one:*

$$\mathrm{N}(ab) = \tau_a(b)\sigma_b(a).$$

The latter correspondence can be simply interpreted via square-diagram *vs* cross-diagram:

For $\mathbf{s} = s_n \cdots s_1$, $\mathbf{t} = t_n \cdots t_1$, $\sigma_q(\mathbf{s}) = \mathbf{t}$, and $\tau_{\mathbf{s}}(q) = r$, we obtain diagrammatically:



We choose on purpose to always draw a normalisation square-diagram backward, such that it coincides with the associated cross-diagram. The function σ_q induced by the state q should map any word $\mathbf{s}$ (read backward) to some word $\mathbf{t}$ (read backward) with $\mathrm{N}(\mathbf{s}q) = \mathrm{N}(r\mathbf{t})$.

We now aim to strike reasonable (most often optimal) hypotheses for a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ associated with an original semigroup S to generate a semigroup $\langle\, \mathcal{M}_{\mathcal{Q},\mathrm{N}} \,\rangle_+$ that approximates S as sharply as possible. Since the generating sets coincide by Definition 9, we shall address the case when S is a quotient of $\langle\, \mathcal{M}_{\mathcal{Q},\mathrm{N}} \,\rangle_+$ (top-approximation, Lemma 10), and next, the case when $\langle\, \mathcal{M}_{\mathcal{Q},\mathrm{N}} \,\rangle_+$ is a quotient of S (bottom-approximation, Proposition 11).

Before establishing our top-approximation statement (Lemma 10), we could stress how semigroups might appear much more difficult to handle than monoids, especially when it comes to automaticity (see [32]) or self-similarity (see [11, 12]). For a semigroup S with a quadratic normalisation on $\mathcal{Q}$, two situations occur. First, if S is a monoid with unit $\mathtt{1}$, it admits a quadratic normalisation satisfying $\mathrm{N}(\mathtt{1}) = \mathtt{1}$ and

$$\mathrm{N}(\mathtt{1}q) = \mathrm{N}(q\mathtt{1}) = \mathtt{1}q \qquad (\boxed{1})$$

for each $q \in \mathcal{Q}$. Second, if S does not admit a unit, one can adjoin a unit $\mathtt{1}$ to obtain a monoid (if needed) with a quadratic normalisation satisfying Condition ($\boxed{1}$). The choice made for such a condition becomes natural whenever we think of the (adjoined or not) unit $\mathtt{1}$ as some *dummy* element that escapes from the normalisation and simply ensures its length-preserving property.

▶ **Lemma 10.** *If S is a monoid with a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ satisfying Condition ($\boxed{1}$), then the Mealy automaton $\mathcal{M}_{\mathcal{Q},\mathrm{N}}$ generates a monoid of which S is a quotient.*

Although specific to a monoidal framework and then requiring the innocuous Condition ($\boxed{1}$), the previous straightforward result relies only on the definition of a quadratic normalisation and on the well-fitted associated Mealy automaton (Definition 9). For the bottom-approximation statement, we consider an extra assumption, which happens to be necessary and sufficient.

▶ **Proposition 11.** *Assume that S is a semigroup with a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$. If Condition ($\diamondsuit$) is satisfied, then the Mealy automaton $\mathcal{M}_{\mathcal{Q},\mathrm{N}}$ generates a semigroup quotient of S. The converse holds provided that Condition ($\boxed{1}$) is satisfied.*

Sketch proof. Let $S = \mathcal{Q}^+/\equiv_{\mathrm{N}}$ and $\mathcal{M}_{\mathcal{Q},\mathrm{N}} = (\mathcal{Q}, \mathcal{Q}, \tau, \sigma)$ as in Definition 9.

($\Leftarrow$) Assume that Condition ($\diamondsuit$) is satisfied and that there exists $(a, b, c, d) \in \mathcal{Q}^4$ with $ab \equiv_{\mathrm{N}} cd$. We have to prove $\sigma_{ab} = \sigma_{cd}$. Without loss of generality, the word ab can be supposed to be N-normal, that is, $\mathrm{N}(ab) = \mathrm{N}(cd) = ab$ holds.

Let $\mathbf{u} = q\mathbf{v} \in \mathcal{Q}^n$ for some $n > 0$ and $q \in \mathcal{Q}$. We shall prove both $\sigma_{ab}(\mathbf{u}) = \sigma_{cd}(\mathbf{u})$ (letterwise) and $\tau_{\mathbf{u}}(ab) \equiv_{\mathrm{N}} \tau_{\mathbf{u}}(cd)$ by induction on $n > 0$. For $n = 1$, we obtain the two square-diagrams on Figure 4 (left). With these notations, we have to prove $q_0'' = q_1''$ and $a'b' \equiv_{\mathrm{N}} c'd'$, the latter meaning $\mathrm{N}(a'b') = \mathrm{N}(c'd')$, that is, with the notations from Figure 4, the conjunction of $a'' = c''$ and $b'' = d''$. Now these three equalities hold whenever $(\mathcal{Q}, \mathrm{N})$ satisfies Condition ($\diamondsuit$), as shown on Figure 4 (right).

This allows to proceed the induction and to prove the implication ($\Leftarrow$).

($\Rightarrow$) Consider an arbitrary length 3 word over $\mathcal{Q}$, say qcd. Let a, b denote the elements in $\mathcal{Q}$ satisfying $\mathrm{N}(cd) = ab$. By definition, we deduce $ab \equiv_{\mathrm{N}} cd$. This implies $\sigma_{ab} = \sigma_{cd}$ by hypothesis. In particular, the images of any word $q\mathbf{v}$ under σ_{ab} and σ_{cd} coincide. Now $\sigma_{ab}(q\mathbf{v}) = \sigma_{cd}(q\mathbf{v})$ decomposes into

$$\sigma_{ab}(q) = q_0'' = q_1'' = \sigma_{cd}(q) \quad \text{and} \quad \sigma_{\tau_q(ab)}(\mathbf{v}) = \sigma_{a'b'}(\mathbf{v}) = \sigma_{c'd'}(\mathbf{v}) = \sigma_{\tau_q(cd)}(\mathbf{v})$$

(with notations of Figure 4). The last equality holds for any original word $\mathbf{v} \in \mathcal{Q}^*$ and implies $\sigma_{a'b'} = \sigma_{c'd'}$. Whenever, Condition ($\boxed{1}$) is satisfied, we deduce $\mathrm{N}(a'b') = \mathrm{N}(c'd')$ according to Lemma 10. For any such arbitrary word $qcd \in \mathcal{Q}^3$, we obtain $\overline{\mathrm{N}}_{121}(qcd) = \overline{\mathrm{N}}_{2121}(qcd)$. Therefore $(\mathcal{Q}, \mathrm{N})$ satisfies Condition ($\diamondsuit$). ◀

Gathering Lemma 10 and Proposition 11, we obtain the following main result.

▶ **Theorem 12.** *Assume that S is a monoid with a quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ satisfying Conditions ($\boxed{1}$) and ($\diamondsuit$). The Mealy automaton $\mathcal{M}_{\mathcal{Q},\mathrm{N}}$ generates a monoid isomorphic to S.*

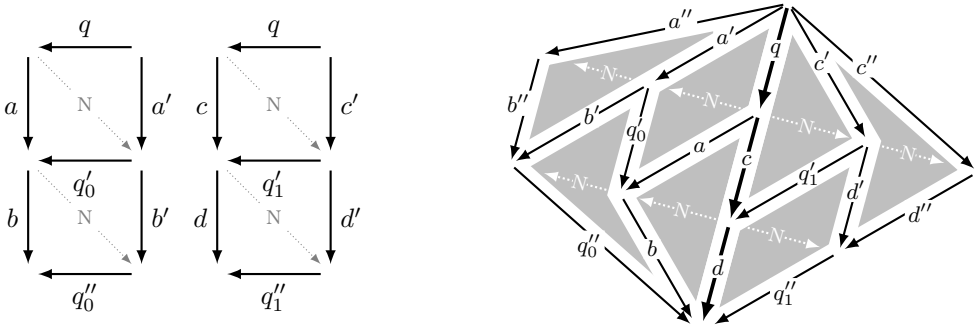


Figure 4 Proof of Proposition 11: initial data (left) can be pasted into Condition ( ) (right).

Proof. By construction, S and $\langle\, \mathcal{M}_{\mathcal{Q},\mathrm{N}} \,\rangle^1_+$ share a same generating subset $\mathcal{Q}$. Now, any defining relation for S maps to a defining relation for $\langle\, \mathcal{M}_{\mathcal{Q},\mathrm{N}} \,\rangle^1_+$ by Proposition 11, and conversely by Lemma 10. ◀

▶ **Corollary 13.** *Any monoid with a quadratic normalisation satisfying Conditions* ( ) *and* ( ) *is residually finite.*

To conclude this main section, we come back to that remark (following Definition 3) about the transducer approach by Thurston.

▶ **Definition 14.** *With any quadratic normalisation* $(\mathcal{Q}, \mathrm{N})$ *is associated its* Thurston transducer *defined as the Mealy automaton* $\mathcal{T}_{\mathcal{Q},\mathrm{N}}$ *with stateset* $\mathcal{Q}$*, alphabet* $\mathcal{Q}$*, and transitions as follows:*

▶ **Corollary 15.** *Assume that* S *is a monoid with a quadratic normalisation* $(\mathcal{Q}, \mathrm{N})$ *satisfying Conditions* ( ) *and* ( )*. The Thurston transducer* $\mathcal{T}_{\mathcal{Q},\mathrm{N}}$ *and the Mealy automaton* $\mathcal{M}_{\mathcal{Q},\mathrm{N}}$ *being dual automaton,* S *possesses both the explicitly dual properties of automaticity and self-similarity.*

These rather unexpected results provide the very first bridge between two fundamental areas that have always been widely seen as irreconcilable: automatic semigroups *vs* automaton semigroups. We choose to conclude by gathering several carefully selected examples, counterexamples, and open problems.

6 Examples and counterexamples

Our very first example is straightforward, but enlightening.

▶ **Example 16.** Every finite monoid $\mathcal{J}$ (in particular every finite group) is an *automaticon* monoid, that is, both an automatic and an automaton monoid. Consider its quadratic normalisation $(\mathcal{J}, \mathrm{N})$ with $\mathrm{N}(ab) = 1(ab)$ for every $(a, b) \in \mathcal{J}^2$. Figure 5 shows how to compute its breadth $(3, 2)$, witness of Condition ( ) for applying Theorem 12.

As mentioned in Section 1 and appearing on Figure 1, there exist automatic semigroups that cannot be automaton semigroups.

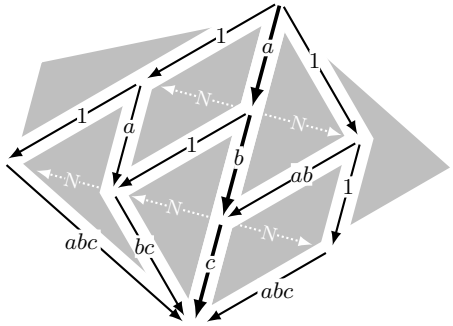

Figure 5 Computing the breadth $(3, 2)$ for any finite monoid $\mathcal{J}$ as in Example 16.

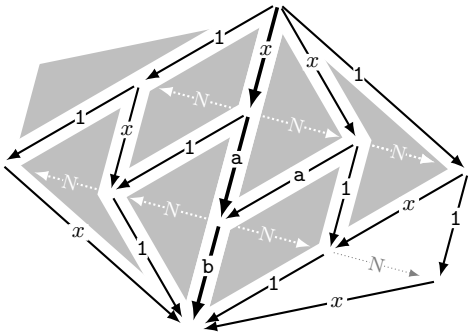

Figure 6 Computing the breadth $(3, 4)$ for the bicylic monoid $\mathbf{B}$ from Example 17.

▶ **Example 17.** The bicyclic monoid $\mathbf{B} = \langle\, \mathtt{a}, \mathtt{b} : \mathtt{ab} = \mathtt{1} \,\rangle^1_+$ is known to be automatic and not residually finite, hence cannot be an automaton monoid. Choose for $\mathbf{B}$ the quadratic normalisation $(\{\mathtt{a}, \mathtt{b}, \mathtt{1}\}, \mathrm{N})$ with $\mathrm{N}(\mathtt{ab}) = \mathtt{11}$, $\mathrm{N}(x\mathtt{1}) = \mathtt{1}x$ for $x \in \{\mathtt{a}, \mathtt{b}\}$, and $\mathrm{N}(xy) = xy$ otherwise. Figure 6 illustrates the computation (on the witness word $x\mathtt{ab}$ with $x \in \{\mathtt{a}, \mathtt{b}\}$) of its breadth $(3, 4)$. The Condition ( ) is hence not satisfied and Theorem 12 cannot apply. Precisely, according to the proof of Proposition 11 and Figure 4, we have $\sigma_{\mathtt{ab}}(x) = \mathtt{1} \neq x = \sigma_{\mathtt{11}}(x)$ for $x \in \{\mathtt{a}, \mathtt{b}\}$, hence $\sigma_{\mathtt{ab}} \neq \sigma_{\mathtt{1}} = \sigma_{\mathtt{11}}$.

By contrast, one of the simplest nontrivial examples could be the following.

▶ **Example 18.** The automatic monoid $\langle\, \mathtt{a}, \mathtt{b} : \mathtt{ab} = \mathtt{a} \,\rangle^1_+$ admits the quadratic normalisation $(\{\mathtt{a}, \mathtt{b}, \mathtt{1}\}, \mathrm{N})$ with $\mathrm{N}(\mathtt{ab}) = \mathtt{1a}$, $\mathrm{N}(x\mathtt{1}) = \mathtt{1}x$ for $x \in \{\mathtt{a}, \mathtt{b}\}$, and $\mathrm{N}(xy) = xy$ otherwise. Condition ( ) is satisfied, and the breadth is (3,3) according to the graph on Figure 7. By Theorem 12, it is therefore an automaton monoid, generated by the Mealy automaton displayed on Figure 7.

The latter happens to be the common smallest nontrivial member of the family of Baumslag–Solitar monoids (see [32] for instance), namely $\mathbf{BS}^1_+(1, 0)$, and of a wide family of right-cancellative semigroups, that we readily call *Artin–Krammer* monoids and that have been introduced and studied in [39] (see also [30, 31, 48]), namely $\mathbf{AK}^1_+(\Gamma)$ associated with the Coxeter-like matrix $\Gamma = \left[\begin{smallmatrix} 1 & 1 \\ 2 & 1 \end{smallmatrix}\right]$.

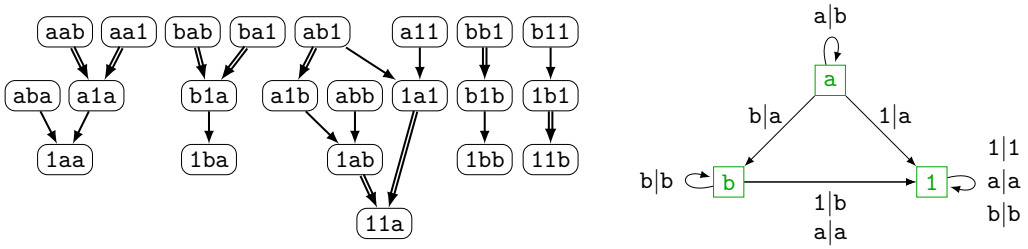

Figure 7 The $\overline{\mathrm{N}}$-graph for the quadratic normalisation associated with $\langle\, \mathtt{a}, \mathtt{b} : \mathtt{ab} = \mathtt{a} \,\rangle^1_+$ from Example 18: simple arrows correspond to $\overline{\mathrm{N}}_1$ and double arrows to $\overline{\mathrm{N}}_2$, while loops are simply omitted for better readability. The breadth is $(3, 3)$ as well. On the right is the associated Mealy automaton.

Examples 19 and 20 describe important members from both these families.

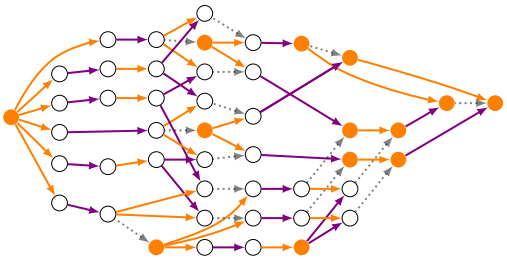

Figure 8 The minimal Garside family of the monoid $\mathbf{AK}^1_+\left(\begin{bmatrix}1&3&2\\4&1&3\\2&4&1\end{bmatrix}\right)$ from Example 19.

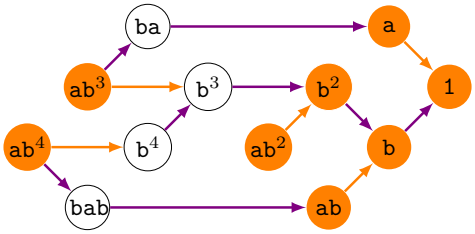

Figure 9 The minimal Garside family of the monoid $\mathbf{BS}^1_+(3,2)$ from Example 20.

▶ **Example 19.** The following Artin–Krammer monoid is emblematic:

$$\mathbf{AK}^1_+\left(\begin{bmatrix}1&3&2\\4&1&3\\2&4&1\end{bmatrix}\right) = \left\langle \mathtt{a},\mathtt{b},\mathtt{c} : \begin{matrix}\mathtt{abab}=\mathtt{aba}\\ \mathtt{ac}=\mathtt{ca}\\ \mathtt{bcbc}=\mathtt{bcb}\end{matrix} \right\rangle^1_+.$$

As displayed on Figure 8, its minimal so-called Garside family forms like a flint which encodes its whole combinatorics and, according to Theorem 12, makes it an automaticon monoid.

▶ **Example 20.** Consider the Baumslag–Solitar monoid $\mathbf{BS}^1_+(3,2) = \langle\, \mathtt{a},\mathtt{b} : \mathtt{ab}^3 = \mathtt{b}^2\mathtt{a} \,\rangle^1_+$. Displayed on Figure 9, its minimal Garside family contains eight elements (orange vertices) and makes it an automaticon monoid. This is an example of a group-embeddable automaton monoid whose enveloping group is not an automaton group. Indeed, the Baumslag–Solitar group $\mathbf{BS}(3,2)$ is precisely known as an example of non-residually finite group, hence cannot be an automaton group. The question remains open for those automaton semigroups whose enveloping group is a group of fractions, see Problem **C** below.

Concerning again group-embeddability, the following gives now an example of a cancellative automaton semigroup which is not group-embeddable.

▶ **Example 21.** The monoid $\mathbf{T} = \langle\, \mathtt{a},\mathtt{b},\mathtt{c},\mathtt{d},\mathtt{a}',\mathtt{b}',\mathtt{c}',\mathtt{d}' : \mathtt{ab}=\mathtt{cd}, \mathtt{a}'\mathtt{b}'=\mathtt{c}'\mathtt{d}', \mathtt{a}'\mathtt{d}=\mathtt{c}'\mathtt{b} \,\rangle^1_+$ is known (by Malcev work [41, 42, 43]) to be cancellative but not group-embeddable: from these three relations, we cannot deduce the relation $\mathtt{ad}' = \mathtt{cb}'$ that holds in the enveloping group. The quadratic normalisation $(\{\mathtt{a},\mathtt{b},\mathtt{c},\mathtt{d},\mathtt{a}',\mathtt{b}',\mathtt{c}',\mathtt{d}'\}, \mathrm{N})$ defined by $\mathrm{N}(\mathtt{ab}) = \mathtt{cd}$, $\mathrm{N}(\mathtt{a}'\mathtt{b}') = \mathtt{c}'\mathtt{d}'$, and $\mathrm{N}(\mathtt{a}'\mathtt{d}) = \mathtt{c}'\mathtt{b}$ for instance has breadth $(3,3)$, hence satisfies Condition ( ) and Theorem 12 applies. This answers in particular a question by Cain [15].

Some classes of neither left- nor right-cancellative monoids have been studied and shown to admit nice normal forms yielding biautomatic structures (see [16]):

▶ **Example 22.** According to Schützenberger [54], plactic monoids are among the most fundamental monoids. The rank 2 plactic monoid is $\mathbf{P}_2 = \langle\, \mathtt{a},\mathtt{b} : \mathtt{aba} = \mathtt{baa}, \mathtt{bab} = \mathtt{bba} \,\rangle^1_+$. As noted in [20, 22], $\mathbf{P}_2$ admits the quadratic normalisation $(\mathcal{Q}, \mathrm{N})$ with $\mathcal{Q} = \{1, \mathtt{a}, \mathtt{b}, \mathtt{ba}\}$, $\mathrm{N}(\mathtt{ba}) = 1(\mathtt{ba})$, $\mathrm{N}((\mathtt{ba})\mathtt{a}) = \mathtt{a}(\mathtt{ba})$, $\mathrm{N}((\mathtt{ba})\mathtt{b}) = \mathtt{b}(\mathtt{ba})$, $\mathrm{N}(1x) = x1$ for $x \in \mathcal{Q}$, and $\mathrm{N}(xy) = xy$ otherwise. The latter has a breadth $(3,3)$, hence satisfies Condition ( ) and Theorem 12 ensures that $\mathbf{P}_2$ is an automaton monoid. Note that, for a higher rank plactic monoid $\mathbf{P}_X$, it suffices to take again for $\mathcal{Q}$ the set of *columns*, that is, the strictly decreasing products of elements of X. Chinese monoids admit quadratic normalisations with breadth $(4,3)$, hence satisfy Condition ( ), and Theorem 12 ensures that they are automaticon monoids [16, 51].

To conclude, we would like to illustrate the duality between "being an automatic semigroup" and "being an automaton semigroup" by highlighting a paradigmatic example.

▶ **Example 23.** The braid monoids were used by Thurston [24, Chapter 9] to describe his idea to build a single transducer that computes the so-called Adjan–Garside–Thurston normal form via iterated runs. The n-strand braid monoid is

$$\mathbf{B}^1_{n+} = \left\langle \sigma_1, \ldots, \sigma_{n-1} : \begin{array}{ll} \sigma_i\sigma_j\sigma_i = \sigma_j\sigma_i\sigma_j & \text{for } |i-j| \leq 1 \\ \sigma_i\sigma_j = \sigma_j\sigma_i & \text{for } |i-j| > 1 \end{array} \right\rangle^1_+ .$$

Garside theory allows to build a suitable generating set $\mathcal{Q}$ of size $n!$ and a corresponding quadratic normalisation with breadth $(3, 3)$. According to Corollary 15, its Thurston transducer and its Mealy automaton make therefore $\mathbf{B}^1_{n+}$ both an automatic and an automaton monoid. Such an approach may hopefully shed some light on the question of whether or not the braid groups are self-similar (Problem **B**). In particular, a positive answer to our following Problem **C** would imply a positive answer to Problem **B**.

Problem C. Is the group of fractions of an automaton monoid an automaton group?

Abstract

Let p be a prime number and let $\mathcal{G}_p$ be the variety of all languages recognised by a finite p-group. We give a construction process of all $\mathcal{G}_p$-preserving functions from a free monoid to a free group. Our result follows from a new noncommutative generalization of Mahler's theorem on interpolation series, a celebrated result of p-adic analysis.

1 Introduction

Throughout this paper, p denotes a prime number. A finite *p-group* is a group whose order is a power of p. Let $\mathcal{G}_p$ denote the variety of all languages recognised by a finite p-group. This variety, first studied over fourty years ago [2, p. 238] is generated by the p-binomial languages, as explained in Section 4.

A function f from A^* to B^* is *regularity-preserving* if, for each regular language L of B^*, the language $f^{-1}(L)$ is also regular. In a series of papers [8, 9, 10], Silva and the first author considered a more general situation: given a variety $\mathcal{V}$ of regular languages, a function f from A^* to B^* is *$\mathcal{V}$-preserving* if $L \in \mathcal{V}$ implies $f^{-1}(L) \in \mathcal{V}$. These functions admit a simple topological characterization. Indeed, one can attach to each variety $\mathcal{V}$ a metric[2] $d_{\mathcal{V}}$, called the *pro-$\mathcal{V}$ metric*, for which the following property holds: a function is $\mathcal{V}$-preserving if and only if it is uniformly continuous with respect to $d_{\mathcal{V}}$ [10, Theorem 4.1]. However, this characterization does not solve the following more difficult question:

Synthesis problem for $\mathcal{V}$. *Provide a construction process of all $\mathcal{V}$-preserving functions.*

For instance, although several families of regularity-preserving functions have been identified, the synthesis problem for these functions is still a major open problem.

The aim of this paper is to solve the synthesis problem for the variety $\mathcal{G}_p$. We actually solve this problem for all functions from A^* to the free group $F(B)$, a slightly more general setting, since the free monoid B^* embeds in $F(B)$. In a free group, the class $\mathcal{G}_p$ is defined in the same way: a subset of $F(B)$ is in $\mathcal{G}_p$ if it is recognized by a finite p-group.

[1] Corresponding author.
[2] Actually, it is only a pseudometric in the general case, but a metric in the case considered in this paper.

One-letter case. If A and B are one-letter alphabets, then A^* is isomorphic to $\mathbb{N}$, $F(B)$ is isomorphic to $\mathbb{Z}$ and d_p is the *p-adic metric*. The *p-adic distance* between two distinct integers r and s is the real p^{-n}, where n is the exponent of p in the prime factorization of $|r-s|$. It turns out that *Mahler's theorem on interpolation series*, a celebrated result in p-adic analysis [4, 5] stated below, leads to a construction process of the $\mathcal{G}_p$-preserving functions from $\mathbb{N}$ to $\mathbb{Z}$.

Mahler's theorem is based on another result of independent interest. *Newton's forward difference formula* states that for each function $f\colon \mathbb{N} \to \mathbb{Z}$, there is a unique sequence of integers $\delta_k f$ such that, for all $n \in \mathbb{N}$, $f(n) = \sum_{k=0}^{\infty} \binom{n}{k} \delta_k f$. The value of these coefficients $\delta_k f$ is given by the formula $\delta_k f = (\Delta^k f)(0)$, where Δ^k is the k-th iteration of the *difference operator* Δ, defined by $(\Delta f)(n) = f(n+1) - f(n)$. A remarkable consequence of Newton's forward difference formula is that the map $f \to (\delta_k f)_{k \geqslant 0}$ defines a *bijection* between functions from $\mathbb{N}$ to $\mathbb{Z}$ and integer sequences. We call this bijection *Newton's bijection*.

Mahler's theorem states that the integer sequences that give rise to $\mathcal{G}_p$-preserving functions are precisely those converging to 0 in the p-adic metric. More precisely:

▶ **Theorem 1.1** (Mahler). *The following conditions are equivalent:*

(1) *$f\colon \mathbb{N} \to \mathbb{Z}$ is a $\mathcal{G}_p$-preserving function,*

(2) *f is uniformly continuous for the p-adic metric,*

(3) *the functions $\Delta^n f$ tend uniformly to the constant function $\mathbf{0}$ when n tends to ∞,*

(4) *the p-adic norm of $\delta_n f$ tends to 0 when n tends to ∞,*

(5) *f is the uniform limit of the polynomial functions $f_r(n) = \sum_{k=0}^{r} \binom{n}{k} \delta_k f$.*

This leads to a simple construction process of all $\mathcal{G}_p$-preserving functions from $\mathbb{N}$ to $\mathbb{Z}$: take a sequence $(\delta_k)_{k \geqslant 0}$ of integers converging to 0 and set $f(n) = \sum_{k=0}^{\infty} \binom{n}{k} \delta_k$.

Functions from A^* to $F(B)$. When B is a one-letter alphabet, a construction process of all $\mathcal{G}_p$-preserving functions was obtained by Silva and the first author in [10, 11]. We rely on this result to treat the general case where B is any finite alphabet.

We first equip both A^* and $F(B)$ with the pro-p metric, a natural extension of the p-adic metric, fully defined in Section 4.1. We follow [7] to extend the difference operators. Let f be a function from A^* to a group G. For each letter a, the *difference operator* Δ^a associates to f the function $\Delta^a f\colon A^* \to G$ defined by $\Delta^a f(u) = f(u)^{-1} f(ua)$. Next we attach a difference operator Δ^w to each word $w = a_1 \cdots a_n$ of A^* by setting $\Delta^w f = \Delta^{a_1}(\Delta^{a_2}(\cdots \Delta^{a_n} f) \cdots)$. Finally, we set $\delta_w f = \Delta^w f(1)$, where 1 is the empty word.

A noncommutative version of Newton's forward difference formula and of Newton's bijection was given by the first author in [7]. We give a simpler proof of these results in Section 2.5. In this noncommutative setting, Newton's bijection is now the map $f \to (\delta_w f)_{w \in A^*}$. If we just keep the elements $\delta_w f$ such that $|w| \leqslant n$ and replace every other $\delta_w f$ by the identity of the free group, the inverse of Newton's bijection gives back a function f_n, called the n-th *Newton polynomial function associated to f*.

Our main result now offers a noticeable analogy with Mahler's theorem:

▶ **Theorem 1.2.** *Let $f\colon A^* \to F(B)$ be a function. The following conditions are equivalent:*

(1) *f is a $\mathcal{G}_p$-preserving function,*

(2) *f is uniformly continuous for the pro-p metric,*

(3) *the functions $\Delta^w f$ tend uniformly to the constant function $\mathbf{1}$ when $|w|$ tends to ∞,*

(4) *the elements $\delta_w f$, where $w \in A^*$, tend to 1 when $|w|$ tends to ∞,*

(5) *f is the uniform limit of its Newton polynomial functions.*

Sequential products. A new operation on functions plays a key role in our proof of Theorem 1.2. Given an element g of a group G and a family $(f_a)_{a\in A}$ of functions from A^* to G, the *sequential product* of g and $(f_a)_{a\in A}$ is the function $f\colon A^* \to G$, defined, for each word $a_1\cdots a_n \in A^*$, by $f(a_1\cdots a_n) = g\prod_{1\leqslant i\leqslant n} f_{a_i}(a_1\cdots a_{i-1})$.

A function f from A^* to a group G is a *Newton polynomial function* if $\delta_w f = 1$ for almost all words w. We prove that the set of Newton polynomial functions from A^* to G is the smallest set of functions containing the constant functions and closed under sequential product. Moreover, if G is a finite p-group equipped with the discrete metric, then the Newton polynomial functions are exactly the uniformly continuous functions from A^* to G.

Two solutions of the synthesis problem. Theorem 1.2 now leads to two construction processes to obtain all $\mathcal{G}_p$-preserving functions from A^* to $F(B)$. The first one consists in taking any family $(\delta_w)_{w\in A^*}$ of elements of the free group converging to 1 when $|w|$ tends to ∞ and to use the inverse of Newton's bijection to get in return a $\mathcal{G}_p$-preserving function from A^* to $F(B)$. The second method is to start with the constant functions, use the sequential product to generate all Newton polynomial functions and finally take the uniform closure.

Related work. Another characterization of $\mathcal{G}_p$-preserving functions using profinite equations was obtained in [1, Lemma 3.3], but it only holds for *regular-preserving* functions. In the case of *sequential* and *rational* functions, $\mathcal{V}$-preserving functions were first investigated by Schützenberger and the second author [12]. For instance, they proved that a sequential function is $\mathcal{G}_p$-preserving if and only if the syntactic semigroup of its minimal sequential transducer is a finite p-group. Our results are of a different nature, since they concern all $\mathcal{G}_p$-preserving functions.

Organization. Difference operators and Newton's forward difference formula are introduced in Section 2. Section 3 is devoted to Newton polynomial functions and Section 4 to topological issues. The proof of our main result is presented in Section 5. Due to space constraints, missing proofs are given in the Appendix.

2 Difference operators and Newton's forward difference formula

Newton's forward difference formula gives an expression of a function from $\mathbb{N}$ to $\mathbb{Z}$ in terms of the initial value of the function and the powers of the forward difference operator. A noncommutative extension of this formula for functions from A^* to $F(B)$ was given in [7]. In this section, we give a new proof of these results. We first need to introduce a noncommutative version of the Magnus transformation.

2.1 Noncommutative Magnus transformation

Let A^{**} denote the free monoid freely generated by A^*. An element of A^{**} is a finite sequence $(w_1,\ldots,w_n)$ of elements of A^*. However, to avoid any confusion between the product in A^* and the product in A^{**}, we adopt an additive notation for A^{**}. This means that we replace the notation $(w_1,\ldots,w_n)$ by $w_1+\cdots+w_n$. The addition of two elements $(u_1+\cdots+u_m)$ and $(v_1+\cdots+v_n)$ of A^{**} is also denoted additively, which is coherent, since

$$(u_1+\cdots+u_m)+(v_1+\cdots+v_n) = u_1+\cdots+u_m+v_1+\cdots+v_n.$$

Accordingly, the neutral element of the monoid A^{**} is denoted 0. Note however that the addition is in general noncommutative. For each $w \in A^*$ and $x = x_1 + \cdots + x_n \in A^{**}$, let $x \cdot w = x_1 w + \cdots + x_n w$. This defines a *monoid right action* of A^* on A^{**}, which means that the following formulas hold for all $w, w_1, w_2 \in A^*$, and for all $x, x_1, x_2 \in A^{**}$,

$$0 \cdot w = 0 \qquad (x_1 + x_2) \cdot w = x_1 \cdot w + x_2 \cdot w \qquad x \cdot (w_1 w_2) = (x \cdot w_1) \cdot w_2.$$

The *noncommutative Magnus transformation* is the mapping μ from A^* into A^{**} defined recursively by setting $\mu(1) = 1$ and, for any $w \in A^*$ and $a \in A$,

$$\mu(wa) = \mu(w) + \mu(w) \cdot a. \tag{2.1}$$

For instance, $\mu(a) = 1 + a$, $\mu(ab) = 1 + a + b + ab$, $\mu(abc) = 1 + a + b + ab + c + ac + bc + abc$ and $\mu(abcd) = 1 + a + b + ab + c + ac + bc + abc + d + ad + bd + abd + cd + acd + bcd + abcd$.

2.2 Difference operators

Let G be a group and let $f\colon A^* \to G$ be a function. Following [7], we define the difference operators as follows. For each letter $a \in A$, $\Delta^a f$ is the function $A^* \to G$ defined by $\Delta^a f(w) = f(w)^{-1} f(wa)$ for any word w in A^*. We obtain in this way a function $a \mapsto \Delta^a$ from A into the set $\mathcal{M}$ of all mappings from G^{A^*} into itself. We view $\mathcal{M}$ as a monoid under the composition of mappings. Since A^* is the free monoid on A, this function from A to $\mathcal{M}$ extends uniquely to a monoid morphism from A^* into $\mathcal{M}$. Denoting $w \mapsto \Delta^w$ this extension, we get $\Delta^1 f = f$ and, for all words u, v in A^*,

$$\Delta^{uv} f = \Delta^u \Delta^v f. \tag{2.2}$$

For instance, one gets, for any $a, b, c \in A$ and $u \in A^*$,

$$(\Delta^1 f)(u) = f(u) \quad (\Delta^a f)(u) = f(u)^{-1} f(ua) \quad (\Delta^{ab} f)(u) = f(ub)^{-1} f(u) f(ua)^{-1} f(uab)$$
$$(\Delta^{abc} f)(u) = f(ubc)^{-1} f(ub) f(u)^{-1} f(uc) f(uac)^{-1} f(ua) f(uab)^{-1} f(uabc)$$

Here are two examples of differential operators. First, let us take $A^* = \mathbb{N}$ and $G = \mathbb{Z}$. Switching to additive notation, we find that $\Delta^1 f(n) = -f(n) + f(n+1)$, the usual difference operator, and more generally $\Delta^k f(n) = f(n+k) - \binom{n}{1} f(n+k-1) + \binom{n}{2} f(n+k-2) - \cdots + (-1)^k \binom{n}{k} f(n)$.

The next example requires an auxiliary definition. The *iterated commutator* $[x_1, x_2, \ldots, x_n]$ of n elements $x_1, x_2, \ldots, x_n$ of a group is defined by induction by setting $[x_1] = x_1$ and for $n \geqslant 2$, $[x_1, x_2, \ldots, x_n] = x_1 [x_2, x_3, \ldots, x_n] x_1^{-1} [x_2, x_3, \ldots, x_n]^{-1}$. In particular, since $[x_1, x_2] = x_1 x_2 x_1^{-1} x_2^{-1}$, one gets $[x_1, x_2, \ldots, x_n] = [x_1, [x_2, x_3, \ldots, x_n]]$.

▶ **Proposition 2.1.** *Let $f\colon A^* \to F(A)$ be the function defined by $f(x) = x^{-1}$. Then for every $n > 0$ and for all $a_1, \ldots, a_n \in A$, $\Delta^{a_1 a_2 \cdots a_n} f(x) = x [a_1, a_2, \ldots, a_n]^{-1} x^{-1}$.*

Difference operators commute with group morphisms:

▶ **Proposition 2.2.** *Let $f\colon A^* \to G$ be a function, let $\varphi\colon G \to H$ be a group morphism and let w be a word. Then $\Delta^w(\varphi \circ f) = \varphi \circ (\Delta^w f)$.*

2.3 The integration problem

Let G be a group and let $f\colon A^* \to G$ be a function. Then f and the functions $\Delta^a f$, for $a \in A$, are related by a functional equation.

▶ **Proposition 2.3.** *Let $a_1 \cdots a_n$ be a word of A^*. Then the following formula holds:*

$$f(a_1 \cdots a_n) = f(1) \prod_{1 \leqslant i \leqslant n} \Delta^{a_i} f(a_1 \cdots a_{i-1}). \tag{2.3}$$

The functional equation (2.3) gives an expression of f in terms of $f(1)$ and of the family $(\Delta^a f)_{a \in A}$. We now address the opposite question, which is somewhat similar to the problem of integrating a function from its derivative.

Integration problem. *Given an element g of G and a family $(f_a)_{a \in A}$ of functions from A^* to G, is there a function f such that $f(1) = g$ and $f_a = \Delta^a f$ for all $a \in A$?*

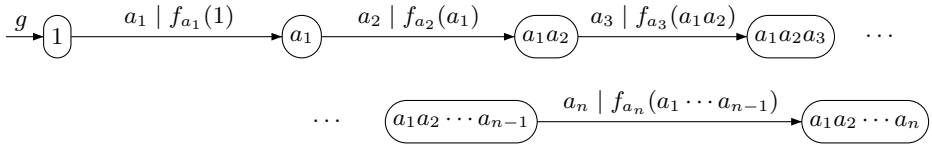
To solve the integration problem, it is convenient to introduce a new definition. Given an element g of G and a family $(f_a)_{a \in A}$ of functions from A^* to G, the *sequential product* $\mathrm{Seq}(g, (f_a)_{a \in A})$ is the function $f \colon A^* \to G$, defined, for each word $a_1 \cdots a_n \in A^*$, by

$$f(a_1 \cdots a_n) = g \prod_{1 \leqslant i \leqslant n} f_{a_i}(a_1 \cdots a_{i-1}). \tag{2.4}$$

By abuse of language, a function $f \colon A^* \to G$ is called *a sequential product of a family $(f_a)_{a \in A}$ of functions from A^* to G* if, for some $g \in G$, $f = \mathrm{Seq}(g, (f_a)_{a \in A})$.

This terminology stems from the fact that f can be realized by a sequential transducer with infinitely many states. Indeed, consider the sequential transducer $\mathcal{A} = (A^*, A, G, 1, \cdot, *, g)$, where A^* is the set of states, A the input alphabet, G the output group, 1 the initial state, g the initial prefix. The transition and the output functions are respectively defined by $u \cdot a = ua$ and $u * a = f_a(u)$.

A typical computation in $\mathcal{A}$ looks like this



and hence $\mathcal{A}$ computes the sequential product f defined by (2.4).

We are now ready to solve the integration problem.

▶ **Proposition 2.4.** *Let $g \in G$ and let $(f_a)_{a \in A}$ be a family of functions from A^* to G. Then the sequential product $\mathrm{Seq}(g, (f_a)_{a \in A})$ is the unique function f such that $f(1) = g$ and $\Delta^a f = f_a$ for all $a \in A$.*

Proof. Let $f = \mathrm{Seq}(g, (f_a)_{a \in A})$. Then $f(1) = g$ by definition. Let $u = a_1 \dots a_n$ be a word and a be a letter. Since $\Delta^a f(u) = f(u)^{-1} f(ua)$, one gets by (2.4)

$$\Delta^a f(u) = \Big(g \prod_{1 \leqslant i \leqslant n} f_{a_i}(a_1 \cdots a_{i-1})\Big)^{-1} g\Big(\prod_{1 \leqslant i \leqslant n} f_{a_i}(a_1 \cdots a_{i-1})\Big) f_a(a_1 \cdots a_n) = f_a(a_1 \cdots a_n)$$

whence $\Delta^a f = f_a$.

To prove uniqueness, consider a function f such that $f(1) = g$ and $\Delta^a f = f_a$ for all $a \in A$. Then for each word $a_1 \cdots a_n \in A^*$, one gets by (2.3),

$$f(a_1 \cdots a_n) = f(1) \prod_{1 \leqslant i \leqslant n} \Delta^{a_i} f(a_1 \cdots a_{i-1}) = g \prod_{1 \leqslant i \leqslant n} f_{a_i}(a_1 \cdots a_{i-1}).$$

and thus $f = \mathrm{Seq}(g, (f_a)_{a \in A})$. ◀

2.4 Newton's forward difference formula

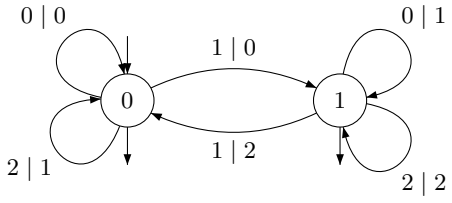
For each $w \in A^*$ and $f\colon A^* \to G$, let us set $\delta_w f = \Delta^w f(1)$ and let $\delta_f\colon A^* \to G$ be the map defined by $\delta_f(w) = \delta_w f$. This map extends to a monoid morphism $\delta_f^*\colon A^{**} \to G$. Thus $\delta_f^*(w) = \delta_w f$ and if $w_1 + \cdots + w_n$ is an element of A^{**}, then $\delta_f^*(w_1 + \cdots + w_n) = \delta_{w_1} f \cdots \delta_{w_n} f$.

▶ **Theorem 2.5.** *The equality $f = \delta_f^* \circ \mu$ holds for each function $f\colon A^* \to G$.*

The equality $f = \delta_f^* \circ \mu$ yields a noncommutative version of Newton's forward difference formula. Indeed, it extends the formula given in [11, Theorem 2.2] for functions from A^* to $\mathbb{Z}$, which itself extends Newton's forward difference formula for functions from $\mathbb{N}$ to $\mathbb{Z}$. To make this formula a little more concrete, let us compute a few values of $f(w)$. Let a, b, c, d be letters of A. Then, using the values of μ computed on page 4, one gets

$$\begin{aligned} f(1) &= \delta_1 f \qquad f(a) = (\delta_1 f)(\delta_a f) \qquad f(ab) = (\delta_1 f)(\delta_a f)(\delta_b f)(\delta_{ab} f) \\ f(abc) &= (\delta_1 f)(\delta_a f)(\delta_b f)(\delta_{ab} f)(\delta_c f)(\delta_{ac} f)(\delta_{bc} f)(\delta_{abc} f) \\ f(abcd) &= (\delta_1 f)(\delta_a f)(\delta_b f)(\delta_{ab} f)(\delta_c f)(\delta_{ac} f)(\delta_{bc} f)(\delta_{abc} f) \\ &\qquad (\delta_d f)(\delta_{ad} f)(\delta_{bd} f)(\delta_{abd} f)(\delta_{cd} f)(\delta_{acd} f)(\delta_{bcd} f)(\delta_{abcd} f). \end{aligned}$$

Here is a more complete example. Let $f\colon \{0,1,2\}^* \to \{0,1,2\}^*$ be the Euclidean division by 2 in base 3, that is, the function which associates to a word $u \in \{0,1,2\}^*$ representing an integer $\overline{u}$ in base 3, the unique word v of the same length as u representing the quotient of the division of $\overline{u}$ by 2. Since 1 is a letter of the alphabet, we let ϵ denote the empty word. The function f can be realized by the sequential transducer represented below.



For instance, $f(1212) = 0221$ since $\overline{1212} = 50$ and $\overline{0221} = 25 = 50/2$. Let us compute the functions $\Delta^x f$. First, we have

$$\Delta^0 f(w) = \begin{cases} 0 & \text{if } \overline{w} \text{ is even} \\ 1 & \text{if } \overline{w} \text{ is odd} \end{cases} \quad \Delta^1 f(w) = \begin{cases} 0 & \text{if } \overline{w} \text{ is even} \\ 2 & \text{if } \overline{w} \text{ is odd} \end{cases} \quad \Delta^2 f(w) = \begin{cases} 1 & \text{if } \overline{w} \text{ is even} \\ 2 & \text{if } \overline{w} \text{ is odd} \end{cases}$$

The other values of $\Delta^x f(w)$ can be obtained through the following result:

▶ **Proposition 2.6.** *Let $u, v \in A^*$ and let $g\colon \{0,1,2\}^* \to A^*$ be the function defined by*

$$g(w) = \begin{cases} u & \text{if } \overline{w} \text{ is even} \\ v & \text{if } \overline{w} \text{ is odd} \end{cases}$$

Then $\Delta^x g(w) = \varepsilon$ if $x \notin 1^*$ and $\Delta^{1^n} g(w) = (u^{-1}v)^{(-1)^{n-1+\overline{w}} 2^{n-1}}$ for $n \geqslant 1$.

It is now easy to compute the elements $\delta_w = (\Delta^w f)(\epsilon)$. One gets $\delta_0 = 0$, $\delta_1 = 0$, $\delta_2 = 1$, $\delta_{1^n 0} = (0^{-1}1)^{(-1)^{n-1}2^{n-1}}$, $\delta_{1^n 1} = (0^{-1}2)^{(-1)^{n-1}2^{n-1}}$, $\delta_{1^n 2} = (1^{-1}2)^{(-1)^{n-1}2^{n-1}}$ and $\delta_w = \epsilon$ in all other cases. We get for instance

$$\begin{aligned} f(1212) &= \delta_\epsilon \delta_1 \delta_2 \delta_{12} \delta_1 \delta_{11} \delta_{21} \delta_{121} \delta_2 \delta_{12} \delta_{22} \delta_{122} \delta_{12} \delta_{112} \delta_{212} \delta_{1212} \\ &= \delta_1 \delta_2 \delta_{12} \delta_1 \delta_{11} \delta_2 \delta_{12} \delta_{12} \delta_{112} = 01(1^{-1}2)0(0^{-1}2)1(1^{-1}2)(1^{-1}2)(1^{-1}2)^{-2} = 0221. \end{aligned}$$

2.5 Newton's bijection

For each $n \in \mathbb{N}$, let C_n be the set of words of A^* of length at most n. Let ρ_n be the monoid endomorphism on A^{**} which maps every element of C_n to itself, and maps any other element of A^* to 0. In other words, if $x = \sum_{1 \leqslant i \leqslant r} u_i$ is an element of A^{**}, where each $u_i \in A^*$, then

$$\rho_n(x) = \sum_{i \in E_n(x)} u_i, \text{ where } E_n(x) = \{i \in \{1, \dots r\} \mid |u_i| \leqslant n\}.$$

For each $n \geqslant 0$, C_n is a finite subset of A^{**} and C_n^* is a free submonoid of A^{**}. The function $\mu_n = \rho_n \circ \mu$ from A^* to the free monoid C_n^* is called the *truncated noncommutative Magnus transformation*. For instance, $\mu_2(abcd) = 1 + a + b + ab + c + ac + bc + d + ad + bd + cd$, a result obtained by only keeping the words of length $\leqslant 2$ in $\mu(abcd)$.

Recall that to each function $f\colon A^* \to G$ is associated the map $\delta_f\colon A^* \to G$ defined by $\delta_f(w) = \delta_w(f)$. The *Newton map* is the map $\delta\colon f \to \delta_f$. Let $f^*\colon A^{**} \to G$ denote the unique monoid morphism extending f and let γ be the map defined by $\gamma(f) = f^* \circ \mu$.

▶ **Theorem 2.7.** *The Newton map δ is a permutation on the set of functions from A^* to G and its inverse permutation is γ.*

Proof. Since $f = \delta_f^* \circ \mu$ by Theorem 2.5, $\gamma \circ \delta$ is the identity function. Therefore γ is surjective, δ is injective and it suffices to prove that γ is injective. Let $g, h\colon A^* \to G$ be such that $g^* \circ \mu = h^* \circ \mu$. Let us show by induction on $|w|$ that $g(w) = h(w)$. If $|w| = 0$, then w is the empty word 1 , $\mu(1) = 1$, $g^*(1) = g(1)$, $h^*(1) = h(1)$ and thus $g(1) = h(1)$. Suppose now that $|w| = n + 1$. Then $\mu(w) = \mu_n(w) + w$ and since g^* and h^* are monoid morphisms, one gets $g^* \circ \mu(w) = g^*(\mu_n(w) + w) = g^*(\mu_n(w))g(w)$ and similarly $h^* \circ \mu(w) = h^*(\mu_n(w))h(w)$. Since $\mu_n(w)$ is a sum of words of length $\leqslant n$, the induction hypothesis gives $g^*(\mu_n(w)) = h^*(\mu_n(w))$. Now since $g^* \circ \mu(w) = h^* \circ \mu(w)$, one gets $g(w) = h(w)$, which concludes the induction step. ◀

Theorem 2.7 solves the following interpolation problem.

▶ **Corollary 2.8.** *For each function $g : A^* \to G$, there exists a unique function $f\colon A^* \to G$ such that, for all $u \in A^*$, $\delta_u f = g(u)$.*

3 Newton polynomial functions

Let G be a group. A function $f\colon A^* \to G$ is called a *Newton polynomial function* if $\delta_w f = 1$ for almost all words $w \in A^*$. Note that by Proposition 2.6, the Euclidean division by 2 in base 3 is not a Newton polynomial function.

Let $\mathbf{1}$ denote the constant function from A^* to G that maps every word to 1. The *degree* of a Newton polynomial function is -1 if $f = \mathbf{1}$; otherwise, it is the smallest d such that $\delta_w f = 1$ for any word of length $d + 1$.

Here is another convenient characterization of Newton polynomial functions.

▶ **Proposition 3.1.** *A function $f\colon A^* \to G$ is a Newton polynomial function of degree d if and only if d is the smallest integer such that $\Delta^w f = \mathbf{1}$ for all words w of length $d + 1$.*

The following result gives a construction process of the set of Newton polynomial functions.

▶ **Theorem 3.2.** *The set of Newton polynomial functions from A^* to G is the smallest set of functions from A^* to G containing the constant functions and closed under sequential product.*

Theorem 3.2 is an immediate consequence of the following proposition.

▶ **Proposition 3.3.** *Let G be a group and let $f\colon A^* \to G$ be a function. The following conditions are equivalent:*

(1) *f is a Newton polynomial function of degree $\leqslant d$,*

(2) *there exists a family $(f_a)_{a\in A}$ of Newton polynomial functions of degree $\leqslant d-1$ such that $f = \mathrm{Seq}(f(1), (f_a)_{a\in A})$.*

In this case, one has $f_a = \Delta^a f$ for every $a \in A$.

Proof. (1) implies (2). Suppose that f is a Newton polynomial function of degree $\leqslant d$. Then for any letter a, $\Delta^a f$ is a Newton polynomial function of degree at most $d-1$. Moreover, Proposition 2.3 shows that $f(a_1\cdots a_n) = f(1)\prod_{1\leqslant i\leqslant n}\Delta^{a_i} f(a_1\cdots a_{i-1})$, which proves (2).

(2) implies (1). Suppose that (2) holds. Proposition 2.4 shows that, for each letter a, $\Delta^a f = f_a$ and hence $\Delta^a f$ is a Newton polynomial function of degree $\leqslant d-1$. It follows that f is a Newton polynomial function of degree $\leqslant d$. ◀

A Newton polynomial function of degree 0 is a constant map different from $\mathbf{1}$. A Newton polynomial function of degree 1 is an *affine morphism*, that is, a function f of the form $f(w) = f(1)g(w)$ for some monoid morphism $g\colon A^* \to G$. Equivalently, conjugating by $f(1)$, one gets $f(w) = h(w)f(1)$ for some monoid morphism $h : A^* \to G$.

The function $f\colon A^* \to F(A)$ defined by $f(a_1\cdots a_n) = a_1(a_1a_2)(a_1a_2a_3)\ \cdots\ (a_1\cdots a_n)$ is a Newton polynomial function of degree 2. Indeed, it is equal to the sequential product $\mathrm{Seq}(1, (f_a)_{a\in A})$ where each f_a is the affine morphism defined by $f_a(u) = ua$.

Recall that δ_f^* is a map from A^{**} to G, but we keep the same notation for its restriction to C_n^*. Let $f\colon A^* \to G$ be a function. For each $n \geqslant 0$, the *n-th Newton polynomial function* associated to f is the function f_n from A^* to G defined by $f_n = \delta_f^* \circ \mu_n$. This terminology is justified by Proposition 3.4 below.

It is not difficult to see that f_0 is the constant function equal to $f(1)$. Indeed, since $\Delta^1 f = f$, one gets $f_0(u) = \delta_f^* \circ \mu_0(u) = \delta_f^*(1) = \delta_1 f = \Delta^1 f(1) = f(1)$.

▶ **Proposition 3.4.** *For each $n \geqslant 0$, f_n is a Newton polynomial function of degree at most n.*

We need an auxiliary lemma.

▶ **Lemma 3.5.** *The following formula holds for all $n > 0$ and $a \in A$.*

$$\Delta^a(f_n) = \delta^*_{\Delta^a f} \circ \mu_{n-1} = (\Delta^a f)_{n-1}$$

Proof of Proposition 3.4. We prove the result by induction on n. For $n = 0$, we have already seen that f_0 is a constant function, and thus a Newton polynomial function of degree $\leqslant 0$. Applying Proposition 2.3 to f_n, one gets, for every word $a_1\cdots a_k \in A^*$, $f_n(a_1\cdots a_k) = f_n(1)\prod_{1\leqslant i\leqslant k}\Delta^{a_i} f_n(a_1\ldots a_{i-1})$. Now, $f_n(1) = \delta_f^* \circ \mu_n(1) = \delta_f^*(1) = f(1)$ and $\Delta^a f_n = (\Delta^a f)_{n-1}$ by Lemma 3.5. It follows that $f_n(a_1\ldots a_k) = f(1)\prod_{1\leqslant i\leqslant k}(\Delta^{a_i} f)_{n-1}(a_1\ldots a_{i-1})$. By the induction hypothesis applied to $\Delta^a f$, $(\Delta^a f)_{n-1}$ is a Newton polynomial function of degree at most $n-1$. Hence by Proposition 3.3, f_n is a Newton polynomial function of degree at most n. ◀

A function $f\colon A^* \to G$ is called a *G-polynomial* if $f(w) = 1$ for almost all words $w \in A^*$. The *degree* of a G-polynomial is -1 if $f = \mathbf{1}$; otherwise, it is the smallest d such that $f(w) = 1$ for any word of length $d+1$. One can now enrich Theorem 2.7 as follows.

▶ **Theorem 3.6.** *For each degree d, the maps δ and γ define mutually inverse bijections between the set of Newton polynomial functions of degree d and the set of G-polynomials of degree d.*

Proof. It suffices to prove that δ and γ define mutually inverse bijections between the set of Newton polynomial functions of degree $\leqslant d$ and the set of G-polynomials of degree $\leqslant d$. Let f be a Newton polynomial function of degree $\leqslant d$. Then by definition, $\delta(f)$ is a G-polynomial of degree $\leqslant d$. Let now f be a G-polynomial of degree $\leqslant d$. Theorem 2.7 shows that $f = \delta \circ \gamma(f) = \delta_{\gamma(f)}$. It follows that for every word w of length $> d$, $1 = f(w) = \delta_{\gamma(f)}(w)$. Thus $\gamma(f)$ is a Newton polynomial of degree $\leqslant d$. ◀

4 Topology

4.1 Pro-p metrics

If $\bar{B}$ is a copy of B, the free group $F(B)$ is the quotient of $(B \cup \bar{B})^*$ under the congruence generated by the relations $b\bar{b} = 1 = \bar{b}b$ for all $b \in B$.

Recall that a group G is called *residually p-finite* if for any $g \neq 1$ in G, there is some finite p-group H and some morphism $G \to H$ whose kernel does not contain g. It is a well-known fact that free groups are residually p-finite.

Let G be a residually p-finite group and let $g \in G$. The *pro-p valuation* of g, denoted $v_p(g)$, is the largest n such that g belongs to the kernel of any morphism from G to a p-group of order p^n. The pro-p valuation is always finite, except for $g = 1$, in which case it is infinite. The *pro-p norm* of g is $|g|_p = p^{-v_p(g)}$, with the usual convention $p^{-\infty} = 0$. Finally G becomes a metric space for the *pro-p metric* $d_p \colon G \times G \to \mathbb{R}$ defined by $d_p(x, y) = |x^{-1}y|_p$.

The condition $d_p(x, y) \leqslant p^{-k}$ means that $x^{-1}y$ is in the kernel of each group morphism from G into a p-group of cardinality at most p^k. We leave to the reader to verify that if $G = \mathbb{Z}$, one recovers the usual p-adic valuation, norm and metric.

Another useful example occurs when G is a finite p-group. Recall that the *discrete metric* on G is the metric d defined by $d(x, y) = 1$ if $x \neq y$ and $d(x, y) = 0$ if $x = y$. In this case, the double inequality $d_p(x, y) \leqslant d(x, y) \leqslant |G|\, d_p(x, y)$ shows that the pro-p metric is uniformly equivalent to the discrete metric.

There are two equivalent ways to define the pro-p metric on a free monoid A^*. The first solution is to view A^* as a subspace of the free group $F(A)$ and to consider the restriction to A^* of the pro-p metric on $F(A)$.

The second solution is to directly define the pro-p metric as follows. Let us say that a finite p-group G *separates* two words u and v of A^* if there exists a monoid morphism $\varphi \colon A^* \to G$ such that $\varphi(u) \neq \varphi(v)$. Then $d_p(u, v) = 0$ if $u = v$ and $d_p(u, v) = p^{-n}$, where p^n is the minimal size of a p-group separating u and v, if $u \neq v$.

▶ **Proposition 4.1.** *Every monoid morphism from A^* to a p-group is uniformly continuous.*

Proof. Let π be a monoid morphism from A^* to a p-group G and let $u, v \in A^*$. If $d_p(u, v) \leqslant |G|^{-1}$, then $\pi(u) = \pi(v)$ and thus $d_p(\pi(u), \pi(v)) = 0$. Thus π is uniformly continuous. ◀

Let us now review the connections with combinatorics on words and regular languages. A word $u = a_1 a_2 \cdots a_n$ (where $a_1, \ldots, a_n$ are letters) is a *subword* of a word v if v can be written as $v = v_0 a_1 v_1 \cdots a_n v_n$. For instance, ab is a subword of $cacbc$.

Following Eilenberg [2] and Lothaire [3, Chapter 6], let $\binom{v}{u}$ denote the number of distinct ways to write a word u as a subword of v. More formally, if $u = a_1 a_2 \cdots a_n$, then

$$\binom{v}{u} = \mathrm{Card}\{(v_0, v_1, \ldots, v_n) \mid v_0 a_1 v_1 \cdots a_n v_n = v\}$$

A language of A^* is *p-binomial* if for some word v and some integer r it is equal to

$$L(v,r) = \{w \in A^* \mid \binom{w}{v} \equiv r \bmod p\}.$$

It follows from [2, p. 238] that a language belongs to $\mathcal{G}_p$ if and only if it is a Boolean combination of p-binomial languages. We will also use the following consequence of [11, Proposition 1.3 and Theorem 1.4].

▶ **Proposition 4.2.** *Let $f\colon A^* \to B^*$ be a function. The following conditions are equivalent:*
(1) *f is uniformly continuous for the pro-p metric,*
(2) *f is $\mathcal{G}_p$-preserving,*
(3) *for each p-binomial language L of B^*, $f^{-1}(L)$ is a Boolean combination of p-binomial languages in A^*.*

4.2 Uniform continuity and Newton polynomial functions

The aim of this section is to describe the uniformly continuous functions from A^* to a finite p-group. We first give a purely algebraic characterization of these functions (Proposition 4.3). Then we show that these functions are closed under applying differential operators (Proposition 4.4) and under taking sequential products (Proposition 4.5).

▶ **Proposition 4.3.** *Let G be a finite p-group and let $f\colon A^* \to G$ be a function. Then f is uniformly continuous for the pro-p metric if and only if there exist a finite p-group K and a monoid morphism $\zeta\colon A^* \to K$ such that f factors through ζ, that is, there is a map $\lambda\colon K \to G$ such that $f = \lambda \circ \zeta$.*

▶ **Proposition 4.4.** *Let G be a finite p-group. If $f\colon A^* \to G$ is uniformly continuous for the pro-p metric, then so is $\Delta^w f$ for any word $w \in A^*$.*

Proof. By induction and by Equation (2.2), it is enough to prove the result for $w = a$ for any letter $a \in A$. In this case, $\Delta^a f\colon A^* \to G$ is the composition of the following functions:

$$\begin{array}{lll} A^* \to A^* \times A^* & A^* \times A^* \to A^* \times A^* & A^* \times A^* \to G \times G \\ \quad u \mapsto (u,u) & \quad (u,v) \mapsto (u,va) & \quad (u,v) \mapsto (f(u),f(v)) \end{array}$$

$$\begin{array}{ll} G \times G \to G \times G & G \times G \to G \\ \quad (g,h) \mapsto (g^{-1},h) & \quad (g,h) \mapsto gh \end{array}$$

as shown by the sequence

$$u \mapsto (u,u) \mapsto (u,ua) \mapsto (f(u),f(ua)) \mapsto ((f(u))^{-1},f(ua)) \mapsto (f(u))^{-1}f(ua) = \Delta^a f(u).$$

Since the pro-p metric is compatible with the monoid structure (see [6, Section 2] or [11, Section 1.4]), each of these functions is uniformly continuous and so is their composition. ◀

▶ **Proposition 4.5.** *Let G be a residually p-finite group. Any sequential product of uniformly continuous functions from A^* to G is uniformly continuous for the pro-p metric.*

Here is an important consequence of these results.

▶ **Proposition 4.6.** *Let G be a finite p-group. Every Newton polynomial function $f\colon A^* \to G$ is uniformly continuous.*

Proof. We prove the result by induction on the degree d of f. If $d \leqslant 0$, then f is a constant function and hence f is uniformly continuous. Otherwise, Proposition 3.3 shows that f is a sequential product of a family $(f_a)_{a\in A}$ of Newton polynomial functions of degree $\leqslant d-1$. By the induction hypothesis, each f_a is uniformly continuous and hence f is uniformly continuous by Proposition 4.5. ◀

We now establish the converse of Proposition 4.6.

▶ **Proposition 4.7.** *Let G be a finite p-group. If a function $f\colon A^* \to G$ is uniformly continuous for the pro-p metric, then f is a Newton polynomial function.*

Several auxiliary definitions are needed to prove this proposition.

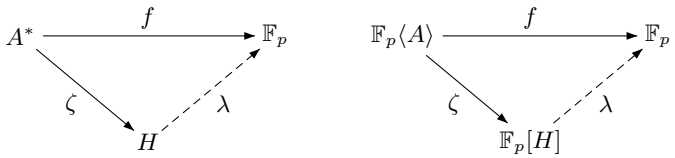
Let $\mathbb{F}_p$ be the field with p elements and let $\mathbb{F}_p[G]$ be the *group algebra* of G over $\mathbb{F}_p$. Each group morphism $G_1 \to G_2$ extends uniquely, by linearity, to an $\mathbb{F}_p$-algebra morphism from $\mathbb{F}_p[G_1]$ to $\mathbb{F}_p[G_2]$. Similarly, each function from G to $\mathbb{F}_p$ extends uniquely, by linearity, to a linear form on $\mathbb{F}_p[G]$.

The vector space of linear forms on a $\mathbb{F}_p$-algebra R (that is, the *dual* of R) is a left R-module: the action is defined, for any elements x, y in R and any linear form f on R by $(x \cdot f)(y) = f(yx)$.

Sketch of the proof of Proposition 4.7. Let p^r be the order of G. We prove the result by induction on r.

For $r = 1$, $G = \mathbb{Z}/p\mathbb{Z}$ and we switch to additive notation. Thus we have to show that $\Delta^w f = \mathbf{0}$ for almost all w. Since $\mathbb{Z}/p\mathbb{Z}$ is the additive group of the field $\mathbb{F}_p$, we may consider f as a function $A^* \to \mathbb{F}_p$. Since f is uniformly continuous, there exist by Proposition 4.3 a finite p-group H, a monoid morphism $\zeta\colon A^* \to H$ and a function $\lambda\colon H \to \mathbb{F}_p$ such that $f = \lambda \circ \zeta$, see the diagram on the left hand side of the figure below.

We extend by linearity all these functions, as explained previously, and denote these extensions by the same letters. We obtain the diagram on the right hand side of the figure below. Now ζ is a morphism of $\mathbb{F}_p$-algebra and f, as well as λ, are $\mathbb{F}_p$-linear forms.



With these notations, one can first show that

$$\Delta^w f = \Delta^{a_1\cdots a_n} f = \big((a_1 - 1)\cdots(a_n - 1)\big)\cdot f|_{A^*}. \tag{4.1}$$

Since $f = \lambda \circ \zeta$ and $\zeta\big((a_1 - 1)\cdots(a_n - 1)\big) = \big(\zeta(a_1) - 1\big)\cdots\big(\zeta(a_n) - 1\big)$, a little bit of work shows that

$$\big((a_1 - 1)\cdots(a_n - 1)\big)\cdot f = \Big(\big((\zeta(a_1) - 1)\cdots(\zeta(a_n) - 1)\big)\cdot\lambda\Big)\circ\zeta \tag{4.2}$$

Let $I_H = \Big\{ \sum_{g\in H} a_g g \mid \sum_{g\in H} a_g = 0 \Big\}$ be the *augmentation ideal* of $\mathbb{F}_p[H]$. It follows from [2, Proposition VIII.10.4] that if $n \geqslant |H|$, then $I_H^n = 0$. Since every element $\zeta(a_i) - 1$ belongs to I_H, one gets $\big(\zeta(a_1) - 1\big)\cdots\big(\zeta(a_n) - 1\big) \in I_H^n$ and hence $\big((\zeta(a_1) - 1)\cdots(\zeta(a_n) - 1)\big) = 0$. Formulas (4.1) and (4.2) now show that $\Delta^w f = \mathbf{0}$, which settles the case $r = 1$.

Suppose now that $r > 1$ and let $f\colon A^* \to G$ be a uniformly continuous function for the pro-p metric. By a standard result of group theory [13, Theorem 6.5, p. 116], G has a normal

subgroup C of order p. Now the quotient map $q\colon G \to G/C$ is uniformly continuous and so is $q \circ f\colon A^* \to G/C$. Since $|G/C| = p^{r-1}$, the induction hypothesis can be applied: there exists n such that for any word v in A^* of length $\geqslant n$, one has $\Delta^v(q \circ f) = \mathbf{1}$.

Since $\Delta^v(q \circ f) = q \circ (\Delta^v f)$ by Proposition 2.2, one has, for $|v| \geqslant n$, $q \circ (\Delta^v f) = \mathbf{1}$ and hence $\Delta^v f$ maps A^* into C. Note that $\Delta^v f$ is uniformly continuous by Proposition 4.4. Applying the first part of the proof to C, we get the following conclusion: for each v of length $\geqslant n$, there exists n_v such that for each word u of length at least n_v, one has $\Delta^u\Delta^v f = \mathbf{1}$. Let N be the maximum of all n_v taken over the finitely many v of length n. Then for each word w of length at least $N + n$, we may write $w = uv$, with $|v| = n$ and $|u| \geqslant N \geqslant n_v$. Then $\Delta^w f = \Delta^u\Delta^v f = \mathbf{1}$ and thus f is a Newton polynomial function. ◀

Putting Propositions 4.6 and 4.7 together, we get the main result of this section.

▶ **Theorem 4.8.** *Let G be a finite p-group. A function $f\colon A^* \to G$ is uniformly continuous for the pro-p metric if and only if it is a Newton polynomial function.*

5 Proof of the main result

We need two results on families of functions uniformly converging for the pro-p metric.

▶ **Proposition 5.1.** *Let $f\colon A^* \to F(B)$ be a function. If the elements $\delta_u f$, $u \in A^*$, tend to 1 when $|u|$ tends to ∞, then the sequence f_n tends uniformly to f.*

▶ **Proposition 5.2.** *A family of functions $(g_u\colon A^* \to F(B))_{u\in A^*}$ converges uniformly to the function $g\colon A^* \to F(B)$ when $|u|$ tends to infinity if and only if, for any finite p-group H and any morphism $\varphi\colon G \to H$, there exists N such that, for all $u \in A^*$ such that $|u| \geqslant N$, one has $\varphi \circ g_u = \varphi \circ g$.*

Proof of Theorem 1.2. The equivalence of (1) and (2) follows from Proposition 4.2. Let us prove that (2) implies (3). Let $f\colon A^* \to F(B)$ be uniformly continuous. Let H be any finite p-group and φ be any group morphism $F(B) \to H$. Since φ is uniformly continuous, so is $\varphi \circ f$. By Proposition 4.7, $\varphi \circ f$ is a Newton polynomial function and hence, for almost all $w \in A^*$, $\Delta^w(\varphi \circ f) = \mathbf{1}$. Thus, by Proposition 2.2, $\varphi \circ (\Delta^w f) = \mathbf{1}$. Thus by Proposition 5.2, (3) holds.

The implication (4) ⇒ (5) follows from Propositions 3.4 and 5.1. Note that (3) ⇒ (4) is clear, and (5) ⇒ (2) follows from general theorems of topology, since, by Proposition 4.6, Newton polynomial functions are uniformly continuous. ◀

6 Conclusion and perspectives

By combining topology, algebra, automata and combinatorics on words, we solved the synthesis problem for $\mathcal{G}_p$ in two different ways. Our results are based on a noncommutative extension of Mahler's theorem, a difficult mathematical result. In addition, we introduced two new concepts that would merit further study: the sequential product and Newton polynomial functions. We used the sequential product to solve the integration problem for a function f from A^* to a group G, knowing its initial value $f(1)$ and the functions $\Delta^a f$ for every letter a. We also proved that Newton's bijection induces a degree-preserving bijection between Newton polynomial functions and functions from A^* to G mapping almost every word to 1, a surprising combinatorial result.

Although these results offer exciting new perspectives, there is still a long way to go before one can solve the synthesis problem for regularity preserving functions. Solving the synthesis problem for other varieties of group languages is the next challenge.

Abstract

We investigate the star-free closure, which associates to a class of languages its closure under Boolean operations and marked concatenation. We prove that the star-free closure of any finite class and of any class of groups languages with decidable separation (plus mild additional properties) has decidable separation. We actually show decidability of a stronger property, called covering. This generalizes many results on the subject in a unified framework. A key ingredient is that star-free closure coincides with another closure operator where Kleene stars are also allowed in restricted contexts.

1 Introduction

This paper investigates a remarkable operation on classes of languages: the *star-free closure*. It builds a new class $SF(\mathcal{C})$ from an input class $\mathcal{C}$ by closing it under union, complement and concatenation. This generalizes an important specific class: the one of *star-free languages*, *i.e.*, the star-free closure of the class consisting of all finite languages. Star-free languages are those that can be defined in first order logic [12]. The correspondence was lifted to the quantifier alternation hierarchy of first order logic by Thomas [30], which corresponds to a classification of star-free languages: the dot-depth hierarchy [4]. These results extend to the star-free closure [22]. For each input class $\mathcal{C}$, $SF(\mathcal{C})$ corresponds to a variant of first-order logic (specified by the set of predicates that are allowed). Moreover, its quantifier alternation hierarchy corresponds to a classification of $SF(\mathcal{C})$: the concatenation hierarchy of basis $\mathcal{C}$.

Schützenberger proved that one may decide whether a regular language is star-free [27]. This result established a framework for investigating and understanding classes of languages, based on the *membership problem*: is it decidable to test whether an input regular language belongs to the class under investigation? Similar results were obtained for other prominent classes. Yet, this fruitful line of research also includes some of the most famous open problems in automata theory. For example, only the first levels of the dot-depth hierarchy are known to have decidable membership (see [14] for a survey).

Recently, these results were unified and generalized. First, the problem itself was strengthened: membership was replaced by separation as a means to investigate classes. The separation problem asks whether two input languages can be separated by one from the class under study. While more general and difficult than membership, separation is also more flexible. This was exploited to show that separation is decidable for several levels in the dot-depth hierarchy [19, 17]. In fact, this is a particular instance of a *generic* result applying to every hierarchy whose basis $\mathcal{C}$ is *finite* and satisfies some mild properties [18, 21]. Moreover,

the same result was obtained when the basis $\mathcal{C}$ is a class of group languages (*i.e.*, recognized by a finite group) with decidable separation [26]. Altogether, these results generalize most of the known results regarding the decidability of levels in concatenation hierarchies.

Contributions. This paper is a continuation of these research efforts. Instead of looking at levels within hierarchies, we investigate the star-free closure as a whole. First, we show that the star-free closure of a finite class has decidable separation. We then use this result to establish our main theorem: the star-free closure of a class of group languages with *decidable separation* has also decidable separation. In both cases, we actually prove the decidability of a stronger property called covering. Let us mention some important features of this work.

A first point is that the case of a finite class is important by itself. Foremost, it is a crucial step for the main result on the star-free closure of classes of group languages. Second, it yields a new proof that covering is decidable for the star-free languages (this is shown in [20] or can be derived from [9, 1]). This new proof is simpler and generic. While the original underlying technique goes back to Wilke [31], the proof has been simplified at several levels. The main simplification is obtained thanks to an abstract framework, introduced in [24]. It is based on the central notion of rating map, which is meant to measure the quality of a separator. For the framework to be relevant, we actually need to generalize separation to multiple input languages, which leads to the covering problem. Another key difference is that previously existing proofs (specific to the star-free languages) involve abstracting words by new letters at some point, which requires a relabeling procedure and a change of alphabet. Here, we cannot use this approach as the classes we build with star-free closure are less robust in general. We work with a fixed alphabet, which also makes the proof simpler.

A crucial ingredient in the proof is the notion of prefix code with bounded synchronization delay. Generalizing a definition of Schützenberger [28] which was also considered by Diekert and Walter [6, 7], we define a new closure operator that permits Kleene stars on such languages (this is a semantic property). This yields an operator that happens to coincide with the star-free closure when applied to the classes that we investigate. It serves as a key intermediary: in our proofs, we heavily rely on Kleene stars to construct languages. We therefore present this important step in the body of the paper (Theorem 7). Moreover, its proof provides yet another characterization of $SF(\mathcal{C})$, which is effective when the class $\mathcal{C}$ is finite (thus generalizing Schützenberger's membership result). At last regarding membership, it is worth pointing out that not only do we cover more cases, but also that it is straightforward to reprove the known algebraic characterizations from our results (see *e.g.*, [3]).

Finally, let us present important applications of our main result applying to input classes made of group languages. First, one may look at the input class containing all group languages. Straubing [29] described an algebraic counterpart of the star-free closure of this class, which was then shown to be recursive by Rhodes and Karnofsky [10]. Altogether, this implies that membership is decidable for the star-free closure of group languages, as noted by Margolis and Pin [11]. Here, we are able to generalize this result to separation and covering as separation is known to be decidable for the group languages [2].

Another important application is the class of languages definable by first-order logic with modular predicates $\mathrm{FO}(<, \mathrm{MOD})$. This class is known to have decidable membership [3]. Moreover, it is the star-free closure of the class consisting of the languages counting the length of words modulo some number. Since this input class is easily shown to have decidable separation (see [26] for example), our main theorem applies.

The third application applies to first-order logic endowed with predicates counting the number of occurrences of a letter before a position modulo some integer. The languages definable in this logic form the star-free closure of the languages recognized by Abelian groups:

this follows from a generic correspondence between star-free closure and variants of first-order logic [22, 13], together with the description of languages recognized by Abelian groups [8]. Our main theorem applies, since the class of Abelian groups has decidable separation [5, 1].

Organization. In Section 2, we recall some useful background. Section 3 presents a generic characterization of star-free closure. Then, Sections 4 and 5 are devoted to our two main theorems applying respectively to finite input classes and those made of group languages. Due to space limitations, several proofs are postponed to the full version of the paper [25].

2 Preliminaries

We fix a finite alphabet A for the whole paper. As usual, A^* denotes the set of all words over A, including the empty word ε. For $u, v \in A^*$, we denote by uv the word obtained by concatenating u and v. A *language* is a subset of A^*. We lift concatenation to languages: for $K, L \subseteq A^*$, we let $KL = \{uv \mid u \in K \text{ and } v \in L\}$. Finally, we use Kleene star: if $K \subseteq A^*$, K^+ denotes the union of all languages K^n for $n \geq 1$ and $K^* = K^+ \cup \{\varepsilon\}$.

A *class of languages* is a set of languages. A class $\mathcal{C}$ is a *Boolean algebra* when it is closed under union, intersection and complement. Moreover, $\mathcal{C}$ is *quotient-closed* if for every $L \in \mathcal{C}$ and $w \in A^*$, the languages $w^{-1}L \stackrel{\text{def}}{=} \{u \in A^* \mid wu \in L\}$ and $Lw^{-1} \stackrel{\text{def}}{=} \{u \in A^* \mid uw \in L\}$ belong to $\mathcal{C}$. All classes considered in the paper are quotient-closed Boolean algebras containing only *regular languages* (this will be implicit in our statements). These are the languages that can be equivalently defined by monadic second-order logic, finite automata or finite monoids. We briefly recall the monoid-based definition below.

We shall often consider *finite* quotient-closed Boolean algebras. If $\mathcal{C}$ is such a class, one may associate a canonical equivalence $\sim_{\mathcal{C}}$ over A^*. For $w, w' \in A^*$, $w \sim_{\mathcal{C}} w'$ if and only if $w \in L \Leftrightarrow w' \in L$ for every $L \in \mathcal{C}$. Moreover, we write $[w]_{\mathcal{C}} \in A^*/\sim_{\mathcal{C}}$ for the $\sim_{\mathcal{C}}$-class of w. One may then verify that the languages in $\mathcal{C}$ are exactly the unions of $\sim_{\mathcal{C}}$-classes. Moreover, since $\mathcal{C}$ is quotient-closed, $\sim_{\mathcal{C}}$ is a congruence for word concatenation (see [22] for proofs).

Regular languages. A *monoid* is a set M endowed with an associative multiplication $(s, t) \mapsto s \cdot t$ (also denoted by st) having a neutral element 1_M. An *idempotent* of a monoid M is an element $e \in M$ such that $ee = e$. It is folklore that for any *finite* monoid M, there exists a natural number $\omega(M)$ (denoted by ω when M is understood) such that s^ω is an idempotent for every $s \in M$. Observe that A^* is a monoid whose multiplication is concatenation (the neutral element is ε). Thus, we may consider monoid morphisms $\alpha : A^* \to M$ where M is an arbitrary monoid. Given such a morphism and $L \subseteq A^*$, we say that L is *recognized* by α when there exists a set $F \subseteq M$ such that $L = \alpha^{-1}(F)$. A language L is *regular* if and only if it is recognized by a morphism into a *finite* monoid. Moreover, it is known that there exists a canonical recognizer of L, which can be computed from any representation of L (such as a finite automaton): the syntactic morphism of L. We refer the reader to [15] for details.

Group languages. A group is a monoid G in which every element $g \in G$ has an inverse $g^{-1} \in G$, *i.e.*, $gg^{-1} = g^{-1}g = 1_G$. A "*group language*" is a language L recognized by a morphism into a *finite group*. All classes of group languages investigated here are quotient-closed Boolean algebras. Typically, publications on the topic consider *varieties* of group languages which is more restrictive: they involve an additional closure property called "inverse morphic image" (see [13]). For example, the class MOD described below is *not* a variety.

▶ **Example 1.** A simple example of quotient-closed Boolean algebra of group languages is the class of *all* group languages: GR. Another one is MOD, which contains the Boolean combinations of languages $\{w \in A^* \mid |w| = k \mod m\}$ with $k, m \in \mathbb{N}$ such that $k < m$.

Decision problems. We rely on three decision problems to investigate classes of languages. Each one depends on a parameter class $\mathcal{C}$, which we fix for the definition. The first problem, *$\mathcal{C}$-membership*, takes a single regular language L as input and asks whether $L \in \mathcal{C}$.

The second one, *$\mathcal{C}$-separation*, takes two regular languages L_1 and L_2 as input and asks whether L_1 is $\mathcal{C}$-separable from L_2 (is there a third language $K \in \mathcal{C}$ such that $L_1 \subseteq K$ and $L_2 \cap K = \emptyset$). This generalizes membership: $L \in \mathcal{C}$ if and only if L is $\mathcal{C}$-separable from $A^* \setminus L$.

The third problem, *$\mathcal{C}$-covering* was introduced in [24]. Given a language L, a *cover of* L is a finite set of languages $\mathbf{K}$ such that $L \subseteq \bigcup_{K \in \mathbf{K}} K$. Moreover, a $\mathcal{C}$-cover of L is a cover $\mathbf{K}$ of L such that all $K \in \mathbf{K}$ belong to $\mathcal{C}$. Consider a pair $(L_1, \mathbf{L}_2)$ where L_1 is a language and $\mathbf{L}_2$ is a *finite set of languages*. We say that $(L_1, \mathbf{L}_2)$ is *$\mathcal{C}$-coverable* when there exists a $\mathcal{C}$-cover $\mathbf{K}$ of L_1 such that for every $K \in \mathbf{K}$, there exists $L \in \mathbf{L}_2$ satisfying $K \cap L = \emptyset$. The *$\mathcal{C}$-covering problem* takes as input a single regular language L_1 and a finite set of regular languages $\mathbf{L}_2$. It asks whether $(L_1, \mathbf{L}_2)$ $\mathcal{C}$-coverable. Covering generalizes separation if $\mathcal{C}$ is closed under union: L_1 is $\mathcal{C}$-separable from L_2, if and only if $(L_1, \{L_2\})$ is $\mathcal{C}$-coverable (see [24]).

Star-free closure and main results. We investigate an operation defined on classes: *star-free closure*. Consider a class $\mathcal{C}$. The *star-free closure of* $\mathcal{C}$, denoted by $SF(\mathcal{C})$, is the least class containing $\mathcal{C}$ and the singletons $\{a\}$ for every $a \in A$, and closed under Boolean operations and concatenation. It is standard and simple to verify that when $\mathcal{C}$ is a quotient-closed Boolean algebra (which will always be the case here), this is also the case for $SF(\mathcal{C})$.

Our main theorems state conditions on the input class $\mathcal{C}$ guaranteeing decidability of our decision problems for $SF(\mathcal{C})$. First, we may handle *finite* classes.

▶ **Theorem 2.** *Let $\mathcal{C}$ be a finite quotient-closed Boolean algebra. Then, membership, separation and covering are decidable for $SF(\mathcal{C})$.*

The second theorem applies to input classes made of group languages.

▶ **Theorem 3.** *Let $\mathcal{C}$ be a quotient-closed Boolean algebra of group languages with decidable separation. Then, membership, separation and covering are decidable for $SF(\mathcal{C})$.*

The remainder of the paper is devoted to proving these theorems. We first focus on *$SF(\mathcal{C})$-membership* in Section 3. Naturally, this is weaker than directly handling $SF(\mathcal{C})$-covering. Yet, detailing membership independently allows to introduce many proof ideas and techniques that are needed to prove the "full" theorems. We detail these theorems in Sections 4 and 5. We only present the algorithms: proofs are deferred to the full paper [25].

3 Bounded synchronization delay and algebraic characterization

This section is devoted to $SF(\mathcal{C})$-membership. We handle it with a generic algebraic characterization of $SF(\mathcal{C})$ (effective under the hypotheses of Theorems 2 and 3), generalizing earlier work by Pin, Straubing and Thérien [29, 16]. We rely on an alternate definition of star-free closure involving a semantic restriction of the Kleene star, which we first present.

3.1 Bounded synchronization delay

We define a second operation on classes of languages $\mathcal{C} \mapsto SD(\mathcal{C})$. We shall later prove that it coincides with star-free closure (provided that $\mathcal{C}$ satisfies mild hypotheses). It is based on the work of Schützenberger [28] who defined a single class SD corresponding to the star-free languages (*i.e.*, $SF(\{\emptyset, A^*\})$). Here, we generalize it as an operation. The definition involves a semantic restriction of the Kleene star operation on languages: it may only be applied to "*prefix codes with bounded synchronization delay*". Introducing this notion requires basic definitions from coding theory that we first recall.

A language $K \subseteq A^*$ is a *prefix code* when $\varepsilon \notin K$ and $K \cap KA^+ = \emptyset$ (no word in K has a strict prefix in K). Note that this implies the following weaker property that we shall use implicitly: every $w \in K^*$ admits a *unique* decomposition $w = w_1 \cdots w_n$ with $w_1, \ldots, w_n \in K$ (this property actually defines *codes* which are more general).

Given $d \geq 1$, a prefix code $K \subseteq A^+$ has *synchronization delay* d if for every $u, v, w \in A^*$ such that $uvw \in K^+$ and $v \in K^d$, we have $uv \in K^+$. Finally, a prefix code $K \subseteq A^+$ has *bounded synchronization delay* when it has synchronization delay d for some $d \geq 1$.

▶ **Example 4.** Let $A = \{a, b\}$. Clearly, $\{ab\}$ is a prefix code with synchronization delay 1: if $uvw \in (ab)^+$ and $v = ab$, we have $uv \in (ab)^+$. Similarly, one may verify that $(aab)^*ab$ is a prefix code with synchronization delay 2 (but not 1). On the other hand, $\{aa\}$ does not have bounded synchronization delay. If $d \geq 1$, $a(aa)^d a \in (aa)^*$ but $a(aa)^d \notin (aa)^*$.

We present the operation $\mathcal{C} \mapsto SD(\mathcal{C})$. The definition involves *unambiguous concatenation*. Given $K, L \subseteq A^*$, their concatenation KL is *unambiguous* when every word $w \in KL$ admits a *unique* decomposition $w = uv$ with $u \in K$ and $v \in L$. Given a class $\mathcal{C}$, $SD(\mathcal{C})$ is the least class containing $\emptyset$ and $\{a\}$ for every $a \in A$, and closed under the following properties:

- **Intersection with $\mathcal{C}$:** if $K \in SD(\mathcal{C})$ and $L \in \mathcal{C}$, then $K \cap L \in SD(\mathcal{C})$.
- **Disjoint union:** if $K, L \in SD(\mathcal{C})$ are disjoint, then $K \uplus L \in SD(\mathcal{C})$.
- **Unambiguous product:** if $K, L \in SD(\mathcal{C})$ and KL is unambiguous, then $KL \in SD(\mathcal{C})$.
- **Kleene star for prefix codes with bounded synchronization delay:** if $K \in SD(\mathcal{C})$ is a prefix code with bounded synchronization delay, then $K^* \in SD(\mathcal{C})$.

▶ Remark 5. Schützenberger proved in [28] that $SD(\{\emptyset, A^*\}) = SF(\{\emptyset, A^*\})$. His definition of $SD(\{\emptyset, A^*\})$ was slightly less restrictive than ours: it does not require that the unions are disjoint and the concatenations unambiguous. It will be immediate from the correspondence with star-free closure that the two definitions are equivalent.

▶ Remark 6. This closure operation is different from standard ones. Instead of requiring that $\mathcal{C} \subseteq SD(\mathcal{C})$, we impose a stronger requirement: intersection with languages in $\mathcal{C}$ is allowed. If we only asked that $\mathcal{C} \subseteq SD(\mathcal{C})$, we would get a weaker operation which does not correspond to star-free closure in general. For example, let $A = \{a, b\}$ and consider the class MOD of Example 1. Observe that $(aa)^* \in SD(\text{MOD})$. Indeed, $\{a\} \in SD(\text{MOD})$ has bounded synchronization delay, $(AA)^* \in \text{MOD}$ and $(aa)^* = a^* \cap (AA)^*$. Yet, one may verify that $(aa)^*$ cannot be built from the languages of MOD with union, concatenation and Kleene star applied to prefix codes with bounded synchronization delay.

3.2 Algebraic characterization of star-free closure

We now reduce deciding membership for $SF(\mathcal{C})$ to computing $\mathcal{C}$-*stutters*. Let us first define this new notion. Let $\mathcal{C}$ be a quotient-closed Boolean algebra and $\alpha : A^* \to M$ be a morphism. A $\mathcal{C}$-*stutter* for α is an element $s \in M$ such that for every $\mathcal{C}$-cover $\mathbf{K}$ of $\alpha^{-1}(s)$, there exists

$K \in \mathbf{K}$ satisfying $K \cap KK \neq \emptyset$. When α is understood, we simply speak of a $\mathcal{C}$-stutter. Finally, we say that α is $\mathcal{C}$-*aperiodic* when for every $\mathcal{C}$-stutter $s \in M$, we have $s^\omega = s^{\omega+1}$. The reduction is stated in the following theorem.

▶ **Theorem 7.** *Let $\mathcal{C}$ be a quotient-closed Boolean algebra and consider a regular language $L \subseteq A^*$. The following properties are equivalent:*
1. $L \in SF(\mathcal{C})$.
2. $L \in SD(\mathcal{C})$.
3. *The syntactic morphism of L is $\mathcal{C}$-aperiodic.*

Naturally, the characterization need not be effective: this depends on $\mathcal{C}$. Deciding whether a morphism is $\mathcal{C}$-aperiodic boils down to computing $\mathcal{C}$-stutters. Yet, this is possible under the hypotheses of Theorems 2 and 3. First, if $\mathcal{C}$ is a finite quotient-closed Boolean algebra, deciding whether an element is a $\mathcal{C}$-stutter is simple: there are finitely many $\mathcal{C}$-covers and we may check them all. If $\mathcal{C}$ is a quotient-closed Boolean algebra of group languages, the question boils down to $\mathcal{C}$-separation as stated in the next lemma (proved in [25]).

▶ **Lemma 8.** *Let $\mathcal{C}$ be a quotient-closed Boolean algebra of group languages and $\alpha : A^* \to M$ be a morphism. For all $s \in M$, s is a $\mathcal{C}$-stutter if and only if $\{\varepsilon\}$ is **not** $\mathcal{C}$-separable from $\alpha^{-1}(s)$.*

Altogether, we obtain the membership part in Theorems 20 and 25. We conclude the section with an extended proof sketch for the most interesting direction in Theorem 7: 3) ⇒ 2) (a detailed proof for the two other directions is provided in the full version of this paper [25]).

Proof of 3) ⇒ 2) in Theorem 7. Let $\mathcal{C}$ be a quotient-closed Boolean algebra and $\alpha : A^* \to M$ be a $\mathcal{C}$-aperiodic morphism. We show that all languages recognized by α belong to $SD(\mathcal{C})$.

Given $K \subseteq A^*$ and $s \in M$, we say that K is s-*safe* when $s\alpha(u) = s\alpha(v)$ for every $u, v \in K$. We extend this notion to sets of languages: such a set $\mathbf{K}$ is s-safe when every $K \in \mathbf{K}$ is s-safe. We shall use s as an induction parameter. Finally, given a language $P \subseteq A^*$, an $SD(\mathcal{C})$-partition of P is a finite partition of P into languages of $SD(\mathcal{C})$.

▶ **Proposition 9.** *Let $P \subseteq A^+$ be a prefix code with bounded synchronization delay. Assume that there exists a 1_M-safe $SD(\mathcal{C})$-partition of P. Then, for every $s \in M$, there exists an s-safe $SD(\mathcal{C})$-partition of P^*.*

We first apply Proposition 9 to conclude the main argument. We show that every language recognized by α belongs to $SD(\mathcal{C})$. By definition, $SD(\mathcal{C})$ is closed under disjoint union. Hence, it suffices to show that $\alpha^{-1}(t) \in SD(\mathcal{C})$ for every $t \in M$. We fix $t \in M$ for the proof.

Clearly, $A \subseteq A^+$ is a prefix code with bounded synchronization delay and $\{\{a\} \mid a \in A\}$ is a 1_M-safe $SD(\mathcal{C})$-partition of A. Hence, Proposition 9 (applied in the case $s = 1_M$) yields a 1_M-safe $SD(\mathcal{C})$-partition $\mathbf{K}$ of A^*. One may verify that $\alpha^{-1}(t)$ is the disjoint union of all $K \in \mathbf{K}$ intersecting $\alpha^{-1}(t)$. Hence, $\alpha^{-1}(t) \in SD(\mathcal{C})$ which concludes the main argument.

It remains to prove Proposition 9. We let $P \subseteq A^*$ be a prefix code with bounded synchronization delay, $\mathbf{H}$ a 1_M-safe $SD(\mathcal{C})$-partition of P and $s \in M$. We need to build an $SD(\mathcal{C})$-partition $\mathbf{K}$ of P^* such that every $K \in \mathbf{K}$ is s-safe. We proceed by induction on the three following parameters listed by order of importance: (1) the size of $\alpha(P^+) \subseteq M$, (2) the size of $\mathbf{H}$ and (3) the size of $s \cdot \alpha(P^*) \subseteq M$. We distinguish two cases depending on the following property of s and $\mathbf{H}$. We say that s *is* $\mathbf{H}$-*stable* when the following holds:

$$\text{for every } H \in \mathbf{H}, \quad s \cdot \alpha(P^*) = s \cdot \alpha(P^*H). \tag{1}$$

The base case happens when s is $\mathbf{H}$-stable. Otherwise, we use induction on our parameters.

Base case: s is H-stable. Since α is $\mathcal{C}$-aperiodic, we have the following simple fact.

▶ **Fact 10.** *There is a* finite *quotient-closed Boolean algebra $\mathcal{D} \subseteq \mathcal{C}$ such that α is $\mathcal{D}$-aperiodic.*

Since $\mathcal{D}$ is finite, we may consider the associated canonical equivalence $\sim_{\mathcal{D}}$ over A^*. We let $\mathbf{K} = \{P^* \cap D \mid D \in A^*/\sim_{\mathcal{D}}\}$. Clearly, $\mathbf{K}$ is a partition of P^*. Let us verify that it only contains languages in $SD(\mathcal{C})$. We have $P \in SD(\mathcal{C})$: it is the disjoint union of all languages in the $SD(\mathcal{C})$-partition $\mathbf{H}$ of P. Moreover, $P^* \in SD(\mathcal{C})$ since P is a prefix code with bounded synchronization delay. Hence, $P^* \cap D \in SD(\mathcal{C})$ for every $D \in A^*/\sim_{\mathcal{D}}$ since $D \in \mathcal{D} \subseteq \mathcal{C}$. Therefore, it remains to show that every language $K \in \mathbf{K}$ is s-safe. This is a consequence of the following lemma which is proved using the hypothesis (1) that s is $\mathbf{H}$-stable.

▶ **Lemma 11.** *For every $u, v \in P^*$ such that $u \sim_{\mathcal{D}} v$, we have $s\alpha(u) = s\alpha(v)$.*

Inductive step: s is not H-stable. By hypothesis, we know that (1) does not hold. Therefore, we get some $H \in \mathbf{H}$ such that the following **strict** inclusion holds,

$$s \cdot \alpha(P^*H) \subsetneq s \cdot \alpha(P^*). \tag{2}$$

We fix this language $H \in \mathbf{H}$ for the remainder of the proof. The following lemma is proved by induction on our second parameter (the size of $\mathbf{H}$).

▶ **Lemma 12.** *There exists a 1_M-safe $SD(\mathcal{C})$-partition $\mathbf{U}$ of $(P \setminus H)^*$.*

We fix the partition $\mathbf{U}$ of $(P \setminus H)^*$ given by Lemma 12 and distinguish two independent subcases. Since $H \subseteq P$ (as H is an element of the partition $\mathbf{H}$ of P), we have $\alpha(P^*H) \subseteq \alpha(P^+)$. We use a different argument depending on whether this inclusion is strict or not.

Sub-case 1: $\alpha(P^*H) = \alpha(P^+)$. Since H is 1_M-safe by hypothesis, there exists $t \in M$ such that $\alpha(H) = \{t\}$. Similarly, since every $U \in \mathbf{U}$ is 1_M-safe, there exists $r_U \in M$ such that $\alpha(U) = \{r_U\}$. The construction of $\mathbf{K}$ is based on the next lemma which is proved using (2), the hypothesis of Sub-case 1 and induction on our third parameter (the size of $s \cdot \alpha(P^*) \subseteq M$).

▶ **Lemma 13.** *For every $U \in \mathbf{U}$, there exists an sr_Ut-safe $SD(\mathcal{C})$-partition $\mathbf{W}_U$ of P^*.*

We are ready to define the partition $\mathbf{K}$ of P^*. Using Lemma 13, we define,

$$\mathbf{K} = \mathbf{U} \cup \bigcup_{U \in \mathbf{U}} \{UHW \mid W \in \mathbf{W}_U\}$$

It remains to show that $\mathbf{K}$ is an s-safe $SD(\mathcal{C})$-partition of P^*. First, $\mathbf{K}$ is a partition of P^* since P is a prefix code and $H \subseteq P$. Indeed, every word $w \in P^*$ admits a *unique* decomposition $w = w_1 \cdots w_n$ with $w_1, \ldots, w_n \in P$. If no factor w_i belongs to H, then $w \in (P \setminus H)^*$ and w belongs to some unique $U \in \mathbf{U}$. Otherwise, let w_i be the leftmost factor such that $w_i \in H$. Thus, $w_1 \cdots w_{i-1} \in (P \setminus H)^*$, which also yields a unique $U \in \mathbf{U}$ such that $w_1 \cdots w_{i-1} \in U$ and $w_{i+1} \cdots w_n \in P^*$ which yields a unique $W \in \mathbf{W}_U$ such that $w_{i+1} \cdots w_n \in W$. Thus, $w \in UHW$ which is an element of $\mathbf{K}$ (the only one containing w).

Moreover, every $K \in \mathbf{K}$ belongs to $SD(\mathcal{C})$. If $K \in \mathbf{U}$, this is immediate by definition of $\mathbf{U}$ in Lemma 12. Otherwise, $K = UHW$ with $U \in \mathbf{U}$ and $W \in \mathbf{W}_U$. We know that $U, H, W \in SD(\mathcal{C})$ by definition. Moreover, one may verify that the concatenation UHW is *unambiguous* since P is a prefix code, $U \subseteq (P \setminus H)^*$ and $W \subseteq H^*$. Hence, $K \in SD(\mathcal{C})$.

Finally, we verify that $\mathbf{K}$ is s-safe. Consider $K \in \mathbf{K}$ and $w, w' \in K$, we show that $s\alpha(w) = s\alpha(w')$. If $K \in \mathbf{U}$, this is immediate: $\mathbf{U}$ is 1_M-safe by definition. Otherwise, $K = UHW$ with $U \in \mathbf{U}$ and $W \in \mathbf{W}_U$. By definition, $\alpha(H) = \{t\}$ and $\alpha(U) = \{r_U\}$ which implies that $s\alpha(w) = sr_U t\alpha(x)$ and $s\alpha(w') = sr_U t\alpha(x')$ for $x, x' \in W$. Moreover, $W \in \mathbf{W}_U$ is $sr_U t$-safe by definition. Hence, $s\alpha(w) = s\alpha(w')$, which concludes the proof of this sub-case.

Sub-case 2: $\boldsymbol{\alpha(P^*H) \subsetneq \alpha(P^+)}$. Consider $w \in P^*$. Since P is a prefix code, w admits a unique decomposition $w = w_1 \cdots w_n$ with $w_1, \ldots, w_n \in P$. We may look at the rightmost factor $w_i \in H \subseteq P$ to uniquely decompose w in two parts (each of them possibly empty): the prefix $w_1 \cdots w_i \in ((P \setminus H)^* H)^*$ and the suffix in $w_{i+1} \cdots w_n \in (P \setminus H)^*$. Using induction, we construct $SD(\mathcal{C})$-partitions of the possible languages of prefixes and suffixes. Then, we combine them to construct a partition of the whole set P^*. We already handled the suffixes: $\mathbf{U}$ is an $SD(\mathcal{C})$-partition of $(P \setminus H)^*$. The prefixes are handled using the hypothesis of Sub-case 2 and induction on our first parameter (the size of $\alpha(P^+)$).

▶ **Lemma 14.** *There exists a 1_M-safe $SD(\mathcal{C})$-partition $\mathbf{V}$ of $((P \setminus H)^* H)^*$.*

Using Lemma 14, we define $\mathbf{K} = \{VU \mid V \in \mathbf{V} \text{ and } U \in \mathbf{U}\}$. It follows from the above discussion that $\mathbf{K}$ is a partition of P^* since $\mathbf{V}$ and $\mathbf{U}$ are partitions of $((P \setminus H)^* H)^*$ and $(P \setminus H)^*$, respectively. Moreover, every $K \in \mathbf{K}$ belongs to $SD(\mathcal{C})$: $K = VU$ with $V \in \mathbf{V}$ and $U \in \mathbf{U}$, and one may verify that this is an *unambiguous* concatenation. It remains to show that $\mathbf{K}$ is s-safe. Let $K \in \mathbf{K}$ and $w, w' \in K$. We show that $s\alpha(w) = s\alpha(w')$. By definition, we have $K = VU$ with $V \in \mathbf{V}$ and $U \in \mathbf{U}$. Therefore, $w = vu$ and $w' = v'u'$ with $u, u' \in U$ and $v, v' \in V$. Since U and V are both 1_M-safe by definition, we have $\alpha(u) = \alpha(u')$ and $\alpha(v) = \alpha(v')$. It follows that $s\alpha(w) = s\alpha(w')$, which concludes the proof of Proposition 9. ◀

4 Covering when the input class is finite

This section is devoted to Theorem 2. We show that when $\mathcal{C}$ is a finite quotient-closed Boolean algebra, $SF(\mathcal{C})$-covering is decidable by presenting a generic algorithm. It is formulated within a framework designed to handle covering questions, which was originally introduced in [24]. We start by briefly recalling it (we refer the reader to [24] for details).

4.1 Rating maps and optimal imprints

The framework is based on an algebraic object called "rating map". These are morphisms of commutative and idempotent monoids. We write such monoids $(R, +)$: the binary operation "$+$" is called *addition* and the neutral element is denoted by 0_R. Being idempotent means that $r + r = r$ for every $r \in R$. For every commutative and idempotent monoid $(R, +)$, one may define a canonical ordering $\leq$ over R: for $r, s \in R$, we have $r \leq s$ when $r + s = s$. One may verify that $\leq$ is a partial order which is compatible with addition.

▶ **Example 15.** For every set E, $(2^E, \cup)$ is an idempotent and commutative monoid. The neutral element is $\emptyset$ and the canonical ordering is inclusion.

A rating map is a morphism $\rho : (2^{A^*}, \cup) \to (R, +)$ where $(R, +)$ is a *finite* idempotent and commutative monoid, called the *rating set of* ρ. That is, ρ is a map from 2^{A^*} to R such that $\rho(\emptyset) = 0_R$ and $\rho(K_1 \cup K_2) = \rho(K_1) + \rho(K_2)$ for every $K_1, K_2 \subseteq A^*$.

For the sake of improved readability, when applying a rating map ρ to a singleton set $\{w\}$, we write $\rho(w)$ for $\rho(\{w\})$. Moreover, we write $\rho_* : A^* \to R$ for the restriction of ρ to A^*: for every $w \in A^*$, we have $\rho_*(w) = \rho(w)$ (this notation is useful when referring to the language $\rho_*^{-1}(r) \subseteq A^*$, which consists of all words $w \in A^*$ such that $\rho(w) = r$).

Most of the theory makes sense for arbitrary rating maps. However, we shall often have to work with special rating maps satisfying additional properties. We define two kinds.

Nice rating maps. A rating map $\rho : 2^{A^*} \to R$ is *nice* when, for every nonempty language $K \subseteq A^*$, there exist finitely many words $w_1, \ldots, w_n \in K$ such that $\rho(K) = \rho(w_1) + \cdots + \rho(w_k)$.

When a rating map $\rho : 2^{A^*} \to R$ is nice, it is characterized by the canonical map $\rho_* : A^* \to R$. Indeed, for $K \subseteq A^*$, we may consider the sum of all elements $\rho(w)$ for $w \in K$: while it may be infinite, this sum boils down to a finite one since R is commutative and idempotent. The hypothesis that ρ is nice implies that $\rho(K)$ is equal to this sum.

Multiplicative rating maps. A rating map $\rho : 2^{A^*} \to R$ is multiplicative when its rating set R has more structure: it needs to be an *idempotent semiring*. A *semiring* is a tuple $(R, +, \cdot)$ where R is a set and "$+$" and "$\cdot$" are two binary operations called addition and multiplication. Moreover, $(R, +)$ is a commutative monoid, $(R, \cdot)$ is a monoid (the neutral element is denoted by 1_R), the multiplication distributes over addition and the neutral element "0_R" of $(R, +)$ is a zero for $(R, \cdot)$ ($0_R \cdot r = r \cdot 0_R = 0_R$ for every $r \in R$). A semiring R is *idempotent* when $r + r = r$ for every $r \in R$, *i.e.*, when the additive monoid $(R, +)$ is idempotent (there is no additional constraint on the multiplicative monoid $(R, \cdot)$).

▶ **Example 16.** A key example of an infinite idempotent semiring is the set 2^{A^*}. Union is the addition and language concatenation is the multiplication (with $\{\varepsilon\}$ as neutral element).

Let $\rho : 2^{A^*} \to R$ be a rating map: $(R, +)$ is an idempotent commutative monoid and ρ is a morphism from $(2^{A^*}, \cup)$ to $(R, +)$. We say that ρ is *multiplicative* when the rating set R is equipped with a multiplication "$\cdot$" such that $(R, +, \cdot)$ is an idempotent semiring and ρ is also a monoid morphism from $(2^{A^*}, \cdot)$ to $(R, \cdot)$. That is, the two following additional axioms have to be satisfied: $\rho(\varepsilon) = 1_R$ and $\rho(K_1 K_2) = \rho(K_1) \cdot \rho(K_2)$ for every $K_1, K_2 \subseteq A^*$.

▶ Remark 17. Rating maps which are both nice and multiplicative are finitely representable. As we explained, if $\rho : 2^{A^*} \to R$ is nice, it is characterized by the canonical map $\rho_* : A^* \to R$. When ρ is also multiplicative, ρ_* is finitely representable: it is a morphism into a finite monoid. Hence, we may speak of algorithms whose input is a nice multiplicative rating map.

Rating maps which are not nice and multiplicative cannot be finitely represented in general. Yet, they are crucial: while our main statements consider nice multiplicative rating maps, many proofs involve auxiliary rating maps which are neither nice nor multiplicative.

Optimal imprints. Now that we have rating maps, we turn to imprints. Consider a rating map $\rho : 2^{A^*} \to R$. Given any finite set of languages $\mathbf{K}$, we define the ρ-imprint of $\mathbf{K}$. Intuitively, when $\mathbf{K}$ is a cover of some language L, this object measures the "quality" of $\mathbf{K}$. The ρ-imprint *of* $\mathbf{K}$ is the following subset of R:

$$\mathcal{I}[\rho](\mathbf{K}) = \{r \mid r \leq \rho(K) \text{ for some } K \in \mathbf{K}\}.$$

We may now define optimality. Consider an arbitrary rating map $\rho : 2^{A^*} \to R$ and a Boolean algebra $\mathcal{C}$. Given a language L, an optimal $\mathcal{C}$-cover of L for ρ is a $\mathcal{C}$-cover $\mathbf{K}$ of L which satisfies the following property:

$$\mathcal{I}[\rho](\mathbf{K}) \subseteq \mathcal{I}[\rho](\mathbf{K}') \quad \text{for every } \mathcal{C}\text{-cover } \mathbf{K}' \text{ of } L.$$

In general, there can be infinitely many optimal $\mathcal{C}$-covers for a given rating map ρ. It is shown in [24] that there always exists at least one (using closure under intersection for $\mathcal{C}$).

Clearly, for a Boolean algebra $\mathcal{C}$, a language L and a rating map ρ, all optimal $\mathcal{C}$-covers of L for ρ have the same ρ-imprint. Hence, this unique ρ-imprint is a *canonical* object for $\mathcal{C}$, L and ρ. We call it the *$\mathcal{C}$-optimal ρ-imprint on L* and we write it $\mathcal{I}_{\mathcal{C}}[L, \rho]$:

$$\mathcal{I}_{\mathcal{C}}[L, \rho] = \mathcal{I}[\rho](\mathbf{K}) \quad \text{for any optimal } \mathcal{C}\text{-cover } \mathbf{K} \text{ of } L \text{ for } \rho.$$

We complete the definition with a simple useful fact (a proof is available in [23]).

▶ **Fact 18.** *Let $\mathcal{C}$ be a Boolean algebra, $\rho : 2^{A^*} \to R$ a rating map and $L_1, L_2 \subseteq A^*$. Then, $\mathcal{I}_{\mathcal{C}}[L_1, \rho] \cup \mathcal{I}_{\mathcal{C}}[L_2, \rho] = \mathcal{I}_{\mathcal{C}}[L_1 \cup L_2, \rho]$.*

Connection with covering. Consider the special case when the language L that needs to be covered is A^*. In that case, we write $\mathcal{I}_{\mathcal{C}}[\rho]$ for $\mathcal{I}_{\mathcal{C}}[A^*, \rho]$. It is shown in [24] that for every *Boolean algebra $\mathcal{C}$*, deciding $\mathcal{C}$-covering formally reduces to computing $\mathcal{C}$-optimal imprints from input nice multiplicative rating maps.

▶ **Proposition 19.** *Let $\mathcal{C}$ be a Boolean algebra. Assume that there exists an algorithm which computes $\mathcal{I}_{\mathcal{C}}[\rho]$ from an input nice multiplicative rating map ρ. Then, $\mathcal{C}$-covering is decidable.*

4.2 Algorithm

We may now present our algorithm for $SF(\mathcal{C})$-covering when $\mathcal{C}$ is a finite quotient-closed Boolean algebra. We fix $\mathcal{C}$ for the presentation. In view of Proposition 19, we need to prove that one may compute $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from an input nice multiplicative rating map ρ.

Our algorithm actually computes slightly more information. Since $\mathcal{C}$ is a finite quotient-closed Boolean algebra, we may consider the equivalence $\sim_{\mathcal{C}}$ over A^*. In particular, the set $A^*/\!\sim_{\mathcal{C}}$ of $\sim_{\mathcal{C}}$-classes is a finite monoid (we write "$\bullet$" for its multiplication) and the map $w \mapsto [w]_{\mathcal{C}}$ is a morphism. Given a rating map $\rho : 2^{A^*} \to R$ we define:

$$\mathcal{P}^{\mathcal{C}}_{SF(\mathcal{C})}[\rho] = \{(C, r) \in (A^*/\!\sim_{\mathcal{C}}) \times R \mid r \in \mathcal{I}_{SF(\mathcal{C})}[C, \rho]\}$$

Observe that $\mathcal{P}^{\mathcal{C}}_{SF(\mathcal{C})}[\rho]$ captures more information than $\mathcal{I}_{SF(\mathcal{C})}[\rho]$. Indeed, it encodes all sets $\mathcal{I}_{SF(\mathcal{C})}[C, \rho]$ for $C \in A^*/\!\sim_{\mathcal{C}}$ and by Fact 18, $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ is the union of all these sets.

Our main result is a least fixpoint procedure for computing $\mathcal{P}^{\mathcal{C}}_{SF(\mathcal{C})}[\rho]$ from a nice multiplicative rating map ρ. It is based on a generic characterization theorem which we first present. Given an arbitrary nice multiplicative rating map $\rho : 2^{A^*} \to R$ and a set $S \subseteq (A^*/\!\sim_{\mathcal{C}}) \times R$, we say that S is *$SF(\mathcal{C})$-saturated for ρ* when the following properties are satisfied:

1. **Trivial elements.** For every $w \in A^*$, we have $([w]_{\mathcal{C}}, \rho(w)) \in S$.
2. **Downset.** For every $(C, r) \in S$ and $q \in R$, if $q \leq r$, then $(C, q) \in S$.
3. **Multiplication.** For every $(C, q), (D, r) \in S$, we have $(C \bullet D, qr) \in S$.
4. ***SF*($\mathcal{C}$)-closure.** For all $(E, r) \in S$, if $E \in A^*/\!\sim_{\mathcal{C}}$ is idempotent, then $(E, r^{\omega} + r^{\omega+1}) \in S$.

▶ **Theorem 20** ($SF(\mathcal{C})$-optimal imprints ($\mathcal{C}$ finite))**.** *Let $\rho : 2^{A^*} \to R$ be a* nice *multiplicative rating map. Then, $\mathcal{P}^{\mathcal{C}}_{SF(\mathcal{C})}[\rho]$ is the least $SF(\mathcal{C})$-saturated subset of $(A^*/\!\sim_{\mathcal{C}}) \times R$ for ρ.*

Given a nice multiplicative rating map $\rho : 2^{A^*} \to R$ as input, it is clear that one may compute the least $SF(\mathcal{C})$-saturated subset of $(A^*/\!\sim_{\mathcal{C}}) \times R$ with a least fixpoint procedure. Hence, Theorem 20 provides an algorithm for computing $\mathcal{P}^{\mathcal{C}}_{SF(\mathcal{C})}[\rho]$. As we explained above, we may then compute $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from this set. Together with Proposition 19, this yields Theorem 2 as a corollary: $SF(\mathcal{C})$-covering is decidable when $\mathcal{C}$ is a finite quotient-closed Boolean algebra. Theorem 20 is proved in the full version of this paper [25].

5 Covering when the input class is made of group languages

This section is devoted to Theorem 3. We show that when $\mathcal{C}$ is a quotient-closed Boolean algebra of group languages with decidable separation, $SF(\mathcal{C})$-covering is decidable.

As in Section 4, we rely on Proposition 19: we present an algorithm computing $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from an input nice multiplicative rating map ρ. We do not work with $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ itself but with another set carrying more information. Its definition requires introducing a few additional concepts. We first present them and then turn to the algorithm. For more details, see [26].

5.1 Preliminary definitions

Optimal ε-approximations. In this case, handling $SF(\mathcal{C})$ involves considering $\mathcal{C}$-optimal covers of $\{\varepsilon\}$. Since $\{\varepsilon\}$ is a singleton, there always exists such a cover consisting of a single language, which leads to the following definition.

Let $\mathcal{C}$ be a Boolean algebra (we shall use the case when $\mathcal{C}$ contains only group languages but this is not required for the definitions) and $\tau : 2^{A^*} \to Q$ a rating map. A *$\mathcal{C}$-optimal ε-approximation for τ* is a language $L \in \mathcal{C}$ such that $\varepsilon \in L$ and $\tau(L) \leq \tau(L')$ for every $L' \in \mathcal{C}$ satisfying $\varepsilon \in L'$. As expected, there always exists a $\mathcal{C}$-optimal ε-approximation for any rating map τ (see the full version of this paper [25] for a proof).

By definition, all $\mathcal{C}$-optimal ε-approximations for τ have the same image under τ. We write it $\mathbb{i}_{\mathcal{C}}[\tau] \in Q$: $\mathbb{i}_{\mathcal{C}}[\tau] = \tau(L)$ for every $\mathcal{C}$-optimal ε-approximation L for τ. It turns out that when τ is nice and multiplicative, computing $\mathbb{i}_{\mathcal{C}}[\tau]$ from τ boils down to $\mathcal{C}$-separation. This is important: this is exactly how our algorithm for $SF(\mathcal{C})$-covering depends on $\mathcal{C}$-separation.

▶ **Lemma 21.** *Let $\tau : 2^{A^*} \to Q$ be a nice rating map and $\mathcal{C}$ a Boolean algebra. Then, $\mathbb{i}_{\mathcal{C}}[\tau]$ is the sum of all $q \in Q$ such that $\{\varepsilon\}$ is not $\mathcal{C}$-separable from $\tau_*^{-1}(q)$.*

Nested rating maps. We want an algorithm which computes $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from an input nice multiplicative rating map ρ for a fixed quotient-closed Boolean algebra of group languages $\mathcal{C}$. Yet, we shall not use optimal ε-approximations with this input rating map ρ. Instead, we consider an auxiliary rating map built from ρ (the definition is taken from [23]).

Consider a Boolean algebra $\mathcal{D}$ (we shall use the case $\mathcal{D} = SF(\mathcal{C})$) and a rating map $\rho : 2^{A^*} \to R$. We build a new map $\xi_{\mathcal{D}}[\rho] : 2^{A^*} \to 2^R$ whose rating set is $(2^R, \cup)$. For every $K \subseteq A^*$, we define $\xi_{\mathcal{D}}[\rho](K) = \mathcal{I}_{\mathcal{D}}[K, \rho] \in 2^R$. It follows from Fact 18 that this is indeed a rating map (on the other hand $\xi_{\mathcal{D}}[\rho]$ need not be nice nor multiplicative, see [23] for details).

We may now explain which set is computed by our algorithm instead of $\mathcal{I}_{SF(\mathcal{C})}[\rho]$. Consider a nice multiplicative rating map $\rho : 2^{A^*} \to R$. Since $\xi_{SF(\mathcal{C})}[\rho] : 2^{A^*} \to 2^R$ is a rating map, we may consider the element $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]] \in 2^R$. By definition, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]] = \xi_{SF(\mathcal{C})}[\rho](L)$ where L is a $\mathcal{C}$-optimal ε-approximation for $\xi_{SF(\mathcal{C})}[\rho]$. Therefore, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ is a subset of $\xi_{SF(\mathcal{C})}[\rho](A^*) = \mathcal{I}_{SF(\mathcal{C})}[A^*, \rho] = \mathcal{I}_{SF(\mathcal{C})}[\rho]$. When $\mathcal{C}$ is a quotient-closed Boolean algebra of group languages, one may compute the whole set $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from this subset.

▶ **Proposition 22.** *Let $\mathcal{C}$ be a quotient-closed Boolean algebra of group languages and $\rho : 2^{A^*} \to R$ a nice multiplicative rating map. Then, $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ is the least subset of R containing $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ and satisfying the three following properties:*

- ***Trivial elements.*** *For every $w \in A$, $\rho(w) \in \mathcal{I}_{SF(\mathcal{C})}[\rho]$.*
- ***Downset.*** *For every $r \in \mathcal{I}_{SF(\mathcal{C})}[\rho]$ and $q \leq r$, we have $q \in \mathcal{I}_{SF(\mathcal{C})}[\rho]$.*
- ***Multiplication.*** *For every $q, r \in \mathcal{I}_{SF(\mathcal{C})}[\rho]$, we have $qr \in \mathcal{I}_{SF(\mathcal{C})}[\rho]$.*

▶ Remark 23. Intuitively, we use $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ to "nest" two optimizations: one for $\mathcal{C}$ and the other for $SF(\mathcal{C})$. Indeed, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]] = \xi_{SF(\mathcal{C})}[\rho](L) = \mathcal{I}_{SF(\mathcal{C})}[L, \rho]$ where L is a $\mathcal{C}$-optimal ε-approximation for $\xi_{SF(\mathcal{C})}[\rho]$. Hence, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ is least set $\mathcal{I}[\rho](\mathbf{K}) \subseteq R$ (with respect to inclusion), over all $SF(\mathcal{C})$-covers $\mathbf{K}$ of some language $L \in \mathcal{C}$ containing ε.

5.2 Algorithm

We may now present our algorithm for computing $\mathcal{I}_{SF(\mathcal{C})}[\rho]$. We fix a quotient-closed Boolean algebra of group languages $\mathcal{C}$ for the presentation. As expected, the main procedure computes $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ (see Proposition 22). In this case as well, this procedure is obtained from a characterization theorem.

Consider a nice multiplicative rating map $\rho : 2^{A^*} \to R$. We define the $SF(\mathcal{C})$-complete subsets of R for ρ. The definition depends on auxiliary nice multiplicative rating maps. We first present them. Clearly, 2^R is an idempotent semiring (addition is union and the multiplication is lifted from the one of R). For every $S \subseteq R$, we use it as the rating set of a nice multiplicative rating map $\eta_{\rho,S} : 2^{A^*} \to 2^R$. Since we are defining a *nice* multiplicative rating map, it suffices to specify the evaluation of letters. For $a \in A$, we let $\eta_{\rho,S}(a) = S \cdot \{\rho(a)\} \cdot S \in 2^R$. Observe that by definition, we have $\mathbb{i}_{\mathcal{C}}[\eta_{\rho,S}] \subseteq R$.

We are ready to define the $SF(\mathcal{C})$-complete subsets of R. Consider $S \subseteq R$. We say that S is *$SF(\mathcal{C})$-complete for ρ* when the following conditions are satisfied:

1. **Downset.** For every $r \in S$ and $q \leq r$, we have $q \in S$.
2. **Multiplication.** For every $q, r \in S$, we have $qr \in S$.
3. **$\mathcal{C}$-operation.** We have $\mathbb{i}_{\mathcal{C}}[\eta_{\rho,S}] \subseteq S$.
4. **$SF(\mathcal{C})$-closure.** For every $r \in S$, we have $r^\omega + r^{\omega+1} \in S$.

▶ Remark 24. The definition of $SF(\mathcal{C})$-complete subsets does not explicitly require that they contain some trivial elements. Yet, this is implied by $\mathcal{C}$-operation. Indeed, if $S \subseteq R$ is $SF(\mathcal{C})$-complete, then $\eta_{\rho,S}(\varepsilon) = \{1_R\}$ (this is the multiplicative neutral element of 2^R). This implies that $1_R \in \mathbb{i}_{\mathcal{C}}[\eta_{\rho,S}]$ and we obtain from $\mathcal{C}$-operation that $1_R \in S$.

▶ **Theorem 25** ($SF(\mathcal{C})$-optimal imprints ($\mathcal{C}$ made of group languages))**.** *Let $\rho : 2^{A^*} \to R$ be a nice multiplicative rating map. Then, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ is the least $SF(\mathcal{C})$-complete subset of R.*

When $\mathcal{C}$-separation is decidable, Theorem 25 yields a least fixpoint procedure for computing $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ from a nice multiplicative rating map $\rho : 2^{A^*} \to R$. The computation starts from the empty set and saturates it with the four operations in the definition of $SF(\mathcal{C})$-complete subsets. It is clear that we may implement downset, multiplication and $SF(\mathcal{C})$-closure. Moreover, we may implement $\mathcal{C}$-operation as this boils down to $\mathcal{C}$-separation by Lemma 21. Eventually, the computation reaches a fixpoint and it is straightforward to verify that this set is the least $SF(\mathcal{C})$-complete subset of R, *i.e.*, $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$ by Theorem 25.

By Proposition 22, we may compute $\mathcal{I}_{SF(\mathcal{C})}[\rho]$ from $\mathbb{i}_{\mathcal{C}}[\xi_{SF(\mathcal{C})}[\rho]]$. Altogether, this yields the decidability of $SF(\mathcal{C})$-covering by Proposition 19. Hence, Theorem 3 is proved.

6 Conclusion

We proved that for any quotient-closed Boolean algebra $\mathcal{C}$, $SF(\mathcal{C})$-covering is decidable whenever $\mathcal{C}$ is either finite or made of group languages and with decidable separation. Moreover, we presented an algebraic characterization of $SF(\mathcal{C})$ which holds for every quotient-closed Boolean algebra $\mathcal{C}$, generalizing earlier results [29, 16]. A key proof ingredient is an

alternative definition of star-free closure: the operation $\mathcal{C} \mapsto SD(\mathcal{C})$ which we prove to be equivalent. This correspondence generalizes the work of Schützenberger [28] who introduced a single class SD (i.e. $SD(\{\emptyset, A^*\})$) corresponding to the star-free languages (i.e. $SF(\{\emptyset, A^*\})$).

Our results can be instantiated for several input classes $\mathcal{C}$. Theorem 2 applies when $\mathcal{C}$ is finite. In this case, the only prominent application is the class of star-free languages itself. It was already known that covering is decidable for this class [9, 20]. However, Theorem 2 is important for two reasons. First, its proof is actually simpler than the earlier ones specific to the star-free languages (this is achieved by relying on the operation $\mathcal{C} \mapsto SD(\mathcal{C})$). More importantly, Theorem 2 is used as a key ingredient for proving our second generic statement: Theorem 3, which applies to classes made of group languages with decidable separation. It is known that separation is decidable for the class GR of all group languages [2]. Hence, we obtain that $SF(\mathrm{GR})$-covering is decidable. Another application is the class MOD consisting of languages counting the length of words modulo some number (deciding MOD-separation is a simple exercise). We get the decidability of $SF(\mathrm{MOD})$-covering. This is important, as the languages in $SF(\mathrm{MOD})$ are those definable in first-order logic with modular predicates $(\mathrm{FO}(<, \mathrm{MOD}))$. A last example is given by the input class consisting of all languages counting the number of occurrences of letters modulo some number. These are exactly the languages recognized by finite commutative groups, for which separation is decidable [5].

Abstract

Every nondeterministic finite-state automaton is equivalent to a deterministic finite-state automaton. This result does not extend to finite-state transducers – finite-state automata equipped with a one-way output tape. There is a strict hierarchy of functions accepted by one-way deterministic finite-state transducers (1DFTs), one-way nondeterministic finite-state transducers (1NFTs), and two-way nondeterministic finite-state transducers (2NFTs), whereas the two-way deterministic finite-state transducers (2DFTs) accept the same family of functions as their nondeterministic counterparts (2NFTs).

We define *multi-head* one-way deterministic finite-state transducers (MH-1DFTs) as a natural extension of 1DFTs. These transducers have multiple one-way reading heads that move asynchronously over the input word. Our main result is that MH-1DFTs can deterministically express any function defined by a one-way nondeterministic finite-state transducer. Of independent interest, we formulate the all-suffix regular matching problem, which is the problem of deciding for each suffix of an input word whether it belongs to a regular language. As part of our proof, we show that an MH-1DFT can solve all-suffix regular matching, which has applications, e.g., in runtime verification.

1 Introduction

Finite-state automata (FAs) are a fundamental model of computation. In its simplest form, a finite-state automaton reads an input word once, from left to right, while updating its state deterministically. FAs accept the regular languages. It is well-known that neither allowing the reading head to move in both directions on the input word nor updating the state nondeterministically extends their expressiveness beyond the regular languages.

A generalization of the finite-state automata are *finite-state transducers* (FTs). FTs extend a finite-state automaton with an output tape and each transition also outputs a (possibly empty) sequence of symbols from an output alphabet. The language accepted by a finite-state transducer is a relation (transduction) between input and output words. A finite-state transducer is *functional* (f-FT) if the relation represents a function. Any deterministic finite-state transducer is functional (hence, we just write DFT instead of

$$\begin{array}{ll} \mathcal{L}(\text{1DFA}) = \mathcal{L}(\text{1NFA}) \subsetneq \mathcal{L}(\text{MH-1DFA}) & \mathcal{L}(\text{1DFT}) \subsetneq \mathcal{L}(f\text{-1NFT}) \subsetneq \mathcal{L}(\text{MH-1DFT}) \\ \quad\quad\quad\quad \| & \quad\quad\quad\quad\quad \not\supseteq \\ \mathcal{L}(\text{2DFA}) = \mathcal{L}(\text{2NFA}) & \mathcal{L}(\text{2DFT}) = \mathcal{L}(f\text{-2NFT}) \end{array}$$

Figure 1 The language hierarchy accepted by models of automata (left) and transducers (right).

f-DFT). For transducers, nondeterminism makes a difference: adding nondeterminism extends the expressiveness of a finite-state transducer to nonfunctional relations. One can also classify finite-state transducers as one-way or two-way (1FTs or 2FTs) depending on whether the reading head can only move forwards or in both directions on the input word.

Another generalization of finite-state automata adds multiple reading heads that move asynchronously over the input word (see, e.g., [6] for a survey). This results in an expressive computational model with problems like emptiness, finiteness, and equivalence not being semi-decidable already for two reading heads [6]. Multi-head finite-state automata induce a strict hierarchy of languages when increasing the number of reading heads [10]. The problem of simulating two-head one-way nondeterministic finite-state automata by multi-head two-way deterministic finite-state automata is equivalent to the $\mathsf{L} \stackrel{?}{=} \mathsf{NL}$ problem [9].

We combine the previous two generalizations to the notion of multi-head finite-state transducers (Section 2). We show that multi-head one-way deterministic finite-state transducers (MH-1DFTs) can simulate any functional one-way nondeterministic finite-state transducer (f-1NFT), and thereby establish inclusion between the classes of languages accepted by these models. Central to our proof is the ability of an MH-1DFT to decide for each suffix of an input word whether it belongs to a regular language (Section 3); we call this transduction *all-suffix regular matching*. Computing this transduction allows us to deterministically find an accepting computation of the nondeterministic transducer, whenever it exists (Section 4).

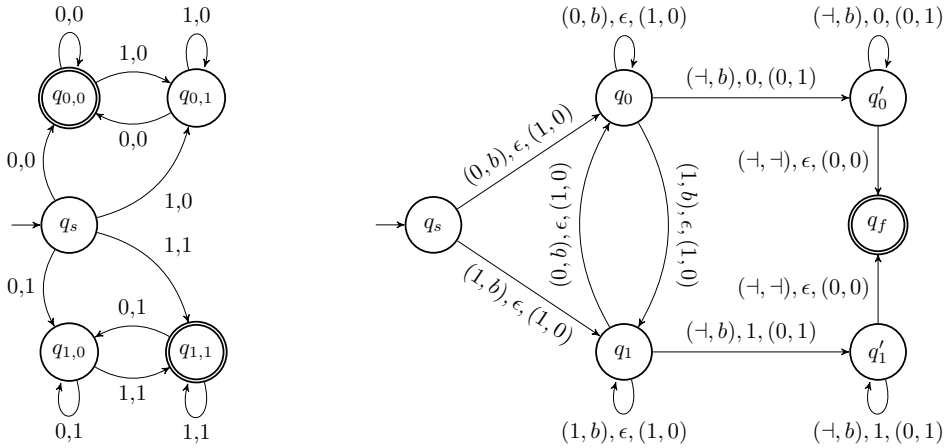
Figure 1 shows how our contributions, the transducer model and the proper inclusion of language classes, highlighted in gray, fit into the landscape of other well-studied language classes. We discuss the remaining inclusions in Section 5.

Preliminaries. Let $\mathbb{I}$ be the set of all finite intervals over the positive integers. We denote an interval $I \in \mathbb{I}$ by $[a..b] = \{x \mid a \leq x \leq b\}$. We define $[a..b) := \emptyset$, if $a \geq b$, and $[a..b) := [a..(b-1)]$, if $a < b$. Moreover, we write $[k]$ for $[1..k]$. Given a finite alphabet Σ, we denote the set of all finite words over Σ by Σ^*, the empty word by ϵ, and the length of a word $w \in \Sigma^*$ by $|w|$. Given a tuple of positions $ps \in [|w|]^{|ps|}$ of length $|ps|$, $w[ps]$ denotes $w[ps_1]w[ps_2]\dots w[ps_{|ps|}]$, i.e., the word consisting of symbols from w at the positions ps.

A *one-way deterministic finite-state automaton* (1DFA) is a tuple $A = (\Sigma, Q, q_s, Q_F, \delta)$, where Σ is the input alphabet, Q is a finite set of states, $q_s \in Q$ is the initial state, $Q_F \subseteq Q$ is the set of accepting states, and $\delta : Q \times \Sigma \to Q$ is the transition function. We extend the function δ to $\delta^* : Q \times \Sigma^* \to Q$ in the natural way. A *one-way nondeterministic finite-state automaton* (1NFA) is obtained by replacing the transition function in the definition of a 1DFA by a transition *relation* $\delta \subseteq Q \times \Sigma \times Q$.

A *one-way nondeterministic finite-state transducer* (1NFT) is derived from an underlying 1NFA by extending its transition relation with output words over an output alphabet Γ, i.e., the transition relation becomes $\delta \subseteq Q \times \Sigma \times Q \times \Gamma^*$. We extend the relation δ to $\delta^* \subseteq Q \times \Sigma^* \times Q \times \Gamma^*$ in the natural way. A 1NFT is functional if the transduction it defines is a function.

▶ **Example 1.** Figure 2a shows a f-1NFT computing the function f that maps a non-empty binary word w to $0^{|w|}$, if w ends with a zero, and $1^{|w|}$, otherwise. In the first step, the transducer guesses the last symbol and moves to a state $q_{i,j}$, where i is the guess and j is



(a) The f-1NFT from Example 1. A transition labeled by i, j represents a transition when reading the symbol i and producing the output j.

(b) The MH-1DFT from Example 3. A transition labeled by $(s_1, s_2), o, (m_1, m_2)$ represents a transition when reading the symbols (s_1, s_2), producing the output o, and advancing the reading heads by the offsets (m_1, m_2). Here, $b \in \{0, 1\}$.

Figure 2 The transducers from Examples 1 and 3.

the current (i.e., first) symbol. In the subsequent steps, the transducer updates the current state based on the current symbol. In each transition, the transducer outputs its original guess. Finally, the transducer accepts if the last symbol equals its guess.

2 Multi-Head One-Way Deterministic Finite-State Transducer

We define multi-head one-way deterministic finite-state transducers (MH-1DFTs) by adapting the definition of multi-head two-way finite-state automata [6] to multi-head one-way deterministic finite-state automata and extending the transition function with output symbols.

The following definition of an MH-1DFT formalizes a transition on a non-final state that reads a κ-tuple of symbols, enters a new state, produces some output, and advances some of the reading heads. We use a special symbol $\dashv$ to mark the end of the input tape, on the right-hand side. We further impose two conditions on the transition function. First, no reading head moves out of the input tape. Second, some reading head advances at each transition except when the new state is accepting. Without loss of generality, the transition relation δ forbids ϵ-transitions to non-final states. Hence, an MH-1DFT can only reject an input word by permitting no further transition. If δ is total, then no input word is rejected and the transduction is a total function.

▶ **Definition 2.** *A multi-head one-way deterministic finite-state transducer (MH-1DFT) is a tuple $A = (\Sigma, \dashv, \Gamma, \kappa, Q, q_s, Q_F, \delta)$, where Σ is an input alphabet, $\dashv \notin \Sigma$ is the right endmarker, Γ is an output alphabet, κ is the number of reading heads, Q is a finite set of states, $q_s \in Q$ is the initial state, $Q_F \subseteq Q$ is a set of accepting states, and $\delta : (Q \setminus Q_F) \times (\Sigma \cup \{\dashv\})^\kappa \to Q \times \Gamma^* \times \{0, 1\}^\kappa$ is the partial transition function such that:*

- *$\delta(q, es) = (q', \tilde{o}, ms)$ and $es_i = \dashv$, for any $i \in [\kappa]$, implies that $ms_i = 0$, and*
- *$\delta(q, es) = (q', \tilde{o}, \vec{0})$ implies that $q' \in Q_F$.*

A *configuration* of an MH-1DFT $A = (\Sigma, \dashv, \Gamma, \kappa, Q, q_s, Q_F, \delta)$ is a tuple $c = (w, o, q, ps) \in \mathcal{C}^A$, where $w \in \Sigma^*$ is the input word, $o \in \Gamma^*$ is the output word produced by A so far, $q \in Q$ is the current state, and $ps \in [|w| + 1]^\kappa$ are the positions of the κ reading heads on the input tape. A configuration is accepting if $q \in Q_F$. A *step* s^A is a relation on

$\mathcal{C}^A$ such that $((w, o, q, ps), (w', o', q', ps')) \in s^A$ if and only if $w = w'$, $o' = o \cdot \tilde{o}$, for some $\tilde{o} \in \Gamma^*$, and $\delta(q, w[ps]) = (q', \tilde{o}, ps' - ps)$. A *computation* of an MH-1DFT A on a word w is a maximal finite sequence of configurations $c_1, c_2, \ldots, c_l$ that starts with the initial configuration $c_1 = (w, \epsilon, q_s, \vec{1})$ and in which all pairs of consecutive configurations are contained in the step relation s^A. (The finiteness is given because $ps' - ps \neq \vec{0}$ except when $q' \in Q_F$ by Definition 2.) A computation is accepting if its last configuration c_l is accepting. Otherwise, it is rejecting.

We say that an MH-1DFT A accepts a language $L \subseteq \Sigma^* \times \Gamma^*$ if the computation on an input word w producing some output o satisfies $(w, o) \in L$ if and only if it is accepting. One can also view a language $L \subseteq \Sigma^* \times \Gamma^*$ accepted by an MH-1DFT A as a function $f : X \to \Gamma^*$, where X is the set of all input words w such that $(w, o) \in L$ for some (unique) output o and $f(w) = o$.

▶ **Example 3.** Figure 2b shows a two-head MH-1DFT computing the function f from Example 1. Initially, the first reading head reads the entire input word to determine the last symbol. Subsequently, the second reading head outputs the last symbol for each input symbol it reads. Once the second reading head has arrived at the right endmarker $\dashv$, the MH-1DFT accepts without advancing any reading head. The empty word ϵ is not mapped to any output as there is no transition from the initial state q_s when reading $(\dashv, \dashv)$.

3 All Suffix Regular Matching

All-suffix regular matching is the problem of deciding for each suffix of an input word whether it belongs to a regular language. More formally, for a regular language L, we define a function $t_L : \Sigma^* \to \{0, 1\}^*$ that maps a word w to a binary word $t_L(w)$ of length $|w| + 1$ such that, for any $1 \leq i \leq |w| + 1$, $t_L(w)[i] = 1$ if and only if the suffix $w[i..|w|]$ is in the language L. The last symbol in $t_L(w)$ denotes whether the empty word ϵ is in the language L.

We show that, for any regular language L, all-suffix regular matching can be solved by an MH-1DFT, i.e., there exists an MH-1DFT computing the function t_L. This construction is subsequently used in our simulation of any f-1NFT by an MH-1DFT (Section 4).

3.1 Informal Account

Let A be a 1DFA with $|Q|$ states. A naive approach to all-suffix regular matching is to run A on each suffix of the input word, i.e., starting from every position. The MH-1DFT solving this problem must output the decisions sequentially starting from the leftmost suffix (the entire word). Suppose we already know the decision for some *past* suffixes and want to compute the decision for a *current* suffix. To reuse the decisions for the past suffixes, we can first run the automaton A again on these suffixes until we reach the current position. Now we continue to run the automaton A on the past suffixes and also run A from its starting state on the current suffix. If the state of A in the run on the current suffix equals at some point the state of A in a run on a past suffix, then we know that the decision for the current suffix is the same as the decision for that past suffix and we can output it without the need to run A further.

Our MH-1DFT keeps a list of decisions and states for past suffixes such that running A on them until the current position yields different states. The length of this list is at most $|Q|$. To compute the decision for the current suffix, our MH-1DFT uses a reading head h positioned at the current position to run A from all the stored states for past suffixes as well as from the initial state for the current suffix. The reading head h stops once the state for the current suffix equals the state for a past suffix (or the end of the input word is reached).

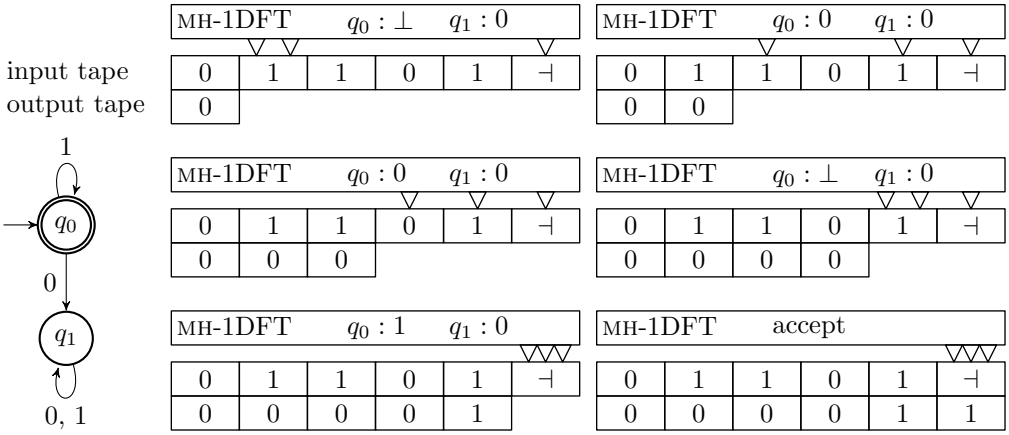


Figure 3 The automaton and configurations of the MH-1DFT from Example 4.

It remains to be shown that a finite number of reading heads suffice, independently of the input word's length. To this end, observe that whenever the reading head h moves on, the list of decisions and different states for past suffixes at that position expands (otherwise, the decision for the current suffix would have been known and h would have stopped). As the length of the list at any position is at most $|Q|$, it suffices to use $|Q| + 1$ reading heads in total. The extra reading head updates the stored states after a decision for the current suffix is computed.

▶ **Example 4.** Consider the regular language L consisting of all binary words without zero. A two-state deterministic automaton A accepting L is depicted in Figure 3. We describe a computation of our MH-1DFT with three reading heads on the input word $w = 01101$.

To compute the decision for the first suffix, one reading head reads the entire input. The remaining two reading heads advance and the decision 0 is stored (with the updated initial state $\delta(q_0, 0) = q_1$) and output (to the output tape, which is below the input tape in Figure 3).

To compute the decision for the second suffix, another reading head positioned at the second symbol advances to the fifth symbol until the two states (for the past and current suffix) become a single state q_1. The only remaining reading head advances and the decision 0 is stored (with the updated initial state $\delta(q_0, 1) = q_0$) and output.

Since the initial state q_0 is now stored with a decision, the decision for the third suffix can be immediately output, the last reading head advanced, and the stored states updated. The decision for the fourth suffix can again be immediately output, the last reading head advanced, and the stored states updated (to a single state q_1 since $\delta(q_0, 0) = \delta(q_1, 0) = q_1$). For the last suffix, the initial state q_0 is no longer stored with a decision, so a reading head reads the last symbol to compute and output the decision 1. Then the last reading head advances and the decision is stored (with an updated initial state $\delta(q_0, 1) = q_0$). Finally, as the last reading head has arrived at the right endmarker, our MH-1DFT outputs the Boolean decision 1 for the empty suffix (the initial state q_0 is accepting) and accepts.

3.2 The Multi-Head Transducer

We now formally define an MH-1DFT that solves the all-suffix regular matching problem for a regular language L. Let A be a 1DFA accepting L. Suppose A's set of states is $Q = \{q_1, q_2, \ldots, q_n\}$ and that the current suffix of an input word w starts at the position

1 $\tilde{\delta}((qbs, q), es)$:
2 $D := \{q_j \mid qbs_j \neq \bot\}; D' := \{q_{j'} \mid \exists j.\ qbs_j = (q_{j'}, \_)\}$
3 $k := |D| + 1; k' := |D'| + 1$
4 if $es_{k'} = \dashv$ then $b := q \in Q_F$
5 else if $\exists j, q_{j'}, \beta_j.\ qbs_j = (q_{j'}, \beta_j) \wedge q = q_{j'}$ then $b := \beta_j$

Figure 4 The transition function $\tilde{\delta}$ of the MH-1DFT $\tilde{A}_L$.

i. Let $\tilde{Q}_i = \{\delta^*(q_s, w[j..i)) \mid j \in [1..i)\}$ be the set of stored states for the past suffixes. For each $i' \in [i, |w| + 1]$, let $\tilde{Q}_{i,i'} = \{\delta^*(q_j, w[i..i')) \mid q_j \in \tilde{Q}_i\}$ be the states obtained by running the stored states for the past suffixes from the current position i up to the position i'. Let $\beta_{w,i}(q)$ equal one if and only if A accepts the word $w[i..|w|]$ when run from the state q.

We define our MH-1DFT $\tilde{A}_L = (\Sigma, \dashv, \Gamma, \kappa, \tilde{Q}, \tilde{q}_s, \tilde{Q}_F, \tilde{\delta})$ as follows. We set the output alphabet to $\Gamma = \{0, 1\}$ and the number of reading heads to $\kappa = |Q| + 1 = n + 1$. The set of states is $\tilde{Q} = (((Q \times \{0, 1\}) \cup \bot)^{|Q|} \times Q) \cup \{\tilde{q}_f\}$, where $\tilde{q}_f$ is a designated accepting state. With the last reading head at the position i, i.e., $ps_{n+1} = i$, and the reading head for the current suffix at the position i' (the current suffix starts at the position i), a state $(qbs, q) \in \tilde{Q}$ consists of an n-tuple qbs whose j-th component $qbs_j = (q_{j'}, \beta_{w,i}(q_j))$ stores the decision $\beta_{w,i}(q_j)$ for a past suffix corresponding to the stored state $q_j \in \tilde{Q}_i$ and the state $q_{j'}$ obtained by running A from the state q_j on $w[i..i')$. If the state q_j is not among the stored states for the current position i, then $qbs_j = \bot$. Furthermore, the state q from the state $(qbs, q) \in \tilde{Q}$ of the MH-1DFT $\tilde{A}_L$ is the state obtained by running A on the current suffix up to the position i', i.e., $q = \delta^*(q_s, w[i..i'))$. We point out that the positions i and i' themselves are not explicitly stored in the state (but $i = ps_{n+1}$ and $i' = ps_{k'}$, with k' as in Figure 4). The initial state is $\tilde{q}_s = (\bot^n, q_s)$. The set of accepting states is $\tilde{Q}_F = \{\tilde{q}_f\}$. The transition function $\tilde{\delta} : (\tilde{Q} \setminus \tilde{Q}_F) \times (\Sigma \cup \{\dashv\})^{n+1} \to \tilde{Q} \times \Gamma^* \times \{0, 1\}^{n+1}$ is defined using pseudocode in Figure 4. The transition function of the MH-1DFT from Example 4 is shown in Figure 5. We use the notation let $q_{j'} := \delta(q_s, es_{n+1})$ in $qbs'_{j'} := (q_{j'}, b)$ for *pattern-matching*, i.e., j' denotes the index of the state $\delta(q_s, es_{n+1})$ in the expression $qbs'_{j'} := (q_{j'}, b)$.

The last reading head is at the current position $i = ps_{n+1}$ and all reading heads j and j' with $j > j'$ satisfy $ps_j \leq ps_{j'}$ (the reading heads do not overtake each other). The transducer maintains the invariant that the number of reading heads beyond the position i' of the reading head for the current suffix equals $|\tilde{Q}_{i,i'}|$. The sets D and D' (Line 2) equal the set of

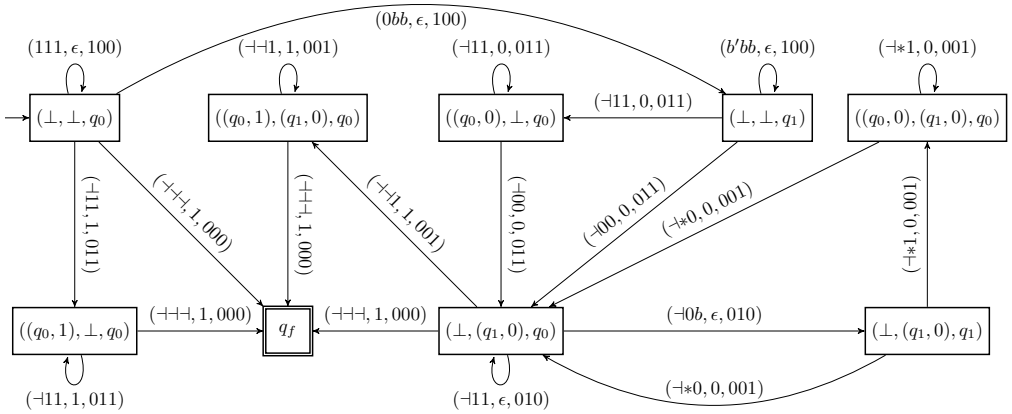

Figure 5 The transition function of the MH-1DFT from Example 4. A transition labeled by $(s_1 s_2 s_3, o, m_1 m_2 m_3)$ represents a transition when reading the symbols (s_1, s_2, s_3), producing the output o, and advancing the reading heads by the offsets (m_1, m_2, m_3). Here, $b, b' \in \{0, 1\}$ denote arbitrary symbols from the input alphabet, whereas $* \in \{0, 1, \dashv\}$ denotes an arbitrary input symbol. (Only states and transitions reachable in a computation on an input word are shown.)

stored states $\tilde{Q}_i$ and the set of states $\tilde{Q}_{i,i'}$, obtained by running A from the stored states $\tilde{Q}_i$ on $w[i..i')$. The invariant implies that $k' = |D'| + 1$ (Line 3) is the reading head for the current suffix.

The transducer $\tilde{A}_L$ first tries to determine the decision for the current suffix (Lines 4–6). If this can be determined, then $\tilde{A}_L$ updates the stored states (Lines 9–11), outputs the decision, advances all reading heads at the current position i, and sets the state for the current suffix to the initial state of A (Line 14). If A's initial state is not among the stored states $D = \tilde{Q}_i$, the reading head for the current suffix has already advanced, i.e., $\tilde{A}_L$ only needs to advance the remaining reading heads $k + 1 = \tilde{k}, \dots, n + 1$ at the current position.

If the decision for i has not been determined, then the states D' and q are updated (Lines 16–17 and 19) and the reading head for the current suffix advances (Line 18).

3.3 Proof of Correctness

To prove that the MH-1DFT $\tilde{A}_L$ computes t_L, we formulate an invariant on a configuration of $\tilde{A}_L$ that is satisfied by each configuration from a computation on an input. For the accepting state $\tilde{q}_f$, the invariant states that the output is correct: $\mathcal{I}(w, o, \tilde{q}_f, ps) \equiv (o = t_L(w))$ (C0).

For a state $(qbs, q) \in \tilde{Q}$, the invariant captures the properties of a state and the reading heads' positions mentioned previously. In addition, it states that correct output has been produced for all positions preceding the current position $i = ps_{n+1}$. In the following, we use the definitions from Lines 2–3 in Figure 4. We further define $i' = ps_{k'}$ to be the position of the reading head for the current suffix. To capture the expansion of the set of stored states by running A on the current suffix, we define $\tilde{Q}'_j = \tilde{Q}_{i,j} \cup \{\delta^*(q_s, w[i..j))\}$, for all $j \in [i..i')$, and $\tilde{Q}'_j = \tilde{Q}_{i,j}$, for all $j \in [i'..(|w| + 1)]$. Then the invariant is as follows:

$$\mathcal{I}(w, o, (qbs, q), ps) \equiv (|o| = ps_{n+1} - 1 \wedge \forall j \in [|o|].\ o_j = t_L(w)[j]) \wedge \quad \text{(C1)}$$

$$\forall j \in [n].\ \forall q_{j'}, \beta_j.\ (qbs_j = (q_{j'}, \beta_j) \implies q_{j'} = \delta^*(q_j, w[i..i')) \wedge \beta_j = \beta_{w,i}(q_j)) \wedge \quad \text{(C2)}$$

$$q = \delta^*(q_s, w[i..i')) \wedge \quad \text{(C3)}$$

$$D = \tilde{Q}_i \wedge \quad \text{(C4)}$$

$$D' = \tilde{Q}_{i,i'} \wedge \tag{C5}$$
$$\forall j \in [i..i'). \, \tilde{Q}_{i,j} \subsetneq \tilde{Q}'_j \wedge \tag{C6}$$
$$(ps_{n+1} \leq \cdots \leq ps_1) \wedge \tag{C7}$$
$$\forall j \in [i..|w|]. \, |\{h \mid ps_h > j\}| = |\tilde{Q}'_j|. \tag{C8}$$

▶ **Lemma 5.** *For any input word w, the initial configuration of $\tilde{A}_L$ satisfies the invariant, i.e., $\mathcal{I}(w, \epsilon, (\bot^n, q_s), 1^{n+1})$ holds.*

Proof. Observe that $i = i' = 1$ and $D = D' = \tilde{Q}_i = \tilde{Q}_{i,j} = \emptyset$, for all $j \in [i..|w|]$. ◀

▶ **Lemma 6.** *Let $c_1 = (w, o, (qbs, q), ps)$ and $c_2 = (w, o', q', ps')$ be two configurations of $\tilde{A}_L$ such that $\mathcal{I}(c_1)$ holds and $(c_1, c_2) \in s^{\tilde{A}_L}$. Then $\mathcal{I}(c_2)$ holds.*

Proof. We refer to Line l in Figure 4 as Ll. Furthermore, we refer to the i-th conjunct in $\mathcal{I}(c_1)$ and $\mathcal{I}(c_2)$ as Ci and Ci', respectively and to the i-th fact labeled in the proof as Fi. Let us denote by i_j, i'_j, D_j, D'_j, k_j, k'_j, ${}^j\tilde{Q}'_{j'}$, ${}^j ps$, $j \in \{1, 2\}$, the respective definitions for the configuration c_j. To derive that $\mathcal{I}(c_2)$ holds, we analyze the transition function $\tilde{\delta}$ in Figure 4.

First we show that $b \neq \bot \implies b = t_L(w)[i_1]$ (F1). If $es_{k'_1} = \dashv$, then $i'_1 = |w| + 1$, C3, and L4 imply that $b = t_L(w)[i_1]$. If L5's condition holds, then C2 and C3 imply that $b = t_L(w)[i_1]$.

Consider the case $b \in \{0, 1\}$ (L8–14). If $es_{n+1} = \dashv$, then $i_1 = i'_1 = |w| + 1$ and $b \neq \bot$ (due to $i'_1 = |w| + 1$ and L4) which with F1 implies $b = t_L(w)[i_1]$. C1 and $b = t_L(w)[i_1]$ imply C0, i.e., $\mathcal{I}(c_2)$ holds since c_2 is accepting and thus $\mathcal{I}(c_2) \equiv$ C0. Otherwise (if $es_{n+1} \neq \dashv$), we have $i_1 \leq |w|$. Because $\tilde{k} = |D_1| + 1 + (q_s \notin D_1) \leq n + 1$, the last reading head advances, i.e., $i_2 = i_1 + 1$ (F2). Now, F1, F2, and C1 imply C1'. Next we show that $|\{h \mid {}^1ps_h > i_1\}| = \tilde{k} - 1$ (F3). From C4, we have $D_1 = \tilde{Q}_{i_1}$. It follows that $|{}^1\tilde{Q}'_{i_1}| = |D_1| + (q_s \notin D_1)$. C8 then implies $|\{h \mid {}^1ps_h > i_1\}| = \tilde{k} - 1$, i.e., that precisely those readings heads at the position i_1 advanced (L13). In particular, this implies C7'. L9–11 and C4 imply $D_2 = D'_2 = \tilde{Q}_{i_1+1} \overset{\text{F2}}{=} \tilde{Q}_{i_2}$ (F4). This immediately implies C4'. Next we show that $i_2 = i'_2$ (F5). If $i_2 = |w| + 1$, then $i_2 = i'_2$ follows from C7'. Suppose that $i_2 \leq |w|$. It follows that $|\{h \mid {}^2ps_h > i_2\}| \overset{\text{F2–3,L13}}{=} |\{h \mid {}^1ps_h > i_1 + 1| \overset{\text{C8}}{=} |{}^1\tilde{Q}'_{i_1+1}|$. If $i'_1 > i_1 + 1$, we derive $|{}^1\tilde{Q}'_{i_1+1}| \overset{i'_1 > i_1+1}{=} |\tilde{Q}_{i_1+1}|$. If $i'_1 \leq i_1 + 1$, we derive $|{}^1\tilde{Q}'_{i_1+1}| \overset{\text{L5}}{=} |\tilde{Q}_{i_1+1}|$. Hence, $|\{h \mid {}^2ps_h > i_2\}| = |\tilde{Q}_{i_1+1}| \overset{\text{F2}}{=} |\tilde{Q}_{i_2}| \overset{\text{F4}}{=} D'_2$, which implies that $i_2 = i'_2$. F5 implies C6' and F5 together with L14 imply C3'. F4–5 imply C5'. L9–11, C2, F1, and F5 further imply C2'. F3 and L13 imply that those reading heads at i_1 advanced. Hence for C8', it suffices to show $|{}^2\tilde{Q}'_j| = |{}^1\tilde{Q}'_j|$, for all $j \in [(i_1 + 1)..|w|]$. We derive $|{}^2\tilde{Q}'_j| \overset{\text{F2,F5}}{=} |\tilde{Q}_{i_1+1,j}|$. If $i'_1 \leq j$, then $|\tilde{Q}_{i_1+1,j}| \overset{\text{L5},i'_1 \leq j}{=} |\tilde{Q}_{i_1,j}| \overset{i'_1 \leq j}{=} |{}^1\tilde{Q}'_j|$. If $i'_1 > j$, then $|\tilde{Q}_{i_1+1,j}| \overset{i'_1 > j}{=} |{}^1\tilde{Q}'_j|$. This completes the proof of C8'. Thus, $\mathcal{I}(c_2)$ holds in the case $b \in \{0, 1\}$.

We continue with the case $b = \bot$ (L17–19). Together with L5, $b = \bot$ implies $|D'_1| < n$. We obtain $k'_1 \leq n$ and that $i_2 = {}^2ps_{n+1} = {}^1ps_{n+1} = i_1$ (F6). Moreover, L17 implies $D_2 \overset{\text{L17}}{=} D_1 \overset{\text{C4}}{=} \tilde{Q}_{i_1} \overset{\text{F6}}{=} \tilde{Q}_{i_2}$ which yields C4'. Since no output is produced, F6 immediately yields C1'. Together with L4, $b = \bot$ implies $i'_1 \leq |w|$. Next we show that $i'_2 = i'_1 + 1$ (F7). We derive $|\{h \mid {}^1ps_h > i'_1\}| \overset{\text{C8},i'_1 \leq |w|}{=} |{}^1\tilde{Q}'_{i'_1}| \overset{\text{C5}}{=} |D'_1| \overset{\text{L3}}{=} k'_1 - 1$ (F8). The fact F8 implies that the single advancing reading head k'_1 is the first reading head at the position i'_1, which further implies C7'. If $i'_1 + 1 = |w| + 1$, then $i'_2 = i'_1 + 1$ follows from $|D'_2| \overset{\text{L17}}{\leq} |D'_1|$. If $i'_1 + 1 \leq |w|$, then $i'_2 = i'_1 + 1$ follows from $|D'_2| \overset{\text{L17}}{=} |{}^1\tilde{Q}'_{i'_1+1}|$ and $|\{h \mid {}^1ps_h > i'_1 + 1\}| \overset{\text{C8},i'_1+1 \leq |w|}{=} |{}^1\tilde{Q}'_{i'_1+1}|$. Then, L17, the facts F6–7 and C2, C4–5 imply C2' and C5'. Furthermore, L19, F6–7 and C3 imply C3'. Together with L5 and F6–7, $b = \bot$ implies that $\tilde{Q}_{i_1,i'_1} \subsetneq {}^2\tilde{Q}'_{i'_1}$ (F9).

F6–7 and F9 together with C6 yield C6'. It suffices to show C8' for $j = i'_1$; otherwise ${}^1\tilde{Q}'_j = {}^2\tilde{Q}'_j$ and the number of heads at positions $> j$ did not change. For $j = i'_1$, we derive $|\{h \mid {}^2ps_h > i'_1\}| \overset{\text{L18}}{=} |\{h \mid {}^1ps_h > i'_1\}| + 1 \overset{\text{C8}}{=} |{}^1\tilde{Q}'_{i'_1}| + 1 \overset{b=\bot,\text{L5}}{=} |{}^2\tilde{Q}'_{i'_1}|$. This completes the proof of C8'. Thus, $\mathcal{I}(c_2)$ holds in the case $b = \bot$. ◀

▶ **Theorem 7.** *For any input word w, the output produced by $\tilde{A}_L$ is $t_L(w)$.*

Proof. Let $c_1, c_2, \ldots, c_l$ be $\tilde{A}_L$'s computation on w. Lemmas 5 and 6 imply that $\mathcal{I}(c_i)$ holds for all configurations c_i, $i \in [l]$. Since $\tilde{A}_L$'s transition function $\tilde{\delta}$ is total (the transducer cannot get stuck), Definition 2 implies that c_l is an accepting configuration. The invariant $\mathcal{I}(w, o, \tilde{q}_f, ps)$ for the last configuration $c_l = (w, o, \tilde{q}_f, ps)$ then implies that $o = t_L(w)$. ◀

4 Simulation

Let A be a f-1NFT and let $L \subseteq \Sigma^* \times \Gamma^*$ be the language accepted by A. We show that there exists an MH-1DFT accepting the same language L. This establishes inclusion between the classes of languages accepted by these models. Because two-head finite-state automata strictly extend the expressiveness of one-head finite-state automata [10], the inclusion is proper.

4.1 Informal Account

To simulate the f-1NFT A with $|Q|$ states on an input w, we first check if w is accepted by A's underlying automaton. This can be done using a single head that reads the entire input. If the automaton rejects, then clearly no $(w, o) \in L$ and our MH-1DFT simulating A may also immediately reject. Otherwise there is exactly one $(w, o) \in L$, since A is functional. Hence, it suffices to follow an accepting computation of the underlying automaton and concatenate the outputs from A's transition relation to produce the output o. A problem with this straightforward approach is the nondeterminism of A that may have multiple transitions from a given state of A on the same symbol. Nonetheless, if we are able to determine a transition to a state from which A's underlying automaton accepts the rest of the input word, then we can follow it, since this transition is part of an accepting computation. So now our problem is reduced to checking from which states a 1NFA accepts a suffix of an input word. But since the language accepted by a 1NFT run from a particular state is regular, this is precisely an instance of all-suffix regular matching, for which we have already constructed an MH-1DFT in the previous section.

Our MH-1DFT simulating A follows the described approach. It tries to find an accepting computation of the underlying automaton of A starting from its initial state. To this end, our MH-1DFT runs $|Q|$ instances of the (distinct) MH-1DFTs for the regular languages accepted by the underlying finite-state automaton of A when run from one of its states. If at some point, no transition can be made from the current state to a new state from which the remainder of the input word is accepted, then our MH-1DFT rejects the input word. Otherwise, it follows one such transition (an arbitrary one if there are multiple transitions) and outputs the output word from the transition of the transducer A. Upon reaching the right endmarker of the input word, our MH-1DFT accepts if the current simulated state is accepting with respect to A.

▶ **Example 8.** We revisit the f-1NFT A from Example 1. In Example 3, we proposed an ad-hoc MH-1DFT that simulates A. Here, we show how to obtain an MH-1DFT that simulates A by following the general approach. First we construct a 1DFA for each regular language accepted by A's underlying automaton when run from one of its states. For instance, the

regular language L_s for the initial state of A contains all non-empty binary words (note that this is the set of all input words w such that $(w, o) \in L$ for some o) and can be accepted by a simple two-state 1DFA. For the states $q_{0,0}$ and $q_{0,1}$, the regular languages $L_{0,0}$ and $L_{0,1}$ contain all non-empty binary words that end with a zero. Analogously, for the states $q_{1,0}$ and $q_{1,1}$, the regular languages $L_{1,0}$ and $L_{1,1}$ contain all non-empty binary words that end with a one. Each of these four regular languages $L_{0,0}$, $L_{0,1}$, $L_{1,0}$, and $L_{1,1}$ can be accepted by a simple three-state 1DFA.

Now, for each of the five regular languages (L_s, $L_{0,0}$, $L_{0,1}$, $L_{1,0}$, and $L_{1,1}$), we construct an MH-1DFT solving all-suffix-pattern matching. The MH-1DFT for L_s has three reading heads and the MH-1DFTs for $L_{0,0}$, $L_{0,1}$, $L_{1,0}$, and $L_{1,1}$ have four reading heads each. Hence, the resulting MH-1DFT $\tilde{A}$ simulating A has $1 + 3 + 4 \cdot 4 = 20$ reading heads.

Let us analyze $\tilde{A}$'s computation on the input word $w = 01101$. The MH-1DFT for L_s computes that the entire input word is accepted by the underlying automaton of A (because w is non-empty). Hence, there exists an accepting computation of A on w that $\tilde{A}$ will simulate. The MH-1DFTs for $L_{0,0}$ and $L_{0,1}$ compute that neither of the first two suffixes is in either of these two regular languages (because w does not end with a zero). In contrast, the MH-1DFTs for $L_{1,0}$ and $L_{1,1}$ compute that both the first two suffixes are in both these regular languages (because w ends with a one). Now, the MH-1DFT $\tilde{A}$ simulating A must decide between the states $q_{1,0}$ and $q_{1,1}$ based on the actual transition relation of A. Since the first symbol of w is a zero, the next simulated state of A is going to be $q_{1,0}$ and the first output symbol is 1 (which is the correct guess of A about the last symbol of the input word). The rest of A's computation on w is in fact deterministic and we omit it.

4.2 The Multi-Head Transducer

We define an MH-1DFT simulating a f-1NFT $A = (\Sigma, \Gamma, Q, q_s, Q_F, \delta)$. Suppose the set of states of A is $Q = \{q_1, q_2, \ldots, q_n\}$. For each $i \in [n]$, let L_i be the regular language accepted by the 1NFA $A_i = (\Sigma, Q, q_i, Q_F, \delta')$, where $\delta' \subseteq Q \times \Sigma \times Q$ is the transition relation obtained from δ by ignoring the output word Γ^*. In particular, note that A_s is the underlying automaton of A and A_i is obtained from A_s by changing the initial state to q_i.

By Theorem 7, there exists an MH-1DFT $\tilde{A}_{L_i} = (\Sigma, \dashv, \{0,1\}, \kappa_i, \tilde{Q}^i, \tilde{q}^i_s, \tilde{Q}^i_F, \tilde{\delta}_i)$ computing the function t_{L_i}, for each $i \in [n]$. We define our MH-1DFT $\tilde{A} = (\Sigma, \dashv, \Gamma, \kappa, \tilde{Q}, \tilde{q}_s, \tilde{Q}_F, \tilde{\delta})$ simulating A as follows. We set the number of reading heads to $\kappa = 1 + \sum_{k=1}^{n} \kappa_i$ (the extra reading head is needed to simulate the actual step of A using its transition relation δ, in particular, to obtain the output word $\tilde{o} \in \Gamma^*$). The set of states is $\tilde{Q} = (Q \times (\tilde{Q}^1 \times \{\epsilon, 0, 1\}^2) \times \cdots \times (\tilde{Q}^n \times \{\epsilon, 0, 1\}^2)) \cup \{\tilde{q}_f\}$, where $\tilde{q}_f$ is a designated accepting state. The first component of a state $\tilde{q} \in \tilde{Q}$ stores the current simulated state $q = q_{i_j} \in Q$ of A. The $(i+1)$-th component of a state $\tilde{q} \in \tilde{Q}$ stores a tuple $(\tilde{q}^i, t_{i,j}, t_{i,j+1})$, where $\tilde{q}^i \in \tilde{Q}_i$ is a state of the MH-1DFT $\tilde{A}_{L_i}$, and $t_{i,j}$ and $t_{i,j+1}$ are the decision for the current and next suffix (or ϵ if they have not been computed yet). The initial state is $\tilde{q}_s = (q_s, (\tilde{q}^1_s, \epsilon, \epsilon), \ldots, (\tilde{q}^n_s, \epsilon, \epsilon))$. The set of accepting states is $\tilde{Q}_F = \{\tilde{q}_f\}$. The transition function $\tilde{\delta} : (\tilde{Q} \setminus \tilde{Q}_F) \times (\Sigma \cup \{\dashv\})^\kappa \to \tilde{Q} \times \Gamma^* \times \{0,1\}^\kappa$ is defined using pseudocode in Figure 6. We point out that the next simulated state $q_{j'}$ of A (Line 14 in Figure 6) needs not be unique and the MH-1DFT $\tilde{A}$ chooses (deterministically) an arbitrary state if it is not unique.

Recall that the only way for an MH-1DFT to reject an input is by getting stuck. In Figure 6, this is represented by the command "reject" (Lines 4 and 19). If the control flow reaches "reject", then the transition function is not defined for the respective input arguments.

```

Figure 6 The transition function $\tilde{\delta}$ of the MH-1DFT $\tilde{A}$.

The first reading head simulates the only reading head of the f-1NFT A. If it reads the right endmarker $\dashv$, then the computation is accepted if and only if the current simulated state q is accepting (Lines 2–4). Otherwise, the MH-1DFT $\tilde{A}$ performs a transition of an MH-1DFT $\tilde{A}_{L_i}$ for which either $t_{i,1}$ or $t_{i,2}$ have not been computed yet (Lines 5–8). The MH-1DFT $\tilde{A}$ maintains the invariant that one such unknown decision exists. Then it updates $t_{i,1}$, $t_{i,2}$ accordingly (Lines 9–11). The definition of the transition function $\tilde{\delta}_i$ (Figure 4) implies that at most a single Boolean decision is produced in each transition.

Once all the decisions $t_{i,1}$ and $t_{i,2}$ have been computed, a step of the f-1NFT A can be simulated (Lines 13–19). If there exists a transition from the current state $q = q_j$ to a new state $q_{j'}$ from which the next suffix is accepted by A, then it is taken (Lines 15–17). The decisions for the next suffix become the decisions for the current suffix and the decisions for the next suffix become unknown (Line 17). Otherwise, the input word is rejected (Line 19).

4.3 Proof of Correctness

To prove that the MH-1DFT $\tilde{A}$ simulates the f-1NFT A, we formulate an invariant on a configuration of $\tilde{A}$ that is satisfied by each configuration from a computation on an input word. For the accepting state $\tilde{q}_f$, the invariant merely states that the input word is accepted by A and the output is correct: $\mathcal{J}(w, o, \tilde{q}_f, ps) \equiv (w, o) \in L$ (D0).

For a state $(q, (\tilde{q}^1, t_{1,1}, t_{1,2}), \ldots, (\tilde{q}^n, t_{n,1}, t_{n,2})) \in \tilde{Q}$, the invariant captures the properties of a state mentioned previously. To express them, it uses the invariant $\mathcal{I}$ on the configurations of the MH-1DFT $\tilde{A}_{L_i}$. In addition, it guarantess the existence of the index i from Line 5 in Figure 6 and that the simulation does not get stuck after it successfully performs its first

step. We denote the positions of the reading heads belonging to $\tilde{A}_{L_i}$, $i \in [n]$, by ps^i.

$$\mathcal{J}(w, o, (q, (\tilde{q}^1, t_{1,1}, t_{1,2}), \ldots, (\tilde{q}^n, t_{n,1}, t_{n,2})), ps) \equiv (q_s, w[1..ps_1), q, o) \in \delta^* \wedge \tag{D1}$$

$$\forall i \in [n].\ \exists ts.\ (|ts| = ps_1 - 1 \wedge \mathcal{I}(w, ts \cdot t_{i_1} \cdot t_{i,2}, \tilde{q}^i, ps^i)) \wedge \tag{D2}$$

$$\exists i \in [n].\ (t_{i,1}, t_{i,2}) \notin \{0,1\}^2 \wedge \tag{D3}$$

$$(ps_1 > 1 \Longrightarrow \exists q_f \in Q_F.\ \exists o'.\ (q, w[ps_1..|w|], q_f, o') \in \delta^*) \tag{D4}$$

▶ **Lemma 9.** *For any input word w, the initial configuration of $\tilde{A}$ satisfies the invariant, i.e., $\mathcal{I}(w, \epsilon, (q_s, (\tilde{q}_s^1, \epsilon, \epsilon), \ldots, (\tilde{q}_s^n, \epsilon, \epsilon)), 1^\kappa)$ holds.*

Proof. The invariant follows directly from Lemma 5. ◀

▶ **Lemma 10.** *Let $c_1 = (w, o, (q, (\tilde{q}^1, t_{1,1}, t_{1,2}), \ldots, (\tilde{q}^n, t_{n,1}, t_{n,2})), ps)$ and $c_2 = (w, o', q', ps')$ be two configurations of $\tilde{A}$ such that $\mathcal{J}(c_1)$ holds and $(c_1, c_2) \in s^{\tilde{A}}$. Then $\mathcal{J}(c_2)$ holds.*

Proof. We refer to Line l in Figure 6 as Ll (e.g., L7 denotes Line 7). Furthermore, we refer to the i-th conjunct from $\mathcal{J}(c_1)$ and $\mathcal{J}(c_2)$ as Di and Di', respectively and to the i-th fact labeled in the proof as Fi. To derive that $\mathcal{J}(c_2)$ holds, we analyze the transition function $\tilde{\delta}$ in Figure 6.

If $es_1 = \dashv$, then $ps_1 = |w| + 1$ and D1 implies $(q_s, w[1..|w|], q, o) \in \delta^*$ (F1). The fact that a step from c_1 to c_2 was taken implies that $q \in Q_F$ (otherwise, the transition from c_1 would be undefined, due to L3–4). The fact F1 together with $q \in Q_F$ imply D0, i.e., $\mathcal{J}(c_2)$ holds as c_2 is accepting and thus $\mathcal{J}(c_2) \equiv (w, o) \in L \equiv$ D0.

Suppose that $es_1 \neq \dashv$. Conjunct D3 implies that the index from L5 is well-defined. Lines L5–11, Conjunct D2, and Lemma 6 imply D2' after L11. Furthermore, L16–17 imply D2' also if the branch L15–17 is reached. If the branch L13–19 is not reached, then D1, D4 immediately imply D1', D4', and L12 implies D3'. Otherwise, the branch L15–17 must be reached (otherwise, the transition from c_1 would be undefined, due to L19). Then Conjunct D1 and Lines L14–17 imply D1'. Furthermore, Lines L12 and L17 directly imply D3' (note that reaching L19 would make the transition from c_1 to c_2 undefined, which is a contradiction). Finally, Lines L13–14 and conjuncts D1–2 together with the definition of the invariant $\mathcal{I}$ imply D4'. ◀

▶ **Theorem 11.** *For any f-1NFT A, there exists an* equivalent MH-*1DFT $\tilde{A}$, i.e., both A and $\tilde{A}$ accept the same language.*

Proof. We again refer to Line l in Figure 6 as Ll. Let $L_{\tilde{A}}$ denote the language accepted by $\tilde{A}$. Let $c_1, c_2, \ldots, c_l$ be the computation of $\tilde{A}$ on an input word w. We refer to the i-th conjunct from $\mathcal{J}(c_l)$ as Di. Let o be the output of the computation of $\tilde{A}$ on w. Lemmas 9 and 10 imply that $\mathcal{J}(c_i)$ holds for all configurations c_i, $i \in [1..l]$.

If the computation is accepting (i.e., $(w, o) \in L_{\tilde{A}}$), then $\mathcal{J}(c_l)$ implies that $(w, o) \in L$. Moreover, since A is functional and $\tilde{A}$ deterministic, there exists no $o' \neq o$ such that $(w, o') \in L$ or $(w, o') \in L_{\tilde{A}}$. If the computation is rejecting, then the transition from c_l is undefined due to L4 or L19. If L4 is reached, then $ps_1 = 1$ (otherwise, D4 would imply $q \in Q_F$, which is a contradiction). With D1 and L2, this implies that $q = q_s$ and $w = \epsilon$. The facts that $q = q_s$, $w = \epsilon$, and $q \notin Q_F$ (due to L3–4) imply that the input word w is rejected by A (i.e., no $(w, o) \in L$). Moreover, no $(w, o) \in L_{\tilde{A}}$, since the deterministic computation of $\tilde{A}$ on w is rejecting.

If L19 is reached, then again $ps_1 = 1$ (otherwise, the branch L15–17 would have been taken by D4 and D2). Then L14 and D2 imply that the input word is rejected by A (i.e., no $(w, o) \in L$). Moreover, no $(w, o) \in L_{\tilde{A}}$, since the deterministic computation of $\tilde{A}$ on w is rejecting. ◀

5 Discussion and Related Work

We review results on the expressiveness of transducer models (as depicted in Figure 1) and connections to a practical application.

Expressiveness of Related Formalisms. It is well-known that neither nondeterminism nor a two-way reading head extends the expresiveness of a one-head finite-state automaton beyond the regular languages [7]. Formally, $\mathcal{L}(\text{1DFA}) = \mathcal{L}(\text{1NFA}) = \mathcal{L}(\text{2DFA}) = \mathcal{L}(\text{2NFA})$. But adding reading heads does make a difference: in fact, there is a strict hierarchy of languages accepted by finite-state automata when increasing the number of reading heads [10]. Formally, $\mathcal{L}(\text{2NFA}) \subsetneq \mathcal{L}(\text{MH-1DFA})$. By viewing a finite-state automaton as a functional finite-state transducer that does not produce any output, this further implies that $\mathcal{L}(\text{MH-1DFT}) \not\subseteq \mathcal{L}(f\text{-2NFT})$. Theorem 11 implies that $\mathcal{L}(f\text{-1NFT}) \subseteq \mathcal{L}(\text{MH-1DFT})$. This yields the proper inclusion $\mathcal{L}(f\text{-1NFT}) \subsetneq \mathcal{L}(\text{MH-1DFT})$.

Let us consider the function f that maps a non-empty binary word w to $0^{|w|}$, if w ends with a zero, and $1^{|w|}$, otherwise. The function f can be computed by the f-1NFT from Example 1. Nevertheless, f cannot be computed by a 1DFT. Intuitively, a 1DFT cannot start producing any output before seeing the last symbol of the input word; but it cannot remember the input word's length needed to produce the output. We conclude that the expressiveness of f-1NFTs strictly extends that of 1DFTs, i.e., $\mathcal{L}(\text{1DFT}) \subsetneq \mathcal{L}(f\text{-1NFT})$.

Now consider the function $w \mapsto w^R$ that maps a binary word to its reverse. It can be computed by a f-2NFT that first moves its reading head to the end of the input word and then reads the word backwards while outputting its symbols in the reversed order (in fact, this transducer behaves deterministically). Nevertheless, $w \mapsto w^R$ cannot be computed by a f-1NFT [5]. We conclude that the expressiveness of f-2NFTs strictly extends the expressiveness of f-1NFTs, i.e., $\mathcal{L}(f\text{-1NFT}) \subsetneq \mathcal{L}(f\text{-2NFT})$. Surprisingly, adding nondeterminism to functional two-way finite-state transducers does not extend their expressiveness [4], i.e., $\mathcal{L}(\text{2DFT}) = \mathcal{L}(f\text{-2NFT})$. We further conjecture that the function $w \mapsto w^R$ cannot be computed by a MH-1DFT either, and thus the languages accepted by MH-1DFT and 2DFT are incomparable.

We also conjecture that MH-1DFTs are closed under composition, i.e., whenever $f : X \to Y$ and $g : Y \to Z$ are computed by some MH-1DFTs, then there exists an MH-1DFT computing $g \circ f : X \to Z$. Such a composition result could give rise to a more modular construction of MH-1DFTs from f-1NFTs, which would recast our MH-1DFT from Figure 6 as a composition.

Monitoring. The use of MH-1DFT and all-suffix regular matching has applications to *monitoring* (also called *runtime verification*), which is the problem of checking the compliance of an event stream, at each position in the stream, to a policy formalized in a specification language. Our recent work [8] provides evidence that exploiting multiple one-way reading heads significantly improves the efficiency of monitoring policies formalized in metric temporal logic (MTL). Since MTL is less expressive than (timed) regular expressions [3], the monitor from [8] does not implement the proposed solution to all-suffix regular matching. Moreover, its underlying transducer's space complexity depends logarithmically on the input length.

6 Conclusion

We proposed multi-head finite-state transducers as a combination of multi-head finite-state automata and finite-state transducers. We showed that multiple one-way reading heads can replace nondeterminism on functions computable by finite-state transducers. The key insight is that multiple one-way reading heads suffice to solve the all-suffix regular matching problem.

As future work, we plan to use the MH-1DFT construction for all-suffix regular matching to implement an efficient monitor for timed regular expressions [1], which are strictly more expressive than metric temporal logic supported by our multi-head monitor [8]. The problem of all-suffix regular matching has already inspired another monitor of ours [2]. In that monitor, as soon as two past suffixes yield the same state of the automaton, the equivalence between them is output (namely, the monitor outputs that the positions associated with the suffixes will have the same verdict); outputting the actual Boolean value for the equivalent positions is postponed, potentially until the input's end. We envision designing an MH-1DFT that outputs an explicit Boolean value for each position in the input word in the order of their appearance.

Abstract

Transducers extend finite state automata with outputs, and describe transformations from strings to strings. Sequential transducers, which have a deterministic behaviour regarding their input, are of particular interest. However, unlike finite-state automata, not every transducer can be made sequential. The seminal work of Choffrut allows to characterise, amongst the functional one-way transducers, the ones that admit an equivalent sequential transducer.

In this work, we extend the results of Choffrut to the class of transducers that produce their output string by adding simultaneously, at each transition, a string on the left and a string on the right of the string produced so far. We call them the string-to-context transducers. We obtain a multiple characterisation of the functional string-to-context transducers admitting an equivalent sequential one, based on a Lipschitz property of the function realised by the transducer, and on a pattern (a new twinning property). Last, we prove that given a string-to-context transducer, determining whether there exists an equivalent sequential one is in coNP.

1 Introduction

Transducers are a fundamental model to describe programs manipulating strings. They date back to the very first works in theoretical computer science, and are already present in the pioneering works on finite state automata [25, 1]. While finite state automata are very robust w.r.t. modifications of the model such as non-determinism and two-wayness, this is not the case for transducers. These two extensions do affect the expressive power of the model. Non-determinism is a feature very useful for modelisation and specification purposes. However, when one turns to implementation, deriving a sequential, *i.e.* input-deterministic, transducer is a major issue. A natural and fundamental problem thus consists, given a (non-deterministic) transducer, in deciding whether there exists an equivalent sequential transducer. This problem is called the *sequentiality problem*.

In [12], Choffrut addressed this problem for the class of functional (one-way) finite state transducers, which corresponds to so-called *rational functions*. He proved a multiple characterisation of the transducers admitting an equivalent sequential transducer. This characterisation includes a machine-independent property, namely a Lipschitz property of the function realised by the transducer. It also involves a pattern property, namely the twinning property, that allows to prove that the sequentiality problem is decidable in polynomial

time for the class of functional finite state transducers [27]. This seminal work has led to developments on the sequentiality of finite state transducers [9, 8]. These results have also been extended to weighted automata [11, 22, 17] and to tree transducers [26]. See also [23] for a survey on sequentiality problems.

While the model of one-way transducers is now rather well-understood, a current challenge is to address the so-called class of *regular functions*, which corresponds to functions realised by two-way transducers. This class has attracted a lot of interest during the last years. It is closed under composition [13] and enjoys alternative presentations using logic [16], a deterministic one-way model equipped with registers, named streaming string transducers [2] (SST for short), a set of regular combinators akin to regular expressions for regular languages [5, 7, 14] as well as a class of functions operating on lists [10]. The class of regular functions is much more expressive than the class of rational functions, as it captures for instance the mirror image and the copy. Yet, it has good decidability properties: equivalence and type-checking are decidable in PSpace [21, 3], Similarly, functionality of non-deterministic SST is also decidable in PSpace [4]. We refer the interested reader to [19] for a recent survey. Intuitively, two-way finite state transducers (resp. SST) extend one-way finite state transducers with two important features: firstly, they can go through the input word both ways (resp. they can prepend and append words to registers), and secondly, they can perform multiple passes (resp. they can perform register concatenation).

In this paper, we lift the results of Choffrut [12] to a class of transducers that can perform the first of the two features mentioned above, thus falling strictly between the classes of rational and regular functions. More precisely, we consider non-deterministic transducers which, at each transition, extend the output word produced so far by prepending and appending two words to it. This operation can be defined as the extension of a word with a context, and we call these transducers the *string-to-context transducers*. However, it is important to notice that they still describe functions from strings to strings.

We characterise the functional string-to-context transducers that admit an equivalent *sequential* string-to-context transducer through i) a machine independent property: the function realised by the transducer satisfies a Lipschitz property that involves an original *factor distance* and ii) a pattern property of the transducer which we call *contextual twinning property*, and that generalises the twinning property to contexts. We also prove that the sequentiality problem for these transducers is in the class coNP.

A key technical tool of the result of [12] was a combinatorial analysis of the loops, showing that the output words of synchronised loops have conjugate primitive roots. For string-to-context transducers, the situation is more complex, as the combinatorics may involve the words of the two sides of the context. Intuitively, when these words do commute with the output word produced so far, it is possible for instance to move to the right a part of the word produced on the left. In order to prove our results, we thus dig into the combinatorics of contexts associated with loops, identifying different possible situations, and we then use this analysis to describe an original determinisation construction.

Our results also have a strong connection with the register minimisation problem for SST. This problem consists in determining, given an SST and a natural number k, whether there exists an equivalent SST with k registers. It has been proven in [15] that the problem is decidable for SST that can only append (and not prepend) words to registers, and the proof crucially relies on the fact that the $k = 1$ case exactly corresponds to the sequentiality problem of one-way finite state transducers. Hence, our results constitute a first step towards register minimisation for SST without register concatenation. The register minimisation problem for *non-deterministic* SST has also been studied in [6] for the case of concatenation-free SST. The targeted model being non-deterministic, the two problems are independent.

2 Models

Words, contexts and partial functions

Let A be a finite alphabet. The set of finite words (or strings) over A is denoted by A^*. The empty word is denoted by ϵ. The length of a word u is denoted by $|u|$. We say that a word u is a *prefix* (resp. *suffix*) of a word v if there exists a word y such that $uy = v$ (resp. $yu = v$). We say that two words $u, v \in A^*$ are *conjugates* if there exist two words $t_1, t_2 \in A^*$ such that $u = t_1 t_2$ and $v = t_2 t_1$. If this holds, we write $u \sim v$. The *primitive root* of a word $u \in A^*$, denoted $\rho(u)$, is the shortest word x such that $u = x^p$ for some $p \geqslant 1$. A word is said to be *primitive*, if it is equal to its primitive root. Given a word $u \in B^*$, we say that v is a *factor* of u if there exist words x, y such that $u = xvy$. For $n, m \in \mathbb{N}_{>0}$, we note by $\gcd(n, m)$ the greatest common divisor of n and m.

▶ **Lemma 1** (Fine and Wilf, [20], Chapter 9 of [24]). *Let $x, y \in A^*$ and $m, n \in \mathbb{N}$. If x^m and y^n have a common factor of length at least $|x| + |y| - \gcd(|x|, |y|)$, then their primitive roots are conjugates.*

Given two words $u, v \in A^*$, the *longest common prefix* (resp. *suffix*) of u and v is denoted by $\mathsf{lcp}(u, v)$ (resp. $\mathsf{lcs}(u, v)$). We define the *prefix distance* between u and v, denoted by $dist_p(u, v)$, as $|u| + |v| - 2|\mathsf{lcp}(u, v)|$.

Given two words $u, v \in B^*$, a *longest common factor* of u and v is a word w of maximal length that is a factor of both u and v. Note that this word is not necessarily unique. We denote such a word by $\mathsf{lcf}(u, v)$. The *factor distance* between u and v, denoted by $dist_f(u, v)$, is defined as $dist_f(u, v) = |u| + |v| - 2|\mathsf{lcf}(u, v)|$. This definition is correct as $|\mathsf{lcf}(u, v)|$ is independent of the choice of the common factor of maximal length.

Using a careful case analysis, we can prove that $dist_f$ is indeed a distance, the only difficulty lying in the subadditivity:

▶ **Lemma 2.** *$dist_f$ is a distance.*

Given a finite alphabet B, a *context* on B is a pair of words $(u, v) \in B^* \times B^*$. The set of contexts on B is denoted $\mathcal{C}(B)$. The empty context is denoted by c_ε. For a context $c = (u, v)$, we denote by $\overleftarrow{c}$ (resp. $\overrightarrow{c}$) its left (resp. right) component: $\overleftarrow{c} = u$ (resp. $\overrightarrow{c} = v$). The *length* of a context c is defined by $|c| = |\overleftarrow{c}| + |\overrightarrow{c}|$. The *lateralized length* of a context c is defined by $\|c\| = (|\overleftarrow{c}|, |\overrightarrow{c}|)$. For a context $c \in \mathcal{C}(B)$ and a word $w \in B^*$, we write $c[w]$ for the word $\overleftarrow{c}\, w\, \overrightarrow{c}$. We define the concatenation of two contexts $c_1, c_2 \in \mathcal{C}(B)$ as the context $c_1 c_2 = (\overleftarrow{c_1}\,\overleftarrow{c_2}, \overrightarrow{c_2}\,\overrightarrow{c_1})$. Last, given a context c and a word u, we denote by $c^{-1}[u]$ the unique word v such that $c[v] = u$, when such a word exists.

Given a set of contexts $C \subseteq \mathcal{C}(B)$, we denote by $\mathsf{lcc}(C)$ the longest common context of elements in C, defined as $\mathsf{lcc}(C) = (\mathsf{lcs}(\{\overleftarrow{c} \mid c \in C\}), \mathsf{lcp}(\{\overrightarrow{c} \mid c \in C\}))$. We also write $C.\mathsf{lcc}(C)^{-1} = \{c' \mid c'.\mathsf{lcc}(C) \in C\}$.

We consider two sets X, Y. Given $\Delta \subseteq X \times Y$, we let $\mathsf{dom}(\Delta) = \{x \in X \mid \exists y, (x, y) \in \Delta\}$. We denote the set of partial functions from X to Y as $\mathcal{F}(X, Y)$. Given $f \in \mathcal{F}(X, Y)$, we write $f : X \hookrightarrow Y$, and we denote by $\mathsf{dom}(f)$ its domain. When more convenient, we may also see elements of $\mathcal{F}(X, Y)$ as subsets of $X \times Y$. Last, given $\Delta \subseteq X \times Y$, we let $\mathsf{choose}(\Delta)$ denote some $\Delta' \in \mathcal{F}(X, Y)$ such that $\Delta' \subseteq \Delta$ and $\mathsf{dom}(\Delta) = \mathsf{dom}(\Delta')$.

String-to-Context and String-to-String Transducers

▶ **Definition 3.** *Let A, B be two finite alphabets. A string-to-context transducer (S2C for short) $\mathcal{T}$ from A^* to B^* is a tuple $(Q, t_{init}, t_{final}, T)$ where Q is a finite set of states, $t_{init} : Q \hookrightarrow \mathcal{C}(B)$ (resp. $t_{final} : Q \hookrightarrow \mathcal{C}(B)$) is the finite initial (resp. final) function, $T \subseteq Q \times A \times \mathcal{C}(B) \times Q$ is the finite set of transitions.*

A state q is said to be *initial* (*resp. final*) if $q \in \mathsf{dom}(t_{init})$ (resp. $q \in \mathsf{dom}(t_{final})$). We depict as $\xrightarrow{c} q$ (resp. $q \xrightarrow{c}$) the fact that $t_{init}(q) = c$ (resp. $t_{final}(q) = c$). A run ρ from a state q_1 to a state q_k on a word $w = w_1 \cdots w_k \in A^*$ where for all i, $w_i \in A$, is a sequence of transitions: $(q_1, w_1, c_1, q_2), (q_2, w_2, c_2, q_3), \ldots, (q_k, w_k, c_k, q_{k+1})$. The *output* of such a run is the context $c = c_k \ldots c_2 c_1 \in \mathcal{C}(B)$, and is denoted by $\mathsf{out}(\rho)$. We depict this situation as $q_1 \xrightarrow{w|c} q_{k+1}$. The set of runs of $\mathcal{T}$ is denoted $\mathcal{R}(\mathcal{T})$. The run ρ is said to be *accepting* if q_1 is initial and q_{k+1} final. This string-to-context transducer $\mathcal{T}$ computes a relation $[\![\mathcal{T}]\!] \subseteq A^* \times B^*$ defined by the set of pairs $(w, edc[\varepsilon])$ such that there are $p, q \in Q$ with $\xrightarrow{c} p \xrightarrow{w|d} q \xrightarrow{e}$. Thus, even if its definition involves contexts on B, the semantics of $\mathcal{T}$ is a relation between words on A and words on B. Given an S2C $\mathcal{T} = (Q, t_{init}, t_{final}, T)$, we define the constant $M_{\mathcal{T}}$ as $M_{\mathcal{T}} = \max\{|c| \mid (p, a, c, q) \in T \text{ or } (q, c) \in t_{init} \cup t_{final}\}$. Given $\Delta : Q \hookrightarrow \mathcal{C}(B)$, we denote by $\mathcal{T}_\Delta$ the S2C obtained by replacing t_{init} with Δ. An S2C is *trimmed* if each of its states appears in some accepting run. W.l.o.g., we assume that the string-to-context transducers we consider are trimmed. An S2C $\mathcal{T}$ from A^* to B^* is *functional* if the relation $[\![\mathcal{T}]\!]$ is a function from A^* to B^*. An S2C $\mathcal{T} = (Q, t_{init}, t_{final}, T)$ is *sequential* if $\mathsf{dom}(t_{init})$ is a singleton and if for every transitions $(p, a, c, q), (p, a, c', q') \in T$, we have $q = q'$ and $c = c'$.

The classical model of finite-state transducers is recovered in the following definition:

▶ **Definition 4.** *Let A, B be two finite alphabets. A string-to-context transducer $\mathcal{T} = (Q, t_{init}, t_{final}, T)$ is a string-to-string transducer (S2S for short) from A^* to B^* if, for all $(q, c) \in t_{init} \cup t_{final}$, $\overleftarrow{c} = \varepsilon$, and for all $(q, a, c, q') \in T$, $\overleftarrow{c} = \varepsilon$.*

Notations defined for S2C hold for classical transducers as is. For an S2S, we write $\xrightarrow{w} q$ (resp. $q \xrightarrow{w}$, and $q \xrightarrow{u|w} q'$) instead of $\xrightarrow{(\varepsilon,w)} q$ (resp. $q \xrightarrow{(\varepsilon,w)}$, and $q \xrightarrow{u|(\varepsilon,w)} q'$).

Given an S2C $\mathcal{T} = (Q, t_{init}, t_{final}, T)$, we define its *right S2S*, denoted $\overrightarrow{\mathcal{T}}$, as the tuple $(Q, \overrightarrow{t_{init}}, \overrightarrow{t_{final}}, \overrightarrow{T})$ where, for all $q \in Q$, $\overrightarrow{t_{init}}(q) = \overrightarrow{t_{init}(q)}$ and $\overrightarrow{t_{final}}(q) = \overrightarrow{t_{final}(q)}$, and, for all $(p, a, c, q) \in T$, $(p, a, \overrightarrow{c}, q) \in \overrightarrow{T}$. Its *left S2S* $\overleftarrow{\mathcal{T}}$ is defined similarly, and by applying the mirror image on its output labels.

▶ **Example 5.** Two examples of S2C (not realisable by S2S) are depicted on Figure 1.

(a) $\mathcal{T}_{mirror}$. **(b)** $\mathcal{T}_{partition}$.

Figure 1 1a Example of a S2C $\mathcal{T}_{mirror}$ computing the function $f_{mirror} : u_1 \ldots u_n \in \{a, b\}^* \mapsto u_n \ldots u_1$. 1b Example of a S2C $\mathcal{T}_{partition}$ computing the function $f_{partition} : u \in \{a, b\}^* \mapsto a^{|u|_a} b^{|u|_b}$.

3 Lipschitz and Twinning Properties

We recall the properties considered in [12], and the associated results.

▶ **Definition 6.** *We say that a function $f : A^* \hookrightarrow B^*$ satisfies the* Lipschitz property *if there exists $K \in \mathbb{N}$ such that $\forall u, v \in \mathsf{dom}(f), dist_p(f(u), f(v)) \leqslant K\, dist_p(u, v)$.*

▶ **Definition 7.** *We consider an S2S and $L \in \mathbb{N}$. Two states q_1 and q_2 are said to be L-*twinned *if for any two runs $\xrightarrow{w_1} p_1 \xrightarrow{u|x_1} q_1 \xrightarrow{v|y_1} q_1$ and $\xrightarrow{w_2} p_2 \xrightarrow{u|x_2} q_2 \xrightarrow{v|y_2} q_2$, where p_1 and p_2 are initial, we have for all $j \geqslant 0$, $dist_p(w_1 x_1 y_1^j, w_2 x_2 y_2^j) \leqslant L$. An S2S satisfies the* twinning property (TP) *if there exists $L \in \mathbb{N}$ such that any two of its states are L-twinned.*

▶ **Theorem 8** ([12]). *Let $\mathcal{T}$ be a functional S2S. The following assertions are equivalent:*
1. *there exists an equivalent sequential S2S,*
2. *$[\![\mathcal{T}]\!]$ satisfies the Lipschitz property,*
3. *$\mathcal{T}$ satisfies the twinning property.*

We present the adaptation of these properties to string-to-context transducers.

▶ **Definition 9.** *We say that $f : A^* \hookrightarrow B^*$ satisfies the* contextual Lipschitz property (CLip) *if there exists $K \in \mathbb{N}$ such that $\forall u, v \in \mathsf{dom}(f), dist_f(f(u), f(v)) \leqslant K\ dist_p(u, v)$.*

▶ **Definition 10.** *We consider an S2C and $L \in \mathbb{N}$. Two states q_1 and q_2 are said to be L-*contextually twinned *if for any two runs $\xrightarrow{c_1} p_1 \xrightarrow{u|d_1} q_1 \xrightarrow{v|e_1} q_1$ and $\xrightarrow{c_2} p_2 \xrightarrow{u|d_2} q_2 \xrightarrow{v|e_2} q_2$, where p_1 and p_2 are initial, we have for all $j \geqslant 0$, $dist_f(e_1^j d_1 c_1[\varepsilon], e_2^j d_2 c_2[\varepsilon]) \leqslant L$. An S2C satisfies the* contextual twinning property (CTP) *if there exists $L \in \mathbb{N}$ such that any two of its states are L-contextually twinned.*

4 Main Result

The main result of the paper is the following theorem, which extends to string-to-context transducers the characterisation of sequential transducers amongst functional ones.

▶ **Theorem 11.** *Let $\mathcal{T}$ be a functional S2C. The following assertions are equivalent:*
1. *there exists an equivalent sequential string-to-context transducer,*
2. *$[\![\mathcal{T}]\!]$ satisfies the contextual Lipschitz property,*
3. *$\mathcal{T}$ satisfies the contextual twinning property.*

Proof. The implications $1 \Rightarrow 2$ and $2 \Rightarrow 3$ are proved in Proposition 12 and Proposition 13 respectively. The implication $3 \Rightarrow 1$ is more involved, and is based on a careful analysis of word combinatorics of loops of string-to-context transducers satisfying the CTP. This analysis is summarised in Lemma 22 and used in Section 6 to describe the construction of an equivalent sequential S2C. ◀

▶ **Proposition 12.** *Let $\mathcal{T}$ be a sequential S2C realizing the function f. Then f satisfies the contextual Lipschitz property.*

Proof. We claim that f is context-Lipschitzian with coefficient $3M_{\mathcal{T}}$. Consider two input words u, v in the domain of f. If $u = v$, then the result is trivial. Otherwise, let $w = \mathsf{lcp}(u, v)$ and let $u = w.u'$, with $0 \leqslant |u'|$. Then we have $[\![\mathcal{T}]\!](u) = c_3 c_2 c_1[\epsilon]$ where c_1 is the context produced along w, c_2 the one produced along u', and c_3 is the final output context. Similarly, we can write (with $v = w.v'$, and $0 \leqslant |v'|$) $[\![\mathcal{T}]\!](v) = d_3 d_2 d_1[\epsilon]$. As $\mathcal{T}$ is sequential, we have $d_1 = c_1$. We also have $|c_3| \leqslant M_{\mathcal{T}}$, $|d_3| \leqslant M_{\mathcal{T}}$, $|c_2| \leqslant M_{\mathcal{T}}\ |u'|$ and $|d_2| \leqslant M_{\mathcal{T}}\ |v'|$. Finally, as $u \neq v$, we have $dist_p(u, v) = |u'| + |v'| \geqslant 1$ and we obtain:

$$dist_f(f(u), f(v)) \leqslant |c_3 c_2| + |d_3 d_2| \leqslant M_{\mathcal{T}}\ (2 + |u'| + |v'|) \leqslant 3M_{\mathcal{T}}\ dist_p(u, v)$$ ◀

▶ **Proposition 13.** *Let $\mathcal{T}$ be a functional S2C realizing the function f. If f satisfies the contextual Lipschitz property, then $\mathcal{T}$ satisfies the contextual twinning property.*

Proof. We consider an instance of the CTP and stick to the notations of Definition 10. We denote by n the number of states of $\mathcal{T}$. As $\mathcal{T}$ is trimmed, there exist runs $q_i \xrightarrow{w_i|f_i} r_i \xrightarrow{g_i}$, with $|w_i| \leqslant n$, for $i \in \{1, 2\}$. We consider the input words $\alpha_j = uv^j w_1$ and $\beta_j = uv^j w_2$, for all $j \geqslant 0$. We have, for every j, $dist_p(\alpha_j, \beta_j) \leqslant |w_1| + |w_2| \leqslant 2n$.

The following property of $dist_f$ can be proven using a case analysis:

Fact. For every $w, w' \in B^*$, $c, c' \in \mathcal{C}(B)$, we have $dist_f(w, w') \leqslant dist_f(c[w], c'[w']) + |c| + |c'|$.

As f is K context-Lipschitzian, for some fixed K, we obtain, for all j:

$$\begin{aligned} dist_f(e_1^j d_1 c_1[\varepsilon], e_2^j d_2 c_2[\varepsilon]) &\leqslant dist_f(g_1 f_1 e_1^j d_1 c_1[\varepsilon], g_2 f_2 e_2^j d_2 c_2[\varepsilon]) + 2(n+1)M_{\mathcal{T}} \\ &\leqslant dist_f(f(\alpha_j), f(\beta_j)) + 2(n+1)M_{\mathcal{T}} \\ &\leqslant K\, dist_p(\alpha_j, \beta_j) + 2(n+1)M_{\mathcal{T}} \leqslant 2Kn + 2(n+1)M_{\mathcal{T}} \end{aligned}$$ ◀

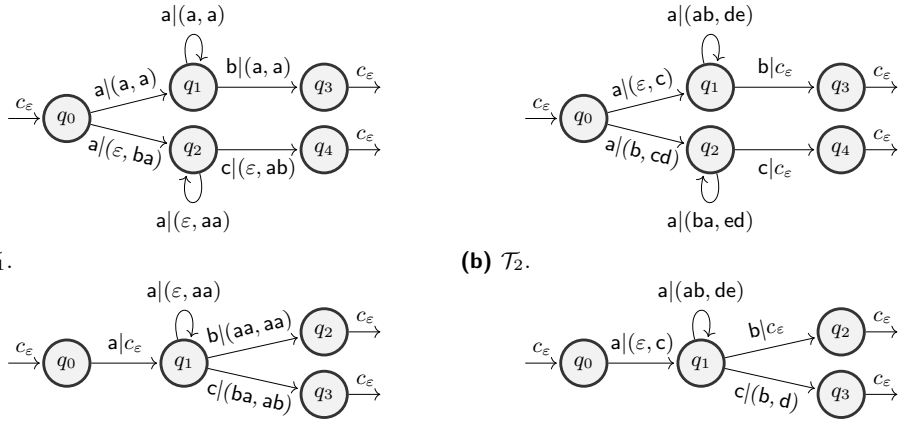
5 Analysis of Loop Combinatorics

The classical twinning property forces the outputs of two runs reading the same input to only diverge by a finite amount. This constraint in turn makes for strong combinatorial bindings between runs involving loops: for two runs $\xrightarrow{w_1} p_1 \xrightarrow{u|x_1} q_1 \xrightarrow{v|y_1} q_1$ and $\xrightarrow{w_2} p_2 \xrightarrow{u|x_2} q_2 \xrightarrow{v|y_2} q_2$, we have $|y_1| = |y_2|$, and $\rho(y_1) \sim \rho(y_2)$. Similar behaviours are expected with string-to-context transducers and lead us to study the combinatorial properties of synchronised runs involving loops in those machines. Throughout this section, we consider a string-to-context transducer $\mathcal{T} = (Q, t_{init}, t_{final}, T)$ that satisfies the contextual twinning property.

5.1 Behaviours of Loops

We start with two examples illustrating how output contexts of synchronised loops can be modified to obtain an equivalent sequential S2C.

▶ **Example 14.** Figure 2a shows an example of a non-sequential functional S2C transducer $\mathcal{T}_1$. The contexts produced on loops around states q_1 and q_2 both commute with word a. This observation can be used to build an equivalent sequential S2C $\mathcal{D}_1$, depicted on Figure 2c. Figure 2b shows an example of a non-sequential functional S2C transducer $\mathcal{T}_2$ where output contexts are non-commuting, but can be slightly shifted so as to be aligned. This observation can be used to build an equivalent sequential S2C $\mathcal{D}_2$, depicted on Figure 2d.



(a) $\mathcal{T}_1$. **(b)** $\mathcal{T}_2$. **(c)** $\mathcal{D}_1$. **(d)** $\mathcal{D}_2$.

Figure 2 2a An S2C $\mathcal{T}_1$ computing the function that maps $a^n b$ to a^{2n+2} and $a^n c$ to $ba^{2n}b$. 2c A sequential S2C $\mathcal{D}_1$ equivalent to $\mathcal{T}_1$. 2b An S2C $\mathcal{T}_2$ computing the function that maps $a^n b$ to $(ab)^{n-1}c(de)^{n-1}$ and $a^n c$ to $b(ab)^{n-1}c(de)^{n-1}d$. 2d A sequential S2C $\mathcal{D}_2$ equivalent to $\mathcal{T}_2$.

The following definition follows from the intuition drawn by the previous example.

▶ **Definition 15** (Lasso, Aligned/Commuting/Non-commuting lasso). *A lasso around a state q is a run ρ of the form $\xrightarrow{c} p \xrightarrow{u|d} q \xrightarrow{v|e} q$ with p an initial state. ρ is said to be productive, if $|e| \neq 0$. We say that ρ is:*

- *aligned w.r.t. f and w, for some $f \in \mathcal{C}(B)$ and $w \in B^*$, denoted as $(f,w)-$*aligned*, if there exists a context $g \in \mathcal{C}(B)$ such that for all $i \in \mathbb{N}$, $e^i dc[\varepsilon] = gf^i[w]$.*
- *commuting w.r.t. x, for some $x \in B^+$, denoted as $x-$*commuting*, if there exists a context $f \in \mathcal{C}(B)$ such that for all $i \in \mathbb{N}_{>0}$, there exists $k \in \mathbb{N}$ such that $e^i dc[\varepsilon] = f[x^k]$.*
- *non-commuting if there exists no word $x \in B^+$ such that ρ is commuting w.r.t x.*

Two lassos $\xrightarrow{c_1} p_1 \xrightarrow{u_1|d_1} q_1 \xrightarrow{v_1|e_1} q_1$ and $\xrightarrow{c_2} p_2 \xrightarrow{u_2|d_2} q_2 \xrightarrow{v_2|e_2} q_2$ are said to be synchronised if $u_1 = u_2$ and $v_1 = v_2$. They are said to be strongly balanced if $\|e_1\| = \|e_2\|$.

Given an integer $k \geqslant 1$, we consider the k-th power of $\mathcal{T}$, that we denote by $\mathcal{T}^k$. A run in $\mathcal{T}^k$ naturally corresponds to k synchronised runs in $\mathcal{T}$, *i.e.* on the same input word. We lift the notion of lasso to $\mathcal{T}^k$, and we denote them by H_1H_2, where H_1 starts in initial states and ends in some state $q = (q_i)_{i\in\{1,\dots,k\}} \in Q^k$, and H_2 is a loop around state q. In the sequel, we will only consider lassos such that q contains pairwise distinct states ($q_i \neq q_j$ for all $i \neq j$). Those lassos are included in the lassos in $\mathcal{T}^{\leqslant|Q|} = \cup_{1\leqslant k\leqslant|Q|}\mathcal{T}^k$.

The intuition given by Example 14 is formalised in the following Lemma:

▶ **Lemma 16.** *Let $H_1H_2 = (\rho_j)_{j\in\{1,\dots,k\}}$ a lasso in $\mathcal{T}^k$, for some $1 \leqslant k \leqslant |Q|$. We write $\rho_j : \xrightarrow{c_j} p_j \xrightarrow{u_1|d_j} q_j \xrightarrow{u_2|e_j} q_j$ for each j. Then there exists an integer $m \in \mathbb{N}$ such that $|e_j| = m$ for all $j \in \{1,\dots,k\}$. If $m > 0$, we say that the lasso H_1H_2 is productive, and:*

- *either there exists $x \in B^+$ primitive such that ρ_j is $x-$*commuting* for all $j \in \{1,\dots,k\}$. In this case, we say that the lasso H_1H_2 is $x-$*commuting*, and we let $\mathsf{pow}_c(x,H_1,H_2) = m/|x|$ and $\mathsf{split}_c(x,H_1,H_2) = \{(q_j,f_j) \mid j \in \{1,\dots,k\}\}$ where $f_j \in \mathcal{C}(B)$ is such that $\forall\alpha \in \mathbb{N}, e_j^\alpha d_j c_j[\varepsilon] = f_j[x^{\alpha\ \mathsf{pow}_c(x,H_1,H_2)}]$.*[1]
- *or there exist $f \in \mathcal{C}(B)$ and $w \in B^*$ such that ρ_j is non-commuting and $(f,w)-$*aligned* for all $j \in \{1,\dots,k\}$. In this case, we say that the lasso H_1H_2 is $(f,w)-$*aligned*, and we let $\mathsf{split}_{nc}(f,w,H_1,H_2) = \{(q_j,g_j) \mid j \in \{1,\dots,k\}\}$ where $g_j \in \mathcal{C}(B)$ is such that $\forall\alpha \in \mathbb{N}, e_j^\alpha d_j c_j[\varepsilon] = g_j f^\alpha[w]$.*[1]

Proof Sketch. As $\mathcal{T}$ satisfies the CTP, the outputs must grow at the same pace when the loops are pumped. This entails that the lengths of the e_j must be equal. Next, the result is proved by considering two productive synchronised lassos, with loops producing respectively e_1 and e_2. If they are not strongly balanced or one of them is $x-$commuting, for some $x \in B^+$, then, using the result of Fine and Wilf (Lemma 1) between $\overleftarrow{e_1}, \overleftarrow{e_2}, \overrightarrow{e_1}$ and $\overrightarrow{e_2}$, we can prove that the other one is also $x-$commuting. Otherwise, they are both non-commuting and strongly balanced. Using again Lemma 1 but first between $\overleftarrow{e_1}$ and $\overleftarrow{e_2}$, and then between $\overrightarrow{e_1}$ and $\overrightarrow{e_2}$, we prove that there exist $f \in \mathcal{C}(B)$ and $w \in B^*$ such that ρ_1 and ρ_2 are $(f,w)-$aligned. Finally, the result is lifted to k productive synchronised lassos. ◀

▶ **Example 17.** We consider the example S2C in Figure 2. The lasso in $\mathcal{T}_1^2$ around (q_1,q_2) is $\mathsf{a}-$commuting. We can compute a pow_c of 2 and $\{(q_1,(\mathsf{a},\mathsf{a})),(q_2,(\mathsf{b},\mathsf{a}))\}$ as a possible split_c. The lasso in $\mathcal{T}_2^2$ around (q_1,q_2) is $((\mathsf{ab},\mathsf{de}),\mathsf{c})-$aligned. We can compute $\{(q_1,c_\varepsilon),(q_2,(\mathsf{b},\mathsf{d}))\}$ as a possible split_{nc}.

[1] Because we only consider lassos around pairwise distinct states, both $\mathsf{split}_c(x,H_1,H_2)$ and $\mathsf{split}_{nc}(f,w,H_1,H_2)$ are partial functions from Q to $\mathcal{C}(B)$.

5.2 Analysis of Loops Consecutive to a Productive Loop

Consider a run that contains two consecutive productive loops. We can observe that the type (commuting or non-commuting) of the lasso involving the first loop impacts the possible types of the lasso involving the second loop. For instance, it is intuitive that a non-commuting lasso cannot be followed by a commuting lasso. Similarly, an $x-$commuting lasso cannot be followed by a $y-$commuting lasso, if x and y are not conjugates. We will see that loops following a first productive loop indeed satisfy stronger combinatorial properties. The following definition characterises their properties.

▶ **Definition 18** (Strongly commuting/Strongly aligned lasso). *Let ρ be a productive lasso $\xrightarrow{c} p \xrightarrow{u|d} q \xrightarrow{v|e} q$ and $x \in B^+$. We say that ρ is:*

- *strongly commuting w.r.t. x, denoted as* strongly$-x-$commuting*, if there exists a context $f \in \mathcal{C}(B)$ such that for all $i, j \in \mathbb{N}_{>0}$, there exists $k \in \mathbb{N}$ such that $e^i dc[x^j] = f[x^k]$.*
- *strongly aligned w.r.t. g, f and x, denoted as* strongly$-(g,f,x)-$aligned*, if there exists a context $h \in \mathcal{C}(B)$ such that for all $i, j \in \mathbb{N}$, $e^j dc[x^i] = hg^j f[x^i]$.*

The following Lemma states the properties of a lasso consecutive to a commuting lasso. To prove it, we proceed as for Lemma 16 by proving the result first for two runs and then lifting it to k runs. The case of two runs is obtained by distinguishing whether they are strongly balanced or not, and using Lemma 1.

▶ **Lemma 19.** *Let H_1H_2 a productive $x-$*commuting *lasso in $\mathcal{T}^{\leqslant |Q|}$, for some $x \in B^+$. Let $\Delta = \mathsf{split}_c(x, H_1, H_2)$ and $H_3H_4 = (\rho_j)_{j\in\{1,\dots,k\}}$ a productive lasso in $\mathcal{T}^k_\Delta$, for some $1 \leqslant k \leqslant |Q|$. We write $\rho_j : \xrightarrow{c_j} p_j \xrightarrow{u_1|d_j} q_j \xrightarrow{u_2|e_j} q_j$ for each j. Then:*

- *either every ρ_j is* strongly$-x-$commuting*: we say that H_3H_4 is* strongly$-x-$commuting*,*
- *or there exist $g, h \in \mathcal{C}(B)$ such that every ρ_j is* strongly$-(h,g,x)-$aligned*. In this case, we say that H_3H_4 is* strongly$-(h,g,x)-$aligned *and we let $\mathsf{extract}_{nc}(h, g, x, \Delta, H_3, H_4) = \{(q_j, h_j) \mid j \in \{1, \dots, k\}\}$ where $h_j \in \mathcal{C}(B)$ is s.t. $\forall \alpha, \beta \in \mathbb{N}, e_j^\alpha d_j c_j[x^\beta] = h_j h^\alpha g[x^\beta]$.*

The following Lemma states that once a non-commuting loop is encountered, then the alignment of production is fixed, *i.e.* no transfer between left and right productions is possible anymore. Hence, the left and right S2S derived from the S2C both satisfy the twinning property:

▶ **Lemma 20.** *Let H_1H_2 be a productive non-commuting lasso that is either*

- *$(f,w)-$*aligned *in $\mathcal{T}^{\leqslant |Q|}$, for some $f \in \mathcal{C}(B)$ and $w \in B^*$, and $\Delta' = \mathsf{split}_{nc}(f, w, H_1, H_2)$,*
- *or* strongly$-(g,f,x)-$aligned *in $\mathcal{T}^{\leqslant |Q|}_\Delta$, for some $g, f \in \mathcal{C}(B)$ and $\Delta \in \mathcal{F}(Q, \mathcal{C}(B))$, and $\Delta' = \mathsf{extract}_{nc}(g, f, x, \Delta, H_1, H_2)$.*

Then $\overleftarrow{\mathcal{T}_{\Delta'}}$ and $\overrightarrow{\mathcal{T}_{\Delta'}}$ both satisfy the twinning property.

5.3 A Two-loop Pattern Property

The following 2-loop property summarises the combinatorial properties of the synchronised runs involving loops in string-to-context transducers that satisfy the CTP.

▶ **Definition 21** (2-loop property). *Given four runs H_1, H_2, H_3, H_4 in $\mathcal{T}^{\leqslant |Q|}$, such that H_1H_2 and $(H_1H_3)H_4$ are lassos in $\mathcal{T}^{\leqslant |Q|}$, we say that they satisfy the 2-loop property if:*

1. *H_1H_2 is*
   - **a.** *either non productive,*
   - **b.** *or productive and $x-$*commuting*, for some $x \in B^+$,*
   - **c.** *or productive, non-commuting and $(f,w)-$*aligned*, for some $f \in \mathcal{C}(B)$ and $w \in B^*$.*

2. *if* H_1H_2 *is productive and* $x-$commuting*, we let* $\Delta = \mathsf{split}_c(x, H_1, H_2)$*, then* H_3H_4 *is a lasso in* $\mathcal{T}_\Delta^{\leqslant |Q|}$*. If productive then it is:*
   a. *either* strongly$-x-$commuting*,*
   b. *or non-commuting and* strongly$-(h, g, x)-$aligned*, for some* $g, h \in \mathcal{C}(B)$*. We let* $\Delta' = \mathsf{extract}_{nc}(h, g, x, \Delta, H_3, H_4)$*, then* $\overleftarrow{\mathcal{T}_{\Delta'}}$ *and* $\overrightarrow{\mathcal{T}_{\Delta'}}$ *both satisfy the twinning property.*
3. *if* H_1H_2 *is productive, non-commuting and* $(f, w)-$aligned*, we let* $\Delta = \mathsf{split}_{nc}(f, w, H_1, H_2)$*, then* $\overleftarrow{\mathcal{T}_\Delta}$ *and* $\overrightarrow{\mathcal{T}_\Delta}$ *both satisfy the twinning property.*

A string-to-context transducer $\mathcal{T}$ *is said to satisfy the 2-loop property if for all runs* H_1, H_2, H_3, H_4 *as above, they satisfy the 2-loop property.*

As a consequence of Lemmas 16, 19 and 20, we have:

▶ **Lemma 22.** *If an S2C* $\mathcal{T}$ *satisfies the CTP then it satisfies the 2-loop property.*

6 Determinisation

Throughout this section, we consider a string-to-context transducer $\mathcal{T} = (Q, t_{init}, t_{final}, T)$ from A^* to B^* that satisfies the 2-loop property. Intuitively, our construction stores the set of possible runs of $\mathcal{T}$, starting in an initial state, on the input word read so far. These runs are incrementally simplified by erasing synchronised loops, and by replacing a prefix by a partial function $\Delta : Q \hookrightarrow \mathcal{C}(B)$. These simplifications are based on the 2-loop property.

Observation. It is worth noticing that, as $\mathcal{T}$ is functional, if two runs reach the same state, it is safe to keep only one of them. This allows us to maintain a set of at most $|Q|$ runs.

Notations. Given $\Delta \in \mathcal{F}(Q, \mathcal{C}(B))$, $c \in \mathcal{C}(B)$, $w \in B^*$, $a \in A$ and $H \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})$, we define the following notations and operations:

- $\Delta c = \{(q, dc) \mid (q, d) \in \Delta\}$,
- $\Delta[w] = \{(q, d[w]) \mid (q, d) \in \Delta\}$,
- $\Delta \bullet a = \mathsf{choose}(\{(q', dc) \mid (q, c) \in \Delta \text{ and } q \xrightarrow{a|d} q'\})$,
- $H \bullet a \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})$ is the run obtained by extending runs of H with consecutive transitions of $\mathcal{T}$ associated with input symbol a, and by eliminating runs so as to ensure that runs reach pairwise distinct states of $\mathcal{T}$,
- $\Delta \bullet H = \mathsf{choose}(\{(q', dc) \mid (q, c) \in \Delta \text{ and there is a run } \rho : q \xrightarrow{x|d} q' \in H\})$,
- $id_\Delta = (q_i)_{1 \leqslant i \leqslant k} \in \mathcal{R}(\mathcal{T}^k)$, for some enumeration $\{q_1, \ldots, q_k\}$ of $\mathsf{dom}(\Delta)$.

Construction. We define an equivalent deterministic string-to-context transducer $\overline{\mathcal{D}} = (\overline{Q}, \overline{t_{init}}, \overline{t_{final}}, \overline{T})$, and we denote by $\mathcal{D}$ its trim part. While $\overline{\mathcal{D}}$ may have infinitely many states, we will prove that $\mathcal{D}$ is finite. Formally, we define $\overline{Q} = \overline{Q}_{\mathsf{start}} \uplus \overline{Q}_{\mathsf{com}} \uplus \overline{Q}_{\neg\mathsf{com}}$ where:

- $\overline{Q}_{\mathsf{start}} = \{(\varepsilon, t_{init}, H) \mid H \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})\}$
- $\overline{Q}_{\mathsf{com}} = \{(x, \Delta, H) \mid x \in B^+, \Delta \in \mathcal{F}(Q, \mathcal{C}(B)), H \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})\}$
- $\overline{Q}_{\neg\mathsf{com}} = \{(\bot, \Delta, id_\Delta) \mid \Delta \in \mathcal{F}(Q, \mathcal{C}(B))\}$.

By definition, we have $\overline{Q} \subseteq (B^* \cup \{\bot\}) \times \mathcal{F}(Q, \mathcal{C}(B)) \times \mathcal{R}(\mathcal{T}^{\leqslant |Q|}) = \overline{Q}_\infty$. Given $\overline{q} = (x, \Delta, H) \in \overline{Q}_\infty$, we let $\Delta_{\overline{q}} = \Delta \bullet H \in \mathcal{F}(Q, \mathcal{C}(B))$. An invariant of our construction is that every starting state of a run in H belongs to $\mathsf{dom}(\Delta)$.

Intuitively, the semantics of a state $\overline{q} = (x, \Delta, H) \in \overline{Q}$ can be understood as follows: x is used to code the type of state ($\overline{Q}_{\mathsf{start}}$, $\overline{Q}_{\mathsf{com}}$ or $\overline{Q}_{\neg\mathsf{com}}$), and Δ and H are used to represent the runs that remain to be executed to faithfully simulate the runs of $\mathcal{T}$ on the input word u read so far. As we have seen in the previous section, loops may either be commuting, allowing to shift some parts of the output from one side of the context to the other side, or they are non-commuting, and then should be aligned, forbidding such modifications. Intuitively, states in $\overline{Q}_{\mathsf{start}}$ correspond to situations in which no productive loop has been encountered yet. States in $\overline{Q}_{\mathsf{com}}$ (with $x \in B^+$) correspond to situations in which only x-commuting loops have been encountered. States in $\overline{Q}_{\neg\mathsf{com}}$ correspond to situations in which a non-commuting loop has been encountered. A representation of $\mathcal{D}$ is given in Figure 3.

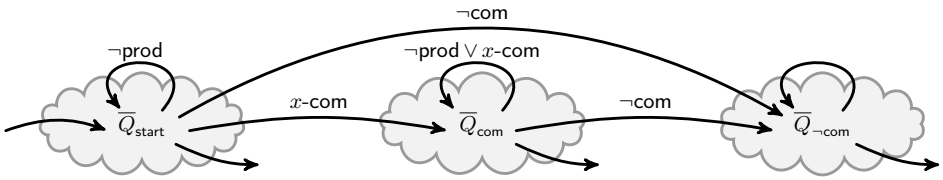


Figure 3 A schematic representation of states and transitions of $\mathcal{D}$.

Initial and final states. They are defined as follows:

- $\overline{t_{init}} = \{(\overline{i}, c_\varepsilon)\}$ where $\overline{i} = (\varepsilon, t_{init}, id_{t_{init}}) \in \overline{Q}_{\mathsf{start}}$
- $\overline{t_{final}} = \mathsf{choose}(\{(\overline{q}, dc) \mid \overline{q} \in \overline{Q}, (p, c) \in \Delta_{\overline{q}}, (p, d) \in t_{final}\})$

Transitions. They are defined as follows:

- $\overline{\mathcal{D}} = \{\overline{p} \xrightarrow{a|c} \overline{q} \mid \overline{p} = (x, \Delta, H) \in \overline{Q}, a \in A \text{ and } (\overline{q}, c) = \textsc{simplify}((x, \Delta, H \bullet a))\}$

Intuitively, a transition of $\overline{\mathcal{D}}$ leaving some state $\overline{p} = (x, \Delta, H) \in \overline{Q}$ with letter $a \in A$ aims at first extending H with a, obtaining the new set of runs $H \bullet a$, and then simplifying this set of runs by removing loops, using the function SIMPLIFY. This function is implemented as Algorithm 2, which calls Algorithm 1 to remove all loops of $H \bullet a$ one by one. Depending on the type of the loop encountered, the type of the state is updated.

We first define EXTEND_WITH_LOOP$(\overline{p}, H_2)$ in Algorithm 1 that takes as input a state $\overline{p} = (x, \Delta, H_1) \in \overline{Q}_{\mathsf{start}} \cup \overline{Q}_{\mathsf{com}}$ and a run H_2 in $\mathcal{T}^{\leqslant |Q|}$ such that $H_1 H_2$ is a lasso in $\mathcal{T}_\Delta^{\leqslant |Q|}$. The algorithm enumerates the possible cases for the type of this lasso, depending on the type of $\overline{p}$. This enumeration strongly relies on the 2-loop property. Depending on the case, the loop is processed, and a pair composed of a new state and a context is returned. This context will be part of the output associated with the transition. By a case analysis, we prove:

▶ **Lemma 23.** *Let $\overline{p} = (x, \Delta, H_1) \in \overline{Q}_{start} \cup \overline{Q}_{com}$ and $H_2 \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})$ such that $H_1 H_2$ is a lasso in $\mathcal{T}_\Delta^{\leqslant |Q|}$. We let $(\overline{q}, c) =$ EXTEND_WITH_LOOP$(\overline{p}, H_2)$.*

- *If $x = \varepsilon$ then $(\Delta_{\overline{p}} \bullet H_2)[\varepsilon] = \Delta_{\overline{q}} c[\varepsilon]$.*
- *If $x \in B^+$ then for all $k \in \mathbb{N}$, $(\Delta_{\overline{p}} \bullet H_2)[x^k] = \Delta_{\overline{q}} c[x^k]$.*

We then define SIMPLIFY$(\overline{p})$ in Algorithm 2 that takes as input a state $\overline{p} \in \overline{Q}_\infty$ (we need to consider $\overline{Q}_\infty$ as input and not only $\overline{Q}$ because of the recursive calls) and returns a pair composed of a new state and a context. Intuitively, it recursively processes the lassos present in the runs stored by the state $\overline{p}$, by using calls to the previous algorithm. The following result is proved by induction, using Lemma 23:

Algorithm 1 Extending a state $\overline{p} = (x, \Delta, H_1) \in \overline{Q}_{\mathsf{start}} \cup \overline{Q}_{\mathsf{com}}$ with $H_2 \in \mathcal{R}(\mathcal{T}^{\leqslant |Q|})$ s.t. H_1H_2 is a lasso in $\mathcal{T}_\Delta^{\leqslant |Q|}$.

1: **function** EXTEND_WITH_LOOP($\overline{p}, H_2$)
2: **if** H_2 is non-productive **then**
3: **return** $(\overline{p}, c_\varepsilon)$
4: **else if** $\overline{p} = (\varepsilon, t_{init}, H_1)$ **then**
5: **if** H_1H_2 is $x-$commuting, for some $x \in B^+$, **then**
6: **let** $\Delta = \mathsf{split}_c(x, H_1, H_2)$ and $k = \mathsf{pow}_c(x, H_1, H_2)$
7: **return** $((x, \Delta, id_\Delta), (\varepsilon, x^k))$
8: **else if** H_1H_2 is $(f, w)-$aligned, for some $f \in \mathcal{C}(B)$ and $w \in B^*$, **then**
9: **let** $\Delta = \mathsf{split}_{nc}(f, w, H_1, H_2)$
10: **return** $((\bot, \Delta, id_\Delta), f \cdot (\varepsilon, w))$
11: **end if**
12: **else if** $\overline{p} = (x, \Delta_0, H_1)$, where $x \in B^+$, **then**
13: **if** H_1H_2 is strongly$-x-$commuting **then**
14: **let** $k = |\mathsf{out}(H_2)|/|x|$
15: **return** $(\overline{p}, (\varepsilon, x^k))$
16: **else if** H_1H_2 is strongly$-(g, f, x)-$aligned, for some $g, f \in \mathcal{C}(B)$, **then**
17: **let** $\Delta = \mathsf{extract}_{nc}(g, f, x, \Delta_0, H_1, H_2)$
18: **return** $((\bot, \Delta, id_\Delta), gf)$
19: **end if**
20: **end if**
21: **end function**

▶ **Lemma 24.** *Let $\overline{p} = (x, \Delta, H) \in \overline{Q}_\infty$ and $(\overline{q}, c) = \text{SIMPLIFY}(\overline{p})$. Then $\overline{q} \in \overline{Q}$ and we have:*

- *If $x = \varepsilon$ then $\Delta_{\overline{p}}[\varepsilon] = \Delta_{\overline{q}}c[\varepsilon]$.*
- *If $x \in B^+$ then for all $k \in \mathbb{N}$, $\Delta_{\overline{p}}[x^k] = \Delta_{\overline{q}}c[x^k]$.*
- *If $x = \bot$ then $\Delta_{\overline{p}} = \Delta_{\overline{q}}c$.*

▶ **Theorem 25.** *$\mathcal{D}$ is a finite sequential string-to-context transducer equivalent to $\mathcal{T}$.*

Proof Sketch. First observe that $\mathcal{D}$ is sequential. The correctness of $\mathcal{D}$ is a consequence of the following property, that we prove using Lemma 24 and an induction on $|u|$: for all $u \in A^*$, if we have $\overline{i} \xrightarrow{u|c} \overline{q}$ in $\mathcal{D}$, then $\Delta_{\overline{q}}c[\varepsilon] = (t_{init} \bullet u)[\varepsilon]$. Last, we prove that $\mathcal{D}$ is finite. By construction, for every state $\overline{q} = (x, \Delta, H)$ of $\mathcal{D}$, H contains no loop, hence its length is bounded by $|Q|^{|Q|}$. This can be used to bound the size of x, as well as the size of Δ, for states in $\overline{Q}_{\mathsf{start}} \cup \overline{Q}_{\mathsf{com}}$. The case of states in $\overline{Q}_{\neg\mathsf{com}}$ is different: when such a state $(\bot, \Delta, id_\Delta)$ is reached, then by the 2-loop property, the transducers $\overleftarrow{\mathcal{T}_\Delta}$ and $\overrightarrow{\mathcal{T}_\Delta}$ both satisfy the (classical) twinning property. It remains to observe that the operations performed on Line 24 precisely correspond to two determinisations of [12], on both sides of the S2C. ◀

7 Decision

In this section, we prove the following result:

▶ **Theorem 26.** *Given a string-to-context transducer, determining whether there exists an equivalent sequential string-to-context transducer is in coNP.*

Algorithm 2 Simplifying a state $\overline{p} = (x, \Delta, H) \in \overline{Q}_\infty$.

22: **function** SIMPLIFY($\overline{p}$)
23: **if** $\overline{p} = (\bot, \Delta, H)$ **then**
24: **let** $\Delta' = \Delta \bullet H$, $c = \mathsf{lcc}(\Delta')$ and $\overline{q} = (\bot, \Delta'.c^{-1}, id_{\Delta'})$
25: **return** $(\overline{q}, c)$
26: **else if** $\overline{p} = (x, \Delta, H_1H_2H_3)$, where $x \in B^*$ and H_2 is the first loop in H, **then**
27: **let** $\overline{q} = (x, \Delta, H_1)$
28: **let** $(\overline{r}, c) =$ EXTEND_WITH_LOOP$(\overline{q}, H_2)$ with $\overline{r} = (x', \Delta', H')$
29: **let** $(\overline{s}, d) =$ SIMPLIFY$((x', \Delta', H'.H_3))$
30: **return** $(\overline{s}, dc)$
31: **else**
32: **return** $(\overline{p}, c_\varepsilon)$
33: **end if**
34: **end function**

In order to show this result, we introduce a restriction of the 2-loop property:

▶ **Definition 27** (small-2-loop property). *A string-to-context transducer $\mathcal{T}$ is said to satisfy the small-2-loop property if, for all runs $H_1, H_2, H_3, H_4 \in \mathcal{T}^2$ with $|H_i| \leqslant |Q|^2$ for each i, H_1H_2, $H_1H_3H_4$ are lassos and they satisfy the 2-loop property (in the sense of Definition 21).*

By definition, if a string-to-context transducer satisfies the 2-loop property then it also satisfies the small-2-loop property. We will show that the two properties are equivalent.

▶ **Lemma 28.** *If a string-to-context transducer $\mathcal{T}$ satisfies the small-2-loop property then $[\![\mathcal{T}]\!]$ satisfies the contextual Lipschitz property.*

Proof Sketch. We claim there exists $K \in \mathbb{N}$ such that for every pair of synchronised runs $H : \xrightarrow{(c_0,d_0)} (p_0, q_0) \xrightarrow{u|(c_1,d_1)} (p_1, q_1)$ in $\mathcal{T}^2$, we have $dist_f(c_1c_0[\varepsilon], d_1d_0[\varepsilon]) \leqslant K$. The result then easily follows. To prove this claim, we apply the main procedure SIMPLIFY (see Section 6) to the state $\overline{p} = (\varepsilon, t_{init}, H)$. This procedure can indeed be applied: as it always processes the *first* loop (see Line 29), the lassos considered satisfy the premises of the small-2-loop property. The claim follows from the proof of finiteness of $\mathcal{D}$. ◀

Proof Sketch of Theorem 26. By Theorem 11 and Lemma 28, $\mathcal{T}$ admits an equivalent sequential S2C transducer iff $\mathcal{T}$ satisfies the small-2-loop property (see also Figure 4). Thus, we describe a procedure to decide whether $\mathcal{T}$ satisfies the small-2-loop property.

The procedure first non-deterministically guesses a counter-example to the small-2-loop property and then verifies that it is indeed a counter-example. By definition of the small-2-loop property, the counter-example can have finitely many shapes. Those shapes require the verification of the properties of the involved lassos: being productive or not, being commuting or not, being aligned or not, satisfying the (classical) twinning property, etc.

Verifying that a lasso in $\mathcal{T}^2$ is not commuting (resp. not aligned) boils down to checking whether there exists no $x \in B^+$ such that the lasso is $x-$commuting (resp. no $f \in \mathcal{C}(B)$ and $w \in B^*$ such that the lasso is $(f, w)-$aligned). In both cases, the search space for the words x, w and context f can be narrowed down to factors of the output contexts of the given lasso. Thus these verifications can be done in polynomial time. The classical twinning property can also be checked in polynomial time. As a summary, we can show that the verifications for all the shapes can be done in polynomial time. Furthermore, all the shapes are of polynomial size, by definition of the small-2-loop property, yielding the result. ◀

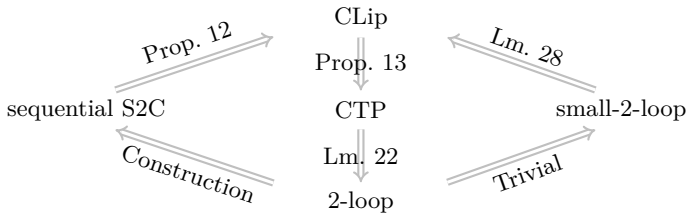

Figure 4 Overview of the equivalent properties we consider.

Note that if one can express in the logic of [18] that a lasso in $\mathcal{T}^2$ is not commuting (resp. not aligned), then this would show that the problem can be solved in polynomial time. However, this seems difficult because of the universal quantification on the factor x.

8 Conclusion

We have proposed a multiple characterisation of string-to-context transducers that admit an equivalent sequential S2C, including a machine independent property, a pattern property, as well as a "small" pattern property allowing to derive a decision procedure running in non-deterministic polynomial time. All these equivalences are summarised in Figure 4. Future work includes a lower bound for the complexity of the problem, the extension of this work to the register minimisation problem for streaming string transducers without register concatenation, and the extension of our results to infinite words.

The Parametric Complexity of Lossy Counter Machines

Sylvain Schmitz
LSV, ENS Paris Saclay & CNRS, Université Paris-Saclay, France
IUF, France
sylvain.schmitz@lsv.fr

Abstract

The reachability problem in lossy counter machines is the best-known ACKERMANN-complete problem and has been used to establish most of the ACKERMANN-hardness statements in the literature. This hides however a complexity gap when the number of counters is fixed. We close this gap and prove F_d-completeness for machines with d counters, which provides the first known uncontrived problems complete for the fast-growing complexity classes at levels $3 < d < \omega$. We develop for this an approach through antichain factorisations of bad sequences and analysing the length of controlled antichains.

2012 ACM Subject Classification Theory of computation → Computational complexity and cryptography

1 Introduction

Mayr and Meyer exhibited in 1981 "the first uncontrived decidable problems which are not primitive-recursive," namely the finite containment and equality problems in Petri nets [31]. McAloon [33], Clote [8], and Howell and Yen [23] subsequently proved Ackermannian upper bounds for these two problems, essentially matching Mayr and Meyer's lower bound.

Such an astronomical complexity could have been an isolated phenomenon with only a few examples related to the original problems, but uncontrived problems with a similar complexity actually occur in logic (e.g., relevance logic [47], data logics [11, 15], interval temporal logic [35], linear logic [28], metric temporal logic [27]), verification (e.g., counter machines [43, 22], fragments of the π-calculus [4], broadcast protocols [42], rewriting systems [20], register automata [11, 17]), and games (e.g., partial observation energy games [36], bisimulation games on pushdown automata [24]), and even higher complexities also occur naturally [29, 6, 37, 19, 18, 10]; see [38, Sec. 6] for an overview.

This abundance of results is largely thanks to a framework [41, 42, 39] that comprises:

- The definition of an ordinal-indexed hierarchy $(\mathsf{F}_\alpha)_\alpha$ of *fast-growing complexity classes*, along with assorted notions of reductions and completeness suitable to work with such high complexities [38]. The previous decision problems are complete for $\mathsf{ACKERMANN} = \mathsf{F}_\omega$ under primitive-recursive reductions; F_ω is the lowest non primitive-recursive class in the hierarchy, where $\mathsf{TOWER} = \mathsf{F}_3$ corresponds to problems solvable in time bounded by a tower of exponentials and where each F_k for a finite k is primitive-recursive.

- The identification of *master* decision problems, which allow to establish completeness more easily than from first principles. For instance, reachability in lossy counter machines [47, 43, 45] plays a similar role for ACKERMANN as, e.g., 3SAT for NP or QBF for PSPACE, and has been used to derive most of the known ACKERMANN-hardness results [4, 11, 15, 35, 27, 22, 20, 17, 24].
- Lower bound techniques for establishing the complexity of such master problems: this typically relies on implementing *weak computers* for *Hardy functions* and their inverses in the formalism at hand, allowing to build a large but bounded working space on which a Turing or a Minsky machine can then be simulated [47, 43, 45, 6, 37, 19, 18].
- Upper bound techniques relying on combinatorial statements, called *length function theorems*, on the length of *controlled bad sequences* over well-quasi-orders, which are used to prove the termination of the decision procedures [33, 8, 49, 7, 14, 40, 3, 37].

From an algorithmic perspective, these results are negative and one could qualify such problems as merely "not undecidable". What we gain however are insights into the computational power of the models, allowing to compare them and to identify the main sources of complexity – e.g., in lossy counter machines, the key parameter is the number of counters. Furthermore, from a modelling perspective, a formalism with a tremendous computational power that nevertheless falls short of Turing completeness can be quite satisfactory.

Contributions. In this paper, we revisit the proof of the best-known result in this area, namely the ACKERMANN-completeness of reachability in lossy counter machines (LCMs). Those are simply multi-counter Minsky machines with a *lossy semantics* that allows the counters to decrease in an uncontrollable manner during executions; see Section 2.

The gap in the current state of knowledge appears when one fixes the key complexity parameter, i.e., the number d of counters. Indeed, the best known lower bound for LCM reachability is F_d-hardness when $d \geq 3$ [39, Thm. 4.9], but the best known upper bound is F_{d+1} [14, 41, 3]. This complexity gap reveals a serious shortcoming of the framework advertised earlier in this introduction, and also impacts the complexity of many problems shown hard through a reduction from LCM reachability.

Our first main contribution in Proposition 8 is an F_d upper bound, which together with the lower bound from [39, Thm. 4.9] entails the following completeness result.

▶ **Theorem 1.** *LCM Reachability is F_ω-complete, and F_d-complete if the number $d \geq 3$ of counters is fixed.*

Note that this provides an uncontrived decision problem for every class F_k with $3 \leq k \leq \omega$, whereas no natural F_k-complete problems were previously known for the intermediate primitive-recursive levels strictly between TOWER and ACKERMANN, i.e., for $3 < k < \omega$.

As we recall in Section 3, reachability in lossy counter machines can be solved using the generic *backward coverability algorithm* for *well-structured* systems [1, 16]. As usual, we derive our complexity upper bound by bounding the length of the bad sequences that underlie the termination argument for this algorithm. The main obstacle here is that the length function theorems in [14, 41, 3] – i.e., the bounds on the length of controlled bad sequences over $\mathbb{N}^d$ – are essentially optimal and only yield an F_{d+1} complexity upper bound.

We circumvent this using a new approach in Section 4. We restrict our attention to *strongly controlled* bad sequences rather than the more general *amortised controlled* ones (see Section 4.1), which in turn allows us to work on the *antichain factorisations* of bad sequences (see Section 4.2). This entails that, in order to bound the length of strongly controlled

bad sequences, it suffices to bound the length of strongly controlled antichains. This is tackled in Section 5, where we prove a *width function theorem* on the length of controlled antichains over $\mathbb{N}^d$; to the best of our knowledge, this is the first statement of this kind specific to antichains rather than bad sequences. We wrap up with the proof of Proposition 8 in Section 6.

The developments of Sections 4 and 5 form our second main contribution. They are of wide interest beyond lossy counter machines, as they can be applied whenever the termination of an algorithm relies on $\mathbb{N}^d$ having finite (controlled) bad sequences or antichains.

2 Lossy Counter Machines

Syntax. A *lossy counter machine* (LCM) [32] is syntactically identical to a Minsky machine $M = (Q, \mathtt{C}, \delta)$, where the transitions in $\delta \subseteq Q \times \mathtt{C} \times \{\mathtt{=0?}, \mathtt{++}, \mathtt{--}\} \times Q$ operate on a finite set Q of control locations and a finite set $\mathtt{C}$ of counters through *zero-tests* `c=0?`, *increments* `c++` and *decrements* `c--`.

Operational Semantics. The semantics of an LCM differ from the usual, 'reliable' semantics of a counter machine in that the counter values can decrease in an uncontrolled manner at any point of the execution. Formally, a *configuration* $q(\boldsymbol{v})$ associates a control location q in Q with a counter valuation $\boldsymbol{v}$ in $\mathbb{N}^{\mathtt{C}}$, i.e. counter values can never go negative. The set of configurations $Q \times \mathbb{N}^{\mathtt{C}}$ is ordered by the product ordering: $q(\boldsymbol{v}) \leq q'(\boldsymbol{v}')$ if $q = q'$ and $\boldsymbol{v}(\mathtt{c}) \leq \boldsymbol{v}'(\mathtt{c})$ for all $\mathtt{c} \in \mathtt{C}$.

A transition of the form $(q, \mathtt{c}, \mathtt{op}, q') \in \delta$ defines a set of *reliable computation steps* $q(\boldsymbol{v}) \to q'(\boldsymbol{v}')$, where $\boldsymbol{v}(\mathtt{c}') = \boldsymbol{v}'(\mathtt{c}')$ for all $\mathtt{c} \neq \mathtt{c}'$ in $\mathtt{C}$ and

- if $\mathtt{op} = \mathtt{=0?}$, then $\boldsymbol{v}(\mathtt{c}) = \boldsymbol{v}'(\mathtt{c}) = 0$,
- if $\mathtt{op} = \mathtt{++}$, then $\boldsymbol{v}(\mathtt{c}) + 1 = \boldsymbol{v}'(\mathtt{c})$, and
- if $\mathtt{op} = \mathtt{--}$, then $\boldsymbol{v}(\mathtt{c}) = \boldsymbol{v}'(\mathtt{c}) + 1$.

A *lossy computation step* is then defined by allowing counter values to decrease arbitrarily between reliable steps: $q(\boldsymbol{v}) \to_\ell q'(\boldsymbol{v}')$ if there exist $\boldsymbol{w} \leq \boldsymbol{v}$ and $\boldsymbol{w}' \geq \boldsymbol{v}'$ such that $q(\boldsymbol{w}) \to q'(\boldsymbol{w}')$. We write as usual $\to_\ell^*$ for the transitive reflexive closure of $\to_\ell$.

Reachability. The decision problem we tackle in this paper is the following.

▶ **Problem** (LCM Reachability).
instance A lossy counter machine $(Q, \mathtt{C}, \delta)$ and two configurations $q_0(\boldsymbol{v}_0)$ and $q_f(\boldsymbol{v}_f)$.
question Is $q_f(\boldsymbol{v}_f)$ reachable from $q_0(\boldsymbol{v}_0)$, i.e., does $q_0(\boldsymbol{v}_0) \to_\ell^* q_f(\boldsymbol{v}_f)$?

Note that, due to the lossy semantics, this is equivalent to the *coverability* problem, which asks instead whether there exists $\boldsymbol{v} \geq \boldsymbol{v}_f$ such that $q_0(\boldsymbol{v}_0) \to_\ell^* q_f(\boldsymbol{v})$. Indeed, such a $\boldsymbol{v}$ exists if and only if $q_0(\boldsymbol{v}_0) \geq q_f(\boldsymbol{v}_f)$ or $q_0(\boldsymbol{v}_0) \to_\ell^* q_f(\boldsymbol{v}_f)$.

While many problems are undecidable in LCMs [32, 44], these systems are in fact *well-structured* in the sense of [1, 16], which means that their coverability problem is decidable, as further discussed in Section 3. The ACKERMANN-hardness of reachability was first shown by Schnoebelen [43] in 2002,[1] while an ACKERMANN upper bound follows from the length function theorems for Dickson's Lemma [33, 8, 14, 41, 3]. Note that LCM reachability is equivalent to reachability in counter machines with *incrementing errors* [11] and to coverability in *reset counter machines* [45, Sec. 6], and this also holds if we fix the number of counters.

[1] Urquhart [47] showed independently in 1999 and using a similar approach the same result for the closely related model of alternating expansive vector addition systems.

3 Well Structured Systems

Well-structured transition systems (WSTS) [1, 16] form a family of computational models where the (usually infinite) set of configurations is equipped with a well-quasi-ordering (see Section 3.1) that is "compatible" with the computation steps (see Section 3.2). The existence of this well-quasi-ordering allows for the decidability of some important behavioural properties like termination (from a given initial configuration) or coverability, see Section 3.3.

3.1 Well-Quasi-Orders

A *quasi-order* (qo) is a pair $(X, \leq)$ where $\leq \subseteq X \times X$ is transitive and reflexive; we write $x < y$ for the associated strict ordering, when $x \leq y$ and $y \not\leq x$, $x \perp y$ for incomparable elements, when $x \not\leq y$ and $y \not\leq x$, and $x \equiv y$ for equivalent elements, when $x \leq y$ and $y \leq x$. The *upward-closure* $\uparrow Y$ of some $Y \subseteq X$ is defined as $\uparrow Y \stackrel{\text{def}}{=} \{x \in X \mid \exists y \in Y \,.\, x \geq y\}$; we write $\uparrow x$ instead of $\uparrow\{x\}$ for singletons and say that a set $U \subseteq X$ is *upwards-closed* when $U = \uparrow U$. We call a finite or infinite sequence $x_0, x_1, x_2, \ldots$ over X *bad* if for all indices $i < j$, $x_i \not\leq x_j$; if $x_i \perp x_j$ for all $i < j$, then $x_0, x_1, x_2, \ldots$ is an *antichain*.

A *well-quasi-order* (wqo) [21, 26] is a qo $(X, \leq)$ where bad sequences are finite. Equivalently, $(X, \leq)$ is a wqo if and only if it is both *well-founded*, i.e., there does not exist any infinite decreasing sequences $x_0 > x_1 > x_2 > \cdots$ of elements in X, and has the *finite antichain condition*, i.e., there are no infinite antichains. Still equivalently, $(X, \leq)$ is a wqo if and only if it has the *ascending chain condition*: any increasing sequence $U_0 \subseteq U_1 \subseteq U_2 \subseteq \cdots$ of upwards-closed subsets of X eventually stabilises, i.e., $\bigcup_{i\in\mathbb{N}} U_i = U_k = U_{k+1} = U_{k+2} = \cdots$ for some k. Still equivalently, $(X, \leq)$ is a wqo if and only if it has the *finite basis property*: any non-empty subset contains at least one, and at most finitely many minimal elements (up to equivalence); thus if $U \subseteq X$ is upwards-closed, then $\min U$ is finite and $U = \uparrow(\min U)$.

For a basic example, consider any finite set Q along with the equality relation, which is a wqo $(Q, =)$ by the pigeonhole principle. Any well-order is a wqo, thus the set of natural numbers and any of its initial segments $[k] \stackrel{\text{def}}{=} \{0, \ldots, k-1\}$ along with their natural ordering are also wqos. More examples can be constructed using algebraic operations: for instance, if $(X_0, \leq_{X_0})$ and $(X_1, \leq_{X_1})$ are wqos, then so are:

- their disjoint sum $(X_0 \sqcup X_1, \leq)$ where $X_0 \sqcup X_1 \stackrel{\text{def}}{=} \{(x, 0) \mid x \in X_0\} \cup \{(x, 1) \mid x \in X_1\}$ and $(x, i) \leq (y, j)$ if $i = j$ and $x \leq_{X_i} y$;
- their Cartesian product $(X_0 \times X_1, \leq)$ where $(x_0, x_1) \leq (y_0, y_1)$ if $x_i \leq_{X_i} y_i$ for all $0 \leq i \leq 1$; in the case of $(\mathbb{N}^d, \leq)$, this result is also known as Dickson's Lemma [12].

Note that the set of configurations $(Q \times \mathbb{N}^C, \leq)$ of an LCM is a wqo for the product ordering.

3.2 Compatibility

An *ordered transition system* $\mathcal{S} = (S, \to, \leq)$ combines a set S of configurations with a transition relation $\to \subseteq S \times S$ and a quasi-ordering $\leq$ of its configurations. An ordered transition system $\mathcal{S} = (S, \to, \leq)$ is *well-structured* if $(S, \leq)$ is a wqo and

$$\forall s_1, s_2, t_1 \in S,\ \big(s_1 \to s_2 \text{ and } s_1 \leq t_1\big) \text{ implies } \exists t_2 \in S,\ \big(t_1 \to t_2 \text{ and } s_2 \leq t_2\big)\,. \tag{1}$$

This property is also called *compatibility* (of the ordering with the transitions). Formally, it just means that $\leq$ is a *simulation* relation for $(S, \to)$, in precisely the classical sense of [34]. The point of (1) is to ensure that a larger configuration can do at least as much as a smaller configuration. For instance, lossy steps in a LCM are visibly compatible with $\leq$ according to (1), and thus the transition system $(Q \times \mathbb{N}^C, \to_\ell, \leq)$ defined by the lossy operational semantics of a LCM is a WSTS.

3.3 Coverability

We focus here on the *coverability problem*: given a WSTS $(S, \to, \leq)$ and two configurations $s, t \in S$, does s *cover* t, i.e., does there exist $t' \geq t$ such that $s \to^* t'$? The decidability of this problem uses a set-saturation method first introduced by Arnold and Latteux [5] for reset Petri nets, but the algorithm was independently rediscovered by Abdulla et al. [2] for lossy channel systems and its generic formulation was popularised in the surveys [1, 16].

Backward Coverability. The algorithm computes $\mathrm{Pre}^*_\exists(\uparrow t) \stackrel{\text{def}}{=} \{s' \in S \mid \exists t' \geq t,\, s' \to^* t'\}$, i.e., the set of configurations that cover t; it only remains to check whether $s \in \mathrm{Pre}^*_\exists(\uparrow t)$ in order to answer the coverability instance. More precisely, for a set of configurations $U \subseteq S$, let us define its (existential) *predecessor set* as $\mathrm{Pre}_\exists(U) \stackrel{\text{def}}{=} \{s \in S \mid \exists s' \in U,\, s \to s'\}$. The algorithm computes the limit of the sequence $U_0 \subseteq U_1 \subseteq \cdots$ defined by

$$U_0 \stackrel{\text{def}}{=} \uparrow t\,, \qquad\qquad U_{n+1} \stackrel{\text{def}}{=} U_n \cup \mathrm{Pre}_\exists(U_n)\,. \tag{2}$$

Note that for all n, $U_n = \{s' \in S \mid \exists t' \geq t,\, s' \to^{\leq n} t'\}$ is the set of configurations that cover t in at most n steps, and that we can stop this computation as soon as $U_{n+1} \subseteq U_n$.

There is no reason for the chain defined by (2) to stabilise in general ordered transition systems, but it does in the case of a WSTS. Indeed, $\mathrm{Pre}_\exists(U)$ is upwards-closed whenever $U \subseteq S$ is upwards-closed, thus the sequence defined by (2) stabilises to $\bigcup_{i\in\mathbb{N}} U_i = \mathrm{Pre}^*_\exists(\uparrow t)$ after a finite amount of time thanks to the ascending chain condition. Moreover, the finite basis property ensures that all the sets U_i can be finitely represented using their minimal elements, and the union or inclusion of two upwards-closed sets can be computed on this representation. The last ingredients are two effectiveness assumptions:

- $(S, \leq)$ should be effective, meaning that S is recursive and the ordering $\leq$ is decidable,
- there exists an algorithm returning the set of minimal predecessors $\min \mathrm{Pre}_\exists(\uparrow s')$ of any given configuration s'; this is known as the *effective pred-basis* assumption.

These two assumptions hold in LCMs: $(Q \times \mathbb{N}^{\mathtt{C}}, \leq)$ is certainly effective, and the minimal predecessors of a configuration $q'(\boldsymbol{v}')$ can be computed by

$$\min \mathrm{Pre}_\exists(\uparrow q'(\boldsymbol{v}')) = \min\{q(\mathrm{pre}_{\mathtt{c\,op}}(\boldsymbol{v}')) \mid (q, \mathtt{c}, \mathtt{op}, q') \in \delta \text{ and } \boldsymbol{v}'(\mathtt{c}) = 0 \text{ if } \mathtt{op} = \mathtt{=0?}\} \tag{3}$$

where $\mathrm{pre}_{\mathtt{c\,op}}(\boldsymbol{v}')$ is a vector in $\mathbb{N}^{\mathtt{C}}$ defined by $\mathrm{pre}_{\mathtt{c\,op}}(\boldsymbol{v}')(\mathtt{c}') \stackrel{\text{def}}{=} \boldsymbol{v}'(\mathtt{c}')$ for all $\mathtt{c}' \neq \mathtt{c}$ in $\mathtt{C}$ and

$$\mathrm{pre}_{\mathtt{c=0?}}(\boldsymbol{v}')(\mathtt{c}) \stackrel{\text{def}}{=} 0\,, \quad \mathrm{pre}_{\mathtt{c++}}(\boldsymbol{v}')(\mathtt{c}) \stackrel{\text{def}}{=} \max\{0, \boldsymbol{v}'(\mathtt{c}) - 1\}\,, \quad \mathrm{pre}_{\mathtt{c--}}(\boldsymbol{v}')(\mathtt{c}) \stackrel{\text{def}}{=} \boldsymbol{v}'(\mathtt{c}) + 1\,. \tag{4}$$

Coverability Pseudo-Witnesses. Let us reformulate the termination argument of the backward coverability algorithm in terms of bad sequences. We can extract a sequence of elements $t_0, t_1, \ldots$ from the ascending sequence $U_0 \subsetneq U_1 \subsetneq \cdots$ defined by (2) before saturation: $t_0 \stackrel{\text{def}}{=} t$ and $t_{i+1} \in U_{i+1} \setminus U_i$ for all i. Note that if $i < j$, then $t_j \in U_j \setminus U_i$ and therefore $t_i \not\leq t_j$: the sequence $t_0, t_1, \ldots$ is bad and therefore finite. In fact, we can even pick t_{i+1} at each step among the minimal elements of $\mathrm{Pre}_\exists(\uparrow t_i)$; we call such a bad sequence $t_0, t_1, \ldots, t_n$ with

$$t_0 \stackrel{\text{def}}{=} t\,, \qquad\qquad t_{i+1} \in \min \mathrm{Pre}_\exists(\uparrow t_i) \setminus U_i\,. \tag{5}$$

a *pseudo-witness* of the coverability of t. The maximal length of pseudo-witnesses is therefore equal to the number of steps of the backward coverability algorithm, and this is what we will bound in the upcoming Sections 4 and 5.

4 Controlled Bad Sequences and Antichains

As we have just discussed, the running time of the backward coverability algorithm is essentially bounded by the length of the bad sequences constructed by its termination argument. Though bad sequences over a wqo are finite, we cannot bound their lengths in general; e.g., $(0, n+1), (0, n), \ldots, (0, 0)$ and $(1, 0), (0, n), (0, n-1), \ldots, (0, 1), (0, 0)$ are bad sequences over $\mathbb{N}^2$ of length $n + 2$ for all n. Nevertheless, a bad sequence produced by an algorithm like the backward coverability algorithm of Section 3.3 is not arbitrary, because its elements are determined by the algorithm's input and the complexity of its operations. We capture this intuition formally through *controlled sequences*.

4.1 Controlling Sequences

Norms. Given a wqo $(X, \leq_X)$, we posit a *norm* function $|\,.\,|_X : X \to \mathbb{N}$; if $x \leq_X x'$ implies $|x|_X \leq |x'|_X$, we call this norm *monotone*. In order to be able to derive combinatorial statements, we require $X_{\leq n} \stackrel{\text{def}}{=} \{x \in X \mid |x|_X \leq n\}$ to be finite for every n; we call the resulting structure $(X, \leq_X, |\cdot|_X)$ a *normed wqo* (nqo).

We will use the following monotone norms on the wqos we defined in Section 3.1: over a finite Q, all the elements have the same norm 0; over $\mathbb{N}$ or $[d]$, n has norm $|n|_{\mathbb{N}} = |n|_{[d]} = n$; over disjoint sums $X_0 \sqcup X_1$, (x, i) uses the norm $|x|_{X_i}$ of its underlying set; finally, over Cartesian products $X \times Y$, (x, y) uses the infinite norm $\max(|x|_X, |y|_Y)$.

Controls. Let $n_0 \in \mathbb{N}$ and let $g : \mathbb{N} \to \mathbb{N}$ be a monotone and inflationary function, i.e., for all $x \leq x'$, $g(x) \leq g(x')$ and $x \leq g(x)$. We say that a sequence $x_0, x_1, x_2, \ldots$ of elements in X is *amortised* (g, n_0)*-controlled* if

$$\forall i \,.\, |x_i|_X \leq g^i(n_0) \,, \tag{6}$$

where g^i denotes the ith iterate of g. We say that it is *strongly* (g, n_0)*-controlled* if

$$|x_0|_X \leq n_0 \quad \text{and} \quad \forall i \,.\, |x_{i+1}|_X \leq g(|x_i|_X) \,. \tag{7}$$

By definition, a strongly controlled sequence is also amortised controlled: $|x_0|_X \leq g^0(n_0) = n_0$, which prompts the name of *initial norm* for n_0, and amortised steps cannot grow faster than g the *control function*.

Previous works like [14, 41, 3] focused on the more general amortised controlled sequences, but strong controlled ones are actually more relevant in practice. For instance, in the case of LCM coverability, the computation of minimal predecessors in (3–4) shows that the pseudo-witnesses from (5) of the coverability of a target configuration $q_f(\boldsymbol{v}_f)$ are strongly $(H, |\boldsymbol{v}_f|)$-controlled by the initial norm $|\boldsymbol{v}_f| = \max_{\mathsf{c} \in \mathsf{C}} \boldsymbol{v}_f(\mathsf{c})$ and the control function $H(x) \stackrel{\text{def}}{=} x + 1$.

Length, Norm, and Width Functions. The point of controlled sequences is that their length can be bounded. Consider for this the tree obtained by sharing the common prefixes of all the strongly (g, n_0)-controlled bad sequences over a normed wqo $(X, \leq_X, |\,.\,|_X)$.

- This tree is finitely branching by (7) – its branching degree is bounded by the cardinal of $X_{\leq g^i(n_0)}$ for a node at depth i – , and
- it has no infinite branches since bad sequences over $(X, \leq_X)$ are finite.

By Kőnig's Lemma, this tree of bad sequences is therefore finite, of some height $L^{\mathsf{s}}_{g,X}(n_0)$ representing the length of the maximal strongly (g, n_0)-controlled bad sequence(s) over X, and we also let $N^{\mathsf{s}}_{g,X}(n_0)$ bound the norms encountered along such sequences; note that

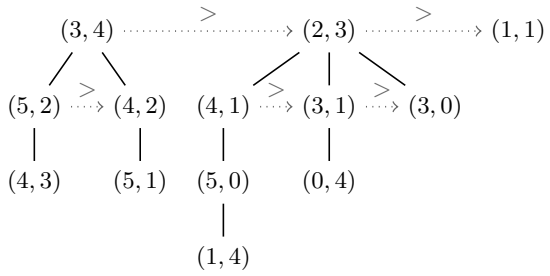

Figure 1 The antichain factorisation of the strongly $(H, 4)$-controlled bad sequence $(3,4)$ $(5,2)$ $(4,3)$ $(4,2)$ $(5,1)$ $(2,3)$ $(4,1)$ $(5,0)$ $(1,4)$ $(3,1)$ $(0,4)$ $(3,0)$ $(1,1)$ over $\mathbb{N}^2$ for $H(x) \stackrel{\text{def}}{=} x + 1$.

$N^{\mathsf{s}}_{g,X}(n_0) \leq g^{L^{\mathsf{s}}_{g,X}(n_0)}(n_0)$ since g is monotone inflationary. Similarly, there exists a maximal length, denoted by $W^{\mathsf{a}}_{g,X}(n_0)$ (resp. $W^{\mathsf{s}}_{g,X}(n_0)$), for amortised (resp. strongly) (g, n_0)-controlled antichains over X. We call $L^{\mathsf{s}}_{g,X}$, $N^{\mathsf{s}}_{g,X}$, and $W^{\mathsf{s}}_{g,X}$ the *strong length*, *strong norm*, and *strong width* functions respectively, and $W^{\mathsf{a}}_{g,X}$ the *width* function. By definition, a strongly controlled antichain is amortised controlled, i.e.,

$$W^{\mathsf{s}}_{g,X}(n_0) \leq W^{\mathsf{a}}_{g,X}(n_0)\,, \tag{8}$$

and the length of a bad sequence where all the elements are of norm at most $N = N^{\mathsf{s}}_{g,X}(n_0)$ is bounded by the cardinal of $X_{\leq N}$, i.e.,

$$L^{\mathsf{s}}_{g,X}(n_0) \leq |X_{\leq N^{\mathsf{s}}_{g,X}(n_0)}|\,. \tag{9}$$

Observe that $L^{\mathsf{s}}_{g,X}(|t|_X)$ bounds the number of steps required by the backward coverability algorithm for a WSTS over $(X, \leq_X, |\,.\,|_X)$ with target configuration t where $s' \in \min \mathrm{Pre}(\uparrow t')$ implies $|s'|_X \leq g(|t'|_X)$. In the case of LCMs, we are therefore interested in $L^{\mathsf{s}}_{H,Q\times N^{\mathsf{c}}}(|\boldsymbol{v}_f|)$.

4.2 Antichain Factorisations

Let $(X, \leq_X, |\,.\,|_X)$ be a nwqo where $|\,.\,|_X$ is monotone – i.e., $x \leq x'$ implies $|x|_X \leq |x'|_X$ –, and let $x_0, x_1, \ldots, x_{\ell-1} \in X^*$ be a strongly (g, n_0)-controlled bad sequence over $(X, \leq_X, |\,.\,|_X)$. Informally, the *antichain factorisation* of $x_0, x_1, \ldots, x_{\ell-1}$ is an ordered forest A where all the branches are strongly (g, n_0)-controlled antichains, siblings are ordered left-to-right by the strict ordering $>_X$, and such that the pre-order traversal of A yields back the bad sequence. Consider for instance the example of Figure 1: this bad sequence has length 13, thus the norm of its elements is at most $H^{12}(4) = 16$, but because the height of its antichain factorisation is 4, we can actually bound the norm by $H^3(4) = 7$.

We can compute this factorisation from any strongly (g, n_0)-controlled bad sequence. Formally, $A \subseteq X^*$ is a prefix-closed finite set of antichains with the prefix ordering as vertical ordering. Two antichains u and v in A are *siblings* if $u = w \cdot x$ and $v = w \cdot y$ for some $w \in X^*$ and $x, y \in X$, and we order such siblings by letting $u >_X v$ if $x >_X y$. Given $x_0, \ldots, x_{\ell-1}$, we let $A \stackrel{\text{def}}{=} \mathrm{Fact}(x_0, 1)$ where

$$\mathrm{Fact}(y_0 \cdots y_m, i) \stackrel{\text{def}}{=} \{y_0 \cdots y_m\} \cup \begin{cases} \emptyset & \text{if } i = \ell\,, \\ \mathrm{Fact}(y_0 \cdots y_m x_i, i+1) & \text{if } \forall j\,.\, y_j \not>_X x_i\,, \\ \mathrm{Fact}(y_0 \cdots y_{k-1} x_i, i+1) & \text{if } k = \min\{j \mid y_j >_X x_i\}\,. \end{cases} \tag{10}$$

This corresponds to scanning the elements x_i of the bad sequence from left to right while building the current "rightmost branch" $y_0 \cdots y_m \in A$, which is (by induction on i) a strongly (g, n_0)-controlled antichain and a scattered subword of $x_0 \cdots x_{i-1}$ (thus $y_j \not\leq x_i$ for all $0 \leq j \leq m$) such that $y_m = x_{i-1}$. If $y_j \not>_X x_i$ for all $0 \leq j \leq m$, then $y_0 \cdots y_m x_i$ is a (g, n_0)-controlled antichain and a scattered subword of $x_0 \cdots x_i$. If otherwise $y_j >_X x_i$ for some y_j, we let k be the minimal such j and we start a new rightmost branch with x_i out of y_{k-1} (x_i is possibly a new root if $k = 0$); crucially, because $|.|_X$ is monotone and $x_i <_X y_k$, we have $|x_i|_X \leq |y_k|_X \leq g(|y_{k-1}|_X)$ (or $|x_i|_X \leq |y_k|_X \leq n_0$ at the root), thus $y_0 \cdots y_{k-1} x_i$ is again a strongly (g, n_0)-controlled antichain and a scattered subword of $x_0 \cdots x_i$.

We deduce a bound on the strong norm function in terms of the strong width function.

▶ **Lemma 2** (Antichain Factorisation). *Let $(X, \leq_X, |.|_X)$ be a normed wqo with $|.|_X$ monotone, n_0 in $\mathbb{N}$, and $g : \mathbb{N} \to \mathbb{N}$ monotone inflationary. Then $N^{\mathsf{s}}_{g,X}(n_0) \leq g^{W^{\mathsf{s}}_{g,X}(n_0)}(n_0)$.*

Lemma 2 combined with (8) shows that the strong norm function $N^{\mathsf{s}}_{g,X}$ can be bounded in terms of the width function $W^{\mathsf{a}}_{g,X}$. By (9), this will also yield a bound on the strong length function $L^{\mathsf{s}}_{g,X}$. We focus therefore on the width function in the upcoming Section 5.

5 Width Function Theorem

As seen in Section 4, by suitably controlling how large the elements can grow in antichains, we can derive upper bounds on the time and space required by the backward coverability algorithm of Section 3. We prove in this section a *width function theorem*, a combinatorial statement on the length of amortised controlled antichains over tuples of natural numbers, which will allow to derive a complexity upper bound for reachability in lossy counter machines.

The high complexities at play here require the use of ordinal-indexed *subrecursive functions* in order to denote non-elementary growths. We first recall the definitions of two families of such functions in Section 5.1; we refer the reader to [46, 41] for further details. We then prove in Section 5.2 a bound on the width function $W^{\mathsf{a}}_{g,\mathbb{N}^d}$ using the framework of [40, 41].

5.1 Subrecursive Hierarchies

Fundamental Sequences and Predecessors. A *fundamental sequence* for a limit ordinal λ is a strictly increasing sequence $(\lambda(x))_{x<\omega}$ of ordinal terms with supremum λ. We use the standard assignment of fundamental sequences to limit ordinals below ε_0 in Cantor normal form, defined inductively by

$$(\gamma + \omega^{\beta+1})(x) \stackrel{\text{def}}{=} \gamma + \omega^{\beta} \cdot (x+1) \,, \qquad (\gamma + \omega^{\lambda})(x) \stackrel{\text{def}}{=} \gamma + \omega^{\lambda(x)} \,. \tag{11}$$

This particular assignment satisfies e.g. $0 < \lambda(x) < \lambda(y)$ for all $x < y$. For instance, $\omega(x) = x + 1$, $(\omega^{\omega^4} + \omega^{\omega^3+\omega^2})(x) = \omega^{\omega^4} + \omega^{\omega^3+\omega\cdot(x+1)}$.

The *predecessor* $P_x(\alpha)$ of an ordinal term $0 < \alpha < \varepsilon_0$ at $x \in \mathbb{N}$ is defined inductively by

$$P_x(\alpha + 1) \stackrel{\text{def}}{=} \alpha \,, \qquad P_x(\lambda) \stackrel{\text{def}}{=} P_x(\lambda(x)) \,. \tag{12}$$

In essence, the predecessor of an ordinal is obtained by repeatedly taking the xth element in the fundamental sequence of limit ordinals, until we finally reach a successor ordinal and may remove 1. For instance, $P_x(\omega^2) = P_x(\omega \cdot (x+1)) = P_x(\omega \cdot x + x + 1) = \omega \cdot x + x$.

Hardy and Cichoń Hierarchies. Let $h\colon \mathbb{N} \to \mathbb{N}$ be a function. The *Hardy hierarchy* $(h^\alpha)_{\alpha\in\varepsilon_0}$ and the *Cichoń hierarchy* $(h_\alpha)_{\alpha\in\varepsilon_0}$ relative to h are defined for all $0 < \alpha < \varepsilon_0$ by

$$h^0(x) \stackrel{\text{def}}{=} x\,, \quad h^\alpha(x) \stackrel{\text{def}}{=} h^{P_x(\alpha)}(h(x))\,, \quad h_0(x) \stackrel{\text{def}}{=} 0\,, \quad h_\alpha(x) \stackrel{\text{def}}{=} 1 + h_{P_x(\alpha)}(h(x))\,. \tag{13}$$

Observe that $h^k(x) = h^{P_x(k)}(h(x)) = h^{k-1}(h(x))$ for some finite k is the kth iterate of h. This intuition carries over: h^α is a "transfinite" iteration of the function h, using diagonalisation in the fundamental sequences to handle limit ordinals. A standard choice for the function h is the successor function, noted $H(x) \stackrel{\text{def}}{=} x + 1$; in that case, we see that a first diagonalisation yields $H^\omega(x) = H^x(x+1) = 2x+1$. The next diagonalisation occurs at $H^{\omega\cdot 2}(x) = H^{\omega+x}(x+1) = H^\omega(2x+1) = 4x+3$. Fast-forwarding a bit, we get for instance a function of exponential growth $H^{\omega^2}(x) = 2^{x+1}(x+1) - 1$, and later a non-elementary function $H^{\omega^3}(x)$ akin to a tower of exponentials of height x, and an "Ackermannian" non primitive-recursive function H^{ω^ω}.

Both h^α and h_α are monotone and inflationary whenever h is monotone inflationary. Hardy functions are well-suited for expressing large iterates of a control function, and therefore for bounding the norms of elements in a controlled sequence. Cichoń functions are well-suited for expressing the length of controlled sequences: we can compute how many times we should iterate h in order to compute $h^\alpha(x)$ using the corresponding Cichoń function [7]:

$$h^\alpha(x) = h^{h_\alpha(x)}(x)\,. \tag{14}$$

5.2 Width Function for Dickson's Lemma

The starting point for our analysis is a *descent equation* for amortised controlled antichains through *residuals*, similar to the equations proven in [14, 40] for bad sequences (see Lemma 3). The key idea introduced in [14] is then to over-approximate the residuals of $\mathbb{N}^d$ by working over *polynomial nwqos*, where disjoint sums are also allowed. Then, the notion of "over-approximation" of residuals of polynomial nwqos is captured formally by showing the existence of a *normed reflection* into another polynomial nwqo. The final step lifts this to ordinals, allowing to relate $W^{\mathsf{a}}_{g,X}$ for a polynomial nwqo X to functions in the Cichoń hierarchy.

Strict Polynomial Normed wqos. Let us write $X \cdot p$ for $\overbrace{X \sqcup \cdots \sqcup X}^{p \text{ times}}$, X^d for $\overbrace{X \times \cdots \times X}^{d \text{ times}}$, and $\mathbf{0}$ for the empty nwqo. We call a nwqo of the form $\mathbb{N}^{d_1} \sqcup \cdots \sqcup \mathbb{N}^{d_m}$ for some $m \geq 0$ and $d_1, \cdots, d_m \geq 1$ a *strict polynomial nwqo*. The set of configurations $Q \times \mathbb{N}^{\mathtt{C}}$ of an LCM with $|Q| = q$ locations and $|\mathtt{C}| = d \geq 1$ counters, along with its ordering and infinite norm, is isomorphic to the strict polynomial nwqo $\mathbb{N}^d \cdot q$.

Residuals and a Descent Equation. Let $(X, \leq_X, |.|_X)$ be a normed wqo and x be an element of X. We write $X_{\perp x} \stackrel{\text{def}}{=} \{y \in X \mid x \perp y\}$ for the *residual* of X in x. By the finite antichain condition, there cannot be infinite sequences of residuations $(\cdots((X_{\perp x_0})_{\perp x_1})_{\perp x_2}\cdots)_{\perp x_i}$ because $x_i \perp x_j$ for all $i < j$ and it would create an infinite antichain.

Consider now an amortised (g, n_0)-controlled antichain $x_0, x_1, x_2, \ldots$ over X. Assuming the sequence is not empty, then for all $i > 0$, $x_0 \perp x_i$, i.e. the suffix $x_1, x_2, \ldots$ is actually an antichain over $X_{\perp x_0}$. This suffix is now amortised $(g, g(n_0))$-controlled, and thus of length bounded by $W^{\mathsf{a}}_{g,X_{\perp x_0}}(g(n_0))$. This yields the following *descent equation* when considering all the possible amortised (g, n_0)-controlled antichains; see the full version for a proof.

▶ **Lemma 3.** *Let $(X, \leq_X, |\,.\,|_X)$ be a nwqo, $n_0 \in \mathbb{N}$ and $g\colon \mathbb{N} \to \mathbb{N}$. Then $W^{\mathsf{a}}_{g,X}(n_0) = \max_{x\in X_{\leq n_0}} 1 + W^{\mathsf{a}}_{g,X_{\perp x}}(g(n_0))$.*

Reflecting Normed wqos. The descent equation, though it offers a way of computing the width function, quickly leads to complex residual expressions. We are going to over-approximate these $X_{\perp x}$'s using *nwqo reflections*, so that the computation can be carried out without leaving the realm of strict polynomial nwqos, leading to an *inductive* over-approximation of $X_{\perp x}$ over the structure of the strict polynomial nwqo X.

A *nwqo reflection* [40] is a mapping $r\colon X \to Y$ between two nwqos $(X, \leq_X, |\,.\,|_X)$ and $(Y, \leq_Y, |\,.\,|_Y)$ that satisfies the two following properties:

$$\forall x, x' \in X. \qquad r(x) \leq_Y r(x') \quad \text{implies} \quad x \leq_X x' \,, \tag{15}$$

$$\forall x \in X. \qquad |r(x)|_Y \leq |x|_X \,. \tag{16}$$

In other words, a nwqo reflection is an order reflection that is not norm-increasing. This induces a quasi-ordering between nwqos, written $X \hookrightarrow Y$. Remark that reflections are compatible with disjoint sums and products [40, Prop. 3.5]:

$$X_0 \hookrightarrow Y_0 \text{ and } X_1 \hookrightarrow Y_1 \quad \text{imply} \quad X_0 \sqcup X_1 \hookrightarrow Y_0 \sqcup Y_1 \text{ and } X_0 \times X_1 \hookrightarrow Y_0 \times Y_1 \,. \tag{17}$$

Crucially, nwqo reflections preserve amortised controlled antichains. Indeed, let $r\colon X \hookrightarrow Y$, and consider a sequence $x_0, x_1, \ldots$ over X. Then by (15), $r(x_0), r(x_1), \ldots$ is an antichain when $x_0, x_1, \ldots$ is, and by (16), it is (g, n)-controlled when $x_0, x_1, \ldots$ is. Hence

$$X \hookrightarrow Y \quad \text{implies} \quad W^{\mathsf{a}}_{g,X}(n) \leq W^{\mathsf{a}}_{g,Y}(n) \text{ for all } g, n \,. \tag{18}$$

Inductive Reflection of Residuals. We provide a strict polynomial wqo reflecting $X_{\perp x}$ by induction over the structure of the strict polynomial nwqo X. The key difference compared to the analysis of bad sequences in [14, 41] occurs for $X = \mathbb{N}$: if $k \in \mathbb{N}$,

$$\mathbb{N}_{\perp k} = \mathbf{0} \,. \tag{19}$$

Regarding disjoint sums $X_0 \sqcup X_1$, it is plain that

$$(X_0 \sqcup X_1)_{\perp(x,i)} = (X_i)_{\perp x} \sqcup X_{1-i} \,. \tag{20}$$

Consider now $(\mathbb{N}^d)_{\perp \boldsymbol{v}}$ where $d > 1$ and $\boldsymbol{v} \in \mathbb{N}^d$. Observe that if $\boldsymbol{u} \in \mathbb{N}^d$ is such that $\boldsymbol{u} \perp \boldsymbol{v}$, then there exists $1 \leq i \leq d$ such that $\boldsymbol{u}(i) < \boldsymbol{v}(i)$, as otherwise we would have $\boldsymbol{u} \geq \boldsymbol{v}$. Thus

$$(\mathbb{N}^d)_{\perp \boldsymbol{v}} \hookrightarrow \bigsqcup_{1 \leq i \leq d} \mathbb{N}^{d-1} \times [\boldsymbol{v}(i)] \hookrightarrow \mathbb{N}^{d-1} \cdot \sum_{1 \leq i \leq d} \boldsymbol{v}(i) \,. \tag{21}$$

Ordinal Notations. As it is more convenient to reason with ordinals than with polynomial nwqos, we use the following bijection between strict polynomial nwqos and ω^ω:

$$w(\mathbf{0}) \stackrel{\text{def}}{=} 0 \,, \qquad w(\mathbb{N}^d) \stackrel{\text{def}}{=} \omega^{d-1} \,, \qquad w(X_0 \sqcup X_1) = w(X_0) \oplus w(X_1) \,. \tag{22}$$

where "$\oplus$" denotes the *natural sum* (aka *Hessenberg sum*) on ordinals: the natural sum $\alpha \oplus \beta$ of two ordinals with Cantor normal forms $\alpha = \sum_{i=1}^{p} \omega^{\alpha_i}$ and $\beta = \sum_{j=1}^{m} \omega^{\beta_j}$ is $\omega^{\gamma_1} + \cdots + \omega^{\gamma_{p+m}}$ where the exponents $\gamma_1 \geq \cdots \geq \gamma_{p+m}$ are a reordering of $\alpha_1, \ldots, \alpha_p, \beta_1, \ldots, \beta_m$. Given a strict polynomial nwqo $X = \bigsqcup_{i=1}^{m} \mathbb{N}^{d_i}$, its associated ordinal is $w(X) = \bigoplus_{i=1}^{m} \omega^{d_i - 1}$. In the case of an LCM with $d \stackrel{\text{def}}{=} |\mathtt{C}|$ counters and $q \stackrel{\text{def}}{=} |Q|$ locations, $w(Q \times \mathbb{N}^{\mathtt{C}}) = \omega^{d-1} \cdot q$.

For each $n \in \mathbb{N}$, we define a relation ∂_n over ordinals in ω^ω that mirrors the inductive residuation and reflection operations on strict polynomial nwqos X over the ordinals $w(X)$:

$$\partial_n \alpha \stackrel{\text{def}}{=} \left\{ \gamma \oplus \partial_n \omega^d \mid \alpha = \gamma \oplus \omega^d \right\} , \qquad \partial_n \omega^d \stackrel{\text{def}}{=} \begin{cases} 0 & \text{if } d = 0, \\ \omega^{d-1} \cdot n(d+1) & \text{otherwise.} \end{cases} \tag{23}$$

The intuition here is that $w(Y) \in \partial_n w(X)$ implies $X_{\perp x} \hookrightarrow Y$ for some $x \in X_{\leq n}$. Observe that $\alpha' \in \partial_n \alpha$ implies $\alpha' < \alpha$, thus $\bigcup_n \partial_n$ is a well-founded relation. This leads to the definition of an over-approximation of the width function $W^{\mathsf{a}}_{g,X}$ (see the full version):

$$M_{g,\alpha}(n) \stackrel{\text{def}}{=} \max_{\alpha' \in \partial_n \alpha} \left\{1 + M_{g,\alpha'}(g(n))\right\} . \tag{24}$$

▶ **Proposition 4.** *Let $(X, \leq_X, |\,.\,|_X)$ be a strict polynomial nwqo, $n_0 \in \mathbb{N}$, and $g\colon \mathbb{N} \to \mathbb{N}$. Then $W^{\mathsf{a}}_{g,X}(n_0) \leq M_{g,w(X)}(n_0)$.*

It remains to compare $M_{g,\alpha}$ with standard subrecursive functions like the Cichoń functions, which was already done in [41, Sec. 2.4.3] for a very similar function; see the full version.

▶ **Proposition 5.** *Let n be in $\mathbb{N}$, $g\colon \mathbb{N} \to \mathbb{N}$ a monotone inflationary function, and $0 < \alpha < \omega^d$. Then $M_{g,\alpha}(n) \leq 1 + M_{g,P_{nd}(\alpha)}(n)$.*

This extra twist of using a predecessor function different from the standard one from (12) can be avoided by instead over-approximating the control function g.

▶ **Theorem 6** (Width Function for Strict Polynomial nwqos)**.** *Let $d > 0$, $(X, \leq_X, |\,.\,|_X)$ be a strict polynomial nwqo with $w(X) < \omega^d$, $n_0 \in \mathbb{N}$, $g\colon \mathbb{N} \to \mathbb{N}$ monotone inflationary, and let $h\colon \mathbb{N} \to \mathbb{N}$ be a monotone function such that $h(x \cdot d) \geq g(x) \cdot d$ for all x. Then $W^{\mathsf{a}}_{g,X}(n_0) \leq h_{w(X)}(n_0 d)$.*

Proof. By Proposition 4, it suffices to show that $M_{g,w(X)}(n) \leq h_{w(X)}(nd)$, which we do by induction over $\alpha \stackrel{\text{def}}{=} w(X)$. If $\alpha = 0$, then $\partial_n \alpha = \emptyset$ thus $M_{g,\alpha}(n) = 0 \leq h_\alpha(nd)$. Otherwise, by Proposition 5, $M_{g,\alpha}(n) \leq 1 + M_{g,P_{nd}(\alpha)}(g(n))$. Because $P_{nd}(\alpha) < \alpha$, we can apply the induction hypothesis, yielding $M_{g,\alpha}(n) \leq 1 + h_{P_{nd}(\alpha)}(g(n)d) \leq 1 + h_{P_{nd}(\alpha)}(h(nd)) = h_\alpha(nd)$, where the last inequality follows from $h(nd) \geq g(n)d$ and the monotonicity of $h_{P_{nd}(\alpha)}$. ◀

Setting $h(x) \stackrel{\text{def}}{=} g(x)d$ always satisfies the conditions of the theorem. There are cases where setting $h \stackrel{\text{def}}{=} g$ suffices: e.g., $g(x) \stackrel{\text{def}}{=} 2x$, $g(x) \stackrel{\text{def}}{=} x^2$, $g(x) \stackrel{\text{def}}{=} 2^x$, and more generally whenever g is *super-homogeneous*, i.e. satisfies $g(dx) \geq g(x)d$ for all $d, x \geq 1$. In the case of LCMs, where $w(Q \times \mathbb{N}^{\mathsf{c}}) < \omega^d$ if $d \stackrel{\text{def}}{=} |\mathsf{C}| > 0$, a control function $g(x) \stackrel{\text{def}}{=} x + 1 = H(x)$ fits, thus setting $h(x) \stackrel{\text{def}}{=} x + d = H^d(x)$ satisfies $h(dx) = dx + d = (x+1)d = g(x)d$.

By (8), Lemma 2, and (14), Theorem 6 also yields a bound on the strong norm function.

▶ **Corollary 7** (Strong Norm Function for Strict Polynomial nwqos)**.** *Let d, X, n_0, g, and h be as in Theorem 6. Then $N^{\mathsf{s}}_{g,X}(n_0) \leq h^{w(X)}(n_0 d)$.*

6 Wrapping up

We have now all the ingredients needed to prove an F_d upper bound on LCM Reachability. Let us first recall the definition of the fast-growing complexity classes from [38].

Fast-Growing Complexity Classes. The *fast-growing* complexity classes [38] form a strict ordinal-indexed hierarchy of complexity classes $(\mathsf{F}_\alpha)_{\alpha < \varepsilon_0}$ using the Hardy functions $(H^\alpha)_{\alpha < \varepsilon_0}$ relative to $H(x) \stackrel{\text{def}}{=} x + 1$ as a standard against which to measure high complexities. Let

$$\mathcal{F}_{<\alpha} \stackrel{\text{def}}{=} \bigcup_{\beta < \omega^\alpha} \mathsf{FDTIME}\big(H^\beta(n)\big) , \qquad \mathsf{F}_\alpha \stackrel{\text{def}}{=} \bigcup_{p \in \mathcal{F}_{<\alpha}} \mathsf{DTIME}\big(H^{\omega^\alpha}(p(n))\big) . \tag{25}$$

Then $\mathcal{F}_{<\alpha}$ is the class of functions computed by deterministic Turing machines in time $O(H^\beta(n))$ for some $\beta < \omega^\alpha$; this captures for instance the class of Kalmar elementary functions as $\mathcal{F}_{<3}$ and the class of primitive-recursive functions as $\mathcal{F}_{<\omega}$ [30, 48]. The class F_α is

the class of decision problems solved by deterministic Turing machines in time $O\big(H^{\omega^\alpha}(p(n))\big)$ for some function $p \in \mathcal{F}_{<\alpha}$. The intuition behind this quantification of p is that, just like e.g. $\mathsf{EXP} = \bigcup_{p\in\mathsf{poly}} \mathsf{DTIME}\big(2^{p(n)}\big)$ quantifies over polynomial functions to provide enough "wiggle room" to account for polynomial reductions, F_α is closed under $\mathcal{F}_{<\alpha}$ reductions [38, Thms. 4.7 and 4.8]. For instance, $\mathsf{TOWER} \stackrel{\text{def}}{=} \mathsf{F}_3$ defines the class of problems that can be solved in time bounded by a tower of exponentials of elementary height in the size of the input, $\bigcup_{k\in\mathbb{N}} \mathsf{F}_k$ is the class of primitive-recursive decision problems, and $\mathsf{ACKERMANN} \stackrel{\text{def}}{=} \mathsf{F}_\omega$ is the class of problems that can be solved in time bounded by the Ackermann function applied to some primitive-recursive function of the input size.

Upper Bound. Recall from Section 3.3 that a pseudo-witness for coverability of a configuration $q_f(\boldsymbol{v}_f)$ in a LCM with $d \stackrel{\text{def}}{=} |\mathtt{C}| > 0$ counters and $q \stackrel{\text{def}}{=} |Q|$ locations is a strongly $(H, |\boldsymbol{v}_f|)$-controlled bad sequence over $Q \times \mathbb{N}^{\mathtt{C}}$, which as discussed in Section 5.2 is a strict polynomial wqo with $w(Q \times \mathbb{N}^{\mathtt{C}}) = \omega^{d-1} \cdot q < \omega^d$, and that $h \stackrel{\text{def}}{=} H^d$ fits the conditions of Theorem 6 and Corollary 7. As stated in Theorem 1, together with the lower bounds from [39], the following entails the F_d-completeness of LCM Reachability with a fixed number $d \geq 3$ of counters.

▶ **Proposition 8** (Upper Bound for LCM Reachability)**.** *LCM Reachability is in F_ω, and in F_d if the number $d \geq 3$ of counters is fixed.*

Proof. Let $n_0 \stackrel{\text{def}}{=} |\boldsymbol{v}_f|$ be the infinite norm of the target configuration, $d \stackrel{\text{def}}{=} |\mathtt{C}| \geq 3$ be the number of counters, and $q \stackrel{\text{def}}{=} |Q| \geq 1$ the number of locations. By Corollary 7, the elements in a pseudo-witness of the coverability of $q_f(\boldsymbol{v}_f)$ are of norm at most $N \stackrel{\text{def}}{=} N^{\mathsf{s}}_{H,Q\times\mathbb{N}^{\mathtt{C}}}(n_0) = h^{\omega^{d-1}\cdot q}(n_0)$ for $h(x) \stackrel{\text{def}}{=} H^d(x)$. Let $n \stackrel{\text{def}}{=} \max\{qd-1, n_0\}$. As shown in the full version, this means that

$$N \leq H^{\omega^{d-1}\cdot qd}(n_0) \leq H^{\omega^{d-1}\cdot qd}(n) \leq H^{\omega^d}(n) \tag{26}$$

by monotonicity of the Hardy functions.

Note that there are at most $q(N+1)^d$ different configurations in $Q \times \mathbb{N}^{\mathtt{C}}$ of norm bounded by N, i.e., $|(Q \times \mathbb{N}^{\mathtt{C}})_{\leq N}| \leq q(N+1)^d$. By (9), this is also a bound on the strong length function $L^{\mathsf{s}}_{H,Q\times\mathbb{N}^d}(n_0)$. Thus the number of steps in the backward coverability algorithm is bounded by $q(N+1)^d$, and each step can be carried in time $O(N)$, hence the algorithm works in deterministic time $O(q(N+1)^{d+1}) = O(f(N)) = O(f(H^{\omega^d}(n)))$ for some elementary function $f \in \mathcal{F}_{<3}$. By [38, Cor. A.9], there exists an elementary inflationary function $p \in \mathcal{F}_{<3}$ such that $f(H^{\omega^d}(n)) \leq H^{\omega^d}(p(n))$: the backward coverability algorithm therefore works in deterministic time $O(H^{\omega^d}(p(n)))$ for some $p \in \mathcal{F}_{<3}$, which is an expression of the form (25).

Therefore, LCM Reachability is in F_d when d is fixed, and in F_ω otherwise because $p(n) \geq n \geq d-1$ and thus $H^{\omega^d}(p(n)) \leq H^{\omega^\omega}(p(n))$. ◀

7 Concluding Remarks

We have shown the F_d-completeness of reachability in lossy counter machines with a fixed number $d \geq 3$ of counters. The key novelty is that we analyse the length of controlled antichains over $\mathbb{N}^d$ rather than that of controlled bad sequences. A possible explanation why this leads to improved upper bounds is that the *ordinal width* of $\mathbb{N}^d$, i.e., the ordinal rank of its antichains, is conjectured to be ω^{d-1} [13], while its *maximal order type*, i.e., the ordinal rank of its bad sequences, is well-known to be ω^d [9].

Our approach might be employed to tackle related parameterised complexity gaps, like the one between $\mathsf{F}_{\omega^{m-2}}$-hardness [25] and $\mathsf{F}_{\omega^{m-1}+1}$ membership [40] of reachability in *lossy channel systems* with $m \geq 4$ channel symbols and a single channel. Those results rely however on the set of finite words over an alphabet of size m being a wqo for Higman's scattered subword ordering [21], for which the ordinal width and maximal order type coincide at $\omega^{\omega^{m-1}}$ [13, 9].

Abstract

We establish an Eilenberg-type correspondence for data languages, i.e. languages over an infinite alphabet. More precisely, we prove that there is a bijective correspondence between varieties of languages recognized by orbit-finite nominal monoids and pseudovarieties of such monoids. This is the first result of this kind for data languages. Our approach makes use of nominal Stone duality and a recent category theoretic generalization of Birkhoff-type theorems that we instantiate here for the category of nominal sets. In addition, we prove an axiomatic characterization of weak pseudovarieties as those classes of orbit-finite monoids that can be specified by sequences of nominal equations, which provides a nominal version of a classical theorem of Eilenberg and Schützenberger.

1 Introduction

In the algebraic theory of formal languages, one studies automata and the languages they represent in terms of associated algebraic structures. This approach has been successfully implemented for numerous types of languages and has proven extremely fruitful because it allows to import powerful algebraic methods into the realm of automata theory. As a prime example, regular languages can be described purely algebraically as the languages recognized by finite monoids, and a celebrated result by McNaughton, Papert, and Schützenberger [12, 19] asserts that a regular language is definable in first-order logic if and only if its syntactic monoid is aperiodic (i.e. it satisfies the equation $x^{n+1} = x^n$ for sufficiently large n). As an immediate application, this algebraic characterization yields an effective procedure for deciding first-order definability. The first systematic approach to correspondence results of this kind was initiated by Eilenberg [6] who proved that *varieties of languages* (i.e. classes of regular languages closed under the set-theoretic boolean operations, derivatives, and homomorphic preimages) correspond bijectively to *pseudovarieties of monoids* (i.e. classes of finite monoids closed under quotients monoids, submonoids, and finite products). Eilenberg's result thus establishes a generic relation between properties of regular languages and properties of finite monoids. In addition, Eilenberg and Schützenberger [7] contributed a model-theoretic description

of pseudovarieties: they are those classes of finite monoids that can be axiomatized by a sequence $(s_n = t_n)_{n\in\mathbb{N}}$ of equations, interpreted as "$s_n = t_n$ holds for sufficiently large n". For instance, the pseudovariety of aperiodic finite monoids is axiomatized by $(x^{n+1} = x^n)_{n\in\mathbb{N}}$.

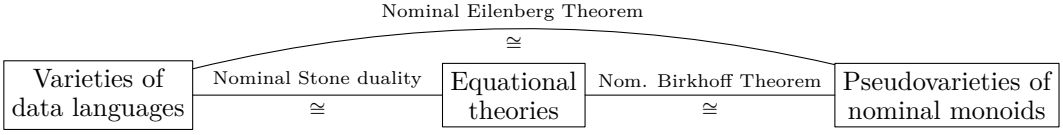
The goal of our present paper is to study *data languages*, i.e. languages over an infinite alphabet, from the perspective of algebraic language theory. Such languages have spurred significant interest in recent years, driven by practical applications in various areas of computer science, including efficient parsing of XML documents or software verification. Mathematically, data languages are modeled using *nominal sets*. Over the years, several machine models for handling data languages of different expressive power have been proposed; see [21, 20] for a comprehensive survey. The focus of this paper is on languages recognized by *orbit-finite nominal monoids*. They form an important subclass of the languages accepted by Francez and Kaminski's *finite memory automata* [10] (which are expressively equivalent to orbit-finite automata in the category of nominal sets [5]) and have been characterized by a fragment of monadic second-order logic over data words called *rigidly guarded MSO* [17]. In addition, Bojańczyk [4] and Colcombet, Ley, and Puppis [17] established nominal versions of the McNaughton-Papert-Schützenberger theorem and showed that the first-order definable data languages are precisely the ones recognizable by aperiodic orbit-finite monoids.

In the light of these results, it is natural to ask whether a generic variety theory akin to Eilenberg's seminal work can be developed for data languages. As the main contribution of our paper, we answer this positively by establishing nominal generalizations of two key results known from the algebraic theory of regular languages. The first one is a counterpart of Eilenberg's variety theorem, which is the first result of this kind for data languages:

▶ **Nominal Eilenberg Theorem.** *Varieties of data languages correspond bijectively to pseudovarieties of nominal monoids.*

Here, the notion of a *pseudovariety of nominal monoids* is as expected: a class of orbit-finite nominal monoids closed under quotient monoids, submonoids, and finite products. In contrast, the notion of a *variety of data languages* requires two extra conditions unfamiliar from other Eilenberg-type correspondences, most notably a technical condition called *completeness* (Definition 4.13). Like the original Eilenberg theorem, its nominal version gives rise to a generic relation between properties of data languages and properties of nominal monoids. For instance, the aperiodic orbit-finite monoids form a pseudovariety, and the first-order definable data languages form a variety, and thus the equivalence of these concepts can be understood as an instance of the nominal Eilenberg correspondence.

On a conceptual level, our results crucially make use of *duality*, specifically an extension of Petrişan's [15] nominal version of Stone duality which gives a dual equivalence between nominal sets and nominal complete atomic boolean algebras. To derive the nominal Eilenberg correspondence, we make two key observations. First, we show that varieties of data languages dualize (under nominal Stone duality) to the concept of an *equational theory* in the category of nominal sets. Second, we apply a recent categorical generalization of Birkhoff-type variety theorems [14] to show that equational theories correspond to pseudovarieties of nominal monoids. Our approach is summarized by the diagram below:



The idea that Stone-type dualities play a major role in algebraic language theory was firmly established by Gehrke, Grigorieff, and Pin [9]. It is also at the heart of our recent line of work [1, 2, 22, 3], which culminated in a uniform category theoretic proof of more than a dozen Eilenberg correspondences for various types of languages. A related, yet more abstract, approach was pursued by Salamánca [18]. The key insight of [22, 18] is that Eilenberg-type correspondences arise by combining a Birkhoff-type correspondence with a Stone-type duality. Our present approach to data languages is an implementation of this principle in the nominal setting. Since the existing categorical frameworks for algebraic language theory consider algebraic-like base categories (which excludes nominal sets) and the recognition of languages by finite structures, our Nominal Eilenberg Theorem is not covered by any previous categorical work and requires new techniques. However, our approach can be seen as an indication of the robustness of the duality-based methodology for algebraic recognition.

As our second main contribution, we complement the Nominal Eilenberg Theorem with a model-theoretic description of pseudovarieties of nominal monoids in terms of sequences of *nominal equations*, generalizing the classical result of Eilenberg and Schützenberger for ordinary monoids. Our result applies more generally to the class of *weak pseudovarieties* of nominal monoids, which are only required to be closed under support-reflecting (rather than arbitrary) quotients. We then obtain the

▶ **Nominal Eilenberg-Schützenberger Theorem.** *Weak pseudovarieties are exactly the classes of nominal monoids axiomatizable by sequences of nominal equations.*

While our main results apply to languages recognizable by orbit-finite monoids, the underlying methods are of fairly general nature and can be extended to other recognizing structures in the category of nominal sets. We illustrate this in section 5 by deriving a (local) Eilenberg correspondence for languages accepted by deterministic nominal automata.

Full proofs of all results can be found in the extended arXiv version [23] of our paper.

2 Nominal Sets

We start by recalling basic definitions and facts from the theory of nominal sets [16]. Some of the concepts considered in this paper are most clearly and conveniently formulated in the language of category theory, but only very basic knowledge of category theory is required from the reader. Fix a countably infinite set $\mathbb{A}$ of *atoms*, and denote by $\mathrm{Perm}(\mathbb{A})$ the group of finite permutations of $\mathbb{A}$ (i.e. bijections $\pi\colon \mathbb{A} \to \mathbb{A}$ that move only finitely many elements of $\mathbb{A}$). A $\mathrm{Perm}(\mathbb{A})$-*set* is a set X with an operation $\mathrm{Perm}(\mathbb{A}) \times X \to X$, denoted as $(\pi, x) \mapsto \pi \cdot x$, such that $(\sigma\pi)\cdot x = \sigma \cdot (\pi \cdot x)$ and $id \cdot x$ for all $\sigma, \pi \in \mathrm{Perm}(\mathbb{A})$ and $x \in X$. If the group action is trivial, i.e. $\pi \cdot x = x$ for all $\pi \in \mathrm{Perm}(\mathbb{A})$ and $x \in X$, we call X *discrete*. For any set $S \subseteq \mathbb{A}$ of atoms, denote by $\mathrm{Perm}_S(\mathbb{A}) \subseteq \mathrm{Perm}(\mathbb{A})$ the subgroup of all finite permutations π that fix S, i.e. $\pi(a) = a$ for all $a \in S$. The set S is called a *support* of an element $x \in X$ if for every $\pi \in \mathrm{Perm}_S(\mathbb{A})$ one has $\pi \cdot x = x$. The intuition is that x is some kind of syntactic object (e.g. a string, a tree, a term, or a program) whose free variables are contained in S. Thus, a variable renaming π that leaves S fixed does not affect x. A *nominal set* is a $\mathrm{Perm}(\mathbb{A})$-set X such that every element of X has a finite support. This implies that every element $x \in X$ has a least support, denoted by $\mathsf{supp}_X(x) \subseteq \mathbb{A}$. A nominal set X is *strong* if, for every $x \in X$ and $\pi \in \mathrm{Perm}(\mathbb{A})$, one has $\pi \cdot x = x$ if and only if $\pi(a) = a$ for all $a \in \mathsf{supp}_X(x)$. The *orbit* of an element x of a nominal set X is the set $\{\pi \cdot x \ : \ \pi \in \mathrm{Perm}(\mathbb{A})\}$. The orbits form a partition of X. If X has only finitely many orbits, then X is called *orbit-finite*. More generally, for any finite set $S \subseteq \mathbb{A}$ of atoms, the S-*orbit* of an element $x \in X$ is the set $\{\pi \cdot x \ : \ \pi \in \mathrm{Perm}_S(\mathbb{A})\}$, and the S-orbits form a partition of X.

▶ **Lemma 2.1.** *Let S be a finite subset of $\mathbb{A}$. Then every orbit-finite nominal set has only finitely many S-orbits.*

A map $f\colon X \to Y$ between nominal sets is *equivariant* if $f(\pi\cdot x) = \pi\cdot f(x)$ for all $\pi \in \mathrm{Perm}(\mathbb{A})$ and $x \in X$, and *finitely supported* if there exists a finite set $S \subseteq \mathbb{A}$ such that $f(\pi\cdot x) = \pi\cdot f(x)$ for all $\pi \in \mathrm{Perm}_S(\mathbb{A})$ and $x \in X$. Equivariant maps do not increase supports, i.e. one has $\mathsf{supp}_Y(f(x)) \subseteq \mathsf{supp}_X(x)$ for all $x \in X$. We write $\mathbf{Nom}_{\mathsf{fs}}$ for the category of nominal sets and finitely supported maps, and **Nom** for the (non-full) subcategory of nominal sets and equivariant maps. We shall use the following standard results about **Nom**:

(1) **Nom** is complete and cocomplete. Finite limits and all colimits are formed on the level of underlying sets. In particular, finite products of nominal sets are given by cartesian products and coproducts by disjoint union.

(2) For every pair X, Y of nominal sets, the *exponential* $[X, Y]$ is the nominal set consisting of all finitely supported maps $f\colon X \to Y$, with the group action given by $(\pi\cdot f)(x) = \pi\cdot f(\pi^{-1}\cdot x)$. Moreover, for every nominal set X, the *nominal power set* $\mathcal{P}X$ is carried by the set of all subsets $X_0 \subseteq X$ with finite support; i.e. for which there exists a finite set $S \subseteq \mathbb{A}$ of atoms such that $\pi\cdot X_0 = X_0$ for $\pi \in \mathrm{Perm}_S(\mathbb{A})$, where $\pi\cdot X_0 = \{\pi\cdot x \;:\; x \in X_0\}$. In particular, every singleton $\{x\}$ is finitely supported by $\mathsf{supp}_X(x)$. The group action on $\mathcal{P}X$ is given by $X_0 \mapsto \pi\cdot X_0$, and we have $\mathcal{P}X \cong [X, 2]$, for the discrete nominal set $2 = \{0, 1\}$.

(3) *Quotients* and *subobjects* in **Nom** are represented by epimorphisms (= surjective equivariant maps) and monomorphisms (= injective equivariant maps), respectively. **Nom** has image factorizations, i.e. every equivariant map $f\colon X \to Y$ has a unique decomposition $f = m\cdot e$ into a quotient $e\colon X \twoheadrightarrow I$ followed by a subobject $m\colon I \rightarrowtail Y$. We call e the *coimage* of f.

(4) Orbit-finite nominal sets are closed under quotients, subobjects, and finite products.

(5) For each $n \geq 0$, the nominal set $\mathbb{A}^{\#n} = \{\,(a_1, \ldots, a_n) \in \mathbb{A}^n \;:\; a_i \neq a_j \text{ for } i \neq j\,\}$ with group action $\pi\cdot(a_1, \ldots, a_n) = (\pi(a_1), \ldots, \pi(a_n))$ is strong and has a single orbit. More generally, the (orbit-finite) strong nominal sets are up to isomorphism exactly the (finite) coproducts of nominal sets of the form $\mathbb{A}^{\#n}$.

3 Pseudovarieties of Nominal Monoids

In this section, we investigate classes of orbit-finite nominal monoids and establish two characterizations of such classes: a categorical one, relating pseudovarieties of nominal monoids to equational theories in the category of nominal sets, and an axiomatic one, describing weak pseudovarieties in terms of sequences of nominal equations. The first of these results is the algebraic foundation of our subsequent treatment of varieties of data languages.

A *nominal monoid* is a monoid $(M, \bullet, 1_M)$ in the category **Nom**; that is, M is equipped with the structure of a nominal set such that the multiplication $\bullet\colon M \times M \to M$ is an equivariant map and the unit $1_M \in M$ has empty support, i.e. it corresponds to an equivariant map $1 \to M$, where 1 is the nominal set with one element. We write **nMon** for the category of nominal monoids and equivariant monoid morphisms (usually just called *morphisms*), and $\mathbf{nMon}_{\mathsf{of}}$ for the full subcategory of orbit-finite nominal monoids. The forgetful functor from **nMon** to **Nom** has a left adjoint assigning to each nominal set Σ the free nominal monoid Σ^* of all words over Σ, with monoid multiplication given by concatentation of words, unit ε (the empty word) and group action $\pi\cdot(a_1\cdots a_n) = \pi(a_1)\cdots\pi(a_n)$ for $\pi \in \mathrm{Perm}(\mathbb{A})$ and $a_1\cdots a_n \in \Sigma^*$. The category **nMon** has products (formed on the level of **Nom**), image factorizations, and surjective and injective morphisms represent *quotients* and *submonoids* of

nominal monoids. A quotient $q\colon M \twoheadrightarrow M'$ is called *support-reflecting* if for every $x' \in M'$ there exists an $x \in M$ with $q(x) = x'$ and $\mathsf{supp}_M(x) = \mathsf{supp}_{M'}(x')$. The following result characterizes the quotient monoids of Σ^* in terms of unary operations:

▶ **Proposition 3.1** (Unary presentation for nominal monoids). *For every nominal set Σ and every surjective equivariant map $e\colon \Sigma^* \twoheadrightarrow M$, the following statements are equivalent:*

(1) *e carries a quotient monoid of Σ^*, i.e. there exists a nominal monoid structure $(M, \bullet, 1_M)$ on M such that $e\colon \Sigma^* \twoheadrightarrow (M, \bullet, 1_M)$ is a morphism of nominal monoids;*

(2) *the maps $\Sigma^* \xrightarrow{w\cdot -} \Sigma^*$ and $\Sigma^* \xrightarrow{-\cdot w} \Sigma^*$ $(w \in \Sigma^*)$ lift along e, i.e. there exist (necessarily unique) maps l_w and r_w making the following squares commute:*

$$\begin{array}{ccc} \Sigma^* & \xrightarrow{w\cdot -} & \Sigma^* \\ {\scriptstyle e}\downarrow & & \downarrow{\scriptstyle e} \\ M & \xrightarrow[l_w]{} & M \end{array} \qquad \begin{array}{ccc} \Sigma^* & \xrightarrow{-\cdot w} & \Sigma^* \\ {\scriptstyle e}\downarrow & & \downarrow{\scriptstyle e} \\ M & \xrightarrow[r_w]{} & M \end{array} \qquad \text{for every } w \in \Sigma^*.$$

In general, the maps $w \cdot -$ and $- \cdot w$ are not equivariant, but finitely supported (with support contained in the one of w). This implies that also l_w and r_w in 2 are finitely supported.

3.1 Equational Theories

In previous work [14] we studied varieties of objects in a general category and their relation to an abstract form of equations. In the following, we instantiate these concepts to the category of nominal sets to derive a characterization of pseudovarieties of orbit-finite monoids.

▶ **Definition 3.2.** Let Σ be a nominal set. A *Σ-generated nominal monoid* is a nominal quotient monoid $e\colon \Sigma^* \twoheadrightarrow M$ of the free monoid Σ^*. We denote by $\Sigma^*{\downarrow}\mathbf{nMon}_{\mathsf{of}}$ the poset of Σ-generated orbit-finite nominal monoids, ordered by $e \leq e'$ iff e' factorizes through e.

▶ **Definition 3.3.** A *local pseudovariety of Σ-generated nominal monoids* is a filter $\mathcal{T}_\Sigma \subseteq \Sigma^*{\downarrow}\mathbf{nMon}_{\mathsf{of}}$ in the poset of Σ-generated orbit-finite nominal monoids; that is, $\mathcal{T}_\Sigma$ is

(1) *upwards closed:* $e \in \mathcal{T}_\Sigma$ and $e \leq e'$ implies $e' \in \mathcal{T}_\Sigma$, and

(2) *downwards directed:* for each pair $e_0, e_1 \in \mathcal{T}_\Sigma$ there exists $e \in \mathcal{T}_\Sigma$ with $e \leq e_0, e_1$.

If we replace (1) by the weaker condition

(1') for each $e\colon \Sigma^* \twoheadrightarrow M$ in $\mathcal{T}_\Sigma$ and each support-reflecting $q\colon M \twoheadrightarrow N$ one has $q \cdot e \in \mathcal{T}_\Sigma$,

then $\mathcal{T}_\Sigma$ is called a *weak local pseudovariety of Σ-generated nominal monoids.*

▶ **Remark 3.4.** By Proposition 3.1, the definition of local pseudovariety can be equivalently stated as follows:

(1) $\mathcal{T}_\Sigma$ is a filter in the poset of orbit-finite quotients of Σ^* in $\mathbf{Nom}$;

(2) for every $e \in \mathcal{T}_\Sigma$ and $w \in \Sigma^*$, the unary operations $w \cdot -$ and $- \cdot w$ on Σ^* lift along e.

Let $\mathbf{Nom}_{\mathsf{of,s}}$ denote the full subcategory of $\mathbf{Nom}$ on orbit-finite strong nominal sets.

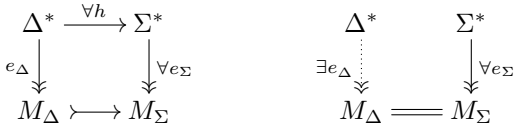
▶ **Definition 3.5** (Equational Theory). A *(weak) equational theory* is a family

$$\mathcal{T} = (\, \mathcal{T}_\Sigma \subseteq \Sigma^*{\downarrow}\mathbf{nMon}_{\mathsf{of}} \,)_{\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}}$$

of (weak) local pseudovarieties with the following two properties (see the diagrams below):

(1) *Substitution invariance.* For each equivariant monoid morphism $h\colon \Delta^* \to \Sigma^*$ with $\Delta, \Sigma \in \mathbf{Nom}_{\mathsf{of,s}}$ and each $e_\Sigma\colon \Sigma^* \twoheadrightarrow M_\Sigma$ in $\mathcal{T}_\Sigma$, the coimage e_Δ of $e_\Sigma \cdot h$ lies in $\mathcal{T}_\Delta$.

(2) *Completeness.* For each $\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}$ and each quotient $e\colon \Sigma^* \twoheadrightarrow M_\Sigma$ in $\mathcal{T}_\Sigma$, there exists $\Delta \in \mathbf{Nom}_{\mathsf{of,s}}$ and a support-reflecting quotient $e_\Delta\colon \Delta^* \twoheadrightarrow M_\Delta$ in $\mathcal{T}_\Delta$ with $M_\Delta = M_\Sigma$.



▶ **Remark 3.6.**

(1) Local pseudovarieties were previously called *equations* [14]. In fact, in many instances of the framework in *op. cit.*, a filter of quotients can be represented as a single quotient of a free algebra on an object Σ, which in turn corresponds to a set of pairs of terms given by the kernel of the quotient, i.e. to the usual syntactic concept of an equation.

(2) The restriction to *strong* nominal sets Σ as generators reflects that the latter are the "free" nominal sets [11], a property crucial for the proof of Theorem 3.8 below. More precisely, letting $\mathcal{P}_f\mathbb{A}$ denote the set of finite subsets of $\mathbb{A}$, the forgetful functor $U\colon \mathbf{Nom} \to \mathbf{Set}^{\mathcal{P}_f\mathbb{A}}$ mapping a nominal set X to the presheaf $S \mapsto \{\, x \in X \;:\; \mathsf{supp}_X(x) \subseteq S \,\}$ has a left adjoint F, and strong nominal sets are exactly the nominal sets of the form FP for $P \in \mathbf{Set}^{\mathcal{P}_f\mathbb{A}}$.

(3) The somewhat technical completeness property cannot be avoided, i.e. a substitution-invariant family of local pseudovarieties is generally incomplete. Indeed, consider the family

$$\mathcal{T} = (\, \mathcal{T}_\Sigma \subseteq \Sigma^* {\downarrow} \mathbf{nMon}_{\mathsf{of}} \,)_{\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}},$$

where $\mathcal{T}_\Sigma$ consists of all Σ-generated orbit-finite nominal monoids $e\colon \Sigma^* \twoheadrightarrow M$ such that e maps each element of Σ^* with a support of size 1 to 1_M.

To see that $\mathcal{T}_\Sigma$ is a filter, suppose that $e\colon \Sigma^* \twoheadrightarrow M$ and $e'\colon \Sigma^* \twoheadrightarrow M'$ are two quotients in $\mathcal{T}_\Sigma$. Form their subdirect product q, viz. the coimage of the morphism $\langle e, e' \rangle\colon \Sigma^* \to M \times M'$. Each $w \in \Sigma^*$ with a support of size 1 is mapped by q to $(e(w), e'(w)) = (1_M, 1_{M'}) = 1_{M \times M'}$. Thus $q \in \mathcal{T}_\Sigma$ and $q \leq e, e'$, i.e. $\mathcal{T}_\Sigma$ is downwards directed. Clearly, $\mathcal{T}_\Sigma$ is also upwards closed.

For substitution invariance, let $h\colon \Delta^* \to \Sigma^*$ be a morphism and $e_\Sigma\colon \Sigma^* \twoheadrightarrow M_\Sigma$ a quotient in $\mathcal{T}_\Sigma$. Then $e_\Sigma \cdot h$ maps each element with a support of size 1 to 1_{M_Σ} since e_Σ does and the equivariant map h does not increase supports. Thus, the coimage of $e_\Sigma \cdot h$ lies in $\mathcal{T}_\Delta$.

Finally, we show that $\mathcal{T}$ is not complete. Fix an arbitrary orbit-finite nominal monoid M containing an element m with $|\,\mathsf{supp}_M\, m| = 1$. Note that $m \neq 1_M$ because 1_M has empty support. Moreover, choose an orbit-finite strong nominal set Σ such that all elements of Σ have least support of size at least 2, and M can be expressed as a quotient $e\colon \Sigma^* \twoheadrightarrow M$. (For instance, one may take $\Sigma = \coprod_{i<k} \mathbb{A}^{\#n}$ where k is the number of orbits of M and $n = \max\{2, |\,\mathsf{supp}_M(x)| : x \in M\}$.) Since all nonempty words in Σ^* have a least support of size at least 2, one has $e \in \mathcal{T}_\Sigma$. For every $\Delta \in \mathbf{Nom}_{\mathsf{of,s}}$ and every quotient $q\colon \Delta^* \twoheadrightarrow M$ in $\mathcal{T}_\Delta$, the set $q^{-1}[\{m\}] \subseteq \Delta^*$ contains no element with least support of size 1, since such elements are mapped by q to $1_M \neq m$. Consequently, q is not support-reflecting. This shows that M is not the codomain of any support-reflecting quotient in $\mathcal{T}_\Delta$.

▶ **Definition 3.7** (Pseudovariety and Weak Pseudovariety)**.** A *pseudovariety of nominal monoids* is a nonempty class $\mathcal{V}$ of orbit-finite nominal monoids closed under finite products, submonoids, and quotient monoids. That is,

(1) for each $M, N \in \mathcal{V}$ one has $M \times N \in \mathcal{V}$;

(2) for each $M \in \mathcal{V}$ and each nominal submonoid $N \rightarrowtail M$ one has $N \in \mathcal{V}$;

(3) for each $M \in \mathcal{V}$ and each nominal quotient monoid $M \twoheadrightarrow N$ one has $N \in \mathcal{V}$.

A *weak pseudovariety of nominal monoids* is a nonempty class of orbit-finite nominal monoids closed under finite products, submonoids, and support-reflecting quotient monoids.

The following result is a special case of the Generalized Variety Theorem [14, Theorem 3.15]. It asserts that equational theories and pseudovarieties are equivalent concepts. Note that (weak) equational theories form a poset ordered by $\mathcal{T} \leq \mathcal{T}'$ iff $\mathcal{T}_\Sigma \leq \mathcal{T}'_\Sigma$ for all $\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}$, where $\mathcal{T}_\Sigma \leq \mathcal{T}'_\Sigma$ holds iff for every $e' \in \mathcal{T}'_\Sigma$ there exists an $e \in \mathcal{T}_\Sigma$ with $e \leq e'$. Similarly, (weak) pseudovarieties of nominal monoids form a poset w.r.t. the inclusion ordering.

▶ **Theorem 3.8.** *(Weak) equational theories and (weak) pseudovarieties of nominal monoids form dually isomorphic complete lattices.*

The isomorphism maps a (weak) equational theory $\mathcal{T}$ to the (weak) pseudovariety $\mathcal{V}(\mathcal{T})$ of all orbit-finite monoids M such that each morphism $h\colon \Sigma^* \to M$ with $\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}$ factorizes through some $e_\Sigma \in \mathcal{T}_\Sigma$. The inverse maps a (weak) pseudovariety $\mathcal{V}$ to the (weak) equational theory $\mathcal{T}(\mathcal{V})$ where $\mathcal{T}(\mathcal{V})_\Sigma$ consists of all quotients $e\colon \Sigma^* \twoheadrightarrow M$ with codomain $M \in \mathcal{V}$.

3.2 The Nominal Eilenberg-Schützenberger Theorem

In addition to their abstract category theoretic characterization in Theorem 3.8, weak pseudovarieties of nominal monoids admit an axiomatic description in terms of sequences of equations, analogous to the classical result of Eilenberg and Schützenberger [7] for pseudovarieties of ordinary monoids. The appropriate concept of equation is as follows:

▶ **Definition 3.9.**

(1) An *equation* is a pair $(s,t) \in X^* \times X^*$, denoted as $s = t$, where X is an orbit-finite strong nominal set. A nominal monoid M *satisfies* $s = t$ if for every equivariant map $h\colon X \to M$ one has $\widehat{h}(s) = \widehat{h}(t)$, where $\widehat{h}\colon X^* \to M$ denotes the unique extension of h to an equivariant monoid morphism.

(2) Given a sequence $E = (s_n = t_n)_{n\in\mathbb{N}}$ of equations (possibly taken over different orbit-finite strong nominal sets X of generators), a nominal monoid M *eventually satisfies* E if there exists an index $n_0 \in \mathbb{N}$ such that M satisfies all the equations $s_n = t_n$ with $n \geq n_0$. We denote by $\mathcal{V}(E)$ the class of all orbit-finite nominal monoids that eventually satisfy E.

▶ **Remark 3.10.** Equations can be presented syntactically as expressions of the form

$$y_1 : S_1, \dots, y_n : S_n \vdash u = v, \tag{1}$$

where $Y = \{y_1, \dots, y_n\}$ is a finite set of variables, $S_1, \dots, S_n \subseteq \mathbb{A}$ are finite sets of atoms, and u, v are words in $(\mathrm{Perm}(\mathbb{A}) \times Y)^*$. A nominal monoid M is said to *satisfy* (1) if for every *variable interpretation*, i.e. every map $h\colon Y \to M$ with $\mathsf{supp}_M(h(y_i)) \subseteq S_i$ for $i = 1, \dots, n$, one has $\overline{h}(u) = \overline{h}(v)$. Here, $\overline{h}\colon (\mathrm{Perm}(\mathbb{A}) \times Y)^* \to M$ is the unique monoid morphism mapping (π, y_i) to $\pi \cdot h(y_i)$. Every equation can be transformed into an expressively equivalent syntactic equation, and vice versa [13, Lemma B.31].

▶ **Theorem 3.11** (Nominal Eilenberg-Schützenberger Theorem)**.** *A class $\mathcal{V}$ of orbit-finite nominal monoids forms a weak pseudovariety iff $\mathcal{V} = \mathcal{V}(E)$ for some sequence E of equations.*

Proof sketch. The proof proceeds along the lines of the one for ordinary monoids [7], although some subtle modifications are required. The "if" direction is a routine verification. For the "only if" direction, let $\mathcal{V}$ be a weak pseudovariety. Using that there are only countably many orbit-finite monoids up to isomorphism, one can construct a sequence $M_0, M_1, M_2, \dots$ of nominal monoids in $\mathcal{V}$ such that each $M \in \mathcal{V}$ is a quotient of all but finitely many M_n's. Let $X_0, X_1, X_2, \dots$ be the sequence of all (countably many) strong orbit-finite nominal sets up to isomorphism, and consider the equivariant congruence relation on X_n^* given by

$$s \equiv_n t \quad \text{iff} \quad M_n \text{ satisfies the equation } s = t.$$

One then shows that the congruence $\equiv_n$ is generated by a finite subset $W_n \subseteq \equiv_n$, and that $\mathcal{V} = \mathcal{V}(E)$ for every sequence E that lists all equations in the countable set $\bigcup_n W_n$. ◀

▶ **Example 3.12.** An orbit-finite nominal monoid M is called *aperiodic* [4, 17] if there exists a natural number $n \geq 1$ such that $x^{n+1} = x^n$ for all $x \in M$. The class of all orbit-finite aperiodic nominal monoids forms a pseudovariety. Taking the set $Y = \{y\}$ of variables, it is not difficult to see that this pseudovariety is specified by the sequence of syntactic equations

$$y : S_n \vdash y^{n+1} = y^n \qquad (n \in \mathbb{N}),$$

where $S_n = \{a_0, a_1, \ldots, a_{n-1}\}$ is the set of the first n atoms in the countably infinite set $\mathbb{A} = \{a_0, a_1, a_2 \ldots\}$ of all atoms, and we write y for $(id, y) \in \mathrm{Perm}(\mathbb{A}) \times Y$.

4 Duality and the Nominal Eilenberg Correspondence

In this section, we establish our nominal version of Eilenberg's variety theorem. It is based on a dual interpretation of the concepts of a (local) pseudovariety of nominal monoids and of an equational theory, introduced in the previous section, under *nominal Stone duality*.

4.1 Nominal Stone Duality

A classical result from duality theory, known as *discrete Stone duality*, states that the category of sets is dually equivalent to the category of complete atomic boolean algebras, i.e. complete boolean algebras in which every non-zero element is above some atom. An analogous duality holds for the category $\mathbf{Nom}_{\mathsf{fs}}$ of nominal sets and finitely supported maps.

▶ **Definition 4.1.** A *nominal complete atomic boolean algebra* (*ncaba*) is a boolean algebra $(B, \vee, \wedge, \neg, \bot, \top)$ in **Nom** such that every finitely supported subset of B has a supremum, and for every element $b \in B \setminus \{\bot\}$ there exists an atom (i.e. a minimal element) $a \in B$ with $a \leq b$. Here, the partial order $\leq$ is defined as usual by $a \leq b$ iff $a \wedge b = a$. We denote by $\mathbf{nCABA}_{\mathsf{fs}}$ the category of ncabas and finitely supported morphisms (i.e. finitely supported maps preserving all the boolean operations and suprema of finitely supported subsets), and by $\mathbf{nCABA}$ the (non-full) subcategory of ncabas and *equivariant* morphisms.

▶ **Theorem 4.2** (Nominal Stone Duality)**.** *The categories* $\mathbf{nCABA}_{\mathsf{fs}}$ *and* $\mathbf{Nom}_{\mathsf{fs}}$ *are dually equivalent. The duality restricts to one between the subcategories* $\mathbf{nCABA}$ *and* $\mathbf{Nom}$*.*

The restricted duality is due to Petrişan [15, Prop. 5.3.11].

▶ **Remark 4.3.**

(1) The equivalence functor $\mathbf{Nom}_{\mathsf{fs}} \xrightarrow{\simeq} \mathbf{nCABA}_{\mathsf{fs}}^{\mathsf{op}}$ maps a nominal set X to the ncaba $\mathcal{P}X$ of finitely supported subsets of X (equipped with the set-theoretic boolean operations), and a finitely supported map $f\colon X \to Y$ to the morphism $f^{-1}\colon \mathcal{P}Y \to \mathcal{P}X$ taking preimages. The inverse equivalence functor $\mathbf{nCABA}_{\mathsf{fs}}^{\mathsf{op}} \xrightarrow{\simeq} \mathbf{Nom}_{\mathsf{fs}}$ maps an ncaba B to the equivariant subset $\mathsf{At}(B)$ of its atoms, with group action restricting the one of B.

(2) The dual equivalence restricts to one between the full subcategories of orbit-finite nominal sets and *atom-finite* ncabas, i.e. ncabas whose set of atoms is orbit-finite. For atom-finite ncabas the property that every finitely supported subset has a supremum is equivalent to the weaker requirement that for every finite set $S \subseteq \mathbb{A}$, every S-orbit has a supremum. Indeed, given a finitely supported subset $X \subseteq B$ (say with finite support $S \subseteq \mathbb{A}$), put $X' := \{\, a \in \mathsf{At}(B) : a \leq x \text{ for some } x \in X \,\}$. Since $\leq$ is an equivariant relation, $X' \subseteq \mathsf{At}(B)$ is a subset with finite support S. Since $\mathsf{At}(B)$ is orbit-finite and thus has only finitely many S-orbits by Lemma 2.1, we can express X' as a finite union $X' = X'_1 \cup \ldots \cup X'_n$ of S-orbits. Using that every element of B is the join of the finitely supported set of all atoms below it, it follows that $\bigvee X = \bigvee X' = \bigvee X'_1 \vee \ldots \vee \bigvee X'_n$, so $\bigvee X$ is a finite join of joins of S-orbits.

4.2 Varieties of Data Languages

For the notion of a *language* over an alphabet $\Sigma \in \mathbf{Nom}$ and the corresponding concept of algebraic recognition by nominal monoids, there are two natural choices: consider equivariant subsets $L \subseteq \Sigma^*$ and their recognition by equivariant monoid morphisms [5, 17], or consider finitely supported subsets $L \subseteq \Sigma^*$ and their recognition by finitely supported monoid morphisms [4]. For our duality-based approach to data languages, it turns out that we need to work with an intermediate concept: finitely supported languages recognizable by equivariant monoid morphisms (see the discussion in Remark 4.12 below). That is, we work with the following

▶ **Definition 4.4.** A *data language* over the alphabet $\Sigma \in \mathbf{Nom}$ is a finitely supported map $L\colon \Sigma^* \to 2$. It is *recognized* by an equivariant monoid morphism $e\colon \Sigma^* \to M$ if there exists a finitely supported map $p\colon M \to 2$ with $L = p \cdot e$. In this case, we also say that M *recognizes* L. A data language is *recognizable* if it recognized by some orbit-finite nominal monoid.

▶ **Remark 4.5.**

(1) Identifying finitely supported maps into 2 with finitely supported subsets, Definition 4.4 can be restated: an equivariant monoid morphism $e\colon \Sigma^* \to M$ *recognizes* a language $L \subseteq \Sigma^*$ if there exists a finitely supported subset $P \subseteq M^*$ with $L = e^{-1}[P]$.

(2) If L is an equivariant recognizable language, then p in Definition 4.4 is also equivariant. Therefore, for equivariant languages we recover the notion of recognition of [5, 17].

(3) If Σ is a finite set (viewed as an orbit-finite discrete nominal set), a data language is just an ordinary formal language over the alphabet Σ. Indeed, the free nominal monoid Σ^* is discrete, and thus every subset of Σ^* is finitely supported. Moreover, every orbit-finite nominal quotient monoid of Σ^* is discrete and finite. Hence, the above notion of language recognition coincides with the classical recognition by finite monoids. In particular, for finite Σ, a recognizable data language is the same as a regular language.

▶ **Example 4.6.** Examples of recognizable data languages over the alphabet $\Sigma = \mathbb{A}$ include (1) every finite or cofinite subset $L \subseteq \mathbb{A}^*$ (see Remark 4.8 below), (2) $a\mathbb{A}^*$ for a fixed atom $a \in \mathbb{A}$, and (3) $\bigcup_{a\in\mathbb{A}} \mathbb{A}^*aa\mathbb{A}^*$. The languages (4) $\{a_1 \dots a_n \ : \ a_i \neq a_j \text{ for } i \neq j\}$, (5) $\bigcup_{a\in\mathbb{A}} a\mathbb{A}^*a\mathbb{A}^*$, and (6) $\mathbb{A}^*a\mathbb{A}^*$ for a fixed atom $a \in \mathbb{A}$ are not recognizable. The equivariant examples (3)–(5) are taken from [4, 5].

In previous work [1] we have given a categorical account of *local varieties of regular languages* [9], i.e. sets of regular languages over a fixed finite alphabet Σ closed under the set-theoretic boolean operations (finite union, finite intersection, complement) and derivatives. This concept can be generalized to data languages. The *derivatives* of a data language $L \subseteq \Sigma^*$ with respect to a word $w \in \Sigma^*$ are given by

$$w^{-1}L = \{\, v \in \Sigma^* \ : \ wv \in L \,\} \quad \text{and} \quad Lw^{-1} = \{\, v \in \Sigma^* \ : \ vw \in L \,\}.$$

Since $\mathsf{supp}(w^{-1}L), \mathsf{supp}(Lw^{-1}) \subseteq \mathsf{supp}(w) \cup \mathsf{supp}(L)$, the derivatives are again data languages.

▶ **Definition 4.7** (Local Variety of Data Languages)**.** Let $\Sigma \in \mathbf{Nom}$. A *local variety of data languages over* Σ is an equivariant set $\mathcal{V}_\Sigma \subseteq \mathcal{P}\Sigma^*$ of recognizable data languages closed under the set-theoretic boolean operations, unions of S-orbits for every finite set $S \subseteq \mathbb{A}$ of atoms (that is, for every $L \in \mathcal{V}_\Sigma$ the language $\bigcup_{\pi\in \mathrm{Perm}_S(\mathbb{A})} \pi \cdot L$ lies in $\mathcal{V}_\Sigma$), and derivatives.

▶ **Remark 4.8.**

(1) If Σ is a finite set (viewed as a discrete nominal set), then by Remark 4.5 a local variety $\mathcal{V}_\Sigma$ consists of regular languages, and the closure under unions of S-orbits is trivial: since $\mathcal{P}\Sigma^*$ is discrete, every S-orbit has a single element. Thus, in this case, a local variety of data languages is precisely a local variety of regular languages.

(2) However, in general the closedness under unions of S-orbits cannot be dropped, as it is neither trivial nor implied by the other conditions. To see this, consider the alphabet $\Sigma = \mathbb{A}$ and the equivariant set $\mathcal{V}_{\mathbb{A}} \subseteq \mathcal{P}\mathbb{A}^*$ of all finite or cofinite subsets of $\mathbb{A}^*$. Note that every finite language $L \subseteq \mathbb{A}^*$ is recognizable: let $n \geq 1$ be an upper bound on the length of words in L, and take the orbit-finite monoid $M = \mathbb{A}^{\leq n} \cup \{0\}$ consisting of all words over $\mathbb{A}$ of length at most n, and a zero element 0. The multiplication $\bullet$ is defined as follows: given $v, w \in \mathbb{A}^{\leq n}$, if the word vw has length at most n, put $v \bullet w = vw$. Otherwise, put $v \bullet w = 0$. Then the equivariant monoid morphism $e\colon \mathbb{A}^* \to M$ extending $a \mapsto a$ recognizes L since $L = e^{-1}[L]$. It follows that also $\mathbb{A}^* \setminus L = e^{-1}[M \setminus L]$. This shows that every language in $\mathcal{V}_{\mathbb{A}}$ is recognizable. Moreover, clearly $\mathcal{V}_{\mathbb{A}}$ is closed under the set-theoretic boolean operations and derivatives. However, the languages $\{a\}$, $a \in \mathbb{A}$, form an orbit in $\mathcal{V}_{\mathbb{A}}$, but their union $\mathbb{A} = \bigcup_{a \in \mathbb{A}} \{a\}$ is not in $\mathcal{V}_{\mathbb{A}}$. Thus $\mathcal{V}_{\mathbb{A}}$ is not a local variety of data languages in the sense of Definition 4.7.

A local variety $\mathcal{V}_\Sigma$ is generally not a subobject of $\mathcal{P}\Sigma^*$ in **nCABA**, because it is not required to be closed under unions of arbitrary finitely supported subsets and also not necessarily atomic as a boolean algebra. However, if the atomic languages in $\mathcal{V}_\Sigma$ form an orbit-finite subset and every language in $\mathcal{V}_\Sigma$ contains some atomic language, then $\mathcal{V}_\Sigma$ is an atom-finite subobject of $\mathcal{P}\Sigma^*$, see Remark 4.32. In this case, we call $\mathcal{V}_\Sigma$ an *atom-finite* local variety.

▶ **Theorem 4.9** (Finite Local Variety Theorem)**.** *The lattice of atom-finite local varieties of data languages over Σ is dually isomorphic to the lattice of Σ-generated orbit-finite monoids.*

The isomorphism maps a Σ-generated orbit-finite monoid $e\colon \Sigma^* \twoheadrightarrow M$ to the atom-finite local variety of all data languages recognized by e.

Proof. By the duality of **Nom** and **nCABA**, orbit-finite equivariant quotients $e\colon \Sigma^* \twoheadrightarrow M$ of Σ^* in **Nom** correspond bijectively to atom-finite subobjects $\mathcal{V}_\Sigma \rightarrowtail \mathcal{P}\Sigma^*$ in **nCABA**, i.e. atom-finite equivariant sets of languages closed under the set-theoretic boolean operations and unions of S-orbits for every finite $S \subseteq \mathbb{A}$. By Proposition 3.1 and the dual equivalence of $\mathbf{Nom}_{\mathsf{fs}}$ and $\mathbf{nCABA}_{\mathsf{fs}}$, the map e represents a nominal quotient monoid of Σ^* if and only if $\mathcal{V}_\Sigma$ is closed under derivatives, i.e. a local variety. The closure under left derivatives is illustrated by the two dual commutative squares below, where the left-hand one lives in $\mathbf{Nom}_{\mathsf{fs}}$ and the right-hand one in $\mathbf{nCABA}_{\mathsf{fs}}$.

$$\begin{array}{ccc} \Sigma^* & \xrightarrow{w\cdot -} & \Sigma^* \\ {\scriptstyle e}\downarrow & & \downarrow{\scriptstyle e} \\ M & \dashrightarrow_{\exists} & M \end{array} \qquad\qquad \begin{array}{ccc} \mathcal{P}\Sigma^* & \xleftarrow{w^{-1}(-)} & \mathcal{P}\Sigma^* \\ {\scriptstyle \subseteq}\uparrow & & \uparrow{\scriptstyle \subseteq} \\ \mathcal{V}_\Sigma & \dashleftarrow_{\exists} & \mathcal{V}_\Sigma \end{array}$$

The elements of $\mathcal{V}_\Sigma$ are precisely the languages recognized by e. Indeed, the former correspond to the morphisms $\mathbb{1} \to \mathcal{V}_\Sigma$ in $\mathbf{nCABA}_{\mathsf{fs}}$, where $\mathbb{1}$ is the free boolean algebra on one generator, the latter to the finitely supported maps $M \to 2$ in $\mathbf{Nom}_{\mathsf{fs}}$, and $\mathbb{1}$ and 2 are dual objects. ◀

Recall that an *ideal* in a poset is a downwards closed and upwards directed subset. For the lattice of local varieties of data languages over Σ (ordered by inclusion), we obtain

▶ **Lemma 4.10.** *The lattice of local varieties of data languages over Σ is isomorphic to the lattice of ideals in the poset of atom-finite local varieties over Σ.*

The isomorphism maps a local variety $\mathcal{V}_\Sigma$ to the ideal of all atom-finite local subvarieties of $\mathcal{V}_\Sigma$. Its inverse maps an ideal $\{\, \mathcal{V}_{\Sigma,i} : i \in I \,\}$ in the poset of atom-finite local varieties to the local variety $\bigcup_{i\in I} \mathcal{V}_{\Sigma,i}$. In order-theoretic terms, the above lemma states that local varieties of data languages form the ideal completion of the poset of atom-finite local varieties. Using Theorem 4.9, Lemma 4.10, and the fact that ideals are dual to filters, we obtain

▶ **Theorem 4.11** (Local Variety Theorem). *For each $\Sigma \in \mathbf{Nom}$, the lattice of local varieties of data languages over Σ is dually isomorphic to the lattice of local pseudovarieties of Σ-generated nominal monoids.*

▶ **Remark 4.12.**

(1) Since data languages are morphisms $L\colon \Sigma^* \to 2$ in $\mathbf{Nom}_{\mathsf{fs}}$, the reader may wonder why we do not entirely work in this category and use monoids with finitely supported multiplication and finitely supported monoid morphisms (rather than the equivariant ones) for the recognition of languages. The reason lies on the dual side: in the proof of Theorem 4.9, we used that equivariant injective maps $\mathcal{V}_\Sigma \rightarrowtail \mathcal{P}\Sigma^*$ can be uniquely identified with equivariant subsets of $\mathcal{P}\Sigma^*$. In contrast, finitely supported injective maps $\mathcal{V}_\Sigma \rightarrowtail \mathcal{P}\Sigma^*$ do not correspond to the finitely supported (or any other kind of) subsets of $\mathcal{P}\Sigma^*$.

(2) Similarly, we cannot restrict ourselves to the category $\mathbf{Nom}$ and only consider equivariant languages $L \subseteq \Sigma^*$ rather than finitely supported ones. Indeed, the Finite Local Variety Theorem then fails: the map sending a Σ-generated orbit-finite monoid $e\colon \Sigma^* \twoheadrightarrow M$ to the set of equivariant languages it recognizes is no longer bijective. To see this, consider the nominal monoids $M = \mathbb{A} \cup \{1\}$ with $a \bullet b = a$ for $a, b \in \mathbb{A}$, and $N = \{0, 1\}$ with $0 \bullet 0 = 0 \bullet 1 = 1 \bullet 0 = 0$. Then the two surjective morphisms $e\colon \mathbb{A}^* \twoheadrightarrow M$, extending $a \mapsto a$, and $f\colon \mathbb{A}^* \twoheadrightarrow N$, extending $a \mapsto 0$, recognize the same equivariant languages, namely $\mathbb{A}^*$, $\mathbb{A}^* \setminus \{\varepsilon\}$, $\{\varepsilon\}$ and $\emptyset$.

In the following, we consider data languages whose alphabet Σ is an orbit-finite strong nominal set (see Remark 3.62). By dualizing the concept of an equational theory, we obtain

▶ **Definition 4.13** (Variety of data languages). A *variety of data languages* is a family

$$\mathcal{V} = (\, \mathcal{V}_\Sigma \subseteq \mathcal{P}\Sigma^* \,)_{\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}}$$

of local varieties of data languages with the following two properties:

(1) *Closedness under preimages.* For each equivariant monoid morphism $h\colon \Delta^* \to \Sigma^*$ with $\Sigma, \Delta \in \mathbf{Nom}_{\mathsf{of,s}}$ and each $L \in \mathcal{V}_\Sigma$, one has $h^{-1}[L] \in \mathcal{V}_\Delta$.

(2) *Completeness.* For each atom-finite local subvariety $\mathcal{V}'_\Sigma \rightarrowtail \mathcal{V}_\Sigma$, there exists an equivariant monoid morphism $h\colon \Sigma^* \to \Delta^*$ and an atom-finite local subvariety $\mathcal{V}'_\Delta \rightarrowtail \mathcal{V}_\Delta$ such that
   a. the map $L \mapsto h^{-1}[L]$ defines a bijection between $\mathcal{V}'_\Delta$ and $\mathcal{V}'_\Sigma$, and
   b. every atomic language $L \in \mathcal{V}'_\Delta$ contains a word $w \in \Delta^*$ with $\mathsf{supp}_{\mathcal{P}\Delta^*}(L) = \mathsf{supp}_{\Delta^*}(w)$.

▶ **Remark 4.14.** Except for the completeness condition, the above concept is analogous to Eilenberg's original notion of a variety of regular languages (i.e. a family of local varieties of regular languages closed under preimages of monoid morphisms). In fact, if Σ is a finite alphabet, and thus $\mathcal{V}_\Sigma$ is just a local variety of regular languages, completeness is trivial: given any finite local subvariety $\mathcal{V}'_\Sigma$ of $\mathcal{V}_\Sigma$, choose $\Delta = \Sigma$, $\mathcal{V}'_\Delta = \mathcal{V}'_\Sigma$, and $h = id\colon \Sigma^* \to \Delta^*$. Then 2a is clear, and 2b holds because each $L \in \mathcal{P}\Sigma^*$ and each $w \in \Sigma^*$ has empty support.

In general, however, the completeness property cannot be dropped. This follows from Remark 3.63 and the observation that the completeness of a variety dualizes to the completeness of the corresponding equational theory (see the proof of Theorem 4.15).

We are ready to state the main result of our paper:

▶ **Theorem 4.15** (Nominal Eilenberg Theorem). *Varieties of data languages and pseudovarieties of nominal monoids form isomorphic complete lattices.*

The isomorphism maps a variety $\mathcal{V}$ of data languages to the pseudovariety $\mathcal{V}$ of all orbit-finite nominal monoids that recognize only languages from $\mathcal{V}$. Its inverse maps a pseudovariety $\mathcal{V}$ to the variety $\mathcal{V}$ of all data languages recognized by some monoid in $\mathcal{V}$.

Proof sketch. We observe that the concept of a variety is dual to that of an equational theory. Indeed, by the Local Variety Theorem 4.11, a family $\mathcal{V} = (\mathcal{V}_\Sigma \subseteq \mathcal{P}\Sigma^*)_{\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}}$ of local varieties of data languages bijectively corresponds to a family $\mathcal{T} = (\mathcal{T}_\Sigma \subseteq \Sigma^* \downarrow \mathbf{nMon}_{\mathsf{of}})_{\Sigma \in \mathbf{Nom}_{\mathsf{of,s}}}$ of local pseudovarieties of nominal monoids. One then shows that (1) $\mathcal{T}$ is substitution-invariant if and only if $\mathcal{V}$ is closed under preimages, and (2) $\mathcal{T}$ is complete if and only if $\mathcal{V}$ is complete. In particular, $\mathcal{T}$ is a theory if and only if $\mathcal{V}$ is a variety of data languages. Since theories correspond to pseudovarieties by Theorem 3.8, this proves the theorem. ◀

5 Adding Expressivity: Regular Data Languages

As recognizing structures for data languages, nominal monoids are of limited expressivity; in particular, they are strictly weaker than deterministic automata in the category of nominal sets [5, 4]. Therefore, we now show how to extend our results for monoid-recognizable data languages and establish a local variety theorem for languages accepted by nominal automata.

▶ **Definition 5.1.** Fix an input alphabet $\Sigma \in \mathbf{Nom}$. A *nominal Σ-automaton* $A = (Q, \delta, q_0)$ consists of a nominal set Q of states, an equivariant transition map $\delta\colon Q \times \Sigma \to Q$, and an initial state $q_0 \in Q$ with empty support. It is called *orbit-finite* if Q is orbit-finite. A *morphism* between nominal automata $A = (Q, \delta, q_0)$ and $A' = (Q', \delta', q_0')$ is an equivariant map $h\colon Q \to Q'$ such that $\delta(h(q), a) = h(\delta(q, a))$ for all $q \in Q$ and $a \in \Sigma$, and $h(q_0) = q_0'$.

The *initial nominal Σ-automaton* is given by $I = (\Sigma^*, \delta, \varepsilon)$ with transition map $\delta(w, a) = wa$ for $w \in \Sigma^*$ and $a \in \Sigma$. It is characterized by the universal property that for every nominal Σ-automaton $A = (Q, \delta, q_0)$, there exists a unique morphism $e_A\colon I \to A$, sending a word $w \in \Sigma^*$ to the state reached from q_0 after reading w. The automaton A is called *reachable* if e_A is surjective. A data language $L \subseteq \Sigma^*$ is *accepted* by A if there exists a finitely supported subset $F \subseteq Q$ with $L = e_A^{-1}[F]$. This corresponds to the usual notion of acceptance of an automaton with final states F: the language L consists of all words $w \in \Sigma^*$ such that A reaches a state in F after reading w. A data language $L \subseteq \Sigma^*$ is called *regular* if there exists an orbit-finite nominal automaton accepting it. In analogy to Proposition 3.1, we get

▶ **Proposition 5.2** (Unary presentation for nominal automata). *For every surjective equivariant map $e\colon \Sigma^* \twoheadrightarrow Q$, the following statements are equivalent:*

(1) *there exists a nominal automaton $A = (Q, \delta, q_0)$ with states Q such that $e = e_A$;*

(2) *the maps $\Sigma^* \xrightarrow{-\cdot w} \Sigma^*$ $(w \in \Sigma^*)$ lift along e, i.e. there exist (necessarily unique) maps $r_w\colon Q \to Q$ such that $e \cdot (- \cdot w) = r_w \cdot e$ for all $w \in \Sigma^*$.*

Define a *local pseudovariety of nominal Σ-automata* to be a class $\mathcal{V}_\Sigma$ of orbit-finite reachable nominal Σ-automata such that (1) $\mathcal{V}_\Sigma$ is closed under quotients (represented by surjective automata morphisms), and (2) for every pair $A, B \in \mathcal{V}_\Sigma$, the reachable part of the product $A \times B$ lies in $\mathcal{V}_\Sigma$. Here, the product of two nominal automata $A = (Q, \delta, q_0)$ and $B = (Q', \delta', q_0')$ is given by $A \times B = (Q \times Q', \delta, (q_0, q_0'))$ with $\delta((q, q'), a) = (\delta(q, a), \delta'(q', a))$ for $(q, q') \in Q \times Q'$ and $a \in \Sigma$, and the reachable part R of $A \times B$ is the coimage $e\colon \Sigma^* \twoheadrightarrow R$ of the unique

morphism $e_{A\times B}\colon \Sigma^* \to A \times B$. Note that a local pseudovariety corresponds precisely to a filter in the poset $\Sigma^*{\downarrow}\Sigma\text{-}\mathbf{nAut}_{\mathsf{of}}$ of orbit-finite reachable nominal Σ-automata. The dual version of this concept is the one of a *local variety of regular data languages over* Σ: an equivariant set $\mathcal{V}_\Sigma \subseteq \mathcal{P}\Sigma^*$ of such languages closed under the set-theoretic boolean operations, unions of S-orbits for every finite set $S \subseteq \mathbb{A}$ of atoms, and *right* derivatives. The following theorem, and its proof, are completely analogous to Theorem 4.11:

▶ **Theorem 5.3** (Local Variety Theorem for Regular Data Languages)**.** *For each* $\Sigma \in \mathbf{Nom}$*, the lattice of local varieties of regular data languages over* Σ *is dually isomorphic to the lattice of local pseudovarieties of nominal* Σ*-automata.*

6 Conclusions and Future Work

We have demonstrated that two cornerstones of the algebraic theory of regular languages, Eilenberg's variety theorem and Eilenberg and Schützenberger's axiomatic characterization of pseudovarieties, can be generalized to data languages recognizable by orbit-finite monoids. Our results are the first of this type for data languages, and thus the present work makes a contribution towards developing a fully fledged algebraic theory of such languages. In a broader sense, the approach taken in this paper can be seen as a further illustration of the power of duality in formal language theory: we believe that without the guidance given by nominal Stone duality, it would have been significantly harder to even come up with the suitable notion of a variety of data languages that makes the nominal Eilenberg correspondence work. The duality-based approach thus adds much conceptual clarity and simplicity. There remain several research questions and interesting directions for future work.

As indicated in section 5, the techniques used in our paper can be adapted without much effort to languages recognized by nominal algebraic structures other than monoids, including deterministic nominal automata. As a first step, we aim to extend the local variety theorem for regular data languages (Theorem 5.3) to a full Eilenberg correspondence. It remains an important goal to further extend our results to more powerful classes of data languages.

Our proof of the (local) Eilenberg correspondence rests on the observation that a local variety of data languages can be expressed as the directed union of its atom-finite subvarieties. From a category theoretic perspective, this suggests that local varieties are formed within the Ind-*completion* (i.e. the free completion under directed colimits) of the category of atom-finite nominal complete atomic boolean algebras. We conjecture that this completion can be described as a category of nominal boolean algebras with joins of S-orbits for each finite set S of atoms. On the dual side, we expect that the Pro-*completion* (i.e. the free completion under codirected limits) of the category of orbit-finite nominal sets consists of some form of nominal Stone spaces. The approach of working with free completions should lead to a topological version of nominal Stone duality similar to the one established by Gabbay, Litak, and Petrişan [8]. More importantly, it might pave the way to the introduction of pro-(orbit-)finite methods for the theory of data languages.

Abstract

Temporal graphs are used to abstractly model real-life networks that are inherently dynamic in nature, in the sense that the network structure undergoes discrete changes over time. Given a static underlying graph $G = (V, E)$, a temporal graph on G is a sequence of *snapshots* $\{G_t = (V, E_t) \subseteq G : t \in \mathbb{N}\}$, one for each time step $t \geq 1$. In this paper we study *stochastic temporal graphs*, i.e. stochastic processes $\mathcal{G} = \{G_t \subseteq G : t \in \mathbb{N}\}$ whose random variables are the snapshots of a temporal graph on G. A natural feature of stochastic temporal graphs which can be observed in various real-life scenarios is a *memory effect* in the appearance probabilities of particular edges; that is, the probability an edge $e \in E$ appears at time step t depends on its appearance (or absence) at the previous k steps. In this paper we study the hierarchy of models *memory-k*, $k \geq 0$, which address this memory effect in an *edge-centric* network evolution: every edge of G has its own probability distribution for its appearance over time, *independently* of all other edges. Clearly, for every $k \geq 1$, memory-$(k-1)$ is a special case of memory-k. However, in this paper we make a clear distinction between the values $k = 0$ (*"no memory"*) and $k \geq 1$ (*"some memory"*), as in some cases these models exhibit a fundamentally different computational behavior for these values of k, as our results indicate. For every $k \geq 0$ we investigate the computational complexity of two naturally related, but fundamentally different, *temporal path* (or *journey*) problems: Minimum Arrival and Best Policy. In the first problem we are looking for the *expected arrival time* of a foremost journey between two designated vertices s, y. In the second one we are looking for the expected arrival time of the *best policy* for actually choosing a *particular* s-y journey. We present a detailed investigation of the computational landscape of both problems for the different values of memory k. Among other results we prove that, surprisingly, Minimum Arrival is *strictly harder* than Best Policy; in fact, for $k = 0$, Minimum Arrival is #P-hard while Best Policy is solvable in $O(n^2)$ time.

1 Introduction

Dynamic network analysis, i.e. analysis of networks that change over time, is currently one of the most active topics of research in network science and theory. A common task in this field is to use our prior knowledge of the network link dynamics to answer questions about the behavior of the network over time, e.g. how quickly information can flow through it. Many modern real-life networks are dynamic in nature, in the sense that the network structure undergoes discrete changes over time [31, 36]. Here we deal with the discrete-time dynamicity of the network links (edges) over a fixed set of nodes (vertices). That is, given an underlying static graph G, the network evolution over G is given by the successive appearance or absence of each edge of G at every time step $t = 1, 2, \ldots$. This concept of dynamic network evolution is given by *temporal graphs* [27, 29], which are also known by other names such as *evolving graphs* [6, 20], or *time-varying graphs* [1]. For a recent attempt to integrate existing models, concepts, and results from the distributed computing perspective, see the survey papers [12, 13] and the references therein.

▶ **Definition 1** (Temporal graph). *Given an underlying static graph $G = (V, E)$ on n vertices and m edges, a* temporal graph *on G is a sequence $\mathcal{G} = \{G_t = (V, E_t) : t \in \mathbb{N}\}$ of graphs such that $E_t \subseteq E$ for all $t \in \mathbb{N}$. Every G_t is the* snapshot *of $\mathcal{G}$ at time step t.*

Another way to think about temporal graphs is by assigning *time-labels* on the edges; for example, if an edge e appears in the snapshots G_3, G_5, and G_8, then we equivalently assign to e the set of labels $\lambda(e) = \{3, 5, 8\}$. Due to the vast applicability of temporal graphs, various structural and algorithmic properties of them have been studied extensively, both via theoretical/algorithmic analysis and via empirical simulation-based analysis. In many of these works, one of the central temporal notions is that of a temporal path. A path in the underlying (static) graph G is a *temporal path* (or *journey*) if there exists an increasing sequence of time-labels as one walks along the edges of the path [27, 29]. Motivated by the fact that, due to causality, information in temporal graphs can only flow along sequences of edges that appear in an increasing time order, many temporal graph parameters and optimization problems that have been studied so far are based on the notion of a temporal path and other related notions, e.g. temporal analogs of distance, diameter, connectivity, reachability, and exploration [4, 3, 23, 33, 10, 8, 14, 19, 21, 7, 28, 18]. In addition to temporal paths, recently also various temporal non-path problems have been introduced and algorithmically studied, such as temporal vertex cover [5], temporal coloring [30], and temporal Δ-cliques [38, 24].

Apart from the focus on the various algorithmic problems that one can study on temporal graphs, one can also view temporal graphs through several different levels of knowledge about the actual network evolution. On the one extreme, we may be given the whole temporal graph instance in advance, i.e. the times of appearance and absence of every edge at all times, as it typically happens e.g. when modeling transportation networks. On the other extreme, the temporal graph may be created by an adversary who reveals it to us snapshot-by-snapshot

at every time step. Here we focus on the intermediate knowledge settings, captured by *stochastic temporal graphs*, where the network evolution is given by a probability distribution that governs the appearance of each edge over time.

▶ **Definition 2** (Stochastic temporal graph). *A* stochastic temporal graph *is a stochastic process* $\mathcal{G} = \{G_t : t \in \mathbb{N}\}$ *whose random variables are snapshots* $G_t \subseteq G$ *of an underlying graph* G*. Every instantiation of* $\mathcal{G}$ *is a temporal graph.*

A natural feature of stochastic temporal graphs which can be observed in various real-life scenarios (and which we address in this paper) is that the appearance probability of a particular edge at a given time step t depends on the appearance (or absence) of the same edge at the previous $k \geq 1$ time steps. This "memory effect" can often be observed, among others, in faulty network communication and in mobile, social, and peer-to-peer networks [15, 37, 34]. Several other models of temporal networks which exhibit some sort of probabilistic behavior have been considered in the past, see e.g. [25].

In this paper, we study a hierarchy of models for stochastic temporal graphs which address an *edge-centric* network evolution, i.e. they assign to every edge of the underlying graph G a probability distribution for its appearance over time, independently of all the other edges. The first and most basic model (*memoryless* or *memory*-0) assigns independently to every edge e a probability p_e such that, at every time step, e appears with probability p_e. In the general model (*memory-k*), at every time step the appearance probability of every edge is a function of the history of its appearances/absences in the last $k \geq 1$ time steps. Clearly, for every $k \geq 1$, the memory-$(k-1)$ model is a special case of the memory-k model. However, in this paper we make a clear distinction between the values $k = 0$ (*"no memory"*) and $k \geq 1$ (*"some memory"*), as in some cases these models exhibit a fundamentally different computational behavior for these values of k, as our results indicate (see Section 4).

Our memory-k model, $k \geq 1$, is a direct generalization of the homogeneous version of the memory-1 model that was introduced in a seminal paper by Clementi et al. [16], in which all edges have the same probability distribution for their appearance, based on their own appearance/absence at the previous step. In this homogeneous memory-1 model, Clementi et al. gave upper bounds for the flooding time and they provided tight characterizations of the graphs on which the flooding time is constant [16]. It is worth noting here that Avin et al. [7] studied the completely opposite extreme of our edge-centric evolution; namely they considered a *graph-centric* evolution model where a global probability distribution assigns specific transition probabilities among different snapshots [7]. Between the two extremes of the edge-centric and the graph-centric network evolution models, there exists a whole hierarchy of locally interdependent probabilistic patterns, i.e. probability distributions where the appearance probability of one edge also depends on the appearance of *other edges* over time; such models remain mostly unexplored.

In both our memoryless and memory-k variations of stochastic temporal graphs, we study two fundamental temporal path (i.e. journey) problems that are defined on two designated vertices s and y. Consider a piece of information that is generated at s at time 1, which we would like to send to y via an s-y journey. The *arrival time* of an s-y journey in a realization of a stochastic temporal graph is the time the information reaches y using this journey. A *foremost* s-y journey is one with the smallest arrival time. In the first part of the paper we investigate the complexity of computing the *expected arrival time* of a *foremost* s-y journey. Basu et al. [9] and Nain et al. [32] studied a similar problem but their work is restricted to the simpler cases where the underlying graph is either a path or a grid.

In the second part of the paper we investigate the complexity of computing the arrival time of a *best policy* for actually choosing a particular s-y journey in the stochastic temporal graph. To illustrate this notion of a best policy, assume that some piece of information

is carried by an entity, say Alice. Alice is given as input the parameters of the stochastic temporal graph (i.e. the probabilistic rules on the edges) and, at every time step, she knows the current snapshot and her current location. Based on this information, Alice has to decide at every step for her next action, while her goal is to reach y as quickly as possible on expectation, starting at time 1. In a very inspiring paper, Basu et al. [8] consider this problem in the special case of the memoryless model where all edges have the same probability of appearance at every time, and give a Dijkstra-like polynomial-time algorithm. Special cases of the memory-1 model were considered in [11].

To illustrate the difference between the two problems we study, we make the following analogy. In the first problem (Minimum Arrival) we try to transfer information from s to y using an unbounded number of messages, i.e. we "flood" the stochastic temporal graph with information. Initially the information is stored at s at time 1 and then, at every step, every informed vertex informs all its neighbors as soon as the edge between them becomes available. In the second problem (Best Policy) we try to transfer a package with a tangible good from s to y. Now, at every step we need to decide for the actual route of the package through the network: when an edge appears, should we ship the package along it or rather wait where we currently are? Best Policy is more relevant to real-life applications than Minimum Arrival, where an actual *good* journey needs to be found in real time.

Our contribution. In the first part of the paper, in Section 3, we provide our results for the problem Minimum Arrival, i.e. for computing the expected arrival time of a foremost s-y journey in a stochastic temporal graph. First we prove in Section 3.1 that Minimum Arrival is #P-hard even for the memoryless model (and thus also for the memory-k model, for every $k \geq 1$). The reduction is done from the problem #PP2DNF which counts the number of satisfying assignments in a positive partitioned 2-DNF Boolean formula [35].

Second, we provide in Section 3.2 a non-trivial approximation scheme for Minimum Arrival, based on dynamic programming, for the memoryless model in the case where the underlying graph G is a series-parallel graph with s and y being its terminals. More specifically, it turns out that this is a *Fully Polynomial-Time Approximation Scheme (FPTAS)* whenever the probabilities p_e are lower bounded by $\frac{1}{n^c}$ for some $c \geq 1$. Let X be the random variable that expresses the arrival time of a foremost s-y journey. For every $\varepsilon \in (0, 1]$, our FPTAS gives an algorithm that produces a value μ where $\mathbb{E}(X) - \varepsilon \leq \mu \leq \mathbb{E}(X)$, and runs in polynomial time in both n and $\frac{1}{\varepsilon}$. Although our main result of Section 3.2 concerns series-parallel graphs, we actually present a more general FPTAS approach (see Theorem 11) which is of independent interest and could lead to FPTASs also for more general classes of underlying graphs G.

Third, we present in Section 3.3 a *Fully Polynomial Randomized Approximation Scheme (FPRAS)* for Minimum Arrival in the memory-k model, for every $k \geq 0$, under the assumption that every edge appearance probability is lower bounded by $\frac{1}{n^c}$ for some $c \geq 1$. Let X be the random variable that expresses the arrival time of a foremost s-y journey. For every $\varepsilon \in (0, 1)$, our FPRAS gives a randomized algorithm that produces an estimate $\widetilde{X}$ where $(1-\varepsilon)\mathbb{E}(X) \leq \widetilde{X} \leq (1+\varepsilon)\mathbb{E}(X)$ with probability tending to 1 as $n \to \infty$, and runs in polynomial time in both n and $\frac{1}{\varepsilon}$.

In the second part of the paper, in Section 4, we provide our results for the problem Best Policy, i.e. for computing the expected arrival time of a best policy for choosing a particular s-y journey. Initially we provide in Section 4.1 a dynamic programming algorithm for the memoryless model which runs in $O(n^2)$ time and space. In wide contrast, we prove in Section 4.2 that Best Policy becomes #P-hard for the memory-k model, where $k \geq 3$, again

by providing a reduction from the problem #PP2DNF. Finally, we provide in Section 4.3 a formulation of Best Policy in the memory-k model using the general *Markov Decision Process (MDP)* framework which allows us to devise in Section 4 an exact doubly exponential-time algorithm with running time $O(2^{(kmn+n\log n)\cdot 2^{km}})$. Due to lack of space, many proofs have been omitted; the full proofs of this paper can be found in our technical report [2].

2 Preliminaries

In this paper we consider temporal graphs (see Definition 1) in which the underlying (static) graph $G = (V, E)$ has n vertices and m edges . A subgraph $H = (V, E_H)$ of G, denoted by $H \subseteq G$, is a graph where $E_H \subseteq E$. For every vertex $u \in V$, the *neighborhood* $\Gamma_G(u)$ of u in G is the set of adjacent vertices of u in G. The *closed neighborhood* $\Gamma_G[u]$ also contains vertex u itself, i.e. $\Gamma_G[u] = \Gamma_G(u) \cup \{u\}$. For simplicity of notation we denote $[n] = \{1, 2, \ldots, n\}$ for every $n \in \mathbb{N}$. Furthermore, sometimes we refer to the discrete time steps $t = 1, 2, \ldots$ as *days*. Throughout the paper we consider stochastic temporal graphs that exhibit an edge-centric evolution, i.e. every edge e of G is assigned one probability distribution for its appearance over time, independently of all other edges. We investigate the case where there is a "memory effect" that governs the probability of appearance of every edge over time. We distinguish now the cases where the the memory is zero or non-zero.

Memoryless (or memory-0) model. Every edge $e \in E$ evolves stochastically and independently of other edges as follows: at every time step $t \in \mathbb{N}$, e appears in G_t with probability p_e and is absent with probability $1 - p_e$, independently of any other time step. The numbers $\{p_e : e \in E\}$ are given parameters of the model. We denote this (memoryless) stochastic temporal graph by $\mathcal{G}^{(0)} = (G, \{p_e : e \in E\})$ or simply $\mathcal{G}^{(0)} = (G, \{p_e\})$.

Memory-k model. This model of temporal graphs exhibits stochastic time-dependency of the edges: we assume an initial (arbitrary) sequence of k snapshots, $G_{-k+1}, \ldots, G_{-1}, G_0 \subseteq G$. At every time step $t \geq 1$, every edge e appears independently of all other edges with probability that depends only on (the edge and) the history of appearance of e in the k previous snapshots. At every time step t, this history is a k-bit binary vector, where a 0-entry (resp. 1-entry) on the i-th position denotes absence (resp. appearance) of e in $E_{t-k+i-1}$, for $i = 1, \ldots, k$. Therefore the snapshot G_t is the graph that appears at time $t \geq 1$ as the result of the following experiment: given the history $H_e^{(k)}$ of the appearance of edge $e \in E$ in the last k snapshots, e belongs to E_t independently with probability $p_e(H_e^{(k)})$. We denote the memory-k stochastic temporal graph by $\mathcal{G}^{(k)}$.

In the particular case where $k = 1$, the memory-1 stochastic temporal graph $\mathcal{G}^{(1)}$ is the sequence $\{G_t = (V, E_t) : t \in \mathbb{N}\}$ of snapshots such that $E_t = \{e \in E : X_t^e = 1\}$, where $\{X_t^e\}_{t\in\mathbb{N}}$ is a Markov chain for the edge $e \in E$ with states $\{0, 1\}$ (corresponding to non-appearance and appearance of e, respectively) and probability transition matrix:

$$M_e = \left(\begin{array}{c|cc} & 0 & 1 \\ \hline 0 & 1-p_e & p_e \\ 1 & q_e & 1-q_e \end{array}\right), \text{ where } 0 \leq p_e, q_e \leq 1.$$

Using this formalism, p_e (resp. q_e) is the probability that the edge e changes its current state from absence to appearance (resp. from appearance to absence) in the next snapshot. Note here that, setting $p_e = p$ and $q_e = q$ for every edge e, we obtain exactly the well-established *edge-Markovian evolving graph* model introduced by Clementi et al. [16].

2.1 The problems

This work studies two main problems, each under the models of stochastic temporal graphs defined above. To describe both of these problems, let us first recall that information in temporal graphs flows via journeys, i.e. temporal paths.

▶ **Definition 3** (Time-edge). *A time-edge in a temporal graph $\mathcal{G} = \{G_t : t \in \mathbb{N}\}$ is a pair (e, t) such that $e \in E_t$.*

▶ **Definition 4** (Journey / temporal path). *Let $\mathcal{G} = \{G_t : t \in \mathbb{N}\}$ be a temporal graph and s, y be two vertices of G. An s-y* journey *(or an s-y* temporal path*) in $\mathcal{G}$ is a sequence $\big((e_1, t_1), \ldots, (e_x, t_x)\big)$ of time-edges over a path $(e_1, \ldots, e_x)$ from s to y in G, where $t_1 < t_2 < \ldots < t_x$. The* arrival time *of the journey is the time t_x of appearance of its last edge.*

▶ **Definition 5** (Foremost Journey). *A foremost s-y journey in a temporal graph $\mathcal{G}$ is an s-y journey with the minimum arrival time amongst all s-y journeys in $\mathcal{G}$.*

Notice that the arrival time of a foremost s-y journey in a stochastic temporal graph is a random variable, which we henceforth denote by $X(s, y)$. The first problem that we study here is how to compute the expected value of the latter, namely $\mathbb{E}[X(s, y)]$.

▶ **Problem 1** (Minimum Arrival). *Given a stochastic temporal graph on an underlying graph $G = (V, E)$ and two distinct vertices $s, y \in V$, compute the expected value of the arrival time of a foremost s-y journey, i.e. $\mathbb{E}[X(s, y)]$.*

Now suppose that an individual (say Alice) is at day 0 at vertex s and would like to arrive at vertex y through a temporal path as quickly as possible. Denote by s_t the vertex where she is located at time t; then $s_0 = s$. Every day t Alice "wakes up" in the morning and looks at which edges are available in today's snapshot; by only knowing her current position, the history of the last k snapshots, and the input parameters of the stochastic temporal graph (i.e. the probabilistic rules of edge appearance), Alice needs to decide whether:

(a) to stay at the vertex s_t she currently is, or

(b) to use an edge of G_t to move to a neighboring vertex.

That is, s_{t+1} is either equal to s_t or equal to some vertex of $\Gamma_{G_t}(s_t)$.

A natural problem we can study here is to compute the expected arrival time of an s-y journey that Alice can follow, using a *best policy*[1] possible, i.e. a policy (sequence of actions) that minimizes her expected arrival time at y. Notice that the arrival time of the journey suggested to Alice by the best policy is a random variable $Y(s, y)$, whose distribution depends on the specific stochastic temporal graph. In particular, in the memoryless model, the expectation of $Y(s, y)$ depends only on the edges' probabilities of appearance. In the memory-k model, the expectation of $Y(s, y)$ also depends on the initial snapshots $G_{-k+1}, \ldots, G_{-1}, G_0$.

▶ **Problem 2** (Best Policy). *Given a stochastic temporal graph $\mathcal{G}^{(k)}$ on an underlying graph $G = (V, E)$ and two distinct vertices $s, y \in V$, compute $\mathbb{E}_{\mathcal{G}^{(k)}}[Y(s, y)]$.*

In particular, we will write $h(s, y) \stackrel{\text{def}}{=} \mathbb{E}_{\mathcal{G}^{(0)}}[Y(s, y)]$ and $h(s, y, G_0) \stackrel{\text{def}}{=} \mathbb{E}_{\mathcal{G}^{(1)}}[Y(s, y)]$.

[1] We use the term "policy" here (instead of "strategy") since, as we will see later, this problem can be formulated using a Markov Decision Process (MDP).

Difference between the two problems

Before we proceed further, we first give an example illustrating that the problems Minimum Arrival and Best Policy are different. In fact, the gap between the solution to Minimum Arrival and the solution to Best Policy can be arbitrarily large: Consider the graph consisting of vertices s and y and $n-2$ vertex disjoint paths of length 2 between s and y. Assume also that, under the memoryless model, every edge incident to s appears each day with probability 1 and every edge incident to y appears each day independently with probability $n^{-0.9}$. Similarly to the above example of the graph with $n-2$ vertex disjoint paths of length 2, here the expected arrival time of a best policy for Alice is $h(s,y) = 1 + n^{0.9}$. On the other hand, the arrival time of the foremost journey from s to y will be equal to the first day after day 1 on which some edge incident to y appears. But the time needed for the latter to happen follows the geometric distribution with success probability $1-(1-n^{-0.9})^{n-2} = 1 - o(1)$. Therefore, the expected arrival time of the foremost journey will be $\mathbb{E}[X(s,y)] = 2 + o(1)$, i.e. much smaller than $h(s,y) = 1 + n^{0.9}$.

As a final note, the expected arrival time $\mathbb{E}[X(s,y)]$ of the foremost s-y journey is always upper-bounded by the minimum among the expected values of the arrival times of all s-y journeys in the temporal graph. This is actually implied by a more general and well-known lemma in Probability Theory (Fatou's lemma [17, p. 29]) which establishes that the expected value of the minimum among n random variables is upper-bounded by the minimum among all the variables' expectations.

3 Computing the expected minimum arrival time

3.1 Hardness of exact computation in the memoryless model

In this section we show that, even in the memoryless model, Minimum Arrival is #P-hard in both undirected graphs and directed acyclic graphs (DAGs). In the proof of the following theorem, the edges can be treated either as oriented, in which case we obtain the result for DAGs, or as non-oriented, in which case we obtain the result for undirected graphs.

▶ **Theorem 6.** Minimum Arrival *in the memoryless model is #P-hard.*

▶ **Corollary 7.** *For every $k \geq 0$,* Minimum Arrival *in the memory-k model is #P-hard.*

3.2 The FPTAS for the memoryless model on series-parallel graphs

3.2.1 The case of paths

In this section we will consider a stochastic temporal graph $\mathcal{P}^{(0)} = (P = (V,E), \{p_e\})$ with the underlying graph being a path $P = (s = v_0, v_2, \ldots, v_n = y)$.

▶ **Lemma 8.** $\mathbb{E}[X_{\mathcal{P}^{(0)}}(s,y)] = \sum_{e \in E} \frac{1}{p_e}$.

Let us denote by μ the expectation $\mu \stackrel{\text{def}}{=} \mathbb{E}[X_{\mathcal{P}^{(0)}}(s,y)] = \sum_{e \in E} \frac{1}{p_e}$. Note that

$$\mu = \sum_{i=1}^{\infty} \Pr[X_{\mathcal{P}^{(0)}}(s,y) \geq i]. \tag{1}$$

In the remainder of this section we will show that the first $O(\mu \ln \mu)$ terms of sum (1) already give a very good approximation of μ. In our analysis we will use the following bound.

▶ **Theorem 9** ([26]). *Let $X = \sum_{i=1}^{n} X_i$, where $n \geq 1$ and X_i, $i = 1, \ldots, n$, are independent geometric random variables with parameters $p_1, p_2, \ldots, p_n \in (0, 1]$, respectively. Let $\mu = \mathbb{E}[X] = \sum_{i=1}^{n} \frac{1}{p_i}$. Then for any $\lambda \geq 1$, $\Pr[X \geq \lambda\mu] \leq e^{1-\lambda}$.*

▶ **Lemma 10.** *Let ε be a number such that $0 < \varepsilon \leq 1$. Then*

$$\mu - \sum_{i=1}^{\tau} \Pr[X_{\mathcal{P}^{(0)}}(s, y) \geq i] = \sum_{i=\tau+1}^{\infty} \Pr[X_{\mathcal{P}^{(0)}}(s, y) \geq i] < \varepsilon,$$

for every $\tau \geq \mu \left(\ln \frac{\mu}{\varepsilon} + 1\right)$, where $\mu = \mathbb{E}[X_{\mathcal{P}^{(0)}}(s, y)]$.

3.2.2 A general FPTAS approach

While deriving analytically and computing efficiently the exact solution of Minimum Arrival in a path is an easy task (cf. Lemma 8), it does not seem to be trivial for a slight generalization of paths, called *parallel compositions of paths*. A parallel composition of paths is the graph obtained from a collection of disjoint paths $P_1, P_2, \ldots, P_\ell$ with end vertices s_i, y_i, $i = 1, \ldots, \ell$, respectively, by identifying the vertices $s_1, s_2, \ldots, s_\ell$ in a single vertex s, and by identifying the vertices $y_1, y_2, \ldots, y_\ell$ in a single vertex y.

It is not clear whether there exists an efficient procedure for computing the expected arrival time from s to y in a parallel composition of paths, even if the parallel paths are of equal length and all the probabilities of edge appearance are the same. In this section we present a general approach for developing *ε-additive approximation algorithms*[2] for computing the expected arrival time of a foremost journey in special classes of stochastic temporal graphs. In Section 3.2.3 we apply this approach to develop an efficient ε-additive approximation algorithm for the problem on the class of stochastic temporal graphs with underlying graphs being series-parallel graphs, which generalize parallel compositions of paths and graphs in which all simple s-y paths are of the same length.

Throughout the section we denote by $\mathcal{G}^{(0)} = (G = (V, E), \{p_e\})$ a memoryless stochastic temporal graph with n vertices and m edges, and by $s, y \in V$ two distinct vertices in G. Furthermore, we denote by $H = (V, E, w)$ the weighted graph obtained from the underlying graph G by assigning to every edge $e \in E$ the weight $w(e) = \frac{1}{p_e}$.

▶ **Theorem 11.** *Let $c \in \mathbb{N}$ and $\varepsilon \in (0, 1]$. Let $p_e \geq \frac{1}{n^c}$ for every $e \in E$ and suppose that there exists an algorithm A that computes in time $O(f(\ell, n, m))$ the probabilities $\Pr[X_{\mathcal{G}^{(0)}}(s, y) \geq i]$, for all $i = 1, \ldots, \ell$. Then there exists an algorithm B that approximates $\mathbb{E}[X_{\mathcal{G}^{(0)}}(s, y)]$ within the additive factor of ε in time*

$$O\left(f\left(n^{c+1} \ln \frac{n}{\varepsilon}, n, m\right) + n \ln n + m\right).$$

Consequently, if $f(\ell, n, m)$ is a polynomial in variables ℓ, n, and m, then B is an FPTAS on the instance $(\mathcal{G}^{(0)}, s, y)$.

Proof. Let $P = (s = v_0, v_1, \ldots, v_r = y)$ be a minimum weight s-y path in H, and let $\mathcal{P}^{(0)}$ be the stochastic temporal subgraph of $\mathcal{G}^{(0)}$ restricted to the edges of P. For convenience, let us denote $e_i = v_{i-1}v_i$ for every $i = 1, \ldots, r$. Then, by definition and Lemma 8, the weight w^*

[2] A feasible solution is *ε-additive approximate* if it is within ε additive factor from the optimal value. An algorithm is called an *ε-additive approximation algorithm* if it returns an ε-additive approximate solution for any instance.

of P is equal to $\sum_{i=1}^{r} \frac{1}{p_{e_i}} = \mathbb{E}[X_{\mathcal{P}^{(0)}}(s,y)]$. Let $\tau := w^* \left(\ln \frac{w^*}{\epsilon} + 1\right)$. Then, by Lemma 10, we have that

$$\sum_{i=\tau+1}^{\infty} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i] \leq \sum_{i=\tau+1}^{\infty} \Pr[X_{\mathcal{P}^{(0)}}(s,y) \geq i] < \varepsilon,$$

and hence

$$\begin{aligned} \sum_{i=1}^{\tau} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i] \quad &\leq \quad \mathbb{E}[X_{\mathcal{G}^{(0)}}(s,y)] \;=\; \sum_{i=1}^{\infty} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i] \\ &< \quad \sum_{i=1}^{\tau} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i] + \varepsilon, \end{aligned}$$

that is, $\sum_{i=1}^{\tau} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i]$ approximates $\mathbb{E}[X_{\mathcal{G}^{(0)}}(s,y)]$ within the additive factor of ε.

Now we define the desired algorithm B as follows:

1. Construct the graph H and compute the minimum weight w^* of an s-y path in H using Dijkstra's algorithm.
2. Using algorithm A, compute the probabilities $\Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i], i = 1, \ldots, \tau$, where $\tau = w^* \left(\ln \frac{w^*}{\epsilon} + 1\right)$.
3. Output $\sum_{i=1}^{\tau} \Pr[X_{\mathcal{G}^{(0)}}(s,y) \geq i]$.

The above discussion implies that algorithm B correctly computes the declared approximation of $\mathbb{E}[X_{\mathcal{G}^{(0)}}(s,y)]$. It remains to justify the time complexity. First, Dijkstra's algorithm can be implemented to work in time $O(n \ln n + m)$ [22]. Second, the assumption on p_e's implies that $w^* = O(n^{c+1})$, and hence $\tau = w^* \left(\ln \frac{w^*}{\epsilon} + 1\right) = O\left(n^{c+1} \ln \frac{n}{\epsilon}\right)$. Therefore the assumption of the theorem implies that the last two steps of the algorithm run in time $O\left(f\left(n^{c+1} \ln \frac{n}{\varepsilon}, n, m\right)\right)$, which in turn implies the complexity bound and completes the proof. ◀

3.2.3 The FPTAS for stochastic temporal series-parallel graphs

In the present section we use the approach from Section 3.2.2 to derive a polynomial-time approximation scheme for stochastic temporal series-parallel graphs.

▶ **Theorem 12.** *Let $\varepsilon \in (0,1]$ and let $\mathcal{G}^{(0)} = \{G = (V,E), \{p_e\}\}$ be a stochastic temporal series-parallel graph, where s and y are the terminals of G and $p_e \geq \frac{1}{n^c}$ for every $e \in E$. Then* Minimum Arrival *on $\mathcal{G}^{(0)}$ admits an FPTAS with running time $O\left(m \cdot n^{2c+2} \ln^2 \frac{n}{\varepsilon}\right)$, where $|V| = n$ and $|E| = m$.*

3.3 The FPRAS for general graphs in the memory-k model, $k \geq 0$

In this section, we present our FPRAS for Minimum Arrival in the memory-k model, for every $k \geq 0$, under the assumption that the appearance probability of every edge e is lower bounded by $\frac{1}{n^c}$ for some $c \geq 1$ regardless of the history $H_e^{(k)}$, i.e. $p_e(x) \geq \frac{1}{n^c}$ holds for all $x \in \{0,1\}^k$.

▶ **Theorem 13.** *Let $\varepsilon \in (0,1)$ and let $\mathcal{G}^{(k)}$ be a memory-k stochastic temporal graph with two designated vertices s, y. Furthermore let every edge appearance probability be at least $\frac{1}{n^c}$ for some $c \geq 1$, regardless of the history $H_e^{(k)}$ of e. Then* Minimum Arrival *admits an FPRAS which runs in $O\left(m \frac{n^{5c+8}}{\varepsilon^4} \cdot \log(\frac{n}{\varepsilon})\right)$ time with probability of success at least $1 - \frac{2}{n}$.*

4 Computing the expected arrival time of a best policy

In this section we investigate the computational complexity of our second problem, namely Best Policy.

4.1 A polynomial-time algorithm for the memoryless model

In this section we focus on the memoryless model and we derive a polynomial-time dynamic-programming algorithm for Best Policy. We define for every vertex v the expected arrival time $h(v,y) \stackrel{\text{def}}{=} \mathbb{E}_{\mathcal{G}^{(0)}}[Y(v,y)]$ of the v-y journey suggested to Alice by a best policy (i.e. when Alice starts her journey at vertex v). For simplicity of presentation, throughout Section 4.1 we write $h(v) \stackrel{\text{def}}{=} h(v,y)$.

Assume for now that for all $v \in V$, the value $h(v)$ is given; let $v_1 = y, v_2, \ldots, v_n$ be an ordering of vertices of V in non-decreasing values of h (ties broken arbitrarily), namely $h(v_1) \leq h(v_2) \leq \cdots \leq h(v_n)$. Clearly, $v_1 = y$ and $h(v_1) = h(y) = 0$.

Let s_t be the vertex that Alice occupied at time t and recall that $\Gamma_{G_t}(v)$ is the neighborhood of vertex v in the snapshot G_t, for all $v \in V$ and all $t \in \mathbb{N}$. Notice that, the best strategy of Alice at time $t+1$ is to look at all neighboring vertices of s_t in G_{t+1} and find one with minimum h-value, namely a vertex $u \in \arg\min\{h(v) : v \in \Gamma_{G_{t+1}}(s_t)\}$. If $h(u) \geq h(s_t)$, then Alice has no incentive to change vertex and thus $s_{t+1} = s_t$. Otherwise, if $h(u) < h(s_t)$, then $s_{t+1} = u$.

Therefore, to find the best choice for Alice, it suffices to find the values $h(v), v \in V$. In view of the above, if Alice is on vertex v_i at time 0 (i.e. she is on the i-th best vertex in terms of closeness to y), she will move to the j-th best (with $j < i$) only if an edge appears between v_i and v_j in the next step, and no edge to a vertex better than v_j appears (i.e. no edge between v_i and v_ℓ, $1 \leq \ell \leq j-1$). This happens with probability $Q_{i,j} = p_{\{v_i,v_j\}} \prod_{\ell=1}^{j-1}(1 - p_{\{v_i,v_\ell\}})$, where $\{v_i, v_\ell\}$ denotes the (undirected) edge between v_i and v_ℓ. Additionally, with probability $Q_i = \prod_{\ell=1}^{i-1}(1 - p_{\{v_i,v_\ell\}})$ no edge to a vertex better than v_i will appear, in which case Alice will stay on v_i. Therefore $h(v_i)$ can be recursively computed by $h(v_i) = \sum_{j=1}^{i-1} Q_{i,j} h(v_j) + Q_i h(v_i) + 1$, or equivalently $h(v_i) = \dfrac{\sum_{j=1}^{i-1} Q_{i,j} h(v_j) + 1}{1 - Q_i}$, with initial condition $h(v_1) = 0$. Indeed, the above equation follows by observing that the expected length of the foremost journey to y when Alice is on v_i is equal to $1 + h(v_1)$ with probability $Q_{i,1}$ (which is the probability that an edge between v_i and $v_1 = y$ exists), plus $1 + h(v_2)$ with probability $Q_{i,2}$ (which is the probability that an edge between v_i and the second best vertex v_2 exists, but there is no edge between v_i and v_1), and so on. In general, the above recurrence states that there is no incentive to visit vertices with larger index and also Alice will visit the smallest index vertex v_j for which the edge $\{v_i, v_j\}$ is present (otherwise, if no such edge exists, she will stay on v_i). Using the above recurrence, we can compute all values of $h(v_i)$ by a bottom-up dynamic programming algorithm.

▶ **Theorem 14.** Best Policy *can be optimally computed in the memoryless model in* $O(n^2)$ *time and space.*

4.2 Hardness of computation for the memory-k model, $k \geq 3$

We now show that Best Policy is #P-hard for memory-3 stochastic temporal graphs on directed acyclic graphs, and consequently also for memory $k \geq 3$.

▶ **Theorem 15.** *When the underlying graph is a Directed Acyclic Graph (DAG), it is #P-hard to compute the expected arrival time of the best policy journey in the memory-3 model.*

Proof. We will provide a reduction from the counting problem #PP2DNF which is known to be #P-hard [35]. This problem takes as input a DNF formula $\Phi = \bigvee_{(i,j)\in E} x_i y_j$ on the sets of variables $X = \{x_1, \ldots, x_n\}$ and $Y = \{y_1, \ldots, y_m\}$, for some $E \subseteq [n] \times [m]$, and the task is to compute the number ψ of truth assignments that satisfy Φ. We create a directed acyclic graph (DAG) H as follows. First, H has one vertex for each of the variables in $X \cup Y$; then we add two distinct vertices s, y and one other vertex v. For every vertex $x_i \in X$ and every vertex $y_i \in Y$ we add the directed edges (s, x_i) and (y_j, y). Furthermore we add the edge (x_i, y_j) whenever $x_i y_j$ is a clause in Φ. Finally we add the edges (s, v) and (v, y). The construction of H is illustrated in Figure 1.

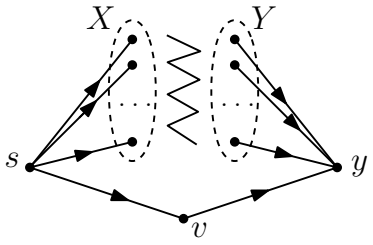

Figure 1 The construction of the DAG H.

Denote by $M = 5 \cdot 2^{n+m}$, and assume that $2^{n+m} \geq 3$ in order to avoid trivialities. All edges (x_i, y_j) appear constantly in H, i.e. they appear at every time step $i \geq 1$ in a memoryless fashion with probability 1. Both edges (s, v) and (v, y) also appear in a memoryless fashion, each of them with probability $\frac{2}{M}$ at every step $i \geq 1$. Moreover, each of the edges (s, x_i) and (y_j, y) appears at each step $i \geq 1$ according to the following table of memory 3. This table has four columns and eight rows. Each column is labeled with the sequence of consecutive time steps $i-3, i-2, i-1$, and i. Each row corresponds to a different triple of appearances of each of the edges in $\{(s, x_i), (y_j, y) : x \in X, y \in Y\}$ at the time steps $i-3, i-2, i-1$ (here 1 means "edge exists" and 0 means "edge does not exist"). At the end of each row there is a pair of numbers $(p, 1-p)$ which denotes that, with the particular history of memory 3, at time step i the edge appears with probability p and it does not appear with probability $1-p$. For simplicity of notation, in the column of time step i, we write "0" and "1" to denote the entries $(0, 1)$ and $(1, 0)$, respectively.

$i-3$	$i-2$	$i-1$	i
0	0	1	0
0	1	0	$(\frac{1}{2}, \frac{1}{2})$
1	0	0	0
0	0	0	0
1	0	1	1
0	1	1	1
1	1	1	1
1	1	0	1

To complete the description of our memory-3 instance, we specify that, in the fictitious initialization snapshots G_{-2}, G_{-1}, G_0, each of the edges (s, x_i) and (y_j, y) appears with probability 0, 0, and 1, respectively, i.e. according to the first row of the above table.

The intuition of this table for the edges (s, x_i) and (y_j, y) is as follows. In the snapshot G_1, none of these edges appears (see the first line of the table). Then, to determine whether each of these edges appears at time step 2 (see the second row of the table), we need to toss an unbiased coin which with probability $\frac{1}{2}$ outputs "appear" and with probability $\frac{1}{2}$ outputs "does not appear". Once this coin has been tossed at time step 2, the status of the edge does not change any more in any subsequent time step $i \geq 3$. That is, if one of the edges (s, x_i) and (y_j, y) appears (resp. does not appear) at time 2, then it appears (resp. does not appear) at all times $i \geq 3$ too. This is easy to be verified by observing the rows 3-7 of the table. Note that the last row of the table is included only for the sake of completeness, as it does not affect the appearance of any edge of H at any time step i.

Let ℓ be the expected s-y arrival time of the best policy in the memory-3 model. Note that, from the above construction of the temporal graph instance, each of the edges (s, x_i) and (y_j, y) appears with probability $\frac{1}{2}$ at all steps $i \geq 2$, while it does not appear at any step $i \geq 2$ with probability $\frac{1}{2}$. Therefore, the probability that there exists a directed temporal path (s, x_i, y_j, y) is equal to $g = \frac{\psi}{2^{n+m}}$, where ψ is the number of satisfying truth assignments of the DNF formula Φ. That is, with probability $1 - g$, there exists no such temporal path from s to y with 3 edges through some vertices x_i and y_j. Furthermore, the expected s-y arrival time through the edges (s, v) and (v, y) is equal to $\frac{M}{2} + \frac{M}{2} = M$. Therefore, since with probability $1 - g$ any policy (also the best one) needs to travel from s to y through vertex v, it follows that $\ell \geq M(1 - g)$.

We now define the following policy: at time step 1 do nothing and just wait for the outcome of the random coin tosses which occur at time step 2. Subsequently, at time step 2 do the following: if there exists a directed temporal path (s, x_i, y_j, y) then follow it, starting at time step 2; otherwise follow the temporal path (s, v, y) which has an expected travel time $\frac{M}{2} + \frac{M}{2} = M$. The expected arrival time of this particular policy is equal to $1 + 3g + M(1 - g)$, and thus it follows that $\ell \leq 1 + 3g + M(1 - g)$. Summarizing, we have:

$$\begin{aligned} M(1-g) &\leq \ell \leq 1 + 3g + M(1-g) \Leftrightarrow \\ 5 \cdot 2^{n+m} - 5\psi &\leq \ell \leq 5 \cdot 2^{n+m} - 5\psi + 3\frac{\psi}{2^{n+m}} + 1. \end{aligned}$$

The first inequality can be written as $2^{n+m} - \frac{\ell}{5} \leq \psi$, while the second one can be written as $\left(1 - \frac{3}{5 \cdot 2^{n+m}}\right)\psi \leq 2^{n+m} - \frac{\ell}{5} + \frac{1}{5}$. Therefore:

$$2^{n+m} - \frac{\ell}{5} \leq \psi \leq \left(1 + \frac{3}{5 \cdot 2^{n+m} - 3}\right)\left(2^{n+m} - \frac{\ell}{5} + \frac{1}{5}\right) \leq 2^{n+m} - \frac{\ell}{5} + \frac{1}{5} + \frac{3}{4},$$

and thus $2^{n+m} - \frac{\ell}{5} \leq \psi \leq 0.95 + 2^{n+m} - \frac{\ell}{5}$. Therefore, knowing the expected value ℓ for the best policy we can derive the exact integer value for ψ in the counting problem #PP2DNF. This completes the #P-hardness reduction. ◀

4.3 An exact algorithm for the memory-k model, $k \geq 1$

In this section we present a doubly exponential-time exact algorithm for computing the best policy for Alice in the memory-k model, where $k \geq 1$. Our results in this section are derived using a Markov Decision Process (MDP) formulation of our problem under the memory-k model.

▶ **Theorem 16.** *Let $k \geq 1$ and $\mathcal{G}^{(k)}$ be a stochastic temporal graph, where the underlying graph G has n vertices and m edges. Then* Best Policy *can be solved on $\mathcal{G}^{(k)}$ in $O(2^{(kmn + n\log n)\cdot 2^{km}})$ time.*

Abstract

This paper provides an in-depth study of the fundamental problems of finding small subgraphs in distributed dynamic networks.

While some problems are trivially easy to handle, such as detecting a triangle that emerges after an edge insertion, we show that, perhaps somewhat surprisingly, other problems exhibit a wide range of complexities in terms of the trade-offs between their round and bandwidth complexities.

In the case of triangles, which are only affected by the topology of the immediate neighborhood, some end results are:

- The bandwidth complexity of 1-round dynamic triangle detection or listing is $\Theta(1)$.
- The bandwidth complexity of 1-round dynamic triangle membership listing is $\Theta(1)$ for node/edge deletions, $\Theta(n^{1/2})$ for edge insertions, and $\Theta(n)$ for node insertions.
- The bandwidth complexity of 1-round dynamic triangle membership detection is $\Theta(1)$ for node/edge deletions, $O(\log n)$ for edge insertions, and $\Theta(n)$ for node insertions.

Most of our upper and lower bounds are *tight*. Additionally, we provide almost always tight upper and lower bounds for larger cliques.

1 Introduction

A fundamental problem in many computational settings is to find small subgraphs. In distributed networks it is particularly vital for various reasons, among which is the ability to perform some tasks much faster if, say, triangles do not occur in the underlying network graph (see, eg., [24, 30]).

Finding cliques is a *local* task that trivially requires only a single communication round if the message size is unbounded. However, its complexity may dramatically increase when the bandwidth is restricted to the standard $O(\log n)$ bits, for an n-node network. For example, the complexity of detecting 4-cliques is at least $\Omega(n^{1/2})$ [11]. For triangles, the complexity is yet a fascinating riddle, where only recently the first non-trivial complexities of $\tilde{O}(n^{2/3})$ and $\tilde{O}(n^{3/4})$ have been given for detection and listing, respectively [25], and the current

state-of-the-art is the $\tilde{O}(n^{1/2})$-round algorithm of [10]. For listing, there is an $\tilde{\Omega}(n^{1/3})$ lower bound [25, 28]. The only non-trivial lower bounds for detection say that a single round is insufficient, as given in [1] and extended for randomized algorithms in [18]. In [1] it was also shown that 1-bit algorithms require $\Omega(\log^* n)$ rounds, improved in [18] to $\Omega(\log n)$.

In this paper, we address the question of detecting small cliques in *dynamic* networks of limited bandwidth. We consider a model that captures real-world behavior in networks that undergo changes, such as nodes joining or leaving the network, or communication links between nodes that appear or disappear. Various problems have been studied in many variants of such a setting (see Section 1.3).

The task of finding cliques is unique, in that it is trivial if the bandwidth is not restricted, and it can be easily guaranteed that at the end of each round all nodes have the correct output. This implies that one does not have to wait for *stabilization* and does not have to assume that the network is *quiet* for any positive number of rounds. If, however, the bandwidth is restricted, the solution may not be as simple, although some problems can still be solved even with very small bandwidth.

As a toy example, consider the case of triangle listing when a new edge is inserted to the graph. The endpoints of the inserted edge simply broadcast a single bit that indicates this change to all of their neighbors, and hence if a new triangle is created then its third endpoint detects this by receiving two such indications.

Nevertheless, we show that this simplified case is far from reflecting the general complexities of clique problems in such a dynamic setting. For example, the above algorithm does not solve the problem of *membership-listing* of triangles, in which *each* node should list all triangles that contain it. Indeed, we prove that this stronger variant *cannot* be solved with constant bandwidth, and, in fact, every solution must use at least $\Omega(\sqrt{n})$ bits.

Our contributions provide an in-depth study of various detection and listing problems of small cliques in this dynamic setting, as we formally define and summarize next.

1.1 Our contributions

For a subgraph H we categorize four types of tasks: Detecting an appearance of H in the network, for which it is sufficient that a single node does so, listing all appearances of H, such that every appearance is listed at least by a single node, and their two *membership* variants, membership-detection and membership-listing, for which each node has to detect whether it is a member of a copy of H, or list all copies of H to which it belongs, respectively.

The model is explicitly defined in Section 1.4. In a nutshell, there can be one topology change in every round, followed by a standard communication round among neighboring nodes, of B bits per message, where B is the bandwidth. An algorithm takes r rounds if the outputs of the nodes are consistent with a correct solution after r communication rounds that follow the last change. In particular, a 1-round algorithm is an algorithm in which the outputs are correct already at the end of the round in which the topology change occurred. Hence, 1-round algorithms are very strong, in the sense that they work even in settings in which no round is free of changes. We note that in what follows, all of our algorithms are deterministic and all of our lower bounds hold also for randomized algorithms.

Triangles. Our upper and lower bounds for triangles ($H = K_3$) are displayed in Table 1.

Most of the complexities in this table are shown to be tight, by designing algorithms and proving matching lower bounds. The one exception is for membership detection with edge insertions, for which we show an algorithm that uses $O(\log n)$ bits of bandwidth, but we do not know whether this is tight. However, we also show a 1-round algorithm for this problem

Table 1 The bandwidth complexities of 1-round algorithms for dynamic triangle problems.

	Node deletions	Edge deletions	Edge insertions	Node insertions
Detection/Listing	0	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$
Membership detection	0	$\Theta(1)$	$O(\log n)$	$\Theta(n)$
Membership listing	0	$\Theta(1)$	$\Theta(\sqrt{n})$	$\Theta(n)$

that works with a bandwidth of $O((\Delta \log n)^{1/2})$, where Δ is the maximum degree in the graph, implying that if our logarithmic algorithm is optimal, then a proof for its optimality must exhibit a worst case in which the maximum degree is $\Omega(\log n)$.

A single round is sufficient for solving all clique problems, given enough (linear) bandwidth. Nevertheless, for the sake of comparison, we show that with just one additional communication round, all of the bandwidth complexities in Table 1 drop to $\Theta(1)$, apart from membership listing of triangles, whose bandwidth complexity for r-round algorithms is $\Theta(n/r)$.

Larger Cliques. We also study the bandwidth complexities for finding cliques on $s > 3$ nodes. Here, too, a single round is sufficient for all problems, and the goal is to find the bandwidth complexity of each problem. Some of the algorithms and lower bounds that we show for triangles carry over to larger cliques, but others do not. Yet, with additional techniques, we prove that for cliques of constant size, almost all of the 1-round bandwidth complexities are the same as their triangle counterparts. Due to lack of space, the study of s-cliques is deferred to the full version [5].

Combining types of changes. In most cases, one can obtain an algorithm that handles several types of changes, by a simple combination of the corresponding algorithms. However, intriguingly, sometimes this is not the case. A prime example is when trying to combine edge insertions and node insertions for triangle detection: a node obtaining 1-bit indications of a change from two neighbors cannot tell whether this is due to an edge inserted between them, or due to an insertion of a node that is a neighbor of both. In some of these cases we provide techniques to overcome these difficulties, and use them to adjust our algorithms to cope with more than one type of change.

1.2 Challenges and techniques

Algorithms. The main challenge for designing algorithms is how to convey enough information about the topology changes that occur, despite non-trivial (in particular, sublinear) bandwidth. Consider, e.g., edge insertions. As described, while listing triangles is trivial with a single indication bit, this fails for membership detection or membership listing.

For membership detection we can still provide a very simple algorithm for which a logarithmic bandwidth suffices, by sending the identity of the new edge, and by *helping* neighbors in the triangle to know that they are such. For membership listing even this is insufficient. To overcome this challenge, we introduce a technique for sending and collecting *digests* of neighborhood information. When all digests from a given neighbor have been collected, one can determine the entire neighborhood of this neighbor. The caveat in using such an approach in a straightforward manner is that a node needs to list its triangles with a newly connected neighbor already at the same round in which they connected, and cannot wait to receive all of its neighbor's digests. By our *specific choice* of a digests, we ensure that a newly-connected neighbor has enough information to give a correct output after a single communication round, despite receiving only a single digest from its latest neighbor.

Lower bounds. For the lower bounds, our goal is to argue that in order to guarantee that all nodes give a correct output, each node must receive enough information about the rest of the graph. To do this, we identify sequences of topology changes that exhibit a worst-case behavior, in the sense that a node cannot give a correct output if it receives too little information.

One approach for doing this is to look at a particular node x, and define as many sequences as possible such that the correct output of x is different for each sequence. At the same time, we ensure that the number of messages that x receives from the other nodes is as small as possible. These two requirements are conflicting – if x can have many different outputs, it must have many different neighbors, which implies that it receives many messages with information. Still, we are able to find such a family of sequences for each problem, and we wrap-up our constructions by using counting arguments to prove the desired lower bounds. In some cases, e.g., membership-listing under edge insertions, even this is insufficient, and we construct the sequences such that one *critical* edge affects the output of x, but it is *added last*, so that it conveys as little information as possible.

The above can be seen as another step in the spirit of the *fooling views* framework, which was introduced in [1] for obtaining the first lower bounds for triangle detection under limited bandwidth. After being beautifully extended by [18], our paper essentially gives another indication of the power of the fooling views framework in proving lower bounds for bandwidth-restricted settings.

On the way to constructing our worst-case graph sequences, we prove combinatorial lemmas that show the existence of graphs with certain desired properties. To make our lower bounds apply also for randomized algorithms, we rely on Yao's lemma and on additional machinery that we develop.

1.3 Additional related work

Dynamic distributed algorithms. Dynamic networks have been the subject of much research. A central paradigm is that of *self-stabilization* [12], in which the system undergoes various changes, and after some quiet time needs to converge to a stable state. The model addressed in this paper can be considered as such, but our focus is on algorithms that do not require any quiet rounds (though we also address the gain in bandwidth complexity if the system does allow them, for the sake of comparison). Yet, we assume a single topology change in each round. A single change in each round and enough time to recover is assumed in recent algorithms for maintaining a maximal independent set [2, 3, 9, 14, 23] and matchings [31], and for analyzing amortized complexity [29]. Highly-dynamic networks, in which multiple topology changes can occur in each round are analyzed in [4, 7], and it is an intriguing open question how efficient can subgraph detection be in such a setting. Various other dynamic settings in which the topology changes can be almost arbitrary have been proposed, but the questions that arise in such networks address the flow of information and agreement problems, as they are highly non-structured. A significant paper that relates to our work is [26], which differs from our setting in the bandwidth assumption. Clique detection in the latter model is trivial, and indeed their paper addresses other problems.

Distributed subgraph detection. In the CONGEST model and in related models, where the nodes synchronously communicate with $O(\log n)$ bits, much research is devoted to subgraph detection, e.g., [1, 10, 13, 20, 22, 25, 27, 28].

A related problem is property-testing of subgraphs, where the nodes need to determine, for a given subgraph H, whether the graph is H-free or *far* from being H-free [6, 8, 16, 17, 19, 21].

1.4 Preliminaries

In the dynamic setting, the network is a sequence of graphs. The initial graph, whose topology is known to the nodes, represents the state of the network at some starting point in time, and every other graph in the sequence is either identical to its preceding graph or obtained from it by a single topology change. The network is synchronized, and in each round, each node can send to each one of its neighbors a message of B bits, where B is the bandwidth of the network. Each node has a unique ID and knows the IDs of all its neighbors. We denote by n the number of possible IDs. Hence, n is an upper bound on the number of nodes that can participate in the network at all times.

Note that the nodes do not receive any indication when a topology change occurs. A node can deduce that a change has occurred by comparing the list of its neighbors in the current round and in the previous round. This implies that a node u cannot distinguish between the insertion of an edge uv and the insertion of a node v which is connected to u, as the list of neighbors of u is the same in both cases.

An algorithm can be designed to handle edge insertions or deletions or node insertions or deletions, or any combination of these. We say that an algorithm is an r-round algorithm if the outputs of the nodes after r rounds of communication starting from the last topology change are correct. The (deterministic or randomized) r-round bandwidth complexity of a problem is the minimum bandwidth for which an r-round (deterministic or randomized) algorithm exists. We denote by $\mathsf{MemList}(H)$, $\mathsf{MemDetect}(H)$, $\mathsf{List}(H)$, and $\mathsf{Detect}(H)$, respectively, the problems of membership listing, membership detection, listing and detection of H. The following is a simple observation.

▶ **Observation 1.** *Let r be an integer and let H be a graph. Denote by B_{MemList}, $B_{\mathsf{MemDetect}}$, B_{List} and B_{Detect} the (deterministic or randomized) r-round bandwidth complexities of $\mathsf{MemList}(H)$, $\mathsf{MemDetect}(H)$, $\mathsf{List}(H)$, and $\mathsf{Detect}(H)$, respectively, under some type of topology changes. Then: $B_{\mathsf{Detect}} \leq B_{\mathsf{List}} \leq B_{\mathsf{MemList}}$ and $B_{\mathsf{Detect}} \leq B_{\mathsf{MemDetect}} \leq B_{\mathsf{MemList}}$.*

Due to this observation, our exposition starts with the more challenging task of membership-listing, then addresses membership-detection, and concludes with listing and detection. Within each case, we first provide algorithms for each type of topology change, and then prove lower bounds. Missing proofs are deferred to the full version [5].

2 Triangle problems

2.1 Membership listing

Table 2 summarizes our results for membership listing of triangles.

Table 2 Bandwidth complexities of $\mathsf{MemList}(K_3)$.

	Node deletions	Edge deletions	Edge insertions	Node insertions
$r = 1$	0	$\Theta(1)$	$\Theta(\sqrt{n})$	$\Theta(n)$
$r \geq 2$	0	$\Theta(1)$	$\Theta(1)$	$\Theta(n/r)$

2.1.1 Upper bounds

Our algorithms for node and edge deletions appear in the full version [5]. Note that combining these algorithms in a direct manner *does not* handle both types of changes. We provide a more subtle combination of the two algorithms for doing so within $O(1)$ rounds. Handling edge insertions and node insertions is much more complicated. We start by showing an algorithm that handles edge insertions.

▶ **Theorem 2.1.** *The deterministic* 1*-round bandwidth complexity of* MemList(K_3) *under edge insertions is* $O(\sqrt{n})$.

Proof. Let $N_u(r)$ be the set of neighbours of u on round r. Note that $N_u(r)$ can be encoded as an n-bit string, which indicates, for every node x, whether or not x is a neighbour of u on round r.

The algorithm is as follows. When a new edge uv is inserted on round r, both u and v send to all their neighbors the identity of their new neighbor, denoted by `NEWID`.

In addition, u sends a bitmask of $\lceil\sqrt{n}\rceil$ bits to v, indicating, for every one of the previous $\lceil\sqrt{n}\rceil$ rounds, whether or not one of u's neighbors has sent a `NEWID` to u. We denote this information by $\texttt{LAST}_u$. Node v sends to u the same information.

Finally, u encodes $N_u(r)$ as an n-bit string, denoted $\texttt{ALL}_u(r)$, and starts sending it to v in chunks of $\lceil\sqrt{n}\rceil$ bits per round. This process begins on round r and ends on round $r + \lfloor\sqrt{n}\rfloor$, when the entire string has been sent. During these rounds, u keeps sending `NEWID` to v, and to all its other neighbors, as described above. Node v does the same. It should be noted that this continuous communication between u and v is not intended for allowing them to detect triangles that appear by the insertion of the edge uv, as these are detected immediately due to previous information. Rather, communicating `ALL` allows u and v to detect triangles that appear by other topology changes that may occur in subsequent rounds, as we show below.

Overall, `NEWID` requires $O(\log n)$ bits, while `LAST` and `ALL` require $O(\sqrt{n})$ bits. Thus, the required bandwidth is $O(\sqrt{n})$.

We show that at the end of each round, every node u has enough information to determine, for every two of its neighbors v and w, whether or not the edge vw exists.

First, since only edge insertions are considered, if the edge vw exists in the initial graph, it exists throughout. Also, if vw is inserted when at least one of the edges uv or uw already exists, then u receives this information through `NEWID`. The only other case is when vw does not exist in the initial graph, and is inserted when u is not yet connected to either v or w. That is, the initial graph does not contain any of these three edges, and vw is inserted before the other two. W.l.o.g. assume that uv is inserted before uw. Now, let t_v be the round in which uv is inserted, and let t_w be the round in which uw is inserted.

If $t_w - t_v \leq \lceil\sqrt{n}\rceil$, then when uv is inserted, v sends a `NEWID` to w. Therefore, when uw is inserted, u can determine from $\texttt{LAST}_w$ that in round t_v a neighbor of w has sent a `NEWID` to w. Since the only edge inserted in that round is uv, u determines that v is a neighbor of w. If $t_w - t_v > \lceil\sqrt{n}\rceil$, then, in round t_w, v has already sent the entire string $\texttt{ALL}_v(t_v)$ to u, which indicates that w is a neighbor of v. Therefore, in all cases, u determines whether or not the edge vw exists, as claimed. ◀

The algorithm given for Theorem 2.1 can be extended to handle edge deletions and node deletions as well. Also, if we are promised a quiet round, the problem can be solved with $O(1)$ bits of bandwidth (see full version [5]). Node insertions are harder to handle than the other types of changes. If we are promised $r - 1$ quiet rounds, a simple algorithm exists that uses only $O\left(\frac{n}{r}\right)$ bits of bandwidth. As we show in Section 2.1.2, this is tight.

▶ **Theorem 2.2.** *For every r, the deterministic r-round bandwidth complexity of* MemList(K_3) *under any type of change is $O(n/r)$.*

Proof. The algorithm is as follows: on every round, every node u prepares an n-bit message that specifies its current list of neighbors. Then, it breaks this message into B-bit blocks, where $B = \lceil \frac{n}{r} \rceil$, and sends it to all its neighbors, one block on every round.

Additionally, on every round, u sends to all its neighbors one bit indicating whether or not its list of neighbors has changed on the current round. Whenever the list of neighbors changes, u builds its new list of neighbors, breaks it into blocks, and starts sending it again.

After at most $r-1$ quiet rounds, all nodes are guaranteed to finish sending their list to all their neighbors, thus every node can determine whether any pair of its neighbors are connected to each other or not, as required. ◀

2.1.2 Lower bounds

The 1-round bandwidth complexities for node and edge deletions are clearly tight. Next, we show that handling edge insertions in 1 round requires at least $\Omega(\sqrt{n})$ bits of bandwidth. By Theorem 2.1, this bound is tight. We first prove the following lemma, which shows that a sufficiently dense bipartite graph includes a large enough complete bipartite subgraph. This has the same spirit as the results of Erdös [15], used in [1, 18] for bounding the number of single-bit rounds for detecting triangles, but here the sides can be of different sizes.

▶ **Lemma 2.3.** *For every $\varepsilon \in (0,1)$ there exist $\alpha, \beta, \gamma \in (0,1)$, such that for every bipartite graph $G = (L \cup R, E)$ having at least $(1-\varepsilon)|L||R|$ edges, there are subsets $A \subseteq L$ and $B \subseteq R$, whose sizes are $|A| \geq \alpha \cdot |L|$ and $|B| \geq \beta \cdot \gamma^{|L|} \cdot |R|$, such that $uv \in E$ for every $u \in A$ and $v \in B$ (i.e., the induced subgraph on $A \cup B$ is a complete bipartite graph).*

Proof. Let $\alpha = \frac{1-\varepsilon}{6}$, and let $\mathcal{A}$ be the set of all subsets of L whose size is exactly $\lceil \alpha \cdot |L| \rceil$. For every $A \in \mathcal{A}$, we denote by N_A the set of all vertices in R which are connected to every vertex in A. Consider the sum $S = \sum_{A \in \mathcal{A}} |N_A|$. Let $M = \max\{|N_A| : A \in \mathcal{A}\}$. Then:

$$S \leq \sum_{A \in \mathcal{A}} M = \binom{|L|}{\lceil \alpha \cdot |L| \rceil} \cdot M \tag{1}$$

On the other hand, the sum S can be computed by counting, for every $v \in R$, the number of sets $A \in \mathcal{A}$ such that $v \in N_A$:

$$S = \sum_{A \in \mathcal{A}} |N_A| = \sum_{A \in \mathcal{A}} \sum_{v \in N_A} 1 = \sum_{v \in R} \sum_{\substack{A \in \mathcal{A}: \\ v \in N_A}} 1 = \sum_{v \in R} |\{A \in \mathcal{A} : v \in N_A\}|$$

For $p \in (0,1)$, let k_p be the number of vertices in R whose degree is at least $p \cdot |L|$. For every $v \in R$ whose degree is $d(v)$ we have $|\{A \in \mathcal{A} : v \in N_A\}| = \binom{d(v)}{\lceil \alpha \cdot |L| \rceil}$. Therefore we can bound the above sum

$$S = \sum_{v \in R} \binom{d(v)}{\lceil \alpha \cdot |L| \rceil} \geq \sum_{\substack{v \in R: \\ d(v) \geq p \cdot |L|}} \binom{d(v)}{\lceil \alpha \cdot |L| \rceil} \geq \sum_{\substack{v \in R: \\ d(v) \geq p \cdot |L|}} \binom{\lceil p \cdot |L| \rceil}{\lceil \alpha \cdot |L| \rceil} = k_p \cdot \binom{\lceil p \cdot |L| \rceil}{\lceil \alpha \cdot |L| \rceil}.$$

Combining this with (1) gives $\binom{|L|}{\lceil \alpha \cdot |L| \rceil} \cdot M \geq k_p \cdot \binom{\lceil p \cdot |L| \rceil}{\lceil \alpha \cdot |L| \rceil}$, which implies:

$$M \geq k_p \cdot \binom{\lceil p \cdot |L| \rceil}{\lceil \alpha \cdot |L| \rceil} \Big/ \binom{|L|}{\lceil \alpha \cdot |L| \rceil} \tag{2}$$

We can bound k_p as follows:

$$|E| = \sum_{v\in R} d(v) = \sum_{\substack{v\in R:\\ d(v)\geq p\cdot|L|}} d(v) + \sum_{\substack{v\in R:\\ d(v)<p\cdot|L|}} d(v) \leq \sum_{\substack{v\in R:\\ d(v)\geq p\cdot|L|}} |L| + \sum_{\substack{v\in R:\\ d(v)<p\cdot|L|}} p\cdot|L|$$
$$= k_p\cdot|L| + (|R|-k_p)\cdot p\cdot|L| = (1-p)\cdot k_p\cdot|L| + p\cdot|L|\cdot|R|$$

On the other hand we have $|E| \geq (1-\varepsilon)\cdot|L|\cdot|R|$, and therefore $(1-p)\cdot k_p\cdot|L| + p\cdot|L|\cdot|R| \geq (1-\varepsilon)\cdot|L|\cdot|R|$, which implies $k_p \geq \frac{1-\varepsilon-p}{1-p}\cdot|R|$. Setting $p=\frac{1-\varepsilon}{2}$ gives $k_p \geq \frac{1-\varepsilon}{1+\varepsilon}\cdot|R|$, and substituting this into (2) gives:

$$M \geq \frac{1-\varepsilon}{1+\varepsilon}\cdot\frac{\binom{\lceil p\cdot|L|\rceil}{\lceil\alpha\cdot|L|\rceil}}{\binom{|L|}{\lceil\alpha\cdot|L|\rceil}}\cdot|R|$$

Finally, we bound the binomial fraction on the right-hand size as follows. For simplicity, define $a=|L|, b=\lceil p\cdot|L|\rceil, c=\lceil\alpha\cdot|L|\rceil$. Note that $a\geq b\geq c$. Now:

$$\frac{\binom{b}{c}}{\binom{a}{c}} = \frac{\prod_{i=1}^{c}(i+b-c)}{\prod_{i=1}^{c}(i+a-c)} = \prod_{i=1}^{c}\frac{i+b-c}{i+a-c} = \prod_{i=1}^{c}(1-\frac{a-b}{i+a-c})$$
$$\geq \prod_{i=1}^{c}(1-\frac{a-b}{a-c}) = \prod_{i=1}^{c}\frac{b-c}{a-c} = \left(\frac{b-c}{a-c}\right)^c$$

Therefore:

$$\frac{\binom{\lceil p\cdot|L|\rceil}{\lceil\alpha\cdot|L|\rceil}}{\binom{|L|}{\lceil\alpha\cdot|L|\rceil}} \geq \left(\frac{\lceil p\cdot|L|\rceil - \lceil\alpha\cdot|L|\rceil}{|L|-\lceil\alpha\cdot|L|\rceil}\right)^{\lceil\alpha\cdot|L|\rceil} \tag{3}$$

In order to choose appropriate values for β and γ, we now distinguish between two cases for the graph G. If $|L|\leq\frac{1}{\alpha}$, then $\alpha|L|\leq 1$. Since there must be a vertex in $|L|$ having at least $(1-\varepsilon)|R|$ neighbors in R, the claim holds for every $\beta\leq 1$ and $\gamma\leq 1-\varepsilon$.

If $|L|>\frac{1}{\alpha}$, we can further develop the right hand side of (3) as follows:

$$\left(\frac{\lceil p|L|\rceil - \lceil\alpha|L|\rceil}{|L|-\lceil\alpha|L|\rceil}\right)^{\lceil\alpha|L|\rceil} \geq \left(\frac{p|L|-(\alpha|L|+1)}{|L|-\alpha|L|}\right)^{\alpha|L|+1} = \left(\frac{p-\alpha}{1-\alpha} - \frac{1}{(1-\alpha)|L|}\right)^{\alpha|L|+1}$$
$$> \left(\frac{p-\alpha}{1-\alpha} - \frac{1}{(1-\alpha)\frac{1}{\alpha}}\right)^{\alpha|L|+1} = \left(\frac{p-2\alpha}{1-\alpha}\right)^{\alpha|L|+1}$$
$$= \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\alpha|L|+1}$$

To sum it all up, we now have $M > \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\alpha\cdot|L|+1}$. Recalling the definition of M, this inequality implies that there exists $A\subseteq L$ whose size is exactly $\lceil\alpha\cdot|L|\rceil$, such that $|N_A| > \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\alpha\cdot|L|+1}$, i.e., there are more than $\left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\alpha\cdot|L|+1}$ vertices in R which are connected to every vertex in A. Therefore, the claim holds for every β and γ such that: $\beta\leq\frac{1-\varepsilon}{5+\varepsilon}, \gamma\leq \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\alpha} = \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\frac{1-\varepsilon}{6}}$. Thus, given $\varepsilon\in(0,1)$, the following values of α,β,γ satisfy the claim for every G:

$$\alpha = \frac{1-\varepsilon}{6}, \beta = \frac{1-\varepsilon}{5+\varepsilon}, \gamma = \min\left\{1-\varepsilon, \left(\frac{1-\varepsilon}{5+\varepsilon}\right)^{\frac{1-\varepsilon}{6}}\right\}.$$

◀

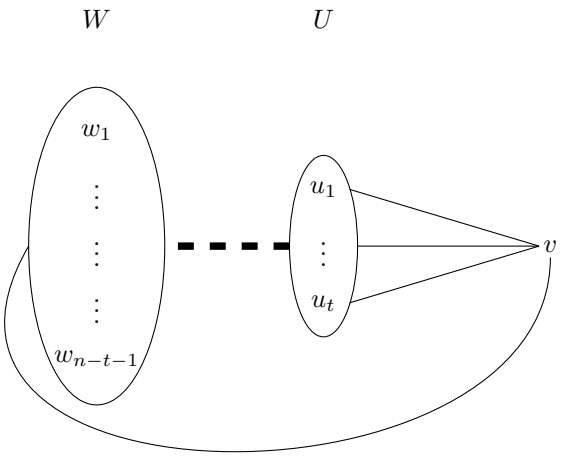

Figure 1 The lower bound sequence for MemList(K_3) with edge insertions. The connections between W and U are chosen. Then, v is connected to all of U. The single edge from v to W is added last.

▶ **Theorem 2.4.** *The randomized* 1*-round bandwidth complexity of* MemList(K_3) *under edge insertions is* $\Omega(\sqrt{n})$.

Proof. Let A be a (randomized) 1-round algorithm that solves MemList(K_3) under edge insertions using bandwidth B with error probability ε. Let t be a parameter to be defined later, and consider a tripartite graph with n nodes as in Figure 1. Let $\mathcal{C}$ be the set of all possible bipartite graphs with vertex sets W and U. Note that $|\mathcal{C}| = 2^{t(n-t-1)}$. For every $C \in \mathcal{C}$ and every $w \in W$, we define a sequence of changes $S_{C,w}$ as follows. We start with no edges. Then, we insert edges between U and W to get the bipartite graph C. During the next t rounds, we connect v to every $u \in U$, one by one. Finally, we insert the edge vw. In the end of $S_{C,w}$, after 1 additional round of communication, node v must output a list of all triangles containing v. By construction, this list is uniquely determined by the set of neighbors of w in U. Thus, node v needs to know the set of all neighbors of w after 1 additional round of communication.

We assume that the output of v is correct with probability at least $1 - \varepsilon$. Therefore, by Yao's lemma, there exists a deterministic algorithm A' that solves the same problem correctly for at least $1 - \varepsilon$ of all inputs. We define a bipartite graph with node sets $\mathcal{C}$ and W, such that the edge $w - C$ exists if and only if the output of v is correct for the sequence $S_{C,w}$.

We have $|W| = n - t - 1$ and $|\mathcal{C}| = 2^{t(n-t-1)}$. Also, by assumption, this graph contains at least $(1 - \varepsilon)$ of all possible edges. Therefore, by Lemma 2.3, there exists $W_1 \subseteq W$ of size at least $\alpha \cdot (n - t - 1)$ and $\mathcal{C}_1 \subseteq \mathcal{C}$ of size at least $\beta \cdot \gamma^{n-t-1} \cdot 2^{t(n-t-1)}$, for some $\alpha, \beta, \gamma \in (0, 1)$ that depend only on ε, such that the output of v is correct for the sequence $S_{C,w}$ for every $C \in \mathcal{C}_1$ and every $w \in W_1$.

Now, consider the input of node v during any sequence $S_{C,w}$. During the first stage of building the bipartite graph C, v is isolated and receives no input. Then, it receives a set of messages from the nodes in U, and finally one additional message from w. Note that the messages v receives from the nodes in U depend only on C, and not on w, since the nodes in U cannot know the identity of w until the final round of communication.

Now, on every round, every node in U can send to v any of 2^B possible messages. Altogether, during the entire sequence, the nodes of U send to v a set of $\frac{t(t+3)}{2}$ messages. Hence, the number of possible inputs from the nodes of U to v is $2^{B\cdot\frac{t(t+3)}{2}}$. Therefore, there exists $\mathcal{C}_2 \subseteq \mathcal{C}_1$ of size at least $2^{-B\cdot\frac{t(t+3)}{2}} \cdot |\mathcal{C}_1|$, such that v receives the same input from all nodes in U for every sequence $S_{C,w}$ for $C \in \mathcal{C}_2$ and every $w \in W_1$. Thus, we have:

$$|\mathcal{C}_2| \geq 2^{-B\frac{t(t+3)}{2}}|\mathcal{C}_1| \geq 2^{-B\frac{t(t+3)}{2}}\beta\gamma^{n-t-1}2^{t(n-t-1)} = \beta\gamma^{n-t-1}2^{t(n-t-1)-B\frac{t(t+3)}{2}} \tag{4}$$

On the other hand, we can bound the size of $\mathcal{C}_2$ by considering the number of possible neighbors of w in any $C \in \mathcal{C}_2$, for every $w \in W$. Recall that during the sequence $S_{C,w}$, v receives only one message from w. Also, for every $w \in W_1$, v must determine the set of all neighbors of w in U. Since there are only 2^B possible inputs v can receive from w, every $w \in W_1$ can have at most 2^B possible sets of neighbors in any $C \in \mathcal{C}_2$.

Every $w \in W \setminus W_1$ can have any subset of U as its set of neighbors, hence it can have at most 2^t possible sets of neighbors. Now, since every $C \in \mathcal{C}_2$ is uniquely determined by set of neighbors of every $w \in W$, we have:

$$|\mathcal{C}_2| \leq \left(\prod_{w\in W_1} 2^B\right)\left(\prod_{w\in W\setminus W_1} 2^t\right) = 2^{B\cdot|W_1|}\cdot 2^{t\cdot(|W|-|W_1|)} = 2^{(B-t)\cdot|W_1|+t(n-t-1)} \tag{5}$$

Combining (4) and (5) gives: $\beta\cdot\gamma^{n-t-1}\cdot 2^{t(n-t-1)-B\cdot\frac{t(t+3)}{2}} \leq 2^{(B-t)\cdot|W_1|+t(n-t-1)}$, and setting $t = \lceil\sqrt{n}\rceil$ gives, with some algebraic manipulations, $B \geq \Omega(\sqrt{n})$. ◀

Finally, for node insertions, we show that every r-round algorithm must use at least $\Omega(n/r)$ bits of bandwidth, which is tight by Theorem 2.2.

▶ **Theorem 2.5.** *For every r, the randomized r-round bandwidth complexity of $\mathsf{MemList}(K_3)$ under node insertions is $\Omega\left(\frac{n}{r}\right)$.*

Proof. Let A be a (randomized) r-round algorithm that solves $\mathsf{MemList}(K_3)$ under node insertions using bandwidth B with error probability ε. We show that $r \cdot B = \Omega(n)$.

Let u be any node, and let $\mathcal{C}$ be the set of all possible graphs on the other $n-1$ nodes. For every $C \in \mathcal{C}$ we define the sequence S_C as follows:

- Start with an empty graph (no nodes and no edges).
- During $n-1$ rounds, insert one node on each round and connect it to the nodes which have been already inserted, according to the edges in C. After $n-1$ rounds, the graph is identical to the graph C.
- On round n insert u and connect to all the other nodes.

After $r-1$ quiet rounds u needs to output the list of all triangles that contain u. Since u is connected to all the other nodes, this implies that u needs to know the graph C. For every $C \in \mathcal{C}$, the output of u is guaranteed to be correct for the sequence S_C with probability at least $(1-\varepsilon)$. Therefore, by Yao's lemma, there exists a deterministic algorithm, A', that guarantees that the output of u is correct for at least $(1-\varepsilon)$ of all sequences. That is, there exists a subset $\mathcal{C}_1 \subseteq \mathcal{C}$, whose size is at least $(1-\varepsilon)\cdot|\mathcal{C}|$, such that A' guarantees the correct output of u for sequences S_C for all $C \in \mathcal{C}_1$.

Now, the number of possible graphs on $n-1$ nodes is $2^{\binom{n-1}{2}}$, hence the size of $\mathcal{C}_1$ is at least $(1-\varepsilon)\cdot 2^{\binom{n-1}{2}}$. Since A' is deterministic, and u needs to distinguish correctly between all possible $C \in \mathcal{C}_1$, this implies that the input u receives from its neighbors must have at

least $(1-\varepsilon)\cdot 2^{\binom{n-1}{2}}$ possible values. Every neighbor of u can send any of 2^B messages on every round, thus the number of possible inputs u can receive on a single round is $2^{B\cdot(n-1)}$. Therefore, during r rounds of communication, the number of possible inputs to u is $2^{r\cdot B\cdot(n-1)}$.

Combining the above we get that $2^{r\cdot B\cdot(n-1)} \geq (1-\varepsilon)\cdot 2^{\binom{n-1}{2}}$, which can be simplified to $r\cdot B \geq \frac{n}{2} + \frac{\log(1-\varepsilon)}{n-1}$, and it follows that $r\cdot B = \Omega(n)$. ◀

2.2 Membership detection

Table 3 summarizes the results of this subsection.

Table 3 Bandwidth complexities of MemDetect(K_3).

	Node deletions	Edge deletions	Edge insertions	Node insertions
$r=1$	0	$\Theta(1)$	$O(\log n)$	$\Theta(n)$
$r\geq 2$	0	$\Theta(1)$	$\Theta(1)$	$\Theta(1)$

2.2.1 Upper bounds

The upper bounds for node deletions and edge deletions follow from Observation 1. The following shows that edge insertions can be handled with $O(\log n)$ bits of bandwidth, which can be extended to handle node/edge deletions as well (see full version [5]).

▶ **Theorem 2.6.** *The deterministic* 1*-round bandwidth complexity of* MemDetect(K_3) *under edge insertions is* $O(\log n)$.

Proof. The algorithm works as follows. On every round, every node sends to all its neighbors an indication whether or not it got a new neighbor on the current round, along with the ID of the new neighbor (if any). We denote this information by `NEWID`. Note that with just this information, for every pair of adjacent edges $u-v-w$, at least one of u and w know that these two edges exist (specifically, the first one connected to v knows that the other one is also connected to v).

Additionally, every node u sends to every neighbor v one bit, indicating whether u knows that v is part of some triangle. We denote this bit by `ACCEPT`.

Suppose the edge uv is inserted and creates at least one triangle uvw. As explained above, in this case at least one of u and v knows that the triangle exists, therefore it sends `ACCEPT` $= 1$ to the two other nodes. Thus all three nodes know that they are part of a triangle. It follows that on each round all nodes can determine whether they are in a triangle. ◀

If we only consider sequences of graphs with bounded degree Δ, and only allow edge insertions, the complexity of Theorem 2.6 can be improved to $O(\sqrt{\Delta\log n})$, using an algorithm similar to that of Theorem 2.1, but with $O(\sqrt{\Delta\log n})$ bits instead of $O(\sqrt{n})$, as follows. On every round, every node sends to all its neighbors an indication whether or not it has a new neighbor. We denote this information by `NEW`. Additionally, whenever a new edge uv is inserted, the following happens:

- u sends to v an indication whether or not it knows about a triangle that contains v.
- For every round i within the last $\left\lceil\sqrt{\Delta\log n}\right\rceil$ rounds, u sends to v an indication whether or not it has had a new neighbor on round i.
- For every round i within the last $\left\lceil\sqrt{\Delta\log n}\right\rceil$ rounds, u sends to v an indication whether or not any of its neighbors has sent `NEW` $= 1$ on round i.

- u computes the list of IDs of all its current neighbors, and starts sending it to v, $\left\lceil \sqrt{\Delta \log n} \right\rceil$ bits on every round. Since u has at most Δ neighbors, after $O(\sqrt{\Delta \log n})$ rounds v has the complete list. Note that by the time this process completes, the list may not be up-to-date.

All of this requires a $O(\sqrt{\Delta \log n})$ bandwidth, and it can be shown, similarly to Theorem 2.1, that this allows every node to give the correct output in all cases. The discussion of what happens when a quiet round is promised, is deferred to the full version [5].

2.2.2 Lower bounds

For node deletions and edge deletions, we have trivial constant lower bounds, which are tight, as shown above. For edge insertions, we have shown a general algorithm that uses $O(\log n)$ bits, and also an algorithm that uses $O(\sqrt{\Delta \log n})$ bits for graphs with bounded degree Δ. The latter algorithm implies that showing a lower bound of B bits for the bandwidth complexity of this problem would require looking at sequences of graphs with degree at least $\Omega(\frac{B^2}{\log n})$. In particular, in order to show that the algorithm of Theorem 2.6 is optimal, one has to consider sequences of graphs with degree at least $\log n$. Other than that, it remains an open question whether or not the algorithm of Theorem 2.6 can be improved.

▶ **Open Question 1.** *What is the* 1*-round bandwidth complexity of* MemDetect(K_3) *under edge insertions?*

Finally, for node insertions, the following theorem shows a lower bound of $\Omega(n)$ bits.

▶ **Theorem 2.7.** *The randomized* 1*-round bandwidth complexity of* MemDetect(K_3) *under node insertions is* $\Omega(n)$.

Proof. Let A be a (randomized) 1-round algorithm that solves MemDetect(K_3) under node insertions using bandwidth B with error probability ε. Fix $x \in V$, let $U = V \setminus \{x\}$, and let $\mathcal{C}$ be the set of all possible graphs on the nodes of U. For every $C \in \mathcal{C}$ and every $u, v \in U$, define the sequence $S_{C,u,v}$ as follows:

- Start with an empty graph (no nodes and no edges).
- During $n-1$ rounds, insert one node of U on each round and connect it to the nodes which have been already inserted, according to the edges in C. After $n-1$ rounds, the graph is identical to the graph C.
- On round n insert x and connect it to u and v.

Then, x should output 1 iff the edge uv exists in C. By our assumption, for every C and every $u, v \in U$, the output is correct with probability at least $1 - \varepsilon$. Note that during the final round, x receives only one message from each of u and v. Also, during this final round, u and v do not know the identity of the other neighbor of x. Hence, the message received from u depends only on the identity of u and the graph C, and not on the identity of v, and the message received from v depends only on the identity of v and the graph C.

Now, consider the following experiment for a given graph $C \in \mathcal{C}$. First, we run the sequence $S_{C,u,v}$ for some $u, v \in U$, and stop just before the last round, in which x is connected to u and v. Then, every node $w \in U$ generates a message to be sent to x, as if it has been connected to x on the final round. For every $w \in U$, let m_w be the message generated by w (note that m_w is a random variable).

Note again, that the messages generated by the nodes of U depend only on the graph C, and not on the other nodes that may have been connected to x on the last round. Therefore, for every $u, v \in U$, given the messages generated by u and v, x should be able to determine, with probability at least $1 - \varepsilon$, whether or not the edge uv exists in C.

Next, for every pair of nodes $u, v \in U$, let I_{uv} be the output of x given the two messages m_u and m_v. Note that for nodes u, v, w, the variables I_{uv} and I_{uw} are not necessarily independent. Now, let C' be the graph on the nodes of U, in which the edge uv exists if and only if $I_{uv} = 1$. We consider C' to be the result of the experiment.

Let p_C denote the probability that at the end of the experiment we have $C' = C$. Since, for every $u, v \in U$, the value of I_{uv} corresponds to the edge uv in the graph C with probability at least $1 - \varepsilon$, we have $p_C \geq (1-\varepsilon)^{\binom{n-1}{2}}$. Summing the above for every $C \in \mathcal{C}$ we get:

$$\sum_C p_C \geq |\mathcal{C}| \cdot (1-\varepsilon)^{\binom{n-1}{2}} = (2-2\varepsilon)^{\binom{n-1}{2}} \tag{6}$$

On the other hand, consider the set of messages generated by the nodes of U at the end of the first stage of the experiment. For every possible set of messages M generated by the nodes of U during the first stage of the experiment, denote by $\phi_C(M)$ the probability for generating exactly the messages of M. Also, for every $C' \in \mathcal{C}$, let $\Psi_M(C')$ denote the probability for the result of the experiment to be equal to C', given the set of generated messages M. We have:

$$\sum_C p_C = \sum_C \sum_M \phi_C(M) \cdot \Psi_M(C) \leq \sum_C \sum_M \Psi_M(C) = \sum_M \sum_C \Psi_M(C) = \sum_M 1 = |\mathcal{M}|$$

where $\mathcal{M}$ is the set of all possible values of M. Since every message has exactly 2^B possible values, the number of possible sets of $(n-1)$ messages is $|\mathcal{M}| = 2^{B(n-1)}$, and hence $\sum_C p_C \leq 2^{B(n-1)}$. Combining this with (6) gives $2^{B(n-1)} \geq (2-2\varepsilon)^{\binom{n-1}{2}}$. After some simplifications we get the desired bound:

$$B \geq \log(2-2\varepsilon) \cdot \frac{n-2}{2} = \Omega(n)$$ ◀

▶ Remark 2.8. The discussion of $\mathsf{List}(K_3)$ and $\mathsf{Detect}(K_3)$, as well as the treatment of s-cliques, appear in the full version [5].

Abstract

We consider the problem of the existence of natural improvement dynamics leading to approximate pure Nash equilibria, with a reasonable small approximation, and the problem of bounding the efficiency of such equilibria in the fundamental framework of weighted congestion game with polynomial latencies of degree at most $d \geq 1$.
In this work, by exploiting a simple technique, we firstly show that the game always admits a d-approximate potential function. This implies that every sequence of d-approximate improvement moves by the players always leads the game to a d-approximate pure Nash equilibrium. As a corollary, we also obtain that, under mild assumptions on the structure of the players' strategies, the game always admits a constant approximate potential function. Secondly, by using a simple potential function argument, we are able to show that in the game there always exists a $(d + \delta)$-approximate pure Nash equilibrium, with $\delta \in [0, 1]$, whose cost is $2/(1 + \delta)$ times the cost of an optimal state.

1 Introduction

Among other solution concepts, the notion of pure Nash equilibrium plays a central role in Game Theory. Pure Nash equilibria in a game characterize situations in which no player has an incentive to unilaterally deviate from the current situation in order to achieve a higher payoff. Unfortunately, it is well known that there are games that do not have pure Nash equilibria. Furthermore, even in games where the existence of pure Nash equilibria is guaranteed, these equilibria could be very inefficient compared to solutions dictated by a central authority. Such negative results significantly question the importance of pure Nash equilibria as solution concepts that characterize the behavior of rational players.

One way to overcome the limitations of the non-existence and inefficiency of pure Nash equilibria is to consider a relaxation of the stability constraints. This relaxation leads to the concept of *approximate* pure Nash equilibrium. This concept characterizes situations where no player can *significantly improve* her payoff by unilaterally deviating from her current strategy. Approximate pure Nash equilibria can accommodate small modeling inaccuracies due to uncertainty (e.g., see the arguments in [5]), therefore they may be more desirable as

solution concepts in practical decision-making settings. Beside mere existence and efficiency, approximate pure Nash equilibria are also an appealing alternative solution concept from a computational point of view [2, 4].

In this work, we investigate the existence and efficiency of approximate pure Nash equilibria in the context of the weighted congestion game. This game is a general framework which models situations in which a group of agents compete for the use of a set of shared resources. In the following, we introduce weighted congestion games and give a formal statement of the problems we address. We conclude this section with a discussion about the current literature and a detailed presentation of our contribution.

Weighted congestion games. In a weighted congestion game, players compete over a set of resources. Each player has a positive weight. Each resource incurs a latency to all players using it; this latency depends on the total weight (congestion) of the players that use the resource according to a resource-specific, non-negative, and non-decreasing latency function. Among a given set of strategies (over sets of resources), each player aims to select one selfishly, trying to minimize her individual total cost, i.e., the sum of the latencies on the resources in her strategy. Typical examples include weighted congestion games in networks, where the network links correspond to the resources and each player has alternative paths that connect two nodes as strategies. Now, let us describe the game more formally.

The WEIGHTED CONGESTION GAME with polynomial latencies of degree at most $d \in \mathbb{Z}^{\geq 1}$ is a collection of instances, denoted by $\texttt{WCG}(d)$, of the form $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$, where $N = \{1, 2, \ldots, |N|\}$ is the set of *players*, $E = \{1, 2, \ldots, |E|\}$ is the set of *resources*, $w_i \in \mathbb{R}^{>0}$ is the *weight* of player i, $S_i \subseteq 2^E$ is the set of *strategies* of player i and $(a_e, k_e) \in \mathbb{R}^{>0} \times \{1, 2, \ldots, d\}$ are the *coefficient* and the *degree* of resource $e \in E$ respectively, which encode the *latency function* $\ell_e : 2^N \mapsto \mathbb{R}^{\geq 0}$ associated with e, mapping every subset of players $P \subseteq N$ to the non-negative real $a_e \left(\sum_{j\in P} w_j\right)^{k_e}$.
The set of *states* of G is denoted by $\mathcal{S}(G) = S_1 \times S_2 \times \ldots \times S_{|N|}$. For every state $\mathbf{s}$ we refer to its i-th component, that is the strategy played by player i in $\mathbf{s}$, by $\mathbf{s}(i)$. For every state $\mathbf{s}$ and resource $e \in E$, we denote by $L_e(\mathbf{s})$ the set of players using resource e in $\mathbf{s}$, i.e., $L_e(\mathbf{s}) = \{j \in N : e \in \mathbf{s}(i)\}$. We refer to the sum of the weights of all the players in $L_e(\mathbf{s})$ as the *congestion* of e in $\mathbf{s}$. For every state $\mathbf{s} \in \mathcal{S}(G)$, the *cost* incurred by player $i \in N$ in $\mathbf{s}$ is $c_i(\mathbf{s}) = \sum_{e\in\mathbf{s}(i)} \ell_e(L_e(\mathbf{s}))$, while the *social cost* of $\mathbf{s}$ is the weighted sum of the players' costs, i.e., $C(\mathbf{s}) = \sum_{i\in N} w_i c_i(\mathbf{s})$. Notice that, by summing over the resources instead of the players, $C(\mathbf{s})$ can be rewritten as $C(\mathbf{s}) = \sum_{e\in E} a_e \left(\sum_{j\in L_e(\mathbf{s})} w_j\right)^{k_e+1}$. Let $w_{\max}$ be the greatest weight in G, we say that G is *mildly congested* if $\ell_e(L_e(\mathbf{s})) \geq (k_e + 1)w_{\max}$, for every resource $e \in E$ and state $\mathbf{s} \in \mathcal{S}(G)$.

Preliminary definitions. We now introduce concepts that are necessary to formally state our problems and present our results.
Let us consider an instance $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ of $\texttt{WCG}(d)$. For every state $\mathbf{s} \in \mathcal{S}(G)$ and every $s \in S_i$, we denote by $[\mathbf{s}_{-i}, s]$ the new state obtained from $\mathbf{s}$ by setting the i-th component, that is the strategy of i, to s and keeping all the remaining components unchanged, i.e., $[\mathbf{s}_{-i}, s](i) = s$. The transition from $\mathbf{s}$ to $[\mathbf{s}_{-i}, s]$ is called a *move* of player i from state $\mathbf{s}$. For $\alpha \geq 1$, we say that a transition from $\mathbf{s}$ to $[\mathbf{s}_{-i}, s]$ is an *α-improvement move* for i if $\alpha c_i([\mathbf{s}_{-i}, s]) \leq c_i(\mathbf{s})$ (it is a *strictly* α-improvement if $\alpha c_i([\mathbf{s}_{-i}, s]) < c_i(\mathbf{s})$). For $\alpha \geq 1$,

we say that a state-value function $\Gamma : \mathcal{S}(G) \mapsto \mathbb{R}^{\geq 0}$ is an *α-approximate potential function* for G if it strictly decreases at every strictly α-improvement move; formally, $\Gamma([\mathbf{s}_{-i}, s]) < \Gamma(\mathbf{s})$ whenever $\alpha c_i([\mathbf{s}_{-i}, s]) < c_i(\mathbf{s})$. If G admits an α-approximate potential function Γ then every sequence of strictly α-improvement moves leads to a *local optimum* of Γ, that is a state in which no further strictly improvement move can be performed; such a state is called α-approximate pure Nash equilibrium. Formally, for $\alpha \geq 1$, we say that a state $\mathbf{s} \in \mathcal{S}(G)$ is an *α-approximate pure Nash equilibrium* if, for every player $i \in N$ and every strategy $s \in S_i$, we have $c_i(\mathbf{s}) \leq \alpha c_i([\mathbf{s}_{-i}, s])$. If $\alpha = 1$ we simply refer to $\mathbf{s}$ as a *pure Nash equilibrium* rather than a 1-approximate pure Nash equilibrium. For $\alpha \geq 1$, we denote by $\mathcal{E}_\alpha(G) \subseteq \mathcal{S}(G)$ the set of all α-approximate pure Nash equilibria of G. Every state $\mathbf{s} \in \mathcal{S}(G)$ minimizing the social cost is called a *social optimum*. We denote by $\mathcal{OPT}(G)$ the set of social optima of G, i.e., $\mathcal{OPT}(G) = \arg\min_{\mathbf{s}\in\mathcal{S}(G)} C(\mathbf{s})$. Let $\mathbf{o} \in \mathcal{OPT}(G)$ be any social optimum of G, we define the *α-approximate price of stability* of G as $\mathrm{PoS}_\alpha(G) = \min_{\mathbf{e}\in\mathcal{E}_\alpha(G)} \frac{C(\mathbf{e})}{C(\mathbf{o})}$.

Problem statement. In this work we consider the problem of the existence of natural improvement dynamics leading to approximate pure Nash equilibria, with a reasonable small approximation, and the problem of bounding the efficiency of such equilibria in the fundamental framework of weighted congestion game with polynomial latencies of degree at most $d \geq 1$. We formally state such problems as follows.

(i) Existence of Convergent sequences of α-improvement moves. In this problem, given any instance G of $\texttt{WCG}(d)$, we seek for a reasonable small $\alpha \geq 1$ for which any sequence of α-improvement moves in G converges to an α-approximate pure Nash equilibrium. This would be equivalent to say that G admits an α-approximate potential function, whose value decreases at every α-improvement move and whose local optima coincide with α-approximate pure Nash equilibria.

(ii) Bounding the approximate price of stability. In this problem, given any instance G of $\texttt{WCG}(d)$, which admits an α-approximate pure Nash equilibrium, we aim at bounding the α-approximate price of stability of G.

Related work. The unweighted congestion game (i.e., when all players have unit weight) has been widely studied in the literature. Rosenthal [16] proved that this game admits a 1-approximate potential function. This immediately implies that every sequence of 1-improvement moves by the players leads the game to a pure Nash equilibrium. For the weighted congestion game, a 1-approximate potential function exists only when the latencies are linear or exponential [10, 13, 15]. For polynomial latencies (of constant maximum degree strictly higher than 1), pure Nash equilibria may not exist [10, 11, 14]. In general, for arbitrary latencies, the problem of deciding whether a given instance of weighted congestion game has a pure Nash equilibrium is NP-hard [9]. Caragiannis et al. [2] proved that every instance of weighted congestion game with polynomial latencies of degree at most d admits a $d!$-approximate potential function. This results has been subsequently improved by Hansknecht et al. [12]; they showed that every instance of weighted congestion game with polynomial latencies admits a $(d+1)$-approximate potential function. The potential function they proposed is a Rosenthal-like potential function. Roughly speaking, they obtained an approximate potential as follows. For each resource, they chose an appropriate fixed ordering of the players. Then, for each resource separately, they computed a discrete integral. Specifically, they sum up the latency of the resource after introducing the first player multiplied

with the weight of the first player, the latency after introducing the first two players multiplied with the weight of the second player, and so on, i.e., $w_1\ell_e(\{w_1\}) + w_2\ell_e(\{w_1 + w_2\}) + \ldots$. The potential obtained depends on the way the players have been initially ordered. The authors showed that, the potential function providing the best approximation for polynomial latencies, that is $d+1$, is the one obtained by ordering the players in non-decreasing order in terms of their weights, i.e., $w_1 \leq w_2 \leq \ldots$.

For the 1-approximate price of stability, for the unweighted game, there exists a bound of 1.577 for linear latencies [8, 3] and a bound of $\Theta(d)$ for polynomial latencies [6]. The 1-approximate price of stability for the weighted game with polynomial latencies has been recently investigated in [7]; they provided a lower bound of $\Omega(d/\log d)^{d+1}$, matching the upper bound in [1]. The authors also showed bounds to the α-approximate price of stability. Specifically, they proved that for the weighted congestion game with polynomial latencies and weights ranging in $[1, W]$, there exists an α-approximate pure Nash equilibrium, for any α in the range $[\frac{2(d+1)W}{2W+d+1}, d+1]$, whose cost is $1 + (\frac{d+1}{\alpha} - 1)W$ the cost of any optimal state. Their proof exploits a potential function called Faulhaber's potential.

Our contribution. Concerning the first problem, we show (Theorem 3) that every instance of $\texttt{WCG}(d)$ admits in general d-approximate potential functions. This implies that every sequence of d-approximate improvement moves by the players always leads the game to a d-approximate pure Nash equilibrium. This result is achieved by using the technique formalised in Theorem 2 and the class of state-value functions Φ_γ defined in Definition 1. Essentially, while Definition 1 provides a simple interesting class of candidate potential functions, Theorem 2 gives a local condition to each resource to determine the approximation guarantee achieved by a given state-value function. So, by exploiting Theorem 2, in Theorem 3 we are able to show that the class Φ_γ contains d-approximate potential functions and, more generally, $(d+\delta)$-approximate potential functions, for every $\delta \geq 0$. We remark that, our potential functions are substantially different from the potential function proposed in [12]. In fact, while the potential in [12] is obtained in a Rosenthal-like fashion, by ordering the players and summing their costs, by assuming that each player is affected only by the congestion caused by preceding players in the ordering, our potential, more simply, is obtained by a suitable scaling of the coefficients of the polynomials. As a matter of fact, our potentials, despite their simplicity, provide an approximation of d instead of $d+1$; although it is worth noticing that, for very small degrees, the two approaches provide the same approximation guarantee. As a corollary of Theorem 3, we also show (Corollary 4) that the social optimum of an instance of $\texttt{WCG}(d)$ is always a $(d+1)$-approximate pure Nash equilibrium, as it has already been observed in [7]. More importantly, Theorem 3 implies that, as state by Corollary 5, every mildly congested instance of $\texttt{WCG}(d)$ always admits a $\frac{e}{e-1}$-approximate potential function, where $\boldsymbol{e}$ is the Euler's number.

We also show that, the class of functions Φ_γ also serves as an essential tool to give a constant bound on the approximate price of stability. In fact, by exploiting Φ_γ, we are able to show (Theorem 8) an upper bound of $2/(1+\delta)$ for the $(d+\delta)$-approximate price of stability, for every $\delta \in [0, 1]$. To prove this bound, we use the standard potential function argument. Specifically, we first give bounds (Lemma 6 and Lemma 7) relating the value of the $(d+\delta)$-approximate potential function for a given state to the social cost of that state; if we then perform a sequence of $(d+\delta)$-improvement moves starting from an optimal state, the potential does not increase, and hence we can bound the cost of any $(d+\delta)$-approximate pure Nash equilibrium that we reach. Notice that our bound does not depend on the range of the players' weights and significantly improves the bound provided in [7], by making use of a different and simpler potential function.

Roadmap. We begin with the definition of a class of state-value functions in Section 2. In Section 3 we first present a simple technique to bound the approximation guarantee of a given state-value function, subsequently we show that some elements of the class introduced in Section 2 provide a good approximation. In Section 4 we present the bound on the approximate price of stability. Finally, in section 5 we present a couple of technical lemmas.

2 A class of state-value functions

In this section we define a class of functions mapping every state of the game to a non-negative real number. This class of functions will be exploited in the subsequent sections.

▶ **Definition 1.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d)*. For every resource $e \in E$ and every $\gamma = (\gamma_e)_{e\in E}$, we define*

$$\Phi_\gamma(\mathbf{s}) = \sum_{e\in E} a_e \Psi_e^{\gamma_e}\big(L_e(\mathbf{s})\big),$$

where, for every nonempty subset of players $P \subseteq N$, we have

$$\Psi_e^{\gamma_e}(P) = \frac{\gamma_e}{k_e+1}\left(\sum_{j\in P} w_j\right)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right)\sum_{j\in P} w_j^{k_e+1}.$$

3 Approximate potential functions

The main result of this section is stated by Theorem 3, where we show the existence of good approximate potential functions. Before showing this result, in Theorem 2 we illustrate our tool to define an approximate potential function. Such tool gives a local condition to each resource to determine the approximation guarantee of a given state-value function. We conclude this section with two corollaries, the first (Corollary 4) showing that the social optimum of an instance of WCG(d) is always a $(d+1)$-approximate pure Nash equilibrium, the second (Corollary 5) showing that, under mild conditions, the game always admits a constant approximate potential function.

▶ **Theorem 2.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d)*. Let $\Gamma : \mathcal{S}(G) \mapsto \mathbb{R}^{>0}$ be a state-value function such that $\Gamma(\mathbf{s}) = \sum_{e\in E} a_e \Gamma_e\big(L_e(\mathbf{s})\big)$, where $\Gamma_e : 2^N \mapsto \mathbb{R}^{>0}$. If, for every resource $e \in E$, every non-empty subset of players $P \subseteq N$ and every player $i \in P$, there exist $\lambda_e, \upsilon_e \in \mathbb{R}^{>0}$, with $\lambda_e \le \upsilon_e$, such that*

$$\frac{w_i \ell_e(P)}{a_e\Big(\Gamma_e(P) - \Gamma_e(P\setminus\{i\})\Big)} \in [\lambda_e, \upsilon_e] \tag{1}$$

then Γ is a $\left(\frac{\upsilon}{\lambda}\right)$-approximate potential function for G, where $\upsilon = \max_{e\in E}\upsilon_e$ and $\lambda = \min_{e\in E}\lambda_e$.

Proof. Let us consider a state $\mathbf{s} \in \mathcal{S}(G)$ and a player i. Let us assume that i can perform an $\frac{\upsilon}{\lambda}$-improvement move by replacing strategy $\mathbf{s}(i)$ with $s \neq \mathbf{s}(i)$, i.e., $\frac{\upsilon}{\lambda} c_i([\mathbf{s}_{-i}, s]) < c_i(\mathbf{s})$. In order to prove the claim we need to show that $\Gamma([\mathbf{s}_{-i}, s]) < \Gamma(\mathbf{s})$. To this aim, let us bound the expression $\Gamma([\mathbf{s}_{-i}, s]) - \Gamma(\mathbf{s})$. We have,

$$
\begin{aligned}
\Gamma([\mathbf{s}_{-i}, s]) - \Gamma(\mathbf{s}) &= \sum_{e \in E} a_e \Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \sum_{e \in E} a_e \Gamma_e\big(L_e(\mathbf{s})\big) \\
&= \sum_{e \in E} a_e \Big[\Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \Gamma_e\big(L_e(\mathbf{s})\big)\Big] \\
&= \sum_{e \in s \setminus \mathbf{s}(i)} a_e \Big[\Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \Gamma_e\big(L_e(\mathbf{s})\big)\Big] \\
&\qquad - \sum_{e \in \mathbf{s}(i) \setminus s} a_e \Big[\Gamma_e\big(L_e(\mathbf{s})\big) - \Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big)\Big] \\
&= \sum_{e \in s} a_e \Big[\Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \Gamma_e\big(L_e(\mathbf{s})\big)\Big] \\
&\qquad - \sum_{e \in \mathbf{s}(i)} a_e \Big[\Gamma_e\big(L_e(\mathbf{s})\big) - \Gamma_e\big(L_e([\mathbf{s}_{-i}, s])\big)\Big] && (2) \\
&\leq \sum_{e \in s} \frac{1}{\lambda_e} w_i \ell_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \sum_{e \in \mathbf{s}(i)} \frac{1}{\upsilon_e} w_i \ell_e\big(L_e(\mathbf{s})\big) && (3) \\
&\leq \frac{1}{\lambda} \sum_{e \in s} w_i \ell_e\big(L_e([\mathbf{s}_{-i}, s])\big) - \frac{1}{\upsilon} \sum_{e \in \mathbf{s}(i)} w_i \ell_e\big(L_e(\mathbf{s})\big) && (4) \\
&= \frac{w_i}{\upsilon} \Big(\frac{\upsilon}{\lambda} c_i([\mathbf{s}_{-i}, s]) - c_i(\mathbf{s})\Big) && (5)
\end{aligned}
$$

where (2) follows from the fact that for every $e \in \mathbf{s}(i) \cap s$ the variation of Γ_e is null since $L_e([\mathbf{s}_{-i}, s]) = L_e(\mathbf{s})$, (3) from (1), (4) from the definition of λ and υ and (5) from the definition of cost.

From (5) we obtain that, if $\frac{\upsilon}{\lambda} c_i([\mathbf{s}_{-i}, s]) < c_i(\mathbf{s})$ then $\Gamma([\mathbf{s}_{-i}, s]) < \Gamma(\mathbf{s})$, from which the claim follows. ◀

We are ready to present the main result of this section.

▶ **Theorem 3.** *Let $G = \langle N, E, (w_i)_{i \in N}, (S_i)_{i \in N}, (a_e, k_e)_{e \in E} \rangle$ be an instance of* WCG(d)*. It holds that*

(a) *if $\gamma_e = 1$, for every $e \in E$, then Φ_γ is a $\rho(G)$-approximate potential function for G, where*

$$
\rho(G) = \max_{e \in E} \sup_{x > 0} \frac{\big(1 + x\big)^{k_e}}{\frac{1}{k_e+1}\big(1 + x\big)^{k_e+1} + \frac{k_e}{k_e+1} - \frac{1}{k_e+1} x^{k_e+1}} \leq d; \tag{6}
$$

(b) *if $\gamma_e = k_e$, for every $e \in E$, then Φ_γ is a d-approximate potential function for G;*

(c) *if $\gamma_e = k_e + \delta$, for every $e \in E$ and $\delta \geq 0$, then Φ_γ is a $(d + \delta)$-approximate potential function for G.*

Proof. We prove the claim using Theorem 2. Therefore, for every resource $e \in E$, every non-empty subset of players $P \subseteq N$ and every player $i \in P$, we bound the ratio

$$
\frac{w_i \ell_e(P)}{a_e\Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})\Big)}. \tag{7}
$$

Let us explicitly rewrite the numerator and denominator of the previous expression. We distinguish between the cases $|P| = \{i\}$ and $|P| \geq 2$.

Let us fist assume $|P| = \{i\}$. In this case, for $w_i \ell_e(P)$ we get

$$w_i \ell_e(P) = w_i a_e (w_i)^{k_e} = a_e w_i^{k_e+1}. \tag{8}$$

On the other hand, for the expression $\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})$, using Definition 1, we have

$$\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\}) = \left[\frac{\gamma_e}{k_e+1} (w_j)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) w_j^{k_e+1} \right] - 0 = w_j^{k_e+1}. \tag{9}$$

Therefore, by combining (8) and (9), we conclude that, for $|P| = \{i\}$, for the ratio (7) we have

$$\frac{w_i \ell_e(P)}{a_e \Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\}) \Big)} = \frac{a_e w_i^{k_e+1}}{a_e w_i^{k_e+1}} = 1. \tag{10}$$

Not let us assume that $|P| \geq 2$. In this case, for $w_i \ell_e(P)$ we get

$$\begin{aligned} w_i \ell_e(P) &= w_i a_e \left(\sum_{j \in P} w_j \right)^{k_e} = w_i a_e \left(w_i + \sum_{j \in P \setminus \{i\}} w_j \right)^{k_e} \\ &= a_e w_i^{k_e+1} \big(1 + \lambda_i(P)\big)^{k_e}. \end{aligned} \tag{11}$$

Now, let us focus on the expression $\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})$. For every $i \in P$, let $\lambda_i(P) = \frac{1}{w_i} \sum_{j \in P \setminus \{i\}} w_j$. Using Definition 1, we have

$$\begin{aligned} &\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\}) \\ &= \frac{\gamma_e}{k_e+1} \left(\sum_{j \in P} w_j \right)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) \sum_{j \in P} w_j^{k_e+1} \\ &\quad - \frac{\gamma_e}{k_e+1} \left(\sum_{j \in P \setminus \{i\}} w_j \right)^{k_e+1} - \left(1 - \frac{\gamma_e}{k_e+1}\right) \sum_{j \in P \setminus \{i\}} w_j^{k_e+1} \\ &= \frac{\gamma_e}{k_e+1} \left(\sum_{j \in P} w_j \right)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) w_i^{k_e+1} - \frac{\gamma_e}{k_e+1} \left(\sum_{j \in P \setminus \{i\}} w_j \right)^{k_e+1} \\ &= \frac{\gamma_e}{k_e+1} \left(w_i + \sum_{j \in P \setminus \{i\}} w_j \right)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) w_i^{k_e+1} - \frac{\gamma_e}{k_e+1} \left(\sum_{j \in P \setminus \{i\}} w_j \right)^{k_e+1} \\ &= \frac{\gamma_e}{k_e+1} w_i^{k_e+1} \big(1 + \lambda_i(P)\big)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) w_i^{k_e+1} - \frac{\gamma_e}{k_e+1} w_i^{k_e+1} \lambda_i(P)^{k_e+1} \\ &= w_i^{k_e+1} \left[\frac{\gamma_e}{k_e+1} \big(1 + \lambda_i(P)\big)^{k_e+1} + \left(1 - \frac{\gamma_e}{k_e+1}\right) - \frac{\gamma_e}{k_e+1} \lambda_i(P)^{k_e+1} \right] \end{aligned} \tag{12}$$

Therefore, by combining (11) and (12), we conclude that, for $|P| \geq 2$, for the expression (7) we have

$$\begin{aligned}
&\frac{w_i \ell_e(P)}{a_e\Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})\Big)} \\
&= \frac{a_e w_i^{k_e+1}\big(1+\lambda_i(P)\big)^{k_e}}{a_e w_i^{k_e+1}\left[\frac{\gamma_e}{k_e+1}\big(1+\lambda_i(P)\big)^{k_e+1} + \Big(1-\frac{\gamma_e}{k_e+1}\Big) - \frac{\gamma_e}{k_e+1}\lambda_i(P)^{k_e+1}\right]} \\
&= \frac{\big(1+\lambda_i(P)\big)^{k_e}}{\frac{\gamma_e}{k_e+1}\big(1+\lambda_i(P)\big)^{k_e+1} + \Big(1-\frac{\gamma_e}{k_e+1}\Big) - \frac{\gamma_e}{k_e+1}\lambda_i(P)^{k_e+1}}. \qquad (13)
\end{aligned}$$

Now we apply Lemma 9 to (13), by setting $x = \lambda_i(P)$, $h = k_e$ and $\beta = \gamma_e$.
If $\gamma_e = 1$, we obtain

$$\frac{w_i \ell_e(P)}{a_e\Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})\Big)} \in \big[1, k_e\big]. \qquad (14)$$

If $\gamma_e = k_e$, we have

$$\frac{w_i \ell_e(P)}{a_e\Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})\Big)} \in \Big[\frac{1}{k_e}, 1\Big]. \qquad (15)$$

Finally, if $\gamma_e = k_e + \delta$, with $\delta \geq 0$, we have

$$\frac{w_i \ell_e(P)}{a_e\Big(\Psi_e^{\gamma_e}(P) - \Psi_e^{\gamma_e}(P \setminus \{i\})\Big)} \in \Big[\frac{1}{k_e+\delta}, 1\Big]. \qquad (16)$$

Claim (a) follows by combining (10), (13) and (14), and by applying Theorem 2. Claims (b) and (c) follow by combining (10), (15) and (16), and by applying Theorem 2. ◀

▶ **Corollary 4.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d)*. Any social optimum of G is a $(d+1)$-approximate pure Nash equilibrium.*

Proof. Let us consider the function $\Phi_\gamma(\mathbf{s}) = \sum_{e\in E} \Psi_e^{\gamma_e}(L_e(\mathbf{s}))$ (defined in Definition 1), with $\gamma_e = k_e + 1$. The claim follows from observing that $\Phi_\gamma(\mathbf{s}) = C(\mathbf{s})$ and from the fact that, by Theorem 3(c), Φ_γ is also a $(d+1)$-approximate potential function. ◀

▶ **Corollary 5.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be a mildly congested instance of* WCG(d)*. If $\gamma_e = 1$, for every $e \in E$, then Φ_γ is a $\frac{\boldsymbol{e}}{\boldsymbol{e}-1}$-approximate potential function for G, where $\boldsymbol{e}$ is the Euler's number.*

Proof Sketch. Since G is mildly congested, we have $\ell_e(L_e(\mathbf{s})) \geq (k_e+1)w_{\max}$, for every resource $e \in E$ and state $\mathbf{s} \in \mathcal{S}(G)$, where $w_{\max}$ denotes the greatest weight in G. Under this condition, we can restrict the proof of Theorem 3 to the case in which the generic subset of player P is such that $\sum_{j\in P} w_j \geq (k_e+1)w_{\max}$. With this condition in place, we have that, for every $i \in P$, $\lambda_i(P)$ is at least k_e. In fact,

$$\lambda_i(P) = \frac{1}{w_i}\left(\sum_{j\in P} w_j - w_i\right) \geq \frac{1}{w_i}\Big((k_e+1)w_{\max} - w_i\Big) \geq \frac{w_{\max}}{w_i}k_e \geq k_e.$$

By using the previous inequality, it is easy to prove that the expression (13) gets always values in the range $[1, \frac{\boldsymbol{e}}{\boldsymbol{e}-1}]$, for every $k_e \geq 1$. The claim follows by applying Theorem 2. ◀

4 Approximate price of stability

In this section we show an upper bound on the α-approximate price of stability, for $\alpha \in [d, d+1]$. This bound is stated by Theorem 8, whose proof is based on Lemma 6 and Lemma 7 presented below.

▶ **Lemma 6.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d). *Let $\gamma_e = k_e + \delta$ and $\delta \in [0,1]$, for every resource $e \in E$. For every resource $e \in E$ and every non-empty subset of players $P \subseteq N$, we have*

$$\Psi_e^{\gamma_e}(P) \leq \left(\sum_{j\in P} w_j\right)^{k_e+1} \leq \frac{k_e+1}{k_e+\delta}\Psi_e^{\gamma_e}(P).$$

Proof. We have

$$\frac{\left(\sum_{j\in P} w_j\right)^{k_e+1}}{\Psi_e^{\gamma_e}(P)} = \frac{\left(\sum_{j\in P} w_j\right)^{k_e+1}}{\frac{k_e+\delta}{k_e+1}\left(\sum_{j\in P} w_j\right)^{k_e+1} + \left(1-\frac{k_e+\delta}{k_e+1}\right)\sum_{j\in P} w_j^{k_e+1}} \tag{17}$$

$$\in \left[1, \frac{k_e+1}{k_e+\delta}\right). \tag{18}$$

where (17) follows from Definition 1 and the definition of γ_e, and (18) follows by applying Lemma 10, where we set $x = \left(\sum_{j\in P} w_j\right)^{k_e+1}$, $y = \sum_{j\in P} w_j^{k_e+1}$ and $\beta = \frac{k_e+1}{k_e+\delta}$. ◀

In the following lemma, we give bounds relating the value of the approximate potential function for a given state to the social cost of that state.

▶ **Lemma 7.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d). *Let $\gamma = (\gamma_e)_{e\in E}$, where $\gamma_e = k_e + \delta$ and $\delta \in [0,1]$. For every state $\mathbf{s} \in \mathcal{S}(G)$ we have*

$$\Phi_\gamma(\mathbf{s}) \leq C(\mathbf{s}) \leq \frac{2}{1+\delta}\Phi_\gamma(\mathbf{s}). \tag{19}$$

Proof. Let $E = \{e_1, e_2, \ldots, e_m\}$. Let us bound the ratio

$$\frac{C(\mathbf{s})}{\Phi_\gamma(\mathbf{s})} = \frac{\sum_{t=1}^m a_{e_t}\left(\sum_{j\in L_{e_t}(\mathbf{s})} w_j\right)^{k_{e_t}+1}}{\sum_{t=1}^m a_{e_t}\Psi_{e_t}^{\gamma_{e_t}}\left(L_{e_t}(\mathbf{s})\right)}.$$

In order to bound $C(\mathbf{s})/\Phi_\gamma(\mathbf{s})$, we consider the ratio between the t-th term in the numerator and the t-th term in the denominator, for every $t \in [1,m]$, that is

$$\frac{\left(\sum_{j\in L_{e_t}(\mathbf{s})} w_j\right)^{k_{e_t}+1}}{\Psi_{e_t}^{\gamma_{e_t}}\left(L_{e_t}(\mathbf{s})\right)}. \tag{20}$$

From Lemma 6, (20) gets values in the interval $\left[1, \frac{k_{e_t}+1}{k_{e_t}+\delta}\right]$. We get that the smallest ratio is 1 while the greatest one is $\max_t \frac{k_{e_t}+1}{k_{e_t}+\delta} \leq \frac{2}{1+\delta}$. It follows that, $C(\mathbf{s})/\Phi_\gamma(\mathbf{s})$ is at least 1 and at most $\frac{2}{1+\delta}$, from which the claim follows. ◀

▶ **Theorem 8.** *Let $G = \langle N, E, (w_i)_{i\in N}, (S_i)_{i\in N}, (a_e, k_e)_{e\in E}\rangle$ be an instance of* WCG(d). *Then* $\mathrm{PoS}_{d+\delta}(G) \leq \frac{2}{1+\delta}$, *for every $\delta \in [0,1]$.*

Proof. Let Φ_γ be the function with $\gamma = (\gamma_e)_{e\in E}$, where $\gamma_e = k_e + \delta$. Let $\mathbf{o} \in \mathcal{OPT}(G)$ be a social optimum. Let us consider any sequence of $(d+\delta)$-improvement moves starting from $\mathbf{o}$. From Theorem 3(c) we know that this sequence converges to a state which is a $(d+\delta)$-approximate pure Nash equilibrium which we denote by $\mathbf{e}$. Moreover, along this sequence of moves, Φ_γ is not increasing. Hence,

$$\Phi_\gamma(\mathbf{e}) \leq \Phi_\gamma(\mathbf{o}). \tag{21}$$

By applying Lemma 7 repeatedly to both $\mathbf{o}$ and $\mathbf{e}$ we obtain

$$C(\mathbf{e}) \leq \frac{2}{1+\delta}\Phi_\gamma(\mathbf{e}) \leq \frac{2}{1+\delta}\Phi_\gamma(\mathbf{o}) \leq \frac{2}{1+\delta}C(\mathbf{o}),$$

where the second inequality follows from (21). From which the claim follows. ◀

5 Technical lemmas

In this section we present two technical lemmas. Lemma 9 is used in the proof of Theorem 3, while Lemma 10 is used in the proof of Lemma 6.

▶ **Lemma 9.** *For every $x \in \mathbb{R}^{>0}$, $h \in \mathbb{Z}^{\geq 1}$ and $\beta \in \mathbb{R}^{\geq 1}$, we have*

$$\frac{(1+x)^h}{\beta\frac{1}{h+1}(1+x)^{h+1} + (1-\beta\frac{1}{h+1}) - \beta\frac{1}{h+1}x^{h+1}} \in \begin{cases} [\frac{1}{\beta}, \frac{h}{\beta}] & \text{if } \beta \in [1,h] \\ [\frac{1}{\beta}, 1] & \text{if } \beta \geq h. \end{cases}$$

Proof. We have

$$\begin{aligned}
&\frac{(1+x)^h}{\beta\frac{1}{h+1}(1+x)^{h+1} + (1-\beta\frac{1}{h+1}) - \beta\frac{1}{h+1}x^{h+1}} \\
&= \frac{\sum_{t=0}^{h}\binom{h}{t}x^t}{\beta\frac{1}{h+1}\sum_{t=0}^{h+1}\binom{h+1}{t}x^t + (1-\beta\frac{1}{h+1}) - \beta\frac{1}{h+1}x^{h+1}} \\
&= \frac{1+\sum_{t=1}^{h}\binom{h}{t}x^t}{1+\beta\frac{1}{h+1}\sum_{t=1}^{h+1}\binom{h+1}{t}x^t - \beta\frac{1}{h+1}x^{h+1}} \\
&= \frac{1+\sum_{t=1}^{h}\binom{h}{t}x^t}{1+\sum_{t=1}^{h}\beta\frac{1}{h+1}\binom{h+1}{t}x^t} \\
&= \frac{1+\sum_{t=1}^{h}\binom{h}{t}x^t}{1+\sum_{t=1}^{h}\beta\frac{1}{h+1}\frac{h+1}{h+1-t}\binom{h}{t}x^t} = \frac{1+\sum_{t=1}^{h}\binom{h}{t}x^t}{1+\sum_{t=1}^{h}\beta\frac{1}{h+1-t}\binom{h}{t}x^t} && (22) \\
&= \frac{1\cdot x^0 + \binom{h}{1}x^1 + \binom{h}{2}x^2 + \ldots + \binom{h}{h}x^h}{1\cdot x^0 + \beta\frac{1}{h}\binom{h}{1}x^1 + \beta\frac{1}{h-1}\binom{h}{2}x^2 + \ldots + \beta\binom{h}{h}x^h}, && (23)
\end{aligned}$$

where (22) holds because

$$\binom{h+1}{t} = \frac{\frac{(h+1)!}{t!(h+1-t)!}}{\frac{h!}{t!(h-t)!}}\binom{h}{t} = \frac{(h+1)!}{t!(h+1-t)!}\frac{t!(h-t)!}{h!}\binom{h}{t} = \frac{h+1}{h+1-t}\binom{h}{t}.$$

In order to bound (23), for every $t \in [0,h]$ we consider the ratio between the coefficient of the term x^t in the numerator and the coefficient of the same term in the denominator. For $t=0$ the ratio is 1, while for $t \in [1,h]$ the ratio is $\frac{h+1-t}{\beta}$. For the case $\beta \in [1,h]$, we get that the smallest ratio is $1/\beta$ while the greatest is h/β. It follows that, when $\beta \in [1,h]$, the expression in (23) is at least $1/\beta$ and at most h/β. For the case $\beta \geq h$, we obtain that the smallest is $1/\beta$ while the greatest ratio is 1df. Therefore, when $\beta \geq h$, the expression in (23) is at least $1/\beta$ and at most 1. From which the claim follows. ◀

▶ **Lemma 10.** *For every $x, y, \beta \in \mathbb{R}^{>0}$ such that $\beta \geq 1$ and $y \leq x$, we have*

$$\frac{x}{\frac{1}{\beta}x + (1-\frac{1}{\beta})y} \in \big[1, \beta\big].$$

Proof. We have

$$\frac{x}{\frac{1}{\beta}x + (1-\frac{1}{\beta})y} = \frac{1}{\frac{1}{\beta} + (1-\frac{1}{\beta})\frac{y}{x}} \geq \frac{1}{\frac{1}{\beta} + (1-\frac{1}{\beta})} = 1,$$

where the last inequality is due to the fact that $y/x \leq 1$.

$$\frac{x}{\frac{1}{\beta}x + (1-\frac{1}{\beta})y} = \frac{1}{\frac{1}{\beta} + (1-\frac{1}{\beta})\frac{y}{x}} < \frac{1}{\frac{1}{\beta}} = \beta,$$

where the last inequality is due to the fact that $y/x > 0$. ◀

Abstract

Let $G = (V, E)$ be an undirected graph on n vertices and $\lambda : E \to 2^{\mathbb{N}}$ a mapping that assigns to every edge a non-empty set of positive integer labels. These labels can be seen as discrete times when the edge is present. Such a labeled graph $\mathcal{G} = (G, \lambda)$ is said to be *temporally connected* if a path exists with non-decreasing times from every vertex to every other vertex. In a seminal paper, Kempe, Kleinberg, and Kumar (STOC 2000) asked whether, given such a temporal graph, a *sparse* subset of edges can always be found whose labels suffice to preserve temporal connectivity – a *temporal spanner*. Axiotis and Fotakis (ICALP 2016) answered negatively by exhibiting a family of $\Theta(n^2)$-dense temporal graphs which admit no temporal spanner of density $o(n^2)$. The natural question is then whether sparse temporal spanners always exist in *some* classes of dense graphs.

In this paper, we answer this question affirmatively, by showing that if the underlying graph G is a complete graph, then one can always find temporal spanners of density $O(n \log n)$. The best known result for complete graphs so far was that spanners of density $\binom{n}{2} - \lfloor n/4 \rfloor = O(n^2)$ always exist. Our result is the first *positive* answer as to the existence of $o(n^2)$ sparse spanners in adversarial instances of temporal graphs since the original question by Kempe et al., focusing here on complete graphs. The proofs are constructive and directly adaptable as an algorithm.

1 Introduction

The study of highly dynamic networks has gained interest lately, motivated by emerging technological contexts (e.g. vehicular networks, wireless sensors, robots, and drones) where the entities move and communicate with each other. The communication links in these networks vary with time, leading to the definition of temporal graph models (also called time-varying graphs or evolving graphs) where temporality plays a central role. In these graphs, the properties of interest are often defined over the time rather than at a given instant.

For example, the graph may never be connected, and yet offer a form of connectivity over time. In [6], a dozen temporal properties were identified that have been effectively exploited in the distributed computing and networking literature. Perhaps the most basic property is that of *temporal connectivity*, which requires that every vertex can reach every other vertex through a temporal path (also called *journey* [5]), that is, a path whose edges are used over a non-decreasing sequence of times. The times may also be required to be strictly increasing (strict journey), both cases being carefully discussed in this paper. Temporal connectivity was considered in an early paper by Awerbuch and Even [3] (1984), and systematically studied from a graph-theoretical point of view in the early 2000's in a number of seminal works including Kempe, Kleinberg, and Kumar [13], and Bui-Xuan, Ferreira, and Jarry [5] (see also [16] for an early study of graphs with time-dependent delays on the edges). More recently, temporal connectivity has been the subject of several algorithmic studies, such as [1] and [4] (discussed below), and [18] and [19], which consider algorithms for computing structures related to temporal connectivity. Broad surveys on these topics can be found, e.g. in [6, 11, 14], although the list is non-exhaustive and the literature is rapidly evolving.

1.1 Sparse Temporal Spanners and Related Work

In the last section of [13] (conference version [12]), Kempe, Kleinberg, and Kumar ask

> "Given a temporally connected network $G = (V, E)$ on n nodes, is there a set $E' \subseteq E$ consisting of $O(n)$ edges so that the temporal network on the subgraph (V, E') is also temporally connected? In other words, do all temporal networks have sparse subgraphs preserving this basic connectivity property?"

Here, Kempe et al. consider a model where each edge has a single label, thus the edges are identified with their labels, but the discussion is more general. What they are asking, essentially, is whether an analogue of spanning tree exists for temporal networks when the labels are *already fixed*. They answer immediately (and negatively) for the particular case of $O(n)$ density, by showing that hypercubes labeled in a certain way need all of their edges to achieve temporal connectivity, thus some temporal graphs of density $\Theta(n \log n)$ cannot be sparsified. The more general question, asking whether $o(n^2)$-sparse spanners always exist in dense temporal graphs remained open for more than a decade, and was eventually settled, again negatively, by Axiotis and Fotakis [4]. The proof in [4] exhibits an infinite family of temporally connected graphs with $\Theta(n^2)$ edges that do not admit $o(n^2)$-sparse spanners. Their construction can be adapted for strict and non-strict journeys.

On the positive side, Akrida et al. [1] show that, if the underlying graph G is complete and every edge is assigned a single globally-unique label, then it is always possible to find a temporal spanner of density $\binom{n}{2} - \lfloor n/4 \rfloor$ edges (leaving the asymptotic density unchanged). Akrida et al. [1] also prove that if the label of every edge in G is chosen uniformly at random (from an appropriate interval), then almost surely the graph admits a temporal spanner with $O(n \log n)$ edges. Both [4] and [1] include further results related to the (in-)approximability of finding a *minimum* temporal spanner, which is out of the scope of this paper.

By its nature, the problem of finding a temporal spanner in a temporal network seems to be significantly different from its classical (i.e., non-temporal) version, whether this version considers a static graph (see e.g. [8, 15, 17]) or the current network topology of an updated dynamic graph (see e.g. [2, 9, 10]). The essential difference is that spanning trees always exist in standard (connected) graphs, thus one typically focuses on the tradeoff between the density of a solution and a quality parameter like the *stretch factor*, rather than to the very existence of a sparse spanner.

1.2 Contributions

In this paper, we establish that temporal graphs built on top of complete graphs *unconditionally* admit $O(n \log n)$-sparse temporal spanners when *non-strict* journeys are allowed. Furthermore, such spanners can be computed in polynomial time. The case of strict journeys requires more discussion. Kempe et al. observed in [13] that if every edge of a complete graph is given the same label, then this graph is temporally connected, but no multi-hop *strict* journey can exist, thus none of the edges can be removed, and the problem is trivially unsolvable. To make the problem interesting when only strict journeys are allowed, one should constrain the labeling to avoid this pathological situation. Thus, in this case, we require that a subset of one label per edge exists in which any two adjacent edges have different labels. This formulation slightly generalizes the single-label global-unicity assumption made in [1] (although essentially equivalent) and eliminates the distinction between strict and non-strict journeys. Under this restriction, we establish that all temporal graphs whose underlying graph is complete admit an $O(n \log n)$-sparse temporal spanner. Moreover, if the restricted labeling is given, then the spanner can be computed in polynomial time. (The problem of deciding whether a general labeling admits such a sub-labeling is not discussed here; it might be an interesting problem on its own, possibly computationally hard.)

Our proofs are constructive. We start by observing that the above two settings one-way reduce to the setting where every edge has a single label and two adjacent edges have different labels. The reduction is "one-way" in the sense that the transformed instance may have less feasible journeys than the original instance, but all of these journeys correspond to valid journeys in the original instance, so that a temporal spanner computed in the transformed instance is valid in the original instance. As a result, the main algorithm takes as input a complete graph $\mathcal{G}$ with single, locally distinct labels, and computes an $O(n \log n)$-sparse spanner of $\mathcal{G}$ in polynomial time. This algorithm is based on several original techniques, which we think may be of interest for other problems related to temporal connectivity.

In summary, our results give the first positive answer to the question of whether sparse temporal spanners always exist in a class of dense graphs, focusing here on the case of complete graphs. This answer complements the negative answer by Axiotis and Fotakis [4] and motivates more investigation to understand where the transition occurs between their negative result (no sparse spanners exist in some dense temporal graphs) and our positive result (they essentially always exist in complete graphs).

The paper is organized as follows. In Section 2, we define the model and notations, and describe the one-way reductions that allows us to concentrate subsequently on single (and distinct) labels. We also mention a technique from [1] and we introduce a basic technique called *pivoting* which is a natural analogue of Kosaraju's algorithm for temporal graphs. In Section 3 we introduce the main concepts used in the rest of the paper, namely *delegation*, *dismountability*, and *k-hop dismountability*, whose purpose is to recursively self-reduce the problem to smaller graph instances. While these technique alone fail in some cases, we extend them and combine them into a more sophisticated algorithm that successfully computes a temporal spanner of $O(n \log n)$ edges. The first step, presented in Section 4, is called *fireworks* and results in a spanner of density (essentially) $\binom{n}{2}/2$. It is sparsified further down to $O(n \log n)$ by exploiting a particular dichotomy in the structure of the residual instance. Due to space limitation, several proofs are omitted. They can be found in the full version [7].

2 Definitions and Basic Results

2.1 Model and definitions

Let $G = (V, E)$ be an undirected graph and $\lambda : E \to 2^{\mathbb{N}}$ a mapping that assigns to every edge of E a non-empty set of integer labels. These labels can be seen as discrete times when the edge is present. In this paper, we refer to the resulting graph $\mathcal{G} = (G, \lambda)$ as a *temporal graph* (other models and terminologies exist, all being equivalent for the considered problem). If λ is single-valued and locally injective (i.e., adjacent edges have different labels), then we say that λ is *simple*, and by extension, a temporal graph is simple if its labeling is simple.

A temporal path in $\mathcal{G}$ (also called *journey*), is a finite sequence of k triplets $\mathcal{J} = \{(u_i, u_{i+1}, t_i)\}$ such that $(u_1, \ldots, u_{k+1})$ is a path in G and for all $1 \leq i < k$, $\{u_i, u_{i+1}\} \in E$, $t_i \in \lambda(\{u_i, u_{i+1}\})$ and $t_{i+1} \geq t_i$. Strict temporal path (strict journeys) are defined analogously by requiring that $t_{i+1} > t_i$. We say that a vertex u can *reach* a vertex v iff a journey exists from u to v (strict or non-strict, depending on the context). If every vertex can reach every other vertex, then $\mathcal{G}$ is *temporally connected*. Interestingly, the distinction between strict and non-strict journeys does not exist in simple temporal graphs, as all the journeys are strict.

In general, one can define a *temporal spanner* of $\mathcal{G} = ((V, E), \lambda)$ as a temporal graph $\mathcal{G}' = ((V', E'), \lambda')$ such that $V = V'$, $E' \subseteq E$ and $\lambda' : E' \to 2^{\mathbb{N}}$ with $\lambda'(e) \subseteq \lambda(e)$ for all $e \in E'$. We call $\mathcal{G}'$ a *valid* spanner if it is temporally connected. Observe that, if $\mathcal{G}$ is simple, then spanners are fully determined by the chosen subset of edges $E' \subseteq E$ (as in the above citation from [13]). Thus, in such cases, we say that E' itself *is* the spanner. Many of these notions are analogous to the ones considered in [1, 4, 13], although they are not referred to as "spanners" in these works.

Finally, when the underlying graph G is a complete graph, we call $\mathcal{G}$ a temporal clique. An example of a (valid) temporal spanner of a *simple temporal clique* is shown in Figure 1.

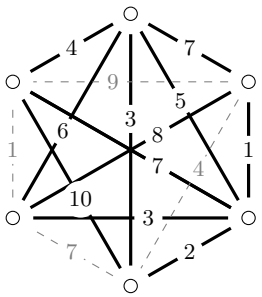

Figure 1 Example of a simple temporal clique and one of its temporal spanners (edges in bold). This spanner is not minimum (nor even minimal) and the reader may try to remove further edges.

2.2 Generality of simple labelings

We claimed in Section 1.2 that if non-strict journeys are allowed, then one can transform a temporal clique $\mathcal{G} = (G, \lambda)$ with *unrestricted* labeling λ into a clique $\mathcal{H} = (G, \lambda_H)$ with *simple* labeling such that any valid temporal spanner of $\mathcal{H}$ induces a valid temporal spanner of $\mathcal{G}$. (As explained, the converse is false, but this is fine because our result is *positive* on $\mathcal{H}$.) The reduction proceeds in two steps: (1) For every edge e, restrict $\lambda(e)$ to a single label chosen arbitrarily; and (2) Whenever k adjacent edges have identical label l, then all labels $l' > l$ are shifted to $l' + k$ and the k labels are assigned a unique value in the interval $[l, l + k]$

(again, arbitrarily). It should not be difficult to see that this reduction produces a simple clique $\mathcal{H}$, such that if a journey exists in $\mathcal{H}$, then the same sequence of edges allows for a (possibly non-strict) journey in $\mathcal{G}$.

As for the case that strict journeys are the only ones allowed, as explained above, we consider that a *simple* sub-labeling of λ exists and is identified prior to the computation. Here, it is even more direct that any journey based on the sub-labeling only is a fortiori available in the complete instance. Based on these arguments, the rest of the paper focuses on simple temporal cliques, sometimes dropping the adjective "simple".

2.3 Preliminary techniques

The best approach so far for sparsifying simple temporal cliques is that of Akrida et al. [1], who prove that one can always remove $\lfloor n/4 \rfloor$ edges without breaking temporal connectivity as follows. (Their paper has other significant contributions.) First, they show that if $n = 4$, then it is always possible to remove at least *one* edge. Then, as $n \to \infty$, one can arbitrarily partition the input clique into (essentially) $n/4$ subcliques of 4 vertices each, and remove an edge from each subclique. The edges *between* subcliques are kept, thus the impact of removals is confined to each subclique. In the full version of the present paper [7], we improve this technique to remove a constant fraction of $\lfloor n^2/12 \rfloor$ edges. However, we consider as unlikely that such purely *structural* techniques could sparsify a graph to $o(n^2)$ edges. The techniques that we develop here are completely different.

Another natural approach that one might think of is discussed in the full version of this paper, inspired by Kosaraju's principle for testing strong connectivity in a directed graph. This principle relies on finding a vertex that all of the other vertices can reach (through directed paths) and that can reach all these vertices in return. This condition is sufficient in standard graphs because paths are transitive. In the temporal setting, transitivity does not hold, but we can define a temporal analogue as follows. A *pivot vertex* p is a vertex such that all other vertices can reach p by some time t (through journeys) and p can reach all other vertices back *after* time t. The union of the tree of (incoming) journeys towards p and the tree of (outgoing) journeys from p is a temporal spanner with at most $2(n-1)$ edges. Unfortunately, pivot vertices may not exist, even in temporal cliques. Both possibilities (positive and negative) are shown in Figure 2. A generic construction to build arbitrarily large non-pivotable graphs is proposed in the full version of this paper.

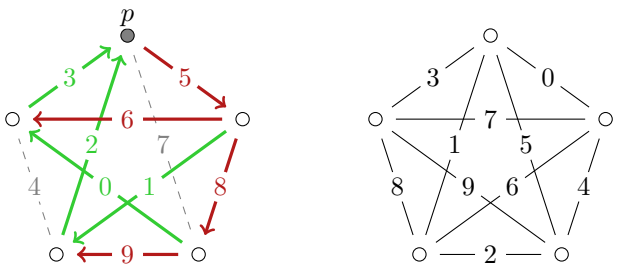

Figure 2 Examples of pivotable graph (left) and non-pivotable graph (right). The (light) green edges in the pivotable graph belong to the tree of incoming journeys to pivot vertex p (with $t = 4$); the (darker) red edges belong to the tree of outgoing journeys; the dashed edges belong to neither.

3 Delegation and Dismountability

This section introduces a number of basic techniques which are subsequently refined and adapted in Sections 4 and 5 in the main algorithm. Given a vertex v, write $e^-(v)$ for the edge with smallest label incident with v, and $e^+(v)$ analogously for the largest label.

▶ **Fact 1.** *Given a temporal clique $\mathcal{G}$, if $\{u,v\} = e^-(v)$, then u can reach all vertices through v. Similarly, if $\{u,w\} = e^+(w)$, then all vertices can reach u through w.*

Fact 1 applies because the underlying graph G is complete. This fact makes it possible for a vertex u to *delegate* its emissions to a vertex v, i.e., exploit the fact that v can still reach all the other vertices (if need be, by a direct edge) *after* interacting with u, thus none of u's other edges are required for reaching the other vertices. By a symmetrical argument, u can delegate its receptions (collections) to a vertex w if w can be reached by all the other vertices (if need be, by a direct edge) *before* interacting with u, so u does not need its other edges to be reached by the other vertices.

This type of delegation suggests an interesting technique to obtain temporal spanners. We say that a vertex u in a temporal clique $\mathcal{G}$ is *dismountable* if there exist two other vertices v and w such that $\{u,v\} = e^-(v)$ and $\{u,w\} = e^+(w)$. The idea of dismountability is to select $e^-(v)$ and $e^+(w)$ for inclusion in a temporal spanner for $\mathcal{G}$ and then reduce the computation to finding a temporal spanner in the smaller clique $\mathcal{G}[V \setminus u]$. We state this more formally in the following theorem.

▶ **Theorem 1** (Dismountability). *Let $\mathcal{G}$ be a temporal clique, and let u, v, w be three vertices in $\mathcal{G}$ such that $\{u,v\} = e^-(v)$ and $\{u,w\} = e^+(w)$. Let S' be a temporal spanner of $\mathcal{G}[V \setminus u]$. Then $S = S' \cup \{\{u,v\},\{u,w\}\}$ is a temporal spanner of $\mathcal{G}$.*

Proof. Since $\{u,v\} = e^-(v)$, all edges incident with v in S' have a larger label than $\{u,v\}$, thus u can reach all the vertices in $\mathcal{G}$ through v and the edges of S'. A symmetrical argument implies that all vertices in $\mathcal{G}$ can reach u through w using only $\{u,w\}$ and the edges of S'. ◀

We call a graph *dismountable* if it contains a dismountable vertex. It is said to be *fully dismountable* if one can find an ordering of V that allows for a recursive dismounting of the graph until the residual instance is a two-vertex graph with a single edge. An example of such dismountable graph is given in Figure 3.

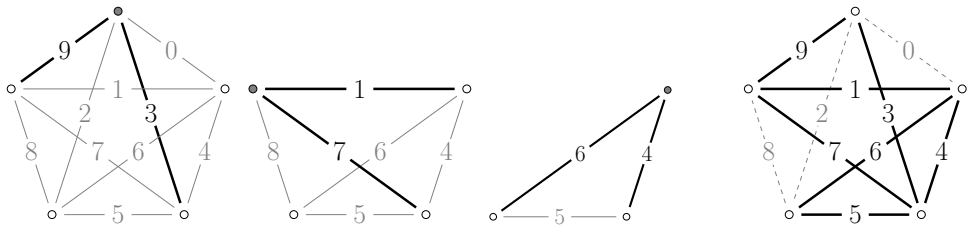

Figure 3 Example of a fully dismountable graph and the resulting spanner.

▶ **Fact 2** (Spanners based on dismountability). *If a graph can be fully dismounted, then the union of the pairs of edges involved in all steps of the recursion, plus the last edge forms a temporal spanner. There are $n-2$ steps, so this spanner has $2(n-2)+1 = 2n-3$ edges.*

Unfortunately, one can design arbitrarily large temporal cliques which are not fully dismountable (we give a generic construction in the full version of this paper). Yet, techniques derived from dismountability are at the core of our algorithm. To start, the concept of dismountability can be generalized to *multi-hop* journeys. The key observation is that a multi-hop journey may exist from a vertex u to another vertex v, say through vertices $u = u_0, u_1, \ldots, u_k = v$ such that $\{u_{k-1}, u_k\} = e^-(v)$, despite the fact that $\{u_{i-1}, u_i\} \neq e^-(u_i)$ for some i. Indeed, it is sufficient that the *last* edge of a journey from u to v is $e^-(v)$ in order to delegate u's emissions to v. Symmetrically, it is sufficient that the *first* edge of a journey from w to u is $e^+(w)$ in order to delegate u's receptions to w. Thus, a vertex u is called *k-hop dismountable* if one can find two other vertices v and w (possibly identical if $k > 1$) such that there are journeys of *at most* k hops (1) from u to v that arrives at v through $e^-(v)$, and (2) from w to u that leaves w through $e^+(w)$.

Temporal spanners can be obtained in a similar way to 1-hop dismountability by selecting all of the edges involved in these journeys for inclusion in the spanner. However, only the edges adjacent to the dismounted vertex are removed in the recursion, thus some edges used in a multi-hop journey may be selected several times over the recursion (with positive impact). We can then extend Fact 2 to k-hop dismountability as follows.

▶ **Fact 3.** *If a temporal graph $\mathcal{G}$ is fully k-hop dismountable, then this process yields a temporal spanner with at most $2k(n-2)+1 \simeq 2kn$ edges.*

Unfortunately, again, there exist arbitrarily large graphs which are not k-hop dismountable for any k (see the full version of this paper [7]). Nonetheless, k-hop dismountability is one of the components of the more sophisticated techniques in Sections 4 and 5.

4 The Fireworks Technique

In this section, we present an algorithm called *fireworks*, which exploits delegations among vertices in a more subtle way than dismountability. In particular, we take advantage of *one-sided delegations*, in which a vertex may be able to delegate only its emissions, or only its receptions. The combination of many such delegations is shown to lead to the removal of essentially half of the edges of the input clique. The residual instance has a particular structure that we exploit in Section 5 to obtain $O(n \log n)$-sparse spanners.

4.1 Forward Fireworks

The purpose of fireworks is to mutualize several one-sided delegations in a transitive way, so that many vertices do not need to reach the others vertices directly, most of their edges being consequently eliminated. Given a temporal clique $\mathcal{G} = (G, \lambda)$ with $G = (V, E)$, define the directed graph $G^- = (V, E^-)$ such that $(u, v) \in E^-$ iff $\{u, v\} = e^-(v)$, except that, if $e^-(u) = e^-(v)$ for some u and v, only one of the arcs is included (chosen arbitrarily).

▶ **Lemma 2.** *Directed paths in G^- correspond to journeys in $\mathcal{G}$.*

By construction, E^- induces a disjoint set of *out-trees* (one source, possibly several sinks). We transform E^- into a disjoint set $\mathcal{T}^- = (V, E_T^-)$ of *in-trees* (one sink, possibly several sources) as follows, see also Figure 4 for an illustration. Let E_T^- be initialized as a copy of E^-. For every v with outdegree at least 2 in E^-, let $(v, u_1), ..., (v, u_\ell)$ be its out-arcs with (v, u_ℓ) being the one with the *largest* label. For every $i < \ell$, if u_i is a sink vertex, then flip the direction of (v, u_i) in E_T^- (i.e., replace (v, u_i) by (u_i, v) in E_T^-); otherwise remove (v, u_i) from E_T^-. Let $\mathcal{T}^- = (V, E_T^-)$ be the resulting set of in-trees $\mathcal{T}_1^-, ..., \mathcal{T}_k^-$ (containing possibly more in-trees than the number of initial out-trees).

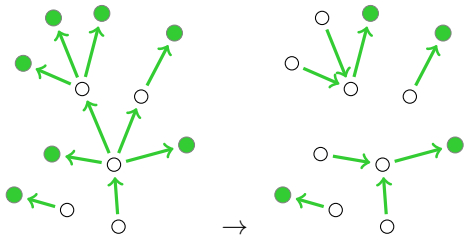

Figure 4 Example of transformation from a disjoint set of out-trees (V, E^-) to a disjoint set of in-trees (V, E_T^-). The colored vertices represent sink vertices.

▶ **Fact 4.** *The set of in-trees $\mathcal{T}^- = (V, E_T^-)$ has the following properties:*

1. *Directed paths in $\mathcal{T}^-$ correspond to journeys in $\mathcal{G}$.*
2. *Every vertex belongs to exactly one tree.*
3. *Every tree contains at least two vertices.*
4. *There is a unique sink in each tree.*
5. *The unique arc incident with a sink s corresponds to $e^-(s)$.*

Fact 4.1 follows from Lemma 2 because an arc (v, u_i) is only replaced by (u_i, v) if the label of (v, u_i) is less than the label of another arc (v, u_ℓ), so $(u_i, v), (v, u_\ell)$ is a journey in $\mathcal{G}$. Observe that some of the journeys induced by the arcs of $\mathcal{T}^-$ may include intermediate hops where the arc's label is not locally minimum for its head endpoint. However, as already discussed in Section 3, a delegation only requires that the label of the last hop of a journey be locally minimum, and that is the case here (Fact 4.5).

The motivation behind this construction is that all the vertices in each in-tree are able to delegate their emissions to the corresponding sink vertex. For this reason, the sink vertex will be called an *emitter* in the rest of the paper. An important consequence of our construction is that the number of emitters in $\mathcal{T}^-$ cannot exceed half of the total number of vertices.

▶ **Lemma 3.** *The number of emitters in $\mathcal{T}^-$ is at most $n/2$*

Proof. After the transformation from E^- to E_T^-, there is only one emitter in each in-tree $\mathcal{T}_i^- \in \mathcal{T}^-$ (Fact 4.4), and at most $n/2$ in-trees, each having at least 2 vertices (Fact 4.3). ◀

We are now ready to define a temporal spanner based on $\mathcal{T}^-$, which consists of the union of all edges involved in an in-tree and all edges incident with at least one emitter. More formally, let $S_T^- = \{\{u, v\} \in E : (u, v) \in \mathcal{T}^-\} \cup \{\{u, v\} \in E : u \text{ is an emitter}\}$.

▶ **Theorem 4.** *S_T^- is a temporal spanner of $\mathcal{G}$.*

Proof. By Fact 4, every vertex v of $\mathcal{G}$ that is a non-emitter in $\mathcal{T}^-$ can reach an emitter s through an edge $e^-(s)$. Furthermore, the inclusion of all edges incident to a vertex s that is an emitter in $\mathcal{T}^-$ ensures that v can still reach all other vertices afterwards and so can s. Therefore, every vertex can reach all other vertices by using only edges from S_T^-. ◀

We call this type of spanner a *forward fireworks cover*. An example is given in Figure 5, the corresponding journeys being depicted on the left side.

▶ **Theorem 5.** *Forward fireworks covers have at most $3\binom{n}{2}/4 + O(n)$ edges.*

Before moving to Section 4.2, we establish a small technical lemma that will be used in Section 5, but is worth being stated here as it pertains to the in-trees.

▶ **Lemma 6.** *Every non-emitter vertex v can reach a vertex v' in the same in-tree $\mathcal{T}_i^-$ (emitter or not) using a journey of length* at most two *that arrives at v' through $e^-(v')$.*

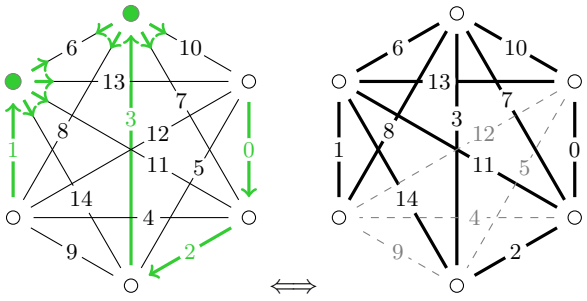

Figure 5 Example of forward fireworks cover and the resulting spanner.

4.2 Backward Fireworks

A symmetrical concept of fireworks can be defined based on the edges $\{u, v\} = e^+(v)$ of a temporal clique $\mathcal{G} = (G, \lambda)$. The above arguments can be adapted in a symmetrical way. First, we build a directed graph $G^+ = (V, E^+)$, which is a disjoint set of *in-trees*. A symmetrical transformation to the above converts this set into a disjoint set $\mathcal{T}^+ = (V, E_T^+)$ of *out-trees*, each with only one source which we call a *collector*. The collector s of an out-tree can reach all of the other vertices in this tree by journeys that leave s through its edge $e^+(s)$, thereby guaranteeing that every vertex that reaches s can reach all other vertices in the tree.

▶ **Lemma 7.** *The number of collectors in $\mathcal{T}^+$ is at most $n/2$*

We build a temporal spanner $S_T^+ = \{\{u, v\} : (u, v) \in \mathcal{T}^+\} \cup \{\{u, v\} : u \text{ is a collector}\}$ which we call a *backward fireworks cover*, and prove the following results by symmetrical arguments to the ones in Subsection 4.1.

▶ **Theorem 8.** *S_T^+ is a temporal spanner of the temporal clique $\mathcal{G}$.*

▶ **Theorem 9.** *Backward fireworks covers have at most $3\binom{n}{2}/4 + O(n)$ edges.*

An example of a backward fireworks cover is given in the full version. Finally, we establish a symmetrical property to the one in Lemma 6, to be used later in Section 5.

▶ **Lemma 10.** *Every non-collector vertex v can be reached by a vertex v' in the same out-tree $\mathcal{T}_i^+$ (collector or not) using a journey of length* at most two *that leaves v' through $e^+(v')$.*

4.3 Bidirectional Fireworks

A forward fireworks cover makes it possible to identify a subset of vertices, the *emitters*, such that every vertex can reach at least one emitter u through $e^-(u)$ and u can reach every other vertex afterwards *through a single edge*. Similarly, a backward fireworks cover makes it possible to identify a subset of vertices, the *collectors*, such that every vertex can be reached by at least one collector v through $e^+(v)$ and v can be reached by every other vertex before this *through a single edge*. Combining both ideas, we can define a sparser spanner that only includes the edges *between* emitters and collectors (plus, of course, the edges used for reaching an emitter and for being reached by a collector).

Precisely, let $\mathcal{T}^-$ be the disjoint set of in-trees obtained during the construction of a forward fireworks cover (see Figure 4), and let $\mathcal{T}^+$ be the disjoint set of out-trees obtained during the construction of a backward fireworks cover. Let X^- be the set of emitters (one per in-tree in $\mathcal{T}^-$) and let X^+ be the set of collectors (one per out-tree in $\mathcal{T}^+$). The two

sets can overlap, as a vertex may happen to be both an emitter in some tree in $\mathcal{T}^-$ and a collector in some tree in $\mathcal{T}^+$, which is not a problem. Let $H = (X^- \cup X^+, E_H)$ be the graph such that $E_H = \{\{u, v\} \in E : u \in X^-, v \in X^+\}$; in other words, H is the subgraph of G that connects all emitters with all collectors. Finally, let $S = \{\{u, v\} : (u, v) \in \mathcal{T}^- \cup \mathcal{T}^+\} \cup E_H$. We call S a bidirectional fireworks cover (or simply a *fireworks cover*).

▶ **Theorem 11.** *S is a temporal spanner of $\mathcal{G}$.*

Proof. Every non-emitter vertex can reach an emitter u through $e^-(u)$. Every emitter can reach *all* collectors afterwards. Every non-collector vertex can be reached by a collector v through $e^+(v)$. ◀

▶ **Theorem 12.** *Bidirectional fireworks covers have at most $\binom{n}{2}/2 + O(n)$ edges.*

5 Recursing or Sparsifying Further

After applying the fireworks technique, one is left with a residual instance (or spanner) made of all the edges between emitters X^- and collectors X^+, together with all the edges corresponding to the arcs of $\mathcal{T}^-$ and $\mathcal{T}^+$, these edges being denoted S^- and S^+ for simplicity. As we will see, the algorithm may recurse several times due to dismountability, thus it is worth mentioning that variables $\mathcal{G}$ and V refer to the instance of the current recursion. The algorithm considers two cases, depending on the outcome of the fireworks procedure. Either $X^- \cup X^+ \neq V$ (Case 1) or $X^- \cup X^+ = V$ (Case 2).

▶ **Case 1 ($X^- \cup X^+ \neq V$).** In this configuration, at least one vertex v is neither emitter nor collector. By Lemma 6, there exists a journey of length at most two from v that arrives at some vertex $u \neq v$ through $e^-(u)$. Similarly, by Lemma 10, there is a journey of length at most two from some vertex $w \neq v$ to v, leaving w through $e^+(w)$. As a result, v is 2-hop dismountable (see Section 3). One can thus select the corresponding edges (at most four) for future inclusion in the spanner and then recurse on $\mathcal{G}[V \setminus v]$, i.e., re-apply the fireworks technique from scratch. Then, either the recursion keeps entering Case 1 and dismounting the graph completely, or it eventually enters Case 2.

▶ **Case 2 ($X^- \cup X^+ = V$).** Both X^- and X^+ have size at most $n/2$ (Lemma 3 and 7), thus if their union is V, then both sets must be disjoint and of size exactly $n/2$. As a result, the graph which connects all vertices in X^- with all vertices in X^+ (called H in Section 4) is a complete bipartite graph. In fact, H possesses even more structure. Firstly, both S^- and S^+ are perfect matchings – by contradiction, if this is not the case, then at least one of the in-tree (out-tree) contains more than one edge, resulting in strictly less emitters (collectors) than $n/2$. Furthermore, every vertex is either an emitter or a collector, thus each of these edges connects an emitter with a collector, implying that the residual instance actually is H itself. Now, recall that every edge in S^- is locally minimum for the corresponding emitter (based on Fact 4.5), and every edge in S^+ is locally maximum for the corresponding collector. We then have the following stronger property.

▶ **Lemma 13.** *If the minimum edge of an emitter is not also minimum for the corresponding collector in H, then the residual instance is 2-hop dismountable. The same holds if the maximum edge of a collector is not also maximum for the corresponding emitter in H.*

Lemma 13 implies that either a vertex v is 2-hop dismountable and the algorithm can recurse as in Case 1, or the edges of the matchings are minimum (resp. maximum) *on both sides*. (An example of the latter case is given in the long version [7].)

In summary, either the algorithm recurses until the input clique is fully dismounted (through Case 1 or Case 2), resulting in an $O(n)$-dense spanner (Fact 3), or the *recursion stops* and the residual instance is sparsified further by a dedicated procedure, described now.

5.1 Sparsifying the Residual Instance

For simplicity, the sparsification of the residual instance is considered as a separate problem. The input is a labeled complete bipartite graph $B = (X^-, X^+, E_B)$ where X^- is the set of emitters, X^+ is the set of collectors, and the labels are inherited from $\mathcal{G}$. There are two perfect matchings S^- and S^+ in B such that the labels of the edges in S^- (resp. S^+) are minimum (resp. maximum) locally to both of their endpoints (Lemma 13). The objective is to remove as many edges as possible from E_B, while preserving S^-, S^+, and the fact that every emitter can reach *all* collectors by a journey. Indeed, these three properties ensure temporal connectivity of the graph (using the same arguments as in Theorem 11).

While both S^- and S^+ are matchings, our algorithm effectively exploits this property with respect to S^+ as follows.

▶ **Fact 5.** *If an emitter can reach another emitter, then it can reach the corresponding collector by adding to its journey the corresponding edge of S^+.*

This property makes it possible to reduce the task of reaching some collectors to that of reaching the corresponding emitter in S^+. It is however impossible for an emitter u to make a complete delegation to another emitter v, because the existence of a journey from u to v arriving through $e^-(v)$ would contradict the fact that S^- is also a matching. For this reason, when a journey from emitter u arrives at emitter v, some of v's edges have already disappeared. Nevertheless, the algorithm exploits such *partial* delegations, while paying extra edges for the missed opportunities (contained within a logarithmic factor). This is done by means of an iterative procedure called *layered delegations*, described over the remaining of this section. Note the term iterative, not recursive; from now on, the instance has a fixed vertex set and it is sparsified until the final bound is reached.

Layered Delegations

The algorithm proceeds by *eliminating* half of the emitters in each step j, while selecting a set S_j of edges for inclusion in the spanner, so that the eliminated emitters can reach all collectors by a mixture of direct edges and indirect journeys through other emitters (partial delegations). The set of non-eliminated emitters at step j (called *alive*) is denoted by X_j^-, with $X_1^- = X^-$. The set of collectors X^+ is invariant over the execution. We denote by $k = n/2$ the initial degree of the emitters in B (one edge shared with each collector), and by $e^i(v)$ the edge with the i^{th} smallest label (label of *rank* i) locally to a vertex v, in particular $e^1(v) = e^-(v)$ and $e^k(v) = e^+(v)$.

The k ranks are partitioned into subintervals of doubling size $\mathcal{I}_j = [2^{j+2} - 7, 2^{j+3} - 8]$, where j denotes the current step of the iteration, ranging from 1 to $\log_2 k - 3$. For simplicity, assume that k is a power of two, we explain below how to adapt the algorithm when this is not the case. For example, if $k = 128$, then $\mathcal{I}_1 = [1, 8], \mathcal{I}_2 = [9, 24], \mathcal{I}_3 = [25, 56]$, and $\mathcal{I}_4 = [57, 120]$. Computation step j is made with respect to the subgraph $B_j = (X_j^-, X^+, E_j)$ where $E_j = \{e^i(v) \in E_B : i \in \mathcal{I}_j, v \in X_j^-\}$, namely the edges of the currently alive emitters, whose ranks are in the interval $\mathcal{I}_j$.

▶ **Lemma 14.** *In each step j, X_j^- can be split into two sets X_a and X_b such that $|X_a| \geq |X_b|$ and every vertex in X_a can reach a vertex in X_b through a 2-hop journey (within B_j).*

Proof. The proof is in the full version [7] (together with an illustration). The main idea is to show that the average degrees of collectors in B_j forces the existence of sufficiently many two-hop journeys among emitters. ◀

▶ Remark 15. The computation of X_a proceeds by repeatedly considering the largest degree d of a collector and assigning $d-1$ of the corresponding emitters to X_a and one to X_b; it is therefore a greedy algorithm. The process is to be stopped whenever X_a reaches half the size of X_j^-. If X_a exceeds this threshold during step j, then some emitters can be arbitrarily transferred from X_a to X_b to preserve the fact that $|X_{j+1}^-|$ is a power of two. The case that $|X_1^-| = k$ is not a power of two is addressed similarly after the first iteration, in order to set the size of X_b to the highest power of two below k.

How X_a and X_b are then used: When an emitter u in X_a can reach another emitter v in X_b, the corresponding journey arrives at v through some edge $e^i(v)$ with $i \in \mathcal{I}_j$. We say that u partially delegates its emissions to v in the sense that all collectors that v can reach after this time can *de facto* be reached from u (through v), the other collectors being possibly no longer reachable from v after this time. Thus, the delegation is *partial*.

▶ **Lemma 16.** *If an emitter u makes a partial delegation to v in step j, then the number of collectors that u may no longer reach through v is at most $2^{j+3} - 8$.*

Proof. This number is the largest value in the current interval; it corresponds to the largest rank of the edge through which the journey from u may have arrived at v. All the edges whose rank locally to v is larger than $2^{j+1} - 2$ can still be used and thus the corresponding collectors are still reachable. (In fact, the collector corresponding to the edge with last index in $\mathcal{I}_j$ locally to v can also be considered as reached, but this is a detail.) ◀

A partial delegation from u to v in step j implies the removal of u from the set of emitters, the selection of the two edges of the journey from u to v, and the selection of at most $2^{j+3} - 8$ direct edges between u and the missed collectors. This implies the following fact.

▶ **Fact 6.** *In each step j, at most 2^{j+3} edges are selected relative to every eliminated emitter.*

More globally, let J_j be the edges used in all the delegation journeys from vertices in X_a to vertices in X_b in step j, and D_j the union of direct edges towards missed collectors. Let $S_j = J_j \cup D_j$. The algorithm thus consists of selecting all the edges in S_j for inclusion into the spanner. Then X_{j+1}^- is set to X_b and the iteration proceeds with the next step. The computation goes for j ranging from 1 to $\log_2 k - 3$, which leaves exactly *eight* final emitters alive. All the remaining edges of these emitters (call them S_{last}) are finally selected. Overall, the final spanner is the union of all selected edges, plus the edges corresponding to the two initial matchings, i.e., $S = (\cup_j S_j) \cup S_{last} \cup S^- \cup S^+$.

▶ **Theorem 17.** *S is a temporal spanner of the complete bipartite graph B and it is made of $O(n \log n)$ edges.*

Proof. The key observation for establishing *validity* of the spanner is that eliminated emitters reach all collectors either directly or through an emitter that can still reach this collector *afterwards*. This property applies transitively (thanks to the disjoint and increasing intervals) until eight emitters remain, all the edges of which are selected for simplicity. Therefore, every initial emitter can reach all collectors. The rest of the arguments are the same as in the proof of Theorem 11: all vertices in the input clique can reach at least one emitter u through $e^-(u)$, and be reached by at least one collector v through $e^+(v)$.

Regarding the size of the spanner, in step j, $\frac{k}{2^j}$ emitters are eliminated and at most 2^{j+3} edges are selected for each of them (Fact 6), amounting to at most $8k = 4n$ edges. The number of iterations is $\Theta(\log k) = \Theta(\log n)$. Finally, the sets S_{last}, S^-, and S^+ each contain $\Theta(n)$ edges (and S^+ is actually included in S_{last}). ◀

▶ **Corollary 18.** *Simple temporal cliques always admit $O(n \log n)$-sparse spanners.*

Proof. In each recursion of the global algorithm, either the residual instance of the fireworks procedure is 2-hop dismountable and the algorithm recurses on a smaller instance induced by a removed vertex, after selecting a *constant* number of edges, or the algorithm computes a $\Theta(n \log n)$-sparse spanner of the residual instance through the layered delegation process. Let n_1 be the number of times the graph is 2-hop dismounted and $n_2 = n - n_1$ be the number of vertices of the residual instance when the layered delegation process begins (if applicable, 0 otherwise). The resulting spanner has $\Theta(n_1) + \Theta(n_2 \log n_2) = O(n \log n)$ many edges. ◀

▶ Remark 19. The running time of the algorithm is polynomial (see the full version).

6 Concluding Remarks

In this paper, we established that sparse temporal spanners always exist in temporal cliques, proving constructively that one can find $O(n \log n)$ edges that suffice to preserve temporal connectivity. Our results hold for non-strict journeys with single or multiple labels on each edge, and strict journeys with single or multiple labels on each edge with the property that there is a subset of locally exclusive single labels. Our results give the first positive answer to the question of whether any class of dense graphs always has sparse temporal spanners.

To prove our results, we introduced several techniques (pivoting, delegation, dismounting and k-hop dismounting, forward and backward fireworks, partial delegation, and layered delegations), all of which are original and some of which might be of independent interest. Whether some of these techniques can be used for more general classes of graphs is an open question. Delegation and dismounting rely explicitly on the graph being complete; however, refined versions of these techniques like partial delegation might have wider applicability.

An open question is whether sparse spanners always exist in more general classes of dense graphs, keeping in mind that some dense graphs are unsparsifiable. Another question is whether a better density than $O(n \log n)$ could be obtained in the particular case of temporal cliques, in particular $O(n)$-dense spanners. At a deeper level, all these questions pertain to identifying and studying analogues of spanning trees in temporal graphs, which do not enjoy the same matroid structure as in standard graphs.

Abstract

In this paper, we investigate a *distributed maximal independent set (MIS) reconfiguration problem*, in which there are two maximal independent sets for which every node is given its membership status, and the nodes need to communicate with their neighbors in order to find a *reconfiguration schedule* that switches from the first MIS to the second. Such a schedule is a list of *independent sets* that is restricted by forbidding two neighbors to change their membership status at the same step. In addition, these independent sets should provide some covering guarantee.

We show that obtaining an actual MIS (and even a 3-dominating set) in each intermediate step is impossible. However, we provide efficient solutions when the intermediate sets are only required to be independent and 4-dominating, which is almost always possible, as we fully characterize.

Consequently, our goal is to pin down the tradeoff between the possible length of the schedule and the number of communication rounds. We prove that a constant length schedule can be found in $O(\texttt{MIS} + \texttt{R32})$ rounds, where `MIS` is the complexity of finding an MIS in a worst-case graph and `R32` is the complexity of finding a $(3, 2)$-ruling set. For bounded degree graphs, this is $O(\log^* n)$ rounds and we show that it is necessary. On the other extreme, we show that with a constant number of rounds we can find a linear length schedule.

1 Introduction

Consider a distributed setting in which each node of a network receives an input from a higher-level application which tells it whether it is *selected* or not, such that the set of selected nodes is a maximal independent set (MIS), which we will denote by α. The reason that the application requires an MIS is because it needs the set of selected nodes to dominate

all nodes for the sake of, say, monitoring the network, but without having violations of two neighbors being in the set, because they may cause conflicting actions. Now, because of changes in the network traffic, the energy consumption, or any one of various conditions that may change, the application needs to change the selected set of nodes. Once a new input MIS, denoted by β, is given to the nodes by the application, the nodes need to *reconfigure* their states to that set while never sacrificing the safety condition of independence. In fact, for compatibility reasons, neighboring nodes cannot change their membership in the set at the same time, so a *sequence* of changes is needed for converging into the new MIS. We call such a sequence a *reconfiguration schedule*.

The length of the schedule is clearly a measure that is required to be minimized. Hence, an extreme solution would be to have all nodes declare themselves as unselected, and then the new set of nodes declare that they are selected. However, this very fast approach suffers from loosing the domination property throughout the reconfiguration schedule. Thus, the structure of the network must be taken into account, but since the topology is unknown, finding a schedule that maintains a good covering at all times necessitates that the nodes communicate. This brings another measure of complexity into question, which is the number of communication rounds that are needed in order to find a short schedule. Our goal in this work is to study the tradeoff between the possible length of the schedule and the number of communication rounds needed for finding it.

Unfortunately, as we show, it is not always possible to find schedules where each set is an MIS. This impossibility holds even if we relax the condition of domination and require only independent 3-dominating sets. Even when 3-domination *is* possible, it may be extremely inefficient (Section 6).

▶ **Theorem 1.** *Requiring* 3*-domination for intermediate steps is costly:*

1. *There exists a class of inputs $G = (V, E)$ with two MIS α and β such that there is no reconfiguration schedule with 3-dominating intermediate steps.*
2. *There exists a class of inputs $G = (V, E)$ with two MIS α and β such that any reconfiguration schedule is of length $\Omega(n)$ and needs $\Theta(n)$ rounds to be found, if intermediate steps must be 3-dominating.*

However, we prove that independence and 4-domination can indeed be obtained. Our main result is the following (Section 3).

▶ **Theorem 2** (informal)**.** *For any graph $G = (V, E)$ of diameter greater than 3 and any input of two MIS α, β, there exists a reconfiguration schedule of constant length* 28*, with independent 4-dominating intermediate steps. Moreover, such a schedule can be found in $O(\texttt{MIS} + \texttt{R32})$ rounds, where* `MIS` *is the complexity of finding an MIS on a worst-case graph and* `R32` *is the complexity of finding a $(3, 2)$-ruling set on a worst-case graph.*

Obtaining the above theorem turns out to be an involved task. Our key ingredients are the following. We prove that graphs with a not-too-small diameter always admit a schedule of reconfiguration steps from a given maximal independent set to another. Moreover, full knowledge of the topology of the graph is not necessary in order to be able to locally add an element to the set after having removed its neighbors (to avoid dependence). Rather, only local manipulations are needed for doing so.

The currently known complexities that give $O(\texttt{MIS} + \texttt{R32})$ are discussed in the related work part. Here, we draw attention to the fact that an immediate corollary of Theorem 2 is that for graphs of bounded degree we can compute the constant length schedule within $O(\log^* n)$ rounds. Further, we show that this is a lower bound by reducing the problem of

finding an MIS on a path to obtaining a constant-length schedule for MIS reconfiguration. The following theorem actually holds even if one requires only d-domination, for some constant $d \geq 4$ (Section 6).

▶ **Theorem 3.** *For any fixed k, there exists a class of k-regular inputs $G = (V, E)$ with two MIS α and β such that any reconfiguration schedule of constant length with 4-domination needs $\Theta(\log^* n)$ rounds to be found.*

If one wants to optimize the communication cost of finding a schedule rather than its length, we show that a (rather lengthy) schedule can be obtained within $O(1)$ rounds (Section 4).

▶ **Theorem 4** (informal). *For any graph $G = (V, E)$ and any input of maximal independent sets α, β to the MIS-reconfiguration problem, there exists a reconfiguration schedule of length $\Theta(f(n))$, where $f(n)$ is the largest identifier among the nodes in the graph, which can be found in $O(1)$ rounds.*

The construction generalizes itself on graphs with a distance-k coloring of c colors, with k big enough. It is possible, from this coloring, to compute a schedule of length $O(c)$ after a constant number of communication rounds. Let Δ be the maximal degree of the graph. A distance-k $O(\Delta^{2k})$ coloring can be found in $O(\log^* n)$ rounds [16], and a distance-k $O(\Delta^k)$ coloring can be found in $O(\log^* n + \sqrt{\Delta^k})$ rounds [4]. Hence, with the same respective communication complexities, we can find schedules of lengths $O(\Delta^{2k})$ and $O(\Delta^k)$.

Finally, as can be inferred from Theorem 2, 4-domination suffices for any graph with diameter greater than 3. For graphs with small diameter, we give an exact characterization of the conditions that allow the existence of a reconfiguration schedule (Section 5). This result implies that our algorithm from Theorem 2, combined with a trivial algorithm that collects the entire graph when the diameter is a small constant, produces an efficient reconfiguration schedule in all cases for which it exists.

1.1 Related work

Distributed Reconfiguration. Questions of distributed reconfiguration were actually not studied before 2018. Then, Bonamy et al. [6] considered distributed reconfiguration of colorings, with the goal of finding which length of schedule can be computed within a given number of communication rounds. The problem being PSPACE complete in the general case, several subcases were explored. Since finding looser restrictions for the transitions is important for making the problem local instead of having to solve a global PSPACE hard problem, the addition of extra colors in the intermediate colorings was allowed. This aided either having a solution, or finding one quickly.

Distributed Constructions. Our constructions sometimes make use of two fundamental subroutines, which find an MIS or a $(3, 2)$-ruling set in a graph. An (x, y)-ruling set is a set $S \subseteq V$ in which every two nodes are at distance at least x, and every node that is not in S is within distance at most y from S. Thus, an MIS is a $(2, 1)$-ruling set. Finding an MIS is one of the most fundamental problems in distributed computing. The celebrated randomized $O(\log n)$-round algorithms of Luby [19] and Alon et al. [1] have been recently improved by Ghaffari to $O(\log \Delta + 2^{O(\sqrt{\log \log n})})$ rounds, where Δ is the maximal degree in the network [9]. Deterministic solutions are the classic network-decomposition based algorithm of Panconesi and Srinivasan that runs in $2^{O(\sqrt{\log n})}$ rounds [21], and the $O(\Delta + \log^* n)$-round algorithm of Barenboim et al. [5]. The classic lower bound of Linial [17] shows that $\Omega(\log^* n)$ rounds

are necessary, Kuhn et al. gives a higher bound of $\Omega(\log \Delta / \log\log \Delta, \sqrt{\log n / \log\log n})$ [15]. The latest results of Balliu et al. [3] give the new best known lower bounds to find a MIS: There is no deterministic algorithm in $o(\Delta + \frac{\log n}{\log\log n})$ nor randomized algorithm in $o(\Delta + \frac{\log\log n}{\log\log\log n})$. The Figure 1 in [3] sums up all the results on MIS. A $(3, 2)$-ruling set can be computed by computing an MIS over G^2, and more general ruling sets have been studied in [2, 13, 14, 20, 22].

Centralized Reconfiguration of Maximal Independent Sets. Reconfigurations problems on graphs have been widely studied in the centralized setting during the last decade. An excellent survey on reconfiguration problems can be found in [23]. In the centralized setting, the transition rules are different, requiring that any intermediate set must be at least of a certain size. While having their own motivation in that setting, these rules are not the ones that are needed in the distributed setting, as they do not give covering guarantees (moreover, such properties would be costly to obtain in a distributed setting, due to their global nature).

In more detail, three kinds of transitions have been studied for the independent set reconfiguration problem. *Token Addition and Removal* [11], or $TAR(k)$: at each transition, one vertex is removed from or added to the current independent set, as long as there are at least k nodes in the independent set. *Token Jumping* [12]: at each transition, one vertex is removed from the independent set and another one is added somewhere else. *Token Sliding* [10]: at each transition, an edge containing a vertex of the independent set is chosen. This vertex is removed from the set and its neighbor on the other side of that edge is added to the set. The two first versions are actually equivalent when k corresponds to the size of the independent sets minus 1. Reconfiguration problems are in PSPACE, and independent set reconfiguration problems are in general PSPACE complete [10]. Studies over subclasses of graphs exist, and some polynomial algorithm or hardness proofs are given. For example, planar graphs [10], perfect graphs [12], trees [8] and bipartite graphs [18].

2 Preliminaries

We work in the classic LOCAL model of computation, in which n nodes in a synchronous network exchange messages with their neighbors in each round of computation.

Let $G = (V, E, U)$ denote a graph with an assigned subset $U \subseteq V$. An input to the MIS-reconfiguration problem is a pair $G_{input} = (V, E, \alpha), G_{output} = (V, E, \beta)$, where α and β are the initial and final maximal independent sets, respectively. We refer to a node $v \in \alpha$ as an *α-node*, and to a node $v \in \beta$ as a *β-node*. Notice that a node may be both an α-node and a β-node. We refer to node $v \in V \setminus (\alpha \cup \beta)$ as an *ϵ-node*. Throughout the proofs, we say that a node v is *covered* or *4-dominated* by a node u if $d(v, u) \leq 4$.

For a vertex $v \in V$, we denote by $N(v)$ the set of neighbors of v (i.e., $N(v) = \{u \in V : (u, v) \in E\}$), and given a set $U \subseteq V$ we define $N_U(v) = U \cap N(v)$ for the subset of neighbors of v that are in U, and we call this set the U-neighbors of v. For a subset $U \subseteq Y \subseteq V$ and a node $v \in Y$, we denote by $d_Y(v, U)$ the distance of v from U in the subgraph induced by Y.

▶ **Definition 5** (Reconfiguration Schedules). *For a given property P of $G = (V, E, U)$, an* (α, β, P)-reconfiguration schedule *(or simply a schedule) S of length ℓ is a sequence of subsets of V, $S = (S_0, \ldots, S_\ell)$, such that the following hold:*

1. *$S_0 = \alpha$ and $S_\ell = \beta$,*
2. *for every $0 < i < \ell$, the graph (V, E, S_i) satisfies P, and*
3. *for every $0 < i \leq \ell$, $S_i \oplus S_{i-1}$ is an independent set of (V, E).*

3 An MIS reconfiguration schedule of constant length

Our main theorem is the following.

▶ **Theorem 2** (formal). *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set. For any graph $G = (V, E)$ of diameter greater than 3 and any input $G_{input} = (V, E, \alpha), G_{output} = (V, E, \beta)$ to the MIS-reconfiguration problem, there exists an (α, β, P)-reconfiguration schedule of constant length 28. Moreover, such a schedule can be found in $O(\texttt{MIS} + \texttt{R32})$ rounds, where $\texttt{MIS}$ is the complexity of finding an MIS on a worst-case graph and $\texttt{R32}$ is the complexity of finding a $(3, 2)$-ruling set on a worst-case graph.*

In particular, Theorem 2 immediately implies a highly efficient solution for bounded degree graphs.

▶ **Corollary 6.** *The constant length schedule of Theorem 2 can be found in $O(\log^* n)$ rounds in graphs of bounded degree.*

We now describe the outline of the algorithm, as follows. Denote by W the set of connected components of $\alpha \cup \beta$. Our main approach is to reconfigure the independent sets according to the components in W. To this end, we first categorize each component in W according to its diameter and whether it is isolated or not: We say that a component $V_i \in W$ is *isolated* if for every ϵ-node u in its neighborhood, $N_\alpha(u)$ and $N_\beta(u)$ are contained in V_i.

Notice that within a constant number of rounds, all α and β-nodes can know whether they are in a component of diameter 0, 1, 2, or at least 3. Moreover, if their diameter is smaller than 3, they can know whether the component is isolated or not.

To avoid excessive notation, we will sometimes say that *we update the component V_i in steps $\{j, j+1\}$*. This means that we remove $\alpha \cap V_i$ from the independent set in step j and we add $\beta \cap V_i$ to the set in step $j+1$. Formally, this means that $S_j = S_{j-1} \setminus (\alpha \cap V_i)$ and $S_{j+1} = S_j \cup (\beta \cap V_i)$. Since we will sometimes update multiple components concurrently, we will have $S_j = S_{j-1} \setminus (\alpha \cap Z_j)$ and $S_{j+1} = S_j \cup (\beta \cap Z_j)$, where $Z_j = \bigcup_{i \in I_j} V_i$, with $I_j = \{i : V_i \text{ is being updated in steps } \{j, j+1\}\}$.

The high-level description of our algorithm is as follows. First, for components in W of diameter 0, we do not need to do anything, as such components are comprised only of nodes in $\alpha \cap \beta$. These nodes remain in the independent set S_i for the entire schedule, and we omit these components and all of their ϵ-neighbors from the remaining discussion. Our algorithm then handles non-isolated components and components of diameter ≥ 3, and finally handles the isolated components of diameter ≤ 2.

We begin by claiming that with an overhead of 2 rounds, we may assume that α and β are disjoint. Indeed, if we never remove nodes in $\alpha \cap \beta$ from the independent set, we no longer need to take care about $\alpha \cap \beta$ nor its neighborhood. You can find a more complete explanation of this in the full version of the paper [7].

3.1 Components of diameter ≥ 3

We continue with the following lemma, which is useful for handling components in W whose diameter is not too small. Roughly speaking, the way we handle components of sufficient diameter is by finding a set of α-nodes that are not too close to each other to ensure that β-nodes can be added not too far from them before we remove them from the independent set. This way, we can reconfigure the rest of the component, and then this set of α-nodes and their neighbors. We present the following lemma before the rest of the algorithm because we will need to use it, but notice that it is not the case that we begin the algorithm by reconfiguring components of diameter ≥ 3.

▶ **Lemma 7.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set, and let $G = (V, E, \alpha)$ and $G = (V, E, \beta)$ be an input to the MIS-reconfiguration problem such that $\alpha \cap \beta = \emptyset$, the set $Y = \alpha \cup \beta$ is a single connected component of diameter at least 3, and each ϵ-node is connected to an α-node and to a β-node. Then, there exists an (α, β, P)-reconfiguration schedule of length 8. Moreover, such a schedule can be found in $O(\texttt{R32})$ rounds.*

Proof. First, assume that the diameter of $Y = \alpha \cup \beta$ is either 3 or 4. Consider a shortest path of length 3 in Y, denoted by (v_1, v_2, v_3, v_4). Either v_1 or v_4 is in α, and is within distance 4 from all other nodes in the component. We denote this node by v, and define $S_1 = \{v\}$ and we have that it 4-dominates the entire component. In addition, it 4-dominates all ϵ-nodes, by the assumption of the lemma that all such nodes are neighbors of β-nodes, because v actually 3-dominates all β-nodes in the component. We then denote $R = \{u \in \beta \mid u \notin N(v)\}$ and define $S_2 = \{v\} \cup R$, and $S_3 = R$, and finally $S_4 = R \cup N(v)$. It is easy to verify that this results in a valid (α, β, P)-reconfiguration schedule. In particular, notice that, without loss of generality, if $v = v_1$, then R contains at least the node v_4, which 4-dominates the entire component.

For a diameter of Y that is at least 5, the high-level idea of the construction is as follows. Consider a $(3, 2)$-ruling set R over the nodes in α, where we imagine an edge between two nodes in α if they are at distance two in the subgraph induced by Y. We reconfigure all β-nodes that are at distance 5 from R in G by removing their α-neighbors first, then by adding them. Then, we do the same for β-nodes that are at distance 3 from R, and finally we repeat this one last time for the β-nodes in the direct neighborhood of R. The choice of a $(3, 2)$-ruling set ensures that all α-nodes in R have a β-node at distance 3 that will be reconfigured in the 4th step. However, while we trust β-nodes at distance 3 from R to cover α-nodes at distance 2 from R while R itself is being reconfigured, we must be careful when handling α-nodes at distance 2 from R that do not have a neighbor at distance 3. We overcome this caveat by taking care of these nodes separately.

Formally, we define a virtual multigraph $\tilde{G} = (\tilde{V}, \tilde{E})$ as follows. The set of virtual nodes $\tilde{V}$ consists of all α-nodes. If v and u in $\tilde{V}$ have a common β-neighbor, we add an edge u, v to $\tilde{E}$. Let R be a $(3, 2)$-ruling set in $\tilde{G}$. It is easy to see that in G, the set of nodes R is a $(6, 5)$-ruling set of Y. We denote R by R_0 and we define R_i for $3 \leq i \leq 5$ as $R_i = \{v \in Y \mid \text{the distance of } v \text{ from } R \text{ in the subgraph induced by } Y \text{ is } i\}$. Then we define $R_1 = \{v \in Y \mid d_Y(v, R) = 1 \text{ and } d_Y(v, R_3) = 2\} \cup \{v \in Y \mid N_Y(v) \subseteq R\}$, which captures all β-neighbors of R that either do not have other α-neighbors, or have other α-neighbors which in turn have β-neighbors that are farther from R. We separate those from the set $R_{-1} = N_Y(R_0) \setminus R_1$. We complete the partition by defining $R_2 = N_Y(R_1) \setminus R_0$ and $R_{-2} = N_Y(R_{-1}) \setminus R_0$. Note that for even i, R_i contains only α-nodes, and for odd i, R_i contains only β-nodes. We have that, for every $-2 \leq i \leq 5$, $N_Y(R_i) \subseteq R_{i-1} \cup R_{i+1}$ (with $R_{-3} = R_6 = \emptyset$). By construction of R, we have that each node in R has a node at distance 3 in R_3, hence it has a node at distance 2 in R_2 and a node at distance 1 in R_1.

We define $S_0 = \alpha$ and for $i = 0, 1, 2, 3$, we define $S_{2i+1} = S_{2i} \setminus R_{4-2i}$, $S_{2(i+1)} = S_{2i+1} \cup R_{5-2i}$. We claim that $S_0, \ldots, S_8$ is an (α, β, P)-reconfiguration schedule.

First, $S_0 = \alpha$ by definition, and because every β-node is within an odd distance of at most 5 from R and every α-node is within an even distance of at most 4 from R, we have that $S_8 = \beta$. This gives condition (1) of Definition 5.

For condition (2), it is easy to see that $S_i \oplus S_{i-1}$ is an independent set of (V, E) for every $1 \leq i \leq 8$. For an odd i this holds because to obtain S_i we only remove α-nodes from S_{i-1}, and no two such nodes can be neighbors. For an even i this holds because to obtain S_i we only add β-nodes to S_{i-1}, and no two such nodes can be neighbors.

It remains to show condition (3) of Definition 5. To show that S_i is independent for $i = 2, 4, 6$, notice that β-nodes in R_j (for $j = -1, 1, 3, 5$) are only added to the sequence after all α-nodes in R_k for $k \geq j - 1$ have been removed. By definition, S_0 is also independent. Hence, for $i = 1, 3, 5, 7$, S_i is independent because it is a subset of S_{i-1}.

Next, we need to show that S_i is 4-dominating for every $1 \leq i \leq 7$. Our focus will be for $i = 1, 3, 5, 7$, and for $i = 2, 4, 6$ it then follows because S_i contains S_{i-1}. We first show it on Y, and will prove it for ϵ-nodes afterward. For $i = 1$ this holds because all nodes in R_j for $j \leq 3$ are in or have neighbors in $R_{-2} \cup R_0 \cup R_2$. All nodes in R_j for $j = 4, 5$ are within distance 3 from R_2. Similarly, S_3 is 4-dominating because nodes in R_j for $j \leq 4$ are covered by R_0, nodes in R_5 are in the current independent set. For S_5, recall that for any node in R, there is a node at distance 3 from it in R_3, that node being in the current independent set since S_4. Hence, R_3 covers R_j for $-1 \leq j \leq 5$. R_{-2} is still included in S_5. Finally, for S_7, R_3 still covers R_j for $-1 \leq j \leq 5$. For each node in R_{-2}, there is a node at distance 3 from it in R_1 that has been added in S_6 that covers it.

Now, let u be an ϵ-node that has a node $a \in \alpha$ and $b \in \beta$ in its neighborhood. We show that a or b are always 3-dominated throughout the sequence. In a step where b has no α-neighbor in the independent set, it must be a step right before b gets added to the independent set. If b is in R_5 or in R_3 then when this happens, it is 3-dominated by an α-node in R_2 or R, respectively, and this node is still in the independent set. If $b \in R_{-1}$ then it is 2-dominated by nodes in R_{-2} and then R_1 (with an overlap in S_6, the construction ensures that such node exist at distance at most 3 from b). Finally, If $b \in R_1$ then either there is a β-node in R_3 that 2-dominates it, and this node is already in the independent set, or b is in $\{v \in Y \mid N_Y(v) \subseteq R\}$. Only in the latter case, we must resort to the α-neighbor of u and check that it is 3-dominated by S_5, as we removed R from S_5 and b is added in S_6.

Let i be such that $a \in R_i$. We need to make sure that a is 3-dominated at the step in which we reconfigure R_1. At this step, all of the β-nodes in R_3, R_5 are in the independent set, and hence their α-neighbors in R_2, R_4 are covered by nodes in distance 1, and nodes in R_0 are covered by nodes in distance 3. For α-nodes in R_{-2} they are still in the independent set at this step, and hence are 3-dominated.

This completes the correctness proof. For the round complexity, notice that simulating the $(3, 2)$-ruling set over $\tilde{G}$ can be done in G with a constant overhead. ◀

3.2 Non-isolated components

We first observe that components of diameter ≤ 2 are such that there is a complete bipartite graph between their α-nodes and β-nodes. Let u be an ϵ-node that is a neighbor of several components. Let W_u be the set of all components that are its neighbors, so that in particular, $V_i, V_j \in W_u$. For each pair of distinct components $V_i, V_j \in W_u$, if there is an α node in $N_\alpha(u) \cap V_i$ and a β node in $N_\beta(u) \cap V_j$, then we say that V_j is (u, α)-covered and that V_i is (u, β)-covered (note that this definition allows a single component to satisfy both conditions). As u is an ϵ-node, there must exist a component $V_{u,\alpha} \in W_u$ that is (u, β)-covered and a component $V_{u,\beta} \in W_u$ that is (u, α)-covered.

We say that a component $V_i \in W$ is α-covered (β-covered) if there is an ϵ-node u for which V_i is (u, α)-covered ((u, β)-covered). A component that is both is $\alpha\beta$-covered.

The key insight is that a (u, α)-covered component of diameter ≤ 2 is covered (dominated at distance 4) by some α-node of the component $V_{u,\beta}$ (and similarly with the β-node of $V_{u,\alpha}$). Moreover, any ϵ-node that is connected to an α-node (a β-node) in that component is covered by $V_{u,\beta}$ (or $V_{u,\alpha}$). This implies that an ϵ-node that is connected to two components that are updated in different steps is always covered by the component that is currently not

being updated. However, during the reconfiguration schedule, we need to be careful about ϵ-nodes that are connected to a single component, and ϵ-nodes that are connected to two components that are updated at the same time.

We denote by $C_{\alpha\beta}$ the set of $\alpha\beta$-covered components of diameter ≤ 2, and by C_α and C_β the sets of α-covered and β-covered components of diameter ≤ 2 that are not in $C_{\alpha\beta}$, respectively. Define the component graph $\tilde{G} = (W, \tilde{E})$, where there is an edge between $V_i, V_j \in W$ iff there exists an ϵ-node u such that V_i is (u, α)-covered and V_j is (u, β)-covered, or vice-versa. Notice that in $\tilde{G}$, the sets C_α and C_β are two disjoint independent sets.

We are finally ready to formally provide the algorithm for handling all components that are either non-isolated or have diameter ≥ 3.

▶ **Lemma 8.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set, and let $G = (V, E, \alpha)$ and $G = (V, E, \beta)$ be an input to the MIS-reconfiguration problem such that $\alpha \cap \beta = \emptyset$, and all connected components of $\alpha \cup \beta$ are either non-isolated or have diameter at least 3. Then, there exists an (α, β, P)-reconfiguration schedule of length 18. Moreover, such a schedule can be found in $O(\texttt{MIS} + \texttt{R32})$ rounds.*

Proof. Our reconfiguration schedule works according to the following *parts*.

1. Update components of diameter ≤ 2 in C_α.
   %Let M be an MIS over all nodes in $C_{\alpha\beta}$.
2. Update components of diameter ≤ 2 that are α-covered by a component in M.
3. Reconfigure components of diameter ≥ 3 using the schedule given by Lemma 7.
4. Update components in M.
5. Update components of diameter ≤ 2 in $C_{\alpha\beta}$ that were not previously updated.
6. Update components of diameter ≤ 2 in C_β that were not previously updated.

First, it is easy to see that the schedule has length 18. The part that reconfigures components of diameter ≥ 3 requires 8 steps, by Lemma 7. Each of the other 5 parts takes exactly 2 steps as described in the definition of updating components (removing α-nodes and then adding β-nodes), which sums to 18 reconfiguration steps in the schedule.

It remains to prove correctness. First, condition (1) of Definition 5 trivially holds, as the schedule reconfigures all nodes. Moreover, by Lemma 7 and by the definition of updating a component, it is also immediate that we do not reconfigure two neighbors in a single step, thus the schedule satisfies condition (3) of Definition 5. For condition (2), Lemma 7 and the definition of updating a component also guarantee that each S_i is an independent set. The remainder of the proof shows that each S_i in the schedule is also 4-dominating.

By the order of the reconfiguration steps in the schedule, each component that is being updated is covered by a component that is not concurrently being updated. This also holds for ϵ-nodes that are connected to a component that is not currently being updated. The main condition that must be verified is that ϵ-nodes remain covered even if all of their neighboring components are being concurrently updated in a certain part of the schedule.

Part 1 guarantees that S_1, S_2 are 4-dominating because for each component that is being updated, the α-node covering it is a member of S_1, S_2 and it also covers the required ϵ-nodes that are neighbors of the updated component, as explained earlier. For part 2, let u be an ϵ-node that is connected to two of the components that are being updated and is not connected to any component that is not being updated. One of the components must be connected to u via an α-node. Let V_i be such a component, let u_1 be the α-node connected to u, and let v be the α-node from a component of M that covers V_i. The distance between v and u_1 is 3: v is a distance 2 to a β-node of V_i and, because V_i is of diameter ≤ 2, within V_i all β-nodes are connected to all α-nodes. Hence, u is at distance 4 from v.

For part 3, the 4-domination within the components that are being reconfigured is given by Lemma 7. Notice that any ϵ-node connected to a component of diameter ≥ 3 is connected either to connected components of diameter ≥ 3 through both an α and a β-node, or to a component that is not being updated in those steps. In the first case it is covered by Lemma 7, and in the second it is covered by the component not being concurrently updated.

For part 4, notice that all components that are β-covering components of M have been updated in steps 2 or 3. Hence, as each component of M is in $C_{\alpha\beta}$, there is a β-node in the current set S_{12} that covers it. As M is independent, we do not have ϵ-node between two components that are being updated. For part 5, the ϵ-nodes between two components that are being updated are covered by an argument that is symmetric to the one used for part 2. Finally, for part 6, for each component that is being updated it holds that the β-node covering it is in a component that has already been updated and hence it is already in S_{16}.

Finally, we note that apart from a constant overhead in communication, the number of rounds required for computing the above schedule is proportional to that of finding the MIS M plus solving the diameter ≥ 3 components, which completes in $O(\texttt{MIS} + \texttt{R32})$ rounds, where `MIS` is the complexity of finding an MIS on a worst-case graph and and `R32` is the complexity of finding a $(3, 2)$-ruling set on a worst-case graph, as claimed. ◀

3.3 Isolated Components

What remains now is to handle components that are isolated and have diameter at most 2. When we address these components, we will also address all of their ϵ-neighbors. Hence, from this point onwards we will slightly abuse our terminology, and when we refer to such a component we refer to its nodes along with their ϵ-neighbors as the component. This means that now the components that we address might have a diameter that is increased by 1, and thus their diameter can be also 3. Note that the diameter cannot be increased by two as all α-nodes are connected to all β-nodes, and each ϵ-node is connected to an α-node and to a β-node of this component, otherwise the component would not be isolated.

By definition of isolated components, the neighborhood of an ϵ-nodes within such a component, besides containing vertices of the component itself, is only composed of other ϵ-nodes. Moreover, there is at least one additional ϵ-node in this neighborhood, as we consider graphs of diameter at least 4. We distinguish two kinds of isolated components, according to whether their diameter is at most 2, or whether it is 3.

For a component V_i of diameter ≤ 2, suppose u is an ϵ-node that is a neighbor of V_i. This node u has an α-node and a β-node in its neighborhood, that both cover the entire component. Therefore, to update such components, it suffices to make sure that a non-ϵ neighbor of u is in the current independent set during the two reconfiguration steps. By considering connected two of those components that cover each other, we can take an MIS M over those. The schedule of length 4 is: update M, and then update the other components.

Assume now that V_i is a component of diameter 3. It holds that there exists an ϵ-node u, an α-node a and a β-node b such that $(u, a) \notin E$ and $(u, b) \notin E$ (otherwise the diameter would be 2). Here is an informal description of a schedule of 6-steps for this component.

1. Remove $N_\alpha(u)$. The node a stays in the independent set and covers the entire component.
2. Add u in the set.
3. Remove the remaining α-nodes of the component. The node u covers everything.
4. Add b to the set. Note that b covers the component.
5. Remove u.
6. Add the remaining β-nodes of the component.

A caveat is encountered in case there are two such components, V_1 and V_2, whose selected ϵ-nodes, u_1 and u_2, are connected. In such case we cannot do the above 6-step schedule in parallel without violating independence. However, observe that if a single of those two ϵ-nodes is added to the set, it actually covers the second component as well, as it has a diameter of 3. As a consequence, taking an MIS over those ϵ-nodes gives us a selection of nodes that cover all the considered components. Hence, consider the schedule above as being for component V_1 and denote $u = u_1$, then we can add the following to steps 3 and 4 above:

3. Remove the remaining α-nodes of V_1 and all α-nodes of V_2. The node u covers everything.

4. Add b and the β-nodes of V_2 to the set. Note that V_2 is updated and b covers V_1.

We now formalize the above intuition in order to prove the following.[1]

▶ **Lemma 9.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set, and let $G = (V, E, \alpha)$ and $G = (V, E, \beta)$ be an input to the MIS-reconfiguration problem such that $\alpha \cap \beta = \emptyset$, and all connected components of $\alpha \cup \beta$ are isolated and have diameter at most 2. Then, there exists an (α, β, P)-reconfiguration schedule of length 10. Moreover, such a schedule can be found in $O(\texttt{MIS})$ rounds.*

3.4 Completing the proof

We can now wrap-up all the ingredients and prove Theorem 2.

Proof of Theorem 2. We describe the full (α, β, P)-reconfiguration schedule S. First, each node v in $V_{\alpha,\beta} = \alpha \cap \beta$ sends a message to its neighbors in $N(v)$ and outputs that it is in S_i for all $0 \leq i \leq 28$. Each node that received such a message, sends a message to its neighbors and outputs that it is not in S_i for all $0 \leq i \leq 28$. The nodes that produced an output terminate and any edges incident to them are removed from the graph.

Next, all nodes collect their 4-hop neighborhood to decide whether they are in a component of diameter ≥ 3 or not, and if not then whether they are in an isolated component.

The components of diameter ≥ 3 and the non-isolated components compute the reconfiguration schedule of 18 steps, as given in Lemma 8, which we denote by $S'_0, \ldots, S'_{18}$. The isolated components of diameter ≤ 3 compute the reconfiguration schedule of 10 steps, as given in Lemma 9, which we denote by $S''_0, \ldots, S''_{10}$.

Formally, the (α, β, P)-reconfiguration schedule is now $S_i = S''_0 \cup S'_i \cup V_{\alpha,\beta}$ for $0 \leq i \leq 18$ and $S_i = S''_{i-18} \cup S'_{18} \cup V_{\alpha,\beta}$ for $18 \leq i \leq 28$. It is computed within $O(\texttt{MIS} + \texttt{R32})$ rounds. ◀

4 MIS reconfiguration in a constant number of rounds

▶ **Theorem 4** (formal). *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set. For any graph $G = (V, E)$ and any input $G_{input} = (V, E, \alpha), G_{output} = (V, E, \beta)$ to the MIS-reconfiguration problem, there exists an (α, β, P)-reconfiguration schedule of length $\Theta(f(n))$, where $f(n)$ is the largest identifier among the nodes in the graph, which can be found in $O(1)$ rounds.*

To prove this, we first prove the following lemma, stating that we can always reconfigure locally an independent set to add elements from β without losing any element in $\alpha \cap \beta$.

[1] You can find all the missing proofs in the full version of the paper [7].

▶ **Lemma 10.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set. For any graph $G = (V, E)$ of diameter greater than 5, two MIS α and β and $v \in \beta \setminus \alpha$, there exists an MIS γ such that*

1. *$(\alpha \cap \beta) \subset \gamma$ and $v \in \gamma$, and*
2. *there exists an (α, γ, P)-reconfiguration schedule of length 6. Moreover, for finding the reconfiguration schedule the nodes only need to know the topology of their 5-hop neighborhood and therefore can be found in $O(1)$ rounds.*

Lemma 10, means that for any element v in β, we can add v to the current MIS in a constant number of steps without losing any element of β already in the MIS. It allows us to prove Theorem 4 as follows.

Proof of Theorem 4. Nodes use their identifiers to know when to start their own reconfiguration. A node with identifier k uses slots $[6k + 1, 6(k + 1)]$ for its schedule. Since a node only needs to know its 5-hop neighborhood, this completes in $O(1)$ rounds. ◀

If the identifiers are guaranteed to be $\{1, \ldots, n\}$ then Theorem 4 gives that a constant number of rounds is sufficient for a linear length schedule. However, we can do even better by using coloring algorithms, as stated in the following corollary.

▶ **Corollary 11.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set. For any graph $G = (V, E)$ and any input $G_{input} = (V, E, \alpha), G_{output} = (V, E, \beta)$ to the MIS-reconfiguration problem, if the nodes are given a k-coloring of G^{10}, then there exists an (α, β, P)-reconfiguration schedule of length $O(k)$, which can be found in $O(1)$ rounds.*

5 A complete characterization for the existence of a reconfiguration schedule with 4-domination

The following gives an exact characterization of inputs for which there exists a reconfiguration schedule with 4-domination. In what follows, we say that two sets of nodes U_1 and U_2 are *fully connected* if every node in U_1 is a neighbor of every node in U_2. If U_1 contains only a single node, then we simply say that this node is fully connected to U_2.

▶ **Theorem 12.** *Let P be the property of (V, E, U) that says that U is a (2,4)-ruling set. For any input $G_{input} = (V, E, \alpha), G_{output} = (V, E, \beta)$ to the MIS-reconfiguration problem, there does not exists an (α, β, P)-reconfiguration schedule if and only if:*

1. *The sets α and β are fully connected.*
2. *Let ϵ_α (resp. ϵ_β) be the set of ϵ-nodes that are fully connected to α (resp. β). Then all the ϵ-nodes are in $\epsilon_\alpha \cup \epsilon_\beta$.*
3. *Let $G' = (V' = \epsilon_\alpha \cup \epsilon_\beta, E' = \overline{E_{V'}})$, where $\overline{E_{V'}}$ is the complementary of E restricted to vertices of V'. Then there is no path from $\epsilon_\alpha \setminus \epsilon_\beta$ to $\epsilon_\beta \setminus \epsilon_\alpha$ in G'.*

6 Impossibility results for MIS reconfiguration

We show here two types of impossibility results. One is the necessity of 4-domination in the sense that 3-domination cannot be obtained, and the other is the necessity of $\Omega(\log^* n)$ rounds with 4-domination, even on bounded degree graphs where it matches the complexity we provide in Corollary 6.

Impossibility of MIS reconfiguration with 3-domination.

▶ **Theorem 1.** *Requiring 3-domination for intermediate steps is costly:*

1. *There exists a class of inputs $G = (V, E)$ with two MIS α and β such that there is no reconfiguration schedule with 3-dominating intermediate steps.*
2. *There exists a class of inputs $G = (V, E)$ with two MIS α and β such that any reconfiguration schedule is of length $\Omega(n)$ and needs $\Theta(n)$ rounds to be found, if intermediate steps must be 3-dominating.*

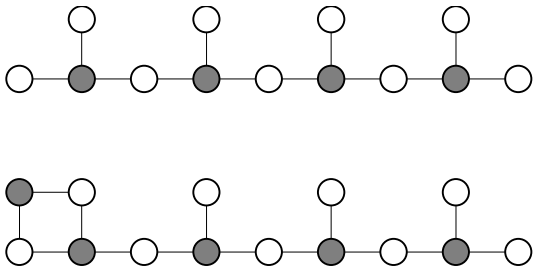

Figure 1 White nodes are α-nodes, and grey nodes are β-nodes. For the graph on the top, there is no schedule with 3-dominating sets. For the graph on the bottom, any schedule with 3-dominating sets must be of linear length and requires a linear number of rounds to be found.

An $\Omega(\log^* n)$ lower bound for MIS reconfiguration with 4-domination.

▶ **Theorem 3.** *For any fixed k, there exists a class of k-regular inputs $G = (V, E)$ with two MIS α and β such that any reconfiguration schedule of constant length with 4-domination needs $\Theta(\log^* n)$ rounds to be found.*

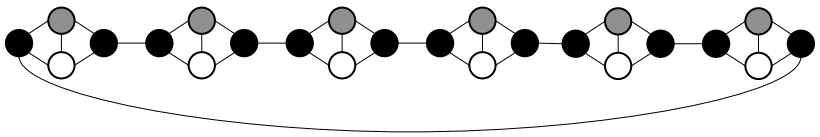

Figure 2 White nodes are α-nodes, grey nodes are β-nodes, and black nodes are ϵ-nodes. Here, $\Omega(\log^* n)$ rounds are needed with 4-domination.

7 Discussion and Open Questions

This paper defines relevant constraints for finding a reconfiguration schedule of maximal independent sets in a distributed setting. For constant-length schedules in bounded-degree graphs we completely settle the required complexity, as we provide an algorithm completing in $\Theta(\log^* n)$ communication rounds, and prove that no lower complexity exists. A main open question that remains is: Can a better complexity be found for general graphs?

Our definition only uses addition and removal of elements to the intermediate independent sets. We propose the following question: Can an efficient distributed reconfiguration schedule be found if the system allows that intermediate steps are 3-dominating and the transitions used can be any combination of addition, removal and Token Sliding?

Finally, we used as a hypothesis that the given independent sets are maximal. Our algorithm still works when the sets are not maximal, as it suffices to complete those. For example, if we are given (2,4)-ruling sets (which is equivalent to the 4-domination condition of P), the problem is solved. An interesting question could be to generalize for other (a, b)-ruling sets. What relation between a and b is needed to ensure that a schedule exists, and that it can be found efficiently with a distributed algorithm?

Abstract

Exploring large-scale networks is a time consuming and expensive task which is usually operated in a complex and uncertain environment. A crucial aspect of network exploration is the development of suitable strategies that decide which nodes and edges to probe at each stage of the process.

To model this process, we introduce the *stochastic graph exploration problem*. The input is an undirected graph $G = (V, E)$ with a source vertex s, stochastic edge costs drawn from a distribution $\pi_e, e \in E$, and rewards on vertices of maximum value R. The goal is to find a set F of edges of total cost at most B such that the subgraph of G induced by F is connected, contains s, and maximizes the total reward. This problem generalizes the stochastic knapsack problem and other stochastic probing problems recently studied.

Our focus is on the development of efficient nonadaptive strategies that are competitive against the optimal adaptive strategy. A major challenge is the fact that the problem has an $\Omega(n)$ adaptivity gap even on a tree of n vertices. This is in sharp contrast with $O(1)$ adaptivity gap of the stochastic knapsack problem, which is a special case of our problem. We circumvent this negative result by showing that $O(\log nR)$ resource augmentation suffices to obtain $O(1)$ approximation on trees and $O(\log nR)$ approximation on general graphs. To achieve this result, we reduce stochastic graph exploration to a memoryless process – the *minesweeper* problem – which assigns to every edge a probability that the process terminates when the edge is probed. For this problem, interesting in its own, we present an optimal polynomial time algorithm on trees and an $O(\log nR)$ approximation for general graphs.

We study also the problem in which the maximum cost of an edge is a logarithmic fraction of the budget. We show that under this condition, there exist polynomial-time oblivious strategies that use $1 + \epsilon$ budget, whose adaptivity gaps on trees and general graphs are $1 + \epsilon$ and $8 + \epsilon$, respectively. Finally, we provide additional results on the structure and the complexity of nonadaptive and adaptive strategies.

1 Introduction

Exploring networked data is a time consuming and expensive task which is also subject to several limitations. For example, social networks can be explored only through the use of specific APIs made available by the provider which restrict the number of nodes that can be probed and limit the number of neighbors of each node that can be discovered with one probe. The cost and the difficulty of exploring large-scale networks can be an obstacle to collecting suitable snapshots for the purpose of testing new network analysis tools. The testing is more often executed on static networks made available in public repositories [18, 17] collected in the past for other purposes. It is therefore of crucial importance the development of effective and efficient methods to explore large-scale networks.

The core of a network exploration method is the definition of a probing strategy that decides which nodes or edges to probe at each stage of the process. Both the edge-probe and the node-probe models are useful in this setting. In the case of the exploration of social networks, a node-probing strategy allows to gain knowledge on a subset of the neighbors of the probed node. In the case of the exploration of the Twitter graph, an edge-probing strategy allows to gain information on those tweets of a user that are retweeted from his followers.

One main difficulty in the definition of an effective probing strategy is the intrinsic uncertain nature in terms of cost and probability of success of the process of discovering links in a network, especially if these links represent complex relationships between nodes. In order to confirm the existence of a link between two nodes, it may be required to execute several experiments whose outcome cannot be predicted in advance. Examples are the in-vitro reactions between proteins needed to discover protein-to-protein interaction networks [22, 6] or the influence between humans in social networks.

The second main difficulty stems from the adaptive nature of the optimal probing strategy that needs to be updated from time to time while new parts of the network are discovered. Adaptive strategies are computationally expensive, given that they must be continuously updated. In the case of large network exploration, the communication cost of adaptive strategies is also high since many machines are usually working in parallel at the exploration process, and the updated strategy must be communicated to the machines participating in the process. We are therefore interested in devising *nonadaptive probing strategies* that are simple and that define the sequence of probes in advance before the process is started. The obvious drawback is that nonadaptive probing strategies may be suboptimal.

Several recent works [20, 21, 16] have focused on the task of exploring real-world networks when a limited budget is available. However, these papers do not provide a comprehensive theoretical study of these problems. In this work we initiated the study of exploring an undirected network from a root node. The graph has costs on the edges and rewards on the vertices. A budget limits the total cost of the of the graph edges that are probed.

More formally, the input of the *stochastic graph exploration problem* is an undirected graph $G = (V, E)$ with a source vertex $s \in V$, *stochastic* edge costs $C : E \to \mathbb{R}_{\geq 0}$ distributed according to π_e, $e \in E$, and deterministic rewards of vertices $w : V \to \mathbb{R}_{\geq 0}$. (The model can be easily extended to rewards distributed according to independent random variables.) During the graph-exploration process we construct a set of edges $F \subseteq E$ that we probe and

we traverse. All vertices of the subgraph of G spanned by F must be connected to s via the edges of F. We probe edges one by one and we add them to F. The actual cost of an edge e, drawn from the distribution π_e, is revealed only when the edge is traversed. The goal is to maximize the total reward from the vertices spanned by the edge set F while the total cost of the edges in F remains bounded by a prespecified budget B. As soon as we probe an edge such that the total cost exceeds B the process terminates.

In the stochastic graph exploration problem, we aim to design simple polynomial-time computable *nonadaptive strategies* with a reward as close as possible to the reward obtained by the optimal *adaptive strategy*, which decides on the next edge to be traversed after the cost of all previously traversed edges is revealed (see Section 2 for precise definitions). This is customary in a class of stochastic optimization problems [4], for which it is common to bound the *adaptivity gap* of the nonadaptive strategy.

The stochastic graph exploration problem generalizes some important stochastic optimization problems. If the graph G is a star graph, our problem models *exactly* the stochastic knapsack problem [8, 4]. Stochastic knapsack admits an $O(1)$ adaptivity gap, that is, there exists an optimal nonadaptive strategy, which approximates the optimal adaptive strategy up to a constant factor. The nonadaptive strategy is devised by exploiting a suitable LP relaxation for the problem because the standard formulation has an unbounded integrality gap defined as the worst-case ratio between the optimal integral cost and optimal fractional cost of the LP. In the LP version of the problem that is used, the costs of the edges are reduced to their truncated (by the maximum budget) expected costs and the rewards are also reduced by the probability that the cost of the item is below the maximum budget.

If the network we need to explore is a tree, the stochastic graph problem is a stochastic knapsack problem with precedence constraints: only a subset of items are available in the beginning and adding each item to the knapsack will make some new items – the direct descendants of the explored node – available. Unfortunately, as opposed to the knapsack problem, the adaptivity gap of the stochastic graph exploration problem that we consider is unbounded even on a tree network and therefore the LP-based approach of stochastic knapsack cannot directly be extended.

The stochastic graph exploration problem also models stochastic graph probing problems. Probing problems in graphs have been introduced [7, 14] because of their applications to kidney exchange and online dating. Consider a probing probability for each edge $p : E \to [0, 1]$, that is, edge e will materialize with probability $p(e)$ each time is probed, independently of the other edges and of the previous probes. The goal is to maximize the number of vertices that are connected to a source vertex s by the set F of edges that have been successfully probed when the total number of probes is limited by B. Nonadaptive strategies probe a list of edges in a sequence till success or the total budget B is reached. The stochastic graph exploration problem we study models the stochastic graph probing problem by setting the costs of the edges distributed according to $\mathbf{Pr}(C_e = i) = (1 - p(e))^{i-1}p(e)$, with i being the number of probes needed to discover edge e.

1.1 Summary of Our Results

Our main contribution is the definition of the stochastic graph exploration problem and the study of the adaptivity gap of nonadaptive probing strategies. Here is a summary of our results:

Our first result is an $\Omega(n)$ adaptivity gap for the stochastic graph exploration problem even on a spider graph, which is a tree containing a single node of degree more than two. (Observe that the problem for a simple path is easy because the optimal strategy will traverse sequentially the edges of the path starting from the root.)

One first direction we pursue to circumvent the impossibility result is to allow a limited amount of resource augmentation: instead of using budget B, we allow the algorithm to use a budget of $\beta \cdot B$, for some value of β. We call an algorithm (α, β)-approximate if it computes a strategy which uses budget $\beta \cdot B$, and obtains an expected reward of at least $1/\alpha$ times the optimal reward (obtained by an adaptive algorithm). We present polynomial time computable nonadaptive strategies in a graph of n vertices that are $(O(1), O(\log nR))$-approximate for trees and $(O(\log nR), O(\log nR))$-approximate for general graphs, with R being the maximum reward of a vertex.

The idea is to transform the stochastic exploration problem into a memoryless stochastic process, which we call the *minesweeper problem*, and which may be of independent interest. In the minesweeper problem, the budget and the edge costs are replaced by probabilities $p(e)$, which are specified for every edge e. When an edge e is probed, the process stops with probability $1 - p(e)$. Hence, the final reward of a vertex is discounted by the probability that the strategy does not stop before the vertex is acquired. The minesweeper problem is, in fact, a special case of stochastic graph exploration, where the support of each π_e (distribution of cost of edge e) is $\{0, B + 1\}$ and the budget is B.

We prove that an α-approximate strategy for the minesweeper problem implies an $(O(\alpha), O(\log nR))$-approximate nonadaptive strategy for the stochastic graph exploration problem. The idea of the reduction is as follows. We construct a minesweeper problem instance, where $p(e) = \mathbf{Pr}(\pi_e < X_B)$, where X_B is random variable that follows an exponential distribution with parameter B. We first show that, for any subset of edges F, the probability that their total cost in the stochastic graph exploration is at most B is at most a constant factor of the probability that minesweeper would stop on this set. On the other hand, the expected additional reward that can be achieved from minesweeper after the total cost becomes larger than $O(B \log nR)$ is negligible.

We then show how to compute in polynomial time an optimal strategy for the minesweeper problem on trees and an $O(\log nR)$-approximate strategy on general graphs. These results imply imply an $(O(1), O(\log nR))$-approximate strategy for trees and an $(O(\log nR), O(\log nR))$-approximate strategy for general graphs. To show the optimal result on trees we prove two facts. First, the order of traversal of the edges in each subtree can be determined independently. Second, we show a simple optimality condition which helps us determine how many edges from each subtree should be probed before switching to a different subtree. We remark that our approach is in a spirit similar to the greedy optimal strategy defined by the Gittins index [10, 9] for multi-armed bandit problems. However, differently from the standard setting of the Gittins index, in the minesweeper problem, a whole new set of arms is made available for each node of the tree reached by the exploration process. Moreover, in the minesweeper problem, the discount factor is not constant because it depends on the probability assigned to the traversed edge. This approach is not viable for general graphs, and we provide an approximate solution instead, by showing a reduction of minesweeper to max-prize problem [5].

We also pursue a second direction to circumvent the lower bound on the adaptivity gap for trees: we restrict the distributions by considering the case when the edge costs are bounded by $\frac{\epsilon^2 B}{c \log n}$ for a suitable constant c. We show, under this condition, the existence of a polynomial time computable $(1 + \epsilon, 1 + \epsilon)$-approximate nonadaptive strategy for trees and $(1 + \epsilon, 8 + \epsilon)$-approximate nonadaptive strategy for any graph G. We note that this approach can be extended to prove a result with resource augmentation similar to the one we obtained through reduction to the minesweeper problem. Yet, we believe that both the minesweeper problem and the reduction technique can be of independent interest.

Our final result is related to the problem of finding a nonadaptive probing strategy that is $(o(n), O(1))$-approximate. We leave open this challenging problem even for trees. However, we establish an interesting result for the characterization of nonadaptive strategies. We prove that any nonadaptive strategy that probes edges in order until it succeeds or until the budget is exceeded can be $(O(1), O(1))$-approximated by a set strategy, which probes all edges at once and obtains a reward only if all edges of a set are successfully probed within budget. We specifically prove that the adaptivity gap of a nonadaptive strategy can be approximated up to a factor of 6 by a set strategy that uses budget $9B$. We use this result to give an algorithm for finding a strategy for trees, which is $(O(1), O(1))$-approximate, compared to the best *nonadaptive* strategy. Surprisingly, the resulting strategy is adaptive.

1.2 Related Work

The adaptivity gap of stochastic problems has been studied for the knapsack problem [8, 4] which is a special case of the problem we study. The adaptivity gap has also been studied for budgeted multi-armed bandits [19, 12, 11] by resorting to suitable linear programming relaxation. Differently from previous work on budgeted multi-armed bandit problems, we consider the setting in which new arms appear after some arms are pulled. Stochastic probing problems have also been studied for matching [1, 7, 2] motivated from kidney exchange and for more general classes of matroid optimization problems [14, 15].

The stochastic graph exploration problem we introduce is also related to the *stochastic orienteering* problem [3, 13]. In stochastic orienteering, the set of traversed edges must form a path in a metric graph with deterministic costs on the edges, while the time spent on a node is a random variable, which follows an a-priori known distribution. In stochastic graph exploration, the random variables are the costs of the edges of the graph but we cannot ensure that the costs on the edges form a metric since the random variables are independent.

1.3 Organization of the Paper

In Section 2 we formally define our problems. In Section 3 we show the lower bounds on the adaptivity gap for stochastic graph exploration. In Section 4 we show our reduction to the minesweeper problem and our results for stochastic graph exploration with resource augmentation. In Section 5 we present a near-optimal set strategy for trees. In Section 6 we present our results for the case of edges of small costs and, finally, in Section 7 we study the power of resource augmentation for relating the cost of nonadaptive strategies to the cost of optimal set strategies.

2 Problem Definition

We start by an auxiliary definition. Let $G = (V, E)$, with $|V| = n$, be an undirected graph and $s \in V$. We say that a set $F \subseteq E$ is *connected to* s if F induces a connected subgraph of G and s is the endpoint of at least one $e \in F$.

Let us now define the StochasticExploration problem (in the following sometimes abbreviated by SGE). This problem instance is given by a tuple (G, s, C, w), where G is an undirected graph $G = (V, E)$, $s \in V$ is a source vertex, C is a function that assigns *stochastic* edge costs to each edge, and $w : V \to \mathbb{R}_{\geq 0}$ is a function that assigns (deterministic) reward to each vertex.[1] And we denote R as the maximum reward of a vertex i.e. $R = \max_{v \in V} w(v)$.

[1] The results hold also if the rewards are random variables that are independent of each other and the

Formally, for each $e \in E$, $C(e)$ is a random variable distributed according to π_e that takes values in $\mathbb{R}_{\geq 0}$, all random variables $C(e)$ being jointly independent. For an edge (u, v) we will often denote $C(u, v) = C((u, v))$.

Consider the following single-player game. The player has an initial budget of B ($B = 1$ if not specified) and maintains an initially empty subset F of E, which we call the set of *acquired edges*. In each step the player can choose an edge $e \in E \setminus F$ and *probe* it (if $F = E$, the game finishes). Probing an edge e is only allowed when $F \cup \{e\}$ is connected to s. When e is probed, the actual cost $C(e)$ of e, drawn from the distribution π_e, is revealed. If the cost e is not greater than the remaining budget, e is *acquired* (added to F) and $C(e)$ is subtracted from the budget. If $C(e)$ exceeds the remaining budget, the game finishes. The goal of the player is to maximize the final *payoff* of F, which is the total reward of all vertices in the subgraph of G induced by F.

Let us now define the MineSweeper problem, which we often abbreviate to MS. This problem is defined by a tuple (G, s, p, w), where G is an undirected graph, $s \in V$ is a start vertex, $p : E \to [0, 1]$ is a function that assigns to each edge e the probability that e materializes and $w : V \to \mathbb{R}_{\geq 0}$ is a function that assigns (deterministic) reward to each vertex. The only difference between MS and SGE is in how edges are probed. There are no edge costs or budget. Instead, whenever an edge e is probed, it materializes (independently of the other edges) with probability $p(e)$ and is acquired immediately. If the edge does not materialize, the process ends immediately. Note that as in SGE, probing an edge e is only allowed when $F \cup \{e\}$ is connected to s. Note that the MineSweeper problem is a special case of the StochasticExploration problem, by letting, for each edge e, π_e be the distribution in which with probability $p(e)$ we obtain the value 0 and with probability $1 - p(e)$ the value $B + 1$.

We consider the following types of strategies for both problems:

- An *adaptive* strategy is a mapping from the set of already acquired edges (and the remaining budget, in the case of SGE) to the next edge to be probed.
- A *nonadaptive* strategy, also called a *list* strategy, is described by a sequence $e_1, \ldots, e_k$ consisting of distinct elements of E, such that for each $1 \leq i \leq k$, the set $\{e_1, \ldots, e_i\}$ is connected to s. In this strategy, the edges are simply probed according to their order in the sequence.
- A *set* strategy is a nonadaptive strategy with the additional restriction that it does not obtain any payoff if it does not acquire all edges from the list.[2]

For a strategy S for SGE, we denote by $r(\mathcal{I}_{\mathrm{SGE}}, S, B)$ the expected payoff of strategy S for the SGE problem instance $\mathcal{I}_{\mathrm{SGE}} = (G, s, C, w)$ with initial budget of B, which is the expected reward of the set of nodes in the returned solution. When $B = 1$ we sometimes omit the third argument of $r(\cdot)$. Similarly, we denote by $r_{\mathrm{MS}}(\mathcal{I}_{\mathrm{MS}}, S)$ the expected payoff of strategy S for the MS problem instance $\mathcal{I}_{\mathrm{MS}}$. We call a strategy S *optimal* for $\mathcal{I}$ with budget B, if for all strategies S', $r(\mathcal{I}, S, B) \geq r(\mathcal{I}, S', B)$. Let $\mathrm{OPT}_{\mathrm{ad}}$ be the optimal adaptive strategy for the SGE problem and $\mathrm{OPT}_{\mathrm{na}}$ be the optimal nonadaptive strategy. We call a strategy S α-approximate, if for each instance $\mathcal{I}$, $r(\mathcal{I}, S) \geq 1/\alpha \cdot r(\mathcal{I}, \mathrm{OPT}_{\mathrm{ad}})$. Finally, an algorithm ALG is (α, β)-approximate if for any instance $\mathcal{I}$ it computes a α-approximate strategy by using a β factor resource augmentation, i.e. $r(\mathcal{I}, \mathrm{ALG}(\mathcal{I}), \beta \cdot B) \geq 1/\alpha \cdot r(\mathcal{I}, \mathrm{OPT}_{\mathrm{ad}}, B)$.

edge costs. It suffices to replace each reward with its expected value.

[2] Note that we abuse earlier definitions slightly for the sake of simplicity.

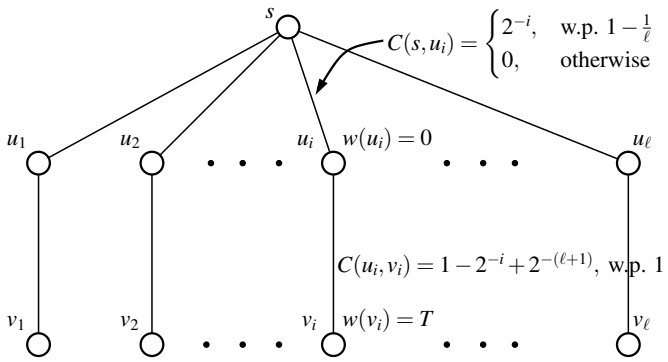

Figure 1 An instance in which the optimal adaptive strategy obtains a payoff which is $\Omega(n)$ larger than the payoff of the optimal nonadaptive strategy.

3 Lower Bounds

In this section we prove a lower bound on the *adaptivity gap* of StochasticExploration. Namely, we show an instance $\mathcal{I}_{LB} = (G, s, C, w)$ such that $r(\mathcal{I}_{LB}, \mathrm{OPT}_{\mathrm{ad}})/r(\mathcal{I}_{LB}, \mathrm{OPT}_{\mathrm{na}}) = \Omega(n)$, where $\mathrm{OPT}_{\mathrm{ad}}$ and $\mathrm{OPT}_{\mathrm{na}}$ denote the optimal adaptive and nonadaptive strategies.

The instance $\mathcal{I}_{LB}$ is shown in Figure 1. The graph G contains the set of nodes $\{s, u_1, u_2, \ldots, u_\ell, v_1, \ldots, v_\ell\}$, and the set of edges (s, u_i) and (u_i, v_i) for each $i \in [\ell]$. For each $i \in [\ell]$ we set $w(u_i) = 0$, $w(v_i) = T$, $C(s, u_i) = 2^{-i}$ with probability $1 - 1/l$ and 0 otherwise, and $C(u_i, v_i) = 1 - 2^{-i} + 2^{-(\ell+1)}$ with probability 1.

▶ **Lemma 1.** *Let OPT_{ad} and OPT_{na} denote the optimal adaptive and nonadaptive strategies for instance $\mathcal{I}_{LB}$. Then, $r(\mathcal{I}_{LB}, OPT_{ad})/r(\mathcal{I}_{LB}, OPT_{na}) = \Omega(n)$.*

One natural approach for StochasticExploration instance is to replace the stochastic edge costs with the truncated expected costs, that is, set the cost of an edge e to $\mathbb{E}[\min\{1, C(e)\}]$. However as this following example illustrates this approach does not lead to a good solution, even if constant budget augmentation is allowed.

▶ **Lemma 2.** *Let OPT_{ad} denote the optimal adaptive strategy for an instance $\mathcal{I}$ and let n be the number of vertices in the instance. Let OPT_{na} be the optimal nonadaptive strategy computed on instance $\mathcal{I}_{TR}$ obtained from $\mathcal{I}$ by setting edge costs $\mathbb{E}[\min\{1, C(e)\}]$, $e \in E$. Assume the nonadaptive algorithm is allowed to use a budget of $1 < c < n/10$. Then, there exists an instance $\mathcal{I}$ such that $r(\mathcal{I}, OPT_{ad})/r(\mathcal{I}_{TR}, OPT_{na}) = \Omega(n/2^{2c})$.*

4 The General Case and the Minesweeper Problem

In this section we describe algorithms for solving StochasticExploration, which use logarithmic budget augmentation. We first show how to reduce an instance of SGE to MineSweeper and then present solutions for MineSweeper on trees and general graphs. During the description of the reduction we also introduce the logarithmic budget augmentation. First, we observe that in the MineSweeper problem we do not have budget so there is no history that an algorithm may have to remember, except for the edges that it has probed (and succeeded). This implies the following:

▶ **Observation 1.** *There exists an optimal strategy for the* MineSweeper *problem that is nonadaptive.*

4.1 Reduction from StochasticExploration to MineSweeper

In this section we show how, given an instance $\mathcal{I}_{\text{SGE}} = (G, s, C, w)$ of StochasticExploration, we transform it to an instance $\mathcal{I}_{\text{MS}} = (G, s, p, w)$ of MineSweeper. The graph and the rewards remain the same; the challenge is to define the correct edge probability function $p(\cdot)$ for MS and relate it to the cost function $C(\cdot)$ of SGE. For each edge e' we transform the cost distribution $C(e')$ to the probability that the edge materializes, $p(e')$ (a scalar). Let $X_{e'}$ be a random variable distributed according to the exponential distribution with parameter 1, let $c_{e'}$ be the cost, which is distributed according to $C(e')$, and we set $p(e') = \mathbf{Pr}(X_{e'} > c_{e'})$. Next we show how this choice couples the two problems.

First, we show that for any subset of edges F the probability that their total cost in SGE is at most 1 is at most a factor e times of the probability that all the edges in F materialize, and therefore MS does not stop on this set. Let $\mathcal{E}_F$ be the event that all the edges in F materialize and $\mathcal{G}_F$ the event that $\sum_{e' \in F} c_{e'} \leq 1$. The following lemma makes use of properties of the exponential distribution.

▶ **Lemma 3.** *For any $F \subseteq E$ we have that $\mathbf{Pr}(\mathcal{G}_F) \leq e \cdot \mathbf{Pr}(\mathcal{E}_F)$.*

This lemma allows us to prove the following lemma, which gives a strategy for MS that is competitive with the optimal adaptive strategy for SGE. The idea behind the proof is to define a strategy for MS in such a way that we can couple the execution of the two strategies in the corresponding problems.

▶ **Lemma 4.** *Consider an* SGE *instance $\mathcal{I}_{\text{SGE}} = (G, s, C, w)$ and let $\mathcal{I}_{\text{MS}} = (G, s, p, w)$ be an instance for* MS *as defined previously. Let OPT_{ad} denote the optimal adaptive strategy for* SGE *and OPT_{MS} the optimal strategy for* MS*. We have that*

$$r((G, s, C, w), OPT_{ad}, 1) \leq e \cdot r_{MS}((G, s, C, w), OPT_{MS}).$$

Recall from Observation 1 that the optimal strategy for the MineSweeper problem is nonadaptive, therefore it can be specified by a list of edges that are selected sequentially until for one of them there is a failure. Let OPT_{MS} be such an optimal sequence of edges. Next we show that the sequence of edges OPT_{MS} can provide an approximate result to the StochasticExploration problem if we allow for some budget augmentation.

▶ **Lemma 5.** *Consider an* SGE *instance $\mathcal{I}_{\text{SGE}} = (G, s, C, w)$ and let $\mathcal{I}_{\text{MS}} = (G, s, p, w)$ be an instance for* MS *as defined previously. Let OPT_{MS} be the optimal sequence of edges for the* MineSweeper *instance, and let S be the (nonadaptive) strategy for* StochasticExploration *that probes the same edges, in the same order. Then we have that*

$$r((G, s, C, w), S, 2\ln(nR)) \geq r_{MS}((G, s, C, w), OPT_{MS}) - o(1),$$

where $R = \max_{v \in V} w(v)$.

Collecting the results of Lemmas 4 and 5 we obtain the following theorem.

▶ **Theorem 6.** *Consider an* SGE *instance $\mathcal{I}_{\text{SGE}} = (G, s, C, w)$ and let $\mathcal{I}_{\text{MS}} = (G, s, p, w)$ be an instance for* MS *as defined previously. Then*

$$r((G, s, C, w), OPT_{na}, 2\ln(nR)) + o(1) \geq r_{MS}((G, s, C, w), OPT_{MS}) \geq \frac{r((G, s, C, w), 1, OPT_{ad})}{e}.$$

4.2 MineSweeper on Trees

We show that the minesweeper problem on trees can be solved optimally in near-linear time.

▶ **Theorem 7.** *Consider the instance $\mathcal{I} = (T, s, p, w)$ of the minesweeper problem, where T is a tree. The optimal strategy, OPT_{MS}, for* MineSweeper *on T can be computed in $O(n \log n)$ time, where n is the number of vertices of T.*

The algorithm is surprisingly simple and based on a greedy approach. We define the utility of an edge to be the expected payoff from probing it, divided by the probability that the edge does not materialize. The algorithm is based on two observations. First, we observe that if there is a node x in the graph with a single child y and the utility of the edge xy is larger than the utility of the edge connecting x and its parent, then without loss of optimality we can assume that the edge xy is probed right after the edge connecting x and its parent, so we can merge these two edges into a single one. Second, if there is a node x, such that one can probe all edges in the subtree of x in the order of decreasing utilities (and not violate the constraint that an edge can be probed only after one of its endpoints has been acquired) then one can replace the entire subtree of x with a line, which is a subtree imposing the concrete order of probing edges. It turns out that by using both these rules one can find the optimal order of probing edges efficiently.

We obtain the algorithm by generalizing some existing results from the area of scheduling. At the same time our analysis is arguably simpler. We give the proof of Theorem 7 in the full version of the paper.

4.3 MineSweeper on general graphs

In this section we present an algorithmic solution to Minesweeper for general graphs, which provides a bicriteria approximation for our problem. We prove the following theorem.

▶ **Theorem 8.** *Consider the instance $\mathcal{I} = (G, s, p, w)$ of the minesweeper problem, where $G = (V, E)$ is an undirected graph. An $O(\log nR)$-approximate strategy can be computed in polynomial time.*

In the following we provide a sketch of the proof. Assume that the optimal solution is the sequence of edges $S^* = (e_1, \ldots, e_k)$. We first observe that the edges in S^* must form a tree. Define $\mathcal{M}(E')$ to be the event that all the edges in the set E' materialize. Also let $w(e_1, \ldots, e_i) = \sum_{j=1}^{i} w(e_i)$. Then S^* is a sequence that maximizes

$$O^* = \sum_{i=1}^{k} \mathbf{Pr}(\mathcal{M}(\{e_1, \ldots, e_i\}), \neg\mathcal{M}(\{e_{i+1}\})) \cdot w(e_1, \ldots, e_i)\,.$$

For $\ell = 0, 1, \ldots, \ln nR$, define $I(\ell)$ to be all values j such that $w(e_1, \ldots, e_j) \in [2^\ell, 2^{\ell+1} - 1]$, and $\iota(\ell)$ to be the smallest such j.

We can write after some manipulations:

$$O^* \leq \sum_{\ell=0}^{\ln nR} 2w(e_1, \ldots, e_{\iota(\ell)}) \cdot \mathbf{Pr}\big(\mathcal{M}(\{e_1, \ldots, e_{\iota(\ell)}\})\big) \leq 2\ln(nR) \cdot w(\tilde{E}) \cdot \mathbf{Pr}\big(\mathcal{M}(\tilde{E})\big)\,,$$

with $\tilde{E} \subset E$ being the set of edges that defines a tree that contains s and maximizes $w(\tilde{E}) \cdot \mathbf{Pr}\big(\mathcal{M}(\tilde{E})\big)$. Therefore, our goal becomes that of finding that set of edges $\tilde{E}$ that forms a tree and maximizes $w(\tilde{E}) \cdot \mathbf{Pr}\big(\mathcal{M}(\tilde{E})\big)$.

For this purpose, we use the problem of *max-prize tree*. In the max-prize tree [5] we are given an undirected graph $G = (V, E)$ with a source vertex $s \in V$, (deterministic) edge costs $c : E \to \mathbb{R}_{\geq 0}$, deterministic rewards on the vertices $w : V \to \mathbb{R}_{\geq 0}$, and a budget $B \in \mathbb{R}$. The objective is to build a subgraph $G' = (V', E')$ of G such that (1) G' is a tree, (2) $s \in V'$, and (3) $\sum_{e \in E'} c(e) \leq B$, that maximizes $\sum_{v \in V'} w(v)$.

We use for our approximation the 8-approximation algorithm for the max-prize–tree problem given by Blum et al. [5].

5 Approximating Set Strategy on Trees

In this section we show an algorithm for computing a strategy for trees, which is $(1, 1+\epsilon)$-approximate compared to the optimal set strategy. The strategy itself is adaptive.

▶ **Lemma 9.** *Let $\mathcal{I} = (G, s, C, w)$ be a* SGE *instance, where G is a tree. Let OPT_{set} be the optimal set strategy for $\mathcal{I}$. Then, in $O(n^4/\epsilon^2)$ time we can compute an adaptive strategy S, such that $r(\mathcal{I}, S, 1+\epsilon) \geq r(\mathcal{I}, OPT_{set}, 1)$. Moreover, if edge costs are not stochastic, that is, the support of each distribution π_e has size 1, the algorithm runs in $O(n^3/\epsilon)$ time and the resulting strategy is not adaptive.*

We briefly describe the ideas behind the algorithm. Consider the instance $\mathcal{I} = (T, s, C, w)$, where T is a tree. We root the tree at s and assume an order on the children of each node. Consider the sequence $P = \langle e_1, \ldots, e_n \rangle$ of the tree edges built with the following recursive algorithm. Given a node of T, iterate through its descendant edges (according to their order) and for each such edge output it and recur on the other endpoint. This traverses the tree in a preorder fashion. We define $\prec$ to be the linear order on the edges of T induced by this traversal. In the following, we assume that the edges are ordered according to $\prec$, for example, by a maximal element of a set of edges, we mean the edges that is largest according to $\prec$.

We say that a subset A of edges of T is *feasible*, if each edge $e \in A$ is either incident to the root of T, or the parent edge of e also belongs to A. Observe that given sufficient budget, a strategy can acquire any feasible set of edges of T. This follows from the fact that for each edge e of T, its parent comes before it in P. Our algorithm will probe some feasible set of edges according to the order $\prec$, that is, after probing an edge e it will not probe any edge f such that $f \prec e$.

The algorithm for computing our strategy is based on dynamic programming. A simple and inefficient approach is to use an exponential number of states. Namely, each state can be characterized by the set of edges acquired so far, denoted by A, and the remaining budget, which we discretize to a multiple of ϵ/n. Knowing the set A allows us to find all such edges e that $A \cup \{e\}$ is a feasible set and e comes after the maximal element of A in the order $\prec$. The key idea is that we can improve the number of states to polynomial, by taking advantage of the following property of the ordering $\prec$.

▶ **Lemma 10.** *Let A be a nonempty feasible set of edges of T and let e be the maximal edge of A. Given e (and without knowing A) we can compute the set F_e of all edges f such that $e \prec f$ and $A \cup \{f\}$ is a feasible set.*

6 Bounded Edge Costs

In this section, we deal with the special case of StochasticExploration, where the cost of each edge is bounded by $O(\frac{\epsilon^2}{\ln n})$ and the ratio between the smallest and largest reward R is polynomial in n. We prove that in this setting a $(O(1), 1+\epsilon)$ strategy for SGE can be computed in polynomial time.

▶ **Theorem 11.** *Let $\mathcal{I} = (G, s, C, w)$ be an instance of* SGE*, where $C(e) = O(\frac{\epsilon^2}{\ln n})$ (for each edge e and some $0 < \epsilon = O(1)$), $R \leq \epsilon n^{O(1)}$, and the smallest reward is 1. Then, in polynomial time, we can compute a nonadaptive $(O(1), 1+\epsilon)$-approximate strategy for $\mathcal{I}$. Additionally, if G is a tree, then in time $O(n^3/\epsilon)$ we can compute a nonadaptive $(1+\epsilon, 1+\epsilon)$-approximate strategy for $\mathcal{I}$.*

To prove the theorem, we consider the following strategy. We replace the stochastic edge costs with their expected values (i.e., the edge cost distributions in the modified instance have size 1). Then, we show that the optimal set strategy using budget augmented by a factor of $1+\epsilon$ gives a $(1+\epsilon)$-approximate solution.

For ease of notation, we scale the edge costs and the budgets by a factor of $\Theta(\epsilon^2/\ln n)$, so that the edge costs are bounded by 1 and the available budget is $B = O(\epsilon^2/\ln n)$.

First, we bound the payoff of an adaptive strategy when the expected cost of its acquired edges is more than $B \cdot (1+\epsilon)$. Let $\mu_e = \mathbf{E}[C(e)]$, and $\mu(F) = \sum_{e \in F} \mu_e$.

▶ **Lemma 12.** *Let $0 < \epsilon < 1/3$ and let $\mathcal{I} = (G, s, C, w)$ be an instance of* SGE*, in which $B \geq 5c/\epsilon^2 \cdot \ln n$. Let F be a set of edges acquired by some adaptive strategy. If $\mu(F) \geq (1+\epsilon) \cdot B$ then the probability that $C(F) \leq B$ is at most n^{-c}.*

Next, we show that if the expected cost of some set of edges is close to the budget, then this cost is highly concentrated around the expected value. This enables us to give a set strategy with small budget augmentation.

▶ **Lemma 13.** *Let $\mathcal{I} = (G, s, C, w)$ be an instance of* SGE*. For any set of edges F and any $\tilde{B} \geq 5c/\epsilon^2 \cdot \ln n$, if $\mu(F) = \tilde{B}$ then the probability that $C(F) \geq (1+\epsilon)\tilde{B}$ is at most n^{-c}.*

▶ **Lemma 14.** *Let $\mathcal{I} = (G, s, C, w)$ be an instance of* SGE*, where $B \geq 5c/\epsilon^2 \ln n$, the maximum reward R satisfies $R \leq \epsilon n^{c-1}$, and the minimum reward is 1. Let $\mathcal{I}_e$ be obtained from $\mathcal{I}$ by replacing each edge cost with its expected value. Let OPT^{ϵ}_{set} be the optimal set strategy using budget $(1+\epsilon)B$ for $\mathcal{I}_e$ and OPT_{ad} be the optimal adaptive strategy using budget B for $\mathcal{I}$. Then, $(1+\epsilon) r(\mathcal{I}, OPT^{\epsilon}_{set}, (1+\epsilon)B) \geq r(\mathcal{I}, OPT_{ad}, B)$.*

Observe that finding the optimal set strategy on $\mathcal{I}_e$ is NP-hard, as it generalizes the knapsack problem. However, it becomes tractable, if we augment the budget. In particular, for trees, we use the algorithm of Lemma 9, and for general graphs, in Section 4.3, we show how to use the solution of the max-prize problem.

7 Nonadaptive strategies

In this section we consider nonadaptive strategies for the stochastic exploration problem. The main result of this section is that, for the graph exploration problem, that there exists a *set-strategy* with a constant budget augmentation, which is a constant competitive compared to the best nonadaptive algorithm. Recall that, a *set-strategy* is to choose a set of edges (without an internal order) and to try to probe all of the edge in that set. The gain of strategy for a set of edges, is non-zero only if the *entire set* was successfully probed (i.e., if the total cost of the set is smaller than the budget), and then it collects the rewards of all the vertices connected to this set. Therefore, the expected gain of *set-strategy* given a set of edges, is the total gain of vertices spanned by these edges times the probability that the total cost of these edges would not be greater than the specified budget.

First, we are able to show how much is the increment in the probability to successfully probe a set, when using a constant budget augmentation.

7.1 Power of Budget Augmentation

Let $S = \{e_1, e_2, \ldots, e_n\}$ be a set of edges and let $c_i \triangleq C(e_i)$. Define $C_k^n = \sum_{i=k}^{n} c_i$ the realized cost of the subset of the edges $\{e_k, \ldots e_n\}$ and, for ease of notation, let $C^j = C_1^j$. For any $i \in [n]$ let $P_i(a)$ be the probability that the sum of cost of the edges $\{e_1, \ldots e_i\}$ is at most a, that is, $P_i(a) = \mathbf{Pr}\big(C^i \leq a\big)$.

The next lemma will allow us to take advantage of budget augmentation.

▶ **Lemma 15.** *Assume that for each edge e_i, $i \in [n]$ we have $c_i \in [0,1]$. Then*

$$P_n(3) \geq P_n(1)\left(1 - \ln(P_n(1))\right).$$

Interestingly, the multiplicative factor increases as the probability to succeed with the original budget decreases. We will use this fact, but to compare to a list-strategy we need stronger guarantees, we simply use the above lemma twice and deduce the following.

▶ **Corollary 16.**

$$P_n(9) \geq P_n(1)\frac{\left(1 - \ln(P_n(1))\right)^2}{2}$$

7.2 List Strategy vs. Set Strategy

Now, we are ready to prove the main claim of this section, that we are able to compare the strategies using a budget augmentation. Consider an SGE problem instance $\mathcal{I} = (G, s, C, w)$. Let $\mathrm{S}_{ls} = \langle e_1, \ldots, e_n \rangle$ be a nonadaptive strategy (a feasible sequence of edges) and let v_i denote the vertex whose reward is obtained when e_i is acquired. The expected payoff of probing the list with budget $B(\geq 1)$ is by linearity of expectation:

$$r(\mathcal{I}, \mathrm{S}_{ls}, B) = \sum_{j=1}^{n} w(v_j) \cdot \mathbf{Pr}\big(C^j \leq B\big).$$

Given a non-adaptive strategy $\mathrm{S}_{ls} = \langle e_1, \ldots, e_n \rangle$, consider n different set strategies S_k, for $k = \{1 \ldots n\}$, where $S_k = \{e_1, \ldots e_k\}$. Note that the expected payoff of S_k with budget $9 \cdot B$ is

$$r(\mathcal{I}, S_k, 9B) = \mathbf{Pr}\big(C^k \leq 9B\big) \cdot \sum_{j=1}^{k} w(v_j).$$

Finally, we show that there exists $k \in \{1, \ldots, n\}$ such that the set strategy S_k with budget $9B$ obtains a constant fraction of strategy S_{ls}.

▶ **Lemma 17.**

$$\max_k \{r(\mathcal{I}, S_k, 9B)\} \geq 0.46 \cdot r(\mathcal{I}, S_{ls}, B).$$

7.3 Algorithm for Trees

By combining Lemma 17 with the algorithm of Lemma 9, we obtain the following.

▶ **Theorem 18.** *Let $\mathcal{I} = (G, s, C, w)$ be a* SGE *instance, where G is a tree. Let OPT_{na} be the optimal nonadaptive strategy for $\mathcal{I}$. Then, in $O(n^4/\epsilon^2)$ time we can compute an adaptive strategy S, such that $r(\mathcal{I}, S, 9 + \epsilon) \geq 0.46 \cdot r(\mathcal{I}, OPT_{na}, 1)$.*

8 Conclusions

In this work we have introduced the stochastic exploration problem on graphs which generalizes the stochastic knapsack problem [8, 4]. We proved that, differently from stochastic knapsack, no $o(n)$ adaptivity gap is possible unless we allow some resource augmentation on the budget. We provided algorithms with bounded adaptivity gap and logarithmic resource augmentation by reducing stochastic exploration to a related memoryless problem – the minesweeper problem. We also considered the case of edges with small costs for which it is possible to provide an algorithm with $O(1)$ adaptivity gap and $O(1)$ resource augmentation. The most challenging problem left open from our work is the one of devising an algorithm with $O(1)$ approximation factor that uses only $O(1)$ resource augmentation for general graphs. The problem is open even for trees. We provided a set of additional results on the structure of optimal adaptive strategies and on the power of resource augmentation for set strategies with respect to list strategies that can help in addressing this problem.

Abstract

Consider two robots that start at the origin of the infinite line in search of an *exit* at an unknown location on the line. The robots can collaborate in the search, but can only communicate if they arrive at the same location at exactly the same time, i.e. they use the so-called *face-to-face* communication model. The group search time is defined as the worst-case time as a function of d, the distance of the exit from the origin, when both robots can reach the exit. It has long been known that for a single robot traveling at unit speed, the search time is at least $9d - o(d)$; a simple doubling strategy achieves this time bound. It was shown recently in [15] that $k \geq 2$ robots traveling at unit speed also require at least $9d$ group search time.

We investigate *energy-time trade-offs* in group search by two robots, where the energy loss experienced by a robot traveling a distance x at constant speed s is given by s^2x, as motivated by energy consumption models in physics and engineering. Specifically, we consider the problem of minimizing the total energy used by the robots, under the constraints that the search time is at most a multiple c of the distance d and the speed of the robots is bounded by b. Motivation for this study is that for the case when robots must complete the search in $9d$ time with maximum speed one ($b = 1;\ c = 9$), a single robot requires at least $9d$ energy, while for two robots, all previously proposed algorithms consume at least $28d/3$ energy.

When the robots have bounded memory and can use only a constant number of fixed speeds, we generalize an algorithm described in [3, 15] to obtain a family of algorithms parametrized by pairs of b, c values that can solve the problem for the entire spectrum of these pairs for which the problem is solvable. In particular, for each such pair, we determine optimal (and in some cases nearly optimal) algorithms inducing the lowest possible energy consumption.

We also propose a novel search algorithm that simultaneously achieves search time $9d$ and consumes energy $8.42588d$. Our result shows that two robots can search on the line in optimal time $9d$ while consuming less total energy than a single robot within the same search time. Our algorithm uses robots that have unbounded memory, and a finite number of dynamically computed speeds. It can be generalized for any c, b with $cb = 9$, and consumes energy $8.42588b^2d$.

1 Introduction

The problem of searching for a treasure at an unknown location in a specified continuous domain was initiated over fifty years ago [6, 7]. Search domains that have been considered include the infinite line [2, 6, 7, 34], a set of rays [10, 11], the unit circle [12, 24, 37], and polygons [27, 33, 35]. Consider a robot (sometimes called a mobile agent) starting at some known location in the domain and looking for *an exit* that is located at an unknown distance d away from the start. What algorithm should the robot use to find the exit as soon as possible? The most common cost measure used for the search algorithm is the worst-case *search time*, as a function of the distance d of the exit from the starting position. For a fixed-speed robot, the search time is proportional to the length of the trajectory of the robot. Other measures such as turn cost [28] and different costs for revisiting [9] have also been studied.

We consider for the first time the *energy* consumed by the robots while executing the search algorithm. The energy used by a robot to travel a distance x at speed s is computed as s^2x and is motivated from the concept of viscous drag in fluid dynamics; see Section 2 for details on the energy model. For a single robot searching on the line, the classic *Spiral Search* algorithm (also known as the doubling strategy) has search time $9d$ and is known to be *optimal* when the robot moves with unit speed. Since in the worst case, the robot travels distance $9d$ at unit speed, the energy consumption is $9d$ as well. Clearly, as the speed of the robot increases, the time to find the exit decreases but the energy used increases. Likewise, as the speed of the robot decreases, the time to find the exit increases, while the energy consumption decreases. Thus there is a natural trade-off between the time taken by the robot to search for the exit and the energy consumed by the robot. To investigate this trade-off, we consider the problem of minimizing the total energy used by the robots to perform the search when the speed of the robot is bounded by b, and the time for the search is at most a multiple c of the distance d from the starting point to the exit.

Group search by a set of $k \geq 2$ collaborating robots has recently gained a lot of attention. In this case, the search time is the time when *all* k robots reach the exit. The problem has also been called *evacuation*, in view of the application when it is desired that all robots reach and evacuate from the exit. Two models of communication between the robots have been considered. In the wireless communication model, the robots can instantly communicate with each other at any time and over any distance. In the face-to-face communication model (F2F), two robots can communicate only when in the same place at the same time. In many search domains, and for both communication models, group search by $k \geq 2$ agents has been shown to take less time than search by a single agent; see for example [24, 27].

In this paper, we focus on group search on the line, by two robots using the F2F model. Chrobak *et al* [15] showed that group search in this setting cannot be performed in time less than $9d - o(d)$, regardless of the number of robots, assuming all robots use at most

unit speed. They also describe several strategies that achieve search time $9d$. In the first strategy, the two robots independently perform the Spiral Search algorithm, using unit speed during the entire search. Next, they consider a strategy first described in [3], that we call the *Two-Turn* strategy, whereby two robots head off independently in opposite directions at speed $1/3$; when one of them finds the exit, it moves at unit speed to chase and catch the other robot, after which they both return at unit speed to the exit. Finally, they present a new strategy, called the *Fast-Slow* algorithm in which one robot moves at unit speed, while the other robot moves at speed $1/3$, both performing a spiral search. The doubling strategy is very energy-inefficient, it uses energy $18d$ if the two robots always travel together, or $14D$ if the robots start by moving in opposite directions. The other two algorithms both use energy $28d/3 > 9d$. Interestingly, the two strategies that achieve an energy consumption of $28d/3$ with search time $9d$, both use two different and pre-computed speeds, but are quite different in terms of the robot capacities needed. In the Two-Turn strategy, the robots are extremely simple and use constant memory; they use only three states. In Fast-Slow and Spiral Search, the robots need unbounded memory, and perform computations to determine how far to go before turning and moving in the opposite direction.

Memory capability, time- and speed-bounded search, and energy consumption by a two-robot group search algorithm on the line: these considerations motivate the following questions that we address in our paper:

1. Is there a search strategy for constant-memory robots that has energy consumption $< 9d$?
2. Is there *any* search strategy that uses time $9d$ and energy $< 9d$?

1.1 Our results

We generalize the Two-Turn strategy for any values of c, b. We analyze the entire spectrum of values of c, b for which the problem admits a solution, and for each of them we provide optimal (and in some cases nearly optimal) speed choices for our robots (Theorem 5). In particular, and somewhat surprisingly, our proof makes explicit how for any fixed c the optimal speed choices do not simply "scale" with b; rather more delicate speed choices are necessary to comply with the speed and search time bounds. For the special case of $c \cdot b = 9$, our results match with the specific Two-Turn strategy described in [15]. Our results further show that no Two-Turn strategy can achieve energy consumption less than $9d$ while keeping the search time at $9d$. In fact, we conjecture that this trade-off is impossible for *any* group search strategy that uses only constant memory robots.

In the unbounded-memory model, for the special case of $c = 9$ and $b = 1$, we give a novel search algorithm that achieves energy consumption of $8.42588d$, thus answering the second question above in the affirmative. This result shows that though two robots cannot search faster than one robot on the line [15], somewhat surprisingly, two robots can search using less total energy than one robot, in the same optimal time. Our algorithm uses robots that have unbounded memory, and a finite number of dynamically computed speeds. Note that our algorithm can be generalized for any c, b with $cb = 9$, and utilizes energy $8.42588b^2d$ (Theorem 16).

1.2 Related Work

Several authors have investigated various aspects of mobile robot (agent) search, resulting in an extensive literature on the subject in theoretical computer science and mathematics (e.g., see [1, 30] for reviews). Search by constant-memory robots has been done mainly for finite-state automata (FSA) operating in discrete environments like infinite grids, their

finite-size subsets (labyrinths) and other graphs. The main concern of this research was the feasibility of search, rather than time or energy efficiency. For example, [14] showed that no FSA can explore all labyrinths, while [8] proved that one FSA using two pebbles or two FSAs, communicating according to the F2F model can explore all labyrinths. However, no collection of FSAs may explore all finite graphs communicating in the F2F model [39] or wireless model [17]. On the other hand, all graphs of size n may be explored using a robot having $O(\log n)$ memory [38].

Exploration of infinite grids is known as the ANTS problem [29], where it was shown that four collaborating FSAs in the semi-synchronous execution model and communicating according to the F2F scenario can explore an infinite grid. Recently, [13] showed that four FSAs are really needed to explore the grid (while three FSAs can explore an infinite band of the 2-dimensional grid).

Continuous environment cases have been investigated in several papers when the efficiency of the search is often represented by the time of reaching the target (e.g., see [2, 6, 7, 34]). Even in the case of continuous environment as simple as the infinite line, after the seminal papers [6, 7], various scenarios have been studied where the turn cost has been considered [28], the environment was composed of portions permitting different search speeds [26], some knowledge about the target distance was available [10] or where some other parameters are involved in the computation of the cost function [9] (e.g. when the target is moving).

The group search, sometimes interpreted as the evacuation problem has been studied first for the disc environment under the F2F [12, 18, 24, 27, 36] and wireless [18] communication scenarios and then also for other geometric environments (e.g., see [27]). Other variants of search/evacuation problems with a combinatorial flavour have been recently considered in [16, 19, 20, 31, 32]. Some papers investigated the line search problem in the presence of crash faulty [25] and Byzantine faulty agents [23]. The interested reader may also consult the recent survey [22] on selected search and evacuation topics.

The energy used by a mobile robot is usually considered as being spent solely for travelling. As a consequence, in the case of a single, constant speed robot the search time is proportional to the distance travelled and the energy used by a robot. Therefore the problems of minimization of time, distance or energy are usually equivalent for most robots' tasks. For teams of collaborating robots, the searchers often need to synchronize their walks in order to wait for information communicated by other searchers (e.g, see [12, 18, 36]), hence the time of the task and the distance travelled are different. However, the distance travelled by a robot and its energy used are still commensurable quantities.

To the best of our knowledge, energy consumption as a function of mobile robot speed which is based on laws of engineering physics (related to the *drag force*) has never been studied in the search literature before. Our present work is motivated by [15], which proves that the competitive ratio 9 is tight for group search time with two mobile agents in the F2F model when both agents have unit maximal speeds. More exactly, it follows from [15] that having more unit-speed robots cannot improve the group search time obtained by a single robot. Nevertheless, our paper shows that using more robots can improve the energy spending, while keeping the group-search time still the best possible.

Chrobak et al [15] present interesting examples of group search algorithms for two distinct speed robots communicating according to the F2F scenario. An interested reader may consult [4], where optimal group search algorithms for a pair of distinct maximal speed robots were proposed for both communication scenarios (F2F and wireless) and for any pair of robots' maximal speeds. It is interesting to note that, according to [4], for any distinct-speed robots with F2F communication, the optimal group search time is obtained only if one of the robots perform the search step not using its full speed.

Paper Organization. In Section 2 we formally define the evacuation problem EE_c^b, and proper notions of efficiency. Our algorithms and their analysis for constant-memory robots is presented in Section 3, while in Section 4 we introduce and analyze algorithms for unbounded-memory robots. Whenever we omit proofs, due to space limitations, we provide an outline of our arguments. The interested reader may consult the full version of our paper [21] for the missing details.

2 Preliminaries

Two robots start walking from the origin of an infinite (bidirectional) line in search of a hidden exit at an unknown absolute distance d from the origin. The exit is considered found only when one of the robots walks over it. An algorithm for group search by two robots specifies trajectories for both robots and terminates when both robots reach the exit. The time by which the second robot reaches the exit is referred to as the *search time* or the *evacuation time*.

Robot models. The two robots operate under the F2F communication model in which two robots can communicate only when they are in the same place at the same time. Each robot can change its speed at any time. We distinguish between *constant-memory* robots that can only travel at a constant number of hard-wired speeds, and *unbounded-memory* robots that can dynamically compute speeds and distances, and travel at any possible speed.

Energy model. A robot moving at constant speed s traversing an interval of length x is defined to use energy $s^2 \cdot x$. This model is well motivated from first principles in physics and engineering and corresponds to the energy loss experienced by an object moving through a viscous fluid [5]. In particular, an object moving with constant speed s will experience a *drag* force F_D proportional[1] to s^2. In order to maintain the speed s over a distance x the object must do work equal to the product of F_D and x resulting in a continuous energy loss proportional to the product of the object's squared speed and travel distance. For simplicity we have taken the proportionality constant to be one.

The total energy that a robot uses traveling at speeds $s_1, s_2, \ldots, s_t$, traversing intervals $x_1, x_2, \ldots, x_t$, respectively, is defined as $\sum_{i=1}^{t} s_i^2 \cdot x_i$. For group search with two robots, the *energy consumption* is defined as the sum total of the two robots' energies used until the search algorithm terminates.

For each $d > 0$ there are two possible locations for the exit to be at distance d from the origin: we will refer to either of these as input instances d for the group search problem. Our goal is to solve the following *optimized* search problem parametrized by two values, $\mathbf{b}$ and $\mathbf{c}$:

▶ **Problem $\mathrm{EE}_{\mathbf{c}}^{\mathbf{b}}$.** Design a group search algorithm for two robots in the F2F model that minimizes the energy consumption for d-instances under the constraints that the search time is no more than $\mathbf{c} \cdot \mathbf{d}$ and the robots use speeds that are at most $\mathbf{b}$. When there are no speed limits on the robots (i.e. $b = \infty$), we abbreviate EE_c^{∞} by EE_c. Note that b, c are inputs to the algorithm, but d and the exact location of the exit are not known.

[1] The constant of proportionality has (SI) units kg/m and depends, among other things, on the shape of the object and the density of the fluid through which it moves.

As it is standard in the literature on related problems, we assume that the exit is at least a known constant distance away from the origin. In this work, we pick the constant equal to 2, although our arguments can be adjusted to any other constant. It is not difficult to show that EE_c^b is well defined for each $b, c > 0$ with $bc \geq 1$, and the optimal offline solution, for instance d, is for both robots to move at speed $\frac{1}{c}$ to the exit. This offline algorithm has energy consumption $\frac{2d}{c^2}$. Consider an online algorithm for EE_c^b, which on any instance d has energy consumption at most $e(c, b, d)$. The *competitive ratio* of the algorithm is defined as $\sup_{d>0} \frac{c^2}{2d}\ e(c, b, d)$.

Due to [15], and when $b = 1$, no online algorithm (for two robots) can have evacuation time less than $9d - \epsilon$ (for any $\epsilon > 0$ and for large enough d). By scaling, using arbitrary speed limit b, we obtain the following fact.

▶ **Observation 1.** *No online F2F algorithm can solve* EE_c^b *if* $cb < 9$.

3 Solving EE_c^b with Constant-Memory Robots

In this section we propose a family of algorithms for solving EE_c^b (including $b = \infty$). The family uses an algorithm that is parametrized by three discrete speeds: s, r and k. The robots use these speeds depending on finite state control as follows:

▶ **Algorithm $\mathcal{N}_{s,r,k}$.** Robots start moving in opposite directions with speed s until the exit is found by one of them. The finder changes direction and moves at speed $r > s$ until it catches the other robot. Together the two robots return to the exit using speed k.

▶ **Lemma 2.** *Let* b, c *be such that there exist* s, r, k *for which* $\mathcal{N}_{s,r,k}$ *is feasible. Then, for instance* d *of* EE_c^b*, the induced evacuation time of* $\mathcal{N}_{s,r,k}$ *is* $d \cdot T(s, r, k)$ *and the induced energy consumption is* $2d \cdot E(s, r, k)$*, where*

$$T(s, r, k) := \frac{2(k + r)}{k(r - s)} + \frac{1}{s}, \quad E(s, r, k) := \frac{r}{r - s}\left(s^2 + r^2 + 2k^2\right)$$

We propose a systematic way in order to find optimal values for s, r, k of algorithm $\mathcal{N}_{s,r,k}$ for optimization problem EE_c^b (including $b = \infty$), whenever such values exist.

▶ **Theorem 3.** *Algorithm* $\mathcal{N}_{s,r,k}$ *gives rise to a feasible solution to problem* EE_c^b *if and only if* $bc \geq 9$*. For every such* $b, c > 0$*, the optimal choices of* $\mathcal{N}_{s,r,k}$ *can be obtained by solving Non Linear Program:*

$$\begin{aligned} &\min_{s,r,k \in \mathbb{R}} E(s, r, k) && (\mathrm{NLP}_c^b)\\ s.t.\ \ &T(s, r, k) \leq c \\ &r \geq s \\ &0 \leq s, r, k \leq b \end{aligned}$$

where functions $E(\cdot, \cdot, \cdot), T(\cdot, \cdot, \cdot)$ *are as in Lemma 2. Moreover, if* s_0, r_0, k_0 *are the optimizers to* NLP_c^b*, then the competitive ratio of* $\mathcal{N}_{s_0,r_0,k_0}$ *equals* $c^2 \cdot E(s_0, r_0, k_0)$.

The following subsections are devoted to solving NLP_c^b, effectively proving Theorem 5. First in Section 3.1 we solve the case $b = \infty$ and we use our findings to solve the case of bounded speeds b in the follow-up Section 3.2.

3.1 Optimal Choices of $\mathcal{N}_{s,r,k}$ for the Unbounded-Speed Problem

In this section we propose solutions to the unbounded-speed problem EE_c. Since EE_c is the same as $\mathrm{EE}_c^\infty$the problem is well-defined for every fixed $c > 0$. Moreover, by the proof of Theorem 3 algorithm $\mathcal{N}_{s,r,k}$ induces a feasible solution for every $c > 0$ as well, and the optimal speeds can be found by solving NLP_c^∞. Indeed, in the remainder of the section we show how to choose optimal values for s, r, k for solving EE_c with $\mathcal{N}_{s,r,k}$. Let

$$\sigma \approx 2.65976, \rho \approx 11.3414, \kappa \approx 6.63709, \tag{1}$$

whose exact values are the roots of an algebraic system and will be formally defined later. The main theorem of this section reads as follows.

▶ **Theorem 4.** *Let σ, ρ, κ as in (1). For every $c > 0$, the optimal speeds of $\mathcal{N}_{s,r,k}$ for problem EE_c are $s = \frac{\sigma}{c}$, $r = \frac{\rho}{c}$, $k = \frac{\kappa}{c}$. Moreover, the competitive ratio of the corresponding solution is independent of c and equals $\frac{\rho\left(2\kappa^2+\rho^2+\sigma^2\right)}{\rho-\sigma} \approx 292.369$.*

A high level outline of the proof of Theorem 4 is as follows. First we show that any optimal choices of the speeds of $\mathcal{N}_{s,r,k}$ must satisfy the time constraint of NLP_c^∞ tightly. Then, we show that finding optimal speeds s, r, k of $\mathcal{N}_{s,r,k}$ for the general problem EE_c reduces to problem EE_1. Finally, we obtain the optimal solution to NLP_1^∞ by standard tools of nonlinear programming (KKT conditions).

3.2 (Sub)Optimal Choices of $\mathcal{N}_{s,r,k}$ for the Bounded-Speed Problem

In this section, we show how to choose optimal values for s, r, k for solving EE_c^b with $\mathcal{N}_{s,r,k}$, for the entire spectrum of c, b values for which the problem is solvable by online algorithms.

The main result of this section is the following:

▶ **Theorem 5.** *Let $\gamma_1 \approx 9.06609$, $\gamma_2 = \rho \approx 11.3414$, and σ, ρ, κ as in (1). For every $c, b > 0$ with $cb \geq 9$, the following choices of speeds s, r, k are feasible for $\mathcal{N}_{s,r,k}$*

	$9 \leq cb \leq \gamma_1$	$\gamma_1 < cb < \gamma_2$	$cb \geq \gamma_2$
s	$\frac{-\sqrt{(bc)^2-10bc+9}+bc-3}{2c}$	$0.532412b - 0.0262661b^2c$	σ/c
r	b	b	ρ/c
k	b	$\frac{2bs}{bcs-b-cs^2-s}$	κ/c

The induced competitive ratio is given by:

$$f(x) := \begin{cases} \frac{1}{2}x\left(x\left(x-\sqrt{(x-9)(x-1)}\right)+\sqrt{(x-9)(x-1)}+3\right), & 9 \leq x \leq \gamma_1 \\ \frac{x^2\left((0.532412-0.0262661x)^2+\frac{11595.8(20.2699-1.x)^2}{(x(x-2.46798)-398.916)+2221.18)^2}+1\right)}{0.0262661x+0.467588}, & \gamma_1 < x < \gamma_2 \\ 292.369 & x \geq \gamma_2 \end{cases}$$

and the induced energy, for instances d, is $f(cb)\frac{2d}{c^2}$. Moreover, the competitive ratio depends only on the product cb.

In particular, the speeds' choices are optimal when $cb \leq \gamma_1$ and when $cb \geq \gamma_2$. When $\gamma_1 < cb < \gamma_2$, the derived competitive ratio is no more than 0.03 additively off from that induced by optimal choices of s, r, k.

▶ **Corollary 6.** *For $c = 9, b = 1$, the bounded-memory robot algorithm $\mathcal{N}_{s,r,k}$ has energy consumption $28d/3$ and competitive ratio 378.*

Theorem 5 is proven by solving NLP_c^b of Theorem 3. Speed values s, r, k, are chosen optimally when cb is either at most γ_1 or at least γ_2 (i.e. optimizers to NLP_c^b admit analytic description). The optimal speed parameters when $\gamma_1 < cb < \gamma_2$ cannot be determined analytically (they are roots of high degree polynomials). The values that appear in Theorem 5 are heuristically chosen, but interestingly induce nearly optimal competitive ratio.

The proof of Theorem 5 is given by Lemma 7 (the case $cb \leq \gamma_1$), Lemma 8 (the case $cb \geq \gamma_2$), and Lemma 9 (the case $\gamma_1 < cb < \gamma_2$). Next we state these Lemmata, and we sketch their proofs.

▶ **Lemma 7.** *For every $c \in (9/b, \gamma_1/b]$, where $\gamma_1 \approx 9.06609$, the optimizers to NLP_c^b are $k = r = b$, and $s_b = \frac{-\sqrt{(bc)^2-10bc+9}+bc-3}{2c}$. The induced competitive ratio is $f(cb)$, (see definition of $f(x)$ for $x \leq \gamma_1$ in statement of Theorem 5), and the energy consumption, for instances d, is $f(cb)\frac{2d}{c^2}$.*

For proving Lemma 7, first we recall the known optimizer for the special case $cb = 9$, and we identify the tight constraints. Requiring that the exact same inequality constraints to NLP_c^b remain tight, we ask how large can the product cb be so as to have KKT condition hold true. From the corresponding algebraic system, we obtain the answer $cb \leq \gamma_1 \approx 9.06609$.

Similarly, from Theorem 4 we know the optimizers to NLP_c^b for large enough values of cb, and the corresponding tight constraints to the NLP. Again, using KKT conditions, we show that the same constraints remain tight for the optimizers as long as $cb \geq \gamma_2 \approx 11.3414$. This way we obtain the following Lemma.

▶ **Lemma 8.** *For every $c > \rho/b \approx 11.3414/b$, the optimal speeds of $\mathcal{N}_{s,r,k}$ for EE_c^b are $s = \sigma/c,\ r = \rho/c,\ k = \kappa/c$, i.e. they are the same as for EE_c^∞. If the target is placed at distance d from the origin, then the induced energy equals $584.738\frac{d}{c^2}$. Moreover, the induced competitive ratio is 292.369, and is independent of b, c.*

The case $\gamma_1 < cb < \gamma_2$ can be solved optimally only numerically, since the best speed values are obtained by roots to a high degree polynomial. Nevertheless, the following lemma proposes a heuristic choice of speeds (that of Theorem 5) which is surprisingly close to the optimal.

▶ **Lemma 9.** *The choices of s, r, k of Theorem 5 when $\gamma_1 < cb < \gamma_2$ are feasible. Moreover, the induced competitive ratio is at most 0.03 additively off from the competitive ratio induced by the optimal choices of speeds (evaluated numerically).*

The trick in order to find "good enough" optimizers to NLP_c^b is to guess the subset of inequality constraints that remain tight when $\gamma_1 < cb < \gamma_2$. First, we observe that constraint $r \leq b$ is tight for the provable optimizers for all c, b when $cb \in [9, \gamma_1] \cup [\gamma_2, \infty)$. As the only other constraint that switches from being tight to non-tight in the same interval is $k \leq b$, we are motivated to maintain tightness for constraints $r \leq b$ and the time constraint. Still the algebraic system associated with the corresponding KKT conditions cannot be solved analytically. To bypass this difficulty, and assuming we know (optimal) speed s, we use the tight time constraint to find speed k as a function of c, b, s. From numerical calculations, we see that optimal speed s is nearly optimal in c, and so we heuristically set $s = \alpha c + \beta$. We choose α, β so as to have s satisfy optimality conditions for the boundary values $cb = \gamma_1, \gamma_2$. After we identify all parameters to our solution, we compare the value of our solution to the optimal one (obtained numerically), and we verify (using numerical calculations) that our heuristic solution is only by at most 0.03 additively off. The advantage of our analysis is that we obtain closed formulas for the speed parameters for all values of $cb \geq 9$.

4 Solving EE_c^b with Unbounded-Memory Robots

In this section we prove Theorem 16, that is we solve EE_c^b by assuming that the two robots have unbounded memory, and in particular that they can perform time and state dependent calculations and tasks. Note that, by scaling, our results hold for all b, c for which $cb = 9$. For simplicity our exposition is for the natural case $c = 9$ and $b = 1$. Also, as before, d will denote the unknown distance to the exit from the origin. Moreover, the exit is still assumed, for the purposes of performance analysis, to be at least 2 away from the origin.

Throughout the execution of our evacuation algorithm, robots can be in 3 different states (similar to the case of constant-memory robots). First, both robots start with the *Exploration State* and they remain in this until the exit is located. While in the exploration state, robots execute an elaborate exploration that requires synchronous movements in which robots, at a high level, stay in good proximity, still they expand the searched space relatively fast. Then, the exit finder enters the *Chasing State* in which the robot, depending on its distance from the origin, calculates a speed at which to move in order to catch and notify the other robot. Lastly, when the two robots meet, they both enter the *Exit State* in which both robots move toward the exit with the smallest possible speed while meeting the time constraint.

Our algorithm takes as input the values of $c = 9, b = 1$, and use a speed value $s \leq b$, that will be chosen later. When the exit finder switches its state from Exploration to Chasing, it remembers the distance d of the exit to the origin, as well as the value k of a counter that was used while in the Exploration State. When the exit finder catches the other robot, they both switch to the Exit State, and they remember their distance p from the origin, as well as the value of time t that their rendezvous was realized. The speed of their Exit State will be determined as a function of p, d, t (and hence of s, c, b as well).

4.1 A Critical Component: l-Phase Explorations

We adopt the language of [15] in order to discuss a structural property that any feasible evacuation algorithm for EE_9^1 satisfies. As a result, the purpose of this section is to provide high level intuition for our evacuation algorithm that is presented in subsequent sections.

We refer to the two robots (starting exploration from the origin) as L and R, intended to explore to the left and to the right of the origin, respectively. The robot trajectories can be drawn on the Cartesian plane where point-location $(x, -t)$ will correspond to point x on the line being visited by some robot at time t. The following Theorem (due to [15]) was originally phrased for the time-evacuation unit-speed robots' problem. We adopt the language of our problem.

▶ **Theorem 10** ([15]). *For any feasible solution to* EE_9^1*, the point-location of any robot lies within the cone spanned by vectors* $\binom{-1}{-3}, \binom{1}{-3}$.

Next we present some preliminaries toward describing our k-phase exploration algorithms. A *phase* is a pair (s, r) where $s \in [0, 1]$ is a speed and $r \in \mathbb{R}$ is a *distance ratio*, possibly negative. An *l-phase algorithm* is determined by a position p_0 on the line and a sequence $S = (s_1, r_1), \ldots, (s_k, r_l)$ of l phases (movement instructions). Whenever $r_i x < 0$, movement will be to the left, whereas $r_i x > 0$ will correspond to movement to the right.

l-PHASE EXPLORATION: GIVEN p_0 AND $S = (s_1, r_1), \ldots, (s_l, r_l)$
Go to p_0 at speed $1/3$
repeat
  $x \leftarrow$ current position
  for $i = 1, \ldots, l$ **do**
    Travel at speed s_i for a distance of $r_i \cdot x$
  end
end

We will make sure that each time the loop is executed, position x and corresponding time induce point-locations of the robots that lie in the boundary of the cone of Theorem 10. If a loop starts at location x, then it takes additional time $\sum_{i\in[l]} \frac{|r_i||x|}{s_i}$ to complete one iteration. We will be referring to quantity $1 + \sum_{i\in[l]} \frac{|r_i|}{3s_i}$ as the expansion factor of Exploration S.

4.2 Algorithm $\mathcal{A}(s)$: The Exploration, Chasing and Exit States

In this section we give a formal description of our evacuation algorithm. The most elaborate part of it is when robots are in Exploration States, in which they will perform 3-phase exploration. It can be shown that 3-phase exploration based evacuation algorithms that do not violate the constraints of problem EE_9^1 have expansion factor at most 4. Moreover, among those, the ones who minimize the induced energy consumption makes robots move at speed 1 in the first and third phase[2]. Robot's speed in the second phase will be denoted by s.

We now present a specific 3-phase exploration algorithm, that we denote by $\mathcal{A}(s)$, complying with the above conditions, with phases $(-1, 1), (4s/(1-s), s)$ and $(4-4s/(1-s), 1)$, where s is an exploration speed to be determined later. Robot L will execute the 3-phase exploration with starting position -1, while robot R with starting position 2. When subroutine $travel(v, p)$ is invoked, the robot sets its speed to v and, from its current position, goes toward position p on the line until it reaches it. We depict the trajectories of the robots while in the Exploration State in Figure 1.

EXPLORATION STATE OF L
$travel(1/3, -1)$
$k \leftarrow 0$
repeat
  $travel(1, 0)$
  $travel(s, -4^{k+1} \cdot \frac{s}{1-s})$
  $travel(1, -4^{k+1})$
  $k \leftarrow k + 1$
end

EXPLORATION STATE OF R
$travel(1/3, 2)$
$k \leftarrow 0$
repeat
  $travel(1, 0)$
  $travel(s, 2 \cdot 4^{k+1} \cdot \frac{s}{1-s})$
  $travel(1, 2 \cdot 4^{k+1})$
  $k \leftarrow k + 1$
end

[2] The proof of these facts is lengthy and technical, and is not required for the correctness of our algorithm, rather it only justifies some parameter choices

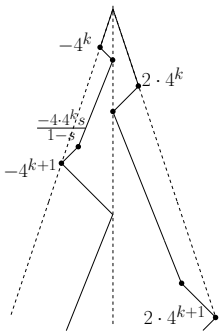

Figure 1 A representation of position (x-axis, vertical dashed line is 0) and time (y-axis), and the trajectory followed by the two robots (solid lines). The two diagonal dashed lines form the "1/3 cone" of Theorem 10.

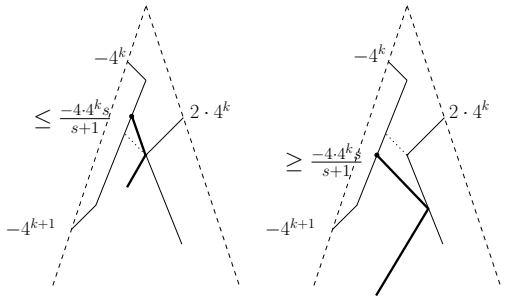

Figure 2 The robots' behavior when the exit is found by L is indicated by the bold line. In the first case (left), the catch-up speed is slower than 1 (and the rendezvous is realized at the turning point of the non-finder), whereas it is 1 in the second case (right).

A complete execution of one repeat loop within the Exploration State will be referred to as a *round*. Variable k counts the number of completed rounds. Each robot stays in the Exploration State till the exit it found. When switching to the Chasing state (which happens only for the exit finder), robot remembers its current value of counter k, as well as the distance d of the exit to the origin. Based on these values (as well as s) it calculates the most efficient trajectory in order to catch the other robot (predicting, when applicable, that the rendezvous can be realized while the other robot is approaching the exit finder). When the rendezvous is realized, robots store their current distance p to the origin, as well as the time t that has already passed. Then, robots need to travel distance $p + d$ to reach the exit. Knowing they have time $9d - t$ remaining, they go to the exit together as slow as possible to reach the exit in time exactly $9d$. Figure 2 provides an illustration of the behavior of the robots after finding the exit.

Chasing State
$K \leftarrow 4^k$
if *I am R* **then**
  $K \leftarrow 2 \cdot 4^k$
end
$s' \leftarrow \min\left\{\frac{d}{4K - d/s}, 1\right\}$
Travel toward the other robot at speed s' until meeting it at distance p from the origin, and at time t.

Exit State
$\bar{s} \leftarrow \frac{p+d}{9d-t}$
Go toward the exit with speed $\bar{s}$.

4.3 Performance Analysis & an Optimal Choice for Parameter s

In this section we are ready to provide the details for proving Theorem 16. Evacuation algorithm $\mathcal{A}(s)$ is not feasible to EE_c^b for all values of speed parameter s (of the Exploration States). We will show later that trajectories induce evacuation time at most $9d$ only if $s \in [1/3, 1/2]$. In what follows, and even though we have not fixed the value of s yet, we

will assume that s has some value between $1/3$ and $1/2$. The purpose of this section is to fix a value for parameter s, show that $\mathcal{A}(s)$ is feasible to EE_9^1, and subsequently compute the induced energy consumption and competitive ratio. As a reminder, each iteration of the repeat loop of the Exploration States is called a round, and k is a counter for these rounds.

▶ **Proposition 11.** *For every $k \geq 0$, and at the start of its k-th round,*
- *robot L is at position -4^k at time $3 \cdot 4^k$, and*
- *robot R, is at position $2 \cdot 4^k$ at time $6 \cdot 4^k$.*

Let $X \in \{L, R\}$ be one of the robots. We define $K(X,k) = 4^k$ if $X = L$, and $K(X,k) = 2 \cdot 4^k$ if $X = R$, i.e. the position of X at the start of round k. We will often analyze 3 cases for the distance d of the exit with respect to $K := K(X,k)$ (as it also appears in the description of the Chasing State), associated with the following closed intervals

$$D_1(K) := [K, 4Ks/(s+1)],\ D_2(K) := [4Ks/(s+1), 4Ks/(1-s)],\ D_3(K) := [4Ks/(1-s), 4K].$$

We may simply write D_1, D_2 and D_3 if K is clear from the context. Note that during the second phase of round K, robot L explores D_1 and D_2, whereas D_3 is explored during the third phase. The same statement holds for R. The following lemma will be useful in analyzing the worst case evacuation time and energy consumption of our algorithm.

▶ **Lemma 12.** *Suppose that robot $X \in \{L, R\}$ finds the exit at distance d when its round counter has value k. Let p and t be, respectively, the position and time at which X first meets with the other robot after having found the exit, and set $K := K(X,k)$. Then the following hold:*
1. *If $d \in D_1$, then $p = 0$ and $t = 8K$.*
2. *If $d \in D_2$, then $|p| = \frac{d+ds-4Ks}{1-s}$ and $t = 8K + \frac{d+d/s-4K}{1-s}$.*
3. *If $d \in D_3$, then $|p| = 2ds/(1-s)$ and $t = 8K + 2d + 2ds/(1-s)$.*

Using the lemma above, we can now prove that $\mathcal{A}(s)$ meets the speed bound and the evacuation time bound.

▶ **Lemma 13.** *For any $s \in [1/3, 1/2]$, evacuation algorithm $\mathcal{A}(s)$ is feasible to EE_9^1.*

Lemma 12 allows us to derive the speed s_{b1}, s_{b2} and s_{b3} at which both robots go toward the exit after meeting for the cases $d \in D_1, d \in D_2$ and $d \in D_3$, respectively. We also know the speed s_{c1} at which the exit-finder catches up to the other robot when $d \in D_1$. We define

$$s_{b1} := \tfrac{d}{9d-8K},\quad s_{c1} = \tfrac{d}{4K-d/s},\quad s_{b2} := \tfrac{2d-4Ks}{d(8-9s-1/s)+4K(2s-1)},\quad s_{b3} := \tfrac{d(1+s)}{d(7-9s)+8K(s-1)}$$

The speed s_{b2} is a simple rearrangement of the speed $\frac{d+qs}{9d-(8K+q)}$, where $q = \frac{d+d/s-4K}{1-s}$, and s_{b3} is obtained by rearranging $\frac{d+2ds/(1-s)}{9d-(8K+2d+2ds/(1-s))}$.

Next we compute the energy consumption. For given K, d and s, denote by $E_L(K,d,s)$ the energy spent by robot L from time 3 to time $9d$ when it exits. Similarly, $E_R(K,d,s)$ is the energy spent by R from time 6 to time $9d$. Then, the energy consumption is $E(K,d,s) := \frac{1}{3} + E_L(K,d,s) + E_R(K,d,s)$. For any K and s, we also define $F(K,s) := (K-1)(5-4s(s+1))$.

▶ **Lemma 14.** *Suppose that robot $X \in \{L, R\}$ finds the exit at distance d when its round counter has value k, and let $K := K(X,k)$. Then*

$$E(K,d,s) = \frac{1}{3} + \begin{cases} F(K,s) + 3K + d(s^2 + s_{c1}^2 + 2s_{b1}^2) & \text{if } d \in D_1 \\ F(K,s) + 3K + \left(\dfrac{2d-4Ks}{1-s}\right)(1 + s^2 + 2s_{b2}^2) & \text{if } d \in D_2 \\ F(K,s) + 3K - 4Ks(s+1) + \dfrac{2d}{1-s}(s^3 + s_{b3}^2(s+1) + 1) & \text{if } d \in D_3. \end{cases}$$

Denote by $E_i(k,d,s)$ the value of $E(K,d,s)$ when $d \in D_i$, $i = 1,2,3$. Our intension now is to fix speed value s that solves the following Nonlinear Program

$$\min_{s\in[1/3,1/2]} \left\{ \max \left\{ \sup_{d\in D_1, k\geq 1, X} \frac{E_1(K,d,s)}{d}, \sup_{d\in D_2, k\geq 1, X} \frac{E_2(K,d,s)}{d}, \sup_{d\in D_3, k\geq 1, X} \frac{E_3(K,d,s)}{d} \right\} \right\}.$$

For every $s \in [1/3, 1/2]$ we show in Lemma 15 that $\frac{E_1(K,d,s)}{d}$ is decreasing in $d \in D_1$, that $\frac{E_2(K,d,s)}{d}$ is increasing in $d \in D_2$, and that $\frac{E_3(K,d,s)}{d}$ is decreasing in $d \in D_3$. Then, the best parameter s can be chosen so as to make all worst case valued $\frac{E_i(K,d,s)}{d}$ equal (if possible) when $i = 1,2,3$. The optimal s can be found by numerically finding the roots of a high degree polynomial, and accordingly, we heuristically set $s = 0.39403$, inducing the best possible energy consumption for algorithm $\mathcal{A}(s)$. All relevant formal arguments are within the proof of the next lemma.

▶ **Lemma 15.** *On instance d of EE_9^1, algorithm $\mathcal{A}(s)$ induces energy consumption at most $8.42588d$, when $s = 0.39403$.*

By Lemma 15, we conclude that for the specific value of s, algorithm $\mathcal{A}(s)$ has competitive ratio $\frac{9^2}{2} 8.42588 \approx 341.24814$, concluding the proof of Theorem 16.

▶ **Theorem 16.** *For every $c, b > 0$ with $cb = 9$, there is an evacuation algorithm for unbounded-memory autonomous robots solving EE_c^b inducing energy consumption $8.42588b^2 d$ for instances d, and competitive ratio 341.24814.*

5 Discussion

The main contribution of our paper was to introduce an energy consumption model appropriate to linear search and investigate how the F2F communication model affects time/energy trade-offs until completion of the search by two robots, considering two different computational capabilities for the robots. Our approach inspired new algorithms that take better account of the impact of the change in the speed of the robots during the course of the search and leads to better understanding through evaluation of trade-offs of the overall performance of the algorithms.

Our paper raises several interesting problems worth investigating. In addition to improving the trade-offs in the algorithms proposed, one may wish to pursue new avenues for research by examining additional search domains, like the unit disk, in the spirit of [18]. It would also be natural to consider more realistic models of linear search with multiple agents some of which may be faulty [23, 25]. Further, it would be interesiting to investigate randomized search algorithms in our setting as well as more general models in which the energy loss experienced by a robot traveling a distance x at constant speed s is given by $s^a x$, for some fixed positive exponent a.

Abstract

We study the problem of finding an exact solution to the consensus halving problem. While recent work has shown that the approximate version of this problem is PPA-complete [28, 29], we show that the exact version is much harder. Specifically, finding a solution with n agents and n cuts is FIXP-hard, and deciding whether there exists a solution with fewer than n cuts is ETR-complete. We also give a QPTAS for the case where each agent's valuation is a polynomial.

Along the way, we define a new complexity class BU, which captures all problems that can be reduced to solving an instance of the Borsuk-Ulam problem exactly. We show that FIXP $\subseteq$ BU $\subseteq$ TFETR and that LinearBU = PPA, where LinearBU is the subclass of BU in which the Borsuk-Ulam instance is specified by a linear arithmetic circuit.

1 Introduction

Dividing resources among agents in a fair manner is among the most fundamental problems in multi-agent systems [16]. Cake cutting [6, 8, 7, 15], and rent division [14, 33, 25] are prominent examples of problems that lie in this category. At their core, each of these problems has a desired solution whose existence is usually proved via a theorem from algebraic topology such as Brouwer's fixed point theorem, Sperner's lemma, or Kakutani's fixed point theorem.

In this paper, we focus on a fair-division problem called *consensus-halving*: an object A represented by $[0, 1]$ is to be divided into two halves A_+ and A_-, so that n agents agree that A_+ and A_- have the same value. Provided the agents have bounded and continuous

valuations over A, this can always be achieved using at most n cuts, and this fact can be proved via the Borsuk-Ulam theorem from algebraic topology [44]. The necklace splitting and ham-sandwich problems are two other examples of fair-division problems for which the existence of a solution can be proved via the Borsuk-Ulam theorem [4, 5, 37].

Recent work has further refined the complexity status of *approximate* consensus halving, in which we seek a division of the object so that every agent agrees that the values of A_+ and A_- differ by at most ϵ. Since the problem always has a solution, it lies in TFNP, which is the class of function problems in NP that always have a solution. More recent work has shown that the problem is PPA-complete [28], even for ϵ that is inverse-polynomial in n [29]. The problem of deciding whether there exists an approximate solution with k-cuts when $k < n$ is NP-complete [27]. These results are particularly notable, because they identify consensus halving as one of the first natural PPA-complete problems.

While previous work has focused on approximate solutions to the problem, in this paper we study the complexity of solving the problem *exactly*. For problems in the complexity class PPAD, which is a subclass of both TFNP and PPA, prior work has found that there is a sharp contrast between exact and approximate solutions. For example, the Brouwer fixed point theorem is the theorem from algebraic topology that underpins PPAD. Finding an approximate Brouwer fixed point is PPAD-complete [37], but finding an exact Brouwer fixed point is complete for (and the defining problem of) a complexity class called FIXP [26].

It is believed that FIXP is significantly harder than PPAD. While PPAD $\subseteq$ TFNP $\subseteq$ FNP, there is significant doubt about whether FIXP $\subseteq$ FNP. The reason for this is that there are Brouwer instances for which all solutions are irrational. This is not particularly relevant when we seek an approximate solution, but is a major difficulty when we seek an exact solution. For example, the square-root-sum problem asks us to decide for integers a_1, a_2, $\ldots$, a_n, t, whether $\sum_{i=1}^{n} \sqrt{a_i} \leq t$. This deceptively simple problem is not known to lie in NP, and can be reduced to the problem of finding an exact Brouwer fixed point [26], which provides evidence that FIXP may be significantly harder than FNP.

Our contribution. In this paper, we study the complexity of solving the consensus halving problem exactly. In our formulation of the problem, the valuation function of the agents is presented as an arbitrary arithmetic circuit, and the task is to cut A such that all agents agree that A_+ and A_- have exactly the same valuation. We study two problems. The (n, n)-Consensus Halving problem asks us to find an exact solution for n-agents using at most n-cuts, while the (n, k)-Consensus Halving problem asks us to decide whether there exists an exact solution for n-agents using at most k-cuts, where $k < n$.

Our results for (n, n)-Consensus Halving are intertwined with a new complexity class that we call BU. This class consists of all problems that can be reduced in polynomial time to the problem of finding a solution of the Borsuk-Ulam problem. We show that (n, n)-Consensus Halving lies in BU, and is FIXP hard. The hardness for FIXP implies that the exact variant of consensus halving is significantly harder than the approximate variant: while the approximate problem is PPA-complete, the exact variant is unlikely to be in FNP.

We show that (n, k)-Consensus Halving is ETR-complete. The complexity class ETR consists of all decision problems that can be formulated in the *existential theory of the reals*. It is known that NP $\subseteq$ ETR $\subseteq$ PSPACE [17], and it is generally believed that ETR is distinct from the other two classes. So our result again shows that the exact version of the problem seems to be much harder than the approximate version, which is NP-complete [27].

Just as FIXP can be thought of as the exact analogue of PPAD, we believe that BU is the exact analogue of PPA, and we provide some evidence to justify this. It has been shown that LinearFIXP = PPAD [26], which is the version of the class in which arithmetic circuits are

restricted to produce piecewise *linear* functions (FIXP allows circuits to compute piecewise polynomials). We likewise define LinearBU, which consists of all problems that can be reduced to a solution of a Borsuk-Ulam problem using a piecewise linear function, and we show that LinearBU = PPA.

The containment LinearBU ⊆ PPA can be proved using similar techniques to the proof that LinearFIXP ⊆ PPAD. However, the proof that PPA ⊆ LinearBU utilises our BU containment result for consensus halving. In particular, when the input to the consensus halving problem is a piecewise linear function, our containment result shows that the problem actually lies in LinearBU. The PPA-hardness results for consensus halving show that piecewise-linear-consensus halving is PPA-hard, which completes the containment [28, 29].

Finally, we show that, for the case where each agent has a non-piecewise polynomial valuation of constant (resp. $O(\log n)$) degree, an approximate solution to the problem can be found using $O(\log n)$ (resp. $O(poly \log n)$) cuts, which then yields a QPTAS for the problem.

For detailed proofs of the results presented, we refer the reader to the full version [22].

Related work. Although for a long period there were a few results about PPA, recently there has been a flourish of PPA-completeness results. The first PPA-completeness result was given by [32] who showed PPA-completeness of the Sperner problem for a non-orientable 3-dimensional space. In [30] this result was strengthened for a non-orientable and locally 2-dimensional space. In [3], 2-dimensional Tucker was shown to be PPA-complete; this result was used in [28, 29] to prove PPA-completeness for approximate consensus halving. In [23] PPA-completeness was proven for a special version of Tucker and for problems of the form "given a discrete fixed point in a non-orientable space, find another one". Finally, in [24] it was shown that octahedral Tucker is PPA-complete. In [35], a subclass of 2DLinearFIXP ⊆ FIXP that consists of 2-dimensional fixed-point problems was studied, and it was proven that 2DLinearFIXP = PPAD.

A large number of problems are now known to be ETR-complete: geometric intersection problems [34, 39], graph-drawing problems [1, 9, 18, 40], matrix factorization problems [42, 43], the Art Gallery problem [2], and deciding the existence of constrained (symmetric) Nash equilibria in (symmetric) normal form games with at least three players [10, 11, 12, 13, 31].

2 Preliminaries

2.1 Arithmetic circuits

An arithmetic circuit represents a continuous function $f : \mathbb{R}^n \to \mathbb{R}^m$, and is defined by a pair $(V, \mathcal{T})$, where V is a set of nodes and $\mathcal{T}$ is a set of gates. There are n nodes in V that are *input nodes*, and m nodes in V that are *output nodes*. When a value $x \in \mathbb{R}^n$ is presented at the input nodes, the circuit computes values for all other nodes $v \in V$, which we will denote as $x[v]$. The values of $x[v]$ for the m output nodes determine the value of $f(x) \in \mathbb{R}^m$.

Every node in V, other than the input nodes, is required to be the output of exactly one gate in $\mathcal{T}$. Each gate $g \in \mathcal{T}$ enforces an arithmetic constraint on its output node, based on the values of some other node in the circuit. Cycles are not allowed in these constraints. We allow the operations $\{\zeta, +, -, *\zeta, *, \max, \min\}$, which correspond to the gates shown in Table 1. Note that every gate computes a continuous function over its inputs, and thus any function f that is represented by an arithmetic circuit of this form is also continuous.

We study two types of circuits in this paper. *General* arithmetic circuits are allowed to use any of the gates that we have defined above. *Linear* arithmetic circuits allow only the operations $\{\zeta, +, -, *\zeta, \max, \min\}$, and the $*$ operation (multiplication of two variables) is disallowed. Observe that a linear arithmetic circuit computes a piecewise linear function.

Table 1 The types of gates and their constraints.

Gate	Constraint
$G_\zeta(\zeta, v_{out})$	$x[v_{out}] = \zeta$, where $\zeta \in \mathbb{Q}$
$G_+(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = x[v_{in1}] + x[v_{in2}]$
$G_-(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = x[v_{in1}] - x[v_{in2}]$
$G_{*\zeta}(\zeta, v_{in}, v_{out})$	$x[v_{out}] = x[v_{in1}] \cdot \zeta$, where $\zeta \in \mathbb{Q}$
$G_*(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = x[v_{in1}] \cdot x[v_{in2}]$
$G_{\max}(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = \max\{x[v_{in1}], x[v_{in2}]\}$
$G_{\min}(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = \min\{x[v_{in1}], x[v_{in2}]\}$

2.2 The Consensus Halving problem

In the consensus halving problem there is an object A that is represented by the $[0, 1]$ line segment, and there are n agents. We wish to divide A into two (not necessarily contiguous) pieces such that every agent agrees that the two pieces have equal value. Simmons and Su [44] have shown that, provided the agents have bounded and continuous valuations over A, then we can find a solution to this problem using at most n cuts.

In this paper we consider instances of the consensus halving problem where the valuations of the agents are presented as arithmetic circuits. Each agent has a valuation function $f_i : [0, 1] \to \mathbb{R}$, but it is technically more convenient if they give us a representation of the *integral* of this function. So for each agent i, we are given an arithmetic circuit computing $F_i : [0, 1] \to \mathbb{R}$ where for all $x \in [0, 1]$ we have $F_i(x) = \int_0^x f(y)\, dy$. Then, the value of any particular segment of $[a, b]$ to agent i can be computed as $F_i(b) - F_i(a)$.

A solution to the consensus halving problem is given by a *k-cut* of the object A, which is defined by a vector of *cut-points* $(t_1, t_2, \ldots, t_k) \in [0, 1]^k$, and a vector of *signs* $(s_1, s_2, \ldots, s_{k+1}) \in \{-1, +1\}^{k+1}$. The cut-points t_i split A into up to $k + 1$ pieces. Note that they may in fact split A into fewer than $k + 1$ pieces in the case where two cut-points $t_i = t_j$ overlap. We define X_i to be the ith piece of A, meaning that $X_0 = [0, t_1]$, $X_i = [t_i, t_{i+1}]$ for all i in the range $1 \leq i < k$, and $X_k = [t_k, 1]$.

The sign vector determines which half of A the piece belongs to. We define $A_+ := \{X_i : s_i = +1\}$ and $A_- := \{X_i : s_i = -1\}$ to be the two halves. For each agent i, we denote the value A_+ to agent i as $F_i(A_+) := \sum_{[a,b] \in A_+} (F_i(b) - F_i(a))$, and we define $F_i(A_-)$ analogously. The k-cut is a solution to the consensus halving problem if $F_i(A_+) = F_i(A_-)$ for all agents i.

We define two computational problems. Simmons and Su [44] have proved that there always exists a solution using at most n-cuts, and our first problem is to find that solution.

(n, n)-Consensus Halving

Input: For every agent $i \in [n]$, an arithmetic circuit F_i computing the integral of agent i's valuation function.
Task: Find an n-cut for A such that $F_i(A_+) = F_i(A_-)$, for every agent $i \in [n]$.

For $k < n$ a solution to the problem may or may not exist. So we define the following decision variant of the problem.

(n, k)-Consensus Halving

Input: For every agent $i \in [n]$, an arithmetic circuit F_i computing the integral of agent i's valuation function.
Task: Decide whether there exists a k-cut for A such that $F_i(A_+) = F_i(A_-)$, for every agent $i \in [n]$.

For either of these two problems, if all of the inputs are represented by linear arithmetic circuits, then we refer to the problem as Linear Consensus Halving. We note that the known hardness results [27, 28] for consensus halving fall into this class. Specifically, those results produce valuations that are piecewise constant, and so the integral of these functions is piecewise linear, and these functions can be written down as linear arithmetic circuits [36].

3 The Class BU

The Borsuk-Ulam theorem states that every continuous function from the surface of an $(d+1)$-dimensional sphere to the d-dimensional Euclidean space maps at least one pair of antipodal points to the same point.

▶ **Theorem 1** (Borsuk-Ulam). *Let $f : S^d \to \mathbb{R}^d$ be a continuous function, where S^d is a $(d+1)$-dimensional sphere. Then, there exists an $x \in S^d$ such that $f(x) = f(-x)$.*

This theorem actually works for any domain D that is antipode-preserving homeomorphism of S^d, where by "antipode-preserving" we mean that for every $x \in D$ we have that $-x \in D$. In this paper, we choose S^d to be the sphere in $d+1$ dimensions with respect to L_1 norm: $S^d := \left\{x \mid x = (x_1, x_2, \ldots, x_{d+1}),\ \sum_{i=1}^{d+1} |x_i| = 1\right\}$.

We define the *Borsuk-Ulam* problem as follows.

Borsuk-Ulam

Input: A continuous function $f : \mathbb{R}^{d+1} \to \mathbb{R}^d$ presented as an arithmetic circuit.
Task: Find an $x \in S^d$ such that $f(x) = f(-x)$.

Note that we cannot constrain an arithmetic circuit to only take inputs from the domain S^d, so we instead put the constraint that $x \in S^d$ onto the solution.

The complexity class BU is defined as follows.

▶ **Definition 2** (BU). *The complexity class* BU *consists of all search problems that can be reduced to* Borsuk-Ulam *in polynomial time.*

3.1 LinearBU

When the input to a Borsuk-Ulam instance is a linear arithmetic circuit, then we call the problem Linear Borsuk-Ulam, and we define the class LinearBU as follows.

▶ **Definition 3** (LinearBU). *The complexity class* LinearBU *consists of all search problems that can be reduced to* Linear Borsuk-Ulam *in polynomial time.*

We will show that LinearBU = PPA. The proof that LinearBU $\subseteq$ PPA is similar to the proof that Etessami and Yannakakis used to show that LinearFIXP $\subseteq$ PPAD [26], while the fact that PPA $\subseteq$ LinearBU will follow from our results on consensus halving in Section 4.

To prove LinearBU $\subseteq$ PPA we will reduce to the *approximate* Borsuk-Ulam problem. It is well known that the Borsuk-Ulam theorem can be proved via Tucker's lemma, and Papadimitriou noted that this implies that finding an approximate solution to a Borsuk-Ulam problem lies in PPA [37]. This is indeed correct, but the proof provided in [37] is for a slightly different problem[1]. Since our results will depend on this fact, we provide our own definition and self-contained proof here. We define the approximate Borsuk-Ulam problem as follows.

ϵ-Borsuk-Ulam

Input: A continuous function $f : \mathbb{R}^{d+1} \to \mathbb{R}^d$ presented as an arithmetic circuit, along with two constants $\epsilon, \lambda \in \mathbb{R}$.
Task: Find one of the following.
1. A point $x \in S^d$ such that $\|f(x) - f(-x)\|_\infty \leq \epsilon$.
2. Two points $x, y \in S^d$ such that $\|f(x) - f(y)\|_\infty > \lambda \cdot \|x - y\|_\infty$.

The first type of solution is an approximate solution to the Borsuk-Ulam problem, while the second type of solution consists of any two points that witness that the function is not λ-Lipschitz continuous in the L_∞-norm. The second type of solution is necessary, because an arithmetic circuit is capable, through repeated squaring, of computing doubly-exponentially large numbers, and the reduction to Tucker may not be able to find an approximate solution for such circuits. We now re-prove the result of Papadimitriou in the following lemma.

▶ **Lemma 4** ([37]). *ϵ-Borsuk-Ulam is in PPA.*

To show that LinearBU $\subseteq$ PPA we will provide a polynomial time reduction from Linear Borsuk-Ulam to ϵ-Borsuk-Ulam. To do this, we follow closely the technique used by Etessami and Yannakakis to show that LinearFIXP $\subseteq$ PPAD [26]. The idea is to make a single call to ϵ-Borsuk-Ulam to find an approximate solution to the problem for a suitably small ϵ, and to then round to an exact solution by solving a linear program. To build the LP, we depend on the fact that we have access to the linear arithmetic circuit that represents f.

▶ **Lemma 5.** *Linear Borsuk-Ulam is in PPA.*

4 Containment Results for Consensus Halving

4.1 (n, n)-Consensus Halving is in BU and LinearBU = PPA

We show that (n, n)-Consensus Halving is contained in BU. Simmons and Su [44] show the existence of an n-cut solution to the consensus halving problem by applying the Borsuk-Ulam theorem, and we follow their approach in this reduction. However, we must show that the approach can be implemented using arithmetic circuits. We take care in the reduction to avoid G_* gates, and so if the inputs to the problem are all linear arithmetic circuits, then our reduction will produce a Linear Borsuk-Ulam instance. Hence, we also show that (n, n)-Linear Consensus Halving is in LinearBU.

▶ **Theorem 6.** *The following two containments hold.*
- (n, n)-Consensus Halving *is in* BU.
- (n, n)-Linear Consensus Halving *is in* LinearBU.

[1] The problem used in [37] presents the function as a polynomial-time Turing machine rather than an arithmetic circuit, and the Lipschitzness of the function is guaranteed by constraining the values that it can take.

We note that this also implies that PPA $\subseteq$ LinearBU, thereby completing the proof that PPA = LinearBU. Specifically, Filos-Ratsikas and Goldberg have shown that *approximate*-(n, n)-Consensus Halving is PPA-complete, and their valuation functions are piecewise constant. Therefore, the integrals of these functions are piecewise linear, and so their approximate-(n, n)-Consensus Halving instances can be reduced to (n, n)-Linear Consensus Halving. Hence (n, n)-Linear Consensus Halving is PPA-hard, which along with Lemma 5 implies the following corollary.

▶ **Corollary 7.** PPA = LinearBU.

4.2 (n, k)-Consensus Halving is in ETR

The existential theory of the reals consists of all true existentially quantified formulae using the connectives $\{\wedge, \vee, \neg\}$ over polynomials compared with the operators $\{<, \leq, =, \geq, >\}$. The complexity class ETR captures all problems that can be reduced in polynomial time to the existential theory of the reals.

We prove that (n, k)-Consensus Halving is in ETR. The reduction simply encodes the arithmetic circuits using ETR formulas, and then constrains $F_i(A_+) = F_i(A_-)$ for every agent i.

▶ **Theorem 8.** (n, k)-Consensus Halving *is in* ETR.

Using the same technique, we can also reduce Borsuk-Ulam to an ETR formula. In this case, we get an ETR formula that always has a solution, and so this result places the problem in TFETR, which is the subclass of ETR in which the formula is guaranteed to be true.

▶ **Theorem 9.** BU $\subseteq$ TFETR.

5 Hardness Results for Consensus Halving

In this section we prove that (n, n)-Consensus Halving is FIXP-hard and that $(n, n-1)$-Consensus Halving is ETR-hard. These two reductions share a common step of embedding an arithmetic circuit into a consensus halving instance. So we first describe this step, and then move on to proving the two individual hardness results.

5.1 Embedding a circuit in a Consensus Halving instance

Our approach is inspired by [27], who provided a reduction from ϵ-GCircuit [19, 38] to approximate consensus halving. However, our construction deviates significantly from theirs due to several reasons.

Firstly, the reduction in [27] works *only* for approximate consensus halving. Specifically, some valuations used in that construction have the form of $1/\epsilon$, where ϵ is the approximation guarantee, so the construction is not well-defined when $\epsilon = 0$ as it is in our case. Many of the gate gadgets used in [27] cannot be used due to this issue, including the max gate, which is crucially used in that construction to ensure that intermediate values do not get too large. We provide our own implementations of the broken gates. Our gate gadgets only work when the inputs and outputs lie in the range $[0, 1]$, and so we must carefully construct circuits for which this is always the case. The second major difference is that the reduction in [27] does not provide any method of multiplying two variables, which is needed in our case. We construct a gadget to do this, based on a more primitive gadget for squaring a single variable.

Table 2 The special types of gates, their constraints and ranges of input.

Special Gate	Constraint	Ranges
$G_{()^2}(v_{in}, v_{out})$	$x[v_{out}] = (x[v_{in}])^2$	$x[v_{in}] \in [0,1]$
$G_{*2}^{[0,1]}(v_{in}, v_{out})$	$x[v_{out}] = x[v_{in}] \cdot 2$	$x[v_{in}] \in [0,1/2]$
$G_{-}^{[0,1]}(v_{in1}, v_{in2}, v_{out})$	$x[v_{out}] = \max\{x[v_{in1}] - x[v_{in2}], 0\}$	$x[v_{in1}], x[v_{in2}] \in [0,1]$

Special circuit. Our reduction from an arithmetic circuit to consensus halving will use a very particular subset of gates. Specifically, we will not use $G_{\min}$, $G_{\max}$, or G_*, and we will restrict $G_{*\zeta}$ so that ζ must lie in $(0,1]$. We do however introduce three new gates, shown in Table 2. The gate $G_{()^2}$ squares its input, the gate $G_{*2}^{[0,1]}$ multiplies its input by two, but requires that the input be in $[0,1/2]$, and the gate $G_{-}^{[0,1]}$ is a special minus gate that takes as inputs $a, b \in [0,1]$ and outputs $\max\{a-b,0\}$. We note that $G_{\min}$, $G_{\max}$, and G_* can be implemented in terms of our new gates according to the following identities.

$$\max\{a,b\} = \frac{a+b}{2} + \frac{|a-b|}{2} = \frac{a}{2} + \frac{b}{2} + \frac{1}{2}\max\{a-b,0\} + \frac{1}{2}\max\{b-a,0\},$$

$$\min\{a,b\} = \frac{a+b}{2} - \frac{|a-b|}{2} = \frac{a}{2} + \frac{b}{2} - \frac{1}{2}\max\{a-b,0\} - \frac{1}{2}\max\{b-a,0\},$$

$$a \cdot b = 2\left[\left(\frac{a}{2} + \frac{b}{2}\right)^2 - \left(\left(\frac{a}{2}\right)^2 + \left(\frac{b}{2}\right)^2\right)\right].$$

Also, a very important requirement of the special circuit is that both inputs of any G_+ gate are in $[0,1/2]$. To make sure of that, we downscale the inputs before reaching the gate, and upscale the output, using the fact that $a + b = (a/2 + b/2) \cdot 2$.

The reduction to consensus halving. The reduction follows the general outline of the reduction given in [27]. The construction is quite involved, and so we focus on the high-level picture here. Each gate is implemented by 4 agents, namely ad, mid, cen, ex in the consensus halving instance. The values computed by the gates are encoded by the positions of the cuts that are required in order to satisfy these agents. Agent ad performs the exact mathematical operation of the gate, and feeds the outcome in mid, who "trims" it in accordance with the gate's actual operation. Then mid feeds her outcome to cen and ex, who make a copy of mid's correct value of the gate, with "negative" and "positive" labels respectively. This value with the appropriate label will be input to other gates.

The most important agents are the ones that perform the mathematical operation of each gate, i.e. agents ad. Figure 1 shows the part of the valuation functions of these agents that perform the operation. Each figure shows a valuation function for one of the agents, meaning that the blue regions represent portions of the object that the agent desires. The agent's valuation for any particular interval is the integral of this function over that interval.

To understand the high-level picture of the construction, let us look at the construction for $G_{*\zeta}$. The precise valuation functions of the agents in the construction ensure that there is exactly one *input* cut in the region v_{in}^+. The leftmost piece due to that cut in that region will belong to A_+, while the rightmost will belong to A_-. It is also ensured that there is exactly one *output* cut in the region v_{out}^a, and that the first piece in that region will belong to A_- and the second will belong to A_+.

Suppose that gate g_i in the circuit is of type $G_{*\zeta}$ and we want to implement it through a Consensus Halving instance. If we treat v_{in}^+ and v_{out}^a in Figure 1 as representing $[0,1]$, then agent ad_i will take as input a cut at point $x \in v_{in}^+$. In order to be satisfied, ad_i will

Gate	$\mathbf{G}_\pi(\mathbf{t})$	Valuation function
$\mathbf{G}_\zeta$	$\begin{cases} 1 & \textbf{if } t \in [v^a_{out,l} + \zeta - \frac{1}{2}, v^a_{out,l} + \zeta + \frac{1}{2}] \\ 0 & \textbf{otherwise} \end{cases}$	$\mathbf{G}_{*\zeta}$	$\begin{cases} 1 & \textbf{if } t \in v^+_{in} \\ 1/\zeta & \textbf{if } t \in [v^a_{out,l}, v^a_{out,l} + \zeta] \\ 0 & \textbf{otherwise} \end{cases}$	$\mathbf{G}_+$	$\begin{cases} 1 & \textbf{if } t \in [v^+_{in1,l}, v^+_{in1,l} + \frac{1}{2}] \\ 1 & \textbf{if } t \in [v^+_{in2,l}, v^+_{in2,l} + \frac{1}{2}] \\ 1 & \textbf{if } t \in v^a_{out} \\ 0 & \textbf{otherwise} \end{cases}$	$\mathbf{G}_{()^2}$	$\begin{cases} 2(t - v^+_{in,l}) & \textbf{if } t \in v^+_{in} \\ 1 & \textbf{if } t \in v^a_{out} \\ 0 & \textbf{otherwise} \end{cases}$	$\mathbf{G}^{[0,1]}_-$	$\begin{cases} 1 & \textbf{if } t \in v^+_{in1} \\ 1 & \textbf{if } t \in v^-_{in2} \\ 1 & \textbf{if } t \in [v^a_{out,l} - 1, v^a_{out,r}] \\ 0 & \textbf{otherwise} \end{cases}$	$\mathbf{G}^{[0,1]}_{*\mathbf{2}}$	$\begin{cases} 1 & \textbf{if } t \in [v^+_{in,l}, v^+_{in,l} + \frac{1}{2}] \\ 1/2 & \textbf{if } t \in v^a_{out} \\ 0 & \textbf{otherwise} \end{cases}$	
Figure 1 Gates and their corresponding functions $G_\pi(t)$.

impose a cut at point $y \in v^a_{out}$, such that $F_i(A_+) = F_i(A_-)$, where: $F_i(A_+) = x + (\zeta - y)/\zeta$ and $F_i(A_-) = (1 - x) + y/\zeta$. Simple algebraic manipulation can be used to show that ad_i is satisfied only when $y = \zeta \cdot x$, as required.

We show that the same property holds for each of the gates in Figure 1. Two notable constructions are for the gates $G_{()^2}$ and $G^{[0,1]}_-$. For the gate $G_{()^2}$ the valuation function of agent ad is non-constant, which is needed to implement the non-linear squaring function.

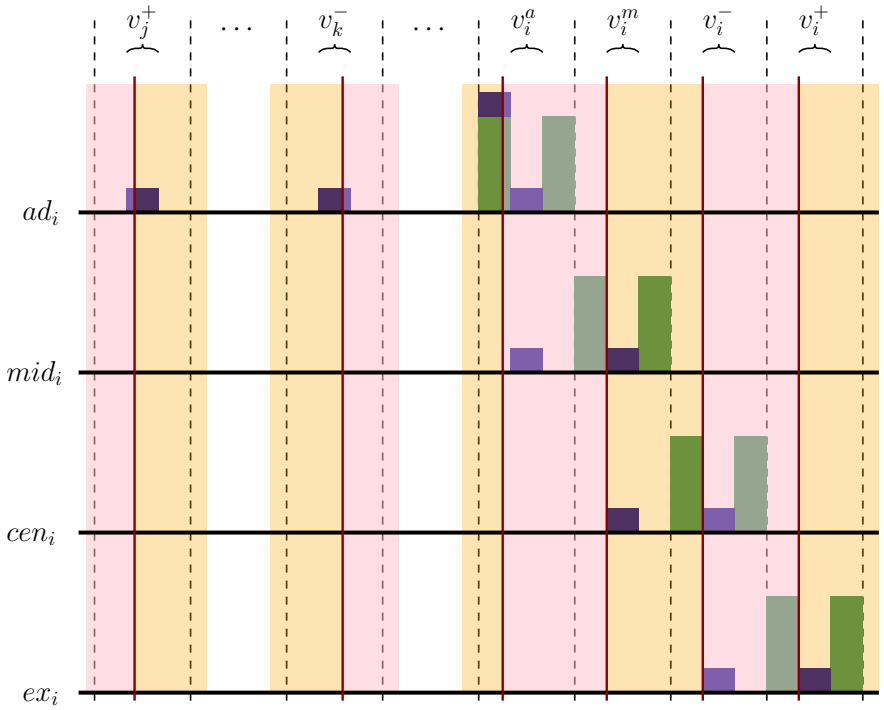

Figure 2 An example where the computation at the output $v_{out} := v_i$ of a $G_-^{[0,1]}$ gate with inputs $v_{in1} := v_j$ and $v_{in2} := v_k$ is simulated by the Consensus Halving instance. Here $x[v_j] = 1/4$ and $x[v_k] = 3/4$, hence $x[v_i] = 0$. The information about the values of the inputs is encoded by the cuts (red lines) in intervals v_j^+, and v_k^- imposed by agents ex_j and cen_k respectively. The blue and green shapes depict the area below the valuation function of each of the 4 agents. The pink regions have label "+" while the yellow have label "−". Agent ad_i performs the subtraction, by demanding that she is satisfied, and places a cut 1/10 to the left of the left endpoint of interval v_i^a. Then agent mid_i gets satisfied by placing a cut at exactly the left endpoint of interval v_i^m, thus encoding the value 0 which is the correct output value of the gate. Finally, agents cen_i, ex_i copy this value by enforcing similar cuts at the left endpoints of intervals v_i^- and v_i^+ respectively. The encoded values in the latter two intervals are the "negative" and "positive" version of $x[v_i]$.

For the gate $G_-^{[0,1]}$, note that the output region v_{out}^a only covers half of the possible output space. The idea is that if the result of $x[v_{in1}] - x[v_{in2}]$ is negative, then the output cut will lie before the output region, which will be interpreted as a zero output by agents mid, cen, ex in the construction. On the other hand, if the result is positive, the result will lie in the usual output range, and will be interpreted as a positive number. An example where $x[v_{in1}] = 1/4$ and $x[v_{in2}] = 3/4$ is shown in Figure 2.

Ultimately, this allows us to construct a consensus-halving instance that implements this circuit. This means that for any $x \in [0,1]^n$, we can encode x as a set of cuts, which then force cuts to be made at each gate gadget that encode the correct output for that gate. The full details of the construction are quite involved, but we are able to show the following result.

▶ **Lemma 10.** *Suppose that we are given an arithmetic circuit with the following properties.*

- *The circuit uses the gates* $G_\zeta, G_+, G_{*\zeta}, G_{()^2}, G_-^{[0,1]}, G_{*2}^{[0,1]}$.
- *Every* G_ζ *and* $G_{*\zeta}$ *has* $\zeta \in \mathbb{Q} \cap (0,1]$.
- *For every input* $x \in [0,1]^n$*, all intermediate values computed by the circuit lie in* $[0,1]$.

We can construct a consensus-halving instance that implements this circuit.

5.2 (n, n)-Consensus Halving is FIXP-hard

We show that (n, n)-Consensus Halving is FIXP-hard by reducing from the problem of finding a Nash equilibrium in a d-player game, which is known to be a FIXP-complete [26]. As shown in [26], this problem can be reduced to the Brouwer fixed point problem: given an arithmetic circuit computing a function $F : [0, 1]^n \to [0, 1]^n$, find a point $x \in [0, 1]^n$ such that $F(x) = x$. In a similar way to [27], we take this circuit and embed it into a consensus halving instance, with the outputs looped back to the inputs. Since Lemma 10 implies that our implementation of the circuit is correct, this means that any solution to the consensus halving problem must encode a point x satisfying $F(x) = x$.

One difficulty is that we must ensure that the arithmetic circuit that we build falls into the class permitted by Lemma 10. To do this, we carefully analyse the circuits produced in [26], and we modify them so that all of the preconditions of Lemma 10 hold.

▶ **Theorem 11.** (n, n)-Consensus Halving *is* FIXP*-hard.*

This theorem, along with Theorem 6 give the following corollary.

▶ **Corollary 12.** FIXP $\subseteq$ BU*.*

5.3 $(n, n-1)$-Consensus Halving is ETR-complete

We will show the ETR-hardness of $(n, n-1)$-Consensus Halving by reducing from the following problem Feasible, which is known to be ETR-complete [41].

▶ **Definition 13** (Feasible, Feasible$_{[0,1]}$)**.** *Let $p(x_1, \ldots, x_m)$ be a polynomial.* Feasible *asks whether there exists a point $(x_1, \ldots, x_m) \in \mathbb{R}^m$ that satisfies $p(x_1, \ldots, x_m) = 0$.* Feasible$_{[0,1]}$ *asks whether there exists a point $(x_1, \ldots, x_m) \in [0, 1]^m$ that satisfies p.*

The idea is to turn the polynomial into a circuit, and then embed that circuit into a consensus halving instance using Lemma 10. As before, the main difficulty is ensuring that the preconditions of Lemma 10 are satisfied. To do this, we must ensure that the the inputs to the circuit take values in $[0, 1]$, which is not the case if we reduce directly from Feasible. Instead, we first consider the problem Feasible$_{[0,1]}$, in which x is constrained to lie in $[0, 1]^n$ rather than $\mathbb{R}^n$, and we show the following result.

▶ **Lemma 14.** Feasible$_{[0,1]}$ *is* ETR*-complete.*

ETR$_{[0,1]}$ is the subclass of ETR in which variables are quantified over $[0, 1]^n$ rather than $\mathbb{R}^n$. The above lemma follows from the fact that ETR$_{[0,1]}$ = ETR, and the fact that Feasible$_{[0,1]}$ is ETR$_{[0,1]}$-hard. This equivalence of classes, together with the completeness of Feasible$_{[0,1]}$ may be of independent interest.

We then proceed to reduce Feasible$_{[0,1]}$ to $(n, n-1)$-Consensus Halving. We still don't quite meet the requirements of Lemma 10, because the intermediate terms may be outside $[0, 1]$. We resolve this by implementing a circuit $p^+(x)$ implementing only the positive terms of $p(x)$ downscaled appropriately, and a circuit $p^-(x)$ implementing the positive terms of $-p(x)$ again downscaled appropriately. The check agent is then satisfied if $p^+(x) = p^-(x)$, which can only occur when $p(x) = 0$.

There will be $n-1$ *choice* agents corresponding to the $(n-1)/4$ nodes of the circuit, who enforce that there is a cut for each of the nodes to the circuit, and together these cuts encode an input x to the polynomial. Each agent introduced by Lemma 10 has an associated cut that is forced by the construction used in that lemma, and these cuts compute the output of the associated gate.

So far, every agent has a corresponding cut that is forced by the construction. There is, however, one final *check* agent who has the following properties.

- If $p(x) = 0$, then the check agent agrees that A has been cut in half without an extra cut being made.
- If $p(x) \neq 0$, then the check agent requires one more cut to be made in order to be satisfied that A has been cut in half.

Hence, if there is a solution to FEASIBLE, then there is a solution to $\text{FEASIBLE}_{[0,1]}$, and there is a $(n-1)$-cut that solves the CONSENSUS HALVING instance. Otherwise there is no such solution.

▶ **Theorem 15.** $(n, n-1)$-CONSENSUS HALVING *is* ETR*-complete.*

6 A QPTAS for Consensus Halving with polynomial valuation functions

In this section we show that an approximate solution to the consensus halving problem can be found in quasi-polynomial time when each agent's valuation function is a single polynomial of constant or even polylogarithmic degree. We will do so by formulating the problem as a formula in the *approximate* existential theory of the reals, and then applying the approximation theorem proved in [20, 21].

Our result implies that these instances can be solved approximately using a polylogarithmic number of cuts. We note that this is one of the most general classes of instances for which we could hope to prove such a result: any instance in which n agents desire completely disjoint portions of the object can only be solved by an n-cut, and piecewise linear functions are capable of producing such a situation. So in a sense, we are exploiting the fact that this situation cannot arise when the agents have non-piecewise polynomial valuation functions.

▶ **Lemma 16.** *For every* CONSENSUS HALVING *instance with n agents, and every $\epsilon > 0$, if each agent's valuation function F_i is a single polynomial of degree at most $O(poly \log n)$, then there exists a k-cut, where $k := O(poly \log n)/\epsilon^4$, and pieces A_+ and A_- such that:*

- *every cut point is a multiple of $1/k = \frac{\epsilon^4}{O(poly \log n)}$;*
- *$|F_i(A_+) - F_i(A_-)| \leq \epsilon$, for every agent i.*

As a consequence, we can perform a brute force search over all possible k-cuts to find an approximate solution, which can be carried out in $n^{O(poly \log n/\epsilon^4)}$ time.

▶ **Theorem 17.** CONSENSUS HALVING *admits a QPTAS when the valuation function of every agent is a single polynomial of degree $O(poly \log n)$.*

Abstract

We consider the problem of finding a treasure at an unknown point of an n-dimensional infinite grid, $n \geq 3$, by initially collocated finite automaton agents (scouts/robots). Recently, the problem has been well characterized for 2 dimensions for deterministic as well as randomized agents, both in synchronous and semi-synchronous models [12, 21]. It has been conjectured that $n+1$ randomized agents are necessary to solve this problem in the n-dimensional grid [17]. In this paper we disprove the conjecture in a strong sense: we show that *three* randomized synchronous agents suffice to explore an n-dimensional grid for *any* n. Our algorithm is optimal in terms of the number of the agents. Our key insight is that a constant number of finite automaton agents can, by their positions and movements, implement a stack, which can store the path being explored. We also show how to implement our algorithm using: four randomized semi-synchronous agents; four deterministic synchronous agents; or five deterministic semi-synchronous agents.

We give a different algorithm that uses 4 deterministic semi-synchronous agents for the 3-dimensional grid. This is provably optimal, and surprisingly, matches the result for 2 dimensions. For $n \geq 4$, the time complexity of the solutions mentioned above is exponential in distance D of the treasure from the starting point of the agents. We show that in the deterministic case, one additional agent brings the time down to a polynomial. Finally, we focus on algorithms that never venture much beyond the distance D. We describe an algorithm that uses $O(\sqrt{n})$ semi-synchronous deterministic agents that never go beyond $2D$, as well as show that any algorithm using 3 synchronous deterministic agents in 3 dimensions, if it exists, must travel beyond $\Omega(D^{3/2})$ from the origin.

1 Introduction

Motivated by the self-organizing behaviour of ants and other social insects, swarm robotics leverages the collective capability of a collection of extremely simple and inexpensive robots. Such robots have very limited computation and communication capabilities, and yet can collectively perform seemingly complex tasks such as: forage for food [14]; form patterns [26]; pull heavy objects [23]; and play *Für Elise* on the piano [15].

A series of recent papers [24, 22, 21, 12, 17] studies the conditions required for such primitive robots (also called agents or scouts) to search for a treasure placed at an unknown location in an infinite two-dimensional grid. In particular, they consider agents whose behaviour is controlled by a finite automaton (FA), who are equipped with a global compass, and can only communicate with other agents that are at the exact same grid location as themselves. Furthermore, this communication is limited to see the current state of other co-located agents. The primary question of interest is: *how many* such agents are needed to search for a treasure located at an unknown location in an infinite n-dimensional grid for $n \geq 2$? As shown in [12, 21] for $n = 2$, the answer depends on the computational power of the agents: whether or not they have access to random bits, the amount of memory they have, and whether or not they are synchronized. Note that for randomized algorithms, we require a finite mean hitting time for every node in the grid. The set of agents is *fully synchronous* if they operate by the same global clock; they are *semi-synchronous*[1] if in every time slot, a subset of adversarially scheduled agents is active. Full details of the agent models are given in Section 2.

The case of the 2-dimensional grid has been completely characterized. It has been shown that if the agents are deterministic and semi-synchronous, 4 agents are necessary [12] and sufficient [21]. If the agents are fully synchronous and deterministic, then 3 agents are necessary and sufficient [21]. In [17], the authors proved that 3 agents are necessary to search the 2-dimensional grid, even if they are fully synchronized and are randomized. They conjectured that in an n-dimensional grid, $n + 1$ agents would be necessary.

▶ **Conjecture 1** ([17]). *For $n \geq 3$, any search strategy on the n-dimensional infinite grid requires at least $n + 1$ agents.*

The main result of this paper is to disprove the above conjecture; we show that three randomized synchronous agents, or 5 deterministic semi-synchronous agents can explore any n-dimensional grid. These algorithms are completely different from previous algorithms for grid exploration, and are based on the key insight that a constant number of finite automata agents can, by their positions and movements, implement a stack that stores the path being explored.

1.1 Our results

Our main result is an algorithm for 3 randomized synchronous agents to explore an n-dimensional grid for any $n \geq 3$. This result is optimal, since 3 agents are necessary to explore even the 2-dimensional grid. Next we show how to "derandomize" the algorithm with the addition of one agent. If the agents are semi-synchronous, the algorithm can be implemented

[1] In some related literature [22, 17, 21] the same model was referred to as asynchronous. We follow the terminology of semi-synchronous of [12] and the vast literature on autonomous mobile robots to avoid confusion with a fully asynchronous model.

with the addition of one more agent, in both the randomized and deterministic cases. We also show that in the 3-dimensional grid, 4 deterministic semi-synchronous agents are sufficient for grid exploration.

The algorithms mentioned above have an exploration cost/time that is exponential in the volume of the smallest ball containing the treasure. In Section 5, we give an algorithm with exploration cost linear in the volume of the ball, which is similar to the algorithm for the 2-dimensional grid given in [21], but with an important modification that enables exploration of the 3-dimensional grid without increasing the number of agents. Our algorithm is optimal in the explored space and also in the number of agents, since 4 agents are necessary to explore even the 2-dimensional grid. In Section 4, we give a deterministic synchronous algorithm for exploring the n-dimensional grid that uses 5 agents and takes time polynomial in D, the distance from the origin to the treasure. A semi-synchronous implementation of this algorithm uses 6 agents. Table 1 shows our results.

Table 1 Exploration of an n dimensional infinite grid. Numbers marked with * indicate that the number of agents used or the exploration cost is optimal. We use c in the exploration cost to indicate a constant.

Model	Number of agents	Section	Exploration cost
Randomized Synchronous	3^*	Section 3.2	c^D
Randomized Semi-synchronous	4	Section 3.2	c^D
Deterministic Synchronous	4	Section 3.3	$O(2^{D+2n})$
	5	Section 4	$D^{O(n)}$
Deterministic Semi-synchronous	4^* $(n = 3)$	Section 5	$O(D^3)$ *
	5 $(n > 3)$	Section 3.3	$O(2^{3D+4n})$
	6 $(n > 3)$	Section 4	$D^{O(n)}$

In Section 6 we describe the following additional results. We give a lower bound of $\Omega(D^{3/2})$ on the distance from the origin that must be travelled by some agent in any 3-agent deterministic synchronous algorithm, and give an algorithm using $O(\sqrt{n})$ deterministic semi-synchronous agents in which no agent travels distance more than $2D$. Lastly, we extend our algorithms to agents without global compass. We show that one additional agent is sufficient in the semi-synchronous model, while two additional agents are sufficient in the synchronous model.

1.2 Related work

There is a lot of related literature on multi-agent systems and the exploration problem: from the early work on the cow-path problem to the more recent work on exploration of graphs, labyrinths, and grids by finite state agents [3, 6, 1, 2, 4, 5, 11, 16, 29, 32, 31, 34, 10, 19, 28, 8, 7, 13, 27, 9]. In this section we briefly mention the work that is most directly relevant to this paper.

The authors of [24] introduced the problem of k randomized mobile agents, starting from the same initial position, and searching for a treasure at an unknown location on the two-dimensional infinite grid. In their model, the agents are Turing machines, but cannot communicate at all. They show that if the agents have a constant approximation of k, the treasure can be found optimally in time $O(D + D^2/k)$, where D is the distance between the initial location and the treasure. The authors of [22] consider semi-synchronous and randomized FA agents and show that the same time complexity can be achieved. The relationship between the number of random bits available and the search time was studied in [33].

Emek et al. [21] posed the question of *how many* agents are required to find the treasure. They studied deterministic as well as randomized agents, synchronous as well as semi-synchronous agents, and FA agents, as well as agents that are controlled by a push-down automaton (PDA). They show that the problem can be solved by any of the following: 4 deterministic semi-synchronous FA agents; 3 deterministic synchronous agents; 3 randomized semi-synchronous FA agents; 1 deterministic FA together with 1 deterministic PDA agent; 1 randomized PDA agent. On the negative side they show that the problem cannot be solved by 2 deterministic (synchronous) FA agents; a single randomized FA agent; a deterministic PDA agent. Cohen et al. [17] prove that at least 2 FA agents are necessary to explore the one-dimensional grid and at least 3 FA agents are needed to explore the two-dimensional grid, thus proving the optimality of the FA-agent deterministic synchronous and randomized semi-synchronous algorithms in [21]. Recently it was shown that 3 deterministic semi-synchronous FA agents cannot perform exploration of the 2-dimensional grid [12], thus proving the optimality of the 4 FA-agent deterministic synchronous algorithm in [21].

A large body of work is devoted to the capabilities of autonomous mobile robots with very limited computational and communication abilities; see [25] for a comprehensive introduction. While we use some of that terminology in this paper, their robots are usually assumed to be identical, anonymous, and communication is limited to being able to "see" each other's positions, regardless of how far they are. In contrast, in our model, the robots follow different algorithms (this can be done by having different initial states of the same FSM), and only see other robots if they are at the same location, and they can exchange a message with the collocated robots. Equivalently, they can be assumed to see the current states of other robots at the same location. This is similar to the "robots with lights" model in the autonomous mobile robot literature [18].

2 Model and Notation

We use the same models (with the exception of Theorem 10 on agents without a global compass) as in [21, 12]. For completeness, we recall key definitions and introduce some notation in this section.

Our search domain is $\mathbb{Z}^n$ with the *Manhattan metric*, i.e., the distance between two points $p, p' \in \mathbb{Z}^n$ is defined as $||p-p'|| = \sum_{i=1}^{n} |p_i - p'_i|$. We refer to $\mathbb{Z}^n$ as the *n-dimensional integer grid* and its elements as *grid points, points, or cells.* A grid point $p = (p_1, p_2, \ldots p_i, \ldots, p_n)$ is *adjacent* to every grid point $(p_1, p_2, \ldots p'_i, \ldots, p_n)$, where $|p_i - p'_i| = 1$ for some i, $1 \leq i \leq n$. We assume that any two grid points cannot be distinguished from each other by an agent, and that includes the origin from which the search starts.

The search for the treasure in the grid is done using a fixed number of agents, each modelled by a finite automaton. These finite automata can be the same, except they typically have a different initial state. Two agents can exchange information with each other only when they occupy the same grid location at the same time. We assume that all agents have the same global n-dimensional compass. Initially, all agents are located in the same grid point, assumed without loss of generality to be the origin of the grid. The treasure is located at distance D from from the origin, where D is unknown to the agents.

Time is divided into discrete units. In each time unit an *active* agent performs a single *look-compute-move* cycle. In the look part of the cycle the agent sees the state of other agents located in its own grid point. In the compute part of the cycle the agent determines,

using its own state and those it sees, to which adjacent node to move to, if at all. The agent also determines its new state. Such a move is then executed in the move part of the cycle. When we consider randomized algorithms, we assume that an agent has access to an infinite one-way tape with i.i.d. random bits. We say that the system is *synchronous* if at each time unit all agents are active. We say that the system is *semi-synchronous* if at each time unit only a subset of agents, chosen by an adversarial scheduler, is active. The adversarial scheduler must schedule each agent infinitely often.

In addition to the question of whether $\mathbb{Z}^n$ can be fully explored by k agents, we are also interested in the efficiency of such exploration procedures. We refer to this measure of interest as *the exploration cost*. Intuitively, we measure how long it takes for k agents to visit all $\Theta(D^n)$ points in a sphere of radius D. In the synchronous model, this measure is simply the number of time units taken by the agents to complete the exploration. In the semi-synchronous case, because of adversarial scheduling, the exploration cost is defined as the total distance travelled by all robots to visit all points in a sphere of radius D. Since the number of robots is constant, we could as well define the exploration cost as the maximum path length travelled. Now that we have discussed this subtlety, we will abuse the terminology and use "exploration cost" and "time" interchangeably.

3 Exploration of n-dimensional Grids

A straightforward generalization of the algorithms for the exploration of 2D grids in [21] to n dimensions results in algorithms that use $\Omega(n)$ agents. Consider, for example, such a simple generalization of a randomized 2D algorithm. The basic idea of the $n+1$-agent randomized algorithm for n dimensions is to make an n-segment walk, starting from the origin, and walking the i-th segment along dimension i. The lengths of the segments are chosen randomly, and one agent per segment is used to mark its endpoint. This allows the agent to find the way back to the origin and start another random trial. In essence, this algorithm uses 2 agents per dimension to store in unary the distance travelled in this dimension, and by an appropriate arrangement we can reuse one of the agents in the successive dimension to bring the number of additional agents per dimension to 1.

The main idea of our approach is a realization that it is not necessary to use $n+1$ agents to store n numbers of segment lengths. Observe that segment lengths are stored and retrieved in this randomized algorithm in the first-in last-out order. Thus this algorithm can be realized if we can store the agent's movements in a stack. It turns out that we can use a *constant* number of agents, independent of the grid's dimension, to *implement a stack* in which the active agent, that does the exploration, stores its walk and subsequently uses to return to the origin. The active agent "carries" the stack along its walk, i.e., it always makes the agents representing the stack to shift by one position in the direction it moves before making that move itself in its walk.

3.1 The Stack Implementation

The format of data stored in the logical stack is the string $\alpha \in (0^*1)^n$, where 0 represents *continue walking in the current direction*, 1 represents *switch to the next dimension*.
The physical implementation of the stack stores this data by interpreting α^r (that is α reversed) as a binary number S and storing it in unary as a distance between two agents located in a row in the first dimension.

We employ the following agents:

- a: the *active* agent that is doing the exploration of the grid; in the semi-synchronous model this is the only agent moving around and manipulating the other agents,
- b: the *base* of the stack, from which measurements are taken, and representing the current logical location of the exploration,
- c: the *counter* agent; this is an auxiliary agent for implementing the stack operations in the semi-synchronous model,
- d: the *distance* agent; its distance from the base b stores the content of the stack in unary,
- e: the *extra* agent used in the deterministic algorithms to store an extra copy of the current stack value.

The basic stack operations we need to implement are *isEmpty()*, *push(v)* where $v \in \{0, 1\}$ and *pop()*. Operation *isEmpty()* simply returns whether b and d are collocated. Implementation of *push()* and *pop()* is model-dependent and given below.

3.1.1 Implementing Semi-Synchronous Stack

Algorithms 1 and 2 show the implementation of push and pop operations for the semi-synchronous stack. Notice that after each push/pop operation the agents b and c in these algorithms are not only collocated, but they actually return to the position they had before push/pop.

Algorithm 1 Semi-synchronous stack: push(v).

On entry: b and c collocated, a and d collocated at $b + Se_1$.
On exit: b and c collocated, a and d collocated at $b + (2S + v)e_1$.
procedure PUSH(v)
    a goes to b and brings c to d
    while b and d are not collocated **do**
        a goes to c, pushes it one step away from b and returns to d
        a pushes d one step closer to b
    end while
    d becomes c
    a goes to c and tells it to become d
    if v=1 **then**
        a pushes d one step away from b
    end if
end procedure

Algorithm 2 Semi-synchronous stack: pop().

On entry: b and c collocated, a and d collocated at $b + Se_1$.
On exit: b and c collocated, a and d collocated at $b + \lfloor S/2 \rfloor e_1$, returns $S \bmod 2 = 1$.
procedure POP
    while b and c are at distance more than 1 **do**
        a pushes d one step closer to b
        a goes to c and pushes it one step away from b
    end while
    $v = d$ is one step from c
    c and d switch roles
    a brings c to a and returns to d
    return v
end procedure

3.1.2 Implementing Synchronous Stack

In the synchronous model, we can synchronize the movements of agents to effectively multiply or divide the stack content by 2 without the need of the counter agent c, see Figure 1.

Algorithm 3 Synchronous stack: push(v).

1: On entry: a and d collocated at $b + Se_1$.
2: On exit: a and d collocated at $b + (2S + v)e_1$.
3: **procedure** PUSH(v)
4: a goes to b and then back towards d until they meet, walking at speed 1
5: d walks away from b at speed 1/3 (move, wait, wait, see Figure 1)
6: **if** v=1 **then**
7: a pushes d one step away from b
8: **end if**
9: **end procedure**

Algorithm 4 Synchronous stack: pop().

1: On entry: a and d collocated at $b + Se_1$.
2: On exit: a and d collocated at $b+\lfloor S/2 \rfloor e_1$, returns $S \bmod 2 = 1$.
3: **procedure** POP
4: a goes to b and then back towards d until they meet, walking at speed 1
5: d walks towards b at speed 1/3 (move, wait, wait, see Figure 1)
6: **if** a and d meet right after d's move **then**
7: return 1
8: **else**
9: return 0
10: **end if**
11: **end procedure**

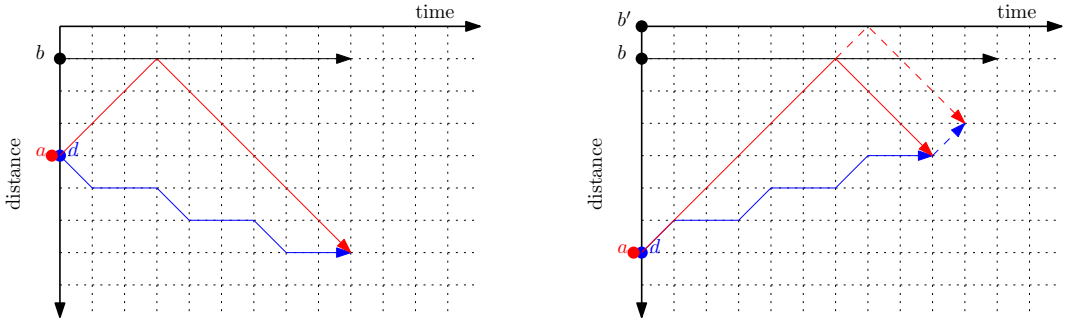

Figure 1 Multiply/divide operations by synchronous agents, shown in time-space diagrams. At left: multiplication by 2 by is done by agent a walking up to b and then down, while agent d walks down at speed 1/3. When a and d meet they have doubled the distance to b. At right: division by 2 is shown, in this case a and d walk towards b at speed 1 and 1/3 respectively; for even case a turns at b else at one node above b, and then walks back until meeting d.

3.2 The Randomized Algorithm

As already stated in the initial part of this section, the main idea of the algorithm is to use the stack to store the random choices during the walk, so that the agent can return to the origin. The agent a "carries" the stack along this walk so that the operations can be applied without the need to search for the stack.

In addition to the stack methods, it uses two new procedures. Procedure *random(p)* returns 1 with probability p, while *moveStack()* moves the whole stack one step in the direction specified. Note that since the whole stack is located on a single line, this can be accomplished by agent a walking to each of the other agents and instructing them to move one step in the specified direction.

The algorithm works in rounds, that we number $1, 2, 3, \ldots$, that correspond to the iteration numbers of the outer while loop. At the beginning of each round, the active robot picks a binary string $R \in \{-1, 1\}^n$ uniformly at random. This string indicates that the robot is

going to explore dimension i in direction R_i. Then for each dimension i from 1 to n, the active robot travels for $Z_i - 1$ steps in direction R_i, where Z_i is geometrically distributed with parameter p (to be determined later). Note that we want Z_i to represent the length of the string pushed onto the stack while moving in dimension i. Since the string pushed on the stack includes the "separator" between dimensions, we have the -1 term for the actual number of moves. We call the concatenation of all such moves over all dimensions *the logical path of the active robot*. If no treasure is found, the active robot uses the stack to retrace its logical path back to the origin by travelling $Z_n - 1$ steps in direction $-R_n e_n$ first, followed by $Z_{n-1} - 1$ steps in direction $-R_{n-1} e_{n-1}$, and so on. To compute the exploration cost of each round, we need a simple helper lemma.

Algorithm 5 Randomized Grid Exploration.

```
1:  while treasure not found do
2:      Pick a random n-bit string R ∈ {−1, 1}^n
3:      for i = 1 to n do
4:          while random(p) = 0 do
5:              push(0)
6:              moveStack(R_i e_i)
7:          end while
8:          if i < n then
9:              push(1)
10:         end if
11:     end for
12:     i = n
13:     while not empty() do
14:         while pop()= 0 do
15:             moveStack(−R_i e_i)
16:         end while
17:         i = i − 1
18:     end while
19: end while
```

▶ **Lemma 2.** *Let S be the maximal stack size during one iteration of the outer while loop of Algorithm 5. The overall cost of this iteration is $O(S^2)$ when implemented by semi-synchronous agents, and is $O(S)$ when implemented by synchronous agents.*

Proof. In the semi-synchronous model, each push() or pop() costs $O(X^2)$, where X is the actual stack size, as the active agent zig-zags between b and d. On the other hand, in the synchronous model, the cost of each operation is linear in the stack size. The cost of moving the stack is linear in both models.

As the stack size grows exponentially, and then reduces exponentially, the overall cost is determined by the cost when the stack is the largest, i.e. $O(S^2)$ and $O(S)$ for the semi-synchronous and synchronous models, respectively. ◀

Observe that during a given round the maximum size of the stack is $2^{Z_1+\cdots+Z_n}$. Thus the exploration cost of each round is at most

$$2(Z_1 + \cdots + Z_n)2^{\Theta(Z_1+\cdots+Z_n)}$$

where $2(Z_1 + \cdots + Z_n)$ is the bound on the overall length of the logical path (there and back) of the active robot, and by Lemma 2 each step of the active path costs $2^{\Theta(Z_1+\cdots+Z_n)}$, since we need to perform operations on the stack of size $2^{Z_1+\cdots+Z_n}$. Also note that

$$2(Z_1 + \cdots + Z_n)2^{\Theta(Z_1+\cdots+Z_n)} = 2^{\Theta(Z_1+\cdots+Z_n)}.$$

Let c be the constant in the Θ notation such that the exploration cost of a round is at most $2^{c(Z_1+\cdots+Z_n)}$.

For simplicity, we will assume that the active robot checks for the treasure only at the far end-point of the logical path in each round. This assumption might lead to a more pessimistic upper bound on the exploration cost than if we assumed that the active robot checks for treasure at each grid point that it visits. However, our assumption simplifies the calculations and is sufficient for our purposes.

▶ **Theorem 3.** *Algorithm 5 locates the treasure in the n-dimensional grid in finite expected time, using either 4 semi-synchronous or 3 synchronous agents.*

Proof. Consider the infinite sequence of random variables $(X_i)_{i=1}^{\infty}$, where X_i is the exploration cost of round i. Note that the X_i are independent and identically distributed. Consider the exploration cost of a particular round, e.g., X_1. Then we have $X_1 \leq 2^{c(Z_1+\cdots+Z_n)}$, where the Z_i and c are as defined above. Therefore:

$$\begin{aligned}
\mathbb{E}(X_1) &\leq \mathbb{E}\left(2^{c(Z_1+\cdots+Z_n)}\right) \\
&= \sum_{i_1=1}^{\infty}\sum_{i_2=1}^{\infty}\cdots\sum_{i_n=1}^{\infty} 2^{c(i_1+\cdots+i_n)} p^{i_1-1}(1-p)p^{i_2-1}(1-p)\cdots p^{i_n-1}(1-p) \\
&= \left(\sum_{i_1=1}^{\infty}(2^c p)^{i_1-1}2^c(1-p)\right)\left(\sum_{i_2=1}^{\infty}(2^c p)^{i_2-1}2^c(1-p)\right)\cdots\left(\sum_{i_n=1}^{\infty}(2^c p)^{i_n-1}2^c(1-p)\right) \\
&= 2^{cn}(1-p)^n\frac{1}{(1-2^c p)^n},
\end{aligned}$$

where the last step holds as long as $2^c p < 1$ that is $p < 1/2^c$.

Define a random variable T to be the minimum t such that the far end-point of X_t coincides with the treasure. That is, our exploration procedure terminates in round T, but not earlier. Suppose that the treasure is located at position $(k_1, \ldots, k_n)$ where $|k_1| + \cdots + |k_n| = D$. By the discussion immediately preceding the statement of this theorem, the probability that the treasure is found in a particular round is $\widehat{p} = 2^{-n}(1-p)^n p^{k_1}\cdots p^{k_n} = 2^{-n}(1-p)^n p^D$, where 2^{-n} is the probability of guessing correctly the signs of the k_i and $p^{k_i}(1-p)$ is the probability of travelling the correct number of steps in dimension i. Thus T is geometrically distributed with parameter $\widehat{p}$. Therefore, $\mathbb{E}(T) = 1/\widehat{p}$.

We are interested in bounding the overall exploration cost, that is, $\mathbb{E}(X_1 + \cdots + X_T)$. Since the X_i are i.i.d. and T is a stopping time, it follows by a generalization of Wald's equation [35] to stopping times that $\mathbb{E}(X_1 + \cdots + X_T) = \mathbb{E}(T)\mathbb{E}(X_1) \leq \frac{1}{\widehat{p}}2^{cn}(1-p)^n\frac{1}{(1-2^c p)^n} < \infty$. This holds as long as we choose $p < 1/2^c$. Since c is a constant, such a probabilistic coin can be implemented by a finite automaton. The statement of the theorem follows by the number of robots sufficient to implement stack operations in each of the models (synchronous vs. semi-synchronous). ◀

3.3 The Deterministic Algorithm

The main idea is to exhaustively go over all possible stack contents in increasing order, interpreting each stack as a specification of a walk. We also keep a backup of the initial stack content, and at the end of the walk we use the backup to return to the origin. The back-up stack is stored using an additional agent. The backup is needed, as reading the stack content during the walk destroys it. Note that after the outward walk, we do not logically reverse the stack; hence the return to the origin does not use the same path as the original walk. However, this is not a problem as the walks along different dimensions are commutative.

Finally, we should mention that some generated stacks do not necessarily have the correct format, some may contain too few or too many 1s. However, this is easy to handle by the algorithm: too few ones just means we walked without using all of the dimensions, which is still a perfectly valid walk. The excessive 1s are simply ignored by taking the first excessive 1 as a directive to end the walk and return to the origin.

Using essentially the same arguments as in Lemma 2 yields:

▶ **Lemma 4.** *The cost of procedure Walk is $O(S^2)$ and $O(S)$ in the semi-synchronous and synchronous models, respectively, where S is the size of the backup stack.*

▶ **Theorem 5.** *Algorithm 6 locates the treasure in the n-dimensional grid with: (a) 5 agents and the exploration cost of $O(2^{3D+4n})$ moves in the semi-synchronous model, and (b) 4 agents and the exploration cost of $O(2^{D+2n})$ in the synchronous model.*

Algorithm 6 Deterministic Grid Exploration.

```
 1: while treasure not found do
 2:     Increment the backup stack
 3:     for every n-bit string R ∈ {−1, 1}^n do
 4:         execute Walk(R, 1)
 5:         execute Walk(R, −1)
 6:     end for
 7: end while
 8:
 9: procedure Walk(R, s)
10:     Restore stack from backup
11:     i = 1
12:     while not empty() and i ≤ n do
13:         while pop()= 0 do
14:             moveStack(sR_i e_i)
15:         end while
16:         i = i + 1
17:     end while
18: end procedure
```

Proof. The number of agents and the correctness follows easily from the construction.

It remains to sum up the cost of all calls to procedure Walk. Note that each point in space uniquely specifies a valid (i.e. with precisely n 1's) stack. Hence, the valid stack for the treasure at distance D contains $D+n$ digits. Therefore, the overall cost of Algorithm 6 is $2^n \sum_{X=1}^{2^{D+n}} O(X^2) = O(2^n(2^{D+n})^3) = 2^{3D+4n}$ in the semi-synchronous model, and $O(2^{D+2n})$ in the synchronous model (the initial 2^n covers all choices for string R). ◀

4 Polynomial time solutions

While designing our exploration algorithms in the previous section, we concentrated on minimizing the number of agents used, and the resulting cost of these algorithms is exponential in the volume $V(D)$, the smallest ball containing the treasure. A natural question to ask is whether this is an unavoidable consequence of using only a constant number of agents in the exploration. In this section we show that this is not the case: a single additional agent is sufficient to bring the cost of exploration down to a polynomial in $V(D)$.

The main reason the cost of algorithms in the preceding section is exponential is the number of incorrect stack contents being considered: as D grows compared to the fixed n, ever larger proportion of stack contents does not have the correct format and they result in repeatedly reaching already explored vertices. To avoid this problem we will efficiently explore an n-dimensional cube q^n of side q centered at the origin. We use again the stack idea to trace the exploration of q^n. The logical stack content now consists of n numbers in q-ary alphabet, describing a location within this cube. However, in this case, we also need to store the scale q. As before, the stack implementation interprets the logical content as a q-ary number and stores it in unary[2]. Since q also needs to be stored on its own, this incurs the additional cost of one agent. However, this allows us to multiply and divide by q, which would not have been possible without the extra agent.

The stack is manipulated using the explicit commands: isDivisible() which checks the divisibility by q; push(0) which multiplies the stack content by q; pop() which divides the stack content by q; and increment() which increments the top of the stack.

4.1 Stack operations: semi-synchronous implementation

In addition to agents a, b and d, we use agent f to maintain the value of q by placing it at $b + qe_1$. Furthermore, two counter agents c_d and c_f are used. At the beginning of the stack operations, f and c_f are collocated, as are b and c_d, and a and d. The basic procedure is a traversal of the whole stack by agent a, manipulating the tokens according to the specific command.

In push(0) (i.e. multiplying the stack content by q), a pushes c_f towards b and c_d away from b. Whenever c_f reaches b, a transports it back to f as well as pushes d one step closer to b. The process terminates when d reaches b; subsequently c_d and d change roles. The detailed procedure is given in Algorithm 8 in [20]. .

In isDivisible(), a pushes c_f towards b and c_d towards d, until c_d reaches d. Whenever c_f arrives to b, it is transported back to f. isDivisible() returns true iff at the moment when c_d reaches d, c_f is at b (or f).

Operation pop() means dividing the stack by q. The process is essentially reverse of push() – in every iteration/traversal of the stack, c_f and d are pushed towards b. Whenever c_f reaches b, it is brought back to f and c_d is pushed away from b. When d reaches b, c_d and d exchange their roles.

The detailed pseudocode of isDivisible() and pop() are straightforward and omitted. It is easy to see that the total cost of each of the stack operations is bounded by $O(S^2)$ where S is the maximal size of the stack during the operation.

[2] This is similar to the simulation of PDAs by counter machines – see Chapter 8.5 in Hopcroft, Motwani, and Ullman text [30]; however, the details of our implementation are completely different.

4.2 Stack operations: Synchronous implementation

A straightforward application of the technique from Section 3 would need agents travelling at speed $\frac{1}{2q+1}$ (for multiply) and $\frac{q-1}{s+q}$ (for divide), which is impossible with finite state agents.

Instead, we take q to be a power of two and implement the operation of multiply, divide by q via repeated applications of multiplication by 2, division by 2, respectively. Thus in this case f is placed at distance $\log q$ from b, instead of placing it at distance of q from b. The counter c_f is used to count the number of multiplications/divisions already performed, while the counter c_d is not used at all, i.e. only agents a, b, d, f and c_f are needed. The operations of doubling and halving were already described in Section 3 and shown to take $O(S)$ time. Since these operations are performed $\log q$ times, the total time complexity of every stack operation is $O(S \log q)$.

4.3 Fast deterministic grid exploration

Our polytime deterministic grid exploration algorithm is described in Algorithm 7. Starting with $q = 2$, and for any fixed value of q, the algorithm generates and visits the addresses (n-tuples from a q-ary alphabet) in lexicographic order. Then the agent a moves to position $(-q, -q, \ldots, -q)$, doubles the value of q, and moves on to the next iteration. Agent a always drags the stack along as it performs the exploration. The procedure $explore(i)$ is a recursive procedure to generate n-tuples in lexicographic order; it is called with logical stack content an i-tuple $x0$. It then iteratively calls $explore(i+1)$ to visit the $(n-i)$-dimensional cube of side q with $(x, j, 0, \ldots, 0)$ as the origin, for j ranging from 0 to $q-1$.

Note that the algorithm as shown in Algorithm 7 is presented using recursive calls for convenience; however, i is maintained in the local state.

▶ **Theorem 6.** *Let $V(D)$ be the volume of the ball of diameter D in the n-dimensional grid. Algorithm 7 locates the treasure in the n-dimensional grid with: (a) 6 agents and the exploration cost of $O(V(D)^3)$ moves in the semi-synchronous model, and (b) 5 agents and the exploration cost of $O(V(D)^2 \log D)$ in the synchronous model.*

Proof. The number of agents and the correctness follows easily from the construction. It remains to sum up the cost of all stack operations on a stack of size S. As already described, the cost of each stack operations is $O(S^2)$ and $O(S \log q)$ in the semi-synchronous and synchronous models, respectively. The maximal stack size S is bound by q^n, which is also the number of points covered by the stack base during one iteration of the outer loop (i.e. for fixed q). This results in the overall cost of $O(S^3)$ and $O(S^2 \log q)$ in the semi-synchronous and synchronous models, respectively. As q grows exponentially, the overall cost is determined by the cost for the last value of q. Finally, it is known that $V(D) = \frac{2^n}{n!} D^n$. As $q < 4D$ (the treasure would had been found if $q \geq 2D$), we get that $S \leq (4D)^n = 2^n n! V(D)$, where n is a constant. This proves the theorem. ◀

5 Exploring 3-dimensional Grids using 4 Semi-Synchronous agents

Our algorithm for the $3D$ grids explores the *sphere* consisting of all points at distance q from the origin for $q = 1, 2, 3, \ldots$, until reaching the sphere containing the treasure. In the Manhattan metric, the points of such a sphere are located on 8 triangular faces of a regular octahedron whose edges contain $q+1$ grid vertices.

The key to our success is an algorithm for exploring one such triangle using four agents, in such a way that (i) the value of q is maintained by the distance between some of the agents while exploring a triangle, so that it can be used for the exploration of all triangles of the

octahedron, (ii) the exploration of all eight triangles can be done in a fixed order, and (iii) the value of q can be increased for the exploration of the larger sphere after the exploration of the sphere of radius q is finished.

The detailed description of this algorithm and the proof of the following theorem appear in the full arXiv version of this paper [20].

▶ **Theorem 7.** *Assume that the treasure is located in a 3D grid at distance D from the origin. Algorithm* Explore3Dgrid *finds the treasure using 4 semi-synchronous agents, with the exploration cost of $O(D^3)$. This is optimal as far as the number of semi-synchronous agents used, and up to a constant factor in the exploration cost.*

6 Additional Results

In this section, we list without proofs three additional results mentioned in Section 1. We point out the sections of the arXiv version of this paper [20] where the details are given.

▶ **Theorem 8.** *Finding a treasure at distance D in an n-dimensional grid can be achieved with $O(\sqrt{n})$ agents, exploration cost $O(D^{n+\sqrt{n}})$, and without agents venturing further than distance $2D$ away from the origin (Section 6.1 of [20]).*

▶ **Theorem 9.** *Consider 3 deterministic synchronous agents that run a protocol for exploring $\mathbb{Z}^3$. In order to visit all grid points in the ball of radius D the distance of some agent from the origin must have been $\Omega\left(D^{3/2}\right)$ (Section 6.2 of [20]) .*

▶ **Theorem 10.** *Every algorithm in this paper which assumes agents with a global compass can be extended to work with agents without it by using one additional agent in the semi-synchronous model, and two additional agents in the synchronous model (Section 7 of [20]).*

7 Conclusions and Open Questions

We studied the exploration of n-dimensional grids for $n \geq 3$ by finite state automata agents. We showed the surprising result that three randomized synchronous agents suffice to find a treasure in an n-dimensional grid for any n; this is optimal in the number of agents. Our strategy can also be implemented by four randomized semi-synchronous agents, or four deterministic synchronous agents, or five deterministic semi-synchronous agents. For the three-dimensional case, we gave a different algorithm for the deterministic semi-synchronous case that uses only 4 agents, and is optimal. Our algorithms for $n \geq 4$ require agents to travel far away from the origin, i.e., exponential in D distance away, while looking for a treasure which is located at distance D from the origin. We also considered the question of whether it is possible to design algorithms that use few agents and do not require travelling much further than distance D away from the origin in order to explore the entire ball of radius D around the origin. We answered the question positively by describing an algorithm that uses $O(\sqrt{n})$ semi-synchronous deterministic agents that never travel beyond $2D$ while exploring the ball of radius D. We also showed that 3 synchronous deterministic agents in 3 dimensions performing search, if such an algorithm exists, must travel $\Omega(D^{3/2})$ away from the origin.

Algorithm 7 Fast Deterministic Grid Exploration.

```
1: q = 2
2: push(0)
3: while treasure not found do
4:     explore(1)
5:     moveStack(−q ∑_{i=1}^{n} e_i)
6:     q = 2q
7: end while
8:
9: procedure EXPLORE(i)
10:    if i > n then
11:        return
12:    end if
13:    repeat
14:        push(0)
15:        explore(i + 1)
16:        increment()
17:        moveStack(e_i)
18:    until isDivisible()
19:    pop()
20:    moveStack(−q e_i)
21: end procedure
```

Many interesting questions about the exploration of the n-dimensional grids remain open. Is it possible for 4 deterministic semi-synchronous agents to explore an n-dimensional grid for $n \geq 4$? For $n \geq 3$, can exploration of an n-dimensional grid be achieved by 3 randomized semi-synchronous agents or deterministic synchronous agents? What is the minimum number of agents that achieve polynomial time exploration? What is the minimum number of agents such that the distance of the furthest visited node from the origin is limited to polynomial in D? Is it possible to save an agent in the case of synchronous unoriented grids?

Abstract

Addressing a fundamental problem in programmable matter, we present the first deterministic algorithm to elect a unique leader in a system of connected amoebots assuming only that amoebots are initially contracted. Previous algorithms either used randomization, made various assumptions (shapes with no holes, or known shared chirality), or elected several co-leaders in some cases.

Some of the building blocks we introduce in constructing the algorithm are of interest by themselves, especially the procedure we present for reaching common chirality among the amoebots. Given the leader election and the chirality agreement building block, it is known that various tasks in programmable matter can be performed or improved.

The main idea of the new algorithm is the usage of the ability of the amoebots to move, which previous leader election algorithms have not used.

1 Introduction

The notion of programmable matter [19], and specifically amoebots [8, 7], envisions matter as composed of tiny weak robots called "particles". Multiple studies have addressed what these particles can achieve by cooperation, and how such weak entities can even cooperate. See e.g., coating of materials [12, 11, 4], bridge building [1], shape formation [9, 3, 10, 15, 5], and shape recovery [14]. An important primitive used often for coordinating such tasks is the election of a unique leader. Interestingly, all deterministic algorithms either elected multiple co-leaders in cases of symmetrical shapes of the matter, or relied on various assumptions on the particles, such as initially forming a specific shape (no holes), or initially having a common chirality.

1.1 Amoebot Model

Under the *amoebot model* [8, 7], each *particle* (an *amoebot*) occupies (alone) a different intersection (or *node*) of the lines of a triangular grid embedded in the plane, as seen in Figure 1.[2] The *degree* of a particle is the number of particles occupying neighboring nodes. A particle is either *contracted* (occupies one node) or *expanded* (occupies two neighboring nodes).

Each particle is *activated* infinitely often by an asynchronous scheduler to act. One *asynchronous round* is completed when each particle is activated at least once. The activation of a particle is atomic, i.e., it is completed before the next particle is activated. Each activation consists of 3 stages: (i) P reads the memories of adjacent particles, (ii) P performs some local computation and may update its own memory and/or the memories of its neighboring particles (sometimes, this is called "sending messages"), and (iii) P may move by either expanding or contracting.[3] Specifically, an expanded particle can contract to either one of the two nodes it occupies. While contracting out of node b, the particle can *pull* a contracted particle Q that occupies a node c that neighbors b; then Q becomes expanded and occupies both c and b. The expansion of P from node b into a neighboring node c is possible if P is contracted and c is not occupied by another contracted particle. After the expansion, P occupies both b (termed P's *tail*) and c (termed P's *head*). Suppose that P's move is an expansion into c, already occupied by a different particle Q who is expanded (Q occupies also a different node e). We then say that Q is *pushed*, Q becomes contracted and occupies only node e. For the sake of convenience, we may sometimes view the (occupied) nodes as the entities taking actions.

Each particle has constant size memory. In the *leader election (LE)* problem, each particle has one of three *LE statuses*: **C** (candidate, the initial state), **L** (leader), and **U** (unelected). and will permanently change its status to either **U** or **L** such that exactly one particle has status **L** by the end of the algorithm.

The particles are classified according to their *chirality* as *clockwise (CW) particles* or *counter-clockwise (CCW)* so that a CW (resp., CCW) particle numbers the *ports* corresponding to the 6 incident edges in (each of) the node(s) it occupies from 0 to 5 in increasing CW (resp., CCW) order; the edge from which this numbering starts is chosen arbitrarily (refer to Figure 2 for an illustration). We assume that the particle chirality classification is

[2] Because of space constraints, all figures are found in the full version.

[3] Note that P allocates memory for each of its ports and that is the memory that can be modified by adjacent particles. In other words, when P receives a message, it knows through which port the message was sent and by extension which particle sent it.

determined by a malicious adversary and that initially, a particle does not know whether its chirality (or a chirality of any other node) is CW or CCW.

The *configuration* of the particle system at any given time is comprised of the location and state of each particle; it is *contracted* if all particles are contracted. We follow the common practice (see [6]) and assume that the particles are, initially, in a contracted configuration. The algorithm terminates in a contracted configuration.

Define a graph $G(t)$, called the *shape*, induced on the grid by the nodes occupied by particles at time t and an edge connects two graph nodes if they represent two neighboring grid nodes. Following the common practice in the amoebot model literature (see [8]), it is required that the shape is connected at all times. Since the shape is a (finite) planar graph associated with a planar embedding, it partitions the plane into *faces* (see [16]), where exactly one of them is the *outer* face. The occupied nodes adjacent to the outer face are said to form the *outer boundary* of the shape. An inner face that includes at least one unoccupied node is called a *hole* in the shape (refer to Figure 3 for an example). The occupied nodes adjacent to a hole are said to form an *inner boundary*. The *length* of a boundary B, denoted L_B, is the number of nodes on B; those are *boundary nodes*, occupied by *boundary particles*. Define $L_{\max} = \max_B L_B$.

1.2 Related Work

Randomized algorithms, assuming common chirality in the initial configuration, are given in [13, 6]. A deterministic algorithm was presented in [15] to both elect a leader and obtain common chirality for the natural special case that the shape did not contain holes; multiple leaders could be elected in some cases (a constant number). They then used the leader(s) to coordinate shape transformation. The no-holes assumption is replaced in [2] by an assumption that the particles start with a common chirality. In a brief announcement, they outlined an interesting algorithm that still may end with several leaders in cases of high symmetry. The current paper adapts and uses a large part of the algorithm of [2] as a procedure. In [17], both common chirality and no-holes are assumed to elect a unique leader. That algorithm also assigns, to each particle, an identifier that is unique within a radius of k. Moreover, beside triangular grids, their algorithm can work also on the square and king grids.[4]

The type of asynchronous scheduler used affects the leader election results. Typically in the literature [13, 6, 17], the scheduler provides conflict resolution mechanisms for movement and communication such that particle activations can be analyzed sequentially, i.e., the activation of each particle is atomic. As the current paper demonstrates, it is *not* impossible to elect a leader deterministically (unless, perhaps, in models when a scheduler is allowed to schedule such particles simultaneously [2, 15]).

1.3 Technical Challenges and Ideas

Multiple ideas are combined here in order to address different cases. Consider, for example, a polygon with a hole. One approach in previous algorithms, assuming no holes, was to remove (from being candidates) boundary nodes repeatedly until only one remains. In the case of one hole (addressed by one of our subroutines), the present algorithm utilizes the ability of particles to move. Intuitively, they may move (eventually) to the center of the polygon, and the particle reaching the center first is the elected one. (Thanks to the sequential scheduler, only one can reach a certain node first).

[4] It is possible to adapt the current paper's leader election algorithm to run on king grids, but this would require some work, while it follows in a natural way for the algorithm of [17].

This, of course, requires our algorithm to perform various maneuvers, to identify the center and to make sure no additional holes remain. In particular, particles have to identify the outer boundary, move outward in order to gain a symmetric shape, and then move inward together so no additional holes are formed. Since multiple polygons may be moving at the same time, two polygons may "collide" and not manage to finish the maneuver. There, we use the idea of reset, to restart the algorithm for the new shape. We managed to upper bound the number of such resets.

Because of the existence of bridge (and semi-bridge particles) (to be defined in the next section, but intuitively particles whose removal disconnects the shape), solving for a single simple polygon is not enough. For example, consider the case that the shape is a long line (possibly connecting simple polygons). Here, we use the fact that there exists only one outer face (borrowing its detection from the algorithm of [2], with some necessary adaptations). The partial leaders of the simple polygons cooperate to define a tree that spans the simple polygons. Final leader election is then performed over the tree.

The assumption of common chirality is used throughout the paper. To remove this assumption and have particles agree on chirality, we use again the detection of the outer face. The particles on the outer boundary agree on chirality (this turned out to be easier for us than agreeing on a leader among them, using the local symmetry breaking provided by the scheduler). Then, the outer boundary particles coordinate and propagate this shared chirality to the other particles within the shape.

1.4 Our Contributions and Paper Organization

The current paper presents the first deterministic protocol that elects exactly one leader on any contracted configuration, even without assuming common chirality. For a comparison of this result to known ones, please see Table 1.

The building blocks may be of interest by themselves. The assumption of common chirality is removed last, in Section 5. Other building blocks are: maximal independent set (MIS) protocol, boundary detection, leader election on a convex polygon without sharp vertices, and leader election on a spanning tree. They are are given in Section 3. Additional definitions required to understand the paper are present in Section 2. The main protocol, $\texttt{Leader} - \texttt{Election} - \texttt{By} - \texttt{Moving}$ (before removing the common chirality assumption), is presented in Section 4 (together with some other small components, such as broadcast with termination detection, and reset).

Table 1 Table comparing the result on leader election to those of previous papers. "No holes" refers to whether the algorithm requires the graph to have no holes initially or not. "Multiple leaders" refers to whether the leader election algorithm may output multiple leaders in certain cases or always outputs a unique leader. The length of the largest boundary in the initial configuration is $L_{\max}$. The length of the outer boundary in the initial configuration is L. The number of particles in the configuration is denoted by n. The terms r and $mtree$ are unique to paper [17].

Paper	Common chirality	Randomness	No holes	Multiple leaders	Running time
[13]	Yes	Yes	No	No	$O(L_{\max})$ rounds on expectation
[6]	Yes	Yes	No	No	$O(L)$ rounds with high probability
[2]	Yes	No	No	Yes	Not analyzed in paper
[15]	No	No	Yes	Yes	$O(n)$ rounds
[17]	Yes	No	Yes	No	$2(r + mtree + 1)$ rounds
Current Paper	No	No	No	No	$O(Ln^2)$ rounds

2 Preliminaries: Shape and Boundaries

We need quite a few definitions related to the shape. A *local boundary* of a particle is an interval $i, i+1, \ldots, i+j \mod 6$ of its ports that lead to unoccupied grid nodes. Note that a contracted particle may have up to three local boundaries, each a part of some boundary of the shape. However, all three may be parts of the same boundary of the shape. Henceforth, we use only the term "boundary" even for local boundaries, when the context makes the usage clear. A *bridge particle* is a *contracted* boundary particle occupying a node b lying on i local boundaries (note that $1 \leq i \leq 3$), each of which is a part of the outer boundary, and having i occupied adjacent nodes in the grid. An example of bridge particles and semi-bridge particles (see next paragraph) with bridge edges is illustrated in Figure 4.

A *semi-bridge particle* is a *contracted* boundary particle occupying a node b lying on 2 outer boundaries, and having 3 or 4 occupied adjacent nodes in the grid. If b is occupied by a bridge or semi-bridge particle, c is an adjacent occupied node, and both sides of the edge (b, c) are on the outer boundary, then edge (b, c) is called a *bridge edge*.[5]

For a boundary node b occupied by particle P with chirality C and lying on boundary B, define b's *predecessor* node a and *successor* node c w.r.t. B and C as the previous occupied node and the next occupied node along B according to C, respectively (refer to Figure 5 for an illustration).[6] Note that node b admits such predecessor a and successor c for each boundary b lies on.

The *boundary count* of b w.r.t. B and C measures the deviation of the line segment formed by b and its successor from the line segment formed by b's predecessor and b w.r.t. B taking C into account. More formally, the boundary count of b w.r.t. B is a function of C and the angle $\angle abc$ that takes on one of the values $-1, 0, 1, 2$, or 3 (as illustrated in Figure 6).[7] Let i be the unique integer that satisfies $\angle abc = 180° - i * 60°$. Let x and y be the port numbers of b corresponding to edges (b, a) and (b, c), respectively. If $(x - y) \mod 6 = 4$, then the boundary count of b w.r.t. B is $-i$, else it is i. When the boundary referred to is clear from context, it is not mentioned when giving the boundary count for a node.

Consider an occupied node b on boundary B with boundary count w. The following definitions for b are all w.r.t. B. Node b is called a *vertex* when $w = -1, 1, 2$, or 3.[8] When $w = 2$, b is a *sharp* vertex. Vertex b is *concave* when $w = -1$ and *convex* when $w = 1$ or 2. A shape whose outer boundary vertices are all convex w.r.t. the outer boundary is a *convex polygon*. A shape consists of *two (or more) simple convex polygons sharing the same contracted semi-bridge particle(s) P (, Q, R, etc.)* when (i) P (, Q, R, etc.) has no adjacent bridge edges, (ii) the shape is disconnected by removing P (, Q, R, etc.), and (iii) all vertices other than those occupied by P (, Q, R, etc.) are convex vertices. Notice that the definition of convex polygon relates only to its outer boundary nodes. Specifically, no assumptions are made on the presence of holes within the shape.

[5] Note that a semi-bridge particle may have 3 adjacent occupied nodes and lie on 2 outer boundaries and 1 inner boundary. In this case, the particle still has 1 bridge edge.

[6] Throughout, we use w.r.t. to abbreviate "with respect to".

[7] Note that it is not possible to have a node with boundary count -2 or -3 w.r.t. some boundary. Also note that the boundary count and its application to calculating the count of a segment, defined and used in the full version, is similar to how [2] uses vertex labeling in deciding the count of a segment in their paper. The actual measurement of the boundary count is similar to how [13] measures the angles between the direction a token enters and exits an agent.

[8] Notice that the angle bisector of a vertex with boundary count 1 or -1 overlaps with a line of the triangular grid.

3 Building Blocks

Let us now present the four building blocks in brief, except Subsection 3.3 that is more detailed. The full version contains all missing details. The description uses some additional definitions. Each boundary particle P maintains a binary flag *seg_head* in each boundary node b that P occupies w.r.t. each boundary that b lies on. When P occupies a boundary node and has $seg\_head = true$ for that boundary, we say P is a *seg-head* for that boundary. Consider two seg-heads P_1 and P_2 on boundary B, occupying nodes b_1 and b_2 with predecessor nodes c_1 and c_2 and successor nodes d_1 and d_2 w.r.t. B, respectively. P_2 is the *previous (resp., next) seg-head* before (resp., after) P_1 iff the particles in successor (resp., predecessor) nodes from b_2 to b_1 w.r.t. B (excluding b_1 and b_2) have *seg_head* set to $false$.

Let P_2 be the next seg-head after P_1 w.r.t. B. P_1's *segment* is the sequence of successor nodes from b_1 to c_2 with *head* b_1 and *tail* c_2. It is said that P_1's segment is *before* P_2's segment or P_2's segment is *after* P_1's segment w.r.t. B. For the sake of convenience, when referring to a procedure/action initiated by the head of a segment involving the participation of the particles in that segment, we just say that a segment runs the procedure/performs the action. It is important to note that a particle P may participate in multiple segments simultaneously (one per boundary P lies on). The algorithm needs to be careful to prevent contradicting actions of such segments (for example, preventing one segment from expanding P into one node while another segment is trying to expand P into a different node).

3.1 MIS Selection

To perform Procedure `MIS − Selection`, P joins the MIS iff no neighbor of P has yet joined the MIS. The following trivial observation breaks with impossibility results in other models when the scheduler is not asynchronous.[9]

▶ **Observation 1.** *When run by particles, procedure* `MIS − Selection` *deterministically computes an MIS in one round.*

3.2 Boundary Detection

`Boundary − Detection` is a parameterized procedure run by boundary nodes with common chirality to tell each such node b, for each boundary B that b lies on, whether B is an inner or outer boundary. This procedure is a modification of the first phase of the algorithm presented in [2], specifically adapting their subroutine `StretchExpansion` to handle (1) inner boundaries and (2) an edge case that may not be needed (and is not addressed) in [2] but is needed here (see Figure 7).[10] These adaptations result in subroutines `Inner − Stretch − Expansion` and `Outer − Stretch − Expansion`, respectively. Due to space constraints, the entire modified boundary detection procedure and proof of the theorem are presented in the full version.

▶ **Theorem 1.** *When executed by contracted boundary particles, procedure* `Boundary − Detection` *terminates in $O(L_{\max}^2)$ rounds resulting in each boundary node b knowing, for each boundary B it is on, whether B is an inner or outer boundary. If b has $seg\_head = true$ w.r.t. boundary B, then b knows how many nodes k, $k \in \{1, 2, 3, 6\}$, are also segment heads w.r.t. B.*

[9] In particular, this procedure selects a leader in a ring of 3 particles.
[10] Recall that [2] is a brief announcement, so this edge case may be handled in the full version of their paper.

3.3 Leader Election on a Convex Polygon without Sharp Vertices

Procedure $\texttt{Convex}-\texttt{Polygon}-\texttt{Leader}-\texttt{Election}$ relies on 3 subroutines, described below. Note that the outer boundary nodes of a convex polygon without sharp vertices form a hexagon in the grid. Let b be a vertex, occupied by particle P, with successor node d w.r.t. the outer boundary. Define *P's side* as the side of the hexagon containing b and d.

Let LSLS stand for largest same length sides and SSLS stand for smallest same length sides. Every possible hexagon is isomorphic to one of the following four. See Figures 8-13.

1. Category 1: The hexagon has exactly either 1 LSLS or 1 SSLS.
2. Category 2: The hexagon has either 2 LSLS and 4 SSLS, 4 LSLS and 2 SSLS, or 2 LSLS, 2 SSLS, and 2 other same length sides.
3. Category 3: The hexagon has exactly 3 LSLS and 3 SSLS.
4. Category 4: The hexagon has 6 sides of the same length.

Let $P_0, P_1, \ldots P_{k-1}$ be the seg-heads on the outer boundary such that $P_{(i+1) \mod k}$ is the next seg-head after P_i. Subroutine $\texttt{Compare}-\texttt{Length}(\texttt{x})$ is initiated by a seg-head P_i to compare the length of P_i's segment with that of $P_{(i+x) \mod k}$'s segment. The procedure simulates the way a Turing machine would perform a similar task, where the segments would be segments of the machine's tape. Since this is a known method, the details are omitted (refer to [15] for an example). The proof of the following lemma can be found in the full version.

▶ **Lemma 2.** *Let x be a constant and assume that there are L nodes on the outer boundary. If the nodes from P_i's segment's head to $P_{(i+x) \mod k}$'s segment's tail run* $\texttt{Compare}-\texttt{Length}(\texttt{x})$*, then the subroutine terminates in $O(L^2)$ rounds, resulting in P_i knowing the size comparison between the two segments.*

Consider two parallel lines M_1 and M_2 of the grid. The *mid-line(s)* between M_1 and M_2 is the line(s) parallel to both M_1 and M_2 which is either equidistant from both M_1 and M_2 or not closer to one of the lines by more than a unit distance. Consider a category 2 hexagon where opposite outer boundary vertices b_1 and b_2, occupied by particles P_1 and P_2 respectively, have $seg\_head = true$ and the remaining nodes have $seg\_head = false$. There exist either 1 or 2 mid-lines between P_1's side and P_2's side. Let c_1 and c_2, occupied by particles Q_1 and Q_2 respectively, be nodes on P_1 and P_2's segments respectively lying on the mid-line (or on the closer mid-line to the head of the segment in the case of 2 mid-lines). The outer boundary particles run subroutine $\texttt{Mid}-\texttt{Line}$ to find c_1 and c_2 and subsequently Q_1 and Q_2 set $seg\_head = true$ and P_1 and P_2 set $seg\_head = false$. See Figures 10 and 11 for examples. A more detailed description of the subroutine is found in the full version. The following observation captures the running time of $\texttt{Mid}-\texttt{Line}$.

▶ **Observation 2.** *Let there be L outer boundary nodes on a category 2 hexagon with opposite vertices b_1 and b_2, occupied by particles P_1 and P_2 respectively, with $seg\_head = true$ and remaining nodes with $seg\_head = false$. Subroutine* $\texttt{Mid}-\texttt{Line}$*, run by the L nodes, terminates in $O(L^2)$ rounds, such that nodes c_1 and c_2, which are the closest nodes in P_1 and P_2's segments lying on mid-lines between P_1's side and P_2's side respectively, now have $seg\_head = true$ and b_1 and b_2 have $seg\_head = false$.*

Intuitively, when the segment heads are on the mid-line as promised by Observation 2, if they move towards the center, they can get next to each other and elect one of them as a leader. The following subroutine $\texttt{Snake}-\texttt{Movement}(\texttt{D},\texttt{x})$ (described in more detail in the full version), is used for election in hexagons of several types. Consider a path p of w nodes occupied by contracted particles with head node b occupied by particle P and tail

node c. P has $seg\_head = true$ w.r.t. the outer boundary and the remaining particles have $seg\_head = false$. See Figure 14 for an example. Particles in p (termed *snake* p) expand, so p becomes longer and its head P moves in direction D for distance $x \leq w$ (without breaking connectivity and while keeping the tail node of p fixed at c). P is the one expanding first, and the particles perform a sequence of expansions and contractions until reaching the desired total length of p. Note that x may not be a constant. Hence, this value is represented distributively on the particles of p by them simulating a tape of a Turing machine. (The value of x is also input to the subroutine and used for the computing in the same manner).

Note that only a segment on the outer boundary can perform this procedure, hence, snake p will not belong to two different segments giving it contradictory instructions to move. One thing that may happen is that the head of snake p reaches a particle Q not in snake p. If Q belongs to another snake p' then p stops. Otherwise, p continues moving in direction D simply by annexing Q who now becomes the head of the snake (that we still call snake p). The proof sketch of the following lemma can be found in the full version.

▶ **Lemma 3.** *Assume that L contracted particles of a snake run* `Snake − Movement(D, x)`*, where $x \leq L$. Then, the subroutine terminates in $O(x^2)$ rounds without breaking connectivity. On termination, either the snake head reached a node at distance x away from the head of the snake in direction D, or the next particle in direction D belongs to another snake.*

Now, procedure `Convex − Polygon − Leader − Election` is described. Note that illustrations expanding on the description are found in the full version. Initially, the 6 particles that occupy vertices on the outer boundary set $seg\_head = true$ while the remaining particles in the polygon set $seg\_head = false$. Each of these 6 particles initiates `Compare − Length(x)` for $1 \leq x \leq 6$, sends messages to the remaining 5 particles with the results of these comparisons, and determines which category hexagon it lies on.[11] The procedure follows one of the following four cases:

1. *Category 1 hexagon:* This case is trivial - the particle at the head of the smallest or largest side becomes the leader. See Figures 8 and 9.
2. *Category 2 hexagon:* If there are exactly 2 LSLS, then those sides' polygon vertices keep $seg\_head = true$ and the remaining vertices set $seg\_head = false$. Else there are 2 SSLS whose vertices keep $seg\_head = true$ while others set $seg\_head = false$. Call particles occupying vertices with $seg\_head = true$, P_1 and P_2, and denote the direction from the successor of P_1 to P_1 as D_1 (similarly denote D_2). Now, P_1 and P_2 initiate `Mid − Line` resulting in two new particles Q_1 and Q_2 setting $seg\_head = true$ and P_1 and P_2 setting $seg\_head = false$ (refer to Figures 10 and 11 for examples).
   The resulting segments of Q_1 and Q_2 form snakes p_1 and p_2 with lengths w_1 and w_2 respectively that run `Snake − Movement(D1, w1)` and `Snake − Movement(D2, w2)` in directions D_1 and D_2, respectively. In addition to the usual termination conditions when running `Snake − Movement(D1, w1)` and `Snake − Movement(D2, w2)`, the subroutines also terminate when the head of p_1 is adjacent to that of p_2. Then, the two heads run `MIS − Selection` and the particle that joins the MIS becomes the leader.
3. *Category 3 hexagon:* Let P_1, P_2, and P_3 occupy vertices b_1, b_2, and b_3 such that P_1, P_2, and P_3's sides are the 3 largest sides. The remaining particles set $seg\_head = false$. See Figure 12. Let D_1, D_2, and D_3 be the directions along the angle bisectors of b_1, b_2, and b_3 respectively toward the center of the hexagon. The two phase procedure followed by P_1's segment is now described. (P_2's and P_3's segments act similarly).

[11] With this information, a particle can compute, using a constant amount of space, the total order on the lengths of sides of the hexagon. Combined with information of which sides are equal in length, a particle can determine both the category of the hexagon it lies on and the type of its own side.

Notice that P_1's segment encompasses 1 SSLS and 1 LSLS with lengths x and y respectively. In phase 1 (simulating a Turing machine), the values of $f = \lfloor (y-x)/3 \rfloor$, $g = x + f$, and $q = (y-x) \mod 3$ are computed and stored in P_1's segment. If $q = 2$, g is incremented by 1. Now P_1 sends a message to the particle Q_1 located f nodes from the head of the segment, telling Q_1 to set $seg\_head = true$ and store D_1, f, g, and q. P_1 subsequently sets $seg\_head = false$. Q_1 is now the head of a segment. Similarly, some Q_2, Q_3 replace P_2, P_3 as heads of their segments. Now Q_1 sends a message along the outer boundary to Q_2 and Q_3 indicating that the first phase is over. Once Q_1 receives similar messages from Q_2 and Q_3, the second phase begins.

In phase two, Q_1's segment runs $\texttt{Snake} - \texttt{Movement}(\texttt{D}_1, \texttt{g})$. If $q = 0$, all three snakes move towards the same final node b. Let p be the snake such that its head particle R is the first to occupy b. R waits until the remaining two snakes reach it and then becomes the leader. If $q \neq 0$, the final nodes occupied by the heads of the three snakes form a triangle. Let R be a head of the snake that occupies one of the triangle's nodes. R waits until the other two triangle's nodes are occupied and then runs $\texttt{MIS} - \texttt{Selection}$. The particle chosen to be in the MIS becomes the leader.

4. *Category 4 hexagon:* All vertices have $seg\_head = true$ (e.g., Figure 13). The procedure here is a simplified version of the case of Category 3 hexagon. See the full version.

▶ **Theorem 4.** *Procedure* $\texttt{Convex} - \texttt{Polygon} - \texttt{Leader} - \texttt{Election}$ *run by contracted particles of a convex polygon without sharp edges results in exactly one leader being elected deterministically in* $O(L^2)$ *rounds, where* L *is the number of particles on the outer boundary.*

Proof Sketch. The readers can convince themselves that all types of hexagons have been accounted for in the four hexagon categories. Let us prove correctness for each category separately. The case of category 1 is trivial.

In a category 2 hexagon, Observation 2 guarantees that particles are chosen such that they lie on the same mid-line or adjacent mid-lines. The distance needed to be traveled by each segment until both heads are adjacent is $\leq L/2$. Since the segments divide the nodes of the outer boundary equally, each segment has enough contracted particles such that it is possible to traverse this distance by expanding every particle in the segment. Moreover, no two snakes can block each other before reaching that distance. $\texttt{MIS} - \texttt{Selection}$ is guaranteed to choose exactly one leader due to Observation 1.

For category 3, inscribe the hexagon in an equilateral triangle with vertices A, B, and D, centroid C, and F trisecting $\overline{AB}$, as seen in Figure 15. Observe that each side of the triangle is of length $2x + y$ and $|\overline{AF}| = |\overline{FC}|$. When $(y-x) \mod 3 = 0$, $\overline{FC}$ coincides with a grid line and all segments move towards C using `Snake-Movement()`. However, if $(y-x) \mod 3 \neq 0$, the segments move to nodes that form a triangle around the centroid, in which case, $\texttt{MIS} - \texttt{Selection}$ is run and Observation 1 guarantees a leader is selected. Note that no two snakes can block each other before reaching the meeting point.

The proof for category 4 is a simplified version of the proof for Category 3. Thus for all four types of hexagons, a leader is chosen. The running time is analyzed in the full version. ◀

3.4 Leader Election on a Spanning Tree

Procedure $\texttt{Spanning} - \texttt{Tree} - \texttt{Leader} - \texttt{Election}$ deterministically elects a unique leader when participating particles form a spanning tree and have common chirality. Note that this can also be performed by the algorithms of [15, 17]. We defer the description to the full version and give the following theorem without a proof.

▶ **Theorem 5.** *Procedure* `Spanning − Tree − Leader − Election` *run by particles forming a spanning tree of diameter x results in exactly one leader being elected deterministically in $O(x)$ rounds.*

4 Leader Election

An overview of deterministic algorithm `Leader − Election − By − Moving` for electing a unique leader is now given, assuming common chirality (an assumption removed later). Additional details and proofs appear in the full version.

The initial contracted configuration of n particles forms a connected shape $G(0)$ at the beginning of round 0 with all particles having status **C**. $H(t), K(t), F_1(t)$, and $F_2(t)$ are virtual graphs at the beginning of round t that are maintained by the particles distributively and are initially empty.[12] Note that the round number is subsequently dropped, as it is apparent from context.

The algorithm has six phases. Graph H is used throughout the algorithm for various purposes depending on the phase of the algorithm. Graph K is a subgraph of G that holds a spanning tree of all particles and is important for phase 6 of the algorithm. Graph F_1 is a forest of trees of all particles used throughout the algorithm. Graph F_2 is a forest of trees of a subset of the particles used only in phase 5 of the algorithm.

Each particle P maintains a phase counter in $[1 \dots 6]$ and appends its value to each message sent. If P receives a message from another particle Q in a different phase, P does not process Q's message until P is in the same phase as Q.[13]

1. *Initialization:* At the end of this phase, every particle is contracted and each boundary particle has identified the type (inner/outer) of each of its boundaries. Furthermore, graph H consists of a set of simple convex polygons, where two simple polygons may share the same semi-bridge particle.
   Each boundary particle runs `Boundary − Detection` for each boundary B it lies on to determine whether B is an inner or outer boundary. Once `Boundary − Detection` terminates, all particles not on the outer boundary set $seg\_head = false$. Thus, there are k, $k \in \{1, 2, 3, 6\}$, particles with $seg\_head = true$ located on the outer boundary. Call these seg-heads $P_1, P_2, \dots, P_k$. If $k = 1$, change P_1's status to **L** and broadcast (by simple flooding [18]) a $final\_terminate$ message to other particles to terminate the algorithm and change their statuses to **U**.
   Each particle that is not a bridge or semi-bridge adds itself and its edges to adjacent nodes to H. Otherwise, semi-bridge particles add themselves and their non-bridge edges to H. Note that all particles are contracted at the end of this phase.
2. *Spanning forest formation:* Each outer boundary node a becomes the root of a tree T and uses the standard broadcast-&-echo method [18] to recruit nodes to its tree. Each node b joins exactly one tree T. Termination detection of the phase is coordinated by seg-heads P_1 to P_k, after all the broadcast-&-echoes terminate. Thus a spanning forest F_1 of trees is formed with outer boundary particles as roots of the trees. Furthermore, each node knows its parent and children in the tree. Note that all particles remain contracted during the phase.

[12] For each graph, each particle maintains locally its own edges in the graph and whether it is in the graph or not. Each particle allots a constant amount of memory for each of the graphs G, H, K, F_1, F_2 and updates them as necessary when activated.

[13] It is trivial to return to a contracted configuration from the configuration the algorithm terminates in, so this "7th phase" is not described. Informally, it consists of particles that performed `Snake − Movement`() as part of `Convex − Polygon − Leader − Election` during phase 5 reversing their movements.

3. *Convexification:* The subgraph H, induced by removing bridge particles from the shape, is a collection of polygons. Each outer boundary particle P w.r.t. H that is a concave vertex and not a semi-bridge particle expands towards the outer boundary along P's angle bisector while coordinating the pulling of P's tree with it. P occupying node b and moving to node c completes one step of convexification when it has moved to node c and all particles in the tree rooted at P in F_1 are back in a contracted state. Convexification is performed repeatedly by particles until no more steps of convexification are possible (refer to Figure 16 for an example).

   At the same time, each seg-head P_i $(1 \leq i \leq k)$ continuously checks its segment for any concave vertices in H. If none are found, the k seg-heads coordinate to terminate this phase. All particles previously in H update their edges in H to reflect current connections to other particles. Bridge and semi-bridge particles add themselves and their bridge edges to virtual graph K. Note that all particles are contracted at the end of this phase.

   The phase as described so far may be stopped before convexification completes if two types of situations arise. *Type 1*: during the movement outward, an outer boundary particle that moved in some direction D to node b in one step of convexification finds out that the node adjacent to b in direction D is occupied. *Type 2*: a semi-bridge particle, bridge particle, or outer boundary particle stops being one. Both types reflect a change in the particles occupying the outer boundary, possibly resulting in particles previously with $seg\_head = true$ no longer lying on the outer boundary. The algorithm then resets to phase 1, as described in the full version (the reset procedure also makes sure that all the particles are reset to a contracted state).

4. *De-sharpification:* In this phase, certain particles remove themselves from H recursively until only convex polygons and two-node lines remain in H. Consider a particle P in H. If P is not a semi-bridge particle and is a sharp vertex w.r.t. the outer boundary in H, then P removes itself from H. If P is a semi-bridge particle and its occupied adjacent nodes are located at ports $x, x+1, x+3$, and $x+4$ (mod 6) for some positive integer value of x, then P removes itself from H.

   At the same time, each seg-head P_i $(1 \leq i \leq k)$ checks its segment continuously for any sharp vertices in H. If none are found, P_i coordinates with the other $k-1$ seg-heads to terminate the phase. The induced subgraph H at the end of the phase is a set containing just two types of polygons: (a) lines consisting of 2 nodes as well as (2) convex polygons without sharp vertices. Note that all the particles remain contracted at the end of this phase.

5. *Leader election on individual polygons and spanning tree formation:* This phase consists of two stages. In stage one, each convex polygon and each line in H elects a unique polygon leader using $\texttt{Convex} - \texttt{Polygon} - \texttt{Leader} - \texttt{Election}$ and $\texttt{MIS} - \texttt{Selection}$, respectively. In stage two, each particle P chosen as a polygon leader in stage one, acts as a root and forms a tree that spans its connected component of $G \setminus K$. The nodes in K that are reachable from P over $G \setminus K$ are leaves of P's tree. Call this forest of polygon leaders rooted trees F_2.

   The termination condition is somewhat long to describe; see the full version for details. Very informally - the polygons are connected by semi-bridge particles. Hence, when a polygon leader finished constructing its tree over the polygon, the semi-bridge particle(s) is notified. The seg-head particles P_i $(1 \leq i \leq k)$ check continuously the semi-bridge particles to know when the construction of F_2 is done.

   At the end of this phase, K is updated to contain all particles in graph G with edges restricted to bridge edges and edges of F_2. It is shown later in a lemma that K now forms a tree, spanning all the candidates (status **C** particles).

6. *Leader election on a spanning tree:* Each particle participates in $\texttt{Spanning}-\texttt{Tree}-\texttt{Leader}-\texttt{Election}$ on the graph K. Once a particle P changes its status to $\mathbf{L}$, P broadcasts a $final\_terminate$ message by flooding along K. This results in one particle, the leader, having status $\mathbf{L}$ and the remaining particles having status $\mathbf{U}$ when the algorithm terminates.

The following lemmas apply to the algorithm, with proofs deferred to the full version.

▶ **Lemma 6.** *Phase 1 terminates in $O(L_m^2)$ rounds, where L_m is the length of the largest boundary of the shape, resulting in each boundary particle knowing what type each of its boundaries is and k, $k \in \{1, 2, 3, 6\}$, particles, $P_1, P_2, \ldots, P_k$, lying on the outer boundary with $seg\_head = true$. Furthermore, at the end of the phase, H consists of a set of simple convex polygons, where two simple polygons may share the same semi-bridge particle. If $k = 1$, the algorithm terminates with one particle as leader in an additional $O(n)$ rounds.*

▶ **Lemma 7.** *Phase 2 terminates in $O(n)$ rounds, resulting in a disjoint forest of trees F_1 covering every particle.*

▶ **Lemma 8.** *Phase 3 terminates in $O(Ln)$ rounds, resulting in either a reset or a graph H containing a set of simple convex polygons, where two simple polygons may share the same semi-bridge particle.*

▶ **Lemma 9.** *There can be at most L resets occurring in phase 3, where L is the length of the outer boundary of the original shape.*

▶ **Lemma 10.** *Phase 4 takes $O(n)$ rounds to complete, resulting in H containing only a set of lines consisting of 2 nodes and convex polygons without sharp vertices.*

▶ **Lemma 11.** *Phase 5 terminates in $O(L^2+n)$ rounds resulting in K containing all particles and forming a spanning tree.*

▶ **Lemma 12.** *Phase 6 terminates in $O(n)$ rounds resulting in a unique leader with status $\boldsymbol{L}$ being chosen and all other nodes having status $\boldsymbol{U}$.*

Combining the above lemmas together, we get the desired results.

▶ **Theorem 13.** *Algorithm* $\texttt{Leader}-\texttt{Election}-\texttt{By}-\texttt{Moving}$*, run by n particles in a contracted configuration, elects a unique leader deterministically and terminates in $O(Ln^2)$ rounds, where L is the number of particles on the outer boundary of the original shape.*

Proof Sketch. From Lemmas 6, 7, and 8, the combined running time of one iteration of phases 1 to 3 is $O(n^2)$ rounds since $L_m = O(n)$. There can be at most $O(L)$ iterations of phases 1 to 3, by Lemma 9. Adding in the running times of phases 4 to 6 from Lemmas 10, 11, and 12, it is clear that the total running time of the algorithm is $O(Ln^2)$ rounds.

The correctness directly follows from Lemma 12. ◀

5 Chirality Agreement

In this section, procedure $\texttt{Chirality}-\texttt{Agreement}$ is described. Consider n contracted particles forming a connected shape with the length of maximum boundary being $L_{\max}$. The particles run $\texttt{Chirality}-\texttt{Agreement}$ and terminate in $O(L_{\max}^2 + n)$ rounds, resulting in all particles agreeing on the same chirality and forming the original shape.

Informally, after the boundary particles identify their boundaries, they first agree on chirality separately for each boundary they lie on. This is easier than leader election given the local symmetry breaking built into the model (atomicity of the scheduler). This is enough to allow the particles to identify the outer boundary similarly to the way it was done for the leader election. Finally, the chirality agreed upon for the outer boundary becomes the chirality of everyone. A detailed explanation of the procedure along with the proof of the following theorem can be found in the full version.

▶ **Theorem 14.** *Procedure* `Chirality − Agreement`*, run by n contracted particles forming a connected shape, terminates in $O(L_{\max}^2)$ rounds, where $L_{\max}$ is the length of the largest boundary in the shape, resulting in all particles having common chirality and retaining the original shape.*

6 Conclusion and Future Work

The results of this paper leave several lines of research open. First, the algorithms here require the particles to move for leader election and for chirality agreement. Is it possible to solve either problem deterministically in the given setting without requiring particles to move? Second, can one reduce the running time or provide a matching lower bound?

Abstract

A temporal graph is a graph whose edge set can change over time. We only require that the edge set in each time step forms a connected graph. The temporal exploration problem asks for a temporal walk that starts at a given vertex, moves over at most one edge in each time step, visits all vertices, and reaches the last unvisited vertex as early as possible. We show in this paper that every temporal graph with n vertices can be explored in $O(n^{1.75})$ time steps provided that either the degree of the graph is bounded in each step or the temporal walk is allowed to make two moves per step. This result is interesting because it breaks the lower bound of $\Omega(n^2)$ steps that holds for the worst-case exploration time if only one move per time step is allowed and the graph in each step can have arbitrary degree. We complement this main result by a logarithmic inapproximability result and a proof that for sparse temporal graphs (i.e., temporal graphs with $O(n)$ edges in the underlying graph) making $O(1)$ moves per time step can improve the worst-case exploration time at most by a constant factor.

1 Introduction

Temporal graphs, or time-varying graphs, are graphs whose edge set changes over time. Due to the prevalence of dynamic networks whose links change over time in many application settings (e.g., wireless mobile networks, transportation networks, social networks), the study of algorithmic aspects of temporal graphs has received increasing attention recently [14]. A temporal graph $\mathcal{G}$ with lifetime τ is a sequence of graphs $G_i = (V, E_i)$, for $i = 1, \ldots, \tau$, that all have the same vertex set, but possibly different edge sets. A particular problem of interest is the *temporal exploration problem* (TEXP) where an agent starts at a given vertex $s \in V$ and aims to visit all vertices in V as quickly as possible (i.e., minimizing the time step in which the last unvisited vertex is reached) while making one move (either stay at the current vertex or move to a neighboring vertex in the current graph) in each time step. The existence of such an exploration is guaranteed if the graph G_i in each time step is a connected graph [13], and so it has become customary to study TEXP for temporal graphs with this property [6, 7, 13]. We make the same assumption throughout this paper. The number of vertices of the temporal graph under consideration is denoted by n.

It is known that every temporal graph (under the assumption that the graph in each step is connected) can be explored in $O(n^2)$ steps and that there are temporal graphs that require $\Omega(n^2)$ steps to be explored [6]. The construction of temporal graphs that require $\Omega(n^2)$ steps for an exploration from [6] produces temporal graphs for which the graph in each step has a vertex of high degree (the graph in each step is a star, so one vertex has degree $n-1$) and in which the edge set changes in every step (the center of the star changes in each step). This poses the natural question whether a better upper bound on the worst-case exploration time holds if any of these properties is avoided, i.e., if the graph in each step has bounded degree or if the edge set of the graph changes only in every other step (which is, up to a factor of two, equivalent to allowing the agent to make two moves instead of one in each step). A first step towards answering this question was made in [7], where it was shown that $O(\log \Delta \cdot \frac{n^2}{\log n})$ steps[1] suffice for the exploration if the graph in each step has maximum degree at most Δ. For constant Δ, this proves that $O(\frac{n^2}{\log n})$ steps suffice.

In this paper, we present a substantial further improvement by showing that $O(n^{1.75})$ steps suffice for an exploration if either the graph in each step has bounded degree, or if the graph in each step has arbitrary degree but the agent can make two moves in each step (or, equivalently, if the agent can make one move per step but the graph changes only in every other step). Surprisingly, the improvement for both cases follows from the same analysis: The key insight is that the better bound on the number of time steps required for an exploration can be proved if the graph in each time step admits a spanning tree of bounded degree. The existence of such a spanning tree is obvious if the graph itself is connected and has bounded degree, and it follows in the model with two moves per step because the square of any connected graph has a spanning tree of bounded degree.

To complement our positive result, we also show that letting the agent make c moves per step, for any constant c, cannot improve the worst-case exploration time for any family of temporal graphs where the underlying graph (the union of the graphs in all steps) has $O(n)$ edges by more than a constant factor. Furthermore, we show that it is *NP*-hard to approximate the exploration time with approximation ratio better than $c \log n$ for some constant c, both for the case of bounded degree and the case of two moves per step.

[1] The conference paper [7] proves a weaker bound of $O(\Delta \log \Delta \cdot \frac{n^2}{\log n})$, but a simple change in one calculation shows that the factor Δ can be avoided.

The remainder of the paper is organized as follows. Section 1.1 discusses related work. Preliminaries are given in Section 2. The main results, showing that exploration in $O(n^{1.75})$ time steps is possible for the case of bounded degree and the case of two moves per step, are presented in Sections 3 and 4, respectively. The result that bounds the improvement obtainable by using c moves per step for sparse temporal graphs and the inapproximability results appear in Sections 5 and 6, respectively. Section 7 concludes the paper.

1.1 Related Work

Brodén et al. [3] studied a temporal analogue of the traveling salesperson problem (TSP) in which the graph is a complete graph in every step and the cost of every edge is either 1 or 2 in each time step, with each edge being allowed to change its cost at most k times over the graph's lifetime. They provided an approximation algorithm with approximation ratio $2 - \frac{2}{3k}$. Michail and Spirakis [13] studied this model as well, showing the general problem to be *APX*-hard and presenting a $(1.7 + \varepsilon)$-approximation algorithm. They also considered the temporal exploration problem and showed that it is *NP*-hard to decide if a temporal graph can be explored if no restrictions are placed on the graph in each step. They therefore suggested making the assumption that the graph is connected in each step, which has turned out to be a very useful model to study. They proved that it is *NP*-hard to approximate the temporal exploration problem under this assumption with ratio $2 - \varepsilon$. Erlebach et al. [6] strengthened this result and proved that approximation with ratio $n^{1-\varepsilon}$ for any $\varepsilon > 0$ is *NP*-hard. Moreover, they constructed a concrete family of temporal graphs for which exploration takes $\Omega(n^2)$ time. They also presented further results for special graph classes, including upper bounds of $O(n^{1.5}k^2 \log n)$ steps for underlying graphs of treewidth k and $O(n \log^3 n)$ steps for the case that the underlying graph is a $2 \times n$ grid. For the case that the underlying graph is a planar graph of maximum degree 4 and the graph in each step is a path, they proved that $\Omega(n \log n)$ steps can be necessary in the worst case. The temporal exploration problem for the special case where the underlying graph is a ring has been studied for the setting of T-interval-connectivity (the intersection of the graphs of any T consecutive time steps is connected) by Ilcinkas and Wade [11]. Decentralized algorithms for the exploration of temporal rings have been studied by Di Luna et al. [5]. Temporal exploration for the case where the underlying graph is a cactus has been studied by Ilcinkas et al. [10].

For surveys of other work on algorithmic aspects and different models of temporal or time-varying graphs we refer to [4, 12]. Examples of recent work include results on the design of temporal networks [1], on temporal (s, t)-separation problems [8, 15], and on temporal vertex cover with sliding time windows [2].

2 Preliminaries

▶ **Definition 2.1** (Temporal Graph). *We represent a temporal graph $\mathcal{G}$ with underlying graph $G = (V, E)$ using an ordered sequence of static graphs: $\mathcal{G} = \langle G_1, G_2, \ldots, G_\tau \rangle$. The subscripts $i \in 1, 2, \ldots, \tau$ indexing the graphs in the sequence are the discrete time steps 1 to τ, where τ is known as the lifetime of G. Each G_i represents the structure of G in time step i. More precisely, $G_i = (V, E_i)$ is a subgraph of G with $V(G_i) = V(G)$ and $E_i \subseteq E$ for all $1 \leq i \leq \tau$.*

▶ **Definition 2.2** (Temporal walk). *A temporal walk W through a temporal graph $\mathcal{G}$ is given as an alternating sequence of vertices and edge-time pairs*

$$W = v_0, (e_0, i_0), v_1, (e_1, i_1), v_2, \ldots, v_{k-1}, (e_{k-1}, i_{k-1}), v_k$$

that starts at vertex v_0 and ends at vertex v_k. Additionally, we require that $i_0 < i_1 < \ldots < i_{k-1}$, so that an agent following W can traverse at most one edge per time step. Each edge-time pair (e_j, i_j) denotes the traversal of edge $e_j = \{v_j, v_{j+1}\}$ at time step i_j. For such a traversal to be possible, e_j must be present in graph G_{i_j}, i.e., $e_j \in E_{i_j}$. We say that the walk W departs at time i_0 (or, at a time $i' \leq i_0$ if we imagine the walk to wait at v_0 from time i' to time i_0), and arrives at time $i_{k-1} + 1$.

We often view a temporal walk W, defined as above, as describing the movement of an agent that is initially located at v_0 and can, in each step, either stay at its current vertex or move to a neighboring vertex in the current graph.

▶ **Lemma 2.3** (Reachability Lemma [6]). *Let $\mathcal{G}$ be a temporal graph with vertex set V, and assume that $\mathcal{G}$ is connected in each step. Then an agent situated at any vertex $u \in V$ at any time $t \leq \tau - n$ can reach any other vertex $v \in V$ in at most $|V| - 1 = n - 1$ steps, i.e., by time step $t + n - 1$.*

▶ **Problem** (Temporal Exploration). *An instance of the* Temporal Exploration *(TEXP) problem is given by a pair $(\mathcal{G}, s)$, where $\mathcal{G} = \langle G_1, G_2, \ldots, G_\tau \rangle$ is an arbitrary temporal graph with lifetime $\tau \geq |V(G)|^2 = n^2$ (in order to ensure that there exist feasible solutions for any instance), and $s \in V(\mathcal{G})$ is a start vertex. The problem then asks for a temporal walk W that departs from vertex s and visits all vertices of $\mathcal{G}$ and minimizes the arrival time at the last unvisited vertex. We make the extra assumption that the graph is connected in each step; without this it could happen that there exists no valid exploration schedule.*

We end the section with an auxiliary lemma used in the next section.

▶ **Lemma 2.4.** *Let $T = (V, E)$ be a tree with maximum degree Δ and $U \subseteq V$. Then $\lfloor |U|/(\Delta + 1) \rfloor$ pairs of vertices in U can be found such that the paths between all pairs are pairwise vertex-disjoint.*

Proof. We root T at an arbitrary vertex and explain how to iteratively select pairs $\{u, v\} \subseteq U$. The procedure will ensure that, whenever we select a pair of vertices in U, there are at most $\Delta - 1$ other vertices in U that can no longer be paired up and have to be removed from U.

Let $u, v \in U$ be two vertices such that their lowest common ancestor $w = \mathrm{lca}(u, v)$ has the largest possible depth. Note that we may have $w = v$ or $w = u$. Since T has maximum degree Δ, w can have at most Δ children. There can be at most $\Delta + 1$ vertices from U in the subtree rooted at w: Each subtree rooted at a child of w contains at most one vertex from U (by our choice of w), and w itself may be in U. Select the pair $\{u, v\}$ and remove u, v and all other vertices that are in the subtree rooted at w from U, a total of at most $\Delta + 1$ vertices. It is easy to see that the paths between the pairs selected by this procedure are vertex-disjoint. ◀

3 Exploration of Degree-Bounded Temporal Graphs

In this section, our goal is to construct a temporal walk using $O(n^{1+\alpha})$ time steps on a temporal n-vertex graph $\mathcal{G}$ for some α with $0 < \alpha < 1$. We assume that the maximum degree of the graph G_i in each step is bounded by a constant $\Delta \in \mathbb{N}$. While constructing the temporal walk, we distinguish between vertices that already belong to our constructed temporal walk, which we call *seen vertices*, and the remaining vertices, called *unseen vertices*. We first show in Section 3.1 that $O(n^{1.8})$ time steps suffice, and then improve the analysis further to get $O(n^{1.75})$ time steps in Section 3.2.

3.1 Phases, Subphases, Labels and Forbidden Sets

Recall that the reachability lemma allows us to easily construct a temporal walk with arrival time $O(n^2)$ by picking an arbitrary order $s = v_1, v_2, \ldots, v_n$ of vertices and searching for a temporal walk from v_1 to v_2, from v_2 to v_3, and so on, each starting when the previous walk arrives and using $O(n)$ time steps. To find a better solution, we have to avoid fixing the order of the vertices without considering the given temporal graph. We divide our construction into so-called *phases*, each consisting of $O(n)$ time steps. Within each phase we construct several *temporal subwalks*, one ending at each unseen vertex. We say that a subwalk is better than another subwalk if it contains more unseen vertices. Among the constructed subwalks, we then choose a best subwalk and use it to extend the temporal walk constructed so far.

By leaving $O(n)$ time steps between two phases, we can easily connect the subwalks of two subsequent phases by the reachability lemma.

Let ℓ be the number of unseen vertices at the beginning of the current phase. The phase is split into *subphases* $1, 2, 3, \ldots$ where the goal of each subphase is to replace a constant fraction of the subwalks by subwalks that have at least one more unseen vertex. For every unseen vertex v we use a *label* $L(v)$ to store the (ordered sequence of the) unseen vertices of the subwalk ending at v. We also keep track of the subwalk that visits all the unseen vertices in $L(v)$, and we use $L(v)$ to refer to that subwalk if no confusion can arise.

We set $L(v) = v$ at the beginning of the phase. Moreover, we maintain the invariant that after the ith subphase, no subwalk has more than $i + 1$ unseen vertices, i.e., $|L(v)| \leq i + 1$ for all unseen vertices v. We cannot guarantee that there is an improvement w.r.t. the total number of unseen vertices of the subwalks in every time step. Instead, at the beginning of each subphase, we place labels on all unseen vertices. In each time step the idea is to propagate labels from a vertex to one of its neighbors and analyze the total improvement in the spread of the labels. Whenever a label reaches another unseen vertex w, a longer subwalk is found that may replace the label of w in the next subphase. A similar approach was used by Erlebach and Spooner [7].

To measure the improvement during the time steps, we additionally define for every vertex v a *home set* $H(v)$ consisting of labels of unseen vertices that can reach v within the time steps of the current subphase. At the beginning of a subphase, we set $H(v) = \{L(v)\}$ for every unseen vertex v, and $H(v) = \emptyset$ for the remaining vertices. For technical reasons, in subphase i, the size of each home set is bounded by $2i + 1$.

During the extension of a subwalk we have to avoid adding the same unseen vertices to a subwalk again. For this purpose, we store for every unseen vertex v a set of vertices whose subwalks cannot be extended by v (because they already contain v). More precisely, we store a *forbidden set* $F(v)$ of every unseen vertex v that consist of all unseen vertices w with $v \in L(w)$. Note that $v \in F(v)$ for every unseen vertex v. We next describe our first operation on the home sets.

Operation 1: If u and v are connected by an edge in the current time step, we are allowed to copy a label L from the home set $H(v)$ into the home set $H(u)$. In addition, we can delete a label L' from $H(u)$, i.e., we can replace a label L' by L in $H(u)$.

As one can easily see by induction, a label of an unseen vertex u can be part of a home set of a vertex v by the start of time step t only if there is a temporal walk from u to v with arrival time t in the current subphase.

In the following, we motivate a second operation. Let v and u be unseen vertices. If $L(u) \in H(w)$ where $w = v$ or w is a neighbor of v, $u \notin F(v)$ and $|L(u)| \geq |L(v)|$ holds, the subwalk $L(u)$ ending at u can be extended by v and this can be a subwalk ending at v that is better than the current subwalk $L(v)$. In this case, we can take the better subwalk for v,

i.e., we define $L_{\text{new}}(v) := L(u) \circ v$. Note that we have that $|L(u)| \leq i$ at the end of subphase $i-1$ by our invariant and hence it follows that $|L_{\text{new}}(v)| \leq i+1$. Thus, the invariant holds also in the next subphase.

For the remaining time steps of the current subphase, it would seem to be useful to start propagating the new label of v starting from v. However, then we would have several labels ending at v and this would increase the total size of the forbidden sets, which we cannot afford. Therefore, we set $L(v) := L_{\text{new}}(v)$ only at the end of the current subphase. For the remainder of the current subphase, we leave all $L(v)$ in the home sets unchanged. In particular, it is still possible that the label $L(v)$ reaches another unseen vertex w – which means that we may also be able to set $L_{\text{new}}(w) := L(v) \circ w$. Altogether, we get the following operation.

Operation 2: If a label $L(u)$ is in $H(x)$ for some vertex x in the closed neighborhood of an unseen vertex v and if $|L(v)| \leq |L(u)|$ as well as $u \notin F(v)$, then we can define $L_{\text{new}}(v) := L(u) \circ v$.

In the following we measure our progress by an increase in the potential function $\phi = |\{u \text{ unseen vertex} \mid L'(u) \neq L(u)\}| + \sum_{v \in V} \sum_{L \in H(v)} |L|$ where $L'(u) := L_{\text{new}}(u)$ if $L_{\text{new}}(u)$ is defined in the current subphase and $L'(u) := L(u)$ otherwise.

▶ **Lemma 3.1.** *Assume that we are in the ith subphase. Given a set of unseen vertices U of size k with $L(u) \in H(u)$, $L'(u) = L(u)$ and $|F(u)| \leq 2i$ for all $u \in U$, the operations from above allow us to modify the labels of the unseen vertices and the home sets of all vertices in such a way that ϕ increases by $\Omega(k/i)$ within one time step.*

Proof. We consider a spanning tree T in the graph of $\mathcal{G}$ in the time step under consideration. Since the graph has maximum degree at most Δ, also T obeys this degree bound.

Next we pair up the unseen vertices in such a way that they are connected by pairwise vertex-disjoint paths. However, we are not allowed to pair up vertices where one is in the forbidden set of the other. Therefore, we compute a set of unseen vertices $U' \subseteq U$ such that we can pair up the vertices in U' without taking the forbidden sets into consideration. To determine U', start with $U' = \emptyset$ and greedily iterate over the vertices $u \in U$. Whenever $F(u) \cap U' = \emptyset$ and $L(u) \cap U' = \emptyset$ holds, add u to U'. The latter condition guarantees $F(v) \cap (U' \cup \{u\}) = \emptyset$ for all v already in U'. Since each vertex u in U' can prevent the insertion of at most $|L(u) \setminus \{u\}| + |F(u) \setminus \{u\}| \overset{\text{invariant}}{\leq} 3i-1$ vertices into U', $|U'| = \Omega(k/i)$. Next, pair up the vertices of U' in such a way that, in T, the paths between every two pairs of vertices are pairwise vertex-disjoint. By Lemma 2.4, we obtain at least $\Omega(k/i)$ pairs since the current graph of $\mathcal{G}$ and thus T has constant degree Δ.

We next show that, for each of the chosen pairs of vertices u and v, ϕ increases by at least one. For this purpose, we focus on the path P between u and v in T, and let w be the neighbor of u in P. W.l.o.g. $|L(u)| \leq |L(v)|$ holds. We consider two cases.

Case 1. The home set of w contains a label $L(x)$ with $x \notin F(u)$ and $|L(x)| \geq |L(u)|$. Then we define $L_{\text{new}}(u) := L(x) \circ u$ using Operation 2 and remove u from U, but leave all occurrences of $L(u)$ in the home sets unchanged. In this way we get a potential increase since u newly satisfies the condition $L'(u) \neq L(u)$.

Case 2. Otherwise, we argue as follows. Note that, if $|H(w)| = 2i+1$ and $|L(x)| \geq |L(u)|$ for all $L(x) \in H(w)$, then we are in Case 1 since $|F(u)| \leq 2i$ for all $u \in U$. Thus, either $|H(w)| < 2i+1$ or $H(w)$ contains a label $L(x)$ that is strictly shorter than $|L(u)|$. Moreover, since $u, v \in U'$, we have $v \notin F(u)$. Since we are not in Case 1, $L(v) \notin H(w)$.

Let f be the function that removes from a set all labels that are shorter than $|L(v)|$. Note that $|f(H(w))| \leq 2i$ because either $|H(w)| \leq 2i$ or $H(w)$ contains a label that is strictly shorter than $|L(u)|$ and thus also strictly shorter than $|L(v)|$.
Now, observe that it is not possible that, for each pair of subsequent vertices x (possibly w) and y (possibly v) on the path from w to v, where x is closer to w than y, $f(H(x)) \supseteq f(H(y))$ holds – this would be a contradiction to $L(v) \notin f(H(w))$ and $L(v) \in f(H(v))$. Therefore, there must be a pair of consecutive vertices x and y on the path, with x closer to w, such that $f(H(x))$ is not a superset of $f(H(y))$. Among all such pairs of vertices, choose the one such that x is closest to w. As we have $|f(H(w))| \leq 2i$, it follows that $|f(H(x))| \leq 2i$. By Operation 1 we copy a label $L \in f(H(y)) \setminus f(H(x))$ from $H(y)$ to $H(x)$. Possibly, we additionally have to remove a shorter label L' from $H(x)$ in order to ensure that $|H(x)|$ remains bounded by $2i + 1$. If $|H(x)| = 2i + 1$, then L' must exist since $H(x)$ has at most $2i$ labels being $\geq |L(v)|$ long. Thus, ϕ increases. In case $x \in U$, we have to be careful that we do not remove $L(x)$ from $H(x)$ in this operation. Therefore, in that case we do not replace $L(x)$ in $H(x)$ by a longer label unless all other labels in $H(x)$ are longer than $L(x)$. If this is the case and we replace $L(x)$ in $H(x)$, then $H(x)$ now contains $2i + 1$ labels longer than $L(x)$ and, since $|F(x)| \leq 2i$, one of these is $L(v')$ for some $v' \notin F(x)$ and we can apply Operation 2 and set $L_{\text{new}}(x) = L(v') \circ x$ and remove x from U. ◀

To guarantee the condition on the size of the forbidden sets in the lemma above, we do not add all unseen vertices u with $L'(u) = L(u)$ into the set U. Instead, we initially define $U = \{u \text{ unseen vertex} \mid L'(u) = L(u) \text{ and } |F(u)| \leq 2i\}$. Since the total label length is at most $i\ell$ by our invariant, there can be at most $\ell/2$ unseen vertices u with $|F(u)| > 2i$. As long as we have $L'(u) \neq L(u)$ for at most $\ell/4$ unseen vertices u in the current subphase, we have $|U| \geq \ell - \ell/2 - \ell/4 = \ell/4$.

Within each time step, the set of vertices u with $L'(u) = L(u)$ shrinks whenever we apply Operation 2. We apply the lemma only while at most $\ell/4$ vertices have been removed from U, so this does not cause a problem.

▶ **Lemma 3.2.** *Given a set of unseen vertices U of size ℓ in the beginning of the ith subphase, $\Theta(ni^3/\ell)$ time steps allow us to increase the length of at least $\ell/4$ subpaths (i.e., labels of unseen vertices) by one.*

Proof. By Lemma 3.1, $\phi \geq \ell/4 + i(2i + 1)n$ after $\Theta(i/4 + i^2(2i + 1)(n/\ell)) = \Theta(ni^3/\ell)$ time steps (or we set L_{new} for at least $\ell/4$ vertices even earlier). This can happen only if $L'(u) \neq L(u)$ for at least $\ell/4$ unseen vertices u since we have in the home sets at most $(2i+1)$ labels of length i for every vertex. ◀

We stop the construction of the temporal walk in phases when fewer than n^α unseen vertices remain for some α with $0 < \alpha < 1$ and finish the temporal walk by adding the remaining n^α unseen vertices in $O(n^{1+\alpha})$ time steps (by visiting them in arbitrary order using the reachability lemma). Therefore, we can assume for the next lemma that the number of unseen vertices is $\ell \geq n^\alpha$.

▶ **Lemma 3.3.** *After $O(n)$ time steps within one phase, a temporal subwalk consisting of $\Theta(\ell^{1/4}) = \Omega(n^{\alpha/4})$ unseen vertices has been found.*

Proof. By Lemma 3.2, we spend $\Theta(ni^3/\ell)$ time steps in subphase i. Since we have $O(n)$ time steps, the number of subphases x within one phase is bounded by the following equation: $\Theta((n/\ell)(1^3+2^3+\ldots+x^3)) \subseteq O(n)$. This means that we can have $x = \Theta(\ell^{1/4})$ subphases. ◀

By choosing $\alpha = 4/5$, we have to run $(n - n^\alpha)/n^{\alpha/4} = \Theta(n^{4/5})$ phases until n^α vertices remain. Thus, this part uses $\Theta(n^{9/5})$ time steps, which is also true for the construction of the rest of the temporal walk.

▶ **Theorem 3.4.** *Let $\mathcal{G}$ be a temporal graph with n vertices that is connected and has constant degree in every time step. Then, $\mathcal{G}$ admits a temporal walk that visits all vertices and arrives at the last unvisited vertex after $O(n^{9/5}) = O(n^{1.8})$ time steps.*

3.2 A Tighter Analysis

For the analysis in the previous section, we have applied Lemma 3.3 with the pessimistic assumption that the number of unseen vertices at the start of each phase is only n^α (giving subwalks visiting $\Theta(n^{\alpha/4}) = \Theta(n^{1/5})$ unvisited vertices). There are clearly more unseen vertices in the earlier phases (e.g., $n-1$ unseen vertices at the start of the first phase, thus admitting a subwalk visiting $\Theta(n^{1/4})$ vertices by Lemma 3.3). To get a tighter bound, we analyze the required number of phases more carefully. Let γ, $0 < \gamma < 1$, be the constant hidden in the bound $\Theta(\ell^{1/4})$ from Lemma 3.3, i.e., each phase visits at least $\gamma \cdot \ell^{1/4}$ unseen vertices if there are ℓ unseen vertices at the start of the phase. An upper bound $f(t)$ on the number of unseen vertices after t phases is now given by the following equation system:

$$\begin{aligned} f(0) &= n \\ f(t) &= f(t-1) - \gamma \cdot (f(t-1))^{1/4}, \text{ for } t \geq 1 \end{aligned} \tag{1}$$

The following claim establishes a closed formula for an upper bound on $f(t)$.

▷ Claim 3.5. $f(t) \leq (n^{3/4} - \frac{3}{4}\gamma t)^{4/3}$ for all $t \geq 0$.

Proof. We prove the claim by induction. For the base of the induction, note that for $t = 0$ we have $f(0) = n = (n^{3/4} - \frac{3}{4}\gamma \cdot 0)^{4/3}$. For the induction step, assume that the claim holds for $t-1$. We want to show that it also holds for t. By the induction hypothesis and using the fact that the function $g(x) = x - \gamma x^{1/4}$ is monotone increasing for $x \geq 1$ (even for $x \geq (\gamma/4)^{4/5}$) we get:

$$\begin{aligned} f(t) &= f(t-1) - \gamma \cdot (f(t-1))^{1/4} \\ &\leq (n^{3/4} - \tfrac{3}{4}\gamma(t-1))^{4/3} - \gamma \cdot \sqrt[4]{(n^{3/4} - \tfrac{3}{4}\gamma(t-1))^{4/3}} \\ &= (n^{3/4} - \tfrac{3}{4}\gamma t + \tfrac{3}{4}\gamma)^{4/3} - \gamma \cdot (n^{3/4} - \tfrac{3}{4}\gamma t + \tfrac{3}{4}\gamma)^{1/3} \end{aligned}$$

We need to show that the right-hand side is bounded by $(n^{3/4} - \frac{3}{4}\gamma t)^{4/3}$. Setting $y = n^{3/4} - \frac{3}{4}\gamma t$, this is equivalent to:

$$\begin{aligned} & (y + \tfrac{3}{4}\gamma)^{4/3} - \gamma \cdot (y + \tfrac{3}{4}\gamma)^{1/3} \leq y^{4/3} \\ \Leftrightarrow \quad & (y + \tfrac{3}{4}\gamma)^{4/3} - y^{4/3} \leq \gamma \cdot (y + \tfrac{3}{4}\gamma)^{1/3} \end{aligned}$$

With $h(x) = x^{4/3}$, the latter inequality is equivalent to

$$h(y + \tfrac{3}{4}\gamma) - h(y) \leq \tfrac{3}{4}\gamma \cdot h'(y + \tfrac{3}{4}\gamma),$$

which holds because the function $h(x)$ is convex. Hence, the inductive step is complete. ◁

Equation (1) is valid as long as the number of unseen vertices is sufficiently large. The value of t for which $f(t)$ becomes smaller than $n^{3/4}$ is clearly smaller than $\frac{4}{3\gamma}n^{3/4}$. Hence, $O(n^{3/4})$ phases of length $O(n)$, a total of $O(n^{1.75})$ time steps, suffice to reduce the number of unseen vertices to a value below $n^{3/4}$, and the remaining unseen vertices can be visited in $O(n^{1.75})$ steps via the reachability lemma.

▶ **Theorem 3.6.** *Let $\mathcal{G}$ be a temporal graph with n vertices and constant degree that is connected in every time step. Then, $\mathcal{G}$ has a temporal walk that visits all vertices and uses $O(n^{7/4}) = O(n^{1.75})$ time steps.*

4 Two Moves per Time Step in a Graph of Unbounded Degree

Erlebach, Hoffmann and Kammer [6] showed that there are temporal graphs of unbounded degree where a temporal walk visiting all vertices needs $\Theta(n^2)$ time steps. We show in this section that we can break this lower bound not only if the graph in each step has bounded degree, but also if we allow up to *two moves* per time step, i.e., in each time step we are allowed to move from a vertex v to a neighbor w of v and then to a neighbor of w.

We handle the two moves in a temporal graph $\mathcal{G} = \langle G_1, G_2, \ldots, G_\tau \rangle$ for some $\tau \in \mathbb{N}$ by adding additional edges between each pair of vertices of distance 2 in each graph G_i $(i = 1, \ldots, \tau)$ to obtain a graph G_i^2, the so-called *square graph* of G_i. Afterwards, we can simply use the "one-move-per-time-step approach" in $\mathcal{G}^2 = \langle G_1^2, G_2^2, \ldots, G_\tau^2 \rangle$.

▶ **Lemma 4.1.** *The square of a connected graph has a spanning tree with maximum degree 3.*

Proof. Let G be a connected graph and G^2 the square of G. Compute a spanning tree T in G. This spanning tree T is also a spanning tree in G^2. Now color all edges of T black. Note that, because the children of every vertex of T are directly connected in G^2, we are allowed to connect them in T and still have a subgraph of G^2.

We next reduce the degree of each vertex in T. First, delete all black edges from each vertex v to all its children except one. Starting from that child, we then connect the children of v by a red path, see also Fig. 1. After applying these changes to each vertex v we can observe the following: Each vertex v (except the root) was either the first child in T or not. In the former case, v has a red edge and the remaining black edges can be to a parent and to at most one child. In the second case, v has at most two red edges to siblings and possible one black edge to a child. Hence, in both cases v has maximum degree 3. ◀

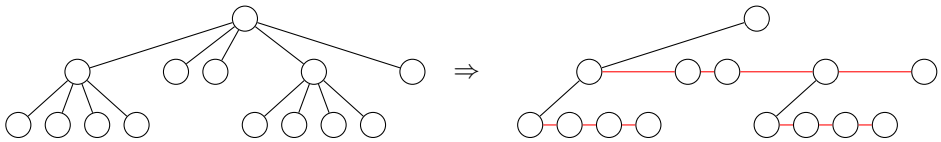

Figure 1 Left: A spanning tree T of a graph G. Right: The transformation of T into a spanning tree in G^2 of maximum degree 3 as shown in Lemma 4.1.

By using the lemma above for the construction of a spanning tree in the proof of Lemma 3.1, we get the following theorem.

▶ **Theorem 4.2.** *Let $\mathcal{G}$ be a temporal graph with n vertices and unbounded degree that is connected in every time step. Then $\mathcal{G}$ has a temporal walk that visits all vertices and uses $O(n^{7/4}) = O(n^{1.75})$ time steps if we allow at least two moves per time step.*

5 Bounded Benefit of c Moves per Step for Sparse Graphs

In the previous section we showed that allowing more than one move per time step enables us to break the existing lower bound of $\Omega(n^2)$ steps on general temporal graphs [6, Theorem 3.5]. We next show that there are certain temporal graph classes where c moves per time step, for an arbitrary integer $c = O(1)$, cannot decrease the worst-case bound on the exploration time by more than a constant factor.

Let $\mathcal{G}$ be a temporal graph with underlying graph $G = (V, E)$. The vertices of G are called *original vertices*. Denote the graph in time step i by G_i. For odd ℓ, we define an operation called *edge-path transformation of length* ℓ that produces a temporal graph $\mathcal{G}'$ with underlying graph G' and graph G'_i in time step i as follows: To construct G' from the underlying graph $G = (V, E)$ of $\mathcal{G}$, the transformation replaces each edge $\{u, v\} \in E$ by a path $\pi_{u,v} = u, a_1, a_2, \ldots, a_{\ell-1}, v$ of ℓ edges, where each a_i is a new *artificial vertex*. For an artificial vertex a_i, we define $o(a_i)$ to be the nearest original vertex, i.e., $o(a_i) = u$ if $i < \ell/2$ and $o(a_i) = v$ if $i > \ell/2$. For an original vertex w, we set $o(w) = w$. If $\{u, v\}$ is present in G_i, the whole path $\pi_{u,v}$ is present in G'_i. If $\{u, v\}$ is not present in G_i, the path $\pi_{u,v}$ without its *middle edge* $\{a_{\lfloor \ell/2 \rfloor}, a_{\lceil \ell/2 \rceil}\}$ is present in G'_i.

A temporal graph with $n \in \mathbb{N}$ vertices is called *sparse* if its underlying graph has $O(n)$ edges. We say that a function $f : \mathbb{N} \to \mathbb{N}$ is *nice* if $f(n/b) = \Omega(f(n))$ holds for any constant $b \geq 1$. For example, it is easy to see that all functions of the form $f(n) = n^g (\log n)^h$ for constant g, h are nice.

▶ **Theorem 5.1.** *Let $c = O(1)$ and let $\mathcal{G}^*$ be a class of sparse temporal graphs such that $\mathcal{G}^*$ is closed under the edge-path transformation of the odd length $\ell \in \{c, c+1\}$. If there is a lower bound on the number of steps for TEXP on $\mathcal{G}^*$ for one move per time step, given as a nice function of the number of vertices, then the same lower bound, up to a constant factor, also applies to TEXP on $\mathcal{G}^*$ if c moves per time step are allowed.*

Proof. Let $\mathcal{G}'$ be the temporal graph obtained from a temporal graph $\mathcal{G} \in \mathcal{G}^*$ by the edge-path transformation of length ℓ. We claim the following: If a temporal walk W' visiting all vertices in $\mathcal{G}'$ uses k time steps with $\leq \ell$ moves per time step, then there is a temporal walk W visiting all vertices in $\mathcal{G}$ consisting of k time steps with one move per time step.

To construct W, we iterate over the time steps and analyze the moves in W' within the current time step. Before and after each time step, we ensure the following invariants. (1) If W' is at a vertex a, then W is at $o(a)$. (2) All original vertices already visited by W' have also been visited by W.

Let a and a' be the (possibly artificial) vertices at which W' is located just before and just after the current time step, respectively. Let $u = o(a)$. Note that W is located at u just before the current step by (1). We let W move from u to $o(a')$ in the current step. Note that, if W' visits during the current step an original vertex that has not yet been visited by W, then that vertex must be $o(a')$. This is because W' starts on the far side of the middle edge on the path to that original vertex, and thus must end on the near side of the middle edge on the same or another path incident with that original vertex. It is easy to see that both invariants hold again after the time step.

Assume there is a lower bound on the worst-case exploration time for $\mathcal{G}^*$ given by a nice function f of the number of vertices. Let $\mathcal{G} \in \mathcal{G}^*$ be a worst case instance where TEXP requires at least $k = f(n)$ steps. Let $\mathcal{G}'$ be obtained from $\mathcal{G}$ by the edge-path-transformation of length ℓ. Using the claim above, we can conclude that TEXP requires at least k steps in $\mathcal{G}'$ even if $\ell \geq c$ moves per time step are allowed. Since $\mathcal{G}' \in \mathcal{G}^*$ and since $\mathcal{G}$ and $\mathcal{G}'$ have the same number of vertices and edges up to constant factors, we have that $k = f(n'/b)$ for some constant b, where n' is the number of vertices of $\mathcal{G}'$. As f is a nice function, we get a lower bound of $\Omega(f(n'))$ for the case where c moves per time step are allowed. ◀

As an application of the theorem above, we can conclude the following from the known lower bound of $\Omega(n \log n)$ steps for sparse temporal graphs in the one-move-per-step model (Theorem 4.1 in [6]).

▶ **Corollary 5.2.** *For a temporal n-vertex graph $\mathcal{G}$ whose underlying graph is planar with maximum degree 4, an optimal exploration can take $\Omega(n \log n)$ steps even if $c = O(1)$ moves per time step are allowed.*

6 Inapproximability Result

▶ **Theorem 6.1.** *It is NP-hard to approximate TEXP with two moves per step on an n'-vertex temporal graph with ratio smaller than $b \log n'$ for some constant $b > 0$.*

Proof. We give a reduction from the Hamiltonian s-t-path problem, which is *NP*-complete even if the input graph is planar and has maximum degree 3 as shown by Garey, Johnson, and Tarjan [9]. Let an instance of the Hamiltonian s-t-path problem be given by a graph G with n vertices and $s, t \in V(G)$. Assume without loss of generality that $n = 2k$ for some $k \in \mathbb{N}$ with $k \geq 2$ (otherwise, simply add a new leaf t' adjacent to t and consider the Hamiltonian s-t'-path problem in the new graph).

We now construct an n'-vertex temporal graph $\mathcal{G}'$ in two *phases*, for some n' specified later. First, we specify the vertex set and all edges that will be present during at least one step of the first phase.

Underlying graph during the first phase. The construction is illustrated in Fig. 2. Create $2n^c$ copies of G (for an arbitrary constant $c \geq 2$). Form two groups of these copies, each of size n^c, calling the first group T and the second group B. Let $T(i)$ be the *i-th T-copy* of G and $B(j)$ the *j-th B-copy* of G. For all $i \in \{1, \ldots, n^c - 1\}$, connect vertex $t \in V(T(i))$ and $s \in V(T(i+1))$ by a *quick link* $e_t(i, i+1)$. Create similar quick links $e_b(i, i+1)$ between the B-copies. Between $t \in V(T(n^c))$ and $s \in V(B(1))$, let there be a *super quick link*.

Moreover, build a path P consisting of further vertices $v_t(1), \ldots, v_t(12n^{c+1})$. Use the first (last) quarter of the path to connect each vertex s in the T-copies (B-copies) of G to the path such that the minimal distance of two such vertices s on the path is at least $3n$. More precisely, for $k \in \{0, \ldots, n^c - 1\}$, connect vertex $v_t(3kn+1)$ with $s \in V(T(k+1))$, and connect $v_t(9n^{c+1} + 3kn + 1)$ with $s \in V(B(n^c - k))$. In total, $\mathcal{G}'$ has $n' = O(n^{c+1})$ vertices.

Temporal realization of the first phase. Let the start vertex be $s \in V(T(1))$. Let the steps $t \in \{1, 2, \ldots, n^{c+1}\}$ constitute the first phase of $\mathcal{G}'$'s lifetime. During this phase, the edges of all $2n^c$ copies of G, the path of length $12n^{c+1}$ and the connections between the T-copies or B-copies and the path P described in the previous paragraph always exist. Additionally, let the edge $e_t(i, i+1)$ be present only in step $in/2$, for all $i \in \{1, \ldots, n^c - 1\}$. Let the super quick link be present only in step $n^{c+1}/2$. Let the edge $e_b(i, i+1)$ be present only in step $(n^{c+1} + in)/2$, again for all $i \in \{1, \ldots, n^c - 1\}$.

It is not hard to see that, if G has a Hamiltonian s-t-path, then a temporal walk with two moves per step can visit all vertices in all copies of G within the first phase: In each copy of G, it uses the $n/2$ time steps to follow the $n - 1$ edges of the Hamiltonian s-t-path and then the quick link (or super quick link) to move to the vertex s of the next copy.

Assume now that G does not have a Hamiltonian s-t-path. If a temporal walk W with two moves per step does not use the super quick link, then none of the vertices in the B-copies have been visited in the first phase.

Otherwise, W must have used all quick links connecting the T-copies. We claim that in any two consecutive T-copies, W has missed at least one vertex. To see this, note that an s-t walk in G consists of at least n edges if there is no Hamiltonian s-t-path. Thus, for the walk to arrive at the ith T-copy via a quick link in step $(i-1)n/2$, visit all vertices of the copy, and leave via a quick link in step $in/2$, it must have used the quick links as the first

move in step $(i-1)n/2$ and as the second move in step $in/2$, respectively. But then it is not possible for the walk to visit all vertices of the $(i+1)$th copy and leave it via a quick link.

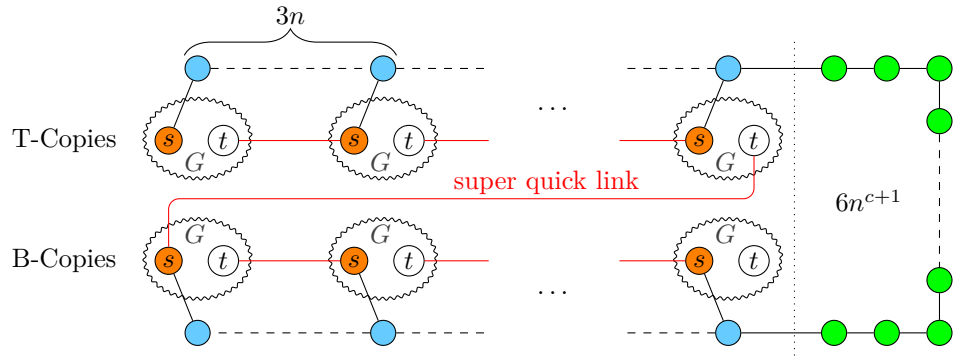

Figure 2 The underlying graph during the first phase. A red line is a quick link.

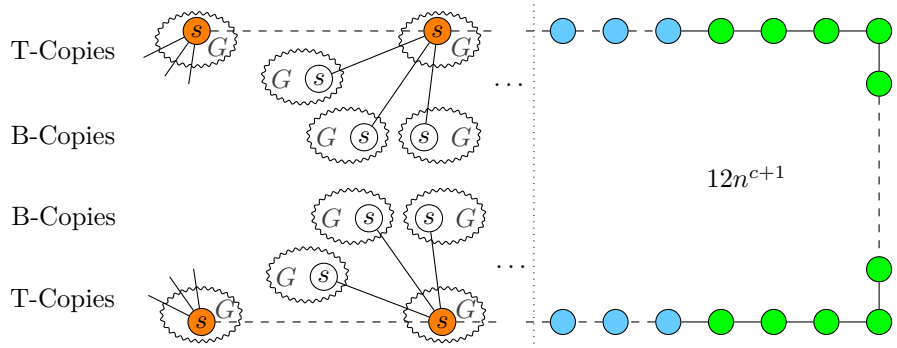

Figure 3 Construction of the temporal graph in the second phase. The connections between the orange vertices differ in the time steps and result from the connections between the labeled vertices in the temporal graph in Fig. 3 in [6].

The second phase. For the whole second phase, the path P is present. Thus, all vertices of P can be visited in $O(n')$ time steps. Therefore, if G has a Hamiltonian s-t-path, $\mathcal{G}'$ can be explored in $O(n')$ time steps.

Erlebach et al. [6, Theorem 4.1] show that TEXP takes $\Omega(N \log N)$ steps on a planar N-vertex temporal graph. More precisely, the proof of their theorem shows that, for arbitrary parameters $r, m \in \mathbb{N}$, there is a planar temporal graph $\mathcal{H}$ with $r+m$ vertices, consisting of r vertices that we call *path vertices* and m vertices that we call *target vertices*, in which $\Omega(r \log m)$ time steps are necessary for visiting all m target vertices. In the temporal graph $\mathcal{H}$, the r path vertices are connected in the form of a path Q in all time steps. The lower bound of $\Omega(r \log m)$ steps for visiting the m target vertices also holds for the model with two moves per step if the length of the rounds in the construction of $\mathcal{H}$ is divided by two. Let $\mathcal{H}'$ be $\mathcal{H}$ with this modification of the length of the rounds.

The idea is now to take in the second phase of our construction the temporal graph $\mathcal{H}'$ for parameters $r = 12n^{c+1}$ and $m = n^c/2$. However, we must construct the temporal graph with the vertices used in Phase 1. Therefore, the second phase of our temporal graph $\mathcal{G}'$ is constructed as follows – see also Fig. 3: Each of the m target vertices v in $\mathcal{H}'$ is identified with a vertex s of a T-copy $T(2i)$ such that no two such vertices s are identified with the same vertex v. Furthermore, the vertex s of each T-copy $T(2i-1)$ is made adjacent to the

vertex s of $T(2i)$. In addition, connect exactly the vertices s of two B-copies to each such vertex v. Our path P becomes the path Q. As in Phase 1, the edges in the copies of G are present in all time steps. Note that the only edges that change during the time steps of the second phase are the edges between the m target vertices of $\mathcal{H}'$. Such an edge exists in the ith time step within Phase 2 exactly if it exists in $\mathcal{H}'$ in the ith time step.

Analysis. Assume that G does not have a Hamiltonian s-t-path. Since we have an unvisited vertex in each pair of consecutive T-copies or in each B-copy after Phase 1, we must visit all m target vertices of $\mathcal{H}'$ to reach the unvisited vertices. Thus, we have to spend $\Omega(r \log m) = \Omega(n^{c+1} \log n^c) = \Omega(n' \log n')$ time steps to explore all vertices of $\mathcal{G}'$, where the last equality follows from $r = \Theta(n')$ and $m = n^c/2 = \Theta((n')^{c/c+1})$.

Since establishing whether $\mathcal{G}'$ can be explored in its entirety in just $O(n')$ steps or requires $\Omega(n' \log n')$ steps also decides whether there exists a Hamiltonian s-t-path in G, we get that it is NP-hard to approximate TEXP with two moves per step with approximation ratio smaller than $b \log n'$ for some constant $b > 0$. ◀

Using a simple variation of the proof of Theorem 6.1, we also get:

▶ **Corollary 6.2.** *It is NP-hard to approximate TEXP on n-vertex temporal graphs whose underlying graph has bounded degree with ratio smaller than $c \log n$ for some constant $c > 0$.*

7 Conclusion

In this paper we have shown that temporal graphs can be explored in $O(n^{1.75})$ time steps if the graph in each step has bounded degree or if two moves per step are allowed. We remark that our proofs are constructive and also yield polynomial-time algorithms to compute such exploration schedules. Moreover, we have shown that TEXP is NP-hard to approximate with ratio better than $b \log n$ for some constant b for the considered cases (bounded degree or two moves per step). The main open problem for these cases is to further reduce the gap between the lower bound of $\Omega(n \log n)$ steps (proved in [6] for bounded degree and in Corollary 5.2 for two moves per step) and the upper bound proved in this paper.

Abstract

We present a constant-time randomized distributed algorithms in the congested clique model that computes an $O(\alpha)$-vertex-coloring, with high probability. Here, α denotes the arboricity of the graph, which is, roughly speaking, the edge-density of the densest subgraph. Congested clique is a well-studied model of synchronous message passing for distributed computing with all-to-all communication: per round each node can send one $O(\log n)$-bit message algorithm to each other node. Our $O(1)$-round algorithm settles the randomized round complexity of the $O(\alpha)$-coloring problem. We also explain that a similar method can provide a constant-time randomized algorithm for decomposing the graph into $O(\alpha)$ edge-disjoint forests, so long as $\alpha \leq n^{1-o(1)}$.

1 Introduction and Related Work

This paper settles the randomized complexity of the graph coloring problem with a number of colors linear in its arboricity, in the congested clique model of distributed computing: we show that constant time suffices. Before formally stating our result, let us start by reviewing the model and the problem statement, as well as state of the art.

1.1 Background: Model, Problem Statement, and State of the Art

The Congested Clique Model. We work with the congested clique model of distributed computing, which was introduced by Lotker et al. [18] and has received extensive attention over the past seven years[1]. There are n processors in the system. We are also given an n-node graph $G = (V, E)$, which has one node corresponding to each processor. This graph

[1] There are many paper, and it is well-beyond the scope of this paper to survey them all. As a prominent example, see the beautiful line of developments for the minimum spanning tree problem [18, 12, 11, 14], which also settled its complexity to be $O(1)$ rounds [14].

can abstract various things. For instance, it might be abstracting the dependencies in a *contention resolution* setting, as follows: processors that are adjacent in the graph are dependent and cannot perform their tasks simultaneously, e.g., they should not transmit their wireless messages simultaneously or they should not read/write to the same memory location simultaneously, or many other similar settings of accessing shared resources. We assume that the graph G is known to the processors in a distributed fashion: each processor/node knows its own neighboring processors/nodes in G. In the congested clique model, we assume that processors can communicate in synchronous rounds, in an all-to-all fashion. Per round, each processor can send one $O(\log n)$-bit message to each other processor. At the end, each processor should know its own part of the output, e.g., the color of its own node.

A discussion about the model, in contrast with other distributed models. Two other well-studied, and in fact more classic, models of distributed computing are CONGEST and LOCAL [23]. In these models, the communication network among the processors is the same as the graph G for which they want to solve the graph problem. In the CONGEST model, per round, each node can send one $O(\log n)$ bit message to each of its neighbors (in the graph, which abstract both the problem and the communication network). The LOCAL model is the variant where there is no upper bound on the message sizes.

These models CONGEST and LOCAL are perfectly suitable for settings such as computer networks, where we want to solve a graph problem about the communication network. This was in fact the original motive of these models. Moreover, there has been a host of beautiful and powerful algorithmic and impossibility results developed in the context of these two models. For some other applications, these models may be less suitable. In particular, when the graph problem is a logical one – as in the abstraction used in the above above example to capture contentions among processor – such a coincidence of communication graph and problem graph may look strange. This is perhaps a partial explanation for the surge of recent interest in distributed algorithms in the congested clique model. Some other reasons are more theoretical and have to do with setting the limitation of locality aside, see the introduction of [11] for a more extensive discussion of this aspect.

The congested clique model is more permissive than CONGEST and we can easily simulate CONGEST-model algorithms in congested clique. But that would not be enough for us, as there is no constant-algorithm for our problem in CONGEST. In fact, in the CONGEST and LOCAL models, the problem has an $\Omega(\log n)$ lower bound [17]. We build on the techniques developed in the CONGEST and LOCAL model, but we also present and use several other algorithmic ideas which allow us to go much further and solve the problem in constant time.

Problem Statement – Arboricity-Dependent Graph Coloring. The graph coloring problem is a well-studied problem with a wide range of applications. It asks for coloring the vertices with few colors in a way that no two adjacent nodes have the same color. For instance, in the context of the contention resolution example mentioned above, this would allow the processors to perform their tasks in a few time slots, without any two dependent processors working concurrently.

Our objective is to compute a coloring whose number of colors is $O(\alpha)$, where α denotes the *arboricity* of the graph. We recall that arboricity is a measure of sparsity of the graph. For a graph $G = (V, E)$, its arboricity is defined as the maximum edge-density $\lceil \frac{E(V')}{|V'|-1} \rceil$ among all induced subgraphs on vertices $V' \subseteq V$ with $|V'| > 1$. Alternatively, by a beautiful result of Nash-Williams[19], an equivalent formulation can be given as the minimum number of edge-disjoint forests into which we can decompose the edges of G. We assume that α is given as an input parameter and the input graph has arboricity at most α.

Any graph with arboricity α admits a coloring with 2α colors and this bound is sharp. For the former, note that we can arrange vertices as a_1 to a_n such that each v_i has at most $2\alpha - 1$ neighbors v_j with a higher index $j > i$. For the latter, a graph consisting of disjoint cliques, each having 2α vertices, gives the sharpness example.

Following [3, 5], we set out target to be obtaining a coloring close to this existentially optimal bound; ideally we would want a coloring with $(2+\epsilon)\alpha$ colors for a small constant $\epsilon > 0$, but we relax it further to $O(\alpha)$ colors, for this paper. Note that $\alpha \leq \Delta$, where Δ denotes the maximum degree of the graph. Hence, coloring with $O(\alpha)$ colors also directly gives a coloring with $O(\Delta)$ colors. However, α can be much smaller than Δ; take for instance a star graph where $\Delta = n - 1$ and $\alpha = 1$. For many graph problems in practice, α is indeed much smaller than Δ: even though they might have a few nodes of high degree, typically they do not contain very dense subgraph, at least not as dense as average degree of Δ.

State-of-the-Art – LOCAL and CONGEST. As it will become clear soon, there is a large body of work on distributed algorithms for graph coloring, and other related problems, and it is well beyond the scope of this paper to review them all. For a survey of the results prior to 2013 on algorithms in the LOCAL and CONGEST models, we refer the reader to the *Distributed Graph Coloring* book by Barenboim and Elkin [3]. We will just mention the best known result in randomized and deterministic settings:

In the LOCAL model, the best known randomized upper bound for $(\Delta+1)$-coloring problem is $2^{O(\sqrt{\log\log n})}$ [7] and the best known deterministic upper bound for $(\Delta+1)$-coloring is $2^{O(\sqrt{\log n})}$[20]. Only if we relax the number of colors to $\Delta^{1+\epsilon}$ for some constant $\epsilon > 0$, a polylogarithmic-time – and particularly $O(\log\Delta\log n)$-round – algorithm is known, thanks a breakthrough of Barenboim and Elkin [2]. For the CONGEST model, the best known randomized algorithm for $(\Delta+1)$-coloring runs in $O(\log\Delta) + 2^{O(\sqrt{\log\log n})}$ rounds [9]. If we parameterize the algorithm's complexity by Δ, the best known algorithm runs in $\tilde{O}(\sqrt{\Delta}) + O(\log^* n)$ rounds [4].

Regarding coloring dependent on α, Linial [17] showed that any coloring with $O(\alpha)$ colors, or even $poly(\alpha)$ colors, needs at least $\Omega(\log n)$ rounds, even in the LOCAL model. Barenboim and Elkin[1] gave a deterministic algorithm that gives a $\Theta(\alpha^2)$ coloring in $O(\log n)$ rounds, and an $O(\alpha^{1+\epsilon})$ coloring in $O(\log\alpha\log n)$ rounds. Ghaffari and Lymouri [10] gave a randomized algorithm that computes a $(2+\epsilon)\alpha$ colors, for constant $\epsilon > 0$, if $\alpha = \tilde{\Omega}(\log n)$, an $O(\alpha\log\alpha)$-coloring in $O(\log n)$ rounds, and an $O(\alpha)$-coloring running in $\tilde{O}(\log n)$ rounds.

State-of-the-Art – CONGESTED-CLIQUE. There has been a sequence of improvements, for coloring with a number of colors dependent on the maximum degree Δ, as we overview next: Hegeman and Pemmaraju [12] gave algorithms for $O(\Delta)$-coloring in the CONGESTED-CLIQUE model, which run in $O(1)$ rounds if $\Delta \geq \Theta(\log^4 n)$ and in $O(\log\log n)$ rounds otherwise. For $(\Delta+1)$ coloring problem, recently Parter [21] designed the first sublogarithmic-time $(\Delta+1)$ coloring algorithm for CONGESTED-CLIQUE, which runs in $O(\log\log\Delta\log^*\Delta)$ rounds. Parter and Su [22] improved the bound to $O(\log^*\Delta)$ round. Finally, the round complexity of $(\Delta+1)$-coloring was settled very recently $O(1)$, by a recent work of Chang, Fischer, Ghaffari, Uitto, and Zheng [6].

For coloring with the number of colors dependent on the arboricity α, we are aware only one prior work in the CONGESTED-CLIQUE: Barenboim and Khazanov[5] gave a deterministic $O(\alpha)$-coloring which runs in α^ϵ rounds, for a constant $\epsilon > 0$, and an $O(\alpha^{2+\epsilon})$-coloring, which runs in $O(\log^* n)$ rounds. For randomized algorithms, we are not aware of any faster algorithm than these deterministic ones, or the randomized algorithms of the CONGEST model (which need at least $\Omega(\log n)$ rounds).

1.2 Our Results

Coloring. We settle the randomized complexity of $O(\alpha)$-coloring in the congested clique model, by showing that constant rounds suffice.

▶ **Theorem 1.** *There is a randomized distributed algorithm that computes an $O(\alpha)$-coloring in constant rounds of the congested clique model, with high probability.*

Forest Decomposition. Our techniques also allow us to compute a decomposition of the graph into $O(\alpha)$ edge-disjoint forests in constant time, so long as $\alpha \leq n^{1-o(1)}$. The best known previous algorithm for this problem was by Barenboim and Khazanov [5] and it uses $O(\log \alpha)$ rounds. The statement of our result appears in the following theorem.

▶ **Theorem 2.** *There is a randomized distributed algorithm that computes a decomposition of the graph into $O(\alpha)$ edge-disjoint forests in constant rounds of the congested clique model, whenever $\alpha \leq n^{1-O(\frac{1}{\sqrt{\log n}})}$, with high probability.*

1.3 Technical Overview

On a high-level, our result makes use of a number of technical ingredients, and puts them together – along with several smaller ideas – in a way that results in the claimed constant-round algorithm for $O(\alpha)$ coloring. We start with a brief list of these technical ingredients:

1. The iterative peeling algorithm of Barenboim and Elkin [1], which partitions vertices into successive layers, along with an orientation from lower layers to higher layers, such that each node has out-degree at most $(2+\epsilon)\alpha$.
2. A topology-gathering procedure which allows us to exponentially speed up some LOCAL model algorithms, on sparse graphs and up to a small locality bound [16, 8].
3. An opportunistic topology-gathering idea which allows us to speed up some LOCAL model algorithms to just $O(1)$ rounds of the CONGESTED-CLIQUE model. Variants of this idea have been used by [14, 6].
4. Some ad-hoc but simple random sampling ideas which allow us to use a much sparser subgraph to perform an approximate peeling about the original graph.
5. A simple random partition idea which allows us to break the case of graphs with large arboricity to several graphs with smaller arboricity, or sometimes graphs that are almost small aboricity, in the sense that they have some number of extra edges.
6. A simple randomized coloring algorithm where per round each node chooses a random color from its palette and keeps it, if none of the neighbors (or sometimes neighbors in certain subsets) chose that color. Variants of this simple idea are standard in distributed coloring algorithms, perhaps the first appearance was in the work of [13].
7. A routing method of Lenzen [15], which by now has become a staple in CONGESTED-CLIQUE algorithms. It is worth noting that the topology gathering ingredients mentioned in items 2 and 3 above also make use of this routing method.

From a bird's eye viewpoint, our algorithm works as follows: we use the random partitioning of item (5) to break the graph into several graphs of much lower arboricity, plus some additional edges. We use the oppurtunistic topology-gathering of item (3) to learn some sufficent local topology in each of these subgraphs, so that we can locally simulate a non-constant number of iterations of the peeling algorithm of item (1) and then apply a

suitable variant of the randomized coloring algorithm of item (6). This will be only a partial coloring, but the number of nodes that remain uncolored will be considerably smaller. Then, we can apply the sampling idea of item (5) and gather the sampled sparse graph, using the routing method of (7), so that we can solve the problem in a centralized fashion, and make even more progress in reducing the number of nodes that remain uncolored. This number at the end will be so small that we can gather all the induced edges by the remaining nodes, using the routing of item (7), and solve the problem in a centralized way. There are several subtleties in this rough outline; we leave the details to the technical sections.

Roadmap. We start with a warm up in Section 2 where we present an $O(\log\log\log n)$ round algorithm for forest-decomposition. Of course, that $O(\log\log\log n)$ complexity is much higher than our claimed bound of $O(1)$ round complexity, but we can introduce a number of the key algorithmic ideas that we use in the context of this simpler but slower algorithm. Then, in Section 3, we present our $O(1)$-round algorithm for $O(\alpha)$-coloring.

2 Warm up: Forest Decomposition in $O(\log\log\log n)$ rounds

In this section, as a warm up, we describe an algorithm for $(2+O(\epsilon))\alpha$ forest decomposition for graphs with $\alpha \leq n^{1-O(\frac{(\log\log n)^2}{\log n})}$, in $O(\log\log\log n)$ rounds of the congested clique model, for any desirably small constant $\epsilon > 0$. This allows us to introduce some of the basics of our end-results, in a simpler setting.

Studying $\alpha = O(\log n)$ Suffices. Before starting our forest-decomposition algorithm, we comment that almost without loss of generality, we can assume that $\alpha = O(\log n/\epsilon^2)$. The reason is as follows: suppose that $\alpha = \Omega(\log n)$. Partition the edges into $k = \epsilon^2\alpha/(10\log n)$ parts $E_1, \ldots, E_k$, randomly. Then, as we show in a simple lemma below, we can see that each group is a subgraph with arboricity $\alpha' = (1+\epsilon)\alpha/k \leq \Theta(\log n)$, with high probability. We describe an algorithm below, which when applied to each of these subgraphs, it decomposes each such subgraph into $(2+\epsilon)\alpha'$ edge-disjoint forests. Thus, overall, the graph is decomposed into $k \cdot (2+\epsilon)\alpha' = (2+\epsilon)\alpha$ forests. We will remark at the end of this section why we have sufficient communication capacity to perform this algorithm on all the subgraphs in parallel.

▶ **Lemma 3.** *If we randomly partition edges of a graph with arboricity $\alpha = \Omega(\log n/\epsilon^2)$ into $k = \epsilon^2\alpha/(10\log n)$ parts $E_1, \ldots, E_k$, then each part is a subgraph with arboricity at most $\alpha' = (1+\epsilon)\alpha/k$, with high probability.*

Proof. We focus on one part E_i. Consider an arbitrary subset of vertices $V' \leq V$, where $|V'| \geq 2$. The expected number of edges of V' that would be put in E_i at most $E(V')/k \leq (|V|'-1)\alpha/k$ edges. By a basic Chernoff bound, the probability that there are more than $(|V|'-1)\alpha/k(1+\epsilon)$ edges is at most $2exp(-(|V|'-1)\alpha/(3k)) \leq exp(-(|V'|\log n)$. Now, we can use a union bound over all possible subset of size $|V'|$, for which there are at most $\binom{n}{|V'|} \ll 2^{|V'|\log n}$ possibilities, and conclude that the edge density of each of them is at most α', with probability $1 - exp(-\Theta(|V'|\log n)) \geq 1 - 1/poly(n)$. Finally, a union bound over all the n possibilities for the value $|V'|$ and at most $\alpha \leq n$ possibilities for index i, in part E_i, concludes the proof. ◀

We will next describe our forest decomposition algorithm for graphs with arboricity $\alpha = O(\log n)$. The algorithm we present in this section will provide a stronger structure, called *H-partition* by Barenboim and Elkin [5], defined as follows: The set V of nodes will

be partitioned into $L = O(\log n)$ disjoint sets V_1, V_2, ..., V_L, which we will call *layers* of the H-partition, such that for each $i \in \{1, 2, \ldots, L\}$, each node $v \in V_i$ has at most $(2+\epsilon)\alpha$ neighbors in $\cup_{j=i}^{L} V_j$.

Given such an H-partition, one can easily obtain a forest-decomposition, i.e., decompose the graph into edge-disjoint forests $F_1, \ldots F_K$, where $K = (2+\epsilon)\alpha$, as follows: (A) orient each edge $\{v, u\}$ between two disinct sets V_i and V_j where $i \neq j$ from the lower index one to the higher indexed one, i.e., from V_i to V_j iff $i < j$. (B) orient each edge $\{v, u\}$ where both endpoints are in the same layer V_i from the lower ID node to the higher ID node. Then, clearly each node has out-degree at most K. Each node v puts each of its outgoing edges in a distinct one of F_1 to F_k. Hence, each F_i is a directed acyclic graph with out-degree at most one. Thus, if we ignore the directions, F_i is a forest. See section 5.1 of the book by Barenboim and Elkin[3], for an elaborate proof.

Our H-partition Algorithm. We build our $O(\log\log\log n)$-round H-partition (and therefore forest decomposition) algorithm in two steps. First, in Section 2.1, we present a slower algorithm that computes H-partition in $O(\log\log n)$ rounds, with high probability. Then, in Section 2.2, we explain a topology-gathering idea (stated in Lemma 9), which allows us to improve this round complexity to $O(\log\log\log n)$, thus proving the following theorem.

▶ **Theorem 4.** *There is a randomized distributed algorithm that for any n-node graph with arboricity $\alpha = O(\log n)$ computes H-partition with parameter $(2+\epsilon)\alpha$ in $O(\log\log\log n)$ rounds with high probability.*

2.1 H-partition in $O(\log\log n)$

We now present our slow $O(\log\log n)$ round algorithm for H-partition. This algorithm relies on two key ingredients: (I) an iterative peeling algorithm of Barenboim and Elkin [5], which on its own would need $R = \Theta(\log n)$ rounds to build the H-partition. (II) A random edge sampling idea which will allow us to compress the last $R - O(\log\log n) = O(\log n)$ rounds of the peeling algorithm into just $O(1)$ rounds of the congested clique.

High-Level Outline. First by running $O(\log\log n)$ iterations of the peeling algorithm of Barenboim and Elkin [5], we reduce the number of nodes to $O(\frac{n}{\log^2 n})$. Then, we use an randomized edge sampling process which allows us to generate a graph with just $O(n)$ edges, using which we can perform the rest of the peeling rounds. Since this graph has just $O(n)$ edges, we can deliver it to a single node, using Lenzen's routing method [15], and thus perform all these remaining peeling rounds in a centralized fashion there, without having to use more rounds of communication in the congested clique model.

Part 1 – Slow Iterative Peeling. First, we perform $O(\log\log n/\epsilon)$ iterations. In iteration i, we remove all nodes whose degree in the remaining graph is at most $(2+\epsilon)\alpha$ and we put them in layer i. Then, we proceed to the next iteration. A more formal description can be found in Algorithm 1.

▶ **Lemma 5.** *After $2\log\log n \cdot \frac{2}{\epsilon}$ iterations of peeling, at most $\frac{n}{\log^2 n}$ nodes remain.*

Proof. After each iteration, the number of remaining nodes reduces by a factor of $\frac{2}{2+\epsilon}$. This is because any remaining graph has arboricity at most α, which means it has average degree at most 2α, and thus only $\frac{2}{2+\epsilon}$ fraction of its nodes can have degree higher than $(2+\epsilon)\alpha$ and remain for the next iteration. Hence, after $2\log\log n \cdot \frac{2}{\epsilon}$ iterations, the number of remaining nodes is at most $(\frac{2}{2+\epsilon})^{\lceil 2\log\log n \cdot \frac{2}{\epsilon} \rceil} n \leq \frac{n}{\log^2 n}$. ◀

Algorithm 1 Computing a partial H-partition for a graph G with arboricity α.

```
1: procedure H-PARTITION((α, ϵ))
2:     An algorithm for each vertex v of G:
3:     i = 1
4:     while i ≤ ⌈(4/ϵ) log log n⌉ do
5:         if v is active and has at most (2 + ϵ)α active neighbors then
6:             make v inactive
7:             add v to H_i
8:             send the message "inactive" and "v joined H_i" to all the neighbors
9:         for each received "inactive" message do
10:            mark the sender neighbor as inactive
11:        i = i + 1
```

Part 2 – Speeding up Peeling via Random Edge Sampling. Next we focus on the remaining nodes and we find an H-partition of them in constant rounds of the congested clique. Let N denote the number of remaining nodes, and notice that we know $N \leq \frac{n}{\log^2 n}$. Consider $O(\log n)$ independent sampling process where in each, each edge of the graph induced by the remaining nodes is sampled with probability $p = min(\frac{1000 \log n}{\epsilon^2 a}, 1)$. Let G_i be the graph with sampled edges in i^{th} process. We will show in Lemma 6 that the total number of sampled edges is $O(n)$, with high probability. Thus, using Lenzen's routing method [15], we can collect all sampled edges in one node in $O(1)$ rounds. Then, we devise an iterative processing algorithm to compute H-partition of the remaining nodes, by processing only these sampled edges (instead of working on the base graph). We note that this iterative process will happen in a centralized fashion in the node that holds all the sampled edges, and thus it needs no communication. At the end, we can report to each node of the graph the peeling iteration in which it was removed. The peeling algorithm based on the randomly sampled edges is described in Algorithm 2. We note that for each iteration, this algorithm uses a different randomly sampled subgraph G_i, and these samplings are performed independent of each other. We will show that even though we are working on a randomly sampled subgraph, our peeling process will still produce a correct H-partition, in the following senses: On one hand, in Lemma 7, we show that in each iteration, all nodes of degree less than $(2 + \frac{\epsilon}{2})\alpha$ in the remaining graph will be removed, with high probability. Hence, we will be done after $O(\log n)$ iterations of peeling. On the other hand, in Lemma 8, we show that any node that gets removed in an iteration has degree at most $(2 + 2\epsilon)\alpha$, with high probability, among the nodes that had remained for that iteration. Hence, each node has at most $(2+2\epsilon)\alpha$ neighbors in its own layer or the future layers. We next present these lemmas and their proofs.

We first show that the number of sampled edges is small enough to allow us to deliver them to one node, via Lenzen's routing.

▶ **Lemma 6.** *The total number of sampled edges is at most $O(n)$, with high probability.*

Proof. The number of remaining nodes is $N \leq \frac{n}{\log^2 n}$. We have $O(\log n)$ independent sampling process, where in each process, each edge is sampled with probability $p = min(\frac{1000 \log n}{\epsilon^2 a}, 1)$. Hence, the expected number of sampled edges is $O(n)$. Moreover, since the samplings are independent (across different edges and different runs of the process), we can apply the Chernoff bound and conclude that with high probability, at most $O(n)$ edges are sampled. ◀

Now, we argue that in each iteration of peeling on the sampled subgraph, we will remove all nodes of relatively small degree in the base graph (among remaining nodes).

Algorithm 2 Computing H-partition for the remaining nodes by processing the sampled subgraphs G_i for $i \in 1, \ldots, \Theta(\log n)$.

```
1: procedure PROCESSING SAMPLED GRAPHS(G_i)
2:     i = 1
3:     while i ≤ Θ(log n) do
4:         for for each vertex v of G_i do
5:             if v has at most (2 + ε)αp neighbors in G_i then
6:                 add v to H_{i+T}
                                ▷ T=Θ(log log n) is the number of iterations in Algorithm 1
7:                 delete v from all G_k for k ∈ {i + 1, ..., Θ(log n)}
8:         i = i + 1
```

▶ **Lemma 7.** *In each iteration of working with the sampled subgraphs, all nodes of degree less than* $(2 + \frac{\epsilon}{2})\alpha$ *in the remaining base graph will be removed, with high probability.*

Proof. Consider iteration i. Let G' be the subgraph of the base graph induced by the nodes that remain in iteration i. Consider a remaining node v and suppose that its degree $d_{G'}(v) \leq (2 + \frac{\epsilon}{2})\alpha$. We argue that such a node will be remove in this iteration, with high probability. Then, in the sample subgraph for process i , each of these edges is sampled with probability p. Thus, the expected number of the sampled edges of v is $(2 + \frac{\epsilon}{2})\alpha p$. Since the sampling for this process is independent of the randomness of the previous processes, and since different edges are sampled independently, we can apply a Chernoff bound and conclude that the number of sampled edges of v is at most $(2 + \epsilon)\alpha p$, with high probability. Hence, node v gets removed in this iteration. ◀

As mentioned before, Lemma 7 allows us to argue that after each iteration the number of nodes reduces by a factor of $\frac{2}{2+\frac{\epsilon}{2}}$ with high probability. Thus, after $O(\log n)$ iterations, the number of nodes that did not find their proper partition is below 1, i.e., no node remains. We also need to ensure that the peeling performs the correct thing in that any node that gets removed in some iteration has degree at most $(2 + 2\epsilon)\alpha$ in the base graph, among the remaining nodes.

▶ **Lemma 8.** *In each iteration of working with the sampled subgraphs, any node that gets removed has degree at most* $(2 + 2\epsilon)\alpha$ *in the base graph among the nodes that remained for that iteration, with high probability.*

Proof. Consider iteration i. Let G' be the subgraph of the base graph induced by the nodes that remain in iteration i. Consider a remaining node v and suppose that its degree $d_{G'}(v) \geq (2 + 2\epsilon)\alpha$. We argue that such a node will be not be removed in this iteration, with high probability. In the sample subgraph for process i , each of these edges is sampled with probability p. Thus, the expected number of the sampled edges of v is at least $(2 + 2\epsilon)\alpha p$. Since the sampling for this process is independent of the randomness of the previous processes, and since different edges are sampled independently, we can apply a Chernoff bound and conclude that the number of sampled edges of v is strictly exceeds $(2 + \epsilon)\alpha p$, with high probability. Hence, node v does not get removed in this iteration. ◀

To conclude, as argued above Lemma 7 implies that we are done in $O(\log n)$ iterations of peeling, and Lemma 8 shows that each node that gets removed in each iteration of peeling has degree at most $(2 + 2\epsilon)\alpha$ among the nodes that had remained for that iteration. That is,

the nodes peeled in different iterations gives a partitioning of the nodes so that each node in a given layer has at most $(2+2\epsilon)\alpha$ neighbors in that layer or the future ones. This gives us an H-partition with out-degree $(2+2\epsilon)\alpha$.

2.2 H-partition in $O(\log\log\log n)$ rounds

In this section, we explain how to speed up the $O(\log\log n)$-round algorithm described in the previous subsection to run in $O(\log\log\log n)$ rounds.

Recall that our previous algorithm had two main part, a slow $O(\log\log n)$ round for iterative peeling, and a fast $O(1)$ round algorithm where all the other peelings happen in constant rounds of the congested clique, by processing a sparse randomly sampled subgraph of the remaining graph. Here, we focus on the first part and improve its complexity to $O(\log\log\log n)$-round, using a topology-gathering idea.

Notice that the first part of the algorithm did not need any all-to-all communication. It was simply iterations of peeling in the graph. Hence, if a node v knew all of the topology within its R hops, it could simulate this peeling process for R rounds. We can learn this R-hop topology much faster than R rounds in the congested clique model, thanks to the all-to-all communication, but subject to some constraint: it is only possible if the topology to be learned is relatively small. In particular, we next discuss a special case of such a topology learning on graphs where the maximum degree is small. Later, we will discuss how to incorporate this maximum degree limitation into our peeling algorithm.

First, we start with a generic topology-gathering lemma, for small-degree graphs. Variants of such a statement have been used in prior work, see [16, 8], for instance.

▶ **Lemma 9.** *Suppose that F is graph with n nodes and maximum degree at most $\log^{100} n$. Then we can make each node $v \in F$ learns its R-hop neighborhood in F for $R = O(\log\log n)$, in $O(\log R) = O(\log\log\log n)$ rounds in congested clique.*

Proof. We use an induction to prove that for any $k \leq O(\log\log\log n)$, in $O(k)$ rounds, we can make the nodes learn the graph $F' = F^{2^k}$, which is formed by connecting each two nodes that are within distance 2^k. After that, each node can directly receive all the edges of all of its F' neighbors and thus know the whole topology within its 2^k-hop neighborhood, using Lenzen's routing[15]. The base case of induction where $k = 1$ is trivial, as that is knowing the graph F itself. Suppose that assume that $O(k)$ rounds have passed and each node already knows its neighbors in the graph F^{2^k}. Now, the number of neighbors in this graph is at most $(\log^{100} n)^{(2^k)} \leq 2^{O((\log\log n)^2)} \ll \sqrt{n}$. Make each node send the names of each of its neighbors in F^{2^k} to each of its neighbors in F^{2^k}. That is at most n messages. Hence, this information can be routing in $O(1)$ round using Lenzen's routing. Then, each node knows its neighbors of neighbors in F^{2^k}, which means it can know it knows all of its neighbors in $F^{2\cdot 2^k} = F^{2^{k+1}}$. ◀

Applying Topology-Gathering to Speed Up Peeling. If we could apply the above topology gathering to our $O(\log\log n)$ round peeling algorithm, we would compress it to $O(\log\log\log n)$ rounds. However, this is not immediately possible. Our original graph may have nodes of very large degree, much larger than $poly(\log n)$, despite its small arboricity $\alpha = O(\log n)$. This means we cannot directly apply the topology gathering idea of the above lemma. However, fortunately, our graph cannot have too many nodes of large degree (exactly because of its small arboricity). This allows us to freeze those few high degree nodes, and still use a peeling process on the rest of the graph to reduce the number of remaining nodes (including the frozen ones) to just $O(\frac{n}{\log^2 n})$.

In particular, freeze each node whose degree is greater than $\log^{100} n$. Notice that since the graph has arboricity $\alpha = O(\log n)$, as we justified this assumption at the beginning of this section and in Lemma 3, the number of frozen nodes is at most $\frac{2n\alpha}{\log^{100}(n)} \leq \frac{2n}{\log^{99} n}$. Now, we apply $O(\log \log n)$ iterations of the peeling algorithm on the remaining nodes, but sped up to $O(\log \log \log n)$ rounds of the congested clique model, using the topology-gathering approach of Lemma 9. The number of nodes that remain from this peeling is $O(n/\log^2 n)$. Hence, even including the at most $\frac{2n}{\log^{99} n}$ frozen nodes, the number of remaining nodes is $O(n/\log^2 n)$. That means, we can now apply the algorithm of the second part, described in the previous subsection, to finish all of the peeling of the H-partition in $O(1)$ rounds of the congested clique (via working on the sampled subgraphs).

Running the Algorithm in Different Parts with Arboricity $O(\log n)$

At the beginning of the section, we explained that we partition graphs with arboricity higher than $\Theta(\log n)$ into many $\alpha/\Theta(\log n)$ subgraphs, each with arboricity $\Theta(\log n)$, and we then decompose each subgraph separately, using the procedure described above. It remains to explain why we can run the algorithm on all these subgraphs simultaneously. Notice that the local communications performed for peeling are in the edges of the subgraph, and therefore those can be performed in parallel. When performing a local topology gathering, each node needs to send or receive $2^{O((\log \log n)^2)}$ bits of information. Hence, even over all the $\alpha/\Theta(\log n)$ subgraphs, the total information that each each node needs to send or receive is $O(n)$, as we have assumed $\alpha \leq n^{1-O(\frac{(\log \log n)^2}{\log n})}$. After that, for the final step of the algorithm, we just need to bring a graph of size $O(n)$ to some leaders node and solve the problem of remaining nodes there, for each subgraph. It suffices to use different such leaders for different subgraphs.

3 Constant-Time Coloring

In this section, we provide our proof of Theorem 1, thus showing a randomized distributed algorithm that colors any graph of arboricity at most α using $O(\alpha)$ colors, w.h.p.

Proof of Theorem 1. The proof has several steps. We start with a high-level outline: we will first argue that it suffices to work with graphs of arboricity at most $O(\log n)$, because higher-arboricity graphs can be broken to this case easily, via randomness. Second, we set aside nodes of degree higher than α^{10}, to color them only later using some other fresh $O(\alpha)$ colors. Then, we explain how we partition any graph with arboricity $\alpha = O(\log n)$ to β/α subgraphs, each being a graph with arboricity almost $\beta = poly(\log \alpha)$ plus a small number of extra edges. Then, we explain how we color almost the entirety of each of these subgraphs, using different colors for different subgraphs. For this partial coloring, we will first explain a slow algorithm in the CONGEST model and then discuss how to simulate it in $O(1)$ rounds of the CONGESTED-CLIQUE model. The nodes that remain uncolored will be so few that we can gather the topology induced by them and color them using some 2α extra colors. We next explain these steps separated by paragraph titles, to reflect the above outline.

Studying $\alpha = O(\log n)$ Suffices. We focus on the case where $\alpha = O(\log n)$. Coloring of graphs with $\alpha = \Omega(\log n)$ arboricity can be transformed easily to this $O(\log n)$-arboricity case: place each node in a randomly chosen one of $k = \alpha/\Theta(\log n)$ parts. Each part will induce a subgraph with arboricity $\Theta(\log n)$, with high probability. The reason is that the original graph with arboricity α admits an orientation with out-degree 2α. Fix such an orientation. We do not need to know this orientation but use it for our analysis, only. When we randomly

partition nodes, we expect each node's out-degree in its own part to be $2\alpha/k = \Theta(\log n)$. Hence, by applying a Chernoff bound, each node's outdegree in this imagined orientation is at most $3\alpha/k$. Thus, each of the subgraphs admits an orientation with out-degree at most $3\alpha/k$, which means it has arboricity at most $3\alpha/k$.

We color each of these parts using $\Theta(\log n)$ separate colors, all in parallel. For each part, we apply the algorithm for graphs with arboricity at most $O(\log n)$, which we describe next.

Setting aside nodes with degree $\Omega(\alpha^{10})$. As a preparation step, we set aside all nodes which have degree at least α^{10}. We note that a graph of arboricity α can have at most $2n/\alpha^9$ such nodes, simply because it has at most $n\alpha$ edges. This number of left-over nodes is small enough that allows us to deal with coloring these nodes later, using some fresh colors.

Partitioning to lower-arboricity subgraphs, plus few extra edges. We now have a graph $G = (V, E)$ with at most n nodes, arboricity $\alpha = O(\log n)$, and maximum degree at most α^{10}. We randomly partition V into $k = \frac{\alpha}{\log^3 \alpha}$ parts $V_1, V_2, \ldots, V_k$, by placing each node in a random part V_i. In Claim 10, we show that, with high probability, the subgraph $G[V_i]$ induced by the nodes in each part V_i is a graph with arboricity $(2+\epsilon)\log^3 \alpha$, plus at most $n/(\alpha)^{10}$ extra edges, for an arbitrarily small constant $\epsilon > 0$. We partially color each part $G[V_i]$ separately, using $O(\log^3 \alpha)$ different colors. This partial coloring will leave some $O(n/\alpha^5)$ nodes uncolored per part. In fact, the partial coloring will be done in two steps, one leaves at most $O(n/\log^3 \alpha)$ uncolored nodes, and the second reduces the number of uncolored nodes to $O(n/\alpha^5)$. At the very end, we will then gather the subgraph induced by all these remaining nodes over all parts – which has at most $k \cdot O(n/\alpha^5) \cdot \alpha = O(n)$ edges – in one node and color them using 2α extra colors.

▷ Claim 10. The subgraph $G[V_i]$ induced by each part V_i is a graph with arboricity $(2+\epsilon)\log^3 \alpha$, plus at most $n/(\alpha)^{10}$ extra edges, for an arbitrarily small constant $\epsilon > 0$.

Proof of Claim 10. Consider a hypothetical orientation of the graph with out-degree 2α and call a node v bad if in the subgraph $G[V_i]$ to which v belongs, its outdegree exceeds $2\alpha/k(1+\epsilon) = (2+\epsilon)\log^3 \alpha$. Notice that the probability of a node being bad is exponentially small in its expected outdegree, i.e., it is at most $exp(-\Theta(\alpha/k)) \leq exp(-\log^2 \alpha)$. Hence, the expected number of nodes that are bad is at most $nexp(-\log^2 \alpha)$. We would like to say that, with high probability, the number of bad nodes is at most $n \cdot exp(-\log^2 \alpha)$. We cannot directly apply the Chernoff bound, because the events of different nodes being bad are not independent of each other. However, the events are independent for any two nodes that do not share a common neighbor. Since we are now on a graph with maximum degree at most α^{10}, as we have set aside nodes of higher degree, we can infer that the even of each node being bad depends on the events of at most $d = \alpha^{20}$ many other nodes – all those within 2 hops. Hence, we can apply the extension of Chernoff to the setting with a bounded degree of dependency[24]. In particular, we get that the probability that the number of bad nodes exceeds $\mu = n \cdot exp(-\log^2 \alpha)$ by more than a constant factor is at most $\Theta(d) \cdot exp(-\Theta(\mu/d)) = \Theta(\alpha^{10}) \cdot exp(-\Theta(n \cdot exp(-\log^2 \alpha)/\alpha^{20})) \ll 1/poly(n)$. Hence, with high probability, the number of bad nodes is less than $\Theta(n \cdot exp(-\log^2 \alpha))$. A node that is bad introduced at most α^5 bad edges, in $G[V_i]$, because it is incident on at most α^{10} edges. Thus, except for at most $n \cdot exp(-\log^2 \alpha) \cdot \alpha^{10} \ll n/(\alpha)^{10}$ edges incident to bad nodes, all other edges can be oriented with out-degree $(2+\epsilon)\log^3 \alpha$. Hence, the subgraph is graph with arboricity $\beta = (2+\epsilon)\log^3 \alpha = O((\log\log n)^3)$, plus at most $n/(\alpha)^{10}$ extra edges. ◁

Outline for First Partial Coloring of Each Part. We now focus on one subgraph $H = G[V_i]$ which is a subgraph with arboricity $\beta = (2+\epsilon)\log^3 \alpha = O((\log\log n)^3)$, plus at most $n/(\alpha)^{10}$ extra edges. We next describe an algorithm $\mathcal{A}$ that runs in $O(\log^2 \beta)$ rounds of the CONGEST model and colors all but $O(n/\beta)$ many of the nodes of H, using $O(\beta)$ colors. Then, we explain how we simulate $\mathcal{A}$ in just $O(1)$ rounds of the CONGEST-CLIQUE model.

A CONGEST Algorithm for Partial Coloring of One Part. We focus on one part $H = G[V_i]$. First, we put aside all nodes of degree greater than β^2. The number of such nodes is $O(n/\beta)$. Then, we attempt to color most of the rest, in $O(\log^2 \beta)$ rounds, as follows. First, for $\ell = 40\log\beta$ iterations, in each iteration j, we remove nodes of degree at most 2.1β and put them in *layer* L_j. Since the graph has arboricity β, in each iteration at least a constant fraction of nodes get removed. Thus, We can show that the number of remaining nodes after $40\log\beta$ iterations is $O(n/(\beta)^5)$. Then, we attempt to color the nodes in layers L_ℓ, $L_{\ell-1}, \ldots L_1$ using 2.2β colors. We spend one phase to color each layer layer, as follows.

We now describe each phase, which is simply $10\log\beta$ repetitions of a simple randomized coloring attempt. In each round of the j^{th} phase, each node of layer L_j picks a color at random from 2.2β colors and keeps it if it is different than the colors of its neighbors in layers $L_{j'}$ for $j' \geq j$. A node that did not choose such a color remains uncolored in this round. After $10\log\beta$ rounds, all nodes of L_j that remain uncolored are removed. Per round, each node gets colored with at least $0.1\beta/2.2\beta = 0.02$, regardless of the choices of its other up to 2.1β neighbors. Hence, the probability of a node remaining uncolored after $10\log\beta$ rounds is at most β^5. Moreover, the events of different nodes remaining uncolored is independent, because in the above argument we only relied on the randomness in the color choices of the node itself. We can conclude that, with high probability, the number of these nodes in L_j is $O(n/(\beta)^2)$. We then proceed to the next phase. Over all the phases, the number of nodes in L_j that remain uncolored is at most $O(n\log\beta/(\beta)^2)$. Moreover, the number of nodes that were not in any of the layers is at most $O(n/(\beta)^2)$. Hence, overall, this process leaves at most $O(n/\beta)$ nodes of H uncolored.

A small final note about algorithm $\mathcal{A}$ is that each node uses at most $O(\log^2 \beta) \ll O(\log n)$ bits of randomness, $O(\log\beta)$ many bits in each round where it picks a random color from $\{1, 2, \ldots, 2.2\beta\}$. We will use this fact about the amount of randomness, later, when we speed up the algorithm in the CONGESTED-CLIQUE model.

CONGESTED-CLIQUE Algorithm for Partial Coloring of One Part. We focus on one part $H = G[V_i]$ and show how we mimic the algorithm described above, in just $O(1)$ rounds of CONGESTED-CLIQUE. As before, we put aside all nodes of degree greater than β^2. We next try to simulate $\mathcal{A}$, using a randomized information gathering approach.

We now use an opportunistic information gathering to compress the round complexity in CONGESTED-CLIQUE to $O(1)$. Concretely, we make each remaining node v send a message to all other nodes, where the message contains the name of v, its degree, and the at most $O(\log n)$-bits of randomness that v uses in algorithm $\mathcal{A}$. Besides the above, each v also sends each of its edges to each other node, but only randomly: each edge is sent to each node with probability $1/\beta^2$, all independent of each other. Notice that the total number of edges that are to be sent to each node is at most $O(n)\cdot\beta^2/\beta^2 = O(n)$, with high probability.

We say a node u successfully received the *relevant ball* of node v – with respect to algorithm $\mathcal{A}$ – if node u received all the edges incident on all nodes w within distance $\Theta(\log^2\beta)$ of v. The number of such edges is at most $\beta^{\Theta(\log^2\beta)} \leq 2^{\Theta(\log^3\beta)}$. The probability of each of them being sent to u is $1/\beta^2$. Thus, the probability that they are all sent to u is $(1/\beta^2)^{2^{\Theta(\log^3\beta)}} \geq 2^{-2\log\beta\cdot 2^{\Theta(\log^3\beta)}} \geq 2^{-2^{\Theta(\log^3\beta)}} \gg 2^{-\sqrt{\log n}}$, given that $\log\beta = \Theta(\log\log\log n)$. Since each

node u successfully receives the ball of v with probability at least $2^{-\sqrt{\log n}}$, and as there are n possibilities for u, with high probability, there is at least one node u that successfully receives the ball of v. Notice that node u realizes this successful event as it knows the degree of each node and it can distinguish whether it has received all of the edges or not. Once u has received the relevant ball of node v, node u can simulate the CONGEST-model algorithm $\mathcal{A}$ and inform node v about the status of node v at the end of $\mathcal{A}$. This status is simply whether v is colored or not, and if yes, with which color.

Notice the small subtlety that there might be many nodes like u that receive the ball. However, since they all use the same randomness to simulate the behavior of each node in this ball (the randomness received from that node), they all get the same output for v.

Second Step of Partial Coloring. Finally, we go back to those $O(n/\beta)$ nodes that remain uncolored and we color enough of them that the number of uncolored nodes reduces to $O(n/\alpha^5)$. Given that H is a graph with arboricity at most β plus some $O(n/\alpha^{10})$ edges, the number of edges induced by the remaining $O(n/\beta)$ nodes is at most $O(n)$. That means we can move all these edges to one node . Then, we run a process similar to algorithm $\mathcal{A}$ on these remaining nodes, but in a centralized fashion. In particular, in $O(\log \alpha)$ iterations, we remove nodes of degree at most 2.1β. Then, we color these removed nodes greedily from the last layer to the beginning, using 2.2β extra colors. The only nodes that are not colored are those that are not in any of these $O(\log \alpha)$ layers. Since each layer of peeling and coloring removes at least a $0.1/2.2$ fraction of nodes (similar to the previous arguments), after $O(\log \alpha)$ such iterations, the number of nodes that remain uncolored is at most $O(n/\alpha^5)$ many.

Final Step, Coloring the Remaining Nodes. Finally, we handle these remaining nodes of different parts. In each of the parts $G[V_i]$, we have $O(n/\alpha^5)$ remaining nodes. Moreover, we had some $O(n/\alpha^9)$ nodes that we set aside at the very beginning, because they had degree greater than α^{10}. We collect the subgraph induced by all remaining nodes into one node, which has no more than $O(n/\alpha^4)$ edges, and we color them using 2α new colors. ◀

Abstract

For fixed $h \geq 2$, we consider the task of adding to a graph G a set of weighted shortcut edges on the same vertex set, such that the length of a shortest h-hop path between any pair of vertices in the augmented graph is exactly the same as the original distance between these vertices in G. A set of shortcut edges with this property is called an *exact h-hopset* and may be applied in processing distance queries on graph G. In particular, a 2-hopset directly corresponds to a distributed distance oracle known as a *hub labeling*. In this work, we explore centralized distance oracles based on 3-hopsets and display their advantages in several practical scenarios. In particular, for graphs of constant highway dimension, and more generally for graphs of constant skeleton dimension, we show that 3-hopsets require *exponentially* fewer shortcuts per node than any previously described distance oracle, and also offer a speedup in query time when compared to simple oracles based on a direct application of 2-hopsets. Finally, we consider the problem of computing minimum-size h-hopset (for any $h \geq 2$) for a given graph G, showing a polylogarithmic-factor approximation for the case of unique shortest path graphs. When $h = 3$, for a given bound on the space used by the distance oracle, we provide a construction of hopset achieving polylog approximation both for space and query time compared to the optimal 3-hopset oracle given the space bound.

1 Introduction

An exact h-hopset for a weighted graph G is a weighted edge set, whose addition to the graph guarantees that every pair of vertices has a path between them with at most h edges (*hops*) and whose length is exactly the length of shortest path between the vertices.

The concept of a hopset was first explicitly described by Cohen [19] in its *approximate* setting, in which the length of h-hop path between a pair of vertices in the hopset should approximate the length of the shortest path in G. Hopsets were introduced in the context of parallel computation of approximate shortest paths. In this paper, we study hopsets in their exact version, with the general objective of optimizing exact shortest path queries.

Data structures which allow for querying distance between any pair of vertices of a graph have been intensively studied under the name of *distance oracles*. The efficiency of an exact distance oracle is typically measured by the interplay between the *space* requirement of the representation of the data structure and its *decoding time*. It is a well-established empirical fact that many real-world networks admit efficient (i.e., low-space and fast) distance oracles [6, 22]. A key example here concerns transportation networks, and specifically road networks, which are empirically known [34, 32, 5] to be augmentable by carefully tailored sets of shortcut edges, allowing for shortest-path computation. These sets of shortcuts may be hopsets (as is the case for the hub-labeling approach which effectively implements a 2-hopset), but may also be considered in some related (and frequently more involved) framework, such as contraction hierarchies [31] or transit-node routing [11].

An interesting theoretical insight due to Abraham et al. [3, 4, 5] provides theoretical bounds on the number of shortcuts required in all of the above-mentioned frameworks. They introduce a parameter describing the structure of shortest paths within ball neighborhoods of a graph, called *highway dimension* $\tilde{h}$. They also express the number of shortcuts that need to be added for each node so as to achieve shortest-path queries in a graph of n nodes with weighted diameter D as a polynomial of $\tilde{h}$, $\log n$, and $\log D$; this approach has been extended in subsequent work [2, 37]. The value of $\tilde{h}$ is known to be small in practice (e.g., typically $\tilde{h} < 100$ for continental-sized road networks [4]), and does indeed appear to be inherently linked to the size of the required shortcut sets. In fact, empirical tests have suggested that the (average) number of necessary shortcuts per node is in fact very close to $\tilde{h}$, laying open the question of whether the additional dependence of the number of shortcuts on logarithmic factors in n and D may be an artifact of the theoretical analysis of the oracles, which for each node require a separate shortcut for every "scale" of distance.

1.1 Results and Organization of the Paper

Our main result is to provide strong evidence that the dependence of the number of shortcuts on such logarithmic factors in n and D is indeed not essential, and we design a simple distance oracle based on a 3-hopset in which the number of shortcuts per node depends only on $\tilde{h}$, $\log\log n$, and the logarithm of the average edge length. This result is in fact shown in the framework of a strictly broader class of graphs, namely, graphs with a bounded value of a parameter known as *skeleton dimension* k ($k \leq \tilde{h}$), describing the width of the shortest-path tree of a node after pruning all branches at a constant fraction α of their depth. Considering various ranges of fraction α for increasing distance ranges was a novel key step for improving over [37, 36] from a 2-hopset construction to a 3-hopset construction.

From a general perspective, our connection between h-hopsets and distance oracles is original and offers new perspectives for studying the trade-off between size and query time of distance oracles. To exemplify this, we provide a construction of h-hopsets for graphs of treewidth t following a classical approach in pre-processing product queries on trees [7, 16]. For 3-hopsets, we obtain a distance oracle with quadratic dependency in t which improves over the construction of [15] (which has cubic dependency) for $t = \omega(\log^2 \log n)$. The space and time-bounds of oracles based on 3-hopsets are presented in Table 1, and compared with the corresponding parameters of oracles based on 2-hopsets. For the case of constant skeleton dimension or constant treewidth, we remark that using a 3-hopset instead of a 2-hopset reduces the number of shortcuts per node from $O(\log n)$ to $O(\log\log n)$ while achieving a query time of $O(\log^2 \log n)$.

Table 1 Comparison of distance oracles based on 2-hopsets (hub labeling [19, 28, 37]) and 3-hopsets (this paper). Size represents the number of shortcut edges in the hopset, i.e., the number of $O(\log n)$-bitsize words when measuring oracle size. The main results concern skeleton dimension and are stated in simplified form, assuming average edge length at most $O(\text{poly}\log n)$, with expected query times given for both types of oracles.

Distance oracle	Treewidth t		Skeleton dimension k	
	Size	*Time*	*Size*	*Time*
2-hopset (hubs):	$n \cdot O(t \log n)$	$O(t + \log\log n)$	$n \cdot O(k \log n)$	$O(k \log n)$
3-hopset:	$n \cdot O(t \log\log n)$	$O(t^2 \log^2 \log n)$	$n \cdot O(k \log k \log\log n)$	$O(k^2 \log^2 k \log^2 \log n)$

A classical assumption (applied, e.g., in almost all literature on transportation networks) resides in the uniqueness of shortest paths. It can be made without loss of generality by slightly perturbing the weights of the edges or by using appropriate tie break rules. In this context of *unique shortest path graph* (USP) graphs where there is a unique shortest path P_{uv} between any two nodes u and v, we propose an LP-based approximation algorithm for constructing h-hopsets with size within a polylog factor from optimal. Our construction can be seen as a non-trivial generalization of the prehub labeling introduced in [9] from 2 to more hops. In the case $h = 3$, we further extend our approach to provide an algorithm which constructs distance oracles in USP graphs based on 3-hopsets, with (approximate) optimality guarantees on size and query time. The form of guarantees we obtain is again novel: for a given size bound $\mathcal{S}$ of 3-hopset based oracle, we construct an oracle with size larger than $\mathcal{S}$ by at most a polylog factor which has average query time within a polylog factor of the performance achieved by the best oracle with size $\mathcal{S}$.

The rest of the paper is organized as follows. In Section 2, we introduce the necessary notions related to h-hopset and give a general approach for how a h-hopset can be used as a distance oracle, focusing on the special case of $h = 3$. In Section 3, we provide our first main result, using 3-hopsets to obtain improved (smaller and faster) distance oracles in graphs with bounded skeleton dimension. In Section 4, we present our second main result about approximating h-hopsets and constructing 3-hopset based oracles in USP graphs. Finally, Section 5, we show how to construct efficient h-hopsets and 3-hopset based oracles for bounded treewidth graphs. We provide full details of omitted and sketched proofs in the full version [33].

Our work is presented in the context of weighted undirected graphs, but all results can easily be extended to weighted directed graphs.

1.2 Other Related Work

Hopsets. Exact hopsets were implicitly constructed in the context of single-source shortest paths parallel computation [43, 35, 18, 40]. Such works study the work versus time trade-offs of such computation. Cohen [19] explicitly introduced the notion of (h, ϵ)-hopset of G as set H of weighted edges such that paths of at most h hops in $G \cup H$ have length within $(1 + \epsilon)$ of the corresponding shortest path in G. The parameter h is called the *hopbound*. For any graph G and $\epsilon, \epsilon' > 0$, she proposed a construction of $(O(\text{poly}\log n), \epsilon)$-hopset of G with size $O(n^{1+\epsilon'})$. More recently, Elkin et al. [24] proposed the construction of $(O(\epsilon^{-1}\log\kappa)^{\log\kappa}, \epsilon)$-hopset with $O(n^{1+1/\kappa}\log n \log\kappa)$ edges for any $\epsilon > 0$ and integral $\kappa \geq 1$. Abboud et al. [1] recently showed the optimality of the Elkin et al. [24] result. In particular, they showed that for any $\delta > 0$ and integer k, any hopset of size less than $n^{1+\frac{1}{2^{k+1}-1}-\delta}$ must have hop bound $h = \Omega(c_k/\epsilon^{k+1})$, where c_k is a constant depending only on k. The linear size case was then improved in [25]. As far as we know, exact hopsets (with $\epsilon = 0$) have not been explicitly studied. However, they are related to the following well studied notion.

Hopsets vs. TC-spanners. In directed graphs, a hopset can be seen as a special case of an *h-transitive-closure spanner (h-TC-spanner)*. Hopsets and TC-spanners are fundamental graph-theoretic objects and are widely used in various settings from distance oracles to pre-processing for range queries in sequential or parallel setting or even in property testing. The concept of adding transitive arcs to a digraph in order to reduce its diameter was introduced by Thorup [41] in the context of parallel processing. Bhattacharyya et al. [12] defined an h-TC-spanner of an unweighted digraph G as a digraph H with same transitive closure as G and diameter at most h. They note that this is a central concept in a long line of work around pre-processing a tree for range queries [7, 16, 42]. A TC-spanner can also be defined as a spanner (for the classical spanner definition [38]) of the transitive closure of a graph that has bounded diameter. We will see that an exact h-hopset defines a h-TC-spanner but that the converse is not necessarily true. Bhattacharyya et al. [12] proposed a construction of h-TC-spanner of size $O(n \log n \lambda_h(n))$ for H-minor-free graphs (where λ_h denotes the hth-row inverse Ackermann function, cf. Section 5).

Exact Distance Oracles. A long line of research studies the interplay between data structure space and query decoding time. A lot of attention has been given to distance oracles for planar graphs [23, 10, 17, 14, 26, 21, 30], and it has recently been shown that a distance oracle with $O(n^{1.5})$ space and $O(\log n)$ query-time is possible [30]. In the context of weighted directed graphs with treewidth t, Chaudhuri and Zaroliagis [15] propose a distance oracle using $O(t^2 n \lambda_h(n))$ space and $O(t^3 h + \lambda_h(n))$ query time for integral $h > 1$ where λ_h is the hth-row inverse Ackermann function (as defined in Subsection 5). In the context of unweighted graphs with treewidth t, Farzan and Kamali [27] obtain distance oracles with $O(t^3 \log^3 t)$ query time using optimal space (within low order terms). This construction heavily relies on the unweighted setting as exhaustive look-up tables are constructed for handling graphs with polylogarithmic size.

Distance Labelings and 2-Hopsets. The distance labeling problem is a special case of a distributed distance oracle, and consists of assigning labels to the nodes of a graph such that the distance between two nodes s and t can be computed from the labels of s and t (see, e.g., [28]).

The notion of 2-hopset studied in this work coincides with the special case of two-hop distance labeling (also called *hub-labeling*), where labels are constructed from hub sets: in hub-labeling, a small hub set $S(u) \subseteq V(G)$ is assigned to each node of a graph G such that for any pair u, v of nodes, the intersection of hub sets $S(u) \cap S(v)$ contains a node on a shortest $u - v$ path. Such a construction is formally proposed in [20] and is implicitly introduced by Gavoille et al. [28] and applied to graphs of treewidth t with labels of $O(t \log n)$ size and allows to answer distance queries in $O(t \log n)$ time; the hub sets have a hierarchical structure, which allows for an improvement of query time to $O(t \log \log n)$ time by a binary search over levels. Hub labelings are the currently best known distance labelings for sparse graphs, achieving sublinear node label size [8, 29], and may also be used to provide a 2-additive-approximation for distance labeling in general graphs using sublinear-space labels [29].

In graphs of bounded highway dimension, hub labels were among the first identified distance oracles to provide label size and query time polynomial in the highway dimension and polylogarithmic in other graph parameters [5]. This result was then extended to the more general class of graphs with bounded skeleton dimension [37, 36].

Hub sets with near to optimal size can be constructed in polynomial time. A greedy set cover-type $O(\log n)$-approximation algorithm (with respect to average size of a hub set) was proposed by Cohen et al. [20]. For the case of USP graphs, this approximation ratio was improved by Angelidakis et al. [9] to the logarithm of the graph hop-diameter D_H, i.e., the maximum number of hops of a shortest path in G, showing an approximation gap between USP and non-USP graphs.

2 Preliminaries

2.1 Definitions

We are given a weighted undirected graph $G = (V, E, \omega)$ where $\omega : E \to \mathbb{R}^+$ associates a weight with each edge of G. For a positive integer parameter h and a pair $u, v \in V$, the *h-limited distance* between u and v, denoted $d^h_G(u, v)$, is defined as the length of the shortest path from u to v that contains at most h edges (aka *hops*). The usual shortest path distance can be defined as $d_G(u, v) = d^{n-1}_G(u, v)$. For the sake of brevity, we often let uv denote the pair $\{u, v\}$ representing an edge from u to v.

▶ **Definition 1.** *An (exact) h-hopset for a weighted graph G is a set of edges H such that $d^h_{G\cup H}(u, v) = d_G(u, v)$ for all u, v in $V(G)$ where $G \cup H = (V, E \cup H, w')$ is the graph augmented with edges of the hopset with weights $w'(u, v) = d_G(u, v)$ for $uv \in H$ and $w'(u, v) = w(u, v)$ for $uv \in E \setminus H$. The parameter h is called the* hopbound *of the hopset. Edges from set H are called* shortcuts *in G.*

By convention, we will assume that all self-loops at nodes of V are included in H. Thus, $G \cup H$ is a graph whose h-th power in the $(\min, +)$ algebra on $n \times n$ matrices of edge weights corresponds to the transitive closure of the weight matrix of graph G.

Equivalently, a h-hopset can be defined as a set H of edges such that for any pair s, t, there exists a path P of at most h edges from s to t in $G \cup H$ and a shortest path Q from s to t in G such that all nodes of P belong to Q and appear in the same order. Note that a h-hopset is completely specified by its set H of edges as the associated weights are deduced from distances in the graph.

2.2 Using a Hopset as a Distance Oracle

Hopsets may be used to answer shortest-path queries in a graph $G = (V, E)$. In general, given a hopset H, the naïve way to approach a query for $d_G(u, v)$ for a given node pair u, v is to perform a bidirectional Dijkstra search in graph $G \cup H$ from this node pair, limited to a maximum of $\lceil h/2 \rceil$ hops distance from each of these nodes. We have, in particular for any pair $u, v \in V$:

$$d_G(u, v) = \min_{w \in V} (d^{\lceil h/2 \rceil}_{G\cup H}(u, w) + d^{\lfloor h/2 \rfloor}_{G\cup H}(v, w)).$$

Different optimizations of this technique are possible.

In this paper, we focus only on the time complexity of the case of $h = 3$, where we perform the following optimization of query execution. We represent set H as the union of two (not necessarily disjoint) sets of shortcuts, $H = H_1 \cup H_2$, where an edge belongs to H_1 if it is used as the first or third (last) hop on a shortest path in $G \cup H$, and it belongs to $G \cup H_2$ if it is used as the second hop on such a path. By convention, we assume that self-loops at nodes are added to H_1, thus e.g. a 3-hop path between a pair of adjacent nodes in G is constructed by taking a self-loop from H_1, the correct edge from $G \subseteq G \cup H_2$, and another self-loop from H_1. (Note that we never directly use edges of G as first or last hops in the hopset; if such an edge is required for correctness of construction, it should be explicitly added to set H_1.) We further apply an orientation to the shortcuts in H_1, constructing a corresponding set of arcs $\vec{H}_1$, such that, for any node pair $u, v \in V$, there exist $x, y \in V$ such that $(u, x) \in \vec{H}_1$, $\{x, y\} \in H_2$, $(v, y) \in \vec{H}_1$, and:

$$d_G(u, v) = d_G(u, x) + d_G(x, y) + d_G(y, v).$$

The orientation (w, z) of an arc in $\vec{H}_1$ indicates that edge $\{w, z\}$ can be used as the first edge of a 3-hop path from w or as the third edge of a 3-hop path to w. We note that $|H_1| \leq |\vec{H}_1| \leq 2|H_1|$, since each shortcut from H_1 corresponds to at most a pair of symmetric

arcs in $\vec{H}_1$. For a node $w \in V$, let $N_1(w) = |\{x \in V : (w,x) \in \vec{H}_1\}|$ represent the out-neighborhood of w in the graph $(V, \vec{H}_1)$. To perform shortest path queries on G, for each node w, we now store the list $\{(x, d_G(w,x)) : x \in N_1(w)\}$. We also store a hash map, mapping all node pairs $\{x,y\} \in H_2$ to the length of the respective link, $d_G(x,y)$. Now, we answer the distance query for a node pair $u, v \in G$ as follows:

$$d_G(u,v) = \min_{x \in N_1(u), y \in N_1(v) : \{x,y\} \in H_2} (d_G(u,x) + d_G(x,y) + d_G(y,v)).$$

Using the given data structures, the query is then processed using $|N_1(u)| \cdot |N_1(v)|$ hashmap look-ups, one for each pair $(x,y) \in N_1(u) \times N_1(v)$, i.e., in time $\mathcal{T}_{uv} = O(|N_1(u)| \cdot |N_1(v)|)$. Time $\mathcal{T}_{uv}$ is simply referred to as the *query time* for the considered node pair in the 3-hopset oracle H. Assuming uniform query density over all node pairs, the *uniform-average query time* $\mathcal{T}(H)$ is given as: $\mathcal{T}(H) \equiv \mathbf{E}_{uv}\mathcal{T}_{uv} = O\left(\frac{1}{n^2}\left(\sum_{u \in V} |N_1(u)|\right)^2\right) = O(|H_1|^2/n^2)$. Thus, in the uniform density setting (which we refer to only in Section 4), the average time of processing a query is proportional to the square of the average degree of a node with respect to edge set H_1.

The size of set H_2 affects only the size of the data structure required by the distance oracle, which is given as at most $\mathcal{S} = O(|E| + |H_1| + |H_2|)$ edges, with each edge represented using $O(\log n)$ bits.

In the 3-hopset distance oracles described in the following sections, we will confine ourselves to describing shortcut sets H_1 and H_2, noting that the correct orientation $\vec{H}_1$ of H_1 will follow naturally from the details of the provided constructions.

3 Bounded Skeleton Dimension

A formal definition of the notion of skeleton dimension relies on the concept of the geometric realization of a graph, cf. [37]. The *geometric realization* $\widetilde{G}$ of G can be seen as the "continuous" graph where each edge is seen as infinitely many vertices of degree two with infinitely small edges, such that for any $uv \in E(G)$ and $t \in [0,1]$, there is a node in $\widetilde{G}$ at distance $td_G(u,v)$ from u on edge uv. Given a shortest-path tree T_u of node u with length function $\ell : E(T_u) \to \mathbb{R}^+$, obtained as the union of shortest paths $\bigcup\{P_{uv} : v \in V(G)\}$, we treat it as directed from root to leaves and consider the geometric realization $\widetilde{T}_u$ of this directed graph. We define the *reach* of $v \in V(\widetilde{T}_u)$ as the distance from v to the furthest leaf in its subtree of the directed tree $\widetilde{T}_u$, i.e., $Reach_{\widetilde{T}_u}(v) := \max_{x : v \in P_{ux}} d_{\widetilde{T}_u}(v,x)$. For a given value $\alpha > 0$, we then define the *skeleton* T_u^* of T_u as the subtree of $\widetilde{T}_u$ induced by nodes with reach at least α times their distance from the root. More precisely, $\widetilde{T}_u^*$ is the subtree of $\widetilde{T}_u$ induced by $\{v \in V(\widetilde{T}_u) \mid Reach_{\widetilde{T}_u}(v) \geq \alpha d_{\widetilde{T}_u}(u,v)\}$.

The *α-skeleton dimension* k_α of a graph G is now defined as the maximum width of the skeleton of a shortest path tree, taken over cuts at all possible distances from the root of the tree: $k = \max_{u \in V(G)} \max_{r > 0} |Cut_r(\widetilde{T}_u^*)|$, where $Cut_r(\widetilde{T}_u^*)$ is the set of nodes $v \in V(\widetilde{T}_u^*)$ with $d_{\widetilde{T}_u^*}(u,v) = r$. When $\alpha = \frac{1}{2}$, $k_{1/2}$ is simply called the *skeleton dimension* of G and we let $k = k_{1/2}$ denote it.

The definition was originally proposed with $\alpha = \frac{1}{2}$ (for comparison with highway dimension) in the context of USP graphs [37]. In the long version [36], the definition is extended to other choices of α with $0 < \alpha < 1$ and applies to any choice of shortest paths trees that pairwise agree on their paths (the path from u to v in T_u must be the reverse of the path from v to u in T_v). In the non-USP case, the skeleton dimension should be measured with the best choice of agreeing trees. In particular, if a small perturbation of the edge weights of G provides unique shortest path trees whose skeletons have width at most k_α, then the skeleton dimension of G is at most k_α. The α-skeleton dimension (with parameter α) was

introduced in [36] for the sake of a general definition with fixed α value in mind. We use it here in a novel manner with α tending towards 0 as we consider larger distances, enabling analysis of our new construction.

For the definition of the related concept of *highway dimension*, we refer the readers to [4]. We note that if a graph G has highway dimension h, then G has skeleton dimension $k = k_{1/2} \leq h$; hence, in all subsequent asymptotic analyses, upper bounds expressed in terms of skeleton dimension can be replaced by analogous bounds in terms of highway dimension.

3.1 Construction of the 3-Hopset

We denote by $L_{\max}$ the maximum length of an edge in graph G. The construction of the 3-hopset H is obtained by taking a union of sets of shortcuts, each of which covers sets of node pairs within a given distance range. The first shortcut set H' covers all node pairs $u, v \in V$ with $d_G(u,v) \leq D'$, for some choice of distance bound D', whereas each of the subsequent shortcut sets $H^{(D)}$ covers nodes at a distance in an exponentially increasing distance range, $d_G(u,v) \in [D, D^{1+\epsilon}]$, where $\epsilon := \frac{1}{2\log_2 k}$ is suitably chosen. We then put:

$$H = H' \cup \bigcup_{i=1,2,\ldots} H^{(D'^{\,i(1+\epsilon)})}.$$

Construction of set H'. We note that a construction of 2-hopsets for graphs of skeleton dimension k was performed in [37]. As a direct corollary of [37][Lem. 2, Cor. 1,2], given a distance bound D', there exists a randomized polynomial-time construction of a set of shortcuts H' for graph G with the property that for any pair of nodes $u, v \in V$ with $d_G(u,v) \leq D'$, we have $d^2_{G \cup H'} = d_G(u,v)$, such that $|H'| = O(nk \log D')$, and moreover for all $u \in V$, we have $\mathbf{E}\deg_{H'}(u) = O(k \log D')$ and $\deg_{H'}(u) = O(k \log D' \log\log n + \log n)$. We directly use set H' for the value $D' := L^4_{\max} k^6 \log^{12} n$, considering H' as a 3-hopset for node pairs $u, v \in V$ with $d_G(u,v) \leq D'$. So we have:

$$|H'| = O(nk(\log\log n + \log L_{\max} + \log k)),$$

and for all $u \in V$:

$$\begin{aligned} \mathbf{E}\deg_{H'}(u) &= O(k(\log\log n + \log L_{\max} + \log k)), \\ \deg_{H'}(u) &= O(k \log\log n(\log\log n + \log L_{\max} + \log k) + \log n). \end{aligned}$$

We remark that, without loss of generality, in asymptotic analysis one may assume that $L_{\max} \leq kL$, where L is the *average* edge length in G, noting that edges longer than kL can be subdivided into edges of length at most kL by inserting additional vertices, increasing the number of nodes of the graph only by a multiplicative constant. Thus, in the above bounds, we can replace $(\log\log n + \log L_{\max} + \log k)$ by $(\log\log n + \log L + \log k)$.

Construction of set $H^{(D)}$. We now proceed to construct a 3-hopset for node pairs u, v with $d_G(u,v) \in [D, D^{1+\epsilon}]$. The construction of set $H^{(D)}$ is randomized and completely determined by assignment of real values $\rho(u) \in [0,1]$ to each node $u \in V$, uniformly and independently at random. We condition all subsequent considerations on the event that all values ρ are distinct, i.e., $|\rho(V)| = |V|$, which holds with probability 1. ($\rho(V) = \{\rho(v) | v \in V\}$)

Now, hopset $H^{(D)}$ is defined as $H^{(D)} := H^{(D)}_1 \cup H^{(D)}_2$, where following our usual notation, $H^{(D)}_1$ is the set of first and last hops, and $H^{(D)}_2$ is the set of middle hops.

Set of first and last hops. For $u \in V$, let $R^{(D)}(u)$ be the set of nodes which lie on a shortest path of length at least D which has one of its endpoints at u, and which have minimum value of ρ among all vertices on this path at distance in $[D/4, D/2]$ from u:

$$R^{(D)}(u) = \bigcup_{v \in V : d_G(u,v) \geq D} \left\{ \text{argmin}_{r \in P_{uv}, d_G(u,r) \in [D/4, D/2]} \rho(r) \right\}.$$

We now put: $H_1^{(D)} := \{ur : u \in V, r \in R(u)\}$.

Set of middle hops. We put in $H_2^{(D)}$ links between all pairs of nodes which have a small value of ρ, satisfy the natural upper bound of $D^{1+\epsilon}$ on distance between them, and have sufficiently large reach, i.e., the shortest path between them can be extended by at least $D/4$:

$$H_2^{(D)} := \left\{ qr : q, r \in \bigcup_{u \in V} R^{(D)}(u) \wedge d_G(q,r) \leq D^{1+\epsilon} - D/2 \wedge (\exists_{v \in V}\ r \in P_{qv} \wedge d_G(r,v) \geq D/4) \right\}.$$

The validity of H as a 3-hopset is immediate to verify from the construction: consider u, v and $i \geq 0$ such that $d_G(u,v) \in [D, D^{1+\epsilon}]$ with $D = D'^{i(1+\epsilon)}$.

For $q = \text{argmin}_{w \in P_{uv}, d_G(u,w) \in [D/4, D/2]} \rho(w)$ and $r = \text{argmin}_{w \in P_{uv}, d_G(u,w) \in [D/2, 3D/4]} \rho(w)$, we then have $uq \in H_1^{(D)}$, $qr \in H_2^{(D)}$ and $vr \in H_1^{(D)}$, yielding a 3-hop shortest path from u to v. For $d_G(u,v) \leq D'$, H' contains a 2-hop shortest path from u to v.

3.2 Bound on 3-Hopset Size and Oracle Time

▶ **Lemma 2.** *Fix $u \in V$ and $D > 0$. We have: $|R^{(D)}(u)| \leq k$.*

From the above Lemma, it follows that for any $u \in V$, we have $\deg_{H_1^{(D)}}(u) \leq k$. Thus summing over all the $O(\log\log(nL_{\max})/\log(1+\epsilon)) = O(\log\log(nL_{\max})\log k)$ levels of the construction, we successively obtain:

$$\deg_{H_1}(u) \leq \deg_{H'}(u) + k \cdot O(\log\log(nL_{\max})\log k) = O(k \log\log n \log k(\log\log n + \log L) + \log n), \quad (1)$$

$$\mathbf{E}\deg_{H_1}(u) \leq \mathbf{E}\deg_{H'}(u) + k \cdot O(\log\log(nL_{\max})\log k) = O(k \log k(\log\log n + \log L)), \quad (2)$$

$$|H_1| \leq |H'| + nk \cdot O(\log\log(nL_{\max})\log k) = O(nk \log k(\log\log n + \log L)). \quad (3)$$

We now proceed to bound the size of the set H_2 of middle hopsets.

▶ **Lemma 3.** *Fix $D \geq D'$. With probability $1 - O(1/n^2)$, it holds that for all $u \in V$ and for all $r \in R^{(D)}(u)$, we have $\rho(r) \leq L_{\max}/D$.*

We now proceed under the assumption that the event from the claim of the Lemma holds. We now consider an arbitrary node $q \in R^{(D)}(u)$ for some $u \in V$, and look at $\deg_{H_2^{(D)}}(q)$. We now have that if $qr \in H_2^{(D)}$, then by the definition of $H_2^{(D)}$ and the above Lemma, the following conditions jointly hold:

- $\rho(r) \leq L_{\max}/D$
- $r \in \{w \in V : \exists_{v \in V}\ D^{1+\epsilon} \geq d_G(q,v) \geq d_G(q,w) + D/4 \wedge P_{qw} \subseteq P_{gv}\} =: W(q)$.

We note that $W(q)$ is the subset of the vertex set of the shortest path tree of node q, pruned to contain only those paths which have reach at least $D/4$ at depth less than $D^{1+\epsilon}$. This tree has depth bounded by $D^{1+\epsilon}$, and width bounded by an α-skeleton dimension k_α (following [36]), with parameter $\alpha = \frac{D/4}{D^{1+\epsilon}} = D^{-\epsilon}/4$. Following [36][Section 6], k_α can be easily expressed using skeleton dimension $k = k_{1/2}$ as:

$$k_\alpha \leq k^{\lceil \log_2(1+1/\alpha) \rceil} < k^{1+\log_2(4D^\epsilon)} = k^3 D^{\epsilon \log_2 k}.$$

We then have $|W(q)| \leq D^{1+\epsilon}k_\alpha < k^3 D^{1+\epsilon(1+\log_2 k)}$. Moreover, by an easy concentration bound, we have that for all $q \in V$, $|\{r \in W(q) : \rho(r) \leq L_{\max}/D\}| = O(\log n) + \frac{2L_{\max}}{D}|W(q)|$, with probability $1 - O(1/n^2)$. It follows that with probability $1 - O(1/n^2)$, we have for all $q \in \bigcup_{u\in V} R^{(D)}(u)$:

$$\deg_{H_2^{(D)}}(q) \leq O(\log n) + \frac{2L_{\max}}{D}|W(q)| \leq O(\log n + L_{\max}k^3 D^{\epsilon \log_2 k}).$$

Noting that with probability $1 - O(1/n^2)$:

$$|\bigcup_{u\in V} R^{(D)}(u)| \leq |\{w \in V : \rho(w) \leq L_{\max}/D| \leq O(\log n + nL_{\max}/D)$$

we finally obtain that with probability $1 - O(1/n^2)$:

$$\begin{aligned}|H_2^{(D)}| &\leq O(\log n + nL_{\max}/D)O(\log n + L_{\max}k^3 D^{\epsilon \log_2 k}) = O(\log^2 n + nL_{\max}^2 k^3 D^{\epsilon \log_2 k - 1}) \\ &\leq O(nL_{\max}^2 k^3 D^{-1/2}) \leq O(nD'^{-1/4}) \leq O(n/\log^3 n),\end{aligned}$$

where in the last two transformations we use the fact that $\epsilon = \frac{1}{2\log_2 k}$ and that $D \geq D' \geq L_{\max}^4 k^6 \log^{12} n$. Using a union bound and summing over all levels of the construction, we eventually obtain that with probability $1 - O(1/n)$:

$$|H_2| \leq O(n/\log_2 n). \tag{4}$$

Thus, the set of middle links is sparse and does not contribute to the asymptotic size of the overall representation of the 3-hopset.

Overall, considering a randomized construction which rejects random choices of ρ for which any of the considered w.h.p. events fail, by combining Eq. (1)–(4) with the hopset-based distance oracle framework described in the Preliminaries, we obtain the following Theorem.

▶ **Theorem 4.** *For a unique shortest path graph with skeleton dimension k and average link length $L \geq 1$, there exists a randomized construction of a 3-hopset distance oracle of size $|H| = O(nk \log k(\log\log n + \log L))$, which for an arbitrary queried node pair performs distance queries in expected time $O(k^2 \log^2 k(\log^2 \log n + \log^2 L))$ (where the expectation is taken over the randomized construction of the oracle), and in time $O(k^2 \log^2 k \log^2 \log n(\log^2 \log n + \log^2 L) + \log^2 n)$ with certainty.*

In particular, for graphs with constant-length edges and small skeleton dimension ($k = O(\log n)$), the 3-hopset has size $|H| = O(nk \log k \log\log n)$, with expected time of any query given as $O(k^2 \log^2 k \log^2 \log n)$.

4 LP-based Approximation Algorithm

In this section, we propose an Integer Linear Programming (ILP) formulation for h-hopsets with a minimum number of edges, which we then relax to a LP formulation. Whereas both formulations are applicable to the general case, we prove relations between them only for USP graphs.

4.1 ILP and LP Formulations

A necessary and sufficient condition for H to be a h-hopset for G is that for every pair of vertices s, t there exists a path $P_{st} = (s = v_0, v_1, \ldots, v_{l_{st}} = t)$ in $G \cup H$ such that $l_{st} \leq h$ and in graph G there exists some shortest $s-t$ path passing through all of the vertices $v_0, \ldots, v_{l_{st}}$, in the given order. For a fixed pair s, t, we consider the directed graph H^{st} with vertex set

$V \times \{0, \ldots, h\} \equiv V_h$ (by convention, elements of V_h will be denoted compactly as v_i, where $v \in V$, $i \in \{0, \ldots, h\}$) and with an arc set defined as follows. For $i \in \{0, \ldots, h-1\}$, we add arc (u_i, v_{i+1}) to H^{st} if and only if $\{u, v\} \in G \cup H$ and u, v lie on some shortest $s-t$ path in the given order, i.e., if $d_G(s,u) + d_G(u,v) + d_G(v,t) = d_G(s,t)$. In particular, all arcs of the form (u_i, u_{i+1}), for $u \in V$ on a $s-t$ shortest path, belong to H^{st}. Now, we have that H is a h-hopset for G if and only if there exists a path from s_0 to t_h in H^{st}. This is equivalent to saying that for all $s, t \in V$, the flow value from s_0 to t_h is at least 1 in H^{st}. Given graph G, we thus have the following ILP formulation for the minimum h-hopset problem, using indicator variables x_{uv} for $G \cup H$ (given as 1 if $\{u, v\} \in G \cup H$ and 0 otherwise) and variables $f^{st}_{u_i v_j}$, representing the flow value along arc (u_i, v_j) in H^{st}:

$$\text{Minimize:} \quad \sum_{u \neq v, \{u,v\} \notin E} x_{uv} \tag{5}$$

Subject to:

$$x_{uv} \in \{0, 1\} \tag{6}$$

$$0 \leq f^{st}_{u_i v_j} \leq \begin{cases} x_{uv}, & \text{if } j = i+1 \text{ and } d_G(s,u) + d_G(u,v) + d_G(v,t) = d_G(s,t), \\ 0, & \text{otherwise.} \end{cases} \tag{7}$$

$$\sum_{u_i} f^{st}_{v_j u_i} - \sum_{u_i} f^{st}_{u_i v_j} = \begin{cases} 0, & \text{for } v_j \in V_h \setminus \{s_0, t_h\} \\ +1, & \text{for } v_j = s_0 \\ -1, & \text{for } v_j = t_h \end{cases}, \tag{8}$$

where indices s, t, u, v traverse V and indices i, j traverse $\{0, \ldots, h\}$.

To obtain an LP relaxation of the above problem, we replace the integral condition $x_{uv} \in \{0, 1\}$ by the fractional one $x_{uv} \in [0, 1]$. We look at the connection between the integral and fractional forms for the special case of unique shortest path graphs.

We remark that the above formulation can be seen as a generalization of the LP and ILP statement of Angelidakis et al. [9] proposed for the special case of 2-hop labeling. In the case of 2-hop labeling, Angelidakis et al. do not rely on an explicit flow formulation but use a single constraint of the simpler form $\sum_{w \in P^{st}} \min\{x_{sw}, x_{wt}\} \geq 1$, where P^{st} represents the set of nodes on some shortest $s-t$ path in G. However, the analysis of the integrality gap does not carry over from the case of $h = 2$ to $h > 2$, i.e., as soon as there exist internal shortcuts which have neither s nor t as one of their endpoints.

4.2 Bounding Integrality Gap for Unique Shortest Path Graphs

We analyze the integrality gap of the above LP formulation for the case of *unique shortest path (USP) graphs*, i.e., graphs in which each pair of nodes $s, t \in V$ is connected by a unique shortest path P^{st} in G. We will occasionally identify P^{st} with its set of nodes, and we will introduce a linear order on its vertices, writing for $u, v \in P^{st}$ that $u <^{st} v$ if $d_G(s,u) < d_G(s,v)$; we will denote the order simply as "$<$" when the path P^{st} is clear from the context. Observe that in the LP formulation, we may have $f^{st}_{u_i v_j} \neq 0$ only if $u <^{st} v$ and $j = i+1$. Thus, fixing $s, t \in V$, the flow $f^{st} = (f^{st}_{u_i v_j} : u_i, v_j \in V_h)$ is non-zero between vertices of $\{P^{st}\} \times \{0, 1, \ldots, h\}$ only, and the flow is oriented towards t on this path.

Let $(x_{uv}, f^{st}_{u_i v_j})$ be a fixed solution to the LP problem in a USP graph, with cost $COST_{\text{LP}} = \sum_{u \neq v, \{u,v\} \notin E} x_{uv}$. We will show how to use this set to construct a valid hopset H'' for G (thus, equivalently, also solving the ILP formulation). We first apply a randomized rounding procedure following the classical scheme of Raghavan and Thomson [39]. We define the family

of independent random variables $(x'_{u_i v_{i+1}} : u, v \in V, i \in \{0, \ldots, h\})$, with $x'_{u_i v_{i+1}} \in \{0, 1\}$. For $u \neq v, \{u, v\} \notin E$ we put $\Pr[x'_{u_i v_{i+1}} = 1] = \min\{Cx_{uv}, 1\}$, where $C \geq 1$ is a suitably chosen probability amplification parameter (we put $C = 8h \ln n$). We will assume, without affecting the validity or cost of the solution, that $x_{uv} = x'_{u_i v_{i+1}} = 1$, when $u = v$ or $\{u, v\} \in E$.

We denote $H' = \{\{u, v\} : u, v \in V \wedge u \neq v \wedge \{u, v\} \notin E \wedge \exists_{i \in \{0,\ldots,h-1\}}\ x'_{u_i v_{i+1}} = 1\}$. Let $\pi : V \to \{1, \ldots, n\}$ be a bijection picked uniformly at random (it is a random permutation when $V = \{1, \ldots, n\}$). We define the set of shortcuts $S(\{u, v\})$ associated with each pair $\{u, v\} \in H'$ as the set of all pairs of nodes on path P^{uv}, one of which is a prefix minimum on this path with respect to π, and the other of which is a suffix minimum with respect to π:

$$S(\{u, v\}) := \left\{ \{u^*, v^*\} : u^*, v^* \in P^{uv} \wedge \pi(u^*) = \min_{z \in P^{uv}, z \leq_{uv} u^*} \pi(z) \wedge \pi(v^*) = \min_{z \in P^{uv}, z \geq_{uv} v^*} \pi(z) \right\}.$$

The obtained solution is given as the set of all such shortcuts: $H'' := \bigcup_{\{u,v\} \in H'} S(\{u, v\})$.

▶ **Proposition 5.** *With probability $1 - O(1/n)$, set H'' is a hopset for G of size $O(h^2 \log^3 n \cdot COST_{\text{LP}})$.*

We remark that the above Proposition implies that the h-hopset problem can be efficiently approximated by finding an optimal fractional LP solution and constructing set H''.

▶ **Theorem 6.** *There exists a randomized polynomial-time $O(\text{poly} \log n)$-approximation algorithm for the h-hopset problem in unique shortest path graphs, for any $h \leq O(\text{poly} \log n)$.*

4.3 Approximating Average Query Time for 3-Hopsets

In order to design an efficient distance oracle based on 3-hopsets, we follow the framework described in the preliminaries and use an LP-rounding technique to obtain sets $H_1 \cup H_2 =: H$. The obtained claim relies on the notion of uniform-average query time introduced in the Preliminaries.

▶ **Theorem 7.** *For any feasible bound $\mathcal{S}$, let $H_{OPT,\mathcal{S}}$ be a 3-hopset for a unique shortest path graph, which satisfies the given bound on the number of edges $|H_{OPT,\mathcal{S}}| \leq \mathcal{S}$ and such that the uniform-average query time $\mathcal{T}(H_{OPT,\mathcal{S}})$ is minimized. Then, there exists a randomized polynomial-time algorithm which finds a 3-hopset H with $|H''| \leq O(\log^3 n)\mathcal{S}$ and $\mathcal{T}(H'') \leq O(\log^4 n)\mathcal{T}(H_{OPT,\mathcal{S}})$.*

We remark that the above Theorem can be directly generalized to a notion of average query time for non-uniform query densities, in which the goal is to minimize expected query time in a model in which each node $v \in V$ is assigned its relative frequency $f_v \in [0, 1]$, and a node pair uv is queried with frequency $f_u f_v$.

5 Bounded Treewidth Graphs

We now show how to obtain h-hopsets for graphs with bounded treewidth by following a classical construction for trees. We first begin with preliminaries recalling the definitions of treewidth and inverse Ackermann function.

Treewidth definition. Recall that a graph G has treewidth t if there exists a tree T whose nodes are subsets of $V(G)$ called *bags* such that: $|X| \leq t + 1$ for all $X \in V(T)$; for all edges $uv \in E(G)$, there exists a bag $X \in V(T)$ containing both u and v $(u, v \in X)$; and for all nodes $u \in V(G)$, the bags containing u form a sub-tree of T. Without loss of generality, we assume that each bag contains exactly $t + 1$ nodes, and that two neighboring bags share exactly t nodes (the decomposition is standard). This implies $|V(T)| \leq n$ as each bag brings

one new node. Note that removing a non-leaf bag separates the graph into several connected components. We consider that all edges of T have weight 1. For convenience, we assume that T is rooted at some bag R and define for each node $u \in V(G)$ the root bag of u as the bag $R_u \in V(T)$ containing u which is closest to the root.

Inverse Ackermann notation. The *kth-row inverse Ackermann* function $\lambda_k(.)$ can be defined by $\lambda_0(n) = \frac{n}{2}$, $\lambda_1(n) = \sqrt{n}$, $\lambda_2(n) = \log n$, $\lambda_3(n) = \log\log n$, $\lambda_4(n) = \log^* n$, and more generally for $k \geq 2$ by the recurrence $\lambda_k(n) = \lambda^*_{k-2}(n)$ where we define for any function f: $f^{(0)}(n) = n$, $f^{(i)}(n) = f(f^{(i-1)}(n))$ for $i > 0$, and $f^*(n) = \min\{j \mid f^{(j)}(n) \leq 1\}$. The *inverse Ackermann* function can be defined as $\alpha(n) = \min\{j \mid \lambda_{2j}(n) \leq j\}$. See [33] for a more formal definition based on Ackermann function.

We first consider the case of (weighted) trees for which the construction of h-hopsets is classical (even though the connection with hopsets was not made). It is implicit in [7, 16], explicit for unweighted trees in [13] and directed trees in [42]. We provide a short construction which fine-grains the dependence of the hopset size on h (e.g., replacing $2h$ by h with respect to the asymptotic analysis in [7]). The construction is based on the following folklore lemma for splitting a tree into smaller sub-trees (it can be seen as a generalization of the existence of a centroid).

▶ **Lemma 8.** *Given a rooted tree T with n nodes and a value $p > 1$, there exists a set P of at most $2p$ nodes such that each connected component of $T \setminus P$ contains less than n/p nodes and is connected to at most two nodes in P. Set P can be computed in linear time through a bottom-up traversal of the tree.*

***h*-hopset construction for trees.** A 1-hopset in a tree T is obtained by adding all pairs as edges with appropriate weight. For $h > 1$, we recursively define a h-hopset of T as follows. Select a set P of $2p$ nodes at most with $p = \frac{n}{\lambda_{h-2}(n)}$ according to Lemma 8. When $h = 2$, we add an edge from each node u of T to each node in P. When $h > 2$, we consider the forest T' induced by nodes in P: it has node set P and edges xy such that y is the closest ancestor of x in T that belongs to P. The weight of such an edge is defined as $w'(x, y) = d_T(x, y)$. We then add a $(h-2)$-hopset of T' to the construction. Additionally, we add one or two edges per node not in P: for each connected component C of $T \setminus P$, add an edge ux for each node $u \in C$ and each $x \in P$ connected to C. Note that Lemma 8 ensures that there are at most two such nodes x for a given component C. In both cases ($h \geq 2$), we construct recursively a h-hopset of each sub-tree induced by a connected component C of $T \setminus P$. In the special case of $h = 3$, the $(h-2)$-hopsets contribute to H_2 while all edges connecting to a node in some selected set P contribute to H_1 according to the $H = H_1 \cup H_2$ convention introduced in the Preliminaries.

Following a similar approach on the tree decomposition of a graph with treewidth t, we obtain the following result (detailed construction is given in the full paper [33]).

▶ **Theorem 9.** *For all $h > 1$, any graph with treewidth t has a h-hopset with $O(tn\lambda_h(n))$ edges and a $2(\alpha(n)+1)$-hopset with $O(t^2 n)$ edges.*

For the special case of $h = 3$, we have $\lambda_3(n) = \log\log n$, and the size required to represent the 3-hop data structure is $\mathcal{S} = O(tn \log\log n)$ edges. Following the convention $H = H_1 \cup H_2$, we note that we have $\deg_{H_1}(v) = O(t \log\log n)$ for any $v \in V$. The following bound on the query time follows.

▶ **Theorem 10.** *Any graph with treewidth t admits a 3-hopset distance oracle represented on $O(tn \log\log n)$ edges of $O(\log n)$ bits, with a query time of $O(t^2 \log^2 \log n)$.*

Abstract

A classical multi-agent fence patrolling problem asks: What is the maximum length L of a line fence that k agents with maximum speeds $v_1, \dots, v_k$ can patrol if each point on the line needs to be visited at least once every unit of time. It is easy to see that $L = \alpha \sum_{i=1}^{k} v_i$ for some efficiency $\alpha \in [\frac{1}{2}, 1)$. After a series of works [3, 8, 9, 10] giving better and better efficiencies, it was conjectured by Kawamura and Soejima [10] that the best possible efficiency approaches $\frac{2}{3}$. No upper bounds on the efficiency below 1 were known.

We prove the first such upper bounds and tightly bound the optimal efficiency in terms of the minimum speed ratio $s = \frac{v_{\max}}{v_{\min}}$ and the number of agents k. Our bounds of $\alpha \leq \frac{1}{1+\frac{1}{s}}$ and $\alpha \leq 1 - \frac{1}{\sqrt{k}+1}$ imply that in order to achieve efficiency $1-\epsilon$, at least $k \geq \Omega(\epsilon^{-2})$ agents with a speed ratio of $s \geq \Omega(\epsilon^{-1})$ are necessary. Guided by our upper bounds, we construct a scheme whose efficiency approaches 1, disproving the conjecture stated above. Our scheme asymptotically matches our upper bounds in terms of the maximal speed difference and the number of agents used.

A variation of the fence patrolling problem considers a circular fence instead and asks for its circumference to be maximized. We consider the unidirectional case of this variation, where all agents are only allowed to move in one direction, say clockwise. At first, a strategy yielding $L = \max_{r \in [k]} r \cdot v_r$ where $v_1 \geq v_2 \geq \dots \geq v_k$ was conjectured to be optimal by Czyzowicz et al. [3] This was proven not to be the case by giving constructions for only specific numbers of agents with marginal improvements of L. We give a general construction that yields $L = \frac{1}{33 \log_e \log_2(k)} \sum_{i=1}^{k} v_i$ for any set of agents, which in particular for the case $1, 1/2, \dots, 1/k$ diverges as $k \to \infty$, thus resolving a conjecture by Kawamura and Soejima [10] affirmatively.

1 Introduction

Patrolling is a fundamental task in robotics, multi-agent systems, and security settings. Given some environment of interest, and a collection of mobile agents, the aim is to coordinate the movements of the agents in order to, for example, guard an area from intrusion by an enemy, prevent accidents or failure of equipment, maintain up-to-date information of the environment, etc. For each of these tasks, ensuring that certain points in the environment get visited/monitored frequently is crucial. Performance of patrolling algorithms is consequently often measured in terms of *idleness* – roughly speaking, the time between two consecutive visits to a point in the environment.

Multi-agent patrolling has been extensively studied in the robotics literature since the early 2000s, e.g., see [1, 11] and the survey [12]. However, even for extremely clean and very simple models, determining optimal patrolling schemes poses many natural mathematical questions with interesting and surprisingly sophisticated answers [2, 3, 4, 5, 6, 7, 8, 9, 10].

1.1 Fence Patrolling

This paper studies a classical fence patrolling problem introduced by Czyzowicz et al. [3], which might be one of the cleanest and most natural patrolling problems: What is the maximum length L of a fence that k agents $a_1, \dots, a_k$ with maximum speeds $v_1, \dots, v_k$ can patrol if each point needs to be visited at least once every unit of time. Czyzowicz et al. introduce two variations of this question – the fence could be either an open curve, or a closed curve. For simplicity, we assume the open curve is a line segment and the closed curve is a circle.

For the line segment, it is easy to see that for any speeds the maximum length L satisfies $L = \alpha \sum_{i=1}^{k} v_i$ for some efficiency $\alpha \in [\frac{1}{2}, 1)$. In particular, in one unit of time an agent a_i can cover a length of at most v_i and all agents can cover at most a total length of $\sum_{i=1}^{k} v_i$. An efficiency of exactly $\alpha = 1$ is furthermore never possible because agents have to turn around eventually. On the other hand, an efficiency of $\alpha = \frac{1}{2}$ can easily be achieved by the following strategy:

Partition-based strategy, $\mathcal{A}_1$: For all $i \in [k]$, agent a_i patrols a subsegment of length $\frac{1}{2}v_i$ by going back and forth on this segment once every unit of time. This patrols a segment of length $L = \frac{1}{2}\sum_{i=1}^{k} v_i$ with idle time 1.

Considering patrol schedules on a circle, the picture is quite different than for a line segment. Again, the length L of any circle that can be patrolled by a set of agents is upper-bounded by the sum of the maximum speeds of the agents, since agent a_i cannot cover a length of more than v_i. Here, however, it is easy to find collections of agents and a corresponding patrol schedule that achieves this exactly – imagine k identical agents starting equidistantly along the circle and moving in unison in the same direction, say counter-clockwise.

1.2 Prior Work on Fence Patrolling

1.2.1 Prior Work on the Line Segment

Czyzowicz et al. [3] observed that the trivial scheme $\mathcal{A}_1$ with efficiency $\frac{1}{2}$ is optimal if the paths of the agents never cross. To see this, note that the leftmost agent a_i cannot walk away further than $\frac{1}{2}v_i$ from the leftmost point of the fence as it would take more than one unit of time between two visits of this point. By the same argument the agent a_j to the

right of agent a_i cannot ever be further away than $\frac{1}{2}(v_i + v_j)$ from the leftmost point of the fence and induction shows that a total fence length of $\frac{1}{2}\sum_{i=1}^{k} v_i$ is best possible. For the special case of all agents having the same speed the assumption that the paths of the agents never cross is furthermore without loss of generality as one can equally well switch identities of agents at a crossing, making the agents bounce off each other instead of crossing. In the worst case an efficiency of $\frac{1}{2}$ is thus optimal and Czyzowicz et al. posited [3] that indeed no better efficiency can be achieved for any speeds.

Surprisingly, Kawamura and Kobayashi [9] disproved this by providing an explicit fence patrolling schedule for 6 agents with speeds $1, 1, 1, 1, \frac{7}{3}$, and $\frac{1}{2}$ for a fence of length $\frac{7}{2}$, thus achieving an efficiency of $\frac{21}{41} > \frac{1}{2}$. This was improved by Dumitrescu, Ghosh and Tóth [8], who proposed a family of patrolling schedules with efficiency approaching $\frac{25}{48}$, and finally by Kawamura and Soejima [10] who achieved an efficiency approaching $\frac{2}{3}$. Kawamura and Soejima furthermore explicitly conjectured that no efficiency better than $\frac{2}{3}$ is possible for any set of speeds [10, Conjecture 6, page 9].

On the other hand, except for the setting of equal speeds discussed above, no upper bounds on the efficiency below 1 have been provided in the literature [3, 9, 8, 10].

1.2.2 Prior work on the Circle

For a general set of agents, Czyzowicz et al. [3] proposed the following universal scheme that generalizes the schedule above for equal speeds:
Runners strategy, $\mathcal{A}_2$: Assume $v_1 \geq v_2 \geq \cdots \geq v_k$. Find the $r \in [k]$ that maximizes $r \cdot v_r$, and let the r fastest agents move equidistantly along the circle at speed v_r. This patrols a circle of length $L = \max_{r\in[k]} r \cdot v_r$ with idle time 1.

Suppose for a collection of agents with maximum speeds $v_1 \geq v_2 \geq \cdots \geq v_k$, $\mathcal{A}_2$ produces a schedule on a circle with length L. Without loss of generality, we can assume $L = 1$. Then $\max_{r\in[k]} r \cdot v_r = 1$, and by possibly increasing the maximum speed of some agents we may assume $v_i = 1/i$ for each $i \in [k]$. Note that increasing speeds in this way can only increase the maximum circumference that can be patrolled with idle time 1 using these agents, but will not increase the length produced by $\mathcal{A}_2$. Thus, if there is any collection of agents where there is a patrol schedule that performs better than $\mathcal{A}_2$, there must be such a schedule in the case of *harmonic* maximum speeds $1, 1/2, \ldots, 1/k$.

To analyse the performance of patrol schemes on the circle, Czyzowicz et al. considered two different cases: *unidirectional* patrol schedules, where agents are only allowed to move in one direction, and general (or *bidirectional*) patrol schedules, where agents are allowed to go in both directions. Clearly, any patrol schedule obtained through $\mathcal{A}_2$ is unidirectional.

In the bidirectional case, it is not too hard to see that there are situations where $\mathcal{A}_2$ is not optimal. Indeed, in the case of harmonic maxiumum speeds, the partition-based strategy $\mathcal{A}_1$, which works in the same way for a circular fence as for a line segment fence, would give $L = (1 + 1/2 + \cdots + 1/k)/2$, which is bigger than 1 as given by $\mathcal{A}_2$ for any $k \geq 4$. In fact, an example with three agents was given in [3] where neither $\mathcal{A}_1$ nor $\mathcal{A}_2$ are optimal. This was strengthened further by Dumitrescu et al. [8], who showed for any $k \geq 4$ there exists a collection of k agents where what they call the *train strategy* $\mathcal{A}_3$ performs strictly better than both $\mathcal{A}_1$ and $\mathcal{A}_2$. To the authors' knowledge, no universal scheme has been proposed to always produce an optimal patrol schedule in this setting.

For the unidirectional case, it was initially conjectured by Czyzowicz et al. that $\mathcal{A}_2$ is optimal for any set of agents. This was proved to be true for up to four agents. However, it was shown incorrect by parallel results by Dumitrescu et al. [8] and Kawamura and Soejima [10], who gave explicit examples of patrol schemes for 32 and 122 agents (with harmonic

speeds) with $L = 1 + \epsilon$ (for a small unspecified $\epsilon > 0$) and $L = 1.05$ respectively. Kawamura and Soejima further conjectured that the maximum length of a unidirectional circle that can be patrolled by agents with speeds $1, 1/2, \ldots 1/k$ diverges as $k \to \infty$.

2 Our Results

This paper advances the understanding of the fence patrolling problem by giving tight upper and lower bounds on the optimal efficiency for the line segment, and a construction for the circle with efficiency of $\Theta(\frac{1}{\log_e \log_2 k})$ for any set of k agents. To a large extent it concludes the main line of inquiry put forward in the works discussed above [3, 9, 8, 10].

2.1 Results for the Line Segment

We provide the first technique to prove general impossibility results for the fence patrolling problem. We explain our ideas in more detail in Section 4 and merely state our main upper bound here:

▶ **Theorem 2.1.** *Any fence patrol schedule with k agents with maximum speeds $v_1, \ldots, v_k$ patrols a fence of length at most*

$$L \leq \sum_{i=1}^{k} \frac{v_i}{1 + \frac{v_i}{\max_j v_j}}.$$

One way to interpret Theorem 2.1 is that the contribution of an agent a_i depends not only on his/her own speed v_i but also on how much slower he/she is than the fastest agent. In particular, instead of always contributing v_i, as in the trivial upper bound, an agent contributes at most $\frac{1}{1+\frac{1}{s_i}} \cdot v_i$ given that the fastest agent patrolling is a factor of s_i faster than a_i. That is, the "relative efficiency" of an agent a_i ranges anywhere between $1/2$ and 1 depending on s_i, which always constitutes an improvement over the trivial upper bound of $\sum_i v_i$.

We also show that Theorem 2.1 can be used to prove an upper bound on the efficiency of a schedule solely in terms of the number of agents:

▶ **Lemma 2.2.** *Any fence patrolling schedule with k agents has an efficiency of at most $1 - \frac{1}{\sqrt{k}+1}$.*

We note that our upper bounds are tight in several interesting special cases. Specifically, for the case of agents having identical speeds, Theorem 2.1 shows that the efficiency of the schedule (and indeed each agent) is at most $\frac{1}{2}$, reproving the result of [3]. In contrast to the symmetry argument about non-crossing agents explained above, our arguments and upper bounds easily extend to near-identical speeds as well. Lastly, it is easy to check that Theorem 2.1 is tight when applied to the configuration of agents used by Dumitrescu et al. [8] and Kawamura and Soejima [10] for their construction to obtain efficiency ratios of $25/48 - o(1)$ and $2/3 - o(1)$, respectively.

Our upper bounds do not exclude schedules with efficiency close to 1. They do however give important restrictions and clues about what an extremely efficient schedule, if it exists, has to look like. In particular, Lemma 2.2 implies that any schedule with efficiency $1 - \epsilon$ has to have at least $\left(\frac{1}{2\epsilon}\right)^2$, i.e., quadratically in $\frac{1}{\epsilon}$ many agents. In the same manner, Theorem 2.1 implies that, with $\epsilon \to 0$, the ratio between the fastest and slowest agent has to be at least $\Omega(\frac{1}{\epsilon})$, i.e. grow unboundedly. Even more interestingly, the way the upper bound in Theorem 2.1 depends on $\max_i v_i$ seems to indicate that even just a single very fast agent can raise the "relative efficiency" of slower agents from $1/2$ to almost 1.

Equipped with this better understanding and guidance from our impossibility results we were, to our surprise, able to design schedules which achieve an efficiency arbitrarily close to 1, thus disproving the conjecture of [10]:

▶ **Theorem 2.3.** *For any sufficiently large k, there exists a fence patrolling schedule with efficiency $1-\frac{3.5}{\sqrt{k}}$. Such a schedule uses $k-1$ agents of speed one and one agent with maximum speed $\Theta(\sqrt{k})$.*

Note that this theorem implies that for any $\epsilon > 0$ there exists a fence patrolling schedule with efficiency $1-\epsilon$ using $O(\frac{1}{\epsilon^2})$ agents – one with speed $\Theta(\frac{1}{\epsilon})$ and all others with speed 1. In other words, the efficiency can be made arbitrarily close to 1 by choosing the appropriate number and maximum speeds of agents.

We remark that Theorem 2.3 also shows that both our upper bounds are asymptotically tight. In particular, the optimal efficiency for any schedule with k agents is indeed $1-\Theta(\frac{1}{\sqrt{k}})$. Furthermore, for any $s \geq 1$, there is a configuration (with $k = \Theta(s^2)$ agents), where the maximum speeds of the agents differ by a factor s and for which the optimal efficiency is $\frac{1}{1+\frac{1}{\Theta(s)}} = 1-\Theta(\frac{1}{s})$.

2.2 Results for the Circle

We resolve the conjecture by Kawamura and Soejima affirmatively. Namely, for any large enough k, we can construct a patrol schedule with idle time 1 using agents with maximum speeds $1, 1/2, \ldots 1/k$ that patrols a unidirectional circle of length $L = \Theta\left(\frac{\log_2 k}{\log_e \log_2 k}\right)$. In fact, our construction extends to a new universal scheme for the unidirectional circle. This is captured in the following theorem.

▶ **Theorem 2.4.** *For k sufficiently large and for any k agents with maximum speeds $v_1, \ldots v_k$ there exists a patrol scheme with idle time 1 that patrols a unidirectional circle of length*

$$L = \frac{1}{33 \log_e \log_2 k} \sum_{i=1}^{k} v_i.$$

The construction of our schedule has two steps: we first divide the agents into $\Theta(\log_2 k)$ groups, reducing the speed of some and discarding others so that each group consists of a power of 2 number of agents that move with the same speed, which is also a power of 2 times the sum of speeds. This allows us to use a randomized construction, in which the agents from each group are placed equidistantly around the circle with a random offset from some fixed "beginning" of the circle, and move around it with the same speed. We show that with this patrol schedule, most points are visited as frequently as required by our theorem. Then as a second phase, we cut out the bad points – that is, the ones that are not visited as frequently as necessary. We move the patrol schedule to a smaller circle, intuitively only consisting of the good bits. Agents move as if they were on the larger circle, but whenever moving though a cut-out segment, they just stand still instead. The details of this scheme together with a proof sketch will be given in Section 6.

2.3 Organization

The rest of the paper is organized as follows: We first give a more formal model description of the fence patrolling problem as well as discuss some related models and works in Section 3. In Section 4 we explain and prove our upper bounds for the line segment. Section 5 explains

and gives a proof sketch of our optimal fence patrolling schedule for the line segment. Finally, Section 6 presents and and gives a proof sketch our schedule for a circle with length $\Theta(\frac{1}{\log_e \log_2 k} \sum_{i=1}^{k} v_i)$. Formal and complete proofs for the two schedules can be found at `https://arxiv.org/abs/1809.06727`.

3 Fence Patrolling and Related Models

In this section we give a more detailed formal definition for the fence patrolling model/problem and briefly discuss related models and results. The fence patrolling model as given by [3] is defined as follows:

- The *environment* $\mathcal{E}$ to be patrolled is 1-dimensional and consists of a line segment of length L or a circle of circumference L. This line segment or circle is also referred to as a *fence*.
- The fence patrolling problem consists of some finite number $k \in \mathbb{N}$ of mobile agents $a_1, a_2, \ldots, a_k$ to patrol the fence, each having a possibly distinct positive maximum speed $v_1, v_2, \ldots, v_k \in \mathbb{R}_+$.
- A *schedule* for the fence patrolling problem consists of a k-tuple of functions $a_1, a_2, \ldots, a_k : [0, \infty) \to \mathcal{E}$ such that, for all $i \in [k]$, $t \geq 0$ and $\epsilon > 0$,

  $$\text{dist}(a_i(t + \epsilon), a_i(t)) \leq \epsilon \cdot v_i.$$

  That is, we assume patrolling starts at $t = 0$ and goes on indefinitely. Each agent follows a predetermined trajectory, in which he/she moves along $\mathcal{E}$ with at most his/her maximum speed. In the case of a circular fence, the function $\text{dist}(x, y)$ refers to the length of the shorter circle arc between $x, y \in \mathcal{E}$. In the case of the unidirectional circle, we have the additional requirement that $\forall i \in [k], t \geq 0$ and $0 < \epsilon < \frac{L}{2v_i}$, the shorter arc between $a_i(t)$ and $a_i(t + \epsilon)$ is the one that spans clockwise from $a_i(t)$.
- We say that a patrol schedule has *idle time* T for some fixed positive parameter T if for all $t \geq T$ and for all $x \in \mathcal{E}$, there is some agent that visits x during $[t - T, t]$. Intuitively, this condition means that an intruder cannot remain undetected at a point for more than T time.
- Given a patrol schedule, we say that a point $(x, t) \in \mathcal{E} \times [T, \infty)$ is *T-covered* if some agent a_i visits the point $x \in \mathcal{E}$ on the fence during the time interval $[t - T, t]$. Note that in this model an agent patrols/monitors a point $x \in \mathcal{E}$ by visiting it. On the one hand, this means the agents are limited to zero line of sight. On the other hand, no additional operation (e.g. stop and look around) is necessary to patrol a point.

One can see that a schedule has idle time T if and only if every point $(x, t) \in \mathcal{E} \times [T, \infty)$ is T-covered. It is easy to observe that any patrol schedule of a fence of length L with idle time T can be rescaled to a schedule of a fence of length $\alpha \cdot L$ with idle time $\frac{1}{\alpha} \cdot T$ for any $\alpha > 0$. Thus, to simplify terminology, we assume henceforth that $T = 1$ and we refer to 1-covered simply as covered.

Related models have been considered in the literature: where agents have positive line of sight [7], where agents have distinct walking and patrolling speeds [5], where some agents may be faulty [4], where only some regions of the environment need to be patrolled [2], or where the environment is a geometric tree [6]. However, all of these models feature identical agents and in particular do not allow for varying maximum speeds. Overall, the model given above is likely the cleanest and most natural model in which agents with different speeds can and have been studied. Despite the extreme simplicity of this model, this paper and prior

works on the fence patrolling problem [3, 9, 8, 10] show that very surprising and intricate phenomena occur when agents have different speeds and that these nontrivial consequences can be studied in the model defined above.

4 Impossibility Results for the Line Segment: Proof of Theorem 2.1 and Lemma 2.2

In this section, we prove two upper bounds on the length of a straight line fence (i.e. $\mathcal{E} = [0, L]$) patrolled by agents of maximum speeds $v_1, \ldots, v_k$.

Proof of Theorem 2.1. The main idea of the proof is to consider the two-dimensional spacetime continuum $\mathcal{S} := [0, L] \times [0, \infty)$ and the trajectories of the agents along with the points they cover. Since, as noted in Section 3, a patrol schedule with agents $a_1, \ldots, a_k$ has idle time 1 if and only if $\forall x \in [0, L], \forall t \geq 1$, $(x, t) \in \mathcal{S}$ is covered by at least one agent a_j, the theorem can be equivalently stated as that, for any patrol schedule such that all points $(x, t) \in S$ with $t \geq 1$ are covered by some agent, we have

$$L \leq \sum_{i=1}^{k} \frac{1}{\frac{1}{v_i} + \frac{1}{v_{\max}}}. \tag{4.1}$$

In fact, we will show (4.1) under the weaker assumption that only points $(x, t) \in S$ with $t \in [1, 2k]$ are covered by some agent.

Given a patrol schedule of $[0, L]$ with agents $a_1, \ldots, a_k$ and a non-empty subset $A \subseteq \{a_1, \ldots, a_k\}$, we define the *right border* (see Figure 2) of A as the function $B^A : [1, \infty) \to [0, L]$ given by $B^A(t) := \max\{x \in [0, L] : (x, t) \text{ is covered by some agent in } A\}$. We show (4.1) by considering consecutively the collections of agents $A_1, \ldots, A_q$, where $A_1 = \{a_{i_1}\}$, $\forall j \in [q] \setminus \{1\}, A_j = A_{j-1} \cup \{a_{i_j}\}$, $i_1, \ldots, i_q$ is a sequence of distinct integers in $[k]$ to be specified later, and $1 \leq q \leq k$ as we might not need to consider all agents. The intuition behind this is that we are starting with an empty set and adding more agents in a specific order until some termination condition is met. It is clear that $\forall t \geq 0, \forall j \in [q-1], B^{A_j}(t) \leq B^{A_{j+1}}(t)$. The key idea of the proof is to consider what happens to the right border of A_j as j increases (that is, as more agents are added). An example of the right borders of A_j and A_{j+1} for some j is shown in Figure 1.

At this point we prove a claim which will be useful in specifying the sequence $i_1, \ldots, i_q$.

▷ Claim 4.1. For any patrol schedule of $[0, L]$ with set of agents $A = \{a_1, \ldots, a_k\}$ and idle time 1, for any subset A' of $\{a_1, \ldots, a_k\}$, and for any point $(p_x, p_t) \in \mathcal{S}$ on the right border of A' (that is, such that $B^{A'}(p_t) = p_x$), there exists an $\varepsilon > 0$ such that there is at least one agent $a_i \in A \setminus A'$ that covers all points $(p_x + \nu, p_t)$ for $\nu \in [0, \varepsilon]$.

Proof. Note that there could not exist three points $(x_1, t), (x_2, t), (x_3, t)$ such that $0 \leq x_1 < x_2 < x_3 \leq L$ and some agent a_j covers (x_1, t) and (x_3, t) but not (x_2, t). This is because the trajectory of every agent can be considered as a continuous function $f_{a_j} : [0, \infty) \to [0, L]$, so it cannot be that $\exists t_1, t_3 \in [t-1, t]$ such that $f(t_1) = x_1$ and $f(t_3) = x_3$ but $\nexists t_2 \in [t-1, t]$ with $f(t_2) = x_2$. It follows that the set of points C_j on the segment between (p_x, p_t) and (L, p_t) covered by some agent a_j must be either the empty set or a segment. Now consider the set of agents A_p in $A \setminus A'$ that cover (p_x, p_t) and note that $\exists \varepsilon > 0$ such that $\exists a \in A_p$ that covers $(p_x + \varepsilon, p_t)$ (otherwise choose the non-empty C_j with $a_j \in A \setminus A'$ with the leftmost left end (p_l, p_t) that is strictly to the right of p_x and notice that all points $(p_{x'}, p_t)$ with $p_{x'} \in (p_x, p_l)$ are not covered by any agent in A, which is impossible as all points in $\mathcal{S}$ should be covered). But now $a \in A_p$ covers both (p_x, p_t) and $(p_x + \varepsilon, p_t)$, therefore it also covers anything in between since the points it covers between (p_x, p_t) and (L, p_t) must form a segment. ◁

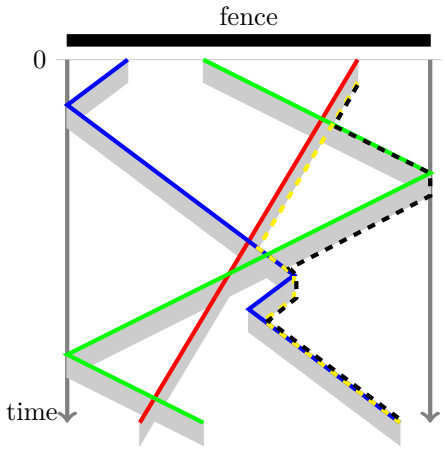

Figure 1 If we have added the blue agent and the red agent so far, then the right border is shown in yellow. If we now also add the green agent, the new right border is shown in black.

Now we can continue with the proof of our main upper bound by specifying $i_1, \ldots, i_q$. Consider a fixed patrol schedule of $[0, L]$ with agents $a_1, \ldots, a_k$ and idle time 1. To pick the sequence $i_1, \ldots, i_q$, consider the following procedure: initially, put $l_0 = (x_0, t_0) = (0, k)$ and pick $i_1 \in [k]$ such that agent a_{i_1} covers l_0. For each consecutive $j = 1, 2, \ldots$, we let $l_j = (x_j, t_j)$ be such that

$$t_j = \arg \min_{t \in [k-j, k+j]} B^{A_j}(t)$$

and $x_j = B^{A_j}(t_j)$. Intuitively, l_j is the leftmost point of B^{A_j} between times $k - j$ and $k + j$. Now if $x_j = L$, we stop adding agents and we set $q := j$. Note that if $j = k$, then $x_j = L$ as agents $a_1, \ldots, a_k$ cover all of $[1, 2k]$. If $x_j < L$, pick as agent $a_{i_{j+1}}$ an agent that covers all the points with coordinates $(x_j + \nu, t_j)$ for $\nu \in [0, \varepsilon]$ for some small enough $\varepsilon > 0$. Such an agent should exist by Claim 4.1. To make sure l_j is always defined for any $j \in \{0, 1, \ldots, q\}$, if $q = k$, set $l_k := (L, k)$.

We note that $x_0, x_1, ..., x_q$ is non-decreasing, $x_0 = 0$ and $x_q = L$ since we either stopped adding agents when $q < k$ because $x_q = L$ or we stopped when $q = k$, in which case all of $[0, L] \times [1, 2k]$ should be covered. Hence the theorem follows if we can show that $\forall j \in \{0, 1, \ldots, q-1\}, x_{j+1} - x_j \leq \frac{1}{\frac{1}{v_{i_{j+1}}} + \frac{1}{v_{\max}}}$.

In order to bound this difference, we investigate how the right border moves when agent $a_{i_{j+1}}$ is added. Note that $\forall t \in [0, \infty)$,

$$B^{A_{j+1}}(t) = \max(B^{A_j}(t), B^{\{a_{j+1}\}}(t)).$$

For any time $t > t_j$, the rightmost point at time t that could be covered by any agent in A_j is $(x_j + (t - t_j)v_{\max}, t)$ since the speed of any agent is at most $v_{\max}$. Similarly, for any time $t < t_j$, the rightmost point at time t that could be covered is $(x_j + (t_j - t)v_{\max}, t)$. Thus, $\forall t \in [0, \infty)$,

$$B^{A_j}(t) \leq x_j + |t - t_j| v_{\max}.$$

Denote by u the ray $(x_j + (t_j - t)v_{\max}, t)$ where $t \leq t_j$, and by w the ray $(x_j + (t - t_j)v_{\max}, t)$ where $t \geq t_j$.

Next, consider $B^{\{a_{j+1}\}}(t)$. Since agent a_{j+1} covers l_j, this means that he/she visits x_j at some time between $t_j - 1$ and t_j, say at point (x_j, t_{visit}). Under the restriction that the trajectory of agent $a_{i_{j+1}}$ should go through (x_j, t_{visit}), it is clear that $B^{\{a_{i_{j+1}}\}}(t)$ is maximized if agent $a_{i_{j+1}}$ comes from the right at maximum speed, hits (x_j, t_{visit}) and then turns around and moves to the right at maximum speed, in which case equality is achieved in

$$\forall t \in [0, \infty), B^{\{a_{i_{j+1}}\}}(t) \leq \min(x' + |t - t'|v_{i_{j+1}}, L),$$

where $(x', t') = (x_j + \frac{v_{i_{j+1}}}{2}, t_{visit} + \frac{1}{2})$. Denote by h the ray $(x' + (t' - t)v_{i_{j+1}}, t)$ where $t \leq t'$ and by g the ray $(x' + (t - t')v_{i_{j+1}}, t)$ where $t \geq t'$.

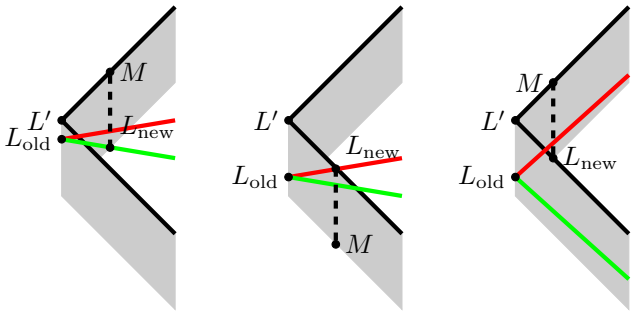

Figure 2 The rays R_1 and R_2 give a bound to the right of the current right border and are given in red and green respectively, and in black and gray we have a bound to the right of the trajectory of the newly added agent a_i and its shadow, i.e. the points that are covered by it.

We thus get $\forall t \in [0, \infty)$,

$$B^{A_{j+1}}(t) = \max(B^{A_j}(t), B^{\{a_{i_{j+1}}\}}(t)) \leq f(t),$$

where $f(t) = \max(x_j + |t - t_j|v_{\max}, x' + |t - t'|v_{i_{j+1}})$. Consider $t_{new} = \arg\min_{t \in [1,\infty)} f(t)$. Let $L_{new} = (x_{new} := f(t_{new}), t_{new})$ be the leftmost point on the aforementioned upper bound on $B^{A_{j+1}}(t)$. Notice that L_{new} is either the intersection of h and w, or the intersection of g and u, or the intersection of g and h. These three cases are illustrated in Figure 2. We have u in red and w in green. Consider the upper bound on $B^{\{a_{i_{j+1}}\}}(t)$ mentioned above. The trajectory of agent $a_{i_{j+1}}$ that would correspond to matching this upper bound is given in black and the points $a_{i_{j+1}}$ would cover if this was his/her trajectory are given in gray. We have that $L_{old} = (x_{old}, t_{old}) := l_j$. It can be seen by inspection of the three cases in Figure 2 that $|t_{new} - t_j| \leq 1$. Then $t_{new} \in [k - (j + 1), k + (j + 1)]$, which makes L_{new} a candidate for l_{j+1}, therefore $l_{j+1} = (x_{j+1}, t_{j+1})$ will have $x_{j+1} \leq x_{new}$. Thus it is enough to show that $x_{new} - x_j \leq \frac{1}{\frac{1}{v_{i_{j+1}}} + \frac{1}{v_{\max}}}$.

We need an upper bound on $d = x_{new} - x_{old}$. We consider the points $M = (x_M, t_M)$ and $N = (x_N, t_N)$ as illustrated in Figure 2, such that in all three cases $x_M = x_{new}$ and $|t_M - t_{new}| = 1$. In Case 1, we consider the segment MN of slope $\frac{1}{v_{i_{j+1}}}$ and $x_M - x_N = d$, and the segment $L_{old}L_{new}$ of w of slope $-\frac{1}{v_{\max}}$ and $x_{new} - x_{old} = d$. This gives us

$$\frac{d}{v_{i_{j+1}}} + \frac{d}{v_{\max}} \leq 1 \Rightarrow d \leq \frac{1}{\frac{1}{v_{i_{j+1}}} + \frac{1}{v_{\max}}}. \tag{4.2}$$

In Case 2, we consider the segment $L_{new}L_{old}$ of u of slope $\frac{1}{v_{\max}}$ and $x_{new} - x_{old} = d$, and the segment NM of slope $-\frac{1}{v_{i_{j+1}}}$ and $x_M - x_N = d$. This implies Equation (4.2) for Case 2

as well. In Case 3, we consider the segment MN of slope $\frac{1}{v_{i_{j+1}}}$ and $x_M - x_N = d$, and the segment NL_{new} of slope $-\frac{1}{v_{i_{j+1}}}$ and $x_{new} - x_N = d$. This means that

$$\frac{2d}{v_{i_{j+1}}} = 1 \Rightarrow d = \frac{v_{i_{j+1}}}{2} \leq \frac{1}{\frac{1}{v_{i_{j+1}}} + \frac{1}{v}}.$$

Therefore, $x_{new} - x_{old} \leq \frac{1}{\frac{1}{v_{i_{j+1}}} + \frac{1}{v_{\max}}}$ as desired. ◀

Proof of Lemma 2.2. We show how $L \leq \left(1 - \frac{1}{\sqrt{k}+1}\right) \sum_{i=1}^{k} v_i$ follows from Theorem 2.1. First note that $L \leq \sum_{i=1}^{k} v_i - \frac{v_{\max}}{2}$ as each agent a_i contributes at most $v_i \cdot \frac{1}{1+\frac{v_i}{v_{\max}}} \leq v_i$ while the agent with maximum speed contributes exactly $\frac{v_{\max}}{2}$. Therefore, if $v_{\max} \geq \frac{1}{\sqrt{k}} \sum_{i=1}^{k} v_i$ the desired upper bound for L follows immediately. It remains to deal with the case $v_{\max} < \frac{1}{\sqrt{k}} \sum_{i=1}^{k} v_i$. For this we first note that $x \cdot \frac{1}{1+\frac{x}{v_{\max}}} = \frac{1}{\frac{1}{x}+\frac{1}{v_{\max}}}$ is a concave function in x for $0 \leq x \leq v_{\max}$, since the second derivative $-\frac{2}{(1+\frac{x}{v_{\max}})^3 v_{\max}}$ is always negative. This allows us to apply Jensen's inequality and thus we have

$$L \leq \sum_{i=1}^{k} \frac{1}{\frac{1}{v_i} + \frac{1}{v_{\max}}} \leq k \frac{1}{\frac{1}{v_{avg}} + \frac{1}{v_{\max}}} = \frac{1}{1 + \frac{\sum_{i=1}^{k} v_i}{k \cdot v_{\max}}} \sum_{i=1}^{k} v_i \leq \left(1 - \frac{1}{\sqrt{k}+1}\right) \sum_{i=1}^{k} v_i,$$

where $v_{avg} = \frac{1}{k} \sum_{i=1}^{k} v_i$. This concludes the proof of Lemma 2.2. ◀

5 A Schedule with Efficiency $1 - \epsilon$ for the Line Segment: Proof of Theorem 2.3

In this section, we give proof sketch that for any k agents, there exist speeds $v_1, \ldots, v_k$ and a scheme for these agents to patrol a fence of length

$$L = \left(1 - \frac{3.5}{\sqrt{k}} + O(1/k)\right) \sum_{i=1}^{k} v_i.$$

This improves the result from [10] and therewith falsifies the corresponding conjecture stated in that paper.

Proof sketch of Theorem 2.3. Assume k is sufficiently large, and, for ease of notation, define $n := k - 2$. Let $L = n - 3/2\sqrt{n}$. We construct a schedule that patrols $\mathcal{E} = [0, L]$ with idle time 1, using $n + 1$ agents with maximum speed 1 and 1 agent with maximum speed $2\sqrt{n} - 1$. Thus we have a total speed of $V = \sum_{i=1}^{k} v_i = n + 2\sqrt{n}$. As the ratio between L and V approaches $1 - \frac{3.5}{\sqrt{k}} + O(1/k)$, Theorem 2.3 follows.

To simplify the presentation of the patrol schedule, we will allow the agents to occasionally "step out of the fence $[0, L]$", i.e. we allow an agent a_i to assume positions $a_i(t) < 0$ and $a_i(t) > L$ (to avoid this, we could also modify the schedule so that they stay at the respective end of the fence for a while). To keep the notation as clean as possible, we henceforth assume that n is a square number. Our schedule works as follows (see Figure 3 for a graphical representation):

SLOW AGENTS $a_1, \ldots, a_n$: For each $i \in \{0, \ldots, n\}$, agent a_i starts at time 0 at position $x = i - i/\sqrt{n}$ and moves $i/(2\sqrt{n})$ time units to the right. Then he or she repeats:

- move to the left for $\sqrt{n}$ time units.
- move to the right for $\sqrt{n}$ time units.

FAST AGENT a_{n+1}: The fast agent a_{n+1} starts at time 0 and repeats the following four steps:

(1) Move from position 0 to position $L + 1/2$ with speed $2\sqrt{n} - 1$.

(2) Move from position $L + 1/2$ to position $-1/2$ during the next $\sqrt{n}/2 + 1$ time units (e.g. with constant speed $(L + 1)/(\sqrt{n}/2 + 1) = 2\sqrt{n} - 7 + (16)/(\sqrt{n} + 2)$).

(3) Move from position $-1/2$ to position L with speed $2\sqrt{n} - 1$.

(4) Move from position L to position 0 in the next $\sqrt{n}/2$ time units (e.g. with constant speed $(L)/(\sqrt{n}/2) = 2\sqrt{n} - 3$).

The idea behind our patrol schedule is to initially place the agents with maximum speed 1 equidistantly along the fence with gaps of length slightly smaller than 1, similar to the schedule for the fast agents in [10]. In contrast to their schedule, this is performed slightly out of phase between the agents. This will cover most of the points on the fence. The only problem appears whenever the agents turn around, as then the points right next to these turning points are not visited for more than 1 time unit, hence creating uncovered triangles in the "spacetime" diagram (white triangles in Figure 3). By timing the turning times of the agents appropriately, we ensure that these uncovered triangles are placed such that they can all be cleaned up by the last fast agent. Figure 3 gives a complete illustration of our schedule for 18 agents and intuitively shows that each point x on the line L is visited at least once every unit of time. ◀

6 A schedule for the unidirectonal circle: Proof of Theorem 2.4

In this section, we will present a schedule with which a group of agents $a_1, \dots, a_k$ with maximum speeds $v_1, \dots, v_k$ can patrol a circle with circumference

$$\frac{1}{33 \log_e \log_2(k)} \sum_{i=1}^{k} v_i,$$

followed by a short sketch of why the proposed schedule behaves as claimed. Our schedule will be divided in two parts. First, we will give a randomized construction for a strategy which allows the agents $a_1, \dots, a_k$ to patrol a circle with circumference 1 such that with probability $1 - o(1)$ "most" of the points are visited at least every $\Theta\left(\log\log(k)/(\sum_{i=1}^{k} v_i)\right)$ time units. Then, we will argue that one can remove the "bad" points and then "blow up" the circle to obtain the desired result.

Proof sketch of Theorem 2.4. We are given a group $a_1, \dots, a_k$ of agents with maximum speeds $v_1 \dots, v_k$ and define $V := \sum_{i=1}^{k} v_i$. We propose the following schedule:

Circle Schedule:

(1) Round speeds down to the next power of 2 and omit too slow agents:
For all $i \in [k]$ let $j_i \in \mathbb{N}$ be the non-negative integer such that $V \cdot 2^{-j_i} \leq v_i < V \cdot 2^{-j_i+1}$. We define $v'_i := V \cdot 2^{-j_i}$ and $I := \left\{i \in [k] : v'_i \geq \frac{V}{4 \cdot k}\right\}$.

(2) Group remaining agents according to their speed:
For all $i \in \{0, \dots, \lceil \log_2(k) \rceil + 2\}$ define $G_i := \left\{j \in I : v'_j = V \cdot 2^{-i}\right\}$.

(3) Reduce number of agents in each group to a power of 2:
For all $i \in \{0, \dots, \lceil \log_2(k) \rceil + 2\}$ let $h_i \in \mathbb{N}$ be the positive integer such that $2^{h_i} \leq |G_i| < 2^{h_i+1}$ and let $G'_i \subseteq G_i$ be an arbitrary subset of G_i of size 2^{h_i}. We denote by $m'_i = |G'_i| \cdot v'_a = V \cdot 2^{h_i - i}$ the *mass of the group* G'_i, where $a \in G'_i$ (that is, each agent in G'_i has maximum speed v'_a after the rounding down in step 1).

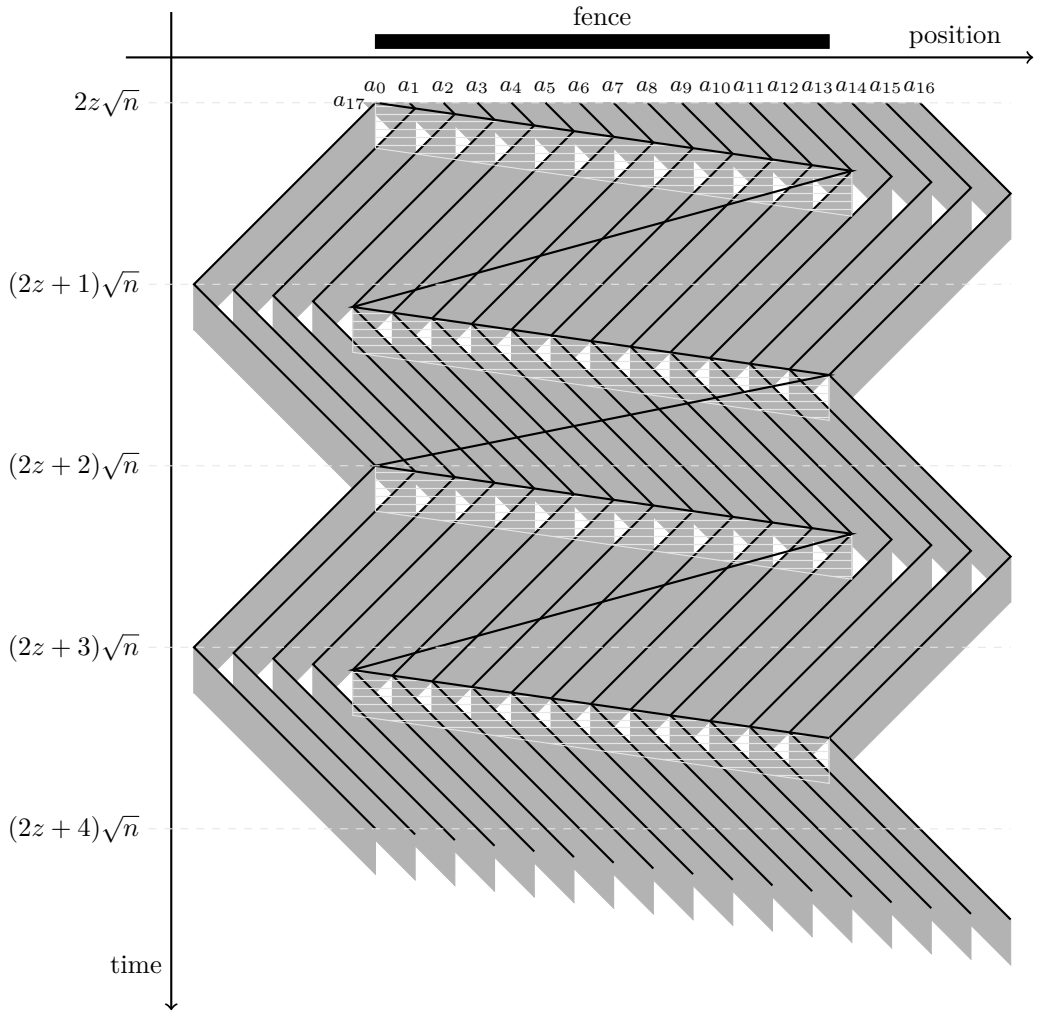

Figure 3 The described schedule for $n = 16$. The dark grey area describes the points (x, t) which are covered by the slow agents $a_0, \ldots, a_n$ while the light grey shaded area describes the points (x, t) which are covered by the fast agent in steps (1) and (3) of his protocol.

(4) Omit groups with too small mass:
Let $J := \left\{ i \in \{0, \ldots, \lceil \log_2(k) \rceil + 2\} : m'_i \geq \frac{V}{16(\lceil \log_2(k) \rceil + 3)} \right\}$.

(5) Patrol schedule: For each $j \in J$, pick an independent uniform random number r_j in the interval $[0, \frac{1}{|G'_j|})$. At time 0, we place the $|G'_j|$ agents from the group G'_j at positions

$$r_j, r_j + \frac{1}{|G'_j|}, \ldots, r_j + \frac{|G'_j| - 1}{|G'_j|},$$

i.e. we place all agents from the same group equidistantly from each other along the circle with a random offset from the origin. Then the agents G'_j walk along the circle with speed v'_j at all times.

Note that the two rounding steps and the two omitting steps each reduced the total "available" speed by a factor of at most 2, therefore we have that $\sum_{j \in J} m'_j \geq V/16$. Defining

$$T = \frac{1}{\min_{j \in J} m'_j} \leq 16(\lceil \log_2(k) \rceil + 3)/V,$$

we observe that after T time units the distribution of agents along the circle repeats itself, i.e. if an agent with speed s is located at position x at time t, then another (or the same) agent of speed s is located at position x at time $t+T$. Cutting the time interval into small pieces of size $\tau \approx 16 \log_e \log_2(k)/V$, one can show that with probability $1-o(1)$, almost all points get visited at least once in each of these small time intervals, and hence all these points get visited at least every 2τ time units. Next, we can "cut away" the few "bad" points for which this is not true and obtain a circle of circumference $1-\epsilon$. Adjusting the above schedule so that agents "stand still" on the smaller circle whenever they cross a "bad" point on the original circle gives us a schedule for which each point (on the small circle) is visited at least every 2τ time units. Rescaling this patrol schedule then gives the scheme to patrol a circle with circumference $(1-\epsilon)\frac{1}{2\tau} \geq \frac{1}{33 \log_e \log_2(k)} \sum_{i=1}^{k} v_i$ as desired. ◀

Abstract

We consider the matroid coflow scheduling problem, where each job is comprised of a set of flows and the family of sets that can be scheduled at any time form a matroid. Our main result is a polynomial-time algorithm that yields a 2-approximation for the objective of minimizing the weighted completion time. This result is tight assuming $P \neq NP$. As a by-product we also obtain the first $(2+\epsilon)$-approximation algorithm for the preemptive concurrent open shop scheduling problem.

1 Introduction

Coflows were introduced in [5] as: "We propose coflows, a networking abstraction to express the communication requirements of prevalent data parallel programming paradigms. Coflows make it easier for the applications to convey their communication semantics to the network, which in turn enables the network to better optimize common communication patterns." Data parallel application frameworks such as MapReduce [9] and Spark [31] have a unique processing pattern that interleaves local computation with communication across machines. Due to the size of the large data sets processed, communication often tends to be a bottleneck in the performance of these platforms and the coflow model abstracts out this bottleneck. Theoretical work on coflow scheduling has primarily focused on the switch model (also called matching model) where the underlying network is assumed to have full-bisection bandwidth and the set of flows that can be scheduled at any time step is restricted to be form a matching.

While there are several reasonable formulations/models of scheduling coflows, the following will be convenient for our purposes. The input consists of a collection J of jobs, where each job $j \in J$ is comprised of a set U_j of tasks (also called flows), a non-negative integer w_j and a release time r_j. Each task $e \in U_j$ has a processing requirement p_e. For example, in the setting of a network supporting MapReduce [9] computations, each job could be a MapReduce job, and a task/flow could represent a required communication within a shuffle phase of a job. Let $U = \cup_{j \in J} U_j$ be the collection of all tasks. Further the input contains a downward-closed set system $\mathcal{M} = (U, \mathcal{I})$. Here $\mathcal{I} \subseteq 2^U$ and elements of $\mathcal{I}$ are called the *independent sets* of $\mathcal{M}$. Conceptually a collection of tasks is independent (and in $\mathcal{I}$) if they can be simultaneously scheduled by the network. A feasible output is a schedule σ that schedules all the flows. That is for each integer time t, σ specifies a collection σ_t of tasks processed/scheduled at time t. In order to be feasible, σ must satisfy the conditions that:

- every task $e \in U$ is scheduled for p_e time steps, and
- at each time t, the scheduled tasks/flows σ_t are in $\mathcal{I}$.

A job j completes at the first time C_j such that every task in U_j has been scheduled fully. The objective is to minimize the total weighted completion time of the jobs. That is, to minimize $\sum_j w_j C_j$.

In this paper, we consider coflow scheduling when the set system $\mathcal{M}$ forms a matroid. The starting point for our investigations is the question whether there is an algorithm to effectively schedule coflows that involve aggregating information, stored at various locations in a network, to a common sink location. Such gathering communication patterns were identified as common in [5]. We model aggregation communications by assuming that for each job j, U_j is a collection of locations in the network where the units of information needed for job j are stored. It is natural to define the independent sets to be locations that can simultaneously be routed to the sink without violating any capacity constraint of the network. In this case, $\mathcal{M}$ is a matroid, and more specifically, a gammoid. Note that the symmetric problem, of disseminating data from a fixed location to various locations in the network, is also common, and essentially equivalent to the aggregation problem.

The matroid coflow scheduling problem as defined here also naturally captures a number of well-studied scheduling problems.

- Parallel Identical Machines Scheduling: Each job j has a single task. The matroid $\mathcal{M} = (U, \mathcal{I})$ is the uniform matroid of rank m, i.e., any set of m jobs can be scheduled in parallel.
- (Preemptive) Concurrent Open Shop Scheduling: In the concurrent open shop scheduling problem, each job j comprises of m tasks, one on each machine, i.e. $U_j = \{t_{ij}\}_{i=1}^m$. Task t_{ij} needs to be scheduled for time p_{ij} and the job is completed when all its tasks are completed. To model this setting, consider $T_i = \{t_{ij}\}_{j=1}^n$ to be set of all tasks that need to be scheduled on machine i. $\mathcal{M}$ is a partition matroid that ensures that a set S of tasks is independent if and only if $|S \cap T_i| \leq 1$ for each machine i.

1.1 Our Contributions

We first consider coflow scheduling on unit length tasks when $\mathcal{M}$ is a matroid. Our main result is:

▶ **Theorem 1.** *There is a deterministic polynomial-time algorithm for coflow scheduling with unit length tasks, when $\mathcal{M}$ is a matroid, that is 2-approximate with respect to the objective of minimizing total weighted completion time.*

We note that Theorem 1 can be extended to the case that tasks may have arbitrary processing times, albeit at a slight loss in the approximation factor.

▶ **Theorem 2.** *There is a deterministic polynomial-time algorithm for coflow scheduling with arbitrary length tasks, when $\mathcal{M}$ is a matroid, that is $(2+\epsilon)$-approximate with respect to the objective of minimizing total weighted completion time, for any constant $\epsilon > 0$.*

As with all the approximation results for coflow scheduling in the literature, our algorithm is based on rounding a natural time-indexed linear program. Intuitively the rounding extracts a deadline C_j^* for each job j. This time is roughly $1/\lambda$ times later than the first time when every task in U_j has been scheduled at least to the extent λ in the solution to LP. Here the value of λ is randomly chosen. The expected value of C_j^* is shown to be at most twice the fractional completion time for j in the solution to LP; this "stretching" (also called slow-motion) idea has been used in other scheduling contexts [12, 22, 27]. This can be viewed as deriving from the LP a fractional schedule where each job j is fully completed by time C_j^*. Then, we observe that the problem of scheduling tasks to meet the C_j^* deadlines can be expressed as a matroid intersection problem. As the matroid intersection polytope is integral [26], one can find an integral schedule meeting these deadlines. Finally, by derandomizing the random choice of λ, we derive our main theorem.

The approximation guarantee in Theorem 1 is tight assuming $P \neq NP$. This is because it is NP-hard to approximate the total weighted completion time for concurrent open shop (even with unit sized tasks) within a factor of $2-\epsilon$ [23], and this problem is a special case of matroid coflow scheduling, where the matroid is a partition matroid. Somewhat surprisingly, even for the concurrent open shop scheduling with release times, the previous best known approximation factor was 3 [10, 17]. (See also additional discussion in [2].) Thus, Theorem 2 immediately yields an improved approximation algorithm for preemptive concurrent open shop with arbitrary release times.

▶ **Corollary 3.** *There is a deterministic, polynomial-time $(2+\epsilon)$ approximation algorithm for the preemptive concurrent open shop scheduling problem when jobs have arbitrary release times, for any constant $\epsilon > 0$. If all the release times and processing requirements are polynomially bounded, then the approximation guarantee improves to 2.*

We believe our primary technical contribution is the high-level approach to reduce a weighted completion time scheduling problem to a deadline-constrained scheduling problem. Our approach to first extract a deadline for each job from the LP solution and then finding an integer schedule that meets those deadlines can be viewed as a strict generalization of processing jobs in increasing order of their completion time derived from the LP, which has been a very common rounding tool in scheduling literature; e.g. [21, 28, 2]. Our novel approach allows us to handle the matroid constraint, which we believe is natural and quite general.

1.2 Related Results

Most of the theoretical/algorithmic work on coflows has been on matching coflows [20, 16, 15, 2, 1]. These results essentially abstract out the network by modeling the network as an n-by-n switch, or equivalently a complete bipartite graph, and by modeling supportable flows by matchings in the graph. This is well motivated in practice as the networks in many data centers are hierarchical, with higher network elements having higher capacities. Thus a matching between servers at leaves of the network is a not unreasonable approximation of a communication supportable by the network. We note that matching coflows correspond

to coflows in our framework when the set system $\mathcal{M}$ is an intersection of two partition matroids. The first constant (16.54) approximation for coflow scheduling in this model was given in [20]. Currently the best known approximation ratios are 5 for when jobs may have variable release times, and 4 when all jobs arrive at time 0 [2, 29], respectively. Note that the 2-approximation algorithms claimed in [18] and [11] are both flawed; see [2] and [11] for the discussion of the flaws.

Jahanjou et al. [14] consider several problems where there is an underlying network with capacities on the edges. If the tasks are paths in the network, and $\mathcal{I}$ consists of collections of paths that don't collectively violate any edge capacity, then their work gives a algorithm for producing a fractional schedule (which is equivalent to time being continuous) that is $O(1)$-approximate with respect to total weighted completion time. If the tasks are (source, sink) pairs in the network, and $\mathcal{I}$ consists of collections of (source, sink) pairs that can be simultaneously routed without violating any edge capacity, then their work gives a algorithm for producing a fractional unsplittable schedule that is $O(\log E / \log \log E)$-approximate with respect to total weighted completion time, together with a matching hardness result; here, E is the number of edges. Our work is not comparable to theirs since different constraints are addressed and our focus is on integer schedules in contrast to theirs on fractional schedules.

Coflow scheduling is a generalization of the classical concurrent open shop scheduling problem [3, 4, 10, 17, 19, 23, 30]. Several 2-approximation algorithms were shown [4, 10, 17] via LP rounding. Matching hardness results were shown in [3, 23]. When jobs have different release times, the same LP relaxations yielded 3-approximations [10, 17]. Later, [19] gave a simple greedy algorithm that matches the best approximation ratio when all jobs arrive at time 0. Recently, [2] gave a combinatorial 3-approximation via a primal-dual analysis when jobs have non-uniform release times.

Coflow scheduling has been actively studied within the networking community; some examples include [5, 6, 7, 18, 32].

1.3 Organization

The rest of the paper is organized as follows. In Section 2 we give some basic definitions and notation. In Section 3 we give the linear programming formulation. In Section 4 we explain how to round a solution to the linear program. In Section 5 we discuss the derandomization. In Section 6, we discuss the extension to tasks with variable processing times.

2 Definitions and Notations

We first consider the matroid coflow scheduling problem with unit length tasks. We will discuss three types of schedules, and two types of objectives. In a discrete-time schedule, we consider that time is divided into unit length intervals (also called time slots), and the schedule specifies the set of jobs processed during each time slot. We let time slot t refer to the interval of time $(t-1, t]$. In an *integer* discrete-time schedule, at each time slot t, an independent set in the matroid is scheduled. In a *fractional* discrete-time schedule, at each time slot t, a convex combination of independent sets from the matroid are scheduled. In other words, in such a fractional schedule, the set of tasks scheduled at time slot t can be expressed as $\sum_{S \in \mathcal{I}} \alpha_S 1_S$, where $\sum_{S \in \mathcal{I}} \alpha_S = 1$, and 1_S is the characteristic vector corresponding to independent set $S \in \mathcal{I}$. A valid feasible solution is restricted to be an integer discrete-time schedule. On the other hand, during our analysis, we will also consider *continuous* schedules. A continuous schedule specifies an independent set of tasks to be scheduled at each instantaneous time τ (as opposed to during a unit-length time slot).

The completion time C_j of a job j is the first time when all tasks in U_j have been completed. We let $q_e(t) : [0, T] \to \{0, 1\}$ denote an indicator function defined for each task $e \in U$, where $q_e(t) = 1$ if and only if task e (more precisely an independent set including e) is scheduled at time t in σ. We let $Q_e(t) = \int_{\tau=0}^{t} q_e(\tau)d\tau$ denote the extent to which task e is scheduled by time t. Let $\tilde{C}_j(v)$ denote the first time when every task in U_j has been scheduled by extent at least v. The fractional completion time of job j is then $\tilde{C}_j = \int_{v=0}^{\infty} \tilde{C}_j(v)dv$. We will use $\text{COST}(\mathsf{LP})$ to denote the optimum objective of the LP, which we will describe soon.

3 Linear Program

In this section we give a linear programming formulation LP of our matroid coflow problem when tasks have unit lengths. Let $x_{j,t}$ be an indicator variable that specifies whether job j completes at time t. For a task $e \in U_j$, let $y_{e,t}$ be an indicator variable that specifies whether task e is assigned to time slot t. Let $\rho(S)$ be the rank function of the matroid.[1] Let $T = |U|$ be an upper bound on the time by which all tasks can be completed. The formulation of LP is then:

$$\mathsf{LP}: \qquad \min \sum_{j \in J} w_j \sum_{t \in [T]} t \cdot x_{j,t}$$

$$\text{s.t.} \quad \forall j \in J, \qquad \sum_{t} x_{j,t} = 1 \tag{1}$$

$$\forall j \in J \text{ and } \forall e \in U_j \text{ and } \forall t \in [T], \qquad \sum_{s \le t} y_{e,s} \ge \sum_{s \le t} x_{j,s} \tag{2}$$

$$\forall S \subseteq U \text{ and } \forall t \in [T], \qquad \sum_{e \in S} y_{e,t} \le \rho(S) \tag{3}$$

$$\forall j \in J \text{ and } \forall e \in U_j \text{ and } \forall t \in [r_j - 1], \qquad y_{e,t} = 0 \tag{4}$$

$$\mathbf{x}, \mathbf{y} \ge 0 \tag{5}$$

Constraint (1) ensures that every job is scheduled. Constraint (2) ensures that all tasks of a job j are scheduled to at least the extent that j is completed by time t. Constraint (3) ensures that at any time step t, the set of tasks assigned to t form an independent set in the given matroid. Constraint (3) is the only constraint set that can potentially have a super-polynomial size. However, for each fixed time t, the constraint is just a polymatroid, and therefore, admits an efficient separation oracle [8, 24, 13]. In case that there are arrival/release times, constraint (4) ensures that no tasks in U_j are processed before j's release time r_j. The objective of LP is fractional weighted completion time.

Note that a solution to LP can be viewed as a fractional discrete schedule. We will use $X_{j,t} := \sum_{s \le t} x_{j,s}$ to denote the extent to which job j has been processed by time t, and use $Y_{e,t} := \sum_{s \le t} y_{e,s}$ to denote the extent to which task e has been processed by time t.

4 Rounding

In this section, we show how to round an optimal solution to LP to obtain a 2-approximate integral (discrete) schedule. For each job j and $v \in (0, 1]$, define $\bar{C}_j(v) = \frac{1}{x_{j,t}}(v - X_{j,t-1}) + (t - 1)$ if $v \in (X_{j,t-1}, X_{j,t}], t \in [T]$. Intuitively, $\bar{C}_j(v)$ is a linear interpolation of the discrete

[1] $\rho(S)$ is defined as $\max_{S' \subseteq S : S' \in \mathcal{I}} |S'|$.

times when job j is partially completed. We set a deadline $C_j^* = \lceil \frac{1}{\lambda} \bar{C}_j(\lambda) \rceil$ for each job j, where $\lambda \in (0, 1]$ is randomly drawn according to the probability density function $f(v) = 2v$. A key portion of the analysis is to show that the expected value of each $w_j C_j^*$ is at most twice the contribution of job j to the LP objective.

To analyze the expected value of C_j^*, we construct several schedules from the LP solution. In Subsection 4.1, we will show how to convert a solution of LP to a continuous schedule σ. In Subsection 4.2 we show how to convert σ into a stretched schedule σ^λ, which is another continuous schedule parameterized by $\lambda \in (0, 1]$. Finally, in Subsection 4.3 we will show how to convert this continuous schedule into (discrete-time) integer schedule with the same cost. We note that we construct schedules in Subsection 4.1 and 4.2 only for the sake of analysis. That is, we can obtain a 2-approximate integral discrete schedule only using the rounding algorithm in Subsection 4.3 with the deadlines $\{C_j^*\}_j$.

4.1 Constructing the Continuous Schedule σ

We construct a continuous schedule σ from the solution to LP. For each time t, we first decompose $\{y_{e,t}\}_{e \in U}$ into a convex combination $\sum_{S \in \mathcal{I}} \alpha_S 1_S$ of independent sets.[2] To create σ this convex combination is "smeared" across all instantaneous times during $(t-1, t]$. That is, in σ each independent set S is scheduled for $\alpha_i(\tau_2 - \tau_1)$ time units during each infinitesimal time interval $(\tau_1, \tau_2] \in (t-1, t]$. This is formalized in Proposition 4. In Lemma 5 we show that the first time when a job j is scheduled to extent v in σ is at most $\bar{C}_j(v)$. In Lemma 6 we show that the fractional weighted completion time of σ is a bit less than the objective value of the solution to LP. This is because any processing of job j done during $(t-1, t]$ has no effect until time t on the LP objective, whereas it can have effect on j's fractional weighted completion time of σ during $(t-1, t]$, before time t.

▶ **Proposition 4.** *Consider the schedule σ. For any integer $t \in [T]$ and $(\tau_1, \tau_2] \in (t-1, t]$, we have, $\int_{\tau=\tau_1}^{\tau_2} q_e(\tau) d\tau = y_{e,t}(\tau_2 - \tau_1)$.*

▶ **Lemma 5.** *Consider the schedule σ. For any j and $v \in (0, 1]$,*

$$\tilde{C}_j(v) \leq \bar{C}_j(v) =: \frac{1}{x_{j,t}}(v - X_{j,t-1}) + (t-1) \text{ if } v \in (X_{j,t-1}, X_{j,t}], t \in [T],$$

and $\tilde{C}_j(0) = 0$.

Proof. By definition, we have $\tilde{C}_j(0) = 0$, so let us assume that $v > 0$. We first show that $\tilde{C}_j(X_{j,t}) = t$. Due to constraint (2), $Y_{e,t} \geq X_{j,t}$ for all $e \in U_j$. Thus, by construction of σ, all tasks in U_j are processed by at least $X_{j,t}$ by time t, i.e., $Q_e(t) \geq X_{j,t}$, meaning that $\tilde{C}_j(X_{j,t}) \leq t$. We also have that $\tilde{C}_j(X_{j,t}) \geq t$ since we know by the optimality of the LP solution that $Y_{e,t} = X_{j,t}$ for some $e \in U_j$, therefore, $Q_e(t) = X_{j,t}$. Thus, we have $\tilde{C}_j(X_{j,t}) = t = \bar{C}_j(X_{j,t})$.

Now consider an arbitrary $v \in (0, 1]$. Let $t \in [T]$ be such that $v \in (X_{j,t-1}, X_{j,t}]$. Then, it follows that $x_{j,t} \neq 0$. Thus, from the above argument, we have $\tilde{C}_j(X_{j,t}) = t$. Let $t_v := \bar{C}_j(v)$ for notational convenience. We want to show $\tilde{C}_j(v) \leq t_v$. By Proposition 4 and construction of σ, we know that the extend to which e is processed by time t_v,

$$Q_e(t_v) = Y_{e,t-1} + y_{e,t}(t_v - (t-1)) = Y_{e,t-1} + \frac{y_{e,t}}{x_{j,t}}(v - X_{j,t-1})$$

[2] This is possible because $\{y_{e,t}\}_e$ lies in the polymatroid associated with the matroid rank function ρ due to constraint (3). It is well-known that this polymatroid is equivalent to the independence set polytope of the matroid, meaning that $\{y_{e,t}\}_e$ can be expressed as a convex combination of characteristic vectors of some independent sets. For more details, see Chapter 44 of [25].

First, if $y_{e,t} \geq x_{j,t}$, we immediately have $Q_e(t_v) \geq v + Y_{e,t-1} - X_{j,t-1} \geq v$ due to constraint (2). Otherwise, since $\frac{1}{x_{j,t}}(v - X_{j,t-1}) \leq 1$, fixing the value of $Y_{e,t} = Y_{e,t-1} + y_{e,t}$, the right-hand-side decreases when we increase $y_{e,t}$. Therefore, we have, $Q_e(t) \geq Y_{e,t-1} - (x_{j,t} - y_{e,t}) + \frac{x_{j,t}}{x_{j,t}}(v - X_{j,t-1}) = v + Y_{e,t} - X_{e,t} \geq v$, again due to constraint (2). Hence, we have $Q_e(t_v) \geq v$ for all $e \in U_j$, which immediately yields $\tilde{C}_j(v) \leq t_v$. ◀

▶ **Lemma 6.** $\sum_{j \in J} w_j \int_{v=0}^{1} \bar{C}_j(v)dv = \text{COST}(\mathsf{LP}) - \sum_{j \in J} w_j/2$

Proof. It suffices to show that $\int_{v=0}^{1} \bar{C}_j(v)dv = \sum_{t \in [T]} t \cdot x_{j,t} - 1/2$, since summing this equation over all $j \in J$ multiplied by their weight w_j yields the lemma.

$$\int_{v=0}^{1} \bar{C}_j(v)dv = \sum_{t \in [T]} \int_{v=X_{j,t-1}}^{X_{j,t}} \bar{C}_j(v)dv = \sum_{t \in [T]: x_{j,t} \neq 0} \int_{v=X_{j,t-1}}^{X_{j,t}} \bar{C}_j(v)dv$$

$$= \sum_{t \in [T]: x_{j,t} \neq 0} \int_{v=X_{j,t-1}}^{X_{j,t}} \left(\frac{1}{x_{j,t}}(v - X_{j,t-1}) + (t-1) \right) dv$$

$$= \sum_{t \in [T]: x_{j,t} \neq 0} \left[\frac{1}{2} x_{j,t} + (t-1)x_{j,t} \right] = -\frac{1}{2} + \sum_{t \in [T]: x_{j,t} \neq 0} t \cdot x_{j,t},$$

where the last equality follows from constraint (1). ◀

4.2 Constructing the Stretched Schedule σ^λ

To construct σ^λ from σ we "stretch" the schedule σ by a factor of $1/\lambda$. More precisely, if an independent set S is scheduled in σ during an infinitesimal interval $(\tau_1, \tau_2]$, the same independent set is scheduled in σ^λ during $(\tau_1/\lambda, \tau_2/\lambda]$. In Lemma 7 we show that σ^λ completes job j by time $C_j^* = \lceil \frac{\bar{C}_j(\lambda)}{\lambda} \rceil$. In Lemma 8 we upper bound the expected cost of $\sum_j w_j C_j^*$ by twice $\text{COST}(\mathsf{LP})$.

▶ **Lemma 7.** *The schedule σ^λ completes every job j by time C_j^*.*

Proof. Lemma 5 shows that $\tilde{C}_j(v) \leq \bar{C}_j(v)$ for all $v \in (0, 1]$, meaning that every task in U_j is completed by v units by time $\bar{C}_j(v)$ in σ. Thus, in the stretched schedule σ^λ, every job j completes by time $\bar{C}_j(\lambda)/\lambda$, for any value of $\lambda \in (0, 1]$. ◀

▶ **Lemma 8.** $\mathbb{E}[\sum_{j \in J} w_j C_j^*] \leq 2\ \text{COST}(\mathsf{LP})$.

Proof. First note that

$$\sum_{j \in J} w_j \mathbb{E}[\bar{C}_j(\lambda)/\lambda] = \sum_{j \in J} w_j \int_{v=0}^{1} \bar{C}_j(v)/v \cdot (2v)dv = 2 \sum_{j \in J} w_j \int_{v=0}^{1} \bar{C}_j(v)dv \tag{6}$$

Thus, we have,

$$\mathbb{E}\Big[\sum_{j \in J} w_j C_j^*\Big] = \mathbb{E}\Big[\sum_{j \in J} w_j \lceil \frac{1}{\lambda} \bar{C}_j(\lambda) \rceil\Big] \leq \Big(\mathbb{E}\Big[\sum_j w_j \frac{1}{\lambda} \bar{C}_j(\lambda)\Big]\Big) + \sum_j w_j$$

$$= 2 \sum_j w_j \int_{v=0}^{1} \bar{C}_j(v)dv + \sum_j w_j \qquad \text{[Eqn. (6)]}$$

$$= 2\Big(\text{COST}(\mathsf{LP}) - \sum_j w_j/2\Big) + \sum_j w_j \qquad \text{[Lemma 6]}$$

$$= 2\ \text{COST}(\mathsf{LP})$$ ◀

4.3 Constructing a Discrete Integer Schedule

Let $y^*_{e,t}$ denote how much task e is processed during time interval $(t-1,t]$. In other words, task e appears in $y^*_{e,t}$ units of independents sets scheduled in σ^λ during the time interval. Then, $\{y^*_{e,t}\}_{e\in U, t\in[T]}$ satisfies the following:

1. For all $j \in J$ and $e \in U_j$, $\sum_{t\in[C^*_j]\setminus[r_j-1]} y^*_{e,t} = 1$; and .
2. For all $S \subseteq U$ and for all $t \in [T]$, $\sum_{e\in S} y^*_{e,t} \le \rho(S)$,

where the second holds true since $\{y^*_{e,t}\}_{e\in U}$ can be expressed as a convex combination of independent sets scheduled during time interval $(t-1,t]$, and therefore, lies in the matroid polytope. We now interpret $\{y^*_{e,t}\}$ as a fractional point in the intersection of two matroid polytopes. We create the following two matroids. The new universe U' is defined as $U' := \{(e,t) \mid t \in [T], j \in J, e \in U_j \text{ s.t. } r_j \le t \le C^*_j\}$. The first matroid M_1 is a partition matroid that forces to choose at most one element out of $\{(e,t)\}_t$, for each $e \in U$. Intuitively, this ensures that no task is scheduled more than once across times. The second matroid ensures that elements scheduled at each time t forms an independent set in $\mathcal{I}$. The following lemma formally defines the second matroid and shows that it is indeed a matroid.

▶ **Lemma 9.** *Define $\mathcal{I}_2 \subseteq 2^{U'}$ such that $S' \subseteq U'$ is in $\mathcal{I}_2$ if and only if for any $t \in [T]$, $\{e \mid (e,t) \in S'\} \in \mathcal{I}$. Then, $M_2 = (U', \mathcal{I}_2)$ is a matroid.*

Proof. Let $\mathcal{I}_2$ denote the family of independent sets of M_2. It is straightforward to see that $\mathcal{I}_2$ is downward closed. Thus, it suffices to show that for any $A', B' \in \mathcal{I}_2$ such that $|A'| < |B'|$, there exists $(e,t) \in B' \setminus A'$ such that $A' \cup \{(e,t)\} \in \mathcal{I}_2$. Let $U'_t := \{(e,t) \mid j \in J, e \in U_j \text{ s.t. } r_j \le t \le C^*_j\}$ denote the subset of U' restricted to time t. Consider any fixed $A', B' \in \mathcal{I}_2$ such that $|A'| < |B'|$. Then, consider any fixed time t^* such that $|A' \cap U'_{t^*}| < |B' \cap U'_{t^*}|$; such a time t^* must exist since $\{U'_t\}_t$ partitions U'. Then, for some $(e^*, t^*) \in (B' \cap U'_{t^*}) \setminus (A' \cap U'_{t^*})$, it must be the case that $\{e^*\} \cup \{e \mid (e,t^*) \in A' \cap U'_{t^*}\} \in \mathcal{I}$. This is because B' has more elements than A' that are paired up with the fixed time t^*, and therefore, the set of elements appearing in $A' \cap U'_{t^*}$ remains independent with some e^* added. Further, for any other time t, the elements appearing in the pairs of A' associated with t remain unchanged, and therefore, is in $\mathcal{I}$. ◀

Then, it is easy to see that $\{y^*_{e,t}\}$ is a point that lies in the intersection of the polymatroids that are defined by M_1 and M_2. Further, $\{y^*_{e,t}\}$ belongs to the base polymatroid of M_1; so we have $\sum_{(e,t)\in U'} y^*_{e,t} = |U|$. Since the matroid intersection polytope is well-known to be integral [26], meaning that every vertex is an integer point, a maximum independent set in the intersection of M_1 and M_2 must have $|U|$ elements. Further, we can find such a maximum independent set in polynomial time. To recap, we have found $S' \in U'$ that is a base of M_1 and is independent in M_2. This set S' immediately gives the desired integer schedule where $\{e \mid (e,t) \in S'\}$ is scheduled at each time t. Indeed, due to S' being a base of M_1, every task in U_j is scheduled exactly once during time interval $[r_j, C^*_j]$. Further, S' being independent in M_2 ensures that the set of tasks scheduled at each time forms an independent set in $\mathcal{I}$.

5 Derandomization

In this section, we discuss how to derandomize the choice of $\lambda \in (0,1]$, which was used to compute the deadlines for the jobs. This will complete the proof of Theorem 1. Let us first define *step* values. We say that $v \in (0,1]$ is a step value if $\sum_{s\le t} x_{j,s} = v$ for some $j \in J$ and integer $t \in [T]$ – in other words, exactly v fraction of some job j is completed by some integer time in the LP solution. Let V denote the set of all step values; $1 \in V$ by definition. Note that that $|V|$ is polynomially bounded in the input size, as the number of variables $x_{j,t}$ we consider in LP is at most $|J| \cdot |U|$.

Recall that in Lemma 8 we showed $\mathbb{E}[\sum_j w_j C_j^*] \leq 2\,\text{COST}(\mathsf{LP})$ when $C_j^* := \lceil \frac{1}{\lambda}\bar{C}_j(\lambda)\rceil$. This implies there exists a certain value of $\lambda \in (0,1]$ such that $\sum_j w_j C_j^* \leq 2\text{COST}(\mathsf{LP})$. For the purpose of derandomization, it suffices to find λ such that $\sum_j w_j \bar{C}_j(\lambda)/\lambda \leq 2\sum_j w_j \int_{v=0}^{1} \bar{C}_j(v)dv$; the equality is shown in equation (6) in expectation.

Towards this end, we aim to find $\lambda \in (0,1]$ that minimizes $\sum_j w_j \bar{C}_j(\lambda)/\lambda$. Suppose λ was set to a value $v \in (v_1, v_2]$, where v_1 and v_2 are two adjacent step values in V. Consider any fixed job j. Let $t \in [T]$ be such that $v \in (X_{j,t-1}, X_{j,t}]$. By definition of step values, we have $(v_1, v_2] \subseteq (X_{j,t-1}, X_{j,t}]$. Thus, we have $\bar{C}_j(v)/v = \frac{1}{x_{j,t}}(1 - \frac{X_{j,t-1}}{v}) + \frac{t-1}{v}$. This becomes a linear function in z over $[1/v_2, 1/v_1)$ if we set $z = 1/v$. Therefore, we get a piece-wise linear function $g(z)$ by summing over all jobs multiplied by their weight and considering all pairs of two adjacent step values in V. We set λ to the the inverse of z's value that achieves the global minimum, which can be found in polynomial time.

6 Arbitrary Processing Times

In this section we show how to extend Theorem 1 to allow tasks with arbitrary processing times with a loss of $(1+\epsilon)$ factor in the approximation ratio for any arbitrary constant $\epsilon > 0$. In this setting, each task e has an arbitrary integer size p_e and the task e completes when p_e independent sets including e are scheduled. As before, at each time we can schedule a set of tasks that is independent in the given matroid and a job completes when all its tasks complete.

6.1 Compact Linear Program

We first describe our new compact LP relaxation. Let $T := \sum_e p_e + \max_j r_j$, which is clearly an upper bound on the maximum time we need to consider. We define a set of times $\mathcal{T}$ that consists of polynomially many time steps. First, let $\mathcal{T}$ include every job's arrival time. Next, let $\mathcal{T}$ include all times appearing in $\{\lfloor (1+\epsilon)^i \rfloor\}_{0 \leq i \leq \lceil \log_{1+\epsilon} T \rceil + 1}$. In words, $\mathcal{T}$ includes exponentially increasing time steps by a factor of $(1+\epsilon)$ starting from 1 but includes no times greater than $(1+\epsilon)^2 T$. Let $t_1 = 1, t_2, \ldots, t_k, \ldots, t_{K+1}$ denote the (integer) times in $\mathcal{T}$ in increasing order. Let $I_i := [t_i, t_{i+1})$ where $i \in [K]$. The idea is to rewrite LP compactly as follows by replacing time-indexed variables with interval-indexed variables.

$$\min \sum_{j \in J} w_j \sum_{i \in [K]} (t_{i+1} - 1) \cdot x_{j,i}$$

$$\text{s.t.} \quad \forall e \in U, \qquad \sum_{i \in [K]} (t_{i+1} - t_i) y_{e,i} = p_e \tag{7}$$

$$\forall j \in J\ \forall e \in U_j\ \forall i \in [K], \qquad \sum_{i' \leq i} y_{e,i'}/p_e \geq \sum_{i' \leq i} x_{j,i'} \tag{8}$$

$$\forall S \subseteq U\ \forall i \in [K], \qquad \sum_{e \in S} y_{e,i} \leq \rho(S) \tag{9}$$

$$\forall j \in J\ \forall e \in U_j\ \forall i \in [K] \text{ s.t. } t_{i+1} \leq r_j, \qquad y_{e,i} = 0 \tag{10}$$

$$\mathbf{x}, \mathbf{y} \geq 0 \tag{11}$$

Here, variable $x_{j,i}$ can be viewed as the average fraction of job j that completes per unit time during I_i; so, when the job j completes during I_i for the first time, we have $\sum_{i' \leq i} x_{j,i'} = 1$. Likewise, $y_{e,i}$ has an analogous meaning for each task e but it denotes the

average *unit* of task e that is processed per unit time during I_i. Constraint (7) ensures that all tasks complete eventually. Constraint (9) ensures that the average vector representing how much each task is processed per unit time during I_t lies in the polymatroid. Constraint (10) enforces that no tasks in U_j are processed before j's arrival time; this is possible since $\mathcal{T}$ includes all jobs arrival times. Before explaining constraint (8), we explain the objective. If all intervals, $\{I_i\}$ were of unit length, the objective would be exactly the fractional total weighted completion time. However, to make the LP compact, when job j completes by $x_{j,i}$ fraction during interval I_i, we pretend that the fraction completes at the end of I_i, i.e., $t_{i+1} - 1$. Thus, we overestimate the fractional objective; but since times in I_i differ by at most $(1 + \epsilon)$ factor, our overestimate is by a factor of at most $(1 + \epsilon)$. Finally, we discuss constraint (8), which caps each job's (cumulative) processed fraction at the analogous quantity of each task of the job, which is measured as how much the task has been processed divided by its processing time. We also note that this compact LP admits the same separation oracle as the one for LP.

6.2 Rounding

As before, we seek to round the optimal LP solution. Recall that we first obtained $C_j^* := \lceil \frac{1}{\lambda} \bar{C}_j \rceil$ and found an integer schedule that completes every job j before C_j^*. We observe that the first procedure is no issue. This is because we can interpret the solution to our compact LP as a solution to LP. To see this, when a task e is processed by δ amount, pretend that there exist p_e different tasks of unit size and they are processed equally by δ/p_e amount. Thus, we can compute $\bar{C}_j(v)$ efficiently for any value of $v \in (0, 1]$. The derandomization can be done similarly.

6.3 Finding An Integer Schedule

It now remains to find an integer schedule meeting the discovered deadlines, $\{C_j^*\}_{j \in J}$. We use essentially the same idea of reducing the problem to finding an integer solution to the intersection of two matroids. However, this reduction requires some careful modifications to be implemented in polynomial time. Also, we will aim to complete every job j by $(1+O(\epsilon))C_j^*$ meeting the deadline slightly loosely.

The main idea is to use the fact that the continuous schedule σ^λ meeting the deadlines $\{C_j^*\}$ only changes polynomially many times. This is because the continuous schedule σ before the stretching is identical at all times during each of the intervals $(0, t_1 - 1], (t_1 - 1, t_2], \ldots, (t_{K-1} - 1, t_K]$ – these intervals are stretched into $(0, (t_1 - 1)/\lambda], ((t_1 - 1)/\lambda, t_2/\lambda], \ldots, ((t_{K-1} - 1)/\lambda, t_K/\lambda]$, respectively. We split the interval including the time $T' = |U|^2/\epsilon^2$ into two, the left one ending at $|U|^2/\epsilon^2$ and the right one starting at $|U|^2/\epsilon^2$. Here, assume that $1/\epsilon$ is an integer. We also add time $\bar{C}_j(\lambda)/\lambda$ for every $j \in J$ and split the intervals accordingly. To simplify the notation, we recycle the notations I_i. By reindexing the resulting intervals and merging some initial intervals, we have $I_0 := (0, T']$, I_1, I_2, ..., $I_{K'}$. We say that an interval is small if its starting time or ending time is not a power of $(1 + \epsilon)$ divided by λ; more precisely, $((t_{i-1} - 1)/\lambda, t_i/\lambda]$ is small if t_{i-1} or t_i is not a power of $(1 + \epsilon)$ divided by λ. Note that there are at most $4|J| + 4 \leq 8|J| \leq 8|U|$ small intervals since each job's arrival time and deadline together can create at most 4 small intervals; the extra four come from time 0, the final time, and T'.

For each interval I_i, let $Q_e(I_i)$ denote the amount of task e processed during I_i, which can be easily computed in polynomial time. For each interval, we will construct an integer schedule that schedules each task as much as the continuous schedule σ^λ does without using

too many time steps compared to the interval's length; more precisely, the integer schedule will process at least $\lceil Q_e(I_i) \rceil$ units of task e. We categorize the intervals into three groups. Depending on the category where each interval belongs, we construct an integer schedule differently or give a different upper bound on the length of the integer schedule. At the end, we will concatenate the constructed integer intervals in increasing order of times. In the following, $|I|$ denotes I's length.

The first interval, $I_0 = (0, T']$. Using the same idea we used for handling unit-sized tasks, we find an integer schedule that processes at least $\lfloor Q_e(I_i) \rfloor$, meeting all job deadlines no greater than T'. Note that I_0 has a polynomial length; thus, the desired integer schedule can be computed in polynomial time. Then, we can greedily schedule each task e per unit time such that $Q_e(I_i)$ is not an integer. Note that such a task e hasn't completed by time T', so the task (more precisely, the job to which the task belongs) has deadline at least T'. Therefore, we will be able to charge the extra delay of at most $|U|$ to the corresponding job's deadline directly.

I_i that is not small, for $i \geq 1$. We seek to construct an integer schedule of length $(1 + O(\epsilon))|I_i|$. Towards this end, we do the following. Suppose we divide the interval into $\lceil \frac{|I_i|}{|U|/\epsilon} \rceil$ subintervals of length $|U|/\epsilon$; there can be at most one subinterval of a smaller length and we will handle it later. Next, for each subinterval of length $|U|/\epsilon$, we try to schedule $\lceil \frac{|U|/\epsilon}{|I_i|} Q_e(I_i) \rceil$ units of each task e. Since the length is polynomial in $|U|$, we can find an integer schedule of length $|U|/\epsilon + 1$ that schedules $\lfloor \frac{|U|/\epsilon}{|I_i|} Q_e(I_i) \rfloor$ units of each task e. By scheduling one task per unit time, we can schedule $\lceil \frac{|U|/\epsilon}{|I_i|} Q_e(I_i) \rceil$ units of each task e for $|U|/\epsilon + 1 + |U| \leq (|U|/\epsilon) \cdot (1 + 2\epsilon)$ time steps. Here, our integer schedule's length is at most $(1 + 2\epsilon)$ times the subinterval's length, $|U|/\epsilon$. This integer schedule is repeated $\lfloor \frac{|I_i|}{|U|/\epsilon} \rfloor$ times. We now handle the smaller subinterval of length less than $|U|/\epsilon$. Using a similar argument, we can process more units of each task than the continuous schedule, using at most $|U|/\epsilon + 1 + |U| \leq 2|U|/\epsilon$ time steps. Here we use the fact that I_i has length significantly greater than $|U|$. To see this, suppose we had not added jobs arrival times, deadlines or T' in the process of creating the intervals. Then the intervals preceding I_i have exponentially decreasing lengths by a factor of $(1 + \epsilon)$. Using this observation, we can argue that I_i's length is at least $\epsilon/2$ times I_i's starting time. Since I_i's starting time is greater than T', we have that I_i's length is at least $(\epsilon/2) \cdot T' = (\epsilon/2) \cdot (|U|^2/\epsilon^2) = |U|^2/(2\epsilon)$. So, we can charge the number of time steps spent to handle the smaller subinterval, which is at most $2|U|/\epsilon$, to the length of I_i. From all these arguments, we can construct an integer schedule of length at most $(1 + 6\epsilon)|I_i|$.

I_i that is small, for $i \geq 1$. We seek to construct an integer schedule of length $(1+O(\epsilon))|I_i|+ 2|U|/\epsilon$. The whole idea is the same for the intervals that are not small. The only difference is that we cannot charge the extra time steps we spend to handle the smaller subinterval, which is at most $2|U|/\epsilon$, to the length of I_i. Thus, we just use the upper bound on the length of our integer schedule.

As mentioned before, we concatenate the integer schedules originating from $I_0, I_1, \ldots, I_K$ in this order to obtain the final schedule. It now remains to show that each job completes by time $(1 + O(\epsilon))C_j^*$. We already showed that our integer schedule completes every job j before its deadline C_j^* if it is smaller than T'. For any other job j, it must be the case that $\bar{C}_j(\lambda)/\lambda$ is greater than T'. Let I_i be the interval including $\bar{C}_j(\lambda)/\lambda$. Due to the way the intervals are

constructed, $\bar{C}_j(\lambda)/\lambda$ must be equal to I_i's finish time. Our goal is to show that we complete j not too late compared to I_i's finish time. That is, we want to show that the total length of the integer schedules originating from $I_0, I_1, \ldots, I_i$ is at most $(1+O(\epsilon))\sum_{i' \le i} |I_{i'}|$. Indeed, the total length is at most,

$$|I_0| + |U| + \sum_{i'=[i]:I_{i'} \text{ is small}} ((1+O(\epsilon))|I_i| + 2|U|/\epsilon) + \sum_{i'=[i]:I_{i'} \text{ is not small}} (1+O(\epsilon))|I_i|$$

$$\le \sum_{i'=0}^{i} (1+O(\epsilon))|I_{i'}| + |U| + (2|U|/\epsilon)\cdot(8|U|) \le \sum_{i'=0}^{i} (1+O(\epsilon))|I_{i'}| + O(\epsilon)|I_0|$$

Here, the first inequality follows from the fact that there are at most $8|U|$ small intervals, as argued above. The second inequality is immediate from $|I_0| = T' = |U|^2/\epsilon^2$. Therefore, we have shown that each job completes by time $(1+O(\epsilon))C^*_j$, which establishes that our final schedule's objective is at most $(1+O(\epsilon))$ times the compact LP's optimum. Since we showed the compact LP lower bounds the optimum times $(1+\epsilon)$, we obtain a $2(1+\epsilon)$-approximate schedule for arbitrary $\epsilon > 0$ by scaling ϵ appropriately.

Abstract

Assume that a treasure is placed in one of M boxes according to a known distribution and that k searchers are searching for it in parallel during T rounds. We study the question of how to incentivize selfish players so that group performance would be maximized. Here, this is measured by the *success probability*, namely, the probability that at least one player finds the treasure. We focus on *congestion policies* $C(\ell)$ that specify the reward that a player receives if it is one of ℓ players that (simultaneously) find the treasure for the first time. Our main technical contribution is proving that the *exclusive policy*, in which $C(1) = 1$ and $C(\ell) = 0$ for $\ell > 1$, yields a *price of anarchy* of $(1 - (1 - 1/k)^k)^{-1}$, and that this is the best possible price among all symmetric reward mechanisms. For this policy we also have an explicit description of a symmetric equilibrium, which is in some sense unique, and moreover enjoys the best success probability among all symmetric profiles. For general congestion policies, we show how to polynomially find, for any $\theta > 0$, a symmetric multiplicative $(1 + \theta)(1 + C(k))$-equilibrium.

Together with an appropriate reward policy, a central entity can suggest players to play a particular profile at equilibrium. As our main conceptual contribution, we advocate the use of symmetric equilibria for such purposes. Besides being fair, we argue that symmetric equilibria can also become highly robust to crashes of players. Indeed, in many cases, despite the fact that some small fraction of players crash (or refuse to participate), symmetric equilibria remain efficient in terms of their group performances and, at the same time, serve as approximate equilibria. We show that this principle holds for a class of games, which we call *monotonously scalable* games. This applies in particular to our search game, assuming the natural *sharing policy*, in which $C(\ell) = 1/\ell$. For the exclusive policy, this general result does not hold, but we show that the symmetric equilibrium is nevertheless robust under mild assumptions.

1 Introduction

Searching in groups is ubiquitous in multiple contexts, including in the biological world, in human populations as well as on the internet [8, 11, 16]. In many cases there is some prior on the distribution of the searched target. Moreover, when the space is large, each searcher typically needs to inspect multiple possibilities, which in some circumstances can only be done sequentially. This paper introduces a game theoretic perspective to such multi-round treasure hunt searches, generalizing a basic collaborative Bayesian framework previously introduced in [8].

Consider the case that a treasure is placed in one of M boxes according to a known distribution f and that k searchers are searching for it in parallel during T rounds, each specifying a box to visit in each round. Assume w.l.o.g. that the boxes are ordered such that lower index boxes have higher probability to host the treasure, i.e., $f(x) \geq f(x+1)$. We evaluate the group performance by the *success probability*, that is, the probability that the treasure is found by at least one searcher.

If coordination is allowed, letting searcher i visit box $(t-1)k+i$ at time t will maximize success probability. However, as simple as this algorithm is, it is very sensitive to faults of all sorts. For example, if an adversary that knows where the treasure is can crash a searcher before the search starts (i.e., prevent it from searching), then it can reduce the search probability to zero.

The authors of [8] suggested the use of *identical non-coordinating* algorithms. In such scenarios all processors act independently, using no communication or coordination, executing the same probabilistic algorithm, differing only by the results of their coin flips. As argued in [8], in addition to their economic use of communication, identical non-coordinating algorithms enjoy inherent robustness to different kind of faults. For example, assume that there are $k+k'$ searchers, and that an adversary can fail up to k' searchers. Letting all searchers run the best non-coordinating algorithm for k searchers guarantees that regardless of which $\ell \leq k'$ searchers fail, the overall search efficiency is at least as good as the non-coordinating one for k players. Of course, since k' players might fail, any solution can only hope to achieve the best performance of k players. As it applies to the group performance we term this property as *group robustness*. Among the main results in [8] is identifying a non-coordinating algorithm, denoted $A^\star$, whose expected running time is minimal among non-coordinating algorithms. Moreover, for every given T, if this algorithm runs for T rounds, it also maximizes the success probability.

The current paper studies the game theoretic version of this multi-round search problem[1]. The setting of [8] assumes that the searchers adhere fully to the instructions of a central entity. In contrast, in a game theoretical context, searchers are self-interested and one needs to incentivize them to behave as desired, e.g., by awarding those players that find the treasure first. For many real world contexts, the competitive setting is in fact the more realistic one to assume. Applications range from crowd sourcing [26], multi-agent searching on the internet [25], grant proposals [18], to even contexts of animals [17]. See the full version for more details.

[1] We concentrate on the normal form version in which players do not receive any feedback during the search (except when the treasure is found in which case the game ends). In particular, we assume that players cannot communicate with each other.

In the competitive setting, choosing a good *rewarding policy* becomes a problem in algorithmic mechanism design [24]. Typically, a reward policy is evaluated by its *price of anarchy (PoA)*, namely, the ratio between the performances of the best collaborative algorithm and the worst equilibrium [19]. Aiming to both accelerate the convergence process to an equilibrium and obtain a preferable one, the announcement of the reward policy can be accompanied by a proposition for players to play particular strategies that form a profile at equilibrium.

This paper highlights the benefits of suggesting (non-coordinating) *symmetric equilibria* in such scenarios, that is, to suggest the same non-coordinating strategy to be used by all players, such that the resulting profile is at equilibrium. This is of course relevant assuming that the *price of symmetric stability (PoSS)*, namely, the ratio between the performances of the best collaborative algorithm and the best symmetric equilibrium, is low. Besides the obvious reasons of fairness and simplicity, from the perspective of a central entity who is interested in the overall success probability, we obtain the group robustness property mentioned above, by suggesting that the $k + k'$ players play according to the strategy that is a symmetric equilibrium for k players. Obviously, this group robustness is valid only provided that the players indeed play according to the suggested strategy. However, the suggested strategy is guaranteed to be an equilibrium only for k players, while in fact, the adversary may keep some of the extra k' players alive. Interestingly, however, in many cases, a symmetric equilibrium for k players also serves as an approximate equilibrium for $k + k'$ players, as long as $k' \ll k$. As we show, this *equilibrium robustness* property is rather general, holding for a class of games, that we call *monotonously scalable* games.

1.1 The Collaborative Search Game

A treasure is placed in one of M boxes according to a known distribution f and k players are searching for it in parallel during T rounds. Assume w.l.o.g. that $f(x) > 0$ for every x and that $f(x) \geq f(x + 1)$.

Strategies. An *execution* of T rounds is a sequence of box visitations $\sigma = x(1), x(2), \ldots x(T)$, one for each round $i \leq T$. We assume that a player visiting a box has no information on whether other players have already visited that box or are currently visiting it. Hence, a *strategy* of a player is a probability distribution over the space of executions of T rounds. Note that the probability of visiting a box x in a certain round may depend on the boxes visited by the player until this round, but not on the actions of other players. A strategy is *non-redundant* if at any given round it always checks a box it didn't check before (as long as there are such boxes).

A *profile* is a collection of k strategies, one for each player. Special attention will be devoted to *symmetric profiles*. In such profiles all players play the same strategy (note that their actual executions may be different, due to different probabilistic choices).

Probability Matrix. While slightly abusing notation, we shall associate each strategy A with its *probability matrix*, $A : \{1, \ldots, M\} \times \{1, \ldots, T\} \to [0, 1]$, where $A(x, t)$ is the probability that strategy A visits x for the first time at round t. We also denote $\widetilde{A}(x, t)$ as the probability that A does not visit x by, and including, time t. That is, $\widetilde{A}(x, t) = 1 - \sum_{s \leq t} A(x, t)$ and $\widetilde{A}(x, 0) = 1$. For convenience we denote by $\delta_{x,t}$ the matrix of all zeros except 1 at x, t. Its dimensions will be clear from context.

Group Performance. A profile is evaluated by its *success probability*, i.e., the probability that at least one player finds the treasure by time T. Formally, let $\mathbb{P}$ be a profile. Then,

$$\texttt{success}(\mathbb{P}) = \sum_x f(x) \left(1 - \prod_{A \in \mathbb{P}} \widetilde{A}(x,T)\right).$$

The expected running time in the symmetric case, which is $\sum_x f(x) \sum_t \widetilde{A}(x,t)^k$, was studied in [8]. That paper identified a strategy, denoted $A^\star$, that minimizes this quantity. In fact, it does so by minimizing the term $\sum_x f(x)\widetilde{A}(x,t)^k$ for each t separately. Note that minimizing the case $t = T$ is exactly the same as maximizing the success probability. Thus, restricted to the case where all searchers use the same strategy, $A^\star$ simultaneously optimizes the success probability as well as optimizes the expected running time. For completeness, a description of $A^\star$ is provided below.

Algorithm $A^\star$. We note that in [8] the matrix of $A^\star$ is given, and then an algorithm is explicitly described that has its matrix (Section 4.3 in [8]). We describe the matrix only, as its details are necessary for this paper.

Denote $q(x) = f(x)^{-1/(k-1)}$. For each t, $\widetilde{A^\star}(x,t) = \min(1, \alpha(t)q(x))$, where $\alpha(t) \geq 0$ is such that $\sum_x \widetilde{A^\star}(x,t) = M - t$. Of course, once $\widetilde{A^\star}$ is known, then so is $A^\star$: $A^\star(x,t) = \widetilde{A^\star}(x,t-1) - \widetilde{A^\star}(x,t)$.

Congestion Policies. A natural way to incentivize players is by rewarding those players that find the treasure before others. A *congestion policy* $C(\ell)$ is a function specifying the reward that a player receives if it is one of ℓ players that (simultaneously) find the treasure for the first time. We assume that $C(1) = 1$, and that C is non-negative and non-increasing. Due to the fact that the policy $C \equiv 1$ is rather degenerate, we henceforth assume that $C \not\equiv 1$. We shall give special attention to the following policies.

- The *sharing policy* is defined by $C_{\texttt{share}}(\ell) = 1/\ell$, namely, the treasure is shared equally among all those who find it first.
- The *exclusive policy* is defined by $C_{\texttt{ex}}(1) = 1$, and $C_{\texttt{ex}}(\ell) = 0$ for $\ell > 1$, namely, the treasure is given to the first one that finds it exclusively; if more than one discover it, they get nothing[2].

A *configuration* is a triplet (C, f, T), where C is a congestion policy, T is a positive integer, and f is a positive non-increasing probability distribution on M boxes.

Values, Utilities and Equilibria. Let (C, f, T) be a configuration. The *value* of box x at round t when playing against a profile $\mathbb{P}$ is the expected gain from visiting x at round t. Formally,

$$\begin{aligned} v_{\mathbb{P}}(x,t) &= f(x) \sum_{\ell=0}^{k-1} C(\ell+1) \Pr\left(\begin{array}{l} x \text{ was not visited before time } t, \text{ and} \\ \text{at time } t \text{ is visited by } \ell \text{ players of } \mathbb{P} \end{array}\right) \\ &= f(x) \sum_{\ell=0}^{k-1} C(\ell+1) \sum_{\substack{I \subseteq \mathbb{P} \\ |I| = \ell}} \prod_{A \in I} A(x,t) \prod_{A \notin I} \widetilde{A}(x,t). \end{aligned}$$

[2] In the one round game, the exclusive policy yields a utility for a player that equals its marginal contribution to the social welfare, i.e., the success probability [27]. However, this is not the case in the multi-round game.

The *utility of A in round t* and the *utility of A* are defined as:

$$U_{\mathbb{P}}(A,t) := \sum_x A(x,t) \cdot v_{\mathbb{P}^{-A}}(x,t), \qquad U_{\mathbb{P}}(A) := \sum_t U_{\mathbb{P}}(A,t), \tag{1}$$

where $\mathbb{P}^{-A}$ is the set of players of $\mathbb{P}$ excluding A. Here are some specific cases we are interested in:

- For symmetric profiles, $v_A(x,t)$ denotes the value when playing against $k-1$ players playing A. Then $v_A(x,t) = f(x)\sum_{\ell=0}^{k-1} C(\ell+1)\binom{k-1}{\ell} A(x,t)^{\ell}\widetilde{A}(x,t)^{k-\ell-1}$.
- For the exclusive policy, $v_{\mathbb{P}}(x,t) = f(x)\prod_{A\in\mathbb{P}}\widetilde{A}(x,t)$.
- For the exclusive policy in symmetric profiles, $v_A(x,t) = f(x)\widetilde{A}(x,t)^{k-1}$.

A profile $\mathbb{P}$ is a *Nash equilibrium* under a configuration, if for any $A \in \mathbb{P}$ and any other strategy B, $U_{\mathbb{P}^{-A}}(A) \geq U_{\mathbb{P}^{-A}}(B)$. Similarly, a strategy A is called a *symmetric equilibrium* if the profile A^k consisting of all k players playing according to A is an equilibrium. We also use the notion of approximate equilibrium. For $\epsilon > 0$, we say a profile $\mathbb{P}$ is a $(1+\epsilon)$-equilibrium if for every $A \in \mathbb{P}$ and for every strategy B, $U_{\mathbb{P}^{-A}}(B) \leq (1+\epsilon)U_{\mathbb{P}^{-A}}(A)$.

A Game of Doubly-Substochastic Matrices. Both the expressions for the success probability and utility solely depend on the values of the probability matrices associated with the strategies in question. Hence we view all strategies sharing the same matrix as *equivalent*. Note that a matrix does not necessarily correspond to a unique strategy, as illustrated by the following equivalent strategies, for which $A(x,t) = B(x,t) = 1/M$ for every $t \leq M$ and 0 thereafter:

- Strategy A chooses uniformly at every round one of the boxes it didn't choose yet.
- Strategy B chooses once $x \in \{0,\ldots,M-1\}$. Then, at round t it visits box $(x+t \mod M)+1$.

Matrices are much simpler to handle than strategies, and so we would rather think of our game as a game of probability matrices than a game of strategies. For this we need to characterize which matrices are indeed probability matrices of strategies. Clearly, a probability matrix is non-negative. Also, by their definition, each row and each column sums to at most 1. Such a matrix is called *doubly-substochastic*. In the extended version we prove the converse, i.e., that every doubly-substochastic matrix is a probability matrix of some strategy. Furthermore, this strategy is implementable as a polynomial algorithm. We will therefore view our game as a game of doubly-substochastic matrices.

Greediness. Informally, a strategy is greedy at a round if its utility in this round is the maximum possible in this round. Formally, given a profile $\mathbb{P}$ and some strategy A, we say that A is *greedy* w.r.t. $\mathbb{P}$ at time t if for any strategy B such that for every x and $s < t$, $B(x,s) = A(x,s)$, we have $U_{\mathbb{P}}(A,t) \geq U_{\mathbb{P}}(B,t)$. We say A is greedy w.r.t. $\mathbb{P}$ if it is greedy w.r.t. $\mathbb{P}$ for each $t \leq T$. A strategy A is called *self-greedy* (or *sgreedy* for short) if it is greedy w.r.t. the profile with $k-1$ players playing A.

Evaluating Policies. Let (C,f,T) be a configuration. Denote by $\text{Nash}(C,f,T)$ the set of equilibria for this configuration, and by $\text{S-Nash}(C,f,T)$ the subset of symmetric ones. Let $\mathcal{P}(T)$ be the set of all profiles of T-round strategies. We are interested in the following measures.

- The *Price of Anarchy (PoA)* is $\texttt{PoA}(C,f,T) := \frac{\max_{\mathbb{P}\in\mathcal{P}(T)} \texttt{success}(\mathbb{P})}{\min_{\mathbb{P}\in\text{Nash}(C,f,T)} \texttt{success}(\mathbb{P})}$.
- The *Price of Symmetric Stability (PoSS)* is $\texttt{PoSS}(C,f,T) := \frac{\max_{\mathbb{P}\in\mathcal{P}(T)} \texttt{success}(\mathbb{P})}{\max_{A\in\text{S-Nash}(C,f,T)} \texttt{success}(A^k)}$.
- The *Price of Symmetric Anarchy (PoSA)* is $\texttt{PoSA}(C,f,T) = \frac{\max_{\mathbb{P}\in\mathcal{P}(T)} \texttt{success}(\mathbb{P})}{\min_{A\in\text{S-Nash}(C,f,T)} \texttt{success}(A^k)}$.

On the Difficulty of the Multi-Round Game. The setting of multi-rounds poses several challenges that do not exist in the single round game. An important one is the fact that, in contrast to the single round game, the multi-round game is not a potential game. Indeed, being a potential game has several implications, and a significant one is that such a game has always a pure equilibrium. However, we show that multi-round games do not always have pure equilibria and hence they are not potential games. Another important difference is that for policies that incur high levels of competition (such as the exclusive policy), profiles that maximize the success probability are at equilibrium in the single round case, whereas they are not in the multi-round game. See the full version of the paper for more details.

1.2 Our Results

Equilibrium Robustness. We first provide a simple, yet general, robustness result, that holds for symmetric (approximate) equilibria in a family of games, termed *monotonously scalable*. Informally, these are games in which the sum of utilities of players can only increase when more players are added, yet for each player, its individual utility can only decrease. Our search game with the sharing policy is one such example.

▶ **Theorem 1.** *Consider a symmetric monotonously scalable game. If A is a symmetric $(1+\epsilon)$-equilibrium for k players, then it is an $(1+\epsilon)(1+\ell/k)$-equilibrium when played by $k+\ell$ players.*

Theorem 1 is applicable in fault tolerant contexts. Consider a monotonously scalable game with $k+k'$ players out of which at most k' may fail. Let A_k be a symmetric (approximate) equilibrium designed for k players and assume that its social utility is high compared to the optimal profile with k players. The theorem implies that if players play A_k, then regardless of which $\ell \leq k'$ players fail (or decline to participate), the incentive to switch strategy would be very small, as long as $k' \ll k$. Moreover, due to symmetry, if the social utility of the game is monotone, then the social utility of A_k when played with k players is guaranteed when playing with more. Thus, in such cases we obtain both group robustness and equilibrium robustness.

General Congestion Policies. Coming back to our search game, we consider general policies, focus on symmetric profiles, and specifically, on the properties of sgreedy strategies.

▶ **Theorem 2.** *For every policy C there exists a non-redundant sgreedy strategy. Moreover, all such strategies are equivalent and are symmetric $(1+C(k))$-equilibria.*

When $C(k)=0$ this shows that a non-redundant sgreedy strategy is actually a symmetric equilibrium. We next claim that this is the only symmetric equilibrium (up to equivalence).

▷ Claim 3. For any policy such that $C(k)=0$, all symmetric equilibria are equivalent.

Theorem 2 is non-constructive because it requires calculating the inverse of non-trivial functions. Therefore, we resort to an approximate solution.

▶ **Theorem 4.** *Given $\theta > 0$, there exists an algorithm that takes as input a configuration, and produces a symmetric $(1+C(k))(1+\theta)$-equilibrium. The algorithm runs in polynomial time in T, k, M, $\log(1/\theta)$, $\log(1/(1-C(k)))$, and $\log(1/f(M))$.*

The Exclusive Policy. Recall that the exclusive policy is defined by $C_{\mathtt{ex}}(1) = 1$ and $C_{\mathtt{ex}}(\ell) = 0$ for every $\ell > 1$. We show that $A^\star$ is a non-redundant and sgreedy strategy in the exclusive policy. Hence, Theorem 2 implies the following.

▶ **Theorem 5.** *Under the exclusive policy, Strategy $A^\star$ of [8] is a symmetric equilibrium.*

Claim 3 together with the fact (established in [8]) that $A^\star$ has the highest success probability among symmetric profiles, implies that both the PoSS and the PoSA of $C_{\mathtt{ex}}$ are optimal (and equal) on any f and T when compared to any other policy. The next theorem considers general equilibria.

▶ **Theorem 6.** *Consider the exclusive policy. For any profile $\mathbb{P}_{\mathtt{nash}}$ at equilibrium and any symmetric profile A, $\mathtt{success}(\mathbb{P}_{\mathtt{nash}}) \geq \mathtt{success}(A)$.*

Observe that, as $A^\star$ is a symmetric equilibrium, Theorem 6 provides an alternative proof for the optimality of $A^\star$ (established in [8]). Interestingly, this alternative proof is based on game theoretic considerations, which is a very rare approach in optimality proofs.

Combining Theorems 5 and 6, we obtain:

▶ **Corollary 7.** *For any f and T, $\mathtt{PoA}(C_{\mathtt{ex}}, f, T) = \mathtt{PoSA}(C_{\mathtt{ex}}, f, T)$. Moreover, for any policy C, $\mathtt{PoA}(C_{\mathtt{ex}}, f, T) \leq \mathtt{PoA}(C, f, T)$.*

At first glance the effectiveness of C_{ex} might not seem so surprising. Indeed, it seems natural that high levels of competition would incentivize players to disperse. However, it is important to note that $C_{\mathtt{ex}}$ is not extreme in this sense, as one may allow congestion policies to also have negative values upon collisions. Moreover, one could potentially define more complex kinds of policies, e.g., policies that depend on time, and reward early finds more. However, the fact that $A^\star$ is optimal among all symmetric profiles combined with the fact that any symmetric policy has a symmetric equilibrium [23] implies that no symmetric reward mechanism can improve either the PoSS, the PoSA, or the PoA of the exclusive policy.

We proceed to show a tight upper bound on the PoA of $C_{\mathtt{ex}}$. Note that as k goes to infinity the bound converges to $e/(e-1) \approx 1.582$.

▶ **Theorem 8.** *For every T, $\sup_f \mathtt{PoA}(C_{\mathtt{ex}}, f, T) = (1-(1-1/k)^k)^{-1}$.*

Concluding the results on the exclusive policy, we study the robustness of $A^\star$ in the full version of the paper. Let $A^\star_k$ denote algorithm $A^\star$ when set to work for k players. Unfortunately, for any ϵ, there are cases where $A^\star_k$ is not a $(1+\epsilon)$-equilibrium even when played by $k+1$ players. However, as indicated below, $A^\star$ is robust to failures under reasonable assumptions regarding the distribution f.

▶ **Theorem 9.** *If $\frac{f(1)}{f(M)} \leq (1+\epsilon)^{\frac{k-1}{k'}}$, then $A^\star_k$ is a $(1+\epsilon)$-equilibrium when played by $k+k'$ players.*

The Sharing Policy. Another important policy to consider is the sharing policy. This policy naturally arises in some circumstances, and may be considered as a less harsh alternative to the exclusive one. Although not optimal, it follows from Vetta [31] that its PoA is at most 2 (see the full version). Furthermore, as this policy yields a monotonously scalable game, a symmetric equilibrium under it is also robust. Therefore, the existence of a symmetric profile which is both robust and has a reasonable success probability is guaranteed.

Unfortunately, we did not manage to find a polynomial algorithm that generates a symmetric equilibrium for this policy. However, Theorem 4 gives a symmetric $(1+\theta)(1+1/k)$-equilibrium in polynomial time for any $\theta > 0$. This strategy is also robust thanks to Theorem 1.

Moreover, the proof in [31] regarding the PoA can be extended to hold for approximate equilibria. In particular, if $\mathbb{P}$ is some $(1+\epsilon)$-equilibrium in the sharing policy, then for every f and T, $\texttt{success}(\mathbb{P}) \geq \frac{1}{2+\epsilon} \max_{\mathbb{P}' \in \mathcal{P}(T)} \texttt{success}(\mathbb{P}')$. See the full version of the paper for the proof.

1.3 Related Works

Fault tolerance has been a major topic in distributed computing for several decades, and in recent years more attention has been given to these concepts in game theory [13, 14]. For example, Gradwohl and Reingold studied conditions under which games are robust to faults, showing that equilibria in anonymous games are fault tolerant if they are "mixed enough" [12].

Restricted to a single round the search problem becomes a coverage problem, which has been investigated in several papers. For example, Collet and Korman studied in [30] (one-round) coverage while restricting attention to symmetric profiles only. The main result therein is that the exclusive policy yields the best coverage among symmetric profiles. Gairing [10] also considered the single round setting, but studied the optimal PoA of a more general family of games called *covering games* (see also [27, 28]). Motivated by policies for research grants, Kleinberg and Oren [18] considered a one-round model similar to that in [30]. Their focus however was on pure strategies only. The aforementioned papers give a good understanding of coverage games in the single round setting. As mentioned, however, the multi-round setting studied here is substantially more complex than the single-round setting.

The area of "incentivizing exploration" also studies the tradeoff between exploration, exploitation and incentives [21, 9, 26, 20]. This area often focuses on different variants of the Multi-Armed Bandit problem. The settings of selfish routing, job scheduling, and congestion games [22, 29] all bear similarities to the search game studied here, however, the social welfare measurements of success probability or running time are very different from the measures studied in these frameworks, such as makespan or latency [1, 3, 24, 2].

2 Robustness in Symmetric Monotonously Scalable Games

Consider a symmetric game where the number of players is not fixed. Let $U_{\mathbb{P}}(A)$ denote the utility that a player playing A gets if the other players play according to $\mathbb{P}$ and let $\sigma(\mathbb{P}) = \sum_{A \in \mathbb{P}} U_{\mathbb{P}-A}(A)$. We say that such a game is *monotonously scalable* if:

1. Adding more players can only increase the sum of utilities, i.e., if $\mathbb{P} \subseteq \mathbb{P}'$ then $\sigma(\mathbb{P}) \leq \sigma(\mathbb{P}')$.
2. Adding more players can only decrease the individual utilities, i.e., if $\mathbb{P} \subseteq \mathbb{P}'$ then for all $A \in \mathbb{P}$, $U_{\mathbb{P}-A}(A) \geq U_{\mathbb{P}'-A}(A)$.

▶ **Theorem 1.** *Consider a symmetric monotonously scalable game. If A is a symmetric $(1+\epsilon)$-equilibrium for k players, then it is an $(1+\epsilon)(1+\ell/k)$-equilibrium when played by $k+\ell$ players.*

Proof. On the one hand by symmetry,

$$U_{A^{k+\ell-1}}(A) = \frac{\sigma(A^{k+\ell})}{k+\ell} \geq \frac{\sigma(A^k)}{k+\ell},$$

where the last step is because σ is non-decreasing. On the other hand, if B is some other strategy,

$$U_{A^{k+\ell-1}}(B) \leq U_{A^{k-1}}(B) \leq (1+\epsilon) U_{A^{k-1}}(A) = (1+\epsilon)\frac{\sigma(A^k)}{k}.$$

The first inequality is because U is non-increasing, and the second is because A is a $(1+\epsilon)$-equilibrium for k players. Therefore, what a player can gain by switching from A to B is at most a multiplicative factor of $(1+\epsilon)(k+\ell)/k = (1+\epsilon)(1+\ell/k)$. ◀

An example of such a game is our setting with the sharing policy. Note however, that our game with the exclusive policy does not satisfy the first property, as adding more players can actually deteriorate the sum of utilities. Another example is a generalization known as *covering games* [10]. This sort of game is the same as our game in a single-round version, except that each player chooses not necessarily one element, but a set of elements, from a prescribed set of sets. Again, to be a monotonously scalable game, the congestion policy should be the sharing policy. Note that one may consider a multi-round version of these games, which will be monotonously scalable as well.

3 General Policies

The proofs of this section appear in the full version of the paper.

3.1 Non-Redundancy and Monotonicity

A doubly-substochastic matrix A is called *non-redundant at time* t if $\sum_x A(x,t) = 1$. It is *non-redundant* if it is non-redundant for every $t \leq M$. In the algorithmic view, as $\sum_x A(x,t)$ is the probability that a new box is opened at time t, then a strategy's matrix is non-redundant iff it never checks a box twice, unless it already checked all boxes.

▶ **Lemma 10.** *If a profile $\mathbb{P}$ is at equilibrium and* $\texttt{success}(\mathbb{P}) < 1$ *then every player is non-redundant.*

We will later see that in the symmetric case the condition in the lemma is not needed. However, the following example shows it is necessary in general. Let $M = k$, $T > 1$, and assume that for every $1 \leq i \leq k$, player i goes to box i in every round. Under the exclusive policy, this strategy is an equilibrium, whereas each player is clearly redundant. The following monotonicity lemmas hold under any congestion policy C.

▶ **Lemma 11.** *Consider two doubly-substochastic matrices A and B. If $A(x,t) > B(x,t)$, and for all $s < t$, $A(x,s) = B(x,s)$ then $v_A(x,t) < v_B(x,t)$.*

▶ **Lemma 12.** *Let A be doubly-substochastic. For every x and t, $v_A(x,t+1) \leq v_A(x,t)$. Moreover, if $A(x,t+1) > 0$ then the inequality is strict.*

Using the above, we prove a stronger result than Lemma 10 for the symmetric case:

▶ **Lemma 13.** *If A is a symmetric equilibrium then it is non-redundant.*

Proof. Because of Lemma 10 it is sufficient to consider only the case where $\texttt{success}(A) = 1$. Let $T' = \min\{M, T\}$, and assume by contradiction that A is redundant. Thus there is some $t \leq T'$ where $\sum_x A(x,t) < 1$. Hence, $\sum_{s \leq T'} \sum_x A(x,s) < T'$. Therefore, there is some x such that $\sum_{s \leq T'} A(x,s) < 1$ and so $\sum_{s \leq t} A(x,s) < 1$. As $\texttt{success}(A) = 1$, there is some $t' > t$ such that $A(x,t') > 0$. Define $A' = A + \epsilon(\delta_{x,t} - \delta_{x,t'})$. Taking $\epsilon > 0$ small enough, A' is doubly-substochastic. Also, $U_A(A') - U_A(A) = \epsilon(v_A(x,t) - v_A(x,t'))$, which is strictly positive by Lemma 12. Contradicting the fact that A is an equilibrium. ◀

3.2 Greedy Strategies

▶ **Lemma 14.** *A non-redundant strategy A is greedy w.r.t. $\mathbb{P}$ at time t iff for every x and y, if $A(x,t) > 0$ and $v_{\mathbb{P}}(x,t) < v_{\mathbb{P}}(y,t)$ then $\widetilde{A}(y,t) = 0$.*

The lemma above gives a useful equivalent definition for greediness. We can then prove:

▶ **Theorem 2.** *For every policy C there exists a non-redundant sgreedy strategy. Moreover, all such strategies are equivalent and are symmetric $(1 + C(k))$-equilibria.*

Proof. See the full version for a proof for the existence of a strategy A that is non-redundant and sgreedy. We prove here that such a strategy is a $(1 + C(k))$-equilibrium. Consider a strategy B. We compare the utility of B to that of A when both play against $k-1$ players playing A. By non-redundancy, all of $v_A(x,t)$ are 0 when $t > M$, and so we can assume $T \leq M$.

Denote $\texttt{maxv}(t) = \max_x v_A(x,t)$. Since the utility of B in any round t is a convex combination of $v_A(x,t)$, we have $U_A(B,t) \leq \texttt{maxv}(t)$. We say that A *fills* box x at round t if $A(x,t) > 0$ and $\widetilde{A}(x,t) = 0$. The following four claims hold for any round t:

1. If A does not fill any box at round t then $U_A(A,t) = \texttt{maxv}(t)$. This is because $U_A(A,t)$ is a convex combination of $v_A(x,t)$ for the boxes where $A(x,t) > 0$, which by the characterization of greediness in Lemma 14, all have the same value at time t.
2. $U_A(A,1) = \texttt{maxv}(1)$. Why? if no box is filled in round 1, then Item 1 applies. Otherwise, for some box x, $A(x,1) = 1$, and all other boxes have $A(\cdot,1) = 0$. The result follows again by Lemma 14.
3. For any $s < t$, $U_A(A,s) \geq \texttt{maxv}(t)$. We prove this by showing that for every x, $U_A(A,s) \geq v_A(x,t)$. If $v_A(x,t) = 0$, then the claim is clear. Otherwise, $A(x,t) > 0$ or $\widetilde{A}(x,t) > 0$ or both. Either way, $\widetilde{A}(x,s) > 0$. Therefore, as A is sgreedy, for every y such that $A(y,s) > 0$, $v_A(y,s) \geq v_A(x,s) \geq v_A(x,t)$. The last inequality follows from monotonicity, i.e., Lemma 12. As $v_A(A,s)$ is a convex combination of such y's we conclude.
4. If A fills box x at time $t > 1$ then for any $s < t$, $v_A(x,t) \leq C(k)v_A(x,s)$. To see why, first note that $v_A(x,s) \geq f(x)C(1)\widetilde{A}(x,s)^{k-1} = f(x)\widetilde{A}(x,s)^{k-1}$. On the other hand, since $\widetilde{A}(x,t) = 0$, $v_A(x,t) = f(x)C(k)A(x,t)^{k-1} \leq f(x)C(k)\widetilde{A}(x,s)^{k-1}$, because $A(x,t) \leq \widetilde{A}(x,t-1) \leq \widetilde{A}(x,s)$. Combining the above two inequalities gives the result.

Denote by X_1 the set of rounds for which there is no box x that is filled by A. Let X_2 be the rest of the rounds, except for $t = 1$ which is in neither. Also denote $t_0 = \min X_2$, and $t_1 = \max X_2$. Since $U_A(B) \leq \sum_t \texttt{maxv}(t)$, by Items 1,2 and 3 above,

$$U_A(B) \leq \sum_{t \in X_1 \cup \{1\}} U_A(A,t) + \texttt{maxv}(t_0) + \sum_{t \in X_2 \setminus \{t_1\}} U_A(A,t) \leq U_A(A) + \texttt{maxv}(t_0).$$

We conclude by using Items 4 and 2 and showing:

$$\texttt{maxv}(t_0) = \max_x v_A(x,t_0) \leq \max_x C(k)v_A(x,1) = C(k)U_A(A,1) \leq C(k)U_A(A). \qquad \blacktriangleleft$$

In the full version we provide an example showing that in the sharing policy, a non-redundant sgreedy strategy is not necessarily at equilibrium. On the other hand, it is worth noting that for any policy, the existence of a symmetric equilibrium follows from [23], and for $C(k) = 0$ we can get a full characterization of such equilibria:

▷ Claim 15. For any policy such that $C(k) = 0$, all symmetric equilibria are equivalent.

Interestingly, this result does not extend to non-symmetric profiles even for the exclusive policy, as is demonstrated by the following example of a non-greedy non-redundant equilibrium. Consider three players and two rounds. $f(1) = f(2) = f(3) = (1-\epsilon)/3, f(4) = \epsilon$, for some small positive ϵ. Player 1 plays first 4 and then 1. Player 2 plays 2 and then 3, and player 3 plays 3 and then 2. This can be seen to be an equilibrium, yet player 1 is not greedy.

Finally, the proof of Theorem 4, which shows how to construct an approximate equilibrium in polynomial time, is presented in the full version of the paper. This proof involves defining notions of approximate greediness and non-redundancy, proving an equivalent of Theorem 2 for them, and then using bounds on the rate of change that $v_A(x,t)$ goes through as a function of $A(x,t)$. This allows us to polynomially find an approximate sgreedy and non-redundant matrix, thus giving a polynomial strategy with our use of the Birkhoff von-Neumann theorem (see the full version).

4 The Exclusive Policy

Missing proofs of this section appear in the full version of this paper. There, we first prove that under the exclusive policy, $A^\star$ is sgreedy and non-redundant. Hence, according to Theorem 2,

▶ **Theorem 5.** *Under the exclusive policy, Strategy $A^\star$ of [8] is a symmetric equilibrium.*

According to Claim 3 all symmetric equilibria under the exclusive policy are equivalent, and thus equivalent to $A^\star$. Hence, the optimality of $A^\star$ (w.r.t. symmetric profiles) implies that both the PoSA and PoSS of the exclusive policy are optimal. That is, for every f, T, and policy C,

$$\texttt{PoSA}(C_{\texttt{ex}}, f, T) = \texttt{PoSS}(C_{\texttt{ex}}, f, T) \leq \texttt{PoSS}(C, f, T).$$

Our next goal is to establish the PoA of the exclusive policy. For this purpose, we first prove that the success probability of any equilibrium is at least as large as that of any symmetric profile. Since $A^\star$ is a symmetric equilibrium, its optimality among symmetric profiles follows. Hence, the proof provides as alternative proof to the one in [8].

▶ **Theorem 6.** *Consider the exclusive policy. For any profile $\mathbb{P}_{\texttt{nash}}$ at equilibrium and any symmetric profile A, $\texttt{success}(\mathbb{P}_{\texttt{nash}}) \geq \texttt{success}(A)$.*

Proof. Let A be a strategy and $\mathbb{P}_{\texttt{nash}}$ be a profile at equilibrium with respect to $C_{\texttt{ex}}$. If $\texttt{success}(\mathbb{P}_{\texttt{nash}}) = 1$, then the inequality is trivial. According to Lemma 10, we can therefore assume that all players of $\mathbb{P}_{\texttt{nash}}$ are non-redundant and that $T \leq M$. Denote the probability of visiting x in profile $\mathbb{P}$ by

$$\texttt{success}(\mathbb{P}, x) = 1 - \prod_{B \in \mathbb{P}} \widetilde{B}(x, T).$$

We say that box x is *high* with respect to a profile $\mathbb{P}$ if $\texttt{success}(\mathbb{P}, x) > \texttt{success}(A, x)$, *low* if $\texttt{success}(\mathbb{P}, x) < \texttt{success}(A, x)$, and *saturated* if they are equal. The next lemma uses the fact that A is symmetric.

▶ **Lemma 16.** *If a profile $\mathbb{P}$ is non-redundant and contains no high boxes, then all boxes are saturated.*

We proceed to prove a weak greediness property for equilibria. Denote a box x *full* for player B if $\sum_t B(x,t) = 1$. Also, for readability of what follows, when $\mathbb{P}$ is clear from the context, we shall denote $v_B(x,t) = v_{\mathbb{P}-B}(x,t) = f(x) \cdot \prod_{A \in \mathbb{P} \setminus \{B\}} \widetilde{A}(x,t)$.

▶ **Lemma 17.** *Consider a profile $\mathbb{P}_{\texttt{nash}}$ at equilibrium. For every $B \in \mathbb{P}_{\texttt{nash}}$ and t, x, y such that y is not full in B, if $B(x,t) > 0$ then $v_B(x,t) \geq v_B(y,t)$.*

Proof. Assume otherwise. Define an alternative matrix B' for player B, as $B' = B + \epsilon(\delta_{y,t} - \delta_{x,t})$. For a sufficiently small $\epsilon > 0$, B' is a doubly-substochastic matrix because y is not full in B. Then, $U_{\mathbb{P}^{-B}_{\texttt{nash}}}(B') - U_{\mathbb{P}^{-B}_{\texttt{nash}}}(B) = \epsilon(v_B(y,t) - v_B(x,t)) > 0$, in contradiction. ◀

Let us define a process that starts with the profile $\mathbb{P}_{\texttt{nash}}$ and changes it by a sequence of *alterations*, each shifting some amount of probability between two boxes. Importantly, we make sure that each alteration can only decrease the success probability. Hence, the proof is concluded once we show that the final profile has a success probability that is higher than that of A.

We first describe the alternations. Each alteration considers the current profile $\mathbb{P}$, and changes it to $\mathbb{P}'$. It takes some high box x, some low box y (both w.r.t. $\mathbb{P}$), and the maximal t such that there is a player $B \in \mathbb{P}$ with $B(x,t) > 0$. It defines $B' = B + \epsilon(\delta_{y,t} - \delta_{x,t})$, and lets the player that played B play B' instead. This ϵ is taken to be the largest so that x does not become low, y does not become high, and such that $\epsilon \leq B(x,t)$, so that the entries remain non-negative. Note that B' is doubly sub-stochastic, because taking care that y remains low, also means that y's row in B' still sums to less than 1.

After this alteration, either x is saturated, y is saturated, or $B'(x,t) = 0$. Clearly, in a finite number of alterations a profile $\mathbb{P}_{\texttt{final}}$ is obtained, for which either no box is high or no box is low.

▶ **Lemma 18.** $\texttt{success}(\mathbb{P}_{\texttt{final}}) \geq \texttt{success}(A)$.

Proof. By Lemma 16, $\mathbb{P}_{\texttt{final}}$ can only contain high and saturated boxes, that is, for every x, $\texttt{success}(\mathbb{P}_{\texttt{final}}, x) \geq \texttt{success}(A, x)$. However, $\texttt{success}(\mathbb{P}) = \sum_x f(x)\,\texttt{success}(\mathbb{P}, x)$, and so $\texttt{success}(\mathbb{P}_{\texttt{final}}) \geq \texttt{success}(A)$. ◀

Lastly, the following lemma concludes the proof of Theorem 6.

▶ **Lemma 19.** *An alteration can only decrease the probability of success.* ◀

Since $A^\star$ is a symmetric equilibrium, we immediately get that for every f and T, the PoA is attained by $A^\star$, that is, $\texttt{PoA}(C_{ex}, f, T) = \max_{\mathbb{P} \in \mathcal{P}(T)} \texttt{success}(\mathbb{P})/\texttt{success}(A^\star)$. Since $A^\star$ has the best success probability among symmetric profiles, and that every policy has some symmetric equilibrium, we get Corollary 7. To make this more concrete, we show that in the worst case,

▶ **Theorem 8.** *For every T, $\sup_f \texttt{PoA}(C_{\texttt{ex}}, f, T) = (1 - (1 - 1/k)^k)^{-1}$.*

Note that as k goes to infinity the PoA converges to $e/(e-1) \approx 1.582$.

5 Future Work and Open Questions

In [8], the main complexity measure was actually the running time and not the success probability. Our results about equilibria are also relevant to this measure, but the social gain is different. For example, it is still true that $A^\star$ is an equilibrium under the exclusive policy, and that all other symmetric equilibria in the exclusive policy are equivalent to it. As $A^\star$ is optimal among symmetric profiles w.r.t. the running time, the PoSA of $C_{\texttt{ex}}$ is equal to the PoSS, and it is also the best among all policies. Furthermore, importing from [8], we know that the PoSA (w.r.t. the running time) is about 4. However, showing the analogue of

Corollary 7, namely, that the PoA of $C_{\mathtt{ex}}$ is that achieved by $A^\star$, seems difficult, especially because general equilibria are not necessarily greedy. Moreover, the results of Vetta [31] do not apply when analyzing the running time, and finding the PoA, PoSA, and PoSS of the sharing policy, for example, remains open.

Another interesting variant would be to consider feedback during the search. For example, assuming that a player visiting a box x knows whether or not other players were there before. Such a feedback can help in the case that the players collaborate [5], but seems to significantly complicate the analysis in the game theoretic variant.

Finally, we would like to encourage game theoretical studies of other frameworks of collaborative search, e.g., [4, 6, 7, 15].

Abstract

Counting the number of nodes in Anonymous Dynamic Networks is enticing from an algorithmic perspective: an important computation in a restricted platform with promising applications. Starting with Michail, Chatzigiannakis, and Spirakis [18], a flurry of papers sped up the running time guarantees from doubly-exponential to polynomial [16]. There is a common theme across all those works: a distinguished node is assumed to be present, because Counting cannot be solved deterministically without at least one.

In the present work we study challenging questions that naturally follow: how to efficiently count with more than one distinguished node, or how to count without any distinguished node. More importantly, what is the minimal information needed about these distinguished nodes and what is the best we can aim for (count precision, stochastic guarantees, etc.) without any. We present negative and positive results to answer these questions. To the best of our knowledge, this is the first work that addresses them.

1 Introduction

The recent excitement around the problem of *Counting*, i.e., computing the number of nodes of an Anonymous Dynamic Network (ADN) comes as no surprise. On one hand, knowing the number of processors is a fundamental requirement to decide termination in a myriad of distributed algorithms. On the other hand, ADN is a very restrictive scenario from an algorithmic perspective: network nodes do not have identifiers and communication links may change arbitrarily and continuously over time. The combination of an important problem with harsh computational conditions is any algorithmist's delight.

Node anonymity in ADNs is motivated by expected applications of such communication infrastructure. For instance, in ad-hoc networks embedded in the Internet of Things, nodes may have to be deployed in a massive scale, and having unique identifiers may simply be impractical or inconvenient. Moreover, low node-cost expectations may introduce uncertainty about the number of nodes that will effectively startup. Hence, the need of Counting.

Strikingly, the progress on deterministic Counting speed-ups over various works ranged over a broad spectrum: from unbounded [11, 12] to polynomial time [16], going through doubly-exponential [11] and exponential time [10, 7]. In all that fruitful work, the ADN model has been equipped with one distinguishable node[1]. The assumption is well motivated: in a seminal paper [18], it was shown that, without at least one such node, Counting cannot be solved deterministically. But what if we have more than one special node? Do these nodes really need to be *special*? In other words, is it enough to put one of two different programs on each of the nodes, that otherwise are all identical? Moreover, can we let the nodes choose at random which program to run and have no special nodes? To the best of our knowledge, this is the first work that considers these questions.

As the more general case where all nodes are identical, only differentiated by the program they run, let the set of n network nodes be formed by ℓ *black* nodes (the "special" ones) and $n - \ell$ *white* nodes (the "regular" ones). **Our first contribution** is negative results. On one hand, if ℓ is unknown, Counting cannot be solved deterministically. On the other hand, for randomized Counting algorithms, we show that if ℓ is unknown or zero, there exist executions when the algorithm does not stop.

Even knowing how many black nodes are in the network, straightforward application of previous ideas for Counting is not clear. Indeed, each black node may carry its own count, but how do we combine or compare final counts? Even passing messages among black nodes is challenging, because black nodes are also indistinguishable among them and communication links change arbitrarily. For instance, a black node is not able to tell whether a received message is even its own, coming back after being previously sent for dissemination.

Our second contribution is a deterministic Counting protocol that computes exactly the number of network nodes. Our protocol uses no information about the network, except the number of black nodes $\ell \geq 1$. After completing its execution, all nodes obtain the exact size of the network and stop. Moreover, they stop all at the same time, allowing the algorithm to be concatenated with other computations.

This protocol resembles our Methodical Counting protocol presented in [16]. So, we call it Methodical multi-Counting (MMC). However, it is not a simple combination of multiple instances of Methodical Counting to handle multiple black nodes. We overcome the challenge of how to combine the actions of multiple indistinguishable black nodes by careful design of a set of alarms, so that *all* black nodes can simultaneously detect when a running estimate of the size is correct. Moreover, the asymptotic performance of MMC is $O(n^{4+\epsilon}(\log^3 n)/\ell)$, for an arbitrarily small $\epsilon > 0$. This is a speed-up by a factor arbitrarily close to $n\ell/\log n$ with respect to Methodical Counting. That is, even for $\ell = 1$, MMC is faster than the best previous work.

In face of the impossibility of deterministic Counting without a distinguished node [18], an enticing question is what is possible introducing randomness. **Our third contribution** is a Counting protocol that computes exactly the number of nodes in an ADN where $\ell = 0$ (no special nodes). That is, we show that randomness breaks the impossibility result of [18], and for the first time it is possible to consider an ADN model where *all* nodes are identical, indistinguishable, and run the same program. Our protocol, called Leader-less Methodical Counting (LLMC), is Monte Carlo; i.e., there is a small probability $\epsilon > 0$ of obtaining the wrong size, and the running time of $O(n^{4+\epsilon} \log^3 n)$ holds with probability $1 - \epsilon$.

[1] Exactly one, usually called *leader*. We refrain from using the name leader to avoid confusion: in our model we may have more than one, and in our algorithm they are not going to select a single one among them. Moreover, they cannot even be local leaders, because due to ADN's dynamicity they may all be connected being their own (local) leaders.

To the best of our knowledge, this is the first comprehensive study of Counting in ADNs where ℓ may be different than one.

2 Previous Work

A comprehensive overview of work related to ADNs can be found in a survey by Casteigts et al. [5] and references in the papers cited here.

With respect to lower bounds, it was proved in [9] that at least $\Omega(\log n)$ rounds are needed, even if D is constant. Also, $\Omega(\mathcal{D})$ is a lower bound since at least one node needs to hear about all other nodes to obtain the right count.

Counting and *Naming* was already studied in [18] for dynamic and static networks, showing that it is impossible to solve Counting without the presence of a distinguished node, even if nodes do not move. The Counting protocol requires knowledge of an upper bound on Δ, and obtains only an upper bound, which may be as bad as exponential.

Conscious Counting [11] computes the exact count, but it needs to start from an upper bound, and it takes exponential time only if the size upper bound is tight. In the same work and follow-up papers [12, 13], more challenging scenarios where Δ is unknown are studied, but protocols either do not terminate [11], or the protocol is terminated heuristically [13]. In experiments [13], such heuristic was found to perform well on dense topologies, but for other topologies the error rate was high. Another protocol in [12] is shown to terminate eventually, without running-time guarantees and under the assumption of having for each node an estimate of the number of neighbors in each round. In [18] it was conjectured that some knowledge of the network such as the latter would be necessary, but the conjecture was disproved later in [10]. On the other hand the protocol in [10] requires exponential space.

Incremental Counting, presented recently in [19], reduced exponentially the best-known running time guarantees. The protocol obtains the exact count, all nodes terminate simultaneously, the topology dynamics is only limited to 1-interval connectivity, it only requires polynomial space, and it only requires knowledge of the dynamic maximum degree Δ. The running time is still exponential, but reducing from doubly-exponential was an important step towards understanding the complexity of Counting.

In a follow-up paper [6], Incremental Counting was tested experimentally showing a promising polynomial behavior. The study was conducted on pessimistic inputs designed to slow the convergence, such as bounded-degree trees rooted at the leader uniformly chosen at random for each round, and a single path starting at the leader with non-leader nodes permuted uniformly at random for each round. The protocol was also tested on static versions of the inputs mentioned, classic random graphs, and networks where some disconnection is allowed. The results exposed important observations. Indeed, even for topologies that stretch the dynamic diameter, the running times obtained are below Δn^3. It was also observed that random graphs, as used in previous experimental studies [13], reduce the convergence time, and therefore are not a good choice to indicate worst-case behavior. These experiments showed good behavior even for networks that sometimes are disconnected, indicating that more relaxed models of dynamics, such as (α, β)-connectivity [14, 15], are worth to study.

All in all, the experiments in [6] showed that Incremental Counting behaves well in a variety of pessimistic inputs, but not having a proof of what a worst-case input looks like, and being the experiments restricted to a range of values of n far from the expected massive size of an ADN, a theoretical proof of polynomial time remained an open problem even from a practical perspective.

A polynomial Counting algorithm was presented in a manuscript [2], relying on the availability of an algorithm to compute average with polynomial convergence time. Such average computation is modeled as a Markov chain with underlying doubly-stochastic matrix, which requires topology information within two hops (cf. [21]). In the pure model of ADN, such information is not available, and gathering it may not be possible due to possible topology changes from round to round.

Recently, we presented the first polynomial-time deterministic Counting algorithm for ADNs in [16], called Methodical Counting. Unlike previous works, Methodical Counting does not require any knowledge of network characteristics, such as dynamic maximum degree or an upper bound on the size. That is, it works in the pure model of ADN. Like previous works, Methodical Counting requires the presence of a distinguished node. In the present work, we generalize that assumption assuming the presence of $\ell \geq 1$ distinguished nodes. As in [16], we leverage previous work on lazy random walks to analyze MMC, but the alarms to detect wrong computations had been completely re-designed to deal with multiple distinguished nodes. Moreover, with respect to Methodical Counting, MMC achieves a $\Omega((\log^2 n)/(n\ell))$ speed-up. That is, even for $\ell = 1$, MMC also provides a speed-up with respect to previous work.

In the same paper [16], we also presented extensions of Methodical Counting to compute more complex functions, such as the sum of input values held by nodes and other algebraic and Boolean functions.

With respect to randomized Counting, a linear Counting algorithm for dynamic networks was presented in [17]. The algorithm requires unique identifiers (i.e., it is not applicable to ADNs), knowledge of an upper bound on the size of the network, and only guarantees an approximation to the network size. To the best of our knowledge, no randomized Counting algorithms for ADNs have been studied before.

Other studies also dealing with the time complexity of information gathering exist [8, 3, 22, 4, 20, 23], but include in their model additional assumptions, such as the network having the same topology frequently enough or node identifiers.

3 Model, Problem, and Notation

We define the Counting problem as follows. An algorithm $\mathcal{A}$ solves the *Counting Problem* if, after completing its execution, all network nodes running $\mathcal{A}$ have obtained the size of the network and stop (not necessarily concurrently). Notice that we focus on *exact* Counting. That is, all nodes obtain the exact size of the network n, rather than an approximation as other works. We define now a class of Counting algorithms.

For a given algorithm $\mathcal{A}$, let an *execution* of $\mathcal{A}$ be a sequence of steps of $\mathcal{A}$ followed in one of the possible sequence of choices made by $\mathcal{A}$. Let $\mathcal{X}(\mathcal{A})$ be the set of all possible executions of $\mathcal{A}$. An algorithm $\mathcal{A}$ is called *eventually stopping* if, for all $X \in \mathcal{X}(\mathcal{A})$, X has finite length.

We will model worst case scenarios assuming the presence of an adversary that controls the topology of the network. In particular, we consider the following adversaries.

Let the sequence $\mathcal{E} = \langle E_1, E_2, \dots \rangle$ be the sets of communication links of an ADN for time slots $t_1, t_2, \dots$. Consider the execution of an algorithm $\mathcal{A}$. We say that an adversary is *oblivious* if it determines the sequence $\mathcal{E}$ completely before the execution of $\mathcal{A}$ begins. On the other hand, we say that an adversary is *adaptive* if it determines the sequence $\mathcal{E}$ during the execution of $\mathcal{A}$, according to the actions of $\mathcal{A}$.

Notice that the distinction between oblivious and adaptive makes sense only for randomized algorithms, given that for deterministic algorithms the actions of the algorithm are defined before the execution.

The following model is customary in the ADNs literature. We consider a network composed by a set V of $n > 1$ network *nodes* with processing and communication capabilities. It was shown in [18] that Counting cannot be solved in Anonymous Networks without the availability of at least one distinguished node in the network. Hence, all previous studies of Counting in ADNs included in the model the presence of such node called the *leader*. However, to the best of our knowledge, nothing is known about deterministic Counting in presence of *multiple* distinguished nodes. In this work, we generalize the ADN model assuming that the number of distinguished nodes is $\ell \geq 1$. Aside from the distinction between distinguished and not-distinguished, all nodes are indistinguishable within their group; we call them black nodes and white nodes resp. All black nodes execute exactly the same program, and all white nodes execute exactly the same program. That is, there are no identifiers that allow to distinguish one black (resp. white) node from another black (resp. white) node. (Although we label the nodes throughout the paper for the sake of presentation and analysis.)

Each pair of nodes that are able to communicate define a communication *link*, and the set of links is called the *topology* of the network. The nodes in a communication link are called *neighbors*. The event of sending a message to neighbors is called a *broadcast* or *transmission*. Nodes and links are reliable, in the sense that no communication or node failures occur. Hence, a broadcasted message is received by all neighbors. Moreover, links are *symmetric*, that is, if node a is able to send a message to node b, then b is able to send a message to a.

Without loss of generality, we discretize time in *rounds*. In any given round, a node may broadcast a message, receive all messages from broadcasting neighbors, and carry out some computations, in that order. Time needed for computations is assumed negligible and the size of messages is unbounded.

The set of links among nodes may change from round to round, and nodes have no way of knowing which were the neighbors they had before. These topology changes are arbitrary, limited only to maintain the network connected in each round. That is, at any given round the topology is such that there is a *path*, i.e., a sequence of links, between each pair of nodes, but the set of links may change arbitrarily from round to round. This adversarial model of dynamics is known as 1-*interval connectivity* in [17].

The following notation will be used. The maximum number of neighbors that any node may have at any given time, called the *dynamic maximum degree*, is denoted as Δ or $d_{\max}$ indistinctively. The maximum length of a path between any pair of nodes at any given time is called the *dynamic diameter* and it is denoted as D. The maximum length of an opportunistic path between any pair of nodes over many time slots is called the *chronopath* [14] and it is denoted as $\mathcal{D}$.

4 Impossibility of Counting

Note that the results of this section hold even for static anonymous networks. The proofs of the following lemmas are left to the full version of this paper for brevity.

▶ **Lemma 1.** *For every positive integer ℓ there are two networks of $\ell + 4$ and $2(\ell + 4)$ nodes, respectively, such that:*

- **(i)** *no deterministic algorithm could successfully accomplish Counting on both of them in finite time, even if some ℓ nodes are black in the former and 2ℓ nodes are black in the latter network.*
- **(ii)** *for any randomized algorithm there is an execution in which no node outputs a correct count in a finite time, if no node is initially black in any of them or even if some ℓ nodes are black in the former and 2ℓ nodes are black in the latter network.*

The following results follow immediately from the lemma.

▶ **Theorem 2.** *If the number of black nodes is not given as a parameter, then there is no deterministic algorithm accomplishing Counting in finite time in ADNs.*

▶ **Theorem 3.** *If the number of black nodes is not given as a parameter or if there is no black node, then for every randomized algorithm there is an execution in which no node outputs correct node count in finite time in some fixed anonymous networks.*

▶ **Corollary 4.** *If there is no black node or their number is not explicitly known to the nodes, there is no eventually stopping randomized algorithm accomplishing Counting in ADNs even with approximation smaller than $\sqrt{2}$ and even against an oblivious adversary.*

Since there is no eventually stopping PTAS algorithm for Counting if the exact number of black nodes is unknown or (in case of randomized algorithms) there is no black node, we pursue two directions. One is to design a polynomial-time deterministic algorithm for exact Counting if the exact number of black nodes is apriori known. The other direction is to design a randomized algorithm computing the exact number of nodes with an arbitrary probability $1 - \epsilon$, for any $\epsilon \in (0, 1)$, even in scenario when no node is black prior the computation. The latter algorithm is polynomial in the sense of expected number of rounds and also holds with high probability (i.e., probability polynomially close to 1 in terms of n).

Remark: the inapproximability result could be extended from $\sqrt{2}$ to *any* constant by considering networks with $c \cdot (\ell + 4)$ nodes, for an arbitrary constant c instead of $c = 2$ used in the above proofs for the ease of arguments.

5 Methodical multi-Counting

In this section we present MMC. For brevity, we give the intuition of the algorithm, leaving the pseudocode to the full version of this paper.

Initially, each of the ℓ black nodes is assigned a potential of 0 and each of the $n - \ell$ white nodes is assigned a potential of ℓ. Then, the algorithm is composed by epochs, each divided into phases composed by rounds of communication. Epoch k corresponds to a size estimate k that is iteratively updated from epoch to epoch until the correct value n is found. Each epoch is divided into p phases. The purpose of each phase is for the black nodes to collect as much potential as possible from white nodes in a mass-distribution fashion as follows.

Each phase is composed by r rounds of communication. In each round, each node broadcasts its potential and receives the potential of all its neighbors. Each node keeps only a fraction $1/d$ of the potentials received. The parameters p, r, and d are functions of k. The specific functions needed to guarantee correctness and saught efficiency are defined in Theorem 14. This varying way of distributing potential is different from previous approaches using mass distribution. After communication, each node updates its own potential accordingly. That is, it adds a fraction $1/d$ of the potentials received, and subtracts a fraction $1/d$ of the potential broadcasted times the number of potentials received. Then, a new round starts. At the end of each phase, each black node "consumes" its potential. That is, it increases an internal accumulator ρ with its current potential, which is zeroed for starting the next phase.

The correctness (or incorrectness) of the estimate is detected by various alarms as follows. A node stops the update of potential described, raises its potential to ℓ, and broadcasts an alarm status "low" in each round until the end of the epoch if any of the following happens: 1) at the end of the first phase its potential is above some threshold τ as defined

in Theorem 14, 2) at any round it receives more than $d-1$ messages, or 3) at any round receives an alarm status "low" from one of its neighbors. Case 1) allows the black nodes to detect that the estimate is wrong when $k^{1+\epsilon} < n$ for some $\epsilon > 0$ (Lemmas 10 and 12), case 2) allows the black nodes to detect that d is too small and hence the estimate is low, and case 3) allows dissemination of these alarms. (In "low" status the potential is set to ℓ to facilitate the analysis, but it is not strictly needed by the algorithm.)

At the end of each epoch, each black node checks the value of ρ and updates its status accordingly. If it is within some range, call it Γ, the current estimate is correct and each black node changes its status to "done". Otherwise, the estimate is incorrect. If ρ is below (resp. above) Γ each black node changes its status to "high" (resp. "low") indicating that the estimate is too big (resp. "low"). The case when ρ is below (resp. above) Γ allows to detect when $k > n$ (resp. $k < n \leq k^{1+\epsilon}$) (c.f. Lemmas 7 and 13 respectively.).

After black nodes update their status, the network is flooded with it for k rounds. If $k \geq n$, those rounds are enough for all white nodes to receive the "done" or "high" status. If they receive "done", after completing the k rounds all nodes stop. Otherwise, after completing the k rounds all nodes update k according to status to start a new epoch. If k has not been detected to be greater than n since the computation started, it is doubled for the next epoch, otherwise it is updated as in binary search.

5.1 Analysis of Methodical multi-Counting

In this section we analyze MMC. We use standard notations $\mathbf{I}$ for the unit vector, and L_p for the norm of vector $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ as $||\mathbf{x}||_p = \left(\sum_{i=1}^{n} |x_i|^p\right)^{1/p}$, for any $p \geq 1$. Only for the analysis, nodes are labeled as $0, 1, 2, \ldots, n-1$. The potential of a node i at the beginning of round s of phase t is denoted as $\Phi_{s,t}[i]$, the potential of all nodes is denoted as a vector $\mathbf{\Phi}_{s,t}$, and the aggregated potential is then $||\mathbf{\Phi}_{s,t}||_1$. The subindices s, t, or both are omitted sometimes for clarity. We will refer to the potential right after the last round of a phase as $\mathbf{\Phi}_{r+1}$. Such round does not exist in the algorithm, but we use this notation to distinguish between the potential right before black nodes consume their own potential and the potential at the beginning of the first round of the next phase.

First, we provide a broad description of our analysis of MMC. Consider the vector of potentials $\mathbf{\Phi}_i$ held by nodes at the beginning of any given phase i. The way that potentials are updated in each round is equivalent to the progression of a d-lazy random walk on the evolving graph underlying the network topology [1], where the initial vector of potentials is equivalent to an initial distribution $\mathbf{\Pi}_i$ on the overall potential $||\mathbf{\Phi}_i||_1$ and the probability of choosing a specific neighbor is $1/d$.

Note that MMC is not a simple "derandomization" of the lazy random walk on evolving graphs. First, in the Anonymous Dynamic Network model neighbors cannot be distinguished, and even their number is unknown at transmission time (only at receiving time the node learns the number of its neighbors). Second, due to unknown network parameters, it may happen in an execution of MMC that the total potential received could be bigger than 1. Third, our algorithm does not know a priori when to terminate and provide a result even with some reasonable accuracy, as the formulas on mixing and cover time of lazy random walks depend on the (a priori unknown) number of nodes n. Nevertheless, we can still use some results obtained in the context of analogous lazy random walks in order to prove useful properties of parts of MMC, namely, some parts in which parameters are temporarily fixed and the number of received messages does not exceed parameter d.

It was shown in [1] that random walks on d-regular explorable evolving graphs have a uniform stationary distribution, and bounds on the mixing and cover time were proved as well. Moreover, it was observed that those properties hold even if the graph is not regular and d is only an upper bound on the degree.[2]

Thus, for the cases where d is an upper bound on the number of neighboring nodes, we analyze the evolution of potentials within each phase leveraging previous work on random walks on evolving graphs. Specifically, we use the following result which is an extension of Corollary 14 in [1].

▶ **Theorem 5** (Corollary 14 in [1]). *After t rounds of a $d_{\max}$-lazy random walk on an evolving graph with n nodes, dynamic diameter D, upper bound on maximum degree $d_{\max}$, and initial distribution $\mathbf{\Pi}_0$, the following holds.*

$$\left|\left|\mathbf{\Pi}_t - \frac{\mathbf{I}}{n}\right|\right|_2^2 \leq \left(1 - \frac{1}{d_{\max} D n}\right)^t \left|\left|\mathbf{\Pi}_0 - \frac{\mathbf{I}}{n}\right|\right|_2^2$$

In between phases, black nodes "consume" their potential, effectively changing the distribution at that point. Then, a new phase starts.

In MMC, given that d is a function of the estimate k, if the estimate is low, there may be inputs for which d is not an upper bound on the number of neighbors. We show in our analysis that in those cases the black nodes detect the error and after some time all nodes increase the estimate.

Structure of the proof

The proof of correctness is structured in the following cases, depending on the relation between the size estimate k and n. For some γ and ϵ, after completing an epoch with size estimate k, we prove that ρ, the potential accumulated by a black node, must be within the following ranges.

$$\begin{aligned}
k = n \quad &\Rightarrow \quad (k-\ell)\left(1 - \frac{1}{k^\gamma}\right) \leq \rho \leq (k-\ell)\left(1 + \frac{1}{k^\gamma}\right) && \text{(Lemma 6)} \\
k > n \quad &\Rightarrow \quad \rho < (k-\ell)\left(1 - \frac{1}{k^\gamma}\right) && \text{(Lemma 13)} \\
k < n \leq k^{1+\epsilon} \quad &\Rightarrow \quad \rho > (k-\ell)\left(1 + \frac{1}{k^\gamma}\right) && \text{(Lemma 7)}
\end{aligned}$$

For the remaining case when $k^{1+\epsilon} < n$, we prove first the following relation between $\Phi_{r+1,1}$, the potential of any node at the end of the first phase, and a threshold τ.

$$\begin{aligned}
k^{1+\epsilon} < n \quad &\Rightarrow \quad \Phi_{r+1,1} > \tau \text{ for at least one node} && \text{(Lemma 10)} \\
k \geq n \quad &\Rightarrow \quad \Phi_{r+1,1} \leq \tau \text{ for all nodes} && \text{(Lemma 11)}
\end{aligned}$$

Thus, if $k^{1+\epsilon} < n$, and only if $k < n$, there is at least one node with potential above τ, which moves to a status "low" and spreads this alarm. We complete the proof with the following.

$$k^{1+\epsilon} < n \quad \Rightarrow \quad \text{all nodes receive an alarm "low" during phase 2} \quad \text{(Lemma 12)}$$

[2] Their analysis relies on Lemma 12, which bounds the eigenvalues of the transition matrix as long as it is stochastic, connected, symmetric, and non-zero entries lower bounded by $1/d$. Those conditions hold for all the transition matrices, even if the evolving graph is not regular.

Analysis

We start the analysis considering the case $k = n$ in the following lemma. The proofs of the lemmata in this section are left to the full version of this paper for brevity.

▶ **Lemma 6.** *If $d \geq k = n$, for an ADN with $\ell < k$ black nodes, for any $\gamma > 0$ there is a $\alpha \geq \max\{2, 1 + \gamma + \log_k 3\}$ such that, after running the MMC protocol for $p \geq (2\gamma \ln k)/\left(\ell\left(\frac{1}{k} + \frac{1}{k^\alpha}\right)\right)$ phases, each of $r \geq 2\alpha d k^2 \ln k$ rounds, the potential ρ consumed by each of the ℓ black nodes is such that*

$$(k-\ell)\left(1 - \frac{1}{k^\gamma}\right) \leq \rho \leq (k-\ell)\left(1 + \frac{1}{k^\gamma}\right).$$

The previous lemma shows that, after running MMC enough time, if for some black node it is $\rho > (k-\ell)\left(1 + \frac{1}{k^\gamma}\right)$ or $\rho < (k-\ell)\left(1 - \frac{1}{k^\gamma}\right)$, for some $\gamma > 0$, we know that the estimate k is wrong. However, the complementary case, that is, $(k-\ell)\left(1 - \frac{1}{k^\gamma}\right) \leq \rho \leq (k-\ell)\left(1 + \frac{1}{k^\gamma}\right)$, may occur even if the estimate is $k \neq n$ and hence the error has to be detected by other means. To prove correctness in that case we further separate the range of k in three cases. The first one, when $k < n \leq k^{1+\epsilon}$, for some $\epsilon > 0$, in the following lemma, which is based on upper bounding the potential left in the system after running MMC long enough. To ensure that $d \geq \Delta + 1$, we restrict $d \geq k^{1+\epsilon}$.

▶ **Lemma 7.** *Under the following conditions $1 < k < n \leq k^{1+\epsilon} \leq d$, $\epsilon > 0$, after running the MMC protocol for $p \geq 2\delta(\ln k)/(\ell\left(1/n + 1/k^\beta\right))$ phases, each of $r \geq 2\beta d k^{2+2\epsilon} \ln k$ rounds, under the following conditions $\beta \geq \log_k(n(2k^\delta + 1))$, $\beta > 2$, $\delta > \log_k(nk^\gamma/(nk^\gamma - (n-1)(k^\gamma + 1)))$, and $\gamma > \log_k(n-1)$. Then, the potential ρ consumed by any black node is $\rho > (k-\ell)(1 + 1/k^\gamma)$.*

We now consider the case $k^{1+\epsilon} < n$. First, we prove the following two claims that establish properties of the potential during the execution of MMC. (Recall that we use round $r+1$ to refer to potentials at the end of the phase right before black nodes consume their potential.)

▷ Claim 8. Given an ADN of n nodes running MMC with parameter d, for any round t of the first phase, such that $1 \leq t \leq r+1$, if d was larger than the number of neighbors of each node x for every round $t' < t$, then $||\mathbf{\Phi}_t||_1 = (n-\ell)\ell$.

▷ Claim 9. Given an ADN of n nodes running MMC, for any round t of any phase and any node x, it is $0 \leq \Phi_t[x] \leq \ell$.

To show that if $k^{1+\epsilon} < n$ MMC detects that the estimate is low, we focus on the first phase. We define a threshold τ and a number of rounds such that, after the first phase is completed, some nodes will have potential above τ and this can happen only if the estimate is low. Then we show that black nodes receive an alarm indicating that.

First, we show an upper bound of at most $k^{1+\epsilon}$ nodes with potential at most τ at the end of the first phase (Lemma 10). Thus, given that $k^{1+\epsilon} < n$, we know that there is at least one node with potential above τ at the end of the first phase. Second, we show that if the estimate is not low, that is $k \geq n$, then all nodes have potential at most τ at the end of the first phase (Lemma 11). That is, a potential above τ can only happen when indeed the estimate is low. Finally, we show that if $k^{1+\epsilon} < n$ an alarm "low" initiated by nodes with potential above τ must be received after $k^{1+\epsilon}$ further rounds of communication (Lemma 12).

▶ **Lemma 10.** *For $\epsilon > 0$, after running the first phase of the MMC protocol, there are at most $k^{1+\epsilon}$ nodes that have potential at most $\tau = \ell(1 - \ell/k^{1+\epsilon})$.*

▶ **Lemma 11.** *If $k \geq n$, $r \geq (4 + 2\epsilon - 2\ln(k^\epsilon - 1)/\ln k)dk^2 \ln k$, and $\epsilon > 0$, given that $k > \ell \geq 1$, at the end of the first phase no individual node should have potential larger than $\tau = \ell(1 - \ell/k^{1+\epsilon})$.*

The previous lemma shows that, if the estimate is "not-low" ($k \geq n$), at the end of the first phase all nodes must have "low" potential ($\Phi_{1,r+1} \leq \tau$). (Notice the inverse relation between estimate and potential.) In the following lemma we show that if $k^{1+\epsilon} < n$ (i.e. low estimate) there are some nodes with $\Phi_{1,r+1} > \tau$ (i.e. high potential), and that all the other nodes will know this within the following phase.

▶ **Lemma 12.** *If $k^{1+\epsilon} < n$, $0 < \epsilon \leq 1 + \log_k 4d$, and $r \geq (4 + 2\epsilon - 2\ln(k^\epsilon - 1)/\ln k)dk^2 \ln k$, within the following $k^{1+\epsilon}$ rounds after the first phase of the MMC protocol, all black nodes have received an alarm status "low".*

Finally, in the following lemma we show that if $k > n$, black nodes detect that the potential consumed is too low for the estimate k to be correct.

▶ **Lemma 13.** *Under the following conditions $d > k > n > \ell > 0$, for $\beta \geq \log_k(n(2k^\delta - 1))$, $\delta > \log_k(k^\gamma(n-\ell)/(k^\gamma - (n-\ell) - 1))$, and $\gamma > \log_k(n - \ell + 1)$, after running the MMC protocol for p phases and r rounds such that $p \leq 2\delta \ln k(1 - \ell\left(\frac{1}{n} - \frac{1}{k^\beta}\right))/(\ell\left(\frac{1}{n} - \frac{1}{k^\beta}\right))$, and $r \geq 2\beta dk^2 \ln k$, the potential ρ consumed by any black node is $\rho < (k - \ell)\left(1 - \frac{1}{k^\gamma}\right)$.*

Based on the above lemmata, we establish the correctness and running time of MMC:

▶ **Theorem 14.** *Given an ADN with n nodes, which include ℓ black nodes such that $n > \ell \geq 1$ black nodes, after running MMC for each estimate $k = \ell+1, \ell+2, \ell+3, \ldots, n$ with parameters: $d = k^{1+\epsilon}$, $p = \left\lceil \frac{2\ln k}{\ell} \max\left\{ \frac{\gamma}{1/k+1/k^\alpha}, \frac{\delta}{1/d+1/k^\beta} \right\} \right\rceil$,*
$r = \left\lceil 2dk^2(\ln k) \max\left\{ \alpha, \beta k^{2\epsilon}, 2 + \epsilon - \frac{\ln(k^\epsilon - 1)}{\ln k} \right\} \right\rceil$, and $\tau = \ell\left(1 - \frac{\ell}{k^{1+\epsilon}}\right)$, under the following conditions: $\epsilon > 0$, $\alpha \geq 1 + \gamma + \log_k 3$, $\beta \geq \log_k(d(2k^\delta + 1))$, $\gamma > \log_k(d-1)$, $\delta > \log_k \frac{dk^\gamma}{k^\gamma + 1 - d}$. Then, all nodes stop after at most $\sum_{k \in E \cup B}(pr + d)$ rounds of communication and output n, for $E = \{2^i(\ell+1) : i = 0, 1, \ldots, \log\lceil n/(\ell+1)\rceil\}$, and $B = \{(2^{\log\lceil n/(\ell+1)\rceil} - 2^i)(\ell+1) : i = 0, 1, \ldots, \log\lceil n/(\ell+1)\rceil - 2\}$.

▶ **Corollary 15.** *The time complexity of MMC on an ADN with ℓ black nodes and $n - \ell$ white nodes is $O\left(\frac{n^{4+\epsilon}}{\ell} \log^3 n\right)$, for any $\epsilon > 0$.*

6 Leader-less Methodical Counting

The main idea of LLMC (cf. Algorithm 1) is to consider consecutive powers of 2 as values of K, and for each such K to select black nodes locally with probability corresponding to the inverse of K and run MMC with $\ell = 1$. If $K \geq n$ and there is indeed one black node, MMC guarantees that all nodes find the proper count n of nodes and stop. There are however two problems: how to recognize if $K \geq n$ and what to do when there is no black node or at lest two black nodes. Algorithm LLMC overcomes these two issues implicitly, by combining the executions of MMC for consecutive powers of 2 with two other techniques:

- introducing parallel threads and carefully counting the number of threads with no black nodes recorded (locally) and requiring that their ratio is bigger than half (this is to recognize whether K is close to n with sufficiently high probability),
- making use of the fact that having more than one black node in the execution of MMC for $\ell = 1$ (as a subroutine of LLMC) cannot return an estimate bigger than as if it was run with one black node; therefore, taking the maximum of returned estimates over threads could mitigate the potential problem of more than one black node.

The main control parameter used in LLMC is K, which is an upper bound for estimates considered in one execution of the While loop (which we call epoch K). We start from sufficiently large K, to assure that starting from this value of K the chance of getting incorrect output or behavior of nodes (e.g., stopping at different times) is smaller than $\epsilon/2$ Within one While loop, we initiate $f(K)$ parallel threads and for each of them we select black nodes for the whole thread – trying to make sure that the chance of getting one black node is sufficiently large (we need it to argue about correct stopping), especially for $K \geq n$ (recall that we could not recognize for sure whether $K \geq n$ or not). Then in each thread independently we run MMC for $\ell = 1$ as a subroutine (hoping that we selected exactly one black node in the beginning of the loop), which checks all possible values of k from 1 to K to find a good estimate of n (i.e., we have to trim the execution of MMC to estimates $k \leq K$).

This approach does not work for $K < n$, as then the probability of getting more than one black node could be bigger than the one for one black node; however, we could eliminate such cases by monitoring the number of threads with no black node, which in case of $K < n$ should be compared with a large threshold (intuitively, we want LLMC to reach this threshold with high probability when K will be close to n). Note that a no-black-node thread will not output any estimate. If a thread identifies a good estimate, it puts it to the set *Count* and we do not enter the next iteration of While loop but stop, returning the maximum value in *Count* - this is to make preference to threads with one black node over those with more than one black node (we will argue that they could return values but not bigger than ones by threads with one black node).

Algorithm 1 LLMC algorithm. $\epsilon \in (0, 1)$.

procedure
  $K \leftarrow \lceil \lceil 12/(\epsilon) \rceil \rceil$ // $\lceil \lceil x \rceil \rceil$: the smallest power of 2 bigger than x
  $Count \leftarrow \emptyset$ // set of potentially "good" estimates computed in threads
  $EmptyThreads \leftarrow 0$ // number of threads with no black node detected
  while $Count = \emptyset$ or $EmptyThreads \leq f(K)/2$ **do**
    $Count \leftarrow \emptyset$, $EmptyThreads \leftarrow 0$
    $K \leftarrow 2K$
    Initiate $f(K) = 64\frac{\log(K/\epsilon)}{\log(e/(e-2))}$ parallel threads
     // parallel computation and messages sharing same resources/medium
    for each thread **do**
      for each node **do**
        Select to be a black node with probability $1/g(K)$, where $g(K) = K/2$
      end for
      $k \leftarrow MMC(K, 1)$ // refer to Algorithm 2
      if $k > 0$ **then**
        $Count \leftarrow Count \cup \{k\}$
      end if
      if no black node detected **then**
        Increase $EmptyThreads$ by 1
      end if
    end for
  end while
  return max($Count$) // Output the maximum number in $Count$ as the size n.
end procedure

Algorithm 2 Subroutine of LLMC.

Input: number of black nodes ℓ, max size estimate K.

procedure MMC (K,ℓ)
  Run MMC modified as follows:
    – Stop iterations when size estimate $k > K$
    – If estimate $k < K$, remain idle until end of phase K // `for synchronization`
    – Include a Boolean p_j in each node j as follows:
      – Initially:
        if node j is black **then** $p_j \leftarrow true$ **else** $p_j \leftarrow false$
      – In each iteration:
        Broadcast and Receive messages including p_j
        if $p_i = true$ received from some neighbor i **then** $p_j \leftarrow true$
  Upon completion:
    if $status = done$ **return** k **else return** 0
end procedure

6.1 Analysis of Leader-less Methodical Counting

We may assume that $n > 1$, otherwise the algorithm would easily recognize $n = 1$ by no received communication. Throughout the whole analysis we consider an adaptive adversary, as we allow network changes to be done online when viewing the whole history of the computation up to the current round.

We call an execution of the While loop for a fixed parameter K *epoch* K. Recall that K is a power of 2 bigger than $12/(\epsilon)$; by $\lceil\lceil x\rceil\rceil$ we denote the smallest power of 2 bigger than x.

Observe from the structure of the algorithm that nodes could only stop at the end of an epoch. In the analysis below, we will often prove some properties under condition that the stopping times are synchronized, i.e., either all nodes stop or none, and remove this assumption at the end of the analysis. That is, we will show that in fact all nodes synchronize their stopping time and output the correct value of n with desired probability at least $1 - \epsilon$. We also conjecture that all arbitrary constants in the algorithm, i.e., in the definition of starting value of K, functions $f(K)$ and $g(K)$, could be substantially lowered, as we set them high to avoid too many cases in the analysis (so making it focused on main arguments).

The proofs of the following lemmata are left to the full version of this paper for brevity.

▶ **Lemma 16.** *The probability that for some epoch K, where $K < n$, the value of EmptyThreads is bigger than $f(K)/2$ at any node is smaller than $1 - \epsilon/2$. Consequently, with probability at least $1 - \epsilon/2$: no node stops during epochs $K < n$.*

Recall from the description of the algorithm that nodes could only stop at the end of an epoch. We prove the following two structural properties of LLMC.

▶ **Proposition 17.** *Consider an epoch $K \geq n$ and assume that all nodes are active in the beginning of this epoch. If some nodes stop while some other do not at the end of epoch K, then there are more than $f(K)/2$ threads with no black node selected and no thread with exactly one black node.*

▶ **Proposition 18.** *Consider an epoch $K \geq n$ and assume that all nodes are active in the beginning of this epoch. If all nodes stop but some of them output incorrect value, then there are more than $f(K)/2$ threads with no black node and no thread with exactly one black node.*

We use these structural properties to estimate the probabilities of the two following events.

▶ **Lemma 19.** *Consider an epoch $K \geq n$ and assume that all nodes are active in the beginning of this epoch. The probability of event: in epoch K there will be some nodes that stop and some other that do not, or all nodes stop with incorrect output, is at most ϵ/K.*

▶ **Lemma 20.** *The probability of some nodes stopping at different times or outputting incorrect value is at most $\epsilon/2$.*

We now analyze good events of correct stopping by all nodes, moreover, simultaneously. We start from stating a structural property and follow with estimating of the probability of correct simultaneous stopping.

▶ **Proposition 21.** *For any epoch $K \geq n$, if all nodes are active in the beginning, the number of threads with no black node is bigger than $f(K)/2$ and there is at least one thread with one black node, then all threads with one black node store the same value in set Count and it is the biggest value stored in Count in this epoch.*

▶ **Lemma 22.** *Consider an epoch $K \geq n$ and assume that all nodes are active in the beginning of this epoch. The probability of event: in epoch K all nodes stop with correct value, is at least $1 - \exp(-f(K)/64) - \exp\left(-\frac{nf(K)}{g(K)e}\right)$.*

▶ **Corollary 23.** *Consider epoch $K = \lceil \lceil 8n \rceil \rceil$ and assume that all nodes are active in the beginning of this epoch. The probability of event: in epoch K all nodes stop with correct value, is at least $1 - \epsilon/n$.*

▶ **Theorem 24.** *For any given $\epsilon > 0$, LLMC simultaneously stops at all nodes returning correct count n of nodes in $O(n^4 \log^4 n)$ rounds, with probability at least $1 - \epsilon$, even when running against an adaptive adversary.*

7 Conclusions

This paper expanded the knowledge about feasibility of polynomial computations in anonymous dynamic environments/networks. In particular, counting-type computations can be done deterministically if symmetry is broken by existing a partition of nodes where the size of one subset is known. It is also feasible without any distinction between the nodes with an arbitrary probability. Natural open directions include a study of the message complexity of MMC and LLMC, randomized approximation solutions and extensions to other related models and problems, as well as deriving tighter upper and lower bounds in the considered setting.

Abstract

We study a process of *averaging* in a distributed system with *noisy communication*. Each of the agents in the system starts with some value and the goal of each agent is to compute the average of all the initial values. In each round, one pair of agents is drawn uniformly at random from the whole population, communicates with each other and each of these two agents updates their local value based on their own value and the received message. The communication is noisy and whenever an agent sends any value v, the receiving agent receives $v + N$, where N is a zero-mean Gaussian random variable. The two quality measures of interest are (i) the total sum of squares $TSS(t)$, which measures the sum of square distances from the average load to the *initial average* and (ii) $\bar{\phi}(t)$, which measures the sum of square distances from the average load to the *running average* (average at time t).

It is known that the simple averaging protocol – in which an agent sends its current value and sets its new value to the average of the received value and its current value – converges eventually to a state where $\bar{\phi}(t)$ is small. It has been observed that $TSS(t)$, due to the noise, eventually diverges and previous research – mostly in control theory – has focused on showing eventual convergence w.r.t. the running average. We obtain the first probabilistic bounds on the convergence time of $\bar{\phi}(t)$ and precise bounds on the drift of $TSS(t)$ that show that although $TSS(t)$ eventually diverges, for a wide and interesting range of parameters, $TSS(t)$ stays small for a number of rounds that is polynomial in the number of agents. Our results extend to the synchronous setting and settings where the agents are restricted to discrete values and perform rounding.

1 Introduction

We consider the problem of distributed averaging by a group of agents (*e.g.,* sensors), initialized with values that represent, for example, different temperature measurements. The agents' goal is to compute the average of all the initial values using the following simple dynamic: In each discrete round, two agents are drawn uniformly at random from the whole population, communicate their values to each other and set their new values to the average of their old value and the received value. Converging to the average plays a key role in many applications, e.g., for sensor networks [56, 50], social insects [10], and robotics [20, 30]. In all of these applications, the agents (sensors, ants, and robots) are very simple and are therefore limited in both memory and communication. Moreover, communication is often erroneouees.[1] This motivates the study of the aforementioned simple averaging dynamic in a setting where the agents only remember one value, do not use any additional memory, and the communication is subject to noise. We model the noise in the communication as follows: Whenever an agent sends any value v, the receiving agent receives $v + N$, where random variable N is distributed according to some zero-mean probability distribution $\aleph$, *e.g.,* a normal distribution. The agents update their values as follows: whenever two agents communicate, each agent sets its new value to the average of their old value and the received value; note that – due to the noise – the two agents might have distinct new values.

The values of the n nodes in step t of the process are denoted by $X_1^{(t)}, X_2^{(t)}, \ldots, X_n^{(t)}$. We consider the following models: (i) the *sequential setting* where one pair of agents is chosen uniformly at random and (ii) the *synchronous setting* where each agent is matched to exactly one other agent chosen uniformly at random. The two quality measures of the convergence used in this work are (i) the total sum of squares $TSS(t) = \sum_i (X_i^{(t)} - \varnothing^{(0)})^2$, where $\varnothing^{(0)} = \sum_i X_i^{(0)}/n$ is the initial average and (ii) the sum of squared distances to the running average $\bar{\phi}(t) = \sum_i (X_i^{(t)} - \varnothing^{(t)})^2$, where $\varnothing^{(t)} = \sum_i X_i^{(t)}/n$ is the *running average*. Our contributions can be informally summarized as follows:

- **(i)** We give, under mild assumptions on the noise, the first bounds on the convergence time of the running average $\bar{\phi}(t)$ in the noisy gossip-based communication setting. The bounds we obtain are – up to a constant factor – tight. In particular, the potential converges to a value that is linear in n and the second moment of the noise $\mathbb{E}\left[N^2\right]$; which is tight. So far it was only known that the process eventually converges to a state where $\bar{\phi}(t)$ is small (*e.g.,* [54]), but precise bounds were not known. (Theorem 1)
- **(ii)** We show that, in contrast to the current belief, one can hope to converge to the *initial* average in addition to convergence to the *running* average as long as the number of rounds are bounded: It was known that $TSS(t)$, due to the noise, eventually diverges (the running average diverges from the initial average) and for this reason related research – mostly in control theory – has focused on showing eventual convergence w.r.t. $\bar{\phi}(t)$; leaving $TSS(t)$ aside. Since we give precise bounds on the convergence time of the running average, we can show the following. Under mild assumptions on the noise, $TSS(t)$ converges to almost the same value as $\bar{\phi}(t)$ as long as the number of time steps t is bounded by $O(n^2)$, where n is the number of nodes. (Corollary 2)
- **(iii)** We pioneer in the discrete setting in which the agents can store only integer values and the noise is also an integer. In this setting the agents in our algorithm perform randomized rounding. We show that this only causes a negligible difference from the continuous case. (Corollary 3)

[1] Consult Subsection 1.1 for a more detailed review of these applications including the limitation of agents and further motivation. Subsection 1.1 also contains related work on the averaging protocol.

(iv) We study both the sequential and the synchronous setting and show that there is no significant difference (up to a scaling of time) between the models. (Corollary 4)
(v) We perform simulations in the setting where nodes are limited in storage, *i.e.,* they can only store values from a bounded range. This leads to a much faster (by order of magnitude) divergence between the running average and the initial average. Our simulations also seem to indicate strong bounds on the distribution of distances to the running average in our main model (unbounded values). (Section 5)

The convergence time of the averaging processes in the gossip-based communication setting *without* noise has been studied before (e.g., [37]). However, to the best of our knowledge, no bounds on the convergence time are known in the gossip-based communication setting with noise. We continue with a detailed motivation for studying noise in the simple averaging dynamic and related work.

1.1 Motivation and Related Work

Converging to the average plays a key role in many applications in which agents have limited computational and communication power, e.g.,

(i) sensor networks [56, 50]: here there is a wide range of application including terrain monitor applications [51], computing an average temperature, PIR sensors measuring the infrared light radiation emitted from objects, and many more applications. In such scenarios links are often faded [46, 14],
(ii) social insects: for ants, values could represent the individuals' different assessments of nest qualities when house hunting [10] or the deficit of workers at a given task [41], and
(iii) robotics [20, 30] and in particular memory-limited robots, *e.g.,* Kilobots exploring the percentage of white tiles in an area [21], or microbots measuring the concentration of chemicals.

In all of these applications the agents (representing sensors, ants or robots) are very simple and severely limited in both memory and communication. Moreover, the communication is often not only limited but also erroneous (e.g., consider wireless communication with obstacles between robots), or received messages are subject to interpretation (e.g., when insects communicate through gestures [39]). Motivated by this unreliable communication in applications we study the simple averaging dynamic where the communication is subject to noise.

We continue with related work. The problem of distributed values converging to the average (often without noise) has been studied in various areas reaching back to early versions studied in statistics [18, 26, 31]. However, to the best of our knowledge, none of the studied models match our model. We review the related work by areas:

(i) average consensus and its applications,
(ii) gossip-based communication models,
(iii) consensus protocols in population protocols,
(iv) biological distributed algorithms,
(v) noise and failures in sensor networks.

Average consensus and its applications. Consensus has been studied intensively in various settings in general network topologies, much of it under the name of *average consensus* [55, 53]. Most of this work is orthogonal to our work: First, due to the general network topology and the fact that, in each step of the studied algorithms, the agents update their values with a weighted average of all of their neighbors' values whereas in our averaging dynamic, an agent can only access a single other value per interaction. Second, while the

potential functions in these works and the noise, if any, are usually identically or similarly defined as in our work the main goal of these papers is – just as in the classic works – to study under which circumstances the processes eventually converge to a state with a small potential function [55], whereas we are interested in the number of interactions until our process obtains a small potential. Recent papers [45, 11, 40, 15] consider the convergence rate of the weighted averaging process, but only in the noiseless setting. Average consensus has also been studied in networks with time-varying topologies [44, 49]. Variants with noisy communication were studied [55, 36], but they only consider additive noise and assume it to be zero-mean with unit variance (as mentioned before, only convergence in the limit is shown). The noisy version of the problem also received ample attention in control theory [52, 48, 47]. Already in the early works on average consensus immediate applications of converging to the average were discovered and intensively studied, e.g., applications to load balancing between parallel machines [9, 17] or to coordinate distributed mobile agents [9, 34, 23]. For a more detailed overview on average linear consensus consult the survey [27].

Gossip-based communication models. Much closer to our work is the study of aggregating information in gossip-based model. In this model, each node can contact one of its neighbors in the network in each round and exchange information with it. Even though a node can be contacted by many neighbors in a single round, this model, if applied to the complete graph, is very similar to our synchronous model. On the complete graph [37] shows that $O(n \cdot \ln n)$ interactions are enough to approximate the average well with high probability. On the one hand they consider more general graphs (in some sense we consider the complete graph); on the other hand they do not consider noise, which simplifies their analysis of the convergence time significantly.

Consensus protocols in population protocols, biological distributed algorithms. Motivated by biological applications, population protocols have also been studied in the noisy setting in the context of biological distributed algorithms. The authors of [24] study rumor spreading and consensus in extremely faulty networks where a bit in a message can be flipped with probability $1/2 - \varepsilon$. This was later generalized in [25] to plurality consensus. The authors of [8] study the differences between pull and push rumor spreading in the noisy setting. Reaching consensus to an opinion in population protocols in the noiseless setting has received much attention (see *e.g.,* [4, 22, 1, 2, 5, 6, 19, 7, 38, 29, 28, 35]).

Noise and failures in sensor networks. The problem of converging to the average (and similar problems) have also been studied in (noisy) sensor networks [56, 50] where nodes again can interact with all their neighbors. In these networks another type of unreliable communication, i.e., packages might be dropped, has received ample attention, e.g., [12] studies the broadcast problem and [13] develops a framework to transform certain algorithms for failure free networks to also work in faulty sensor networks.

An interesting type of failure has been studied in [32]. There failures do not happen during the communication but the algorithm itself might be faulty, i.e., a state machine run at an agent might switch to a wrong state.

1.2 Formal Results

We now formally state our main theorems. For the ease of presentation, in the discussion we assume that noise is normally distributed with unit variance, $N \sim \mathcal{N}(0,1)$, but our results hold for general variance σ^2. Let $\phi_0 = \bar{\phi}(\mathbf{X}^{(0)})$ be the initial potential. Our first

theorem shows that the agents converge to a small value of $\bar{\phi}(t) = O(n)$ after parallel time[2] that is logarithmic in ϕ_0/n. In particular, if we use b to denote the initial imbalance ($b = \max_{i,j}\{x_i^{(0)} - x_j^{(0)}\}$), then it takes $O(\ln b)$ parallel steps for the potential to become $\bar{\phi}(t) = O(n)$. Note that $\bar{\phi}(t) = O(n)$ means that the "average" difference between the values of any two agents is constant and we show that the constant hidden in the O-notation is actually very small. It is worth mentioning that this is tight in two senses: (i) In expectancy we have $\bar{\phi}(t) = \Omega(n)$ for any fixed time step $t \geq n$, (i.e., after one parallel time step). Even in the case where all nodes initially have the same value, our results show that the potential increases after n interactions in expectation by $\Omega(n\mathbb{E}\left[N^2\right]) = \Omega(n)$. (ii) At least $\Omega(\ln b)$ parallel time steps are required[3] to decrease the potential to $O(n)$, since the potential only drops in expectation by a constant factor in each parallel step. The formal statement is as follows.

▶ **Theorem 1** (Convergence to Running Avg.). *Consider any noise-distribution $\aleph$ with (at least) exponential-decay[4]. Fix any $\delta \in \mathbb{R}$. Let $n = n(\delta)$ be large enough. The following hold:*

- **(i)** *for any $t = \Omega\left(n \ln\left(\frac{\phi_0}{\delta\sigma^2 n}\right)\right)$ with probability at least $1-\delta$ we have $\bar{\phi}(\mathbf{X}^{(t)}) = O(\sigma^2 n \ln(1/\delta))$,*
- **(ii)** *for any $t \geq n$ (parallel time) with constant probability we have $\bar{\phi}(\mathbf{X}^{(t)}) = \Omega(\sigma^2 n)$ and*
- **(iii)** *even without noise, for any $t = o\left(n \ln\left(\frac{\phi_0}{\sigma^2 n}\right)\right)$ we have $\mathbb{E}\left[\bar{\phi}(\mathbf{X}^{(t)})\right] = \omega(\sigma^2 n)$.*

While the above theorem shows a quick convergence to the running average, this does not imply convergence to the initial average. In fact, as time progresses the distance to the initial average ($TSS(\mathbf{X}^{(t)})$) is likely to increase. Nonetheless, in the case of the Gaussian white noise model we can bound the drift of the running average from the initial average in a time window of $O(n^2)$ steps (see Lemma 17). Theorem 1 roughly says that after at least $t = \Omega(n \log n)$ steps the distance to the running average is small if we start with a potential that is polynomial in n. Thus, as long as $t = \Omega(n \log n)$ and $t = O(n^2)$ we obtain $TSS(\mathbf{X}^{(t)}) = O(n)$. After the $O(n^2)$ step time window the potential starts to increase again, which, is unavoidable, due to the noise causing drift of the running average; in Gaussian white noise model, the running average after t steps diverges with constant probability from the initial average by $\frac{\sqrt{t}}{n}$ (Lemma 17). This in turn implies that $TSS(\mathbf{X}^{(t)}) \geq t/n$.

▶ **Corollary 2** ((Bounded) Divergence from Initial Avg.). *In the case of Gaussian white noise model, for any $\delta \in \mathbb{R}$ and large enough $n = n(\delta)$ and all $t = \Omega\left(n \ln\left(\frac{\bar{\phi}(\mathbf{X}^{(0)})}{\delta\sigma^2 n}\right)\right)$ we have*

- **(i)** *"non-divergence for $O(n^2)$ steps", i.e., $TSS(\mathbf{X}^{(t)}) = O\left(\left(\frac{t}{n} + n\right)\sigma^2 \ln(1/\delta)\right)$ with probability at least $1-\delta$ and*
- **(ii)** *"divergence for $\omega(n^2)$ steps", i.e., $TSS(\mathbf{X}^{(t)}) = \Omega\left(\left(\frac{t}{n} + n\right)\sigma^2\right)$ with constant probability.*

If one can bound the divergence between the running average and the initial average for a general noise-distribution $\aleph$ with (at least) exponential-decay[5] the following remark is useful to obtain a similar bound for the $TSS(\mathbf{X}^{(t)})$ as in Corollary 2. Recall that $\varnothing^{(t)} = \sum_i X_i^{(t)}/n$ and in particular, $\varnothing^{(0)}$ denotes the initial average.

[2] Recall that in parallel time we scale time by a factor of n for a fair comparison with the synchronous time model.
[3] For the case where constant fraction of the values are at distance b.
[4] In fact we only require the function to be smooth, which we define later. This class is much broader and contains most of the famous distributions including the normal distribution, geometric distribution and the Poisson distribution.
[5] Again, we only require the function to be smooth, which we define in Section 3.

▶ Remark 2. Fix any $\delta \in \mathbb{R}$. Let $n = n(\delta)$ be large enough. For any fixed $t = \Omega\left(n \ln\left(\frac{\phi_0}{\delta\sigma^2 n}\right)\right)$ with probability at least $1-\delta$ we have $TSS(\mathbf{X}^{(t)}) = \Theta\left(n\left(\varnothing^{(t)} - \varnothing^{(0)}\right)^2 + \sigma^2 n \ln(1/\delta)\right)$.

Remark 2 follows by rewriting $TSS(t) = \bar{\phi}(\mathbf{X}^{(t)}) + n \cdot \left(\varnothing^{(0)} - \varnothing^{(t)}\right)^2$ (cf. Fact 9) and plugging in the first part of Theorem 1. Corollary 2 then follows by plugging in the bounded deviation of the running average from the initial average for the Gaussian white noise model (cf. Lemma 17).

The Influence of Rounding. Agents with limited computational power might not be able to store real values. Motivated by this we also consider the setting where agents can only store integers. In particular, we consider the case that the averaging protocol is augmented with the following rounding procedure: Assume that the noise $N \sim \aleph$ takes only integer variables. After a node i receives the value from node j, the node averages it as before and then rounds up or down with equal probability. In the full version we show how to relate the setting of rounding to the original setting allowing us to derive the following corollary.

▶ **Corollary 3.** *The bounds of Theorem 1 and Corollary 2 hold even if rounding is used.*

The Synchronous Model. In the full version, we show how our results extend to the synchronous setting. It turns out that the results are the same up to a rescaling of time.

▶ **Corollary 4** (Synchronous Setting)**.** *The bounds of Theorem 1 and Corollary 2 hold even in the synchronous setting, where time is rescaled by a factor of* $2/n$.

Experimental Results. In Section 5, we simulate the averaging dynamic in various settings. In the first setting, we consider the distribution of the distances between agents' values and the running average. Our simulations show that these distances seem to follow an exponential law, i.e., the concentration is even stronger than what Theorem 1 implies.

Due to the limited memory of agents it would be desirable to obtain similar results as in Theorem 1 for the averaging dynamic in the setting where agents can only store values from a bounded range. However, our simulations in Section 5 show that this setting leads to a much faster (by order of magnitude) divergence between the running average and the initial average.

1.3 Technical Contributions

While it is not hard to show that in expectation the potentials $TSS(t)$ and $\bar{\phi}(t)$ decrease in one step as long as their value is large, it is surprisingly challenging to derive probabilistic bounds on either potential at an arbitrary point in time, *i.e.,* bounds of the type $\mathbb{P}\left[\bar{\phi}(t) \geq b\right] \leq p(b)$. Two of the reasons are as follows. (i) The potential decreases (expectedly) only conditioned on the fact that it is large enough. In fact, when the potential is small, then due to the noise it will increase in expectation. (ii) Since we study general distributions and in particular the normal distribution, the noise in a given round can be arbitrarily large leading to an arbitrarily large increase in $\bar{\phi}(t)$; if the protocol runs long enough (possibly exponentially long in n) we, indeed, will have encountered some time steps with a very large potential increase. There are surprisingly few analytical tools for using potentials as $\bar{\phi}(t)$ with challenges (i) and (ii). One notable exception is Hajek's theorem [33], which can be used to bound the value of

such a potential at a given time t. However, in our setting – with our potential function – the results obtained are very weak.[6]

Instead, we use a more sophisticated approach that at its core has a decomposition of the potential change in a single time step into three additive (but dependent) random variables. We iterate this decomposition over time throughout some interval $\mathcal{I} = (t_0, t_1]$ and sum the respective variables which we will denote as $S^-(\mathcal{I})$, $S'(\mathcal{I})$, and $S^*(\mathcal{I})$. Then (cf. Proposition 12) we are able to bound the potential change at the end of the interval as

$$\bar{\phi}(\mathbf{X}^{(t_1)}) \leq \left(1 - \frac{S^-(\mathcal{I})}{t_1 - t_0}\right)^{t_1 - t_0} \cdot \bar{\phi}(\mathbf{X}^{(t_0)}) + S'(\mathcal{I}) + S^*(\mathcal{I}). \tag{1}$$

Due to the dependencies between the three variables we use strong Martingale concentration bounds to separately upper bound $S'(\mathcal{I}) + S^*(\mathcal{I})$ and lower bound $S^-(\mathcal{I})$ (cf. Lemma 14). We then use a union bound – to circumvent the dependencies – to bound each of these variables allowing us to get a bound on Equation 1. It is critical that we define the random variable S^- in such a way that it always has an expected decrease. This is in stark contrast to the entire potential, which, as we mentioned before in (i), only decreases in expectation when it is large. Having an unconditional decrease of S^- allows us to consider arbitrarily large intervals. With these bounds at hand one can use Equation 1 to obtain probabilistic bounds on the potential at any given point time t_1. However, due to the bound on $S'(\mathcal{I}) + S^*(\mathcal{I})$ the total bound becomes very weak for large intervals. As a remedy, we carefully trace the change in the potential in different regimes (with several phases in each regime) and we separately apply the aforementioned analysis with a fresh (small) interval in each phase. The intervals (and thus also the phases) have variable length – decreasing geometrically or even exponentially, depending on the regime.

All missing proofs can be found in the full version [43].

2 Model

In this section we present the model including all assumptions. We have a collection of n agents that have initial values $X_1^{(0)}, X_2^{(0)}, \ldots, X_n^{(0)}$. Time is discrete and $X_i^{(t)}$ denotes the value of agent $i \in [n]$ at time t. Recall that $\varnothing^{(t)} = \sum_i X_i^{(t)}/n$ denotes the average value at time t; in particular, $\varnothing^{(0)}$ denotes the initial average. For two random variables X and Y we write $X \stackrel{d}{=} Y$ if they have the same (probability) distribution. Next, we define the communication models.

▶ **Definition 5** (Communication Models)**.** We consider two communication models.

- **(i)** *Sequential model*: At every discrete time step two of the agents i, j are chosen uniformly at random (with replacement[7]) and send their current values x_i and x_j to each other, where the values received are $x_i + N_i$ and $x_j + N_j$, where $N_i, N_j \stackrel{d}{=} N$.
- **(ii)** *Synchronous model*: At every discrete time step a perfect matching is chosen u.a.r. among all perfect matchings on the n agents[8]. All matched agents interchange their

[6] Hajek's theorem considers the moment generating function of the potential. In order to apply the theorem to our potential, it seems that one would need to consider a logarithmic version of the potential, which together with the moment generating function results in bound that is weaker than a simple union bound.

[7] This is not crucial to our results, but simplifies the calculations slightly.

[8] Again, we allow matchings of the kind (i, i) for simplicity. It is easy but slightly less aesthetic to modify our results to exclude matchings (i, i).

values as in the sequential model.

We use the *parallel time*, which was first defined in [3], to denote the time step t/n in the sequential model. This notion eases the comparison of results in both models, as the total number of interactions is up to a factor of 2 equal.

▶ **Definition 6** (Noise Models)**.** Let v be the value sent by an agent. The value received is $v + N$, where N is distributed according to some zero-mean noise distribution $\aleph$ with $\sigma^2 = \mathrm{Var}[N]$.

We consider general noise distributions and our results depend on the moments of N. The following two models are of special interest in this paper.

(i) *Gaussian white noise model* where $\aleph = \mathcal{N}(0, \sigma^2)$ for an arbitrary σ.

(ii) *Discrete white noise model* where $\aleph = \mathcal{D}(p)$, with $\mathbb{P}[N = i] = \frac{1}{2}p(1-p)^{|i|}$, for $i \in \mathbb{Z}\setminus\{0\}$ and $\mathbb{P}[N = 0] = p$, where $p \in (0, 1]$. Note that $\mathrm{Var}[N] = \frac{1-p}{p^2}$.

From now on we assume that the noise N is distributed according to a fixed noise distribution $\aleph$ that is independent of n.

▶ **Definition 7** (Averaging Dynamic)**.** We consider the real valued and the discrete valued algorithm. A node with value v at time receiving the input w sets its new value to

(i) $v' = {}^{(v+w)}/_{2}$ in the *real valued model*.

(ii) $v' = \begin{cases} \lceil {}^{(v+w)}/_{2} \rceil & \text{w.p. } \frac{1}{2} \\ \lfloor {}^{(v+w)}/_{2} \rfloor & \text{otherwise} \end{cases}$ in the *discrete valued model*.

A probability distribution $\mathcal{D}$ is called *sub-Gaussian* if for $X \sim \mathcal{D}$ we have that there exists positive constants c_1, c_2 such that for every x we have $\mathbb{P}[|X| \geq x] \leq c_1 \exp(-c_2 x^2)$.

Whenever we calculate the new values $\mathbf{X}^{(t+1)}$ by conditioning on the current state, $\mathbf{X}^{(t)} = \mathbf{x}^{(t)}$ we use small letters $x_i^{(t)}$ to denote fixed values and capitalized letters $X_i^{(t+1)}$ to denote random variables. Furthermore, we use bold-face to denote vectors. Throughout the paper we will assume that the number of agents n is large enough and in particular $n\mathbb{E}\left[N^2\right] \geq 1$.

We define the following potentials which are essential in all our proofs and formal results.

▶ **Definition 8** (Potentials)**.**

$$TSS(\mathbf{x}^{(t)}) = \sum_i \left(x_i^{(t)} - \varnothing^{(0)}\right)^2, \quad \bar{\phi}(\mathbf{x}^{(t)}) = \sum_i \left(x_i^{(t)} - \varnothing^{(t)}\right)^2, \quad \phi(\mathbf{x}^{(t)}) = \sum_{i,j} \left(x_i^{(t)} - x_j^{(t)}\right)^2.$$

When clear from the context we drop the time index t and we write $\mathbf{x}$ instead of $\mathbf{x}^{(t)}$, x_i instead of $x_i^{(t)}$, etc. Similarly we will use the following short forms $TSS(t) = TSS(\mathbf{x}^{(t)})$ and $\bar{\phi}(t) = \bar{\phi}(\mathbf{x}^{(t)})$. We emphasize that the difference between $\bar{\phi}(\mathbf{x})$ and $TSS(t)$ is that the former measures the squared distance w.r.t. the *running average* and the latter w.r.t. *initial average*. Initially, we have $\bar{\phi}(\mathbf{x}^{(0)}) = TSS(0)$. In [43] we prove the following fact that shows how $\bar{\phi}(\mathbf{X}^{(t)})$ relates to $TSS(t)$ and how $\bar{\phi}$ relates to ϕ.

▶ **Fact 9.** *We have that*

1. $TSS(t) = \bar{\phi}(\mathbf{X}^{(t)}) + n \cdot \left(\varnothing^{(0)} - \varnothing^{(t)}\right)^2$ *and*
2. $\phi(\mathbf{x}) = 2n \cdot \bar{\phi}(\mathbf{x})$.

Note that many alternative ways to define the potential at a time t such as the max distance and $\ell 1$ norm give only a very partial picture: The max distance to the mean for example does not distinguish between just one node being far and all nodes being far. On the other hand, the $\ell 1$ norm does not "punish" outliers enough: there is no difference between n nodes being off by 1 from the average and one node being off by n.

Notation

We use $X \sim \mathcal{D}$ to denote that X is distributed according to probability distribution $\mathcal{D}$. For two random variables X and Y we write $X \leq^{\text{st}} Y$ if X is *stochastically dominated* by Y, i.e., $\mathbb{P}[X \geq x] \leq \mathbb{P}[Y \geq x]$ for all $x \in \mathbb{R}$. We use $\|\mathbf{x}\|_2$ to denote the $L2$-norm. In the sequential model we have two random variables $N_1^{(t)}$ and $N_2^{(t)}$ for the noise of the channel at time step t (recall that $N_1^{(t)}$ and $N_2^{(t)}$ are distributed according to $\aleph$). We define the following two random variables $N'^{(t)}$ and $N^{*(t)}$ that will play a key role in our analysis:

$$N'^{(t)} = \left(N_1^{(t)}\right)^2 + \left(N_2^{(t)}\right)^2, \qquad N^{*(t)} = N_1^{(t)} + N_2^{(t)} .$$

▶ **Fact 10.** *In the Gaussian noise model, we have* $N^{*(t)} \sim \mathcal{N}(0, 2\sigma^2)$ *and* $N'^{(t)} \sim \Gamma(1, 2\sigma^2)$, *where* $\Gamma(\cdot,\cdot)$ *denotes the gamma distribution.*

When clear from the context we simply write N' and N^* instead of $N'^{(t)}$ and $N^{*(t)}$, respectively. We use $\mathcal{F}_t$ to denote the filtration at time t, which encapsulates all randomness up to time t as well as the initial values of the nodes; hence it defines the state at time t completely.

3 The Sequential Setting: Convergence towards the Running Average

Conditioning on all the randomness until time t, *i.e.*, conditioning on $\mathcal{F}_t$, we define

$$\Delta^{(t+1)} = \begin{cases} \frac{\left(x_i^{(t)} - x_j^{(t)}\right)^2}{2\bar{\phi}(\mathbf{x}^{(t)})} & \text{for } \bar{\phi}(\mathbf{x}^{(t)}) > 0 \\ 1/n & \text{otherwise} \end{cases}, \text{ where } i \text{ and } j \text{ are the chosen in round } t.$$

▶ **Lemma 11** (One Step Bound). *Fix an arbitrary potential at time t. Suppose the pair i, j was chosen to communicate and condition on the filtration $\mathcal{F}_t$ (all events that happened up to round t). Then, the following holds*

$$\bar{\phi}(\mathbf{X}^{(t+1)}) - \bar{\phi}(\mathbf{x}^{(t)}) \leq -\Delta^{(t+1)}\bar{\phi}(\mathbf{x}^{(t)}) + \frac{N'^{(t+1)}}{4} + N^{*(t+1)}\left(\frac{x_i^{(t)} + x_j^{(t)}}{2} - \varnothing^{(t)}\right) .$$

Further we have $\mathbb{E}\left[\Delta^{(t+1)} \mid \mathcal{F}_t\right] = \frac{1}{n}$.

In order to prove the statement, we first calculate the exact expected change in one step (which we do in the full version). We then majorize (stochastic dominance) with the slightly more convenient statement above.

For an arbitrary time interval $\mathcal{I}$ define

$$S'(\mathcal{I}) = \sum_{\tau \in \mathcal{I}} N'^{(\tau)}/4, \quad S^*(\mathcal{I}) = \sum_{\tau \in \mathcal{I}} N^{*(\tau)}\left(\frac{x_i^{(\tau-1)} + x_j^{(\tau-1)}}{2} - \varnothing^{(\tau)}\right), \quad S^-(\mathcal{I}) = \sum_{\tau \in \mathcal{I}} \Delta^{(\tau)} .$$

Note that, in the definition of S^*, we sum up over all time steps τ in the interval $\mathcal{I}$ and we consider the pair i and j that is chosen in round τ (in each round a different pair i and j can be chosen). With Lemma 11 and the definitions of S', S^* and S^- we can deduce the following decomposed bound on the potential for an arbitrary interval.

▶ **Proposition 12** (Decomposition of Potential). *Fix arbitrary t_0, t_1 and consider the interval $\mathcal{I} = (t_0, t_1]$. For $t = t_1 - t_0$ we have that*

$$\bar{\phi}(\mathbf{X}^{(t_1)}) \leq \left(1 - \frac{S^-(\mathcal{I})}{t}\right)^t \bar{\phi}(\mathbf{X}^{(t_0)}) + S'(\mathcal{I}) + S^*(\mathcal{I}). \tag{1}$$

Our results only hold for smooth noise distributions, which we define in the following. Let

$$m_{t,\delta} = \arg\max_{\ell} \left\{ \mathbb{P}\left[\max\left(\left\{ N'^{(t_0)}, \ldots, N'^{(t_0+t)} \right\} \cup \left\{ N^{*(t_0)}, \ldots, N^{*(t_0+t)} \right\} \right) \leq \ell \right] \geq 1-\delta \right\}.$$

▶ **Definition 13.** A noise distribution $\aleph$ is *smooth* if for all $\delta > 0$ and all $t > 0$ we have $m_{t,\delta} \leq \left(\frac{t}{\delta}\right)^{1/20}$.

Any (sub-)linear probability distribution and even some inverse polynomial distributions are smooth. Thus many practically relevant distributions such as Gaussian, binomial and Poisson distributions are smooth. For example, for the standard normal distribution ($N \sim \mathcal{N}(0,1)$) we have $m_{t,\delta} = \log(t/\delta)$, since in each time step the probability that the N^2 exceeds $\log(t/\delta)$ is equal to the probability that N exceeds $\sqrt{\log(t/\delta)}$ which happens w.p. at most δ/t. Taking union bound over all t steps shows that it is smooth.

Using strong martingale concentration bounds (see the full version for details) and bounding the variance, we deduce the following upper bound on $S^* + S'$ and lower bound on S^-.

▶ **Lemma 14.** *Let t_0, t_1 be such that $t_1 > t_0$ and consider the interval $\mathcal{I} = (t_0, t_1]$.*

(i) *With probability $1-\delta$ we have*

$$S^*(\mathcal{I}) + S'(\mathcal{I}) \leq \frac{t}{4}\mathbb{E}\left[N'\right] + 5\sqrt{\frac{t}{n}}\left(\ln(4t/\delta) m^*_{t,\delta/4}\right)^2 \left(2 + \mathbb{E}\left[N'\right]\right)\sqrt{\bar{\phi}(\mathbf{x}^{(t_0)}) + 9t\mathbb{E}\left[N'\right] + 2}\,.$$

(ii) *For any $\gamma < 1$, w.p. at least $1 - \exp\left(-\frac{3\gamma^2 t}{8n}\right)$ we have $S^-(\mathcal{I}) \geq (1-\gamma)\frac{t}{n}$.*

The following proposition almost directly implies Theorem 1.

▶ **Proposition 15.** *Fix any $\delta \in (0,1]$ and assume that the noise distribution is smooth. There exists a constant c such that for a time step t_0 with potential $\bar{\phi}(\mathbf{x}^{(t_0)})$ we have*

$$\mathbb{P}\left[\bar{\phi}(\mathbf{X}^{(t^*)}) \geq \ln(1/\delta) n \mathbb{E}\left[N'\right] + b \mid \mathcal{F}_{t_0} \right] \leq \delta,$$

where $t^* = t_0 + cn\ln\left(\frac{\bar{\phi}(\mathbf{x}^{(t_0)})}{\mathbb{E}[N']n\delta}\right)$ and $b = 2\left(1 + \mathbb{E}\left[N'\right]\right)\left(\ln(1/\delta)\right)^9 n^{9/10}$.

Proof Sketch. We only sketch the proof idea for a simplified setting; during the sketch we assume that $N \sim \mathcal{N}(0,1)$ (with $\mathbb{E}\left[N'\right] = O(1)$) and also that δ is at least $1/n^3$. The main ingredients for the proof are Proposition 12 and Lemma 14. For an interval $\mathcal{I} = (t_0, t_1]$ Proposition 12 upper bounds the potential at time t_1 by

$$\bar{\phi}(\mathbf{X}^{(t_1)}) \leq \left(1 - \frac{S^-(\mathcal{I})}{t}\right)^t \bar{\phi}(\mathbf{X}^{(t_0)}) + S'(\mathcal{I}) + S^*(\mathcal{I}), \tag{2}$$

where t is the length of the interval. Lemma 14 lower bounds $S^-(\mathcal{I})$ and upper bounds the sum $S'(\mathcal{I}) + S^*(\mathcal{I})$. To prove Proposition 15 we have to show that the initial potential $\bar{\phi}(\mathbf{x}^{(t_0)})$ decreases to $O(n)$ after $O(n \cdot \log \bar{\phi}(\mathbf{x}^{(t_0)}))$ time steps with probability $1-\delta$. Optimally, we would use a single application of Proposition 12 to upper bound the potential as in Equation 2 and then bound the terms $S^-(\mathcal{I})$ and $S'(\mathcal{I}) + S^*(\mathcal{I})$ via Lemma 14. However, the bounds on S^- and $S' + S^*$ given by Lemma 14 are too loose to yield the desired result via a single application of Proposition 12 and Lemma 14 with the whole time interval $\mathcal{I} = [t_0, t_0 + O(n \log \bar{\phi}(\mathbf{x}^{(t_0)}))]$. For example, the bound on $S' + S^*$ inherently has a term

of order $\sqrt{\bar{\phi}}$, where $\bar{\phi}$ is the potential at the start of the interval for which Lemma 14, i is applied. Thus a one shot proof as described above can never reach a potential below $\sqrt{\bar{\phi}}$. This is not sufficient if the initial potential is large, e.g., say for $\bar{\phi} \gg n^{8/3}$.

To circumvent this problem we apply Proposition 12 and Lemma 14 several times for smaller time intervals: More detailed, we split the proof of Proposition 15 into two regimes. In regime 2 we use several phases to decrease the potential to $\Theta(n^{4/3})$. If the potential is $\bar{\phi}$ at the beginning of a phase a single application of Proposition 12 and Lemma 14 reduces the potential to $\bar{\phi}^{3/4}$. The length of each such phase is geometrically decreasing by a factor 3/4 where the first phase is of length $O\left(n \ln\left(\frac{\bar{\phi}(\mathbf{x}^{(t_0)})}{n\delta}\right)\right)$. After the last phase of regime 2 the potential is of order $n^{4/3}$.

Then, in regime 1 the potential reduces from $\Theta(n^{4/3})$ to $O(n)$, again through several phases. If the first phase of regime 1 starts with a potential of size B, the phase has length $t = O(n \ln(B))$. If there was no additive increase due to the noise, then this would reduce the potential to 0. However, there is an additive increase of $\Theta(t) = \Theta(n \ln(B))$ which leaves us with a potential of size $O(n \ln(B))$. The next phase will therefore be of length $n \ln \ln(B)$ etc. This is repeated for $\ln^*(B)$ phases until the potential reduces to $O(n)$, which, as we explained in Subsection 1.2, is the furthest the potential can be decreased .

Putting everything together, we get that after $O\left(n \ln\left(\frac{\bar{\phi}(\mathbf{x}^{(t_0)})}{n\delta}\right)\right)$ rounds the potential reduces to $O(n)$. ◀

The full proof of Proposition 15 handles general $\mathbb{E}[N']$ and general δ and thus it is significantly more technical. It can be found in the full version. From Proposition 15 we are able to derive Theorem 1.

4 Deviation from the Initial Average

An informal argument for the statements in this section in the special case of $\sigma = 1$ can be found in [54]. Before we state our results we need the following result on the standard normal distribution.

▶ **Theorem 16** ([16]). *Let $\Phi(x)$ denote the cumulative distribution function of the standard normal distribution. We have for $x \geq 0$:*

$$\frac{1}{\sqrt{2\pi}} \frac{x}{x^2+1} \exp\left(-x^2/2\right) \leq \Phi(x) \leq \frac{1}{\sqrt{2\pi}} \frac{1}{x} \exp\left(-x^2/2\right).$$

We can now state and prove the main results of this section.

▶ **Lemma 17.** *For any t and any $\delta < 1$, we have $\varnothing^{(t)} - \varnothing^{(0)} \sim \frac{\sum_{\tau=1}^{2t} N^{(\tau)}}{2n}$ with probability at least $1-\delta$, where $N^{(\tau)}$ is the noise of the channel. In particular, for the Gaussian white noise model setting where $N \sim \mathcal{N}(0, \sigma^2)$ we have $\sum_{\tau=1}^{2t} N^{(\tau)} \sim \mathcal{N}(0, 2t\sigma^2)$. Thus*

(i) $|\varnothing^{(t)} - \varnothing^{(0)}| \leq \frac{\sigma\sqrt{t \ln(1/\delta)}}{n}$ *w.p. at least* $1-\delta$

(ii) $|\varnothing^{(t)} - \varnothing^{(0)}| \geq \frac{\sigma\sqrt{t \ln(1/\delta)}}{n}$ *w.p. at least* $\frac{\delta}{2\sqrt{2\ln(1/\delta)}}$.

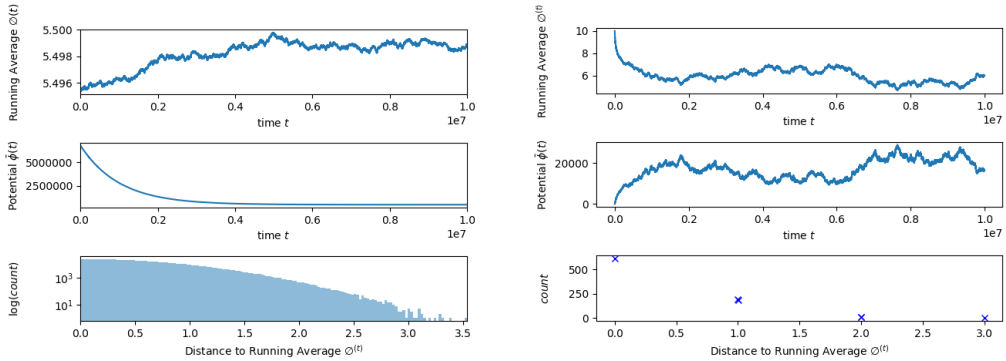
Using the Berry-Esseen theorem, one can easily prove similar bounds for any distribution with bounded third moment including *discrete white noise*.

In the following we consider the potential $(\varnothing_t)_{t\geq 0}$ as a Martingale to derive the desired concentration bounds. The following bound is weaker than the aforementioned bounds, however, it is useful whenever the noise is such that $m_{t,\delta/(2t)}$ is small.

▶ **Proposition 18.** *For any $t \geq 2$ and any $\delta < 1$, we have $-m_{t,\delta/(2t)}\sigma\sqrt{2t} \leq \varnothing^{(t)} - \varnothing^{(0)} \leq m_{t,\delta/(2t)}\sigma\sqrt{2t}$ with probability at least $1-\delta$.*

5 Experimental Results

The goal of this section is twofold. First, we seek to better understand the distribution $\mathcal{D}$ of the distances $x_i^{(t)} - \varnothing^{(t)}$. Second, we simulate a setting in which the range of values is bounded, motivated by computational and storage limited agents. All results in this section are based on an implementation of the simple averaging dynamic. The code (python3) for the experiments can be found here [42].



(a) The setting of this example is: $n = 10^6$, initial distribution of values is uniformly at random in the range $[1, n^2]$, $10n$ iterations, Gaussian white noise with variance 1, unbounded range.

(b) The setting of this example is: $n = 1000$, all values equal to 10, using discrete white noise model $\mathcal{D}(0.8)$ (see Definition 6), bounded range in the interval $[1, 10]$, $10^4 n$ iterations. The avg. of the values drifts from 10 to 6.

Figure 1 The figure depicts the distribution of distances as well as the bounded value setting.

5.1 The Distribution of the Distances

The experiments suggest that the distance decays at least exponentially. Note that the experiments only show a single iteration, however, this phenomena was observable in every single run. The bound on $\mathbb{E}\left[\bar{\phi}\left(\mathbf{X}^{(t)}\right)\right]$ we obtained in Theorem 1 only implies that $\mathcal{D}$ is at most $O(1/d^3)$. However, we conjecture, for sub-Gaussian noise that $\mathbb{P}\left[|X_i^{(t)} - \varnothing^{(t)}| \geq x\right] = O(\exp^{-x})$ (cf. Figure 1a). Showing this rigorously is challenging due to the dependencies among the values. Nonetheless, such bounds are very important since they immediately bound the maximum difference and we consider this the most important open question.

5.2 The Bounded Values Setting

One of the motivations for the very simple averaging dynamic arises in the setting of limited computational power of the interacting agents. So far we assumed that agents can store and transmit (intermediate) values from an unbounded range. For many applications and in particular motivated by agents with bounded memory one would hope for similar results if there is a maximum and a minimum value that can be stored or transmitted. The formal definition is as follows: values can only be from the range $[v_{min}, v_{max}]$ ($= [1, 10]$ in our experiments). We assume noise of the channel cannot produce values larger than v_{max} or smaller than v_{min}, which can be motivated as follows in the setting where the values correspond to amplitudes: here v_{max} and v_{min} are simply the amplitudes (high amplitude and no amplitude) where the signal-to-noise ratio is very large, and noise becomes negligible. An equivalent model is that the agents know the range of possible communication values,

and hence, they can simply correct every value larger than v_{max} to v_{max}. In particular when agents only have limited storage, the communication range will often be bounded, and even rounding might become necessary (see the full version).

We refer to these equivalent models as the model with *cutoffs*. While the experiments indicate that values still converge towards the running average, there is a clear drift of the running average from the initial average if the input values are chosen unsuitably. In our experiments, we set the range of values to $[1, 10]$, use the noise described in the discrete noise model together with rounding. Initially, all agents have value 10. We see a drastic drift of the running average (see Figure 1b). Even though the initial average is 10, the running average appears to approach the midpoint of the range, i.e., 5. The histogram of distances to the initial average shows even more clearly that the values are not concentrated around the initial average. Although the experiments only show a single iteration, this phenomena was observable in every single run. We believe that the reason for this is simply that the noise is no longer symmetric and no longer zero-mean due to the cutoffs $[1, 10]$. Proving convergence to the running-average in this model seems challenging and interesting.

We believe that the insights in bounding this potential might be useful in similar problems.

6 Conclusion and Open Problems

In this paper we showed bounds on the convergence time for the unbounded setting. Our simulations in Section 5 yield two interesting open problems: (i) study the setting where the values are restricted to some interval (in this case the noise is no longer symmetrical) and (ii) prove tail bounds on the distance distribution w.r.t. to the running or initial average. Another interesting research direction is to move away from zero-mean noise and consider biased noise models: how quickly can the bias(es) be estimated and is convergence still feasible by compensating for the (learned) bias?

Abstract

Bandit-style algorithms have been studied extensively in stochastic and adversarial settings. Such algorithms have been shown to be useful in multiplayer settings, e.g. to solve the wireless network selection problem, which can be formulated as an adversarial bandit problem. A leading bandit algorithm for the adversarial setting is EXP3. However, network behavior is often repetitive, where user density and network behavior follow regular patterns. Bandit algorithms, like EXP3, fail to provide good guarantees for periodic behaviors. A major reason is that these algorithms compete against fixed-action policies, which is ineffective in a periodic setting.

In this paper, we define a periodic bandit setting, and periodic regret as a better performance measure for this type of setting. Instead of comparing an algorithm's performance to fixed-action policies, we aim to be competitive with policies that play arms under some set of possible periodic patterns F (for example, all possible periodic functions with periods $1, 2, \cdots, P$). We propose Periodic EXP4, a computationally efficient variant of the EXP4 algorithm for periodic settings. With K arms, T time steps, and where each periodic pattern in F is of length at most P, we show that the periodic regret obtained by Periodic EXP4 is at most $O\big(\sqrt{PKT \log K + KT \log |F|}\big)$. We also prove a lower bound of $\Omega\big(\sqrt{PKT + KT\frac{\log |F|}{\log K}}\big)$ for the periodic setting, showing that this is optimal within log-factors. As an example, we focus on the wireless network selection problem. Through simulation, we show that Periodic EXP4 learns the periodic pattern over time, adapts to changes in a dynamic environment, and far outperforms EXP3.

1 Introduction

The *multi-armed bandit* problem is an online learning problem in which a player has access to a set of choices (i.e., "arms") each of which provides some reward (i.e., "gain"). At each time step, the player chooses an arm and gets some reward. In stochastic variants, rewards are determined by some probabilistic distribution. In adversarial variants, an adversary specifies

the rewards. Amazingly, even when rewards are adversarially chosen, the player can do fairly well! For example, the EXP3 algorithm [6] minimizes the player's "regret", ensuring that the player does almost as well as if she had selected the single fixed best arm throughout. Another fascinating property of bandit algorithms is that they work well in multi-player settings [27, 16], converging to close variants of a Nash equilibrium.

Recently, it has been shown that bandit-style algorithms can efficiently solve the *wireless network selection problem*, yielding good performance both in theory and in practice [1, 2, 7]. In this problem, each user has access to a collection of networks (e.g., a few different WiFi networks and a 4G connection); the goal is to pick networks with higher data rates. Selecting the best network is challenging, especially in dynamic environments where the "best" network changes over time, as users move and network bandwidth fluctuates. This can be modeled as an adversarial bandit problem and solved with EXP3 and its variants.

Bandit algorithms have one major weakness in dynamic settings (such as wireless network settings): they are designed to learn the average payoff of each arm, and to converge to the arm that provides the best average performance. In the stochastic case, this is exactly what you want. In the adversarial case, it leads to minimum regret, i.e., the user does almost as well as if they knew the best network in advance. If, however, the situation is changing over time, and especially if it is changing in some predictable manner, then learning the average payoff of each arm is not productive.

Periodic, repetitive patterns are a particularly common type of dynamic behavior. Take, for example, the problem of network selection. Network behavior is often repetitive, with user density and network quality following regular patterns: for example, office WiFi networks have no users at night, their performance drops when workers arrive in the morning, and the performance improves again during lunch hour. Other networks are clogged with streaming video during lunch hour and in the evenings. Periodic patterns are ubiquitous.

Unfortunately, bandit algorithms will fail badly in the case of periodic behavior. As an example, suppose a player is playing a slot machine with two arms. The first arm gives a reward of 1 when pulled on odd-numbered hours and 0 otherwise, while the second arm does the reverse, with a reward of 1 on even-numbered hours and 0 otherwise. In this simple case, a bandit algorithm will never learn this pattern, instead converging to the best single-action policy; and the best policy can only reap half of the maximum reward. The player will receive an average payout of only 1/2 per selection, despite a very predictable pattern. And when this case is extended to cycle among K arms, the best fixed choice of arm gives only $1/K$ of the total obtainable reward. Thus, algorithms like EXP3 that minimize the regret do not guarantee good performance on periodic problems.

1.1 Contributions

Our goal in this paper is to develop an efficient adversarial bandit algorithm for periodic settings, and to demonstrate the effectiveness of this algorithm in the context of the wireless network selection problem, yielding a new approach to network selection in dynamic, periodic environments. The first step is to establish the right metric by which to evaluate bandit algorithms. The performance of an adversarial bandit algorithm is heavily characterized by the definition of "regret," which forms the baseline that it competes against. And traditionally, the regret is computed with respect to the best fixed strategy.

For the periodic bandit setting, we define a better performance measure, "periodic regret", which compares an algorithm's performance against the best periodic choice of arms. No choice of period may match the input data perfectly, but the goal of periodic regret is to compare against the best choice. Moreover, we provide a generalized notion of periodicity, so that this notion of periodic regret can capture different types of patterned behavior.

Next, we develop an algorithm that minimizes periodic regret, Periodic EXP4, a computationally efficient variant of EXP4 (Exponential-weight algorithm for Exploration and Exploitation using Expert advice) [6]. We show that the algorithm minimizes periodic regret in the following sense: with K arms, $|F|$ possible periods, with each possible period of at most length P, then in an execution of length T the periodic regret is at most $O\left(\sqrt{PKT \log K + KT \log |F|}\right)$. We also prove a lower bound of $\Omega\left(\sqrt{PKT + KT\frac{\log |F|}{\log K}}\right)$ on periodic regret in an adversarial setting, showing that this is optimal within log-factors. An important aspect of Periodic EXP4 is that it is a polynomial time algorithm: we leverage the structure provided by the target periodic patterns to reduce the computational complexity. This is in contrast to EXP4 which requires exponential time and space in this context.

The other major contribution of this paper is a new algorithm for network selection that is especially optimized for environments with periodic, patterned behaviors. We simulate the network selection problem, comparing Periodic EXP4 to EXP3 and to a "randomized optimal" omniscient solution. (We have previously seen in [1] that these types of simulations are reasonably predictive of real-world behavior.)

Our first observation is that Periodic EXP4 does in fact efficiently learn periodic patterns and adapts relatively quickly to changes in network data rates (both discrete and continuous). We also see that Periodic EXP4 does indeed outperform EXP3 in periodic settings, as expected, potentially yielding significant real-world improvements.

Our second question involved the robustness of Periodic EXP4 to noisy patterns. Real-world periodic patterns are rarely perfectly periodic, suffering noise and variance. We experiment with noisy patterns, and see that Periodic EXP4 continues to work well.

Finally, our third set of experiments looked at the performance of Periodic EXP4 in the context of user mobility. We simulate several scenarios where users change location over time, leading to changes in which networks they can access (and hence changes in the load on those networks). For example, we imagine a typical office scenario where users arrive at the office in the morning, take a break for lunch, return to work, and then head home at the end of the day. We observe that Periodic EXP4 can also learn this type of periodic behavior, again, learning to adapt the users' network selection in a near-optimal fashion. In fact, we compare two versions of the algorithm: one in which the algorithm is notified when networks become unavailable, and one in which it is not – we observe that even in the latter case where it is completely oblivious to the changes, the user strategy converges to near-optimal choices.

Overall, we conclude that periodic adversarial bandit algorithms may have significant value, that Periodic EXP4 is an efficient algorithm for the problem, and that it yields a potentially interesting and useful approach to network selection.

2 Related work

In this section, we discuss relevant work done on bandit algorithms, and state-of-art wireless network selection approaches. Multi-armed bandit techniques have been successfully applied to wireless network selection [1, 2, 7]. They have also been considered for other resource selection problems, such as channel selection [13, 27], selection of the right sensors to query in a sensor network [14], and selection of replica server for content distribution networks [28].

Many variations of bandit problems have been studied, in both stochastic and adversarial settings. EXP3 is the most well-known algorithm for the standard adversarial bandit problem. With K arms and T time steps, it establishes a pseudo-regret upper bound of $O(\sqrt{KT \log K})$, which almost matches the lower bound of $\Omega(\sqrt{KT})$ [6]. The $\log K$ gap in the bounds has been recently closed by [5] bringing the upper bound down to $O(\sqrt{KT})$. But, these bound the regret against the best single-action policy, limiting their usefulness in a periodic setting.

A related problem is that of bandits with expert advice, defined in the same paper [6]. It defines a more general notion of regret, by competing against the best policy from a set. With K arms, T time steps and N experts, the EXP4 algorithm gives a pseudo-regret bound of $O(\sqrt{KT \log N})$. However, its possibly high running time and memory cost limit its use in practice. There are other algorithms for bandits with expert advice, like Context-FTPL. The latter is more computationally efficient, but has a weaker regret bound [26]. A lower bound of $\Omega(\sqrt{KT\frac{\log N}{\log K}})$ [23] has been shown, but the $\log K$ gap in bounds has not been closed.

An equivalent formulation of our generalized periodic regret (explained later in Section 4.2) has been briefly discussed in [10, Chapter 4.2.1], phrased as a contextual bandit problem where the algorithm competes against the best context set from a class of context sets. The possible use of EXP4 is mentioned, but an alternative algorithm with a weaker regret bound is instead discussed as it has a reasonable polynomial-time performance unlike EXP4.

While much of the existing literature assume a single best arm, there are other efforts to look beyond this. One approach to the stochastic version of the problem is to allow reward distributions of the arms to occasionally change [9, 22]. Our work on the other hand is fully adversarial, and makes no assumptions on the rewards produced by the adversary.

Numerous wireless network selection approaches have been proposed. Some are centralized [3, 8, 18, 25]; hence, not scalable and limited to managed networks. A number of distributed approaches have been proposed, with various limitations. Some rely on coordination from networks [15], while others require cooperation of wireless devices [12]. Others assume global knowledge [20, 4, 19], or availability of some information [30, 11]. A continuous-time multi-armed bandit approach in a stochastic setting has been considered in [29]. A similar setting to ours, though non-periodic and in the stochastic setting, is considered in [7].

3 Wireless Network Selection

Here, we describe the wireless network selection problem, discuss the periodicity of events in wireless environments, and formulate the network selection problem as a bandit problem.

3.1 Wireless network selection problem.

We consider an environment with multiple wireless devices and heterogeneous wireless networks, such as the one depicted in Figure 1. The latter illustrates four mobile users with their (active) mobile devices, and five wireless networks, namely four WiFi networks and a cellular network (represented using 3 cellular base stations). The wireless networks have limited areas of coverage. Hence, each mobile device may have access to a different set of wireless networks depending on their location, e.g. different networks are available at home and at the office. The bandwidths of wireless networks may also vary with time. Each mobile device aims to quickly identify and associate with the best network, which may vary over time, to maximize their data rates.

Mobile users tend to have daily routines that follow repetitive patterns - going to the office each morning, lunch at noon, returning home in the evening; these activities are performed at fixed times each weekday. Figure 1 broadly depicts the daily routine of a mobile user, Alice. Network behavior, which is affected by user density, is also often repetitive and follows a regular pattern. For example, the available bandwidth of office WiFi networks is likely to be higher during lunch hours, where the office is nearly empty. A good network selection protocol learns and adapts to periodic patterns in network quality for better performance.

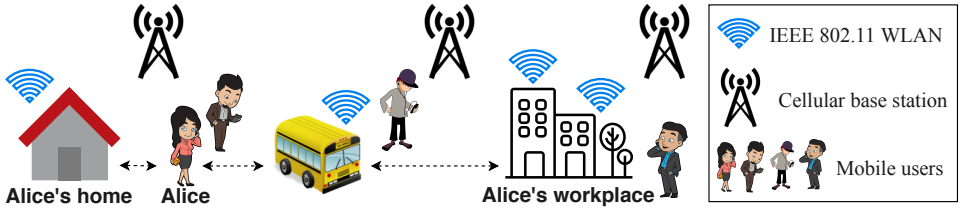

Figure 1 Mobile devices with access to a different set of wireless networks as the user moves.

3.2 Wireless network selection as a bandit problem

A device must be aware of the bit rate it can observe from each network to perform an optimal network selection. While this information is unknown at the time of selection, the device can estimate the achievable bit rate by exploring the networks. The network selection problem can be seen as a multi-armed bandit problem in a multi-player setting. A mobile device is a player, and each network can be considered as an arm. Every so often (e.g. once per minute), a device selects a network (analogous to pulling an arm) and observes a bit rate (gain) for that network. The gain from other networks is unknown to the device. Given that mobile devices operate in a dynamic environment, they must continuously explore and adapt to changes, by deciding which networks to select in sequence. The goal of each device is to maximize its cumulative gain over time. Since the quality of a wireless network is affected by its number of clients, other mobile devices in the environment may be considered to be adversaries. We hence use the adversarial setting. A leading bandit algorithm in this setting is EXP3.

4 Periodic Bandit Problem

In this section, we introduce the periodic bandit problem and discuss periodic regret.

We consider a general bandit problem. On each time step, an algorithm is allowed to pick any one out of K possible arms, and each arm produces a certain amount of reward. These rewards are unknown to the algorithm, which can only observe the reward of the arm it picked. We aim to maximize the total reward obtained by the algorithm. We study the adversarial setting with a possibly adaptive adversary, which decides on the distribution of rewards at each time step, taking into consideration the outcomes of past random events.

Let K be the number of arms. The set of arms is $[K] := \{1, 2, \cdots, K\}$. Let $x_i(t) \in [0, 1]$ be the reward earned by arm $i \in [K]$ at time step t. Let $a(t) \in [K]$ be the arm played by the algorithm at time t. Let T be the total number of time steps. The set of time steps is $[T] := \{1, 2, \cdots, T\}$. Thus, the total reward earned by the algorithm after T iterations is $\sum_{t=1}^{T} x_{a(t)}(t)$. The commonly used performance measure for bandit algorithms is regret. Regret compares the total reward obtained by the algorithm against a "best possible" reward "OPT" after some number of time steps T. Different types of regret compare the algorithm's result to different notions of the optimal result.

We can define a form of regret where OPT is allowed to pick any arm in $[K]$ at each time step. For later reference we will refer to this as full regret, defined as follows:

$$R_{full}(T) = \sum_{t=1}^{T} \max_{i \in [K]} E\Big[x_i(t)\Big] - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big]$$

The above definition uses what is commonly known as pseudo-regret, rather than expected regret. For the rest of this paper, we will often refer to pseudo-regret as simply "regret". Expectations are taken over the possible randomness of the algorithm and adversary.

In most studies of adversarial bandits, a weaker definition of regret is used. This is because full regret uses too powerful an adversary, and it is impossible to achieve better than linear expected full regret in the worst case (we include a proof in the full version of the paper [21]). Therefore, it is common to define a notion of regret where OPT is required to use the same arm for all T time steps. We refer to this as weak regret, defined as follows:

$$R_{weak}(T) = \max_{i \in [K]} \sum_{t=1}^{T} E\Big[x_i(t)\Big] - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big]$$

Weak regret however, severely limits what OPT can do, and being competitive with an algorithm that can only pick one arm and stick to it may not be a very strong result.

4.1 Periodic Regret

We can bridge the two with a periodic definition of regret. Taking the idea that a periodic choice of arms is likely to perform well in situations with periodic patterns, we can define a regret function which measures how competitive an algorithm is with the best periodic choice of arms. For example, we can say OPT is forced to play the same arm every $\tau \in \mathbb{N}$ steps. This defines a regret function as follows,

$$R_\tau(T) = \sum_{\ell=1}^{\tau} \max_{i \in [K]} \sum_{\bar{t}=0}^{\lfloor \frac{T-\ell}{\tau} \rfloor} E\Big[x_i(\bar{t}\tau + \ell)\Big] - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big]$$

As OPT may optionally still pick the same arm on all time steps, this is a generalization of weak regret. This makes for a regret value in between weak regret and full regret.

If we were competing against the regret for a specific, known value of τ, this would be equivalent to playing τ independent instances of the adversarial bandits problem over approximately T/τ time steps each. By playing τ separate instances of an algorithm for weak regret, and by Theorem 2 in Section 6.1, we have an upper/lower bound of $\Theta(\sqrt{\tau KT})$.

However, if we were to consider that the "best possible" period τ may not be known (for example, if OPT were to consist of the best periodic function for any of the possible periods $\tau \in \{1, \cdots, P\}$), these bounds do not apply as easily.

4.2 Generalized Periodic Regret

A generalization of the periodic case is the use of partition functions. Fix a maximum number of labels P. We define this upper bound P for use in our analysis later on. A partition function $f : [T] \to [P]$ is a function that assigns every time step a label from 1 to P. We consider two partition functions the same if their choice of label assignments are permutations of each other. The regret under function f would be when OPT is forced to play the same arm for all timesteps with the same label as assigned by f.

$$R_f(T) = \sum_{\ell \in [P]} \max_{i \in [K]} \sum_{\bar{t} \in f^{-1}(\ell)} E\Big[x_i(\bar{t})\Big] - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big] \tag{1}$$

Consider a set of partition functions $F \subseteq \{f : [T] \to [P]\}$ for some $P \in \mathbb{N}$. F is necessarily finite. The regret under the function set f would be when OPT can choose to play using any of the partition functions in F. This gives the following regret definition:

$$R_F(T) = \max_{f \in F} \sum_{\ell \in [P]} \max_{i \in [K]} \sum_{\bar{t} \in f^{-1}(\ell)} E\Big[x_i(\bar{t})\Big] - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big] \tag{2}$$

This definition (2) of periodic regret gives us more choice in how we want to define our potential periodic patterns to learn, through deciding on the labels on each time step for each function. We demonstrate this with our choice of partition functions in Section 7.

To model the example described earlier with periods $\tau \in \{1, 2, \cdots, P\}$, we can use the set of partitions $F = \{f_1, f_2, \cdots, f_P\}$, where $f_\tau(t) := (t \bmod \tau) + 1$ for each $t \in [T]$, $\tau \in [P]$.

5 The Periodic EXP4 Algorithm

We discuss the relationship between our generalized periodic setting and the problem of bandits with expert advice, and hence the applicability of EXP4 [6] to the problem. We use this to introduce Periodic EXP4, an efficient algorithm for generalized periodic regret.

5.1 Applying Bandits with Expert Advice to Periodic Bandit Problems

Periodic bandit problems can be reduced to the problem of bandits with expert advice. In the problem of bandits with expert advice, we are given a set Π of N experts. Each expert predicts an arm on each time step. We fix the number of time steps T. Thus an expert can be seen as a function $\pi : [T] \to [K]$. An algorithm to solve this problem would make use of each expert's predictions on each time step, to obtain a reward competitive with the best expert in the set. This gives us the following regret definition:

$$R_\Pi(T) = \max_{\pi \in \Pi} \sum_{t=1}^{T} x_{\pi(t)}(t) - E\Big[\sum_{t=1}^{T} x_{a(t)}(t)\Big]$$

This can be used to model all of the above notions of regret. For full regret, we have $\Pi := \{\pi : [T] \to [K]\}$, the set of all possible functions from $[T]$ to $[K]$. For weak regret, Π is the set of all constant functions from $[T]$ to $[K]$.

In the generalized periodic setting, let F be the set of partition functions $f : [T] \to [P]$. For each function $f \in F$, let Θ_f be the set of all possible mappings $\theta : f([T]) \to [K]$ from the image set $f([T])$ of f to the set of arms $[K]$ (thus $|\Theta_f| = K^{|f([T])|}$). Each composition $\theta \circ f$, $f \in F$, $\theta \in \Theta_f$ thus represents a possible mapping of the time steps $[T]$ to arms. Thus, for the generalized periodic setting, $\Pi = \{\theta \circ f \mid f \in F, \theta \in \Theta_f\}$.

We note that when $\Pi_1 \subseteq \Pi_2$, we will have $R_{\Pi_1}(T) \leq R_{\Pi_2}(T)$. Let Π_{full}, Π_{weak} and Π_F be the sets of functions corresponding to full regret, weak regret and generalized periodic regret under some function set F respectively. Thus, for any nonempty set F of partition functions, we have $R_{\Pi_{weak}}(T) \leq R_{\Pi_F}(T) \leq R_{\Pi_{full}}(T)$.

An existing algorithm for this problem is the EXP4 algorithm [6], which achieves a regret upper bound of $O(\sqrt{KT \log N})$, where $N := |\Pi|$. We can thus apply EXP4 directly to our problem. However, a commonly cited drawback of the EXP4 algorithm is that its running time and memory cost are at least linear in N. This is an issue as N is often very large. For example, in the generalized periodic setting, the size of N could easily be on the order of

          else
            $b_i^{\ell,f}(t+1) = b_i^{\ell,f}(t)$

$|F|K^P$, which is exponential in P. However, we show below that in the generalized periodic setting, we can devise an algorithm that is distributionally equivalent to EXP4 and can be made to run in time polynomial in $|F|$, K and P.

The EXP4 algorithm works by assigning a weight w_π (with initial value 1) to each expert $\pi \in \Pi$. The probability $p_i(t)$ of playing an arm $i \in [K]$ would then be $\sum_{\pi(t)=i} w_\pi(t) / \sum_\pi w_\pi(t)$, the ratio of the combined weights of the experts agreeing to play arm i to the total weight of the experts. Whenever an arm $i \in [K]$ is played, each expert who suggested arm i will have their weight adjusted by some factor $\exp(\frac{\gamma}{K} x_i(t)/p_i(t))$. More details on EXP4 are given in [6]. Note that it discusses a more general form of expert advice where each expert suggests a probability vector on the arms. However, we only require the case where at each time step, each expert suggests one arm with probability 1, and all other arms with probability 0.

5.2 Periodic EXP4, Memory and Running Time Costs

Periodic EXP4 (Algorithm 1) is distributionally equivalent to the EXP4 algorithm when run with the set of experts $\Pi = \{\theta \circ f \mid f \in F, \theta \in \Theta_f\}$. The key intuition behind this algorithm is that the generalized periodic setting produces many symmetries in the weight computation for each expert. Specifically, we take advantage of how for each partition function f, the set of experts contains every possible combination of arm assignments to labels in the image set $f([T])$. This allows us to compute the probabilities that EXP4 would play each arm at each time step without computing the individual weights of every expert.

For brevity, let $P_f := |f([T])|$ be the number of labels used by the function f. Necessarily $P_f \leq P$. The memory requirement is $O(K \sum_{f \in F} P_f)$, which is at most $O(KP|F|)$. A naive implementation of the algorithm gives a running time of $O(K^2 \sum_{f \in F} P_f)$ per time step, but with some pre-computation, the running time can be lowered as shown in the full paper [21].

5.3 Correctness of Periodic EXP4

To show correctness, we show that our algorithm produces the same probability distribution over arms as EXP4 in every time step. Define $\pi_{\theta,f}$ as the expert which at time t recommends arm $\theta \circ f(t)$ with probability 1 and all other arms with probability 0. We show this algorithm is distributionally equivalent to EXP4, where $\Pi = \{\pi_{\theta,f} | f \in F, \theta \in \Theta_f\}$. In EXP4, each expert $\pi_{\theta,f}$ would have some weight $w_{\theta,f}(t)$ at time step t. At time step t, EXP4 plays arm i with probability $p_i(t)$ represented by the following expression:

$$p_i(t) = \frac{\sum_{f \in F, \theta \in \Theta_f, \theta \circ f(t) = i} w_{\theta,f}(t)}{\sum_{f \in F, \theta \in \Theta_f} w_{\theta,f}(t)}$$

Thus, to show that the two algorithms are distributionally equivalent, as $p_i(t) := r_i(t)/\sum_{j=1}^{K} r_j(t)$ in our algorithm, for each successive time step t, we only need to show the following:

$$r_i(t) = \sum_{f \in F, \theta \in \Theta_f, \theta \circ f(t) = i} w_{\theta,f}(t)$$

The details of this derivation is given in the full paper [21]. We can thus formally state a regret upper bound as follows (Theorem 1). This upper bound comes directly from EXP4's regret bound of $O(\sqrt{KT \log N})$, where the number of experts $N = \sum_{f \in F} K^{|f([T])|} \leq |F| K^P$.

▶ **Theorem 1.** *With K arms, T time steps, $|F|$ partition functions, with every function having at most P labels, Periodic EXP4 gives a regret upper bound of $O\left(\sqrt{PKT \log K + KT \log |F|}\right)$.*

6 Lower Bounds

In this section, we provide lower bounds for the case of a single partition and for a set of partitions. We demonstrate that the upper and lower bounds differ by a factor of $\log K$.

The existing regret lower bound for the problem of bandits with expert advice [23] is $\Omega(\sqrt{KT \frac{\log N}{\log K}})$. This lower bound is derived by dividing the time steps $[T]$ into $\frac{\log N}{\log K}$ equal parts. For the generalized periodic setting, as this lower bound uses an instance that can be modeled with a single partition function, it does not give immediate insight into whether having multiple different periods or partition functions increases the difficulty of the problem.

6.1 Lower Bound for a Single Partition

We consider the case with only a single partition function $f : [T] \to [P]$, which partitions the time steps into P labels $1, 2, \cdots, P$. The sizes of the partitions are $|f^{-1}(1)|$, $|f^{-1}(2)|$, $\cdots$, $|f^{-1}(P)|$ respectively. It seems like intuitively, by seeing this as P separate instances of the weak regret setting, and by the existing $\Theta(\sqrt{KT})$ upper/lower bounds on weak regret [6, 5], we would have an upper/lower bound of $\Theta(\sum_{\ell=1}^{P} \sqrt{K|f^{-1}(\ell)|})$. For equally sized partitions of size approximately $\frac{T}{P}$ each, this bound would be $\Theta(\sqrt{PKT})$.

However, while the upper bound is clearly met by running P independent instances of an algorithm for weak regret, the lower bound is less clear. Even when considering it as P separate instances, there is a possibility of an algorithm "reacting" to losses in other instances to play differently in the current instance, obtaining a higher total reward as a result. For completeness, we include a proof for the lower bound (Theorem 2) in the full paper [21].

▶ **Theorem 2.** *Fix a partition function $f : [T] \to [P]$ which assigns a label to each time step. Assume that for each $\ell \in f([T])$, there are at least $K/(4 \ln \frac{4}{3})$ time steps with label ℓ. Then the minimax pseudo-regret (1), over all algorithms a and adversaries R, has a lower bound as follows, for some positive constant c:*

$$\inf_a \sup_R \left(\max_{\theta \in \Theta_f} E\Big[\sum_{t \in [T]} x_{\theta \circ f(t)}(t) \Big] - E\Big[\sum_{t \in [T]} x_{a(t)}(t) \Big] \right) \geq \sum_{\ell \in [P]} \sqrt{cK|f^{-1}(\ell)|}$$

If we consider the simple case where OPT may play only periodic functions from any period $\tau \in \{1, 2, \cdots, P\}$, it can do no worse than if it were only allowed to play at period P. We thus obtain a lower regret bound of $\sqrt{PKT}$.

6.2 Lower Bound for the Generalized Periodic Setting

Let F be the set of partitions, so $|F|$ is the number of partitions. Let P be the maximum number of labels of any partition in F. For sufficiently large T and $K \leq P$, we obtain a pseudo-regret(2) lower bound of $\Omega(\sqrt{PKT} + \sqrt{KT \frac{\log |F|}{\log K}})$. It is proved in the full paper [21].

If $P < K$ instead, a simple lower bound can be obtained by using only P out of the K arms, so we obtain a problem with P arms and maximum partition size P. This gives us a lower bound of $\Omega\Big(\sqrt{PKT} + \sqrt{PT \frac{\log |F|}{\log P}}\Big)$. We can then merge these two lower bounds into a single expression $\Omega\Big(\sqrt{PKT} + \sqrt{\min(P, K) T \frac{\log |F|}{\log \min(P,K)}}\Big)$.

6.3 Analysis of Bounds

A conclusion we can make from Section 6.2 is that having multiple periods indeed increases the difficulty of the problem - we have obtained a lower bound higher than the known upper bound of $O(\sqrt{PKT})$ had only one partition function of the maximum period P been used.

With K arms, T time steps, $|F|$ partition functions, with every function having at most P labels, Periodic EXP4 gives an upper bound of $O\big(\sqrt{PKT \log K + KT \log |F|}\big)$. On the other hand, we have a lower bound of $\Omega\big(\sqrt{PKT + KT \frac{\log |F|}{\log K}}\big)$ in the case where $K \leq P$. This gives a gap of $\sqrt{\log K}$ between the two bounds. Interestingly, this log-factor is the same as the current gap between the upper and lower bounds in the problem of bandits with expert advice. This is possibly because we use a similar lower bound proof to the problem of bandits with expert advice [23], as well as a similar algorithm for the upper bound.

7 Experimental Evaluation

In this section, we discuss the implementation details of Periodic EXP4 and parameter values chosen, evaluate the algorithm via simulation, and compare its performance to EXP3 [6]. We show how Periodic EXP4 (a) learns periodic patterns over time under both discrete and continuous changes in network data rates, (b) outperforms EXP3, (c) is robust to noisy patterns, and (d) adapts to changes due to mobility of users.

We benchmark against "Optimal Random", a player with prior knowledge of the actual bandwidths of each network. In each time slot, it picks a network from a probability distribution equal to the ratios of the bandwidths. For example, with network bandwidths $4, 10$ and 6, the probability of picking the networks will be 0.2, 0.5 and 0.3, respectively.

All the algorithms are implemented in Python, using SimPy [24], while the core algorithm is written in C++. We use a time-varying learning rate $\gamma = t^{-\frac{1}{10}}$ [17] for both Periodic EXP4 and EXP3; γ slowly tends to zero to ensure convergence [27] while at the same time ensures that the algorithm does not take too long to learn (it learns slowly when γ is very small). Although they are not pre-requirements of Periodic EXP4, for simplicity, we assume that (a) a network's bandwidth is equally shared among its clients, and (b) devices are time-synchronized. To reduce numerical error in our simulations, we substitute computations of $\sum_{x \in Y} \exp(x)$ with $\exp(\max_{x \in Y} x)$. In nearly all cases, sums of exponentials in our algorithm are heavily dominated by a single term, making the values of the two expressions approximately equal. Experimentally, we find that this has negligible effects on the values computed within the algorithm.

We do simulations on synthetic data. We consider setups with 20 mobile devices and 3 wireless networks, unless otherwise specified. While the number of devices remain constant throughout the simulation run, the data rates and availability of networks may change. We assume that a network selection is performed once every minute; hence, 1440 time slots is one simulated day. All results presented are from 20 simulation runs, of 86,400 time slots each (i.e., 2 simulated months). The pattern of network behavior and/or user mobility over the first 1440 time slots is repeated 60 times; we refer to each repetition as an "iteration".

We apply Periodic EXP4 in the generalized periodic setting. We define a partition function of period τ as one which divides each iteration of 1440 time slots into τ equal contiguous segments, labeled 1 to τ in chronological order. The same labels are used for each successive repetition. Unless otherwise specified, we use the period set $\{1, \cdots, 24\}$. This refers to using 24 partition functions, of periods 1 to τ respectively.

7.1 Evaluation Criteria

Good assignments of devices to networks divide the available bandwidth evenly among the devices. We thus evaluate the performance of the algorithms based on the lowest data rate observed by any of the devices. We compare this to the optimal allocation of devices, which maximizes the lowest data rate observed by any device. If a device with the lowest data rate observes 3Mbps, but the optimal's lowest is 5Mbps, we say it loses 40% of its achievable gain. We refer to this percentage loss as the "distance to optimal minimum" in our results.

We do not use average cumulative gain as a performance measure because in our problem setting, average gain is maximized as long as there is at least one user in each network.

7.2 Performance Comparison of Algorithms

We consider two setups, both at an office with two WiFi networks and a cellular network. The data rates of these networks vary over time. The first setup involves discrete changes in network bandwidths at fixed time intervals (Figure 2a). In the second setup, the data rates vary continuously with time (Figure 2b). Figures 3a and 3b show that in both setups, the distance to optimal minimum of Periodic EXP4 drops over time while EXP3 shows no noticeable improvement with time.

Figure 4 for the continuous setup explains this improvement. The figure for the discrete setup is in the full paper [21]. At each time step, each user has a probability of picking each

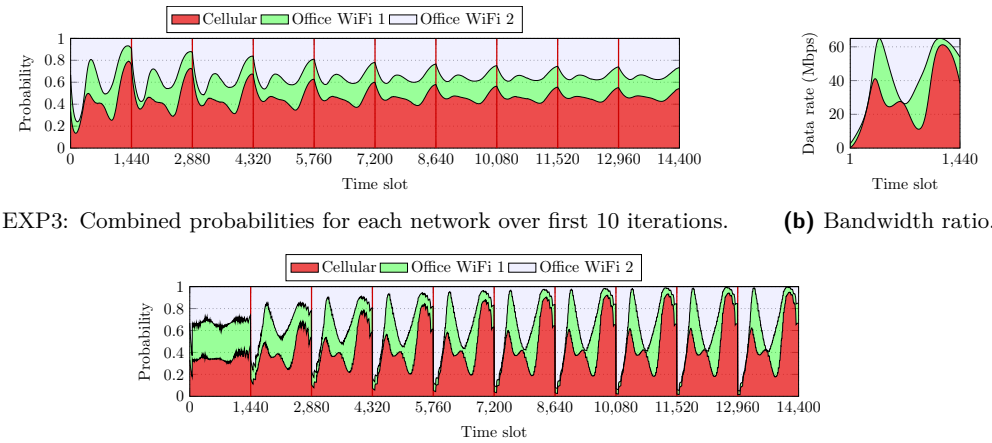
Figure 3 Distance to optimal minimum of Periodic EXP4 and EXP3 over 60 iterations.



(a) EXP3: Combined probabilities for each network over first 10 iterations. **(b)** Bandwidth ratio.

(c) Periodic EXP4: Combined probabilities for each network over first 10 iterations.

Figure 4 Area chart showing the time variation of combined probabilities in the continuous setup. Figure 4b shows the actual ratio of the bandwidths of the three networks within any one iteration.

of the networks. If we consider the combined probability of picking each network, we can see that in Periodic EXP4, these probabilities converge towards the ratios of the bandwidths of the networks (Figures 4c). This is despite the continuous setup having no obvious best period. On the other hand, EXP3's probabilities slowly flatten out (Figure 4a). This is consistent with what we would expect, as EXP3 seeks to be competitive with the best fixed-action policy, meaning that it only seeks out the best fixed arm to play.

Figure 5 shows that while EXP3 initially learns more quickly, Periodic EXP4 eventually outperforms EXP3 (which converges to the network with the best average performance), with a performance similar to Optimal Random. From our experiments, we find that while all algorithms have similar total cumulative gains, we may note that Periodic EXP4 is fairer than EXP3, with significantly lower variance. We present these results in the full paper [21].

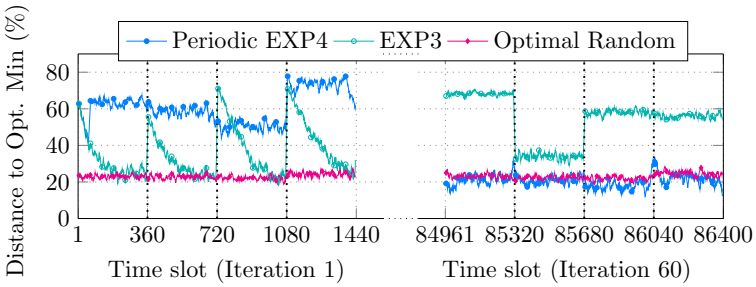


Figure 5 Distances to Optimal minimum in the first and last repetitions of the discrete setting in Figure 2a. Vertical lines indicate points where data rates change.

7.3 Other Experiments

In the full version of the paper [21], we discuss a few more experiments, the results of which are briefly summarized as follows:

1. **Performance in Noisy Settings:** On each time step, we apply a 10% Gaussian noise to each of the networks' data rates. We find that our algorithms are largely unaffected by noise in the data, giving similar results with and without noise.
2. **Comparison of Period Sets:** We do a comparison between different possible period sets F. We find that the algorithm learns more slowly with larger period sets (e.g. $\{1, 2, \cdots, 45\}$, as compared to $\{1, 2, \cdots, 15\}$), but can converge to better results on more complex instances (instances where the bandwidth may fluctuate more wildly).
3. **Mobility of Users:** We consider a setup where users move around and have access to different sets of networks at different times. We compare Vanilla Periodic EXP4, which is oblivious to networks possibly becoming unavailable, against an optimized version, which selects only from the set of currently available networks. While the optimized version initially yields a better performance, they eventually perform equally well when the Vanilla Periodic EXP4 algorithm learns the pattern.

8 Conclusion

In this paper, we develop an efficient variant of EXP4 for the periodic bandit problem, give nearly matching upper and lower bounds for it, and demonstrate its advantages in learning periodic behavior in the context of the network selection problem.

An interesting issue raised in contrasting this paper and [9, 22] is whether non-stationary bandit problems are better modeled stochastically or adversarially. While these papers address non-stationary rewards primarily in a stochastic setting with some adversarial aspects, we tackle the periodic bandit problem in a fully adversarial setting. Using the adversarial setting has the benefit of not placing any constraints on the adversary; we adapt to the periodic setting only through our definition of regret. A proper comparison of stochastic and adversarial methods for network selection is a possible future line of work.

Abstract

We consider the problem of transforming a given graph G_s into a desired graph G_t by applying a minimum number of primitives from a particular set of *local graph transformation primitives*. These primitives are local in the sense that each node can apply them based on local knowledge and by affecting only its 1-neighborhood. Although the specific set of primitives we consider makes it possible to transform any (weakly) connected graph into any other (weakly) connected graph consisting of the same nodes, they cannot disconnect the graph or introduce new nodes into the graph, making them ideal in the context of supervised overlay network transformations. We prove that computing a minimum sequence of primitive applications (even centralized) for arbitrary G_s and G_t is NP-hard, which we conjecture to hold for any set of local graph transformation primitives satisfying the aforementioned properties. On the other hand, we show that this problem admits a polynomial time algorithm with a constant approximation ratio.

1 Introduction

Overlay networks are used in many contexts, including peer-to-peer systems, multipoint VPNs, and wireless ad-hoc networks. In fact, any distributed system on top of a shared communication infrastructure usually has to form an overlay network (i.e., its participating sites have to know each other or at least some server) to allow the exchange of information.

A fundamental task in the context of overlay networks is to maintain or adapt its topology to a desired topology, where the desired topology might either be pre-defined or depend on a certain objective function. The problem of reaching a pre-defined topology has been extensively studied in the context of self-stabilizing overlay networks (e.g., [29, 21, 12, 5, 22, 7]), and the problem of adapting the topology based on a certain objective function has been studied in the context of self-adapting and -optimizing overlay networks (e.g., [33, 14, 2, 19, 11, 3, 10, 8]). Many of these approaches are decentralized, and because of that,

the work (in terms of number of edge changes) they need to adapt to a desired topology might be far away from the minimum possible work to reach that topology. In fact, no non-trivial results on the competitiveness of decentralized overlay network adaptations are known so far other than handling single join or leave operations, and it is questionable whether any good competitive result can be achieved with a decentralized approach. An alternative approach would be that a server is available for controlling the network adaptations, and this has already been considered in the context of so-called supervised overlay networks. In a *supervised overlay network* there is a dedicated, trusted node called *supervisor* that controls all network adaptations but otherwise is not involved in the functionality of the overlay network (such as serving search requests), which is handled in a peer-to-peer manner. This has the advantage that even if the supervisor is down, the overlay network is still functional. Solutions for supervised overlay networks have been proposed in [24, 15], for example, and the results in [24] imply that, for specific overlay networks, any set of node arrivals and departures can be handled in a constant competitive fashion (concerning the work needed for adding and removing edges) to get back to a desired topology. But no general result is known so far for supervised overlay networks concerning the competitiveness of converting an initial topology into a desired topology. Also, no result is known so far on how to handle the problem that a supervisor could be faulty or even act maliciously.

A malicious supervisor would pose a significant problem for an overlay network since it could easily launch *Sybil attacks* (i.e., flooding the overlay network with fake or adversarial nodes) or *Eclipse attacks* (i.e., isolating nodes from other nodes in the overlay network). We thus ask: Can we limit the power of a supervisor such that it cannot launch an eclipse or sybil attack while still being able to convert the overlay network from any connected topology to any other connected topology?

We answer the question to the affirmative by determining a set of graph transformation commands, also called *primitives*, that only the supervisor may issue to the nodes. These primitives are powerful enough to transform any (weakly) connected topology into any other (weakly) connected topology but still allow the nodes to locally check that applying them does not disconnect the network or introduce a new node into the network. We additionally aim at minimizing the reconfiguration overhead, i.e., the number of commands to be issued (and, related to this, the number of changes to be made to node neighborhoods) to reach a desired topology. Unfortunately, as we will show, this cannot be done efficiently for the set of primitives we consider unless $\mathsf{P} \neq \mathsf{NP}$, and we conjecture that this holds for any set of commands that has the aforementioned property of giving the participants the ability to locally check that they cannot be used for eclipse or sybil attacks. However, we are able to give an $O(1)$-approximation algorithm for this problem.

1.1 Model and Problem Statement

We model the overlay network as a graph, i.e., nodes represent participants of the network and if there is a directed edge (u, v) in the graph, this means that there is a connection from u to v. Undirected edges $\{u, v\}$ model the two connections from u to v and from v to u. Since there may be multiple connections between the same pair of participants, the graphs we consider in this work are multigraphs, i.e., edges may appear several times in the (multi-)set of edges. For convenience throughout this work we will use the term "graph" instead of multigraph and refer to "edge sets" even though their elements need not be unique.

We consider the following set P_d of four primitives for the manipulation of directed graphs, first introduced by Koutsopoulos et al. [25] in the context of overlay networks:

Introduction. If a node u has a reference of two nodes v and w with $v \neq w$, u *introduces* w to v if u sends a message to v containing a reference of w while keeping the reference.

Delegation. If a node u has a reference of two nodes v and w s.t. u, v, w are all different, then u *delegates* w's reference of v if u sends a message to v containing a reference of w and deletes the reference of w.

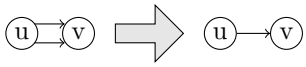
Fusion. If a node u has two references v and w with $v = w$, then u *fuses* the two references if it only keeps one of these references.

Reversal. If a node u has a reference of some other node v, then u *reverses* the connection if it sends a reference of itself to v and deletes its reference of v.

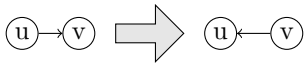
The four primitives are visualized in Figure 1. Note that for the Introduction primitive, it is possible that $w = u$, i.e., u introduces itself to v. To simplify the description, we sometimes say that a node u introduces or delegates the *edge* (u, v) if u introduces v to some other node or delegates v's reference to some other node, respectively.

(a) Introduction Primitive.

(b) Delegation Primitive.



(c) Fusion primitive.



(d) Reversal primitive.

Figure 1 The four primitives in P_d in pictures.

The primitives in P_d are known to be universal (c.f. [25]), i.e., it is possible to transform any weakly connected graph into any other weakly connected graph by using only the primitives in P_d. Note that for every edge (u, v) used in any of the primitives, either (u, v) still exists after the corresponding primitive is applied, or there is still an (undirected) path from u to v in the resulting graph. This directly implies that no application of the primitives can disconnect the graph. We assume that all connections are *authorized*, meaning that both endpoints are aware of the other endpoint of this connection. Thus, if for an edge (u, v) that is supposed to be transformed into (v, u) by an application of the Reversal Primitive, v checks that u actually was the previous endpoint of the former edge then the primitives cannot be used to introduce new nodes into the graph.

For undirected graphs, consider the set P_u containing only the primitives Introduction, Delegation and Fusion (defined correspondingly). These three primitives, accordingly, are universal on undirected graphs, i.e., any connected undirected graph can be transformed into any other connected undirected graph by applying the primitives in P_u (c.f. [25]).

We make the following observation:

▶ **Observation 1.** *The Introduction primitive is the only primitive that can increase the number of edges in a graph. The Fusion primitive is the only primitive that can decrease the number of edges in a graph. The Delegation primitive is the only primitive that can remove the last edge between two nodes (i.e., an edge of multiplicity one).*

A *computation* C is a finite sequence $G_1 \Rightarrow G_2 \Rightarrow \cdots \Rightarrow G_l$ of either directed or undirected graphs, in which each graph G_{i+1} is obtained from G_i by the application of a single primitive from P_d or P_u, respectively. The graphs G_1 and G_l are called the *initial* and the *final* graphs of C, respectively. The variable l is called the *length of the computation*.

We define the *Undirected Local Graph Transformation Problem* (ULGT) as follows: given two connected undirected graphs G_s, G_t, find a computation of minimum length whose initial graph is G_s and whose final graph is G_t. The corresponding decision problem κ-ULGT is defined as follows: given a positive integer k and two connected undirected graphs G_s and G_t, decide whether there is a computation with initial graph G_s and final graph G_t of length at most k. Accordingly we define the *Directed Local Graph Transformation Problem* (DLGT) and κ-DLGT, which differ from the according problems in that the graphs are directed.

1.2 Related Work

Graph transformations have been studied in many different contexts and applications, including but not limited to pattern recognition, compiler construction, computer-aided software engineering, description of biological developments in organisms, and functional programming languages implementation (for a more detailed introduction and literature overview, we refer the reader to [4], [20], or [31, 13]). Simply put, a graph transformation (or graph-rewriting) system consists of a set of rules $L \to R$ that may be applied to subgraphs isomorphic to L of a given graph G thus replacing L with R in G. Since changing the labels assigned to a graph (graph relabeling) is also a kind of graph transformation, basically every distributed algorithm can be understood as a graph transformation system (c.f. [13]). The type of graph transformations probably closest related to our work is the area of *Topology Control* (TC). In simple terms, the goal of TC is to select a subgraph of a given input graph that fulfills certain properties (such as connectivity) and optimizes some value (such as the maximum degree). This problem has been studied in a variety of settings (for surveys on this topic see, e.g., [27], or [6]) and although the usual approach is decentralized, there are also some centralized algorithms in this area (see, e.g., [30]). However, these works only consider the complexity of computing an optimal topology (instead of the complexity of transforming the graph by a minimum number of rule applications). There is one work by Lin [28] proving the NP-hardness of the *Graph Transformation Problem*, in which the goal is to find the minimum integer k such that an initial graph G_s can be transformed into a final graph G_t by adding and removing at most k edges in G_s. Our work differs from that work in that we do not allow arbitrary edge relocations but restrict them to a set of rules that can be applied locally (and we also provide constant-factor approximation algorithms).

Our approximation algorithms use an approximation algorithm for the Undirected Steiner Forest Problem as a black-box (also known as the Steiner Subgraph Problem with edge sharing, or, in generalizations, the Survivable Network Design Problem or the Generalized Steiner Problem). 2-approximations of this problem were first given by Agrawal, Klein, and Ravi [1], and by Goemans and Williamson [16], and later also by Jain [23]. Gupta and Kumar [18] showed a simple greedy algorithm to have a constant approximation ratio and recently, Groß et al. [17] presented a local-search constant approximation for Steiner Forest.

1.3 Our Contribution

The main contributions of this paper are as follows: We prove the Undirected and the Directed Local Graph Transformation Problem to be NP-hard in Section 2. Furthermore, in Section 3 we show that they belong to APX, i.e., there exist constant approximation algorithms for these two problems.

2 NP-hardness results

In this section, we show the NP-hardness of the Undirected Local Graph Transformation Problem by proving the NP-hardness of k-ULGT (see Section 2.1). Since k-DLGT's NP-hardness is very similar for k-ULGT, we omit its proof and only briefly sketch the differences in the full version of this paper [32].

Throughout this section, for any positive integer i we use the notation $[i]$ to refer to the set $\{1, 2, \ldots, i\}$.

2.1 k-ULGT is NP-hard

We prove k-ULGT's hardness via a reduction from the Boolean satisfiability problem (SAT) which was proven to be NP-hard by Cook [9] and, independently, by Levin [26]. We briefly recap SAT as follows:

▶ **Definition 1** (SAT). *Given a set X of n Boolean variables $x_1, \ldots, x_n$ and a Boolean formula Φ over the variables in X in conjunctive normal form (CNF), decide whether there is a truth assignment $t : X \to \{0, 1\}$ that satisfies Φ.*

To reduce SAT to k-ULGT, we use the following reduction function:

▶ **Definition 2** (Reduction function). *Let $S = (X, \Phi)$ be a SAT instance, in which $X = \{x_1, \ldots, x_n\}$ is the set of Boolean variables and $\Phi = C_1 \wedge \cdots \wedge C_m$ for clauses $C_1, \ldots, C_m$. Then $f(S) = (G_s, G_t, k)$ in which $k = 2n + m$ and G_s and G_t are undirected graphs defined as follows. Without loss of generality, assume that each literal $y_i \in \{x_i, \overline{x_i}\}$ occurs only once in each clause. We say $y_i \in C_j$ if literal y_i occurs in C_j.*

We define the following sets of nodes: $V_C = \{C_1, \ldots, C_m\}$, and $V_{X_i} = \{x_i, \overline{x_i}, s_i, t_i\}$. Then, the set of nodes of G_s and G_t is $V = \bigcup_{1 \le i \le n} V_{X_i} \cup V_C \cup \{r\}$. For the set of edges, define $E_{X_i} = \{\{s_i, x_i\}, \{\overline{x_i}, s_i\}, \{x_i, t_i\}, \{t_i, \overline{x_i}\}\}$, $E_{C_j} = \{\{y_i, C_j\} | y_i \in \{x_i, \overline{x_i}\} \wedge y_i \text{ occurs in } C_j\}$, $E_{sr} = \{\{s_i, r\} | 1 \le i \le n\}$, $E_{tr} = \{\{t_i, r\} | 1 \le i \le n\}$, $E_{Cr} = \{\{C_j, r\} | 1 \le j \le m\}$. Both G_s and G_t have the edges in $\bigcup_{1 \le i \le n} E_{X_i} \cup \bigcup_{1 \le j \le m} E_{C_j}$. Additionally, G_s has the edges in E_{sr} and G_t has the edges in $E_{tr} \cup E_{Cr}$.

Intuitively, each variable x_i is mapped to a *gadget* X_i consisting of the four nodes $x_i, \overline{x_i}, s_i$, and t_i. Also each clause C_j is connected with each literal occurring within it. Lastly, in G_s, each of the s_i is connected with the node r, whereas in G_t, each of the t_i and each of the C_j are connected with r. Figure 2 shows an example of the output of the reduction function for a given formula in CNF.

We now show that every SAT instance S is satisfiable if and only if $f(S)$ is a "yes" instance of k-ULGT. We start with the "only if" part for this is the simpler direction:

▶ **Lemma 3.** *If a SAT instance S as in Definition 2 is satisfiable then $f(S) = (G_s, G_t, k)$ with $k = 2n + m$ is a k-ULGT instance and there is a computation with initial graph G_s and final graph equal to G_t of length at most $2n + m$.*

Proof. Assume there is a satisfying truth assignment $t : X \to \{0, 1\}$ of S. For every $1 \le i \le n$ let $y_i := x_i$ if $t(x_i) = 1$ or $y_i := \overline{x_i}$ if $t(x_i) = 0$. We construct the following computation with initial graph G_s and final graph G_t:

1. For every $1 \le i \le n$, s_i delegates the edge $\{s_i, r\}$ to y_i.
2. For every $C_j \in \{C_1, \ldots, C_m\}$ choose one neighbor $z_j \in \{y_1, \ldots, y_n\}$ (we show below that this exists), and let z_j introduce r to C_j.
3. For every $1 \le i \le n$, y_i delegates the edge $\{y_i, r\}$ to t_i.

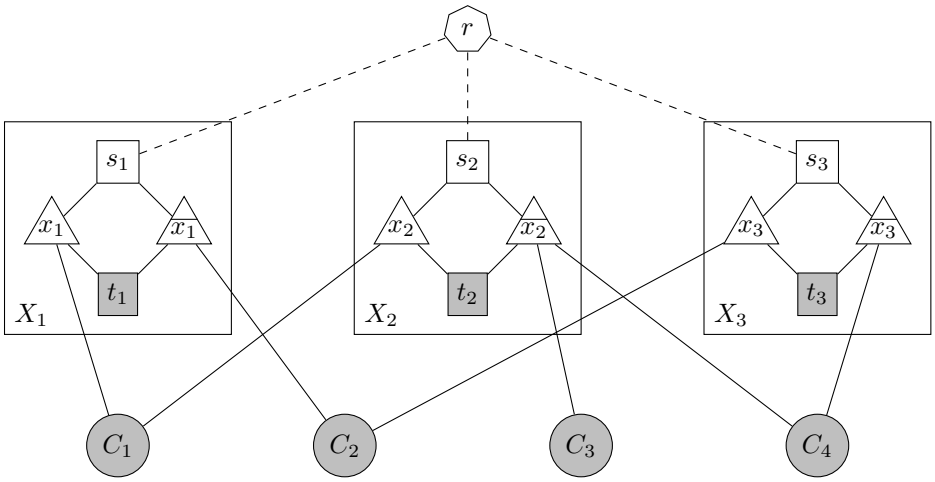


Figure 2 Graph G_s returned by the reduction function for the (example) Boolean formula $(x_1 \vee x_2) \wedge (\overline{x_1} \vee \overline{x_3}) \wedge (\overline{x_2}) \wedge (\overline{x_2} \vee \overline{x_3})$. G_t differs from G_s in that the dashed edges do not exist and all grey nodes share an edge with node r.

Obviously, the length of this computation is $2n + m$. To prove the missing part, recall that every C_j is satisfied under t, i.e., there is at least one literal z_j in C_j that evaluates to true, i.e., there is an $i \in [n]$ such that $z_j = x_i$ if $t(x_i) = 1$, or $z_j = \overline{x_i}$ if $t(x_i) = 0$. By definition of y_i, $z_j = y_i$. Thus because z_j occurs in C_j, y_i was a neighbor of C_j during Step 2. ◀

The "if" part is more complex. We begin with the following insight that will prove helpful in the course of this part.

▶ **Lemma 4.** *Suppose the nodes in the initial graph of a computation C can be decomposed into disjoint sets $V_1, \ldots, V_k, P$ such that there is no edge $\{u, v\}$ for some $u \in V_i$, $v \in V_j$, $i, j \in [k]$, $i \neq j$ and throughout C none of the nodes in P applies a primitive. Then there is no edge $\{u, v\}$ for some $u \in V_i$, $v \in V_j$, $i, j \in [k]$, $i \neq j$ in any graph of the computation.*

Proof. Assume there is a computation C and sets $V_1, \ldots, V_k, P$ as defined above and assume for contradiction that the claim is not true. We consider the first edge $\{u, v\}$ such that $u \in V_i$, $v \in V_j$, $i, j \in [k]$, $i \neq j$. Clearly, it cannot have been created by the application of a Fusion primitive. Thus it must have been created by an Introduction or Delegation primitive applied by a node w that knew both u and v before the application of this primitive. By definition of P, $w \notin P$, i.e., $w \in V_l$ for some $l \in [k]$. However, by the definition of $\{u, v\}$, u and v must have been from V_l as well, yielding a contradiction. ◀

The next lemma we show represents a main building block of the proof of the "if" part.

▶ **Lemma 5.** *Let S be a* SAT *instance and let $(G_s, G_t, k) = f(S)$. For every computation C with initial graph G_s and final graph equal to G_t of length at most $2n + m$ it holds: There are $y_1, \ldots, y_n$, $y_i \in \{x_i, \overline{x_i}\}$ for every $i \in [n]$, such that in C there are no edges other than $E(G_s) \cup E(G_t) \cup \{\{y_i, r\} | i \in [n]\}$ and no edge occurs twice (where $E(G_s)$ and $E(G_t)$ denote the edge set of G_s and G_t, respectively).*

Due to space constraints, we only sketch the proof here, whereas the full proof can be found in the full version of this paper [32]. The general idea of the proof of Lemma 5 is the following: To obtain the target graph, for each $j \in [m]$ the edge $\{C_j, r\}$ has to be created and for

each $i \in [n]$ the edge $\{t_i, r\}$ has to be created. Each of these creations involves a distinct application of a primitive. Therefore, only n applications of primitives are left in a feasible computation. We show that the nodes in each gadget i have to apply at least one primitive p_i that does not create one of the above edges. This implies that each gadget may apply no other primitive than p_i to create an edge that is not in the target graph and that the nodes r and C_j themselves cannot apply any primitives at all which by Lemma 4 means that there are no inter-gadget edges. We use these facts to prove that p_i is used to remove the edge $\{s_i, r\}$ thereby creating either $\{x_i, r\}$ or $\{\overline{x_i}, r\}$.

The rest of the proof of the "if" part, as formalized by the following lemma, is comparably straightforward.

▶ **Lemma 6.** *Let S be a* SAT *instance as in Definition 2. If $f(S) = (G_s, G_t, k)$ with $k = 2n + m$ is a* K-ULGT *instance and there is a computation with initial graph G_s and final graph equal to G_t of length at most $2n + m$ then S is satisfiable.*

Proof. In the following, we refer to the variables defined in Definition 2. Furthermore, we say a computation is *feasible* if and only if its initial graph is G_s, its target graph is G_t and its length is at most $2n + m$. Moreover, we say that the edge that is established during the application of an Introduction or Delegation primitive (the edge (v, w) in Figures 1a and 1b) is the *result* of the Introduction or Delegation, respectively.

Assume that $f(S) = (G_s, G_t, 2n + m)$ is a K-ULGT instance and there is a feasible computation C for $f(S)$. According to Lemma 5 there are $y_1, \ldots, y_n$, $y_i \in \{x_i, \overline{x_i}\}$ for every $i \in [n]$ such that in C there are no edges other than $E(G_s) \cup E(G_t) \cup \{\{y_i, r\}|[n]\}$. Note that in G_t, for every $j \in [m]$ there is an edge $\{C_j, r\}$ and each such edge must have been the result of an introduce or Delegation primitive applied by an y_i, $i \in [n]$ (as throughout C, the C_js do not have any other neighbors with an edge to r that could possible create this edge) . Let $g : \{C_1, C_2, \ldots, C_m\} \to \{y_1, y_2, \ldots, y_n\}$ be the mapping of each C_j to the y_i who applied a primitive that resulted in the edge $\{C_j, r\}$. Consider the truth assignment $t : X \to \{0, 1\}$ such that $t(x_i) = 1$ if $y_i = x_i$ and $t(x_i) = 0$ if $y_i = \overline{x_i}$. Observe that $t(y_i) = 1$ for every $i \in [n]$. Assume for contradiction that there is a clause C_j in S that does not evaluate to 1 under t. Note that $g(C_j)$ must occur in C_j by construction. However, since $g(C_j) = y_i$ for some $i \in [n]$ and $t(y_i) = 1$, we obtain the desired contradiction. ◀

3 Approximation Algorithms

In this section, we first describe an approximation algorithm for ULGT (see Section 3.1) and prove it to have a constant approximation ratio (see Section 3.2). Note that a constant approximation factor algorithm for DLGT can be obtained by a slight adaptation of this algorithm. For a description of this, we refer the reader to the full version [32] due to space constraints.

As an ingredient our algorithm uses a 2-approximation algorithm (see Section 1.2) for the Undirected Steiner Forest Problem (USF) defined as follows: Given a graph G and a set S of pairs of nodes from G, find a forest F in G with a minimum number of edges such that the two nodes of each pair in S are connected by a path in F.

3.1 Algorithm Description

For an initial graph $G_s = (V, E_s)$ and a final graph $G_t = (V, E_t)$, we define the set of *additional* edges $E_\oplus := E_t \setminus E_s$ and the set of *excess* edges $E_\ominus := E_s \setminus E_t$. We now describe the algorithm in detail and then summarize its pseudo-code in Algorithm 1. Our algorithm consists of two parts, the first of which dealing with establishing all additional edges and the second of which dealing with removing all excess edges.

Algorithm 1 Approximation algorithm for ULGT.

Input: Initial graph G_s and final graph G_t.

First part:

1: Compute a 2-approximate solution $F_{ALG,\oplus}$ for the USF with input G_s, and the set $E_\oplus$ as the set of pairs of nodes.
2: For each tree T in $F_{ALG,\oplus}$, select a root node r_T and connect all nodes in T that are incident to an edge in $E_\oplus$ with r_T (details below).
3: For each $\{u, v\} \in E_\oplus$, the root of the tree u and v belong to applies the Introduction primitive to create the edge $\{u, v\}$.
4: For each tree T in $F_{ALG,\oplus}$, delegate all superfluous edges (i.e., not belonging to G_s or $E_\oplus$) created during Step 2 bottom up in T rooted at r_T, starting with the lowest level. At each intermediate node fuse all of these edges before delegating them to the next predecessor.

Second part:

5: Compute a 2-approximate solution $F_{ALG,\ominus}$ for the USF with input G_t, and the set $E_\ominus$ as the set of pairs of nodes.
6: For each $e \in E_\ominus$, let $s(e)$ be an arbitrary of the two endpoints of e. For each tree T in $F_{ALG,\ominus}$, select a root node r_T and for each $e \in E_\ominus$ whose endpoints belong to T, connect $s(e)$ with r_T (similar to Step 2, details below).
7: For each $e \in E_\ominus$, $s(e)$ delegates the other endpoint to r_T.
8: For each tree T in $F_{ALG,\ominus}$, delegate all superfluous edges bottom-up and fuse multiple edges as in Step 4.

In the first part, using an arbitrary 2-approximation algorithm for the USF as a black box the algorithm computes a 2-approximate solution to the following USF instance: The given graph is G_s, and the set of pairs of nodes is $E_\oplus$. Note that the result is a forest such that for every edge $\{u, v\} \in E_\oplus$, u and v belong to the same tree. For each tree T in this forest the algorithm then selects an arbitrary root r_T and connects all nodes in T that are incident to an edge in $E_\oplus$ to r_T. The exact details of this will be described when we analyze the length of the resulting computation. In the next step, for every T, for every $\{u, v\} \in E_\oplus$ such that u and v belong to T, r_T introduces u to v to each other, thereby creating the edge $\{u, v\}$. After that, the superfluous edges are deleted in a bottom-up fashion: every node that does not have a descendant with a superfluous edge (in the tree T this node belongs to when viewing this tree as rooted by r_T), fuses all superfluous edges and delegates the last such to its predecessor in the tree. Note that all superfluous edges in the same tree T have r_T as one of their endpoints.

The second part of the algorithm is similar to the first, with the following differences: In the fifth step, the USF is approximated for the graph G_t and $E_\ominus$ as the set of pairs. Note that the solution is a subgraph of the graph obtained after the first part of the algorithm. In the sixth step, only one of the two endpoints of an edge from $E_\ominus$ is selected to become connected with the root of the tree the endpoints belong to. In the seventh step (where in the first part the additional edges are created by the r_T nodes), for each edge $e \in E_\ominus$, the endpoint selected in the sixth step delegates this edge to r_T (resulting in the edge $\{r_T, v\}$).

3.2 Analysis

In this section we show that Algorithm 1 is a constant-approximation algorithm for ULGT, which is formalized by the following theorem:

▶ **Theorem 7.** ULGT ∈ APX.

For convenience we will analyze the two parts of the algorithm individually. Therefore, for a given initial graph G_s and final graph G_t, let $ALG_1(G_s, G_t)$ be the length of the computation of the first part of the algorithm for this instance, $ALG_2(G_s, G_t)$ be the length of the computation of the second part, and $ALG(G_s, G_t) := ALG_1(G_s, G_t) + ALG_2(G_s, G_t)$. Furthermore, let $OPT(G_s, G_T)$ be the length of an optimal solution to ULGT for initial graph G_s and final graph G_t. We also define the intermediate graph $G' = (V, E_s \cup E_\oplus)$. In the course of the analysis we will establish a relationship between $ALG_1(G_s, G_t)$ and $OPT(G_s, G')$ and between $ALG_2(G_s, G_t)$ and $OPT(G', G_t)$. This will aid us in determining the approximation factor of Algorithm 1 due to the following lemma:

▶ **Lemma 8.** $OPT(G_s, G') + OPT(G', G_t) \leq 2OPT(G_s, G_t) + |E_\oplus|$.

Proof. Let $\mathcal{P}$ denote the problem equal to κ-ULGT with initial graph G_s and final graph G_t with the additional requirement that the computation must contain G' and let $OPT'(G_s, G_t)$ be the length of an optimal solution to it. Clearly, $OPT(G_s, G') + OPT(G', G_t) \leq OPT'(G_s, G_t)$ (otherwise, split the computation at G' and improve either $OPT(G_s, G')$ by the first part obtained or $OPT(G', G_t)$ by the second part obtained). We now show that $OPT'(G_s, G_t) \leq 2OPT(G_s, G_t) + |E_\oplus|$.

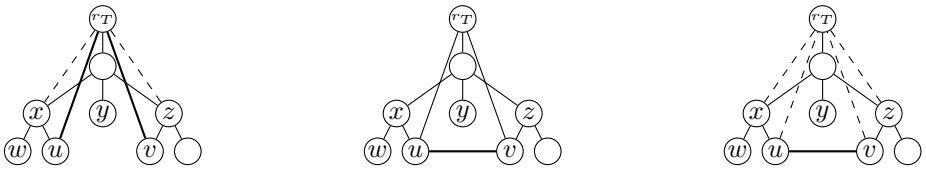
Consider a computation C whose initial graph is G_s, whose final graph is G_t and whose length is $OPT(G_s, G_t)$ (note that such a computation is an optimal solution to ULGT). We now transform C into a computation that represents a solution to $\mathcal{P}$. This transformation increases its length by only $OPT(G_s, G_t) + |E_\oplus|$ and thus proves the above claim (recall that any solution to $\mathcal{P}$ has at least the size of an optimal solution to it). First, because the final graph does not contain any edge $\{u, v\} \in E_\ominus$, for every such edge there is one last Delegation in C that removes this edge (recall Observation 1). We replace each of these last delegations by an introduction and obtain a new computation C' of equal length. Note that changing these delegations to introductions does not make the computation infeasible as this only causes the graph to have additional edges. The final graph of C' is $(V, E_t \cup E_\ominus) = (V, E_s \cup E_\oplus) = G'$ (recall that $E_t = (E_s \cup E_\oplus) \setminus E_\ominus$). Next we append C' by C and obtain the computation C'' of length $2OPT(G_s, G_t)$. Note that since C transformed G_s to G_t, this second half of C'', which starts from $G' = (V, E_s \cup E_\oplus)$, has the final graph $G'' = (V, E_t \cup E_\oplus)$, i.e., each edge from $E_\oplus$ appears twice in G''. Thus we extend C'' by fusing each edge from $E_\oplus$ with its double, resulting in a computation C''' of length $2OPT(G_s, G_t) + |E_\oplus|$. Since C''' represents a solution to $\mathcal{P}$ for initial graph G_s and final graph G_t, this completes the proof. ◀

In the rest of the analysis we show that $ALG_1(G_s, G_t) \leq 11OPT(G_s, G')$ (Lemma 9) and that $ALG_2(G_s, G_t) \leq 7OPT(G', G_t)$ (Lemma 10). By Lemma 8 this implies that $ALG(G_s, G_t) \leq 11(2OPT(G_s, G_t) + |E_\oplus|) \leq 33OPT(G_s, G_t)$ (since, clearly, $OPT(G_s, G_t) \geq |E_\oplus|$), which yields the claim of Theorem 7.

We begin with the former claim, which is formalized by the following lemma:

▶ **Lemma 9.** $ALG_1(G_s, G_t) \leq 11OPT(G_s, G')$.

Proof. Let $F_{OPT,\oplus}$ be an optimal solution for the USF with input G_s and $E_\oplus$ as the set of nodes and recall that $F_{ALG,\oplus}$ is the USF approximation computed in Step 1 of Algorithm 1. Throughout the analysis, $|F_{OPT,\oplus}|$ and $|F_{ALG,\oplus}|$ will denote the number of edges in these



(a) Step 2 connects all endpoints of edges in $E_\oplus$ belonging to T with r_T.

(b) In Step 3, r_T creates the edges in $E_\oplus$ that belong to T by an Introduction.

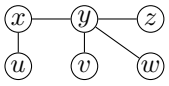
(c) Step 4 removes all superfluous edges by delegating and fusing them up in the tree.

Figure 3 Example of a tree T with root r_T for Step 2-4 of Algorithm 1 assuming $\{u, v\} \in E_\oplus$. $ST(x)$ consists of x, w, and u. x is relevant, whereas y is not. Dashed edges exist temporarily during the displayed step.

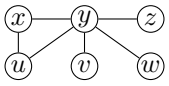
solutions. In the first part of this proof, we show that $ALG_1(G_s, G_t) \leq 4|F_{OPT,\oplus}| + 3|E_\oplus|$. The second part then consists in proving $OPT(G_s, G') \geq |F_{OPT,\oplus}| - |E_\oplus|$, which together with the observation that $OPT(G_s, G') \geq |E_\oplus|$ yields the claim.

To upper bound $ALG_1(G_s, G_t)$, we analyze the number of primitives applied in each of the steps of the first part of the approximation algorithm. In Step 1, no primitive is applied. To keep the number of edges as low as possible (which saves Fusion primitives in Step 4), the algorithm for every T in $F_{ALG,\oplus}$ connects the desired nodes to r_T in Step 2 in the following way: To simplify the description, we view T as rooted at r_T and for a node $u \in T$ denote by $ST(u)$ the set consisting of u and all of its descendants in the tree T rooted at r_T. We say a node u is *relevant* if $ST(u)$ contains a node with an endpoint in $E_\oplus$. See Figure 3 for an illustration of these notions. First of all, r_T introduces itself to all relevant children. Then, starting from the second level, we proceed level-wise in the tree: For each level i, every node u at level i checks whether u is an endpoint of an edge in $E_\oplus$ or $\{u, r_T\}$. If so, it introduces r_T to all relevant children. Otherwise, it introduces r_T to all but one of its relevant children (chosen arbitrarily) and delegates r_T to the relevant child it did not introduce r_T to. One can check that the result of this procedure is that each node incident to an edge in $E_\oplus$ has an edge to r_T for the tree T it belongs to, see Figure 3a. Note that according to the definition of $F_{ALG,\oplus}$, for each pair $\{u, v\} \in E_\oplus$ u and v belong to the same tree T. The above procedure increases the number of edges by at most $2|E_\oplus|$ and requires at most $|F_{ALG,\oplus}|$ applications of primitives (since each tree T with k edges contains at most $k + 1$ nodes and for each node u in T, at most one primitive is applied to create $\{u, r_T\}$ and this is done for neither r_T nor the nodes at level 1). It is easy to see that Step 3 (c.f. Figure 3b) involves exactly $E_\oplus$ applications of primitives. For the length of Step 4 (c.f. Figure 3c), note that for every tree T at most $|T|$ delegations have to be applied because every node in each tree has to apply at most one Delegation (causing $|F_{ALG,\oplus}|$ delegations in total) and at most $2|E_\oplus|$ fusions have to be applied for this is the number of superfluous edges created during Step 2. All in all, Step 2, Step 3, and Step 4 involve $|F_{ALG,\oplus}|$, $E_\oplus$, and $|F_{ALG,\oplus}| + 2|E_\oplus|$ applications of primitives, respectively. This makes a total of $2|F_{ALG,\oplus}| + 3|E_\oplus|$. Since $F_{ALG,\oplus}$ is a 2-approximation of $F_{OPT,\oplus}$, we obtain $ALG_1(G_s, G_t) \leq 4|F_{OPT,\oplus}| + 3|E_\oplus|$.

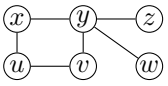
For the lower bound on $OPT(G_s, G')$, assume for contradiction that there is a computation C with initial graph G_s and final graph G' of length $L < |F_{OPT,\oplus}| - |E_\oplus|$. Let $G_s = G_1 \Rightarrow G_2 \Rightarrow \cdots \Rightarrow G_L$ be the sequence of graphs of this computation. For every $\{u, v\} \in E_\oplus$ we iteratively create a path from u to v in the following way: Begin with $P^L_{u,v} := (u, v)$. Note that $P^L_{u,v}$ exists in G_L. We iterate through C in reverse order and for every graph G_i, if $P^{i+1}_{u,v}$ exists in G_i, $P^i_{u,v} := P^{i+1}_{u,v}$. Otherwise, since G_{i+1} is the result of a single application of a primitive to G_i, there is exactly one edge $\{x, y\}$ in $P^{i+1}_{u,v}$ that exists in G_{i+1} but not in G_i and this edge was created by the application of an Introduction or Delegation primitive of some node w such that $\{w, x\}$ and $\{w, y\}$ exist in G_i. Thus, let $P^i_{u,v}$ be $P^{i+1}_{u,v}$ with (x, y) replaced



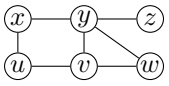
(a) Initial graph G_1.



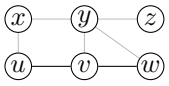
(b) G_2: x has introduced u to y.



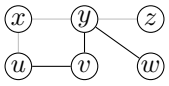
(c) G_3: y has delegated u to v.



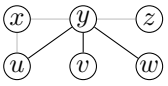
(d) G_4: y has introduced v to w.



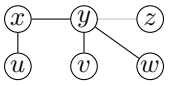
(e) G_4: $P^4_{u,v} = (u, v)$ and $P^4_{v,w} = (v, w)$.



(f) G_3: $P^3_{u,v} = (u, v)$ and $P^3_{v,w} = (v, y, w)$.



(g) G_2: $P^2_{u,v} = (u, y, v)$ and $P^2_{v,w} = (v, y, w)$.



(h) G_1: $P^1_{u,v} = (u, x, y, v)$ and $P^1_{v,w} = (v, y, w)$.

Figure 4 Example of an optimal computation C with initial graph G_1 and $E_\oplus = \{\{u, v\}, \{v, w\}\}$, and the notions used in the proof of Lemma 9. The upper row shows C in order, the lower row illustrates the path sets $P^i_{u,v}$ and $P^i_{v,w}$, which are defined by iterating through C in reverse order. In the lower row, the edges drawn black in G_i are the edges belonging to to F^i. Observe that F_1 represents a solution to the USF for graph G_1 and node pairs $E_\oplus$.

by (x, w, y) and note that $P^i_{u,v}$ exists in G_i. Eventually, we obtain a path $P^1_{u,v}$ that exists in G_s. For $i \in \{1, \dots, L\}$, let $F^i := \bigcup_{\{u,v\} \in E_\oplus} E(P^i_{u,v})$ (where $E(P)$ is the set of all edges on the path P) and note that F^1 represents a solution to the USF with input G_s and $E_\oplus$ as the set of node pairs. An example is given in Figure 4. For an arbitrary $i \in \{1, \dots, L-1\}$, note that $|F^i| \leq |F^{i+1}| + 1$: if G_{i+1} was obtained from G_i by the application of a Fusion primitive, this inequality trivially holds as none of the above paths changes in this case. Otherwise, G_{i+1} was obtained from G_i by an application of an Introduction or Delegation primitive by some node w causing at most one edge $\{x, y\}$ to exist in G_{i+1} that does not exist in G_i. In this case, we further know that $\{w, x\}$ and $\{w, y\}$ exist in G_i and by the definition of the above paths, for every pair $\{u, v\}$ such that $P^{i+1}_{u,v}$ contains the edge $\{x, y\}$ the path $P^i_{u,v}$ contains (x, w, y) as a sub-path instead and for all other pairs $\{u', v'\}$, $P^i_{u',v'} = P^{i+1}_{u',v'}$. By the definition of F^i and F^{i+1}, this implies $|F^i| \leq |F^{i+1}| + 1$ also in this case. All in all we obtain that $|F^1| \leq |F^L| + L = |E_\oplus| + L$ because $F^L = E_\oplus$ (note the definition of F^L). By the assumption that $L < |F_{OPT,\oplus}| - |E_\oplus|$, we obtain $|F^1| < |F_{OPT,\oplus}|$, which represents a contradiction. ◀

▶ **Lemma 10.** $ALG_2(G_s, G_t) \leq 7OPT(G', G_t)$.

Proof. The general structure of this proof follows the line of the proof of Lemma 9, but differs in the details. Similar to the notation used in that proof, let $F_{OPT,\ominus}$ be an optimal solution for the USF with input G_t and $E_\ominus$ as the set of nodes and recall that $F_{ALG,\ominus}$ is the USF approximation computed in Step 5 of Algorithm 1. Analogously, $|F_{OPT,\ominus}|$ and $|F_{ALG,\ominus}|$ denote the number of edges in these solutions. In the first part of this proof, we show that $ALG_2(G_s, G_t) \leq 4|F_{OPT,\ominus}| + 3|E_\ominus|$. The second part then consists in proving $OPT(G', G_t) \geq |F_{OPT,\ominus}|$, which together with the observation that $OPT(G', G_t) \geq |E_\ominus|$ yields the claim.

To upper bound $ALG_2(G_s, G_t)$, we analyze the number of primitives applied in each step of the second part of the approximation algorithm. Of course, no primitive is applied in Step 5. The connections required in Step 6 can be created in a similar fashion as in Step 2 (see the proof of Lemma 9: For each tree T, we proceed top-down in the T rooted at r_T again. Here, each intermediate node u checks whether $u = s(e)$ for some $e \in E_\ominus$. If so, it introduces r_T to all relevant children (here a node v is *relevant* if $ST(v)$ contains a node w such that $w = s(e')$ for some $e' \in E_\ominus$). Otherwise, it introduces r_T to all but one relevant children and delegates

it to the remaining one. In the end, for every edge $e \in E_\ominus$, $s(e)$ has an edge to r_T, the number of edges in the graph has increased by at most $|E_\ominus|$, and the process involved at most $|F_{ALG,\ominus}|$ applications of primitives. In Step 7, clearly exactly $|E_\ominus|$ edges have to be delegated. Step 8 is similar to Step 4 and for analogous reasons requires at most $|F_{ALG,\ominus}|$ delegations and at most $2|E_\ominus|$ fusions (recall that up to $|E_\ominus|$ edges were added in Step 6 and the edges delegated in Step 7 have to be removed as well). All in all, Step 6, Step 7 and Step 8 of the algorithm involve at most $|F_{ALG,\ominus}|$, $|E_\ominus|$ and $|F_{ALG,\ominus}| + 2|E_\ominus|$ applications of primitives, respectively, which yields: $ALG_2(G_s, G_t) \leq 2|F_{ALG,\ominus}| + 3|E_\ominus| \leq 4|F_{OPT,\ominus}| + 3|E_\ominus|$ (since $F_{ALG,\ominus}$ is a 2-approximation of $F_{OPT,\ominus}$).

To lower bound the value of $OPT(G', G_t)$, assume for contradiction that there is a computation C with initial graph G' and final graph G_s of length $L < |F_{OPT,\ominus}| - |E_\ominus|$. Let $G_s = G_1 \Rightarrow G_2 \Rightarrow \cdots \Rightarrow G_L$ be the sequence of graphs of this computation. Similar to the proof of Lemma 9, for every $\{u, v\} \in E_\ominus$, we create a path from u to v, but this time we start with $P^1_{u,v} := (u, v)$ and consider the graphs in increasing order: For $i \in \{2, \ldots, L\}$, if $P^{i-1}_{u,v}$ exists in G_i, $P^i_{u,v} := P^{i-1}_{u,v}$. Otherwise since G_i is the result of a single application of a primitive to G_{i-1}, there is exactly one edge $\{x, y\}$ in $P^{i-1}_{u,v}$ that exists in G_{i-1} but not in G_i and this edge must have been delegated by either x or y to some node w. In the following denote the node that applied the Delegation by z and denote by $\overline{z}$ the other node from $\{x, y\}$. In G_{i-1}, z must share an edge with w and this edge still exists in G_i (for only one primitive is applied in the transition from G_{i-1} to G_i). Since $\{z, \overline{z}\}$ was delegated to w, in G_i the edge $\{w, \overline{z}\}$ exists in G_i. Thus, let $P^i_{u,v}$ be $P^{i-1}_{u,v}$ with (x, y) replaced by (x, w, y) and observe that $P^i_{u,v}$ exists in G_i. Eventually, we obtain a path $P^L_{u,v}$ that exists in G_t. Define $F^i := \bigcup_{\{u,v\} \in E_\ominus} E(P^i_{u,v})$ (where $E(P)$ is the set of all edges on the path P) for all $i \in \{1, \ldots, L\}$, and note that F^L represents a solution to the USF with input G_t and $E_\ominus$ as the set of nodes. Furthermore, for an arbitrary $i \in \{1, \ldots, L-1\}$, note that $|F^{i+1}| \leq |F^i| + 1$ because there is at most one edge $\{x, y\}$ that exists in G_i but not in G_{i+1} and thus causes the replacement of (x, y) by (x, w, y) for some fixed node w for all paths that contain (x, y) as a sub-path. This yields that $|F^L| \leq |F^1| + L = |E_\ominus| + L$ because $F^1 = E_\ominus$ (note the definition of F^1. By the assumption that $L < |F_{OPT,\ominus}| - |E_\ominus|$, we obtain $|F^L| < |F_{OPT,\ominus}|$, which represents a contradiction. ◀

4 Conclusion

We proposed a set of primitives for topology adaptation that a server may use to adapt the network topology into any desired (weakly) connected state but at the same time cannot use to disconnect the network or to introduce new nodes into the system. So far, we only assumed that the server could act maliciously but that the participants of the network are honest and correct, i.e., they refuse any graph transformation commands beyond the four primitives. What, however, if some participants also behave in a malicious manner? Is it still possible to avoid Eclipse or Sybil attacks? It seems that in this case the only measure that would help is to form quorums of nodes that are sufficiently large so that at least one node in each quorum is honest.

Besides these security-related aspects, our results give rise to additional questions: For example, does the NP-hardness apply to any set of local primitives, or is there a set of local primitives that can transform arbitrary initial graphs much faster into arbitrary final graphs than the set considered in this work? Furthermore, is it possible to obtain decentralized versions of the algorithms presented in Section 3, and, if so, what is their competitiveness when compared to the centralized ones?

Abstract

We study a two-sided network investment game consisting of two sets of players, called providers and users. The game is set in two stages. In the first stage, providers aim to maximize their profit by investing in bandwidth of cloud computing services. The investments of the providers yield a set of usable services for the users. In the second stage, each user wants to process a task and therefore selects a bundle of services so as to minimize the total processing time. We assume the total processing time to be separable over the chosen services and the processing time of each service to depend on the utilization of the service and the installed bandwidth. We provide insights on how competition between providers affects the total costs of the users and show that every game on a series-parallel graph can be reduced to an equivalent single edge game when analyzing the set of subgame perfect Nash equilibria.

1 Introduction

With the increasing availability of a fast and reliable internet connection, the demand for and the importance of cloud-computing services is heavily growing. That is why large IT-companies such as Amazon, Google or Microsoft have been investing massively in the improvement of their cloud services in recent years. New high-speed cables are being placed, high performance hardware has been installed, new software has been developed, and machine numbers have been scaled up [21]. Interestingly, prices for these services are typically charged per usage time (see for example, Amazon Web Services [3], Microsoft Azure [26] and Google Cloud [17]). This might a-priory lead to a situation, where a non-optimal infrastructure takes longer to process the users' tasks, and thus even leads to a higher income for the corresponding provider. This paper addresses this issue by means of a theoretical model and provides some results on how competition between providers helps to prevent this behavior of providers.

We study the problem by means of a two-stage game, which we call a network investment game. In the first stage, a set of providers invests in bandwidths of services that are used by users in the second stage to process their task. These services could be different types of on-demand cloud computing, storage, data-base, security or media services. We assume that these services are either complements or substitutes to each other. This implies that the set of feasible bundles of services for the users can be represented by means of source-sink paths in a series-parallel network. Two services that are complementary can be modeled as two edges that are connected in series, whereas two services that are substitutes to each other can be modeled by means of two parallel edges. A similar idea has been used by Correa et al. in [14]. We call this underlying graph the technology graph. However, before a user can use a particular service, there must be a provider that has invested in bandwidth for that particular service. In other words, the investments of the providers induce a subgraph, the set of usable services, of the original technology graph that can be used by the users to process their task. Each user selects a bundle of services that is needed to perform the user's task at minimum total processing time. The total processing time of a service depends on the quantity of users that chooses the particular service and the installed bandwidth of the providers. We assume that each user has a given willingness to pay for taking part in the game and is only present if the total costs do not exceed this value. Given that users impose externalities on each other, we assume that users in the second stage choose their bundle of services according to a Wardrop equilibrium [33] in the corresponding graph of usable services.

Given that prices for services are typically charged per usage time, we use the users' costs as a proxy for the total revenue of the providers investing in a service. This total revenue is shared proportionally among those providers investing in the service. Proportional sharing is used in many different settings, e.g., in cooperative game theory [28] and in the context of congestion games [27]. We assume that the providers' aim is to maximize profit, which depends on the amount of users using their services and the total amount invested. Intuitively, little investment in a service implies a high processing time and thus a high price paid by users, but only a small fraction of users will choose the service. Too much investment might lead to a large fraction of users, but only for a low price.

1.1 Contribution

We are interested in how competition between selfish providers affects the choices made by the users in the network investment game. More formally, we study the existence and uniqueness of subgame perfect Nash equilibria in which in the first stage, providers maximize profit and in the second stage, users choose a Wardrop equilibrium given the strategies of the providers in the first stage. We then consider the performance of equilibria in terms of the price of anarchy [23]. The price of anarchy measures the difference in performance between the worst subgame perfect Nash equilibrium and the social optimum. In fact, for all instances we consider, the performance of all subgame perfect Nash equilibria is the same and we are able to provide an exact characterization of this performance.

Our main result, Theorem 3.2, provides a simplification of the structure of equilibrium investments for series-parallel networks. We focus on series-parallel networks as this represents bundles of services consisting of complements and substitutes. We show that we can restrict attention to investments in which each provider invests in shortest paths (with respect to the number of services). This means that providers have no incentive to diversify their portfolio and invest in complements, nor to invest in services that can be replaced by less services. The result has some interesting implications. When being interested in either a subgame

perfect Nash equilibrium, the social optimum, or combining both in the price of anarchy, it is without loss of generality to assume that the network consists of a single edge. This greatly simplifies the remaining analysis.

We then study the quality of subgame perfect Nash equilibria for different classes of users. In Section 4, we assume that all users have a fixed common willingness to pay. We precisely characterize the society's surplus and the providers' profits both in a corresponding optimal solution and in every subgame perfect Nash equilibrium. It turns out that the price of anarchy with respect to society's surplus can be bounded by a constant, whereas the ratio with respect to providers' profits can grow linearly with the number of providers. In Section 5, we redo the same analysis for users that have different willingnesses to pay and obtain similar results as for the fixed reservation value case.

1.2 Related work

Our model is closely related to several different classes of recently studied models. There is a close connection with network design games, as introduced by Anshelevich et al. [5] and extended by Anshelevich et al. [4]. In these games, selfish agents want to connect a personal source to sink by means of a path, and they share the costs of an edge in case multiple agents use that edge in their path. In network investment games, providers do not share the cost of an edge, but rather the revenue from the users using that edge. As a result, we obtain that providers want to invest in paths in equilibrium, an assumption that is not made a-priori.

In network investment games, we assume that users in the second stage behave as in a non-atomic network congestion game. The idea behind congestion games is that selfish users try to minimize their cost in an already existing network. The best-known solution concept for these games is the Wardrop equilibrium [33]. Beckmann et al. [7] and Dafermos and Sparrow [16] proved some structural results of this equilibrium concept. Roughgarden and Tardos [30] were the first to obtain a bound on the price of anarchy for non-atomic routing games.

Recently, starting with Acemoglu and Ozdaglar [1], several authors considered a two-stage game in which edge owners compete for users by means of tolling. In those games, the users in the second stage also choose a Wardrop equilibrium. Acemoglu and Ozdaglar [1] only considered parallel networks, which was then generalized to parallel-serial networks by Acemoglu and Ozdaglar [2]. Ozdaglar [29] and Hayrapetyan et al. [20] allowed for elastic users. Johari et al. [22] studied an extension that includes entry and investments decisions. Recently, Correa et al. [13] and Harks et al. [18] considered the game in which a central authority is allowed to impose price caps. In the former paper, caps are allowed to be different on different edges, in the latter the cap is uniform. Almost all of the above models, with the exception of Acemoglu and Ozdaglar [2], impose the simplifying assumption that the topology of the network is restricted to be parallel. We allow for arbitrary series-parallel graphs and do not impose any restriction on the strategy space of the providers, that is, every provider is allowed to invest in every edge of the network.

A slightly different, but closely related model is the game analyzed by Correa et al. [14]. Here each edge in a series-parallel network represents a producer that competes by selecting a markup that then determines a price function. The main difference to our work is that producers are identified by an edge and thus do not have the possibility to compete on other edges.

Leader-follower models as the previous ones are also known as Stackelberg games [32]. Recently, lots of attention has been placed on Stackelberg pricing games. Starting with Labbé et al. [24], who considered the problem in which a leader sets prices on a subset of edges and

the follower chooses a shortest path, several authors generalized to different combinatorial problems for the follower. For example, Cardinal et al. [12] studied the Stackelberg minimum spanning tree problem, and Bilò el al. [8] and later Cabello [11] investigated the Stackelberg shortest path tree problem. Balcan et al. [6] and Briest et al. [10] considered the power of single-price strategies. Böhnlein et al. [9] extended the analysis of this simple algorithm beyond the combinatorial setting.

Lastly, there is a close connection to some of the traditional models of competition in economics, like Cournot competition [15]. We refer to Harks and Timmermans [19] for some other recent work connecting atomic splittable congestion games to multimarket Cournot oligopolies.

2 Preliminaries

We consider a two-sided market in which users purchase bundles of services. The set of feasible bundles is specified by a technology graph $G_{st} = (V, E)$, which is a directed series-parallel network with source $s \in V$ and sink $t \in V$. Each edge corresponds to a service. Every s-t path in G_{st} describes a feasible bundle of services. Note that serial edges in G_{st} correspond to complements, whereas parallel edges correspond to substitutes.

We model such a market as a two-stage game. In the first stage, a set of providers chooses to invest into services represented by edges. In the second stage, the users select bundles of services or paths in G_{st} given the investments of the providers in the first stage.

The amount of investment affects the speed of the services. We assume for simplicity that prices for each service are charged automatically on a per-time basis. That is, the price function of an edge directly depends on the chosen investments into the corresponding service in the first stage and the current load induced by the users in the second stage. These two quantities highly influence the time that is needed to finish a job on a cloud computing device. Our choice of the price functions and the model of network investment games are motivated by time-dependent prices that are implemented in Amazon Web Services [3], Microsoft Azure [26] and Google Cloud [17] for using on-demand virtual machines.

We assume for simplicity that each user is of infinitesimal size which allows us to model the second stage as a non-atomic routing game. However it is important to note that the overall demand is not fixed, but depends on the total price the users have to pay for the services. The demand thus depends on the investment of the providers.

More formally, a *network investment game* is given by a tuple $\mathcal{G} = (G_{st}, N, u)$, where $G_{st} = (V, E)$ is a directed series-parallel network with source $s \in V$ and sink $t \in V$, $N = \{1, \dots, n\}$ is the set of providers, and $u : \mathbb{R}_+ \to \mathbb{R}_+$ is the reservation function. Reservation functions model the users' willingness to pay and impose elastic demand. This concept has already been used in the work of Beckmann, McGuire, and Winsten [7]. Intuitively, there is a total demand of x in the game if the total price for bundles of services under demand x is not larger than $u(x)$. We assume that u is non-increasing.

The Provider's Strategies. Each provider $i \in N$ chooses an investment $b_{i,e} \geq 0$ for every edge $e \in E$. Let $b_i = (b_{i,e})_{e \in E}$ be the investments of provider i. Given an investment matrix $b = (b_i)_{i \in N}$, the total investment on edge e is $b_e = \sum_{i \in N} b_{i,e}$. Given $b \in \mathbb{R}_+^{N \times E}$, we define the set of *relevant edges* by $E^+(G_{st}) = \{e \in E(G_{st}) \mid b_e > 0\}$. The price c_e for a user using an edge e, i.e., a service, is an increasing function of the amount of users f_e using edge e and defined by

$$c_e(f_e, b_e) = \begin{cases} \frac{f_e}{b_e} & e \in E^+(G_{st}), \\ \infty & \text{otherwise.} \end{cases}$$

Note that this cost function is a very simple model for prices that depend on the total load of a service and the total investment. Here, we use the simplifying assumption that the time that is needed to complete a service request scales linearly with the load on the machines and inverse linearly with the investment.

The User's Actions. Let $\mathcal{P}(G_{st})$ denote the set of s-t paths, and let $\mathcal{P}^*(G_{st})$ denote the set of s-t paths with minimum number of edges in G_{st}. We model the behavior of the users by a flow in G_{st}. The flow is defined to be a non-negative vector $f(G_{st}) = (f_P)_{P\in\mathcal{P}(G_{st})}$. Note that we stick to the path-definition of flows, because we assume strong flow conservation. For a flow $f(G_{st})$ and an edge $e \in E(G_{st})$, let $f_e = \sum_{P\ni e} f_P$ denote the amount of flow on edge e. Let $|f(G_{st})| = \sum_{P\in\mathcal{P}(G_{st})} f_P$ be the total amount of users that are routed through the network under $f(G_{st})$.

For a given investment matrix b, we call some flow $f(G_{st})$ a *Wardrop equilibrium* if for all $P, P' \in \mathcal{P}(G_{st})$ with $f_P > 0$, we have

$$\sum_{e\in P} c_e(f_e, b_e) \leq \sum_{e\in P'} c_e(f_e, b_e) \text{ and } \sum_{e\in P} c_e(f_e, b_e) < \infty.$$

In a network investment game, we assume that both the providers and the users act selfishly. For simplicity, we assume that users are infinitesimal small and thus, a Wardop flow arises in the second stage. We will remark below that, for a given investment matrix and a given non-increasing reservation function, the arising Wardrop flow is uniquely defined, which is necessary for our model to be well-defined. Given the investment matrix b, we denote the corresponding Wardrop flow by $f(G_{st}, b)$. If G_{st} and/or b is clear from the context, we often omit the dependency on G_{st} and/or b in order to improve readability. If s and t are clear from the context, we sometimes write G instead of G_{st}.

The Provider's Profits. The profit of provider $i \in N$ depends on the associated Wardrop flow f, the investment matrix b and the actual cost for the users $c_e(f_e, b_e)$. We define it by

$$\pi_i(b) = \sum_{e\in E^+} \frac{b_{i,e}}{b_e} \cdot f_e \cdot c_e(f_e, b_e) - \sum_{e\in E^+} b_{i,e} = \sum_{e\in E^+} b_{i,e} \cdot \frac{f_e^2}{b_e^2} - \sum_{e\in E^+} b_{i,e}.$$

where $\frac{b_{i,e}}{b_e}$ is the proportional share of provider $i \in N$ and $\sum_{e\in E^+} b_{i,e}$ her investment costs. This profit function is motivated by that fact that each user pays a load-dependent price for using a service of the provider, which is proportionally divided among those providers investing in the service, and the provider has some cost for installing bandwidth for the services. We consider the very simple model that investment costs are linear and the profit is given by the payment of the users minus the investment costs.

We call an investment matrix $b \in \mathbb{R}_+^{N\times E}$ a *subgame perfect Nash equilibrium* if for all $i \in N$ and all $b'_i \in \mathbb{R}_+^E$,

$$\pi_i(b) \geq \pi_i(b'_i, b_{-i}).$$

Given $b \in \mathbb{R}_+^{N\times E}$, we call b'_i a *better response* for provider $i \in N$ if $\pi_i(b'_i, b_{-i}) > \pi_i(b)$. In a subgame perfect Nash equilibrium, no provider has a better response. We call a better response b'_i *demand preserving* if $|f(b'_i, b_{-i})| = |f(b)|$.

The Social Welfare. or social surplus, is traditionally defined as the sum of the providers' surplus and the user's surplus. In our model, similarly as in Hayrapetyan et al. [20], this boils down to,

$$SW(b) = \sum_{i \in N} \pi_i(b) + \int_0^{|f|} u(x)\, dx - \sum_{e \in E^+} f_e c_e(f_e, b_e) = \int_0^{|f|} u(x)\, dx - \sum_{e \in E} b_e.$$

Note that payments do not appear in the social welfare, as they are transfers from users to providers. An investment matrix b^* is called a *social optimum* if b^* maximizes the social welfare.

For a given instance $\mathcal{G}$, let $\mathcal{E}(\mathcal{G})$ denote the set of subgame perfect Nash equilibria. Notice that $\mathcal{E}(\mathcal{G})$ might be empty. A natural question is to quantify the loss in social welfare due to competition. Typically, researchers provide upper bounds for the loss in efficiency. We are able to precisely bound this inefficiency for any given instance. To this end, we define the *price of anarchy* and *price of stability* for a given instance as

$$PoA(\mathcal{G}) = \frac{\sup\limits_{b^* \in \mathbb{R}_+^N} SW(b^*)}{\inf\limits_{b \in \mathcal{E}(\mathcal{G})} SW(b)}, \text{ and } PoS(\mathcal{G}) = \frac{\sup\limits_{b^* \in \mathbb{R}_+^N} SW(b^*)}{\sup\limits_{b \in \mathcal{E}(\mathcal{G})} SW(b)}.$$

We assume that $0/0 = 1$ and $PoA(\mathcal{G}) = PoS(\mathcal{G}) = \infty$ if $\mathcal{E}(\mathcal{G})$ is empty.

A second natural question is to quantify the loss in total profit due to competition. We call this the *providers' price of anarchy* and *providers' price of stability*, and define it by

$$PPoA(\mathcal{G}) = \frac{\sup\limits_{b^* \in \mathbb{R}_+^N} \sum_{i \in N} \pi_i(b^*)}{\inf\limits_{b \in \mathcal{E}(\mathcal{G})} \sum_{i \in N} \pi_i(b)}, \text{ and } PPoS(\mathcal{G}) = \frac{\sup\limits_{b^* \in \mathbb{R}_+^N} \sum_{i \in N} \pi_i(b^*)}{\sup\limits_{b \in \mathcal{E}(\mathcal{G})} \sum_{i \in N} \pi_i(b)}.$$

As before, we assume that $0/0 = 1$ and $PPoA(\mathcal{G}) = PPoS(\mathcal{G}) = \infty$ if $\mathcal{E}(\mathcal{G})$ is empty.

We start with some simple observations on Wardrop equilibria for this model. To calculate the flow that models the users, we distinguish between two cases. Either there exists a s-t path $P \in \mathcal{P}$ such that $b_e > 0$ for all $e \in P$, or not. Put differently, either there is a path P such that for all $e \in P$ we have $e \in E^+(G_{st})$, or all paths have investment 0 for at least one edge. If there is no s-t path with strictly positive investment on every edge, the Wardrop equilibrium is the empty flow with $|f| = 0$. If there is some $P \in \mathcal{P}$ with $b_e > 0$ on all edges $e \in P$, we obtain the following results.

▶ Remark 2.1 ([7, 16]). If f is a Wardrop equilibrium, then there is a constant $c_b \geq 0$ such that $\sum_{e \in P} c_e(f_e, b_e) = c_b$ whenever $P \in \mathcal{P}$ with $f_e > 0$ for all $e \in P$, and $\sum_{e \in P} c_e(f_e, b_e) \geq c_b$ otherwise.

▶ Remark 2.2 ([7, 16]). For two Wardrop flows f, f' with $|f| = |f'|$ in a network with strictly increasing cost functions on every edge, we have that $f_e = f'_e$ for all $e \in E$.

Note that, by Remarks 2.1 and 2.2, we have that the cost per user in the network investment game c_b, as defined in Remark 2.1, only depends on the total demand $|f|$ for all Wardrop flows f and a fixed b. Let us focus on this dependence and write $c_b(|f|)$ instead of c_b. It turns out that $c_b(|f|)$ is in fact strictly increasing in $|f|$. The following proposition is due to Lin, Roughgarden, and Tardos [25]. However, in their variant of the proposition they only assume non-decreasing cost functions and show that $c_b(|f|)$ is non-decreasing in $|f|$. Since we have strictly increasing cost functions, we modify their proof in the full version [31] such that we get a slightly stronger statement.

▶ **Proposition 2.3** ([25]). *$c_b(|f|)$ is strictly increasing in $|f|$.*

We note that we can extend Proposition 2.3 and show that for network investment games, $c_b(|f|)$ is even linear in $|f|$. The proof uses the series-parallel structure of the graph and can be found in the full version [31].

▶ **Proposition 2.4.** *Given a vector of investment levels b, $c_b(|f|)$ is a linear function of $|f|$.*

The above two propositions are very important for the setup of network investment games. We assume that demand directly depends on the actual cost for the users, and thus indirectly on b. In order to do so, we use that the costs for each user are given by a linear function $c_b(|f|)$. Combining this with the reservation function u stating that an amount of $u(x)$ has a willingness to pay at least x, we define

$$|f| = \inf\{x \in \mathbb{R}_+ \mid u(x) \leq c_b(x)\}.$$

Note that this infimum is well defined, since u is non-increasing and $c_b(\cdot)$ is strictly increasing due to Proposition 2.3. Furthermore, let us illustrate the dependence of $|f|$ on b by the following observation. An increase of some b_e for fixed f induces a change in the corresponding edge cost $c_e(f_e, b_e)$ and weakly decreases the cost of the flow f. Since Wardrop flows are optimal flows for linear cost functions, this weakly decreases the value of $c_b(x)$ for any fixed x. Overall, one can show that a change of b changes the slope of $c_b(x)$ in the definition above, which then might result in a different demand.

3 Characterization of Equilibria

In this section, we derive some important properties of subgame perfect Nash equilibria. First, we prove our main result that in every subgame perfect Nash equilibrium, every provider only invests in shortest (with respect to the number of edges) paths. The implications of this result are quite significant and twofold. First, it implies a nice characterization of markets that can be modeled by means of a network investment game. Second, the result simplifies the further analysis of the game significantly. As long as we are interested in equilibrium investments, the analysis gets notably easier. Instead of considering a strategy space in which every provider is allowed to invest in every edge separately, we can restrict attention to strategies in which providers invest in shortest paths. We will heavily use this characterization in the later sections.

▶ **Definition 3.1.** *We call a strategy b_i a* path strategy *of provider i if there exist values $(b_{i,P})_{P\in\mathcal{P}}$ with $b_{i,P} \geq 0$ such that $b_{i,e} = \sum_{P:e\in P} b_{i,P}$ for all $e \in E$.*

Note that the definition ensures that we can always decompose a path strategy $(b_{i,e})_{e\in E}$ of a provider $i \in N$ defined on edges into a path decomposition. Thus, when considering path strategies, we can work with the path decomposition of investments, instead of the investments defined on edges. If all providers' investments are path strategies, it is immediately clear that we can also define $b_P = \sum_{i\in N} b_{i,P}$ for all $P \in \mathcal{P}$ and $|b| = \sum_{P\in\mathcal{P}} b_P$.

Note that, when using the term *shortest paths*, we always refer to shortest paths with respect to the number of edges in the path. Now, we are able to state and prove our main theorem of this section.

▶ **Theorem 3.2.**

(i) *In every subgame perfect Nash equilibrium, every provider $i \in N$ chooses a path strategy on shortest paths.*

(ii) *Let $i \in N$. If every provider $j \in N \setminus \{i\}$ chooses a path strategy on shortest paths then the following holds: For every strategy b_i of provider i, there is a path strategy on shortest paths b_i' inducing the same amount of flow and at least the same profit for provider i.*

For the proof of Theorem 3.2, we need the following two lemmas. In the first lemma we observe that in equilibrium a provider cannot choose positive investments on two paths of different length. If so, there is always a better response that only invests in the shorter of the two paths.

▶ **Lemma 3.3.** *Let (G, s, t) be a series-parallel graph that is a parallel composition of series-parallel graphs (G_1, s, t) and (G_2, s, t). Let b be a vector of path strategies of paths that all are either shortest s-t paths in G_1 with length k or shortest s-t paths in G_2 with length ℓ. If $k < \ell$, and $b_{i,P_2} > 0$ for some provider $i \in N$ and $P_2 \in \mathcal{P}^*(G_2)$, then there is a demand preserving better response for i with $b_{i,P_2} = 0$.*

Next we turn to graphs that are a series composition of two subgraphs. Assuming that every provider's strategy can be decomposed into two path strategies for the two subgraphs, we show that in equilibrium they must invest the same value in both subgraphs. Furthermore, if all other providers play shortest path strategies, for all strategies of a provider, the provider always has an at least as good strategy in shortest paths.

▶ **Lemma 3.4.** *Let (G, s, t) be a series-parallel graph that is a series composition of series-parallel graphs (G_1, s, v) and (G_2, v, t). Let b be a vector of investments $(b_{i,e})_{i \in N, e \in E}$ that can be partitioned into $(b^1_{i,e})_{i \in N, e \in E(G_1)}$ and $(b^2_{i,e})_{i \in N, e \in E(G_2)}$ such that b^1 and b^2 are shortest path strategies in their corresponding graphs G_1 and G_2, respectively.*

(i) *If $\sum_{P \in \mathcal{P}^*(G_1)} b^1_{i,P} \neq \sum_{P \in \mathcal{P}^*(G_2)} b^2_{i,P}$ for some provider $i \in N$, then there is a demand preserving better response for some $j \in N$.*

(ii) *If, additionally, $\sum_{P \in \mathcal{P}^*(G_1)} b^1_{m,P} = \sum_{P \in \mathcal{P}^*(G_2)} b^2_{m,P}$ for all providers $m \neq i$, then the following holds. For every strategy b_i there is a shortest path strategy b_i' with $|f(b_{-i}, b_i)| = |f(b_{-i}, b_i')|$ and at least the same profit for provider i, i.e., $\pi_i(b_{-i}, b_i) \leq \pi_i(b_{-i}, b_i')$.*

Now, we are ready to prove Theorem 3.2.

Proof of Theorem 3.2. The main difficulty in proving statements on strategy changes of providers lies in the fact that the users' costs and, hence, demand and flow might change. However, we are able to circumvent the dependency on the reservation function by only considering demand preserving better responses. In fact, we prove the first statement of the theorem by showing the following stronger statement. *(i') If there is a provider $i \in N$ such that b_i is not a path strategy on shortest paths, then there is a provider $j \in N$ with a demand preserving better response.* Note that statement (i') implies part (i) of the theorem. We show statement (i') and part (ii) of the theorem by induction on the structure of the series-parallel graph G. For the base case, a graph with a single edge, both statements are trivially fulfilled. For the induction step, assume the statements are true for series-parallel graphs G_1 and G_2, and we will argue that the statements are true for a new series-parallel graph that either arises from a parallel composition or a series composition of G_1 and G_2.

For (i'), observe the following: If there is a provider i such that b_i is not a path strategy in one of the two subgraphs G_1 or G_2, we can assume w.l.o.g. that it is not a path strategy in G_1. Then there is a demand preserving better response in G_1 for some provider j. This is

also a demand preserving better response for j in G, since it is demand preserving in G_1, and thus does not change any flow in G_2, and thus any profit in G_2. So we can assume that the investments b_i are shortest paths within G_1 and within G_2 for all $i \in N$.

Case 1: Parallel Composition. Assume G is the result of a parallel composition of series-parallel networks G_1 and G_2. For proving (i'), denote the length of the shortest paths in G_1 by k and the length of the shortest paths in G_2 by ℓ. If $k \neq \ell$ and there is a provider i that invests in the longer path, we can apply Lemma 3.3 to show that there is a demand preserving better response for provider i. For (ii), observe that if b_j is a path strategy on shortest paths for every provider $j \in N \setminus \{i\}$, it is also a path strategy on shortest paths in both subgraphs. Thus, by induction, provider i has a shortest path strategy b'_i that is demand preserving w.r.t. b_i within G_1 and G_2. Note that this is already a strategy on paths that does not change the overall demand and yields at least as much profit as b_i. Note that this is not a shortest path strategy in G only if $k \neq \ell$, say w.l.o.g. $k < \ell$ and i invests in G_2. In this case, we apply Lemma 3.3 and conclude that i has a demand preserving better response and, thus in fact has the desired strategy on shortest paths in G.

Case 2: Series Composition. Assume G is the result of a series composition of series-parallel networks G_1 and G_2. For (i'), note that have already argued that b is a shortest path strategy within G_1 and within G_2 for every provider. However, if b_i it is not a shortest path strategy in G for some $i \in N$, we fulfill the conditions of Lemma 3.4 (i).

For (ii), note that we also fulfill the additional condition of Lemma 3.4 (ii). By using the lemma, we can conclude that for every strategy b_i, provider i has a strategy b'_i on shortest paths inducing the same demand and at least the same profit. ◀

Note that we have proven that in a subgame perfect Nash equilibrium, all providers invest in shortest path strategies. Additionally, for proving that some investment matrix is an equilibrium, we can restrict the strategy set to shortest path strategies.

We proceed with a proposition that significantly reduces the set of shortest path strategies. We show that if each provider chooses an investment on shortest paths, it is irrelevant how this investment is distributed over the shortest paths. The proof of the proposition is omitted and can be found in the full version [31] .

▶ **Proposition 3.5.** *Let b and b' be investment matrices such that for all $i \in N$, b_i and b'_i are path strategies, and b_i and b'_i can be decomposed into path decompositions $(b_{i,P})_{P\in\mathcal{P}^*}$ and $(b'_{i,P})_{P\in\mathcal{P}^*}$ only using shortest paths, respectively. Additionally, let $\sum_{P\in\mathcal{P}^*} b_{i,P} = \sum_{P\in\mathcal{P}^*} b'_{i,P}$ for all $i \in N$. Then, $\pi_i(b') = \pi_i(b)$ for all $i \in N$ and $|f(b)| = |f(b')|$.*

By using Proposition 3.5, we can classify shortest path strategies into equivalence classes, represented by a single number.

▶ **Observation 3.6.** *In order to analyze subgame perfect Nash equilibria and check their existence, it is sufficient to check investments on shortest paths. By Proposition 3.5, we know that it is irrelevant on which shortest path a provider invests. Thus, we can assume that each strategy of a provider is not a vector of investments $(b_{i,e})_{e\in E}$, but a single number $\sum_{P\in\mathcal{P}^*} b_{i,P}$ representing the total investment in shortest paths.*

4 Homogeneous Users

In this section, we assume that all users are homogeneous and have the same fixed reservation value $R \in \mathbb{R}_+$ for processing a task, and decide not to process their task if the price is above R. More formally, we assume that $u(x) = R$ for all $x \in [0, d]$, and $u(x) = 0$ for all $x > d$, where $d \in \mathbb{R}_+$ represents the size of the population of users. We show that there always exists a subgame perfect Nash equilibrium and analyze the inefficiency of equilibria in terms of the PoA and PPoA.

Recall that, by Observation 3.6, we can restrict the strategy spaces of the providers to path strategies on shortest paths and denote them by a single number. We slightly abuse notation and denote the strategy chosen by provider i by $b_i \in \mathbb{R}_+$.

We first compute the demand and profits of providers in a network investment game with a fixed reservation value.

▶ **Lemma 4.1.** *For $u(x) = R$ for all $x \in [0, d]$, and $u(x) = 0$ for all $x > d$, where $d \in \mathbb{R}_+$,*

(i) *the demand $|f(b)|$ is given by the function $|f(b)| = \min\left\{\frac{R \cdot |b|}{k}, d\right\}$ and*

(ii) *the profit π_i is given by $\pi_i(b_i, b_{-i}) = \min\left\{k \cdot \left(\frac{R^2}{k^2} - 1\right) \cdot b_i, k \cdot \left(\frac{d^2}{|b|^2} - 1\right) \cdot b_i\right\}$,*

where k denotes the length of a shortest s-t path.

Using the closed form for the demand and the profit, we show by a case distinction of $R < k$, $R = k$ and $R > k$ in the full version [31] that a subgame perfect Nash equilibrium always exists and has the same total investment.

▶ **Theorem 4.2.** *There always exists a subgame perfect Nash equilibrium.*

The following example illustrates that a subgame perfect Nash equilibrium need not be unique.

▶ **Example 4.3.** Let G consist of a single edge connecting s to t, $n = 2$, and $u(x) = 2$ for all $x \in [0, 1]$, and $u(x) = 0$ for all $x > 1$. Then for $i = 1, 2$, $\pi_i(b) = \min\left\{3b_i, \left(\frac{1}{|b|^2} - 1\right) \cdot b_i\right\}$. From the first order conditions of provider $i = 1, 2$, we get that all $b \in \mathbb{R}_+^2$ with $\frac{3}{16} \leq b_1 \leq \frac{5}{16}$ and $b_1 + b_2 = \frac{1}{2}$ are subgame perfect Nash equilibria. Notice that the total investment is the same in all subgame perfect Nash equilibria.

Given that a subgame perfect Nash equilibrium exists, we might wonder about the induced performance of an equilibrium. In order to answer this question, we consider two different measures of performance: the social welfare and the total providers' profits.

The main result of this section gives a tight characterization on the price of anarchy for fixed reservation value users.

▶ **Theorem 4.4.** *For an instance $\mathcal{G}$ with $u(x) = R$ for all $x \in [0, d]$, and $u(x) = 0$ for all $x > d$, where $d \in \mathbb{R}_+$,*

$$PoA(\mathcal{G}) = PoS(\mathcal{G}) = \begin{cases} \frac{(R+k)\cdot(R-k)}{R\cdot(R-k\sqrt{\frac{n-2}{n}})} & \text{if } R > k \text{ and } \sqrt{\frac{n-2}{n}} \geq \frac{k}{R}, \\ 1 & \text{otherwise.} \end{cases}$$

Proof. First, observe from the definition of the social welfare that $SW(b) = b \cdot \left(\frac{R^2}{k} - k\right)$ for all $b \in \mathbb{R}_+^N$ with $|b| \leq \frac{d \cdot k}{R}$. Moreover, $SW(b)$ is decreasing in $|b|$ for $|b| > \frac{d \cdot k}{R}$. This implies that $\sup_{b \in \mathbb{R}_+^{N \times E}} SW(b)$ is attained at some $b^* \in \mathbb{R}_+^N$ with $|b|^* \leq \frac{d \cdot k}{R}$. In particular, if $R \leq k$, all subgame perfect Nash equilibrium maximize the social welfare.

So assume that $R > k$. Then, $|b|^* = \frac{d \cdot k}{R}$. From the proof of Theorem 4.2, it follows that either $|b| = \frac{d \cdot k}{R}$ or $|b| = d \cdot \sqrt{\frac{n-2}{n}}$. In the former case, we have that all subgame perfect Nash equilibrium maximize the social welfare. In the latter case, we have $\frac{d \cdot R - k \cdot \frac{d \cdot k}{R}}{d \cdot R - k \cdot d \cdot \sqrt{\frac{n-2}{2}}} = \frac{(R+k)\cdot(R-k)}{R \cdot (R - k\sqrt{\frac{n-2}{n}})} \leq 1 + \frac{k}{R} < 2$, where the last inequality follows since $R > k$. ◀

▶ **Corollary 4.5.** *For all $\mathcal{G}$ with $u(x) = R$ for all $x \in [0, d]$, and $u(x) = 0$ for all $x > d$, where $d \in \mathbb{R}_+$, $PoA(\mathcal{G}) < 2$.*

Note that the above result is quite robust, and states that, independent of R, the social welfare under competition is at least $1/2$ the optimal social welfare.

However, the following result shows that the providers' price of anarchy is not bounded by a constant, but could grow linearly with the number of providers (by at most $n/2$), even for fixed reservation value users.

▶ **Theorem 4.6.** *For an instance $\mathcal{G}$ with $u(x) = R$ for all $x \in [0, d]$, and $u(x) = 0$ for all $x > d$, where $d \in \mathbb{R}_+$,*

$$PPoA(\mathcal{G}) = PPoS(\mathcal{G}) = \begin{cases} \frac{n \cdot \sqrt{\frac{n-2}{n}} \cdot (R^2 - k^2)}{2 \cdot R \cdot k} & \text{if } R > k \text{ and } \sqrt{\frac{n-2}{n}} \geq \frac{k}{R}, \\ 1 & \text{otherwise.} \end{cases}$$

Proof. First, observe that if $R \leq k$, then $\sum_{i \in N} \pi_i(b) \leq 0$ for all $b \in \mathbb{R}_+^N$ and thus all subgame perfect Nash equilbria maximize the sum of providers' profits.

Second, if $R > k$, then by Lemma 4.1, $b^* = \arg\max_{b \in \mathbb{R}_+^N} \sum_{i \in N} \pi_i(b)$ has $|b^*| = \frac{d \cdot k}{R}$. In particular, if $\sqrt{\frac{n-2}{n}} < \frac{k}{R}$, all subgame perfect Nash equilibrium maximize the sum of the providers' profits.

Third, if $R > k$ and $\sqrt{\frac{n-2}{n}} \geq \frac{k}{R}$, then from the proof of Theorem 4.2, it follows that in a subgame perfect Nash equilibrium, $|b| = d \cdot \sqrt{\frac{n-2}{n}}$. Hence, we get

$$\frac{k \cdot \left(\frac{d^2}{\left(\frac{d \cdot k}{R}\right)^2} - 1 \right) \cdot \frac{d \cdot k}{R}}{k \cdot \left(\frac{d^2}{\left(d \cdot \sqrt{\frac{n-2}{n}}\right)^2} - 1 \right) \cdot d \cdot \sqrt{\frac{n-2}{n}}} = \frac{n \cdot \sqrt{\frac{n-2}{n}} \cdot (R^2 - k^2)}{2 \cdot R \cdot k}.$$

◀

5 Heterogeneous Users

We now turn to reservation functions that correspond to heterogeneous users with differing reservation values. As an example we choose one of the arguably simplest class of functions. We note that the study of different and application specific functions is an interesting open question. Here, we consider the reservation functions $u(x) = \frac{1}{x^{1/\alpha}}$, where $\alpha > 0$, for all $x \in \mathbb{R}_+$. We distinguish between one and multiple provider games as for one provider games a subgame perfect Nash equilibrium might not exist. We study equilibrium existence, equilibrium uniqueness and the inefficiency in terms of the PoA and PPoA. Note that we again restrict the strategy spaces of the providers to path strategies on shortest paths and denote them by a single number $b_i \in \mathbb{R}_+$ due to Observation 3.6.

We show that for network investment games with a single provider a monopoly equilibrium exists if and only if $\alpha > 1$. If $\alpha \leq 1$, it is always beneficial for the provider to decrease investment to a smaller, strictly positive amount. For the case of $n \geq 2$ there is a unique subgame perfect equilibrium.

▶ **Theorem 5.1.** *Let k denote the length of a shortest s-t path in G. For $n = 1$, there exists a subgame perfect Nash equilibrium if and only if $\alpha > 1$. If $\alpha > 1$, the equilibrium is unique and given by $b_1 = \frac{\left(1-\frac{2}{(\alpha+1)}\right)^{\frac{\alpha+1}{2}}}{k^\alpha}$.*

For $n \geq 2$, there is a unique Nash equilibrium given by $b_i = \frac{1}{|N|} \cdot \frac{\left(1-\frac{2}{(\alpha+1)\cdot|N|}\right)^{\frac{\alpha+1}{2}}}{k^\alpha}$ for all $i \in N$.

For $n = 1$, we refer to the full version [31]. For the proof of the theorem for $n \geq 2$, we need the following lemmas that are proven in the full version [31].

▶ **Lemma 5.2.** *Let S be the set of providers $i \in N$ with $b_i > 0$ for some investment vector b. Then, if there is some $i \in S$ with $b_i \neq \frac{1}{|S|} \cdot \frac{\left(1-\frac{2}{(\alpha+1)\cdot|S|}\right)^{\frac{\alpha+1}{2}}}{k^\alpha}$, then b is not a subgame perfect Nash equilibrium.*

▶ **Lemma 5.3.** *Let S be the set of providers $i \in N$ with $b_i > 0$. If $S \neq N$, then this is not a subgame perfect Nash equilibrium.*

Proof of Theorem 5.1. Assume $n \geq 2$. First, note that by Lemma 5.3 all providers have to invest and by Lemma 5.2 in a Nash equilibrium all have to invest $\tilde{b} = \frac{1}{|N|} \cdot \frac{\left(1-\frac{2}{(\alpha+1)\cdot|N|}\right)^{\frac{\alpha+1}{2}}}{k^\alpha}$. Thus, $b = \tilde{b} \cdot \mathbb{1} \in \mathbb{R}^N$ is the only possibility for a Nash equilibrium. It remains to show that b is in fact a Nash equlibrium. In order to do so, we fix some provider $i \in N$ and prove that $\tilde{b}$ is in fact a best response to $b = \tilde{b} \cdot \mathbb{1}$. First, we observe in a lemma in the full version [31] that $\pi_i(b_i, b_{-i})$ is continuous in b_i. We proceed by showing that (i) $\tilde{b}$ is the only value fulfilling the first order conditions and (ii) yields a positive profit. For (i) note that

$$\frac{\partial \pi_i(b_i, b_{-i})}{\partial b_i} = \frac{k^{\frac{1-\alpha}{\alpha+1}}}{(b_i + |b|_{-i})^{\frac{2}{\alpha+1}}} \cdot \left(1 - \frac{2}{(\alpha+1)} \cdot \frac{b_i}{b_i + |b|_{-i}}\right) - k.$$

We have shown in Lemma 5.2 that $\tilde{b}$ fulfills the first order condition for all $i \in N$. For showing uniqueness, define $h(x) = \left(1 - \frac{2}{(\alpha+1)} \cdot \frac{x}{x+|b|_{-i}}\right)$ and observe that if $h(\hat{x}) < 0$ for some $\hat{x}$, then $h(x) < 0$ for all $x \geq \hat{x}$. We conclude that all values b^* fulfilling the first order condition have the property $b^* < \hat{x}$. However, for all $b^* < \hat{x}$, the $h(b^*)$ is decreasing in b^*. This shows that there is in fact only one value fulfilling the first order condition.

For (ii), observe that $\pi_i(b)$ evaluates to $\tilde{b}\left(k\left(1 - \frac{2}{(\alpha+1)n}\right)^{-1} - k\right)$, which is positive since $\left(1 - \frac{2}{(\alpha+1)n}\right)^{-1} > 1$. ◀

We are now ready to precisely quantify the inefficiency of subgame perfect Nash equilibria for any instance of a network investment game with reservation function $u(x) = \frac{1}{x^{1/\alpha}}$, where $\alpha > 1$. The proof can be found in the full version [31]. As in immediate consequence, we obtain that the price of anarchy is upper bounded by a surprisingly small constant of approximately 1.22 for every graph and every $\alpha > 1$.

▶ **Theorem 5.4.** *For an instance $\mathcal{G}$ with $u(x) = \frac{1}{x^{1/\alpha}}$, where $\alpha > 1$,*

$$PoA(\mathcal{G}) = PoS(\mathcal{G}) = \left(\frac{\alpha n}{n(\alpha+1) - 2}\right)^{\frac{\alpha-1}{2}} \frac{2\alpha n}{n(\alpha+1) + 2(\alpha-1)} \leq 2\sqrt{\frac{1}{e}}.$$

As an interesting consequence, we would like to point out that the equilibrium for a two providers game is in fact optimal.

▶ **Corollary 5.5.** *For* $u(x) = \frac{1}{x^{1/\alpha}}$*, where* $\alpha > 1$*, and* $n = 2$*, we have* $PoA = 1$*.*

We now consider the total providers' profit and derive tight bounds on the PPoA. Interestingly, in contrast to the PoA, the PPoA is not constant but grows almost linearly with the number of providers.

▶ **Theorem 5.6.** *For an instance* $\mathcal{G}$ *with* $u(x) = \frac{1}{x^{1/\alpha}}$*, where* $\alpha > 0$*, and* $n \geq 2$*,*

$$PPoA(\mathcal{G}) = PPoS(\mathcal{G}) = \begin{cases} \infty & \text{if } \alpha < 1, \\ n\left(\frac{(\alpha+1)n-2}{n(\alpha-1)}\right)^{\frac{1-\alpha}{2}} & \text{otherwise.} \end{cases}$$

6 Conclusion

We have considered a class of games, called network investment games, in which providers invest in bandwidth of particular services that are then used by users to process a specific task. We studied the existence and inefficiency of subgame perfect Nash equilibria when the underlying technology graph is series-parallel, reflecting that services can be either complements or substitutes. We showed that it is essentially without loss of generality to restrict attention to one-edge networks. For two particular classes of reservation functions we studied the performance of subgame perfect Nash equilibria and we quantified this performance in terms of the social welfare and the total providers' profit.

Several questions remain open. We have given examples for which subgame perfect Nash equilibria exist and do not exit, and we have shown that for series-parallel graphs the existence of subgame perfect Nash equilibria is essentially independent of the technology graph. It would be interesting to know if there is a (general) property of the reservation functions that characterize the existence of subgame perfect Nash equilibria. In case there is such an existence condition, it would be nice to find a price of anarchy bound that is independent of the class of reservation functions being used? Unfortunately, our results have far less implications for graphs that are not series-parallel, like for example the Braess' graph. Is it still true that for more general networks providers only invest in shortest paths in equilibrium?
