LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B: Automata, Logic, Semantics, and Theory of Programming

Track C: Foundations of Networks and Multi-Agent Systems: Models, Algorithms and Information Management

Preface

This volume contains the papers presented at ICALP 2019, the 46th edition of the International Colloquium on Automata, Languages and Programming, held in Patras, Greece during July 8–12, 2019. ICALP is a series of annual conferences of the European Association for Theoretical Computer Science (EATCS), which first took place in 1972. This year, the ICALP program consisted of three tracks:

- Track A: Algorithms, Complexity, and Games,
- Track B: Logic, Semantics, Automata and Theory of Programming,
- Track C: Foundations of Networked Computation: Models, Algorithms, and Information Management.

In response to the call for papers, a total 490 submissions were received: 316 for track A, 103 for track B, and 71 for track C. Each submission was assigned to at least three Program Committee members, aided by many subreviewers. Out of these, the committee decided to accept 146 papers for inclusion in the scientific program: 94 papers for Track A, 31 for Track B, and 21 for Track C. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper for each of the three tracks, selected by the Program Committees.

The best paper awards were given to the following papers:

- Track A: Bingkai Lin. "A Simple Gap-producing Reduction for the Parameterized Set Cover Problem".
- Track B: Christof Löding and Anton Pirogov. "Determinization of Büchi Automata: Unifying the Approaches of Safra and Muller-Schupp".
- Track C: Keren Censor-Hillel and Mikaël Rabie. "Distributed Reconfiguration of Maximal Independent Sets".

The best student paper awards, for papers that are solely authored by students, were given to the following papers:

- Track A: Joran van Apeldoorn & András Gilyén. "Improvements in Quantum SDP-Solving with Applications".
- Track B: Marie Fortin. "FO = FO3 for linear orders with monotone binary relations".

Apart from the contributed talks, ICALP 2019 included invited presentations by Michal Feldman, Martin Grohe, Ola Svensson, Frits Vaandrager and Mihalis Yannakakis. This volume of the proceedings contains all contributed papers presented at the conference together with the abstracts of the invited speakers.

The program of ICALP 2019 also included presentation of the EATCS Award 2019 to Thomas Henzinger, the Alonzo Church Award 2019 to Murdoch J. Gabbay and Andrew M. Pitts, the Presburger Award 2019 to Karl Bringmann and Kasper Green Larsen, and the EATCS Distinguished Dissertation Awards.

Four satellite events of ICALP were held on July 8th, 2019:

- Workshop on Theoretical Aspects of Fairness (WTAF)
- Parameterized Approximation Algorithms Workshop (PAAW)

46th International Colloquium on Automata, Languages, and Programming (ICALP 2019).
Editors: Christel Baier, Ioannis Chatzigiannakis, Paola Flocchini, and Stefano Leonardi
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- Workshop on Algorithmic Aspects of Temporal Graphs II
- Logic and Computational Complexity Workshop (LCC 2019)

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all referees who assisted the Program Committees in the evaluation process. We are also grateful to the Conference Co-Chairs Sotiris Nikoletseas and Christos Zaroliagis and all the support staff of the Organizing Committee from the University of Patras and the Computer Technology Institute & Press "Diophantus" for organizing ICALP 2019.

We are grateful for generous support from University of Patras and the Department of Computer Engineering & Informatics for their support for the conference. We also thank the Center for Perspicuous Computing CPEC (supported by CPEC - TRR 248) for their support for the travelling costs of the invited speakers.

We would like to thank Anca Muscholl for her continuous support and Paul Spirakis, the president of EATCS, for his generous advice on the organization of the conference.

July 2019

Organization

Program Committee

Track A

Stefano Leonardi	Sapienza University of Rome, Italy, Chair
Yossi Azar	Tel-Aviv University, Israel
Aaron Bernstein	Massachusetts Institute of Technology, United States
Sayan Bhattacharya	Duke University, United States
Karl Bringmann	Max Planck Institute for Informatics, Germany
Gerth Stølting Brodal	Aarhus University, Denmark
Jaroslaw Byrka	University of Wroclaw, Poland
Parinya Chalermsook	Aalto University, Finland
Paul Duetting	London School of Economics, United Kingdom
Uriel Feige	Weizmann Institute, Israel
Claudio Gentile	Google Research, United States
Mohsen Ghaffari	ETH Zurich, Switzerland
Antoine Joux	Fondation Partenariale de l'UPMC, IMJ-PRG, France
Telikepalli Kavitha	Tata Institute of Fundamental Research, Mumbai, India
Thomas Kesselheim	University of Bonn, Germany
Michal Koucky	Czech Academy of Sciences, Czechia
Alexander Kulikov	St. Petersburg Department of Steklov Institute of Mathematics, Russia
Sophie Laplante	IRIF, Université Paris Diderot Paris 7, France
Francois Le Gall	Kyoto University, Japan
Ramanujan M. Sridharan	The University of Warwick, United Kingdom
Evangelos Markakis	Athens University of Economics and Business, Greece
Renato Paes Leme	Google, United States
Marcin Pilipczuk	Institute of Informatics, University of Warsaw, Poland
Adi Rosén	CNRS and Université Paris Diderot, France
Eva Rotenberg	Technical University of Denmark, Denmark
Rahul Santhanam	University of Oxford, United Kingdom
Alessandra Scafuro	North Carolina State University, United States
Sandeep Sen	Dept of CSE, IIT Delhi, India
Francesco Silvestri	University of Padova, Italy
Paul Spirakis	University of Liverpool and University of Patras, Greece
Leen Stougie	Centrum voor Wiskunde en Informatica (CWI), Netherlands
Chaitanya Swamy	University of Waterloo, Canada
Stefan Szeider	Vienna University of Technology, Austria
Rico Zenklusen	ETH Zurich, Switzerland

Track B

Christel Baier	TU Dresden, Germany, Chair
Parosh Aziz Abdulla	Uppsala University, Sweden
Krishnendu Chatterjee	Institute of Science and Technology (IST), Austria
Thomas Colcombet	CNRS, France
Pedro R. D'Argenio	Universidad Nacional de Córdoba - CONICET, Argentina

Laure Daviaud	City, University of London, United Kingdom
Rocco De Nicola	IMT - School for Advanced Studies Lucca, Italy
Josee Desharnais	Laval University, Canada
Mariangiola Dezani-Ciancaglini	Dipartimento di Informatica, Università di Torino, Italy
Amina Doumane	PPS, France
Nathanaël Fijalkow	CNRS, LaBRI, University of Bordeaux, United Kingdom
Wan Fokkink	Vrije Universiteit Amsterdam, Netherlands
Christoph Haase	University of Oxford, United Kingdom
Ichiro Hasuo	National Institute of Informatics, Japan
Radha Jagadeesan	DePaul University, United States
Markus Lohrey	University of Siegen, Germany
P. Madhusudan	University of Illinois at Urbana-Champaign, United States
Radu Mardare	Aalborg University, Denmark
Matteo Mio	CNRS/ENS-Lyon, France
Mickael Randour	F.R.S.-FNRS & UMONS - Université de Mons, Belgium
Sven Schewe	University of Liverpool, United Kingdom
Lutz Schröder	Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany
Helmut Seidl	Technical University of Munich, Germany
Michał Skrzypczak	University of Warsaw, Poland
Pawel Sobocinski	University of Southampton, United Kingdom
Christine Tasson	Laboratoire IRIF - Université Paris 7, France

Track C

Paola Flocchini	University of Ottawa, Canada, Chair
Amotz Bar-Noy	City University of New York, United States
Vittorio Biló	University of Salento, Italy
Bogdan Chlebus	University of Colorado Denver, United States
Xiaotie Deng	Peking University, China
Leszek Gasieniec	University of Liverpool, United Kingdom
Olga Nikolaevna Goussevskaia	Federal University of Minas Gerais, Brazil
Magnús Halldórsson	Reykjavik University, Iceland
Tobias Harks	Augsburg University, Germany
Christos Kaklamanis	University of Patras, Greece
Ralf Klasing	CNRS and University of Bordeaux, France
Max Klimm	Humboldt Universität zu Berlin, Germany
Ravi Kumar	Google, United States
Silvio Lattanzi	Google, Switzerland
Toshimitsu Masuzawa	Osaka University, Japan
Ruta Mehta	University of Illinois at Urbana-Champaign, United States
Ariel Orda	Department of Electrical Engineering, Technion, Israel
Gopal Pandurangan	University of Houston, United States
Pino Persiano	Università degli Studi di Salerno, Italy
Maria Potop-Butucaru	UPMC Sorbonne Universités, LIP6, Paris, France
Giuseppe Prencipe	Università di Pisa, Italy
Andrea Richa	Arizona State University, United States
Nicola Santoro	Carleton University, Canada
Jukka Suomela	Aalto University, Finland
Patrick Thiran	Ecole Polytechnique Fédérale de Lausanne, Switzerland
Peter Widmayer	ETH Zurich, Switzerland, Switzerland

Organizing Committee

Efstratios Gallopoulos	University of Patras, Greece
John Garofalakis	University of Patras and CTI, Greece
Christos Kaklamanis	University of Patras and CTI, Greece
Sotiris Nikoletseas	University of Patras and CTI, Greece, Conference Co-Chair
Christos Zaroliagis	University of Patras and CTI, Greece, Conference Co-Chair

Steering Committee

Javier Esparza	TUM Munich, Germany
Leslie Ann Goldberg	Oxford University, UK
Thore Husfeldt	Lund University, Sweden and IT University of Copenhagen, Denmark
Giuseppe Italiano	Università di Roma Tor Vergata, Italy
Christos Kaklamanis	University of Patras and CTI Diophantus, Greece
Daniel Marx	Hungarian Academy of Sciences, Hungary
Emanuela Merelli	University of Camerino, Italy
Anca Muscholl	Bordeaux University, France), Steering Committee Chair
Luke Ong	Oxford University, UK
Jiří Sgall	Charles University, Prague, Czech Rep.
Paul Spirakis	University of Liverpool, UK and University of Patras, Greece

Financial Sponsors

University of Patras, Greece
Center for Perspicuous Computing CPEC, Germany

Auction Design under Interdependent Values

Michal Feldman
Blavatnik School of Computer Science, Tel-Aviv University, Israel
michal.feldman@cs.tau.ac.il

Abstract

We study combinatorial auctions with interdependent valuations. In such settings, every agent has a private signal, and every agent has a valuation function that depends on the private signals of all the agents. Interdependent valuations capture settings where agents lack information to determine their own valuations. Examples include auctions for artwork or oil drilling rights. For single item auctions and assume some restrictive conditions (the so-called single-crossing condition), full welfare can be achieved. However, in general, there are strong impossibility results on welfare maximization in the interdependent setting. This is in contrast to settings where agents are aware of their own valuations, where the optimal welfare can always be obtained by an incentive compatible mechanism.

Motivated by these impossibility results, we study welfare maximization for interdependent valuations through the lens of approximation. We introduce two valuation properties that enable positive results. The first is a relaxed, parameterized version of single crossing; the second is a submodularity condition over the signals. We obtain a host of approximation guarantees under these two notions for various scenarios.

Abstract

Deciding if two graphs are isomorphic, or equivalently, computing the symmetries of a graph, is a fundamental algorithmic problem. It has many interesting applications, and it is one of the few natural problems in the class NP whose complexity status is still unresolved. Three years ago, Babai (STOC 2016) gave a quasi-polynomial time isomorphism algorithm. Despite of this breakthrough, the question for a polynomial algorithm remains wide open.

Related to the isomorphism problem is the problem of determining the similarity between graphs. Variations of this problems are known as robust graph isomorphism or graph matching (the latter in the machine learning and computer vision literature). This problem is significantly harder than the isomorphism problem, both from a complexity theoretical and from a practical point of view, but for many applications it is the more relevant problem.

My talk will be a survey of recent progress on the isomorphism and on the similarity problem. I will focus on generic algorithmic strategies (as opposed to algorithms tailored towards specific graph classes) that have proved to be useful and interesting in various context, both theoretical and practical.

Abstract

The matching problem is one of our favorite benchmark problems. Work on it has contributed to the development of many core concepts of computer science, including the equation of efficiency with polynomial time computation in the groundbreaking work by Edmonds in 1965.

However, half a century later, we still do not have full understanding of the complexity of the matching problem in several models of computation such as parallel, online, and streaming algorithms. In this talk we survey some of the major challenges and report some recent progress.

F.Vaandrager@cs.ru.nl

Abstract

Automata learning is emerging as an effective technique for obtaining state machine models of software and hardware systems. I will present an overview of recent work in which we used active automata learning to find standard violations and security vulnerabilities in implementations of network protocols such as TCP and SSH. Also, I will discuss applications of automata learning to support refactoring of legacy control software and identifying job patterns in manufacturing systems. As a guiding theme in my presentation, I will show how Galois connections (adjunctions) help us to scale the application of learning algorithms to practical problems.

mihalis@cs.columbia.edu

Abstract

Many problems from a wide variety of areas can be formulated mathematically as the problem of computing a fixed point of a suitable given multivariate function. Examples include a variety of problems from game theory, economics, optimization, stochastic analysis, verification, and others. In some problems there is a unique fixed point (for example if the function is a contraction); in others there may be multiple fixed points and any one of them is an acceptable solution; while in other cases the desired object is a specific fixed point (for example the least fixed point or greatest fixed point of a monotone function). In this talk we will discuss several types of fixed point computation problems, their complexity, and some of the common themes that have emerged: classes of problems for which there are efficient algorithms, and other classes for which there seem to be serious obstacles.

Abstract

Blind delegation protocols allow a client to delegate a computation to a server so that the server learns nothing about the input to the computation apart from its size. For the specific case of *quantum computation* we know, from work over the past decade, that blind delegation protocols can achieve information-theoretic security (provided the client and the server exchange some amount of quantum information). In this paper we prove, provided certain complexity-theoretic conjectures are true, that the power of *information-theoretically secure* blind delegation protocols for quantum computation (ITS-BQC protocols) is in a number of ways constrained.

In the first part of our paper we provide some indication that ITS-BQC protocols for delegating polynomial-time quantum computations in which the client and the server interact only classically are unlikely to exist. We first show that having such a protocol in which the client and the server exchange $\mathsf{O}(\mathsf{n}^\mathsf{d})$ bits of communication, implies that $\mathsf{BQP} \subset \mathsf{MA}/\mathsf{O}(\mathsf{n}^\mathsf{d})$. We conjecture that this containment is unlikely by proving that there exists an oracle relative to which $\mathsf{BQP} \not\subset \mathsf{MA}/\mathsf{O}(\mathsf{n}^\mathsf{d})$. We then show that if an ITS-BQC protocol exists in which the client and the server interact only classically and which allows the client to delegate quantum sampling problems to the server (such as BosonSampling) then there exist non-uniform circuits of size $2^{\mathsf{n}-\Omega(\mathsf{n}/\log(\mathsf{n}))}$, making polynomially-sized queries to an NP^NP oracle, for computing the permanent of an $n \times n$ matrix.

The second part of our paper concerns ITS-BQC protocols in which the client and the server engage in one round of quantum communication and then exchange polynomially many classical messages. First, we provide a complexity-theoretic upper bound on the types of functions that could be delegated in such a protocol by showing that they must be contained in $\mathsf{QCMA}/\mathsf{qpoly} \cap \mathsf{coQCMA}/\mathsf{qpoly}$. Then, we show that having such a protocol for delegating NP-hard functions implies $\mathsf{coNP}^{\mathsf{NP}^{\mathsf{NP}}} \subseteq \mathsf{NP}^{\mathsf{NP}^{\mathsf{PromiseQMA}}}$.

1 Introduction

An important area of research in modern cryptography is that of performing *computations on encrypted data*. The general idea is that a client wants to compute some function f on some input x, but lacks the computational power to do this in a reasonable amount of time. Luckily, the client has access to a computationally powerful server (cloud, cluster etc) which can compute $f(x)$ quickly. However, because the computation might involve sensitive or classified information, or the server could be compromised remotely, we would like the input x to be hidden from the server at all times. The client can simply encrypt x, but this raises the question: how can the server compute $f(x)$ if it doesn't know x? The general problem of computing on encrypted data was first considered by Rivest, Adleman and Dertouzos [52]. Since then, instances of this problem have appeared in many areas of modern research including those of electronic voting, machine learning on encrypted data, program obfuscation and others [22, 32, 11, 28, 37, 41].

It was shown in 2009, when Gentry produced the first *fully homomorphic encryption scheme*, that performing classical computations on encrypted data is possible [29]. In homomorphic encryption the client has a pair of efficient algorithms (Enc, Dec), which respectively perform encryption and decryption, and which satisfy the property $Dec(f, x, Eval(f, Enc(x))) = f(x)$, for any function f from some set $\mathcal{C}$. In other words, the server evaluates f on the encrypted input $Enc(x)$ using $Eval$ and returns this to the client which can then decrypt it to $f(x)$. Of course, the server should not be able to infer information about x from $Enc(x)$, a condition which is typically expressed through the criterion of *semantic security* [40]. If the set $\mathcal{C}$ contains all polynomial-sized circuits then the scheme becomes a fully homomorphic encryption scheme, commonly abbreviated FHE. All known FHE schemes are secure under *cryptographic assumptions*.

Computing on encrypted data becomes particularly interesting when the server is a *quantum computer*. This is because efficient quantum algorithms have been found for various problems which are believed to be intractable for classical computers. In fact, it has been shown that if a classical computer and a quantum computer are both given black-box or oracle access to certain functions, then the quantum computer exponentially outperforms the classical computer [13, 55, 23, 5]. Classical clients would therefore be highly motivated to delegate problems to quantum computers. However, ensuring the privacy of their inputs is challenging. In particular, we'd have to solve the following problems:

- Devise an encryption scheme which is secure against quantum computers and does not leak information to the server about the client's input.
- Ensure that the encryption scheme allows the client to recover the output of the computation from the result provided by the quantum server.
- Ensure that the protocol is efficient for the client. Ideally, the number of rounds of interaction between the client and the server as well as the client's local computations, should scale at most polynomially with the size of the input.

In spite of these stringent requirements, protocols that achieve these properties already exist and are known collectively as *delegated blind quantum computing schemes* [26]. In such protocols, a probabilistic polynomial-time client is able to delegate polynomial-time quantum computations to a server in such a way that the client's input (apart from an upper bound on its size) is kept hidden from the server in an *information-theoretic* sense. All of the above schemes require the client and the server to share at least one round of quantum communication. *Universal Blind Quantum Computation* (UBQC), shown schematically in Figure 1, is an example of such a protocol [19].

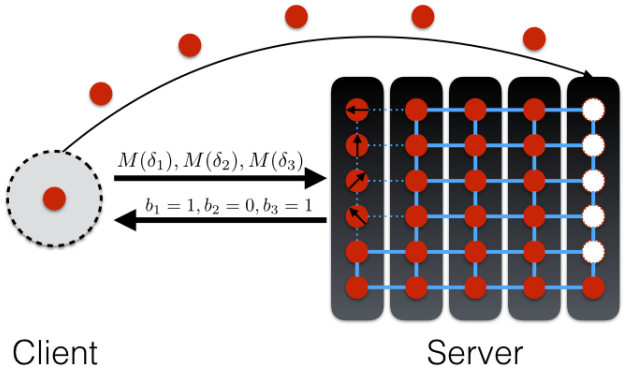

Figure 1 Universal Blind Quantum Computation [19]. In UBQC, a classical client augmented with the ability to prepare single-qubit states sends these qubits to the server along with instructions on how to entangle and measure them in order to perform a computation. The $M(\delta_i)$ indicate measurement instructions and the b_i indicate the server's responses for these instructions (if he follows the protocol, these responses would represent the outcomes of the measurements that the client instructed him to perform).

The first blind delegation protocol was devised by Childs in [21], and since then these protocols have been improved and extended in various works [47, 31, 44, 27, 45, 46, 39, 38]. UBQC and related protocols require the client and the server to exchange only one quantum message, while the rest of the communication is classical [19, 9, 18]. This quantum message (which is sent by the client to the server) consists of a tensor product of single-qubit states. As such, the only quantum capability the client needs is the ability to prepare single-qubit states. In this paper, we explore two questions pertaining to blind delegation protocols:

(1) Is there a scheme for blind quantum computing that is information-theoretically secure, and that requires only classical communication between client and server?

(2) For schemes in which the client and the server are allowed one round of quantum communication, which functions can the client delegate to the server while maintaining information-theoretic security? In particular, could the client delegate the evaluation of NP-hard functions?

We provide some indication, based on complexity-theoretic conjectures, that the answer to the first question is no. In other words, provided these complexity-theoretic conjectures hold, a classical client running in polynomial time and communicating only classically with a

server cannot delegate arbitrary polynomial-time quantum computations to that server while keeping its input hidden in an information-theoretic sense. Importantly, our result does not contradict recent results on quantum fully homomorphic encryption with a classical client [43, 15], since those schemes are based on cryptographic assumptions: *we are interested only in information-theoretic security.*

In answer to the second question, we provide a complexity-theoretic upper bound on the types of functions that can be evaluated by UBQC-type protocols (i.e. protocols in which the client can send one quantum message to the server[2]). We show that, under plausible complexity-theoretic assumptions, this upper bound prevents the client from delegating NP-hard functions to the server. Thus, allowing for quantum communication between the client and the server expands the set of functions that the client can delegate to the server to include BQP, but not enough so as to include NP as well.

1.1 Main results

We phrase our results formally using the concept of a *generalised encryption scheme* (GES) introduced by Abadi, Feigenbaum and Killian [8]. Roughly speaking, a GES is a protocol between a probabilistic polynomial-time classical client and a computationally unbounded server for computing on encrypted data. The client sends the server a description of some function[3] $f : \{0,1\}^n \to \{0,1\}$. Using some polynomial-time algorithm denoted E, the client encrypts its input x, and sends $E(x)$ to the server. The server and the client then interact for a number of rounds which is polynomial in the length of x. Finally, using a polynomial-time decryption algorithm denoted D, the client decrypts the server's responses and obtains $f(x)$ with probability $1/2 + 1/\operatorname{poly}(n)$. Importantly throughout the protocol, the server learns no more than the length of x. Because the server is computationally unbounded, the scheme requires information-theoretic security. Abadi et al. gave a complexity theoretic upper bound on the types of functions that admit such a scheme. They showed that any function f that the client could delegate in a GES must be contained in the class $\mathsf{NP/poly} \cap \mathsf{coNP/poly}$.

The GES framework allows us to restate the questions we address in this paper as follows:

(1) Can we design a GES for delegating BQP functions? Note that, by the Abadi et al. result, this is the same as asking whether $\mathsf{BQP} \subset \mathsf{NP/poly} \cap \mathsf{coNP/poly}$. We will consider two variants on the GES framework: one which allows the client to delegate sampling problems to the server, and one in which the total communication between client and server is bounded by $\mathsf{O}(\mathsf{n}^\mathsf{d})$, for some constant $d > 0$. For the former, we show that having such a scheme for quantum sampling problems, like BosonSampling, implies that circuits exist which can compute the permanent of a matrix more efficiently than we believe is possible. For the latter, having a GES with bounded communication for polynomial-time quantum computation implies that $\mathsf{BQP} \subset \mathsf{MA/O}(\mathsf{n}^\mathsf{d})$, and we argue that this containment is unlikely by providing an oracle separation between these classes.

(2) If we change the GES framework to allow one round of quantum communication between the client and the server, what functions can the client delegate to the server? We answer this question by "quantising" the Abadi et al. result and showing that such

[2] In fact our result concerns protocols in which the client and the server start with *one round* of quantum communication, followed by polynomially-many rounds of classical communication. In other words, not only is there one quantum message from the client to the server, but the server is also allowed to respond with a quantum message.

[3] Unless otherwise specified, we restrict our attention to decision problems. This is why the function f has the codomain $\{0,1\}$.

functions would be contained in $\mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$ (a quantum analogue of $\mathsf{NP/poly} \cap \mathsf{coNP/poly}$). We also show that $\mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$ is unlikely to contain NP-hard functions.

The complete proofs for our results can be found in the full version of our paper [7].

1.1.1 Generalised encryption scheme for BQP decision problems

As we have mentioned, for the case of decision problems, Abadi et al. showed that the class of problems that a client can delegate to a server using the GES framework is contained in $\mathsf{NP/poly} \cap \mathsf{coNP/poly}$. They also observed that if NP-hard functions could be delegated by the client using a GES, then $\mathsf{NP} \subset \mathsf{NP/poly} \cap \mathsf{coNP/poly}$, and, in particular, $\mathsf{NP} \subset \mathsf{coNP/poly}$. Yap showed that having such a containment leads to a collapse of the polynomial hierarchy at the third level [58]. In other words, it seems unlikely that NP-hard problems would admit a GES.

What about BQP-hard functions? The Abadi et al. result implies that having a GES for BQP-hard functions leads to $\mathsf{BQP} \subset \mathsf{NP/poly} \cap \mathsf{coNP/poly}$. While we would like to argue, similarly, that such a containment leads to a collapse of the polynomial hierarchy, even $\mathsf{BQP} = \mathsf{P}$ isn't known to lead to such a collapse. We instead consider a modified GES in which the total communication between the client and the server is upper bounded by a polynomial of *fixed* degree, $d > 0$, in the size of the input[4]. In that case, it can be shown that $\mathsf{BQP} \subset \mathsf{MA/O}(\mathsf{n^d}) \cap \mathsf{coMA/O}(\mathsf{n^d})$. We argue that this containment is unlikely based on the following result:

▶ **Theorem 1.** *For each $d \in \mathbb{N}$, there exists an oracle O_d such that BQP^{O_d} is not contained in $(\mathsf{MA/O}(\mathsf{n^d}))^{O_d}$.*

Essentially, the theorem shows that relative to an oracle O_d, there are problems that can be solved by a polynomial-time quantum algorithm, but which a classical client cannot delegate to a server in a GES with bounded communication. Since the oracle is parameterised by d, we are in fact defining a family of oracles. The specific problem on which the oracle O_d is based is a version of *Simon's problem* [55]. Simon's problem is the following: for an input of size n, and given oracle access to a function $g : \{0,1\}^n \to \{0,1\}^n$ that is guaranteed to be either an injective function, or a 2-to-1 and periodic function[5], the task is to decide which is the case. Simon provided a polynomial-time quantum algorithm for solving this problem, thus showing that it belongs to BQP (relative to the function oracle). For the case in which one should accept when the function is 2-to-1, the problem can be shown to be outside of MA (relative to the function oracle). As such, Simon's problem provides an oracle separation between BQP and MA.

In Simon's original construction, the oracle function is the same for all inputs of size n. Note that, this version of the problem can be solved with one bit of advice: for all inputs of size n, the advice bit simply specifies whether the function is 1-to-1 or 2-to-1 and periodic. Therefore such a setup would not be useful in our case. For this reason, in our proof of Theorem 1, the function that the oracle provides access to is input-dependent. The problem we define, relative to this oracle, is again to decide whether the function is 1-to-1 or the function is 2-to-1 and periodic. However, we can show that, by considering a sufficiently

[4] Note that we impose no such restriction on the running time of the client.
[5] In other words, there exists a period $s \in \{0,1\}^n$, $s \neq 0^n$, such that for all $x, y \in \{0,1\}^n$, $x \neq y$, it is the case that $g(x) = g(y)$ iff. $x = s \oplus y$.

large domain for these functions – in other words, by letting $g : \{0,1\}^{n^D} \to \{0,1\}^{n^D}$ for some $D > d$ – the problem is not contained in $(\mathsf{MA}/\mathsf{O}(\mathsf{n}^\mathsf{d}))^{O_d}$, but is nevertheless contained in BQP. The proof uses a diagonalisation argument and can be found in the full version of our paper [7].

Unfortunately, the same oracle cannot be used to separate BQP from $\mathsf{NP/poly}$. This is because D is a function of d; to prove a separation with respect to $\mathsf{NP/poly}$, where the length of the advice string can be any polynomial, we would have to find an oracle that works *for all* possible values of d. It would be interesting to see whether the oracle that Raz and Tal [51] recently used to prove a separation between BQP and PH could also be used in order to separate BQP from $\mathsf{NP/poly}$, or even from $\mathsf{PH/poly}$. We leave this as an open problem.

One can argue that oracle results do not constitute compelling evidence on the relationships between complexity classes. For example, it has been known for a while that there exist oracles O_1, O_2 such that $\mathsf{P}^{O_1} \neq \mathsf{NP}^{O_1}$ but $\mathsf{P}^{O_2} = \mathsf{NP}^{O_2}$, and that, while $\mathsf{IP} = \mathsf{PSPACE}$, there is an oracle such that $\mathsf{IP}^O \neq \mathsf{PSPACE}^O$. Nonetheless, oracles allow us to study the query complexity of problems in different models of computation. In fact, there are situations in practice where computer programs are restricted to making black-box calls to functions in order to determine their properties [36]. Apart from this, oracle results have also inspired a number of important developments in algorithms and complexity theory[6]. For more arguments concerning the usefulness of oracle results, see Section 1.3 of [2].

1.1.2 Generalised encryption scheme for BQP sampling problems

We consider what would happen if we have a generalised encryption scheme which allowed a client to delegate a sampling problem, such as BosonSampling, to the server. BosonSampling, defined by Aaronson and Arkhipov in [6], is essentially the problem of simulating the statistics of photons (bosons) passing through a linear optics network. One starts with a configuration of identical photons in known locations (referred to as *modes*). The photons then pass through the linear optics network, which consists of optical elements (beamsplitters and phase shifters). Finally, one performs a measurement to determine the new locations of the photons in the *output modes* of the system. The reason this is referred to as a sampling problem is because we have a probability distribution over the different configurations of photons in the output modes. In *exact* BosonSampling, which is the problem we consider, the task is to produce a sample from that probability distribution. Aaronson and Arkhipov showed that the probability of observing a particular configuration of photons is proportional to the squared permanent of a matrix that can be obtained efficiently from the description of the optical network. They also showed that no polynomial-time probabilistic algorithm can sample from this distribution, unless the polynomial hierarchy collapses at the third level [6]. As such, while a quantum computer could simulate the optical network and sample from the target distribution in polynomial time, it seems unlikely that classical computers could do the same.

Sampling problems, like BosonSampling, are of interest because of their potential use in demonstrating *quantum computational supremacy* [35]. This entails having a quantum device perform a computational task that no classical computer would be able to reproduce *efficiently*. Sampling problems are natural candidates for this task for two main reasons. Firstly, many of the quantum sampling problems that have been considered could in principle be performed on a small-scale quantum computer having up to (or on the order of) 100

[6] A notable example is the fact that Simon's oracle separation between BPP and BQP led to Shor's algorithm for factoring and computing the discrete logarithm [54]

qubits and not requiring fault-tolerance [50]. Secondly, it has been shown that having a polynomial-time classical algorithm that can sample from the distribution of the quantum sampling problem leads to a collapse of the polynomial hierarchy. Contrast this to tasks such as factoring for which the existence of an efficient classical algorithm is not known to lead to any "disastrous" complexity-theoretic consequences.

Given that sampling problems are primarily considered in the context of demonstrating quantum computational supremacy, one could ask why a client would like to delegate such a problem to the server via a GES. Firstly, all existing schemes for blind delegated quantum computation allow the client to delegate both decision and sampling problems [26]. It is therefore natural to ask whether such a scheme, involving only classical communication, can also exist. Secondly, there is currently no known way for a classical client to efficiently certify whether the server has sampled from the correct distribution (at least with an information-theoretic guarantee). In fact, in certain cases the client would require exponentially many samples from the server in order to perform this verification [34]. However, if a GES for quantum sampling problems existed, the client might be able to leverage it in order to perform the certification, in the same way that many delegated quantum computation protocols leverage blindess to achieve verifiability [30]. Finally, due to the equivalence between sampling and searching shown in [3], our result holds if we substitute sampling problems with search problems.

In a GES for exact BosonSampling, the client's input would be a description of a linear optics network[7]. The client would like to delegate to the server the task of sampling from the BosonSampling distribution associated with this network, while keeping the description of the network hidden from the server. In other words, upon interacting with the server and decrypting its responses, the client should obtain a sample from the BosonSampling distribution. At the same time, the server learns at most an upper bound on the size of the network. We show the following:

▶ **Theorem 2.** *If exact* BosonSampling *admits a GES, then for any matrix* $X \in \{-1, 0, 1\}^{n\times n}$*, there exist circuits of size* $2^{n-\Omega\left(\frac{n}{\log n}\right)}$*, making polynomially-sized queries to an* $\mathsf{NP}^{\mathsf{NP}}$ *oracle, for computing the permanent of* X*.*

Computing the permanent of a matrix is a problem known to be #P-hard. By Toda's theorem, this means that if computing the permanent were possible at any level of the polynomial hierarchy, the hierarchy would collapse at that level [56]. Moreover, the best known algorithm for computing the permanent, by Björklund, has a run-time of $2^{n-\Omega\left(\sqrt{n/\log(n)}\right)}$ [14]. Prior to that, the leading algorithm for computing the permanent was Ryser's algorithm, developed over 50 years ago, which requires $O(n2^n)$ arithmetic operations [53]. We conjecture that the circuits of Theorem 2 do not exist and, thus, that there can be no GES for BosonSampling.

1.1.3 Quantum generalised encryption scheme

While having a GES for delegating BQP computations seems unlikely, we know that giving the client some minimal quantum capabilities removes this limitation: schemes such as UBQC exist which allow for the information-theoretically secure blind delegation of quantum

[7] In principle, one could also specify the configuration of the photons in the input modes as part of the client's input. Equivalently, however, one can always initialise the input modes to some fixed initial state, and produce whichever starting state is in fact desired by altering the linear optics network.

computations. In the spirit of the Abadi et al. result, it is natural to consider *quantum generalised encryption schemes* (or QGES), in which the client is no longer classical, and investigate the complexity-theoretic upper bounds on functions that admit such a protocol. For the QGES, we are still assuming information-theoretic security and that the encryption scheme leaks at most the size of the input. However, unlike the GES, the client is now assumed to be a quantum computer performing polynomial-time computations[8]. Additionally, the client and the server perform one round of quantum communication at the beginning of the protocol. The rest of the communication is classical.

We impose one other restriction on the QGES, known as *offline-ness*. Roughly speaking, an offline protocol is one in which the client does not need to commit to any particular input (of a given size), after having sent the quantum message to the server. The quantum message only depends on the size of the input. We note that offline-ness is a property which UBQC and all other currently known blind quantum computing protocols share. From a practical perspective, this presents the client with the option of sending the first quantum message to the server and deciding at a later time on which input the server should perform the computation. One could imagine, for instance, that the client and the server have access to a quantum channel for a limited amount of time. In practice, such a situation can occur if the communication between the parties is mediated by a satellite, as is the case with satellite-based quantum-key distribution [42]. In this case, the satellite is in the line of sight of the two parties for only a few minutes at a time. Our result is the following:

▶ **Theorem 3.** *The class of functions that a client can delegate to a server in an offline QGES is contained in* $\mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$.

Note that the class $\mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$ can be seen as a quantum analogue of the class $\mathsf{NP/poly} \cap \mathsf{coNP/poly}$ which we encounter in the GES case. We therefore view Theorem 3 as a "quantisation" of the Abadi et al. bound on the power of generalised encryption schemes.

Again, in the spirit of the Abadi et al. result, one can ask whether NP-complete functions are contained in $\mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$. In other words: does giving quantum capabilities to the client increase the class of functions that it can securely delegate so that this class contains NP? We give an indication that the answer is no:

▶ **Theorem 4.** $\mathsf{NP} \subset \mathsf{QCMA/qpoly} \cap \mathsf{coQCMA/qpoly}$ *implies* $\mathsf{coNP}^{\mathsf{NP}^{\mathsf{NP}}} \subseteq \mathsf{NP}^{\mathsf{NP}^{\mathsf{PromiseQMA}}}$.

Note that if PromiseQMA in the above expression were replaced with NP, this would imply a collapse of the polynomial hierarchy at the third level. Our result is as close to a collapse of the polynomial hierarchy as one can reasonably hope to get, given a quantum hypothesis. Hence, while a QGES does allow the client to delegate BQP computations, it seems to be no more useful than the regular GES for delegating NP-hard functions.

One could ask why we would even be interested in delegating NP-hard problems to a quantum computer, given that we do not expect quantum computers to be able to solve such problems in polynomial time [1]. First of all, from a theoretical perspective, note that in the QGES formalism we are not limiting the server to polynomial-time quantum computations, but instead assuming that it has unbounded computational power. Therefore, the way to view this result is not as "how can a client blindly delegate the evaluation of NP-hard functions to a quantum computer?" but as "can quantum communication help in blindly delegating the evaluation of NP-hard functions to an unbounded server?".

From a practical perspective, while we do not believe that quantum computers can solve NP-complete problems in polynomial time, they could, in principle, solve such problems quadratically faster than classical computers, thanks to Grover's algorithm [33]. Even

[8] It should be noted that our upper bound on the power of QGES schemes also holds if the client is restricted to BPP computations (as is the case in UBQC), since $\mathsf{BPP} \subseteq \mathsf{BQP}$.

though the speedup of Grover's algorithm is only quadratic, from (say) 2^n to $2^{n/2}$, our result is only concerned with the length of the computation performed on the client side, and therefore applies to Grover's algorithm just as it would to a quantum algorithm achieving exponential speedup. In fact, as is mentioned in [4], there are NP-complete problems for which quantum computers provide a superpolynomial speedup, at least with respect to the best known classical algorithms. Our no-go theorem indicates that clients cannot exploit such speedups by delegating the computation to the server, even when allowing some quantum communication, if we also want to keep their inputs hidden in an information-theoretic sense.

Proofs of these results can be found in the full version of our paper [7].

1.2 Related work

As mentioned, the problem of computing on encrypted data was first considered by Rivest, Adleman and Dertouzos [52], which then led to the development of *homomorphic encryption* and eventually to fully homomorphic encryption with Gentry's scheme [29]. Since then there have been many other FHE protocols relying on more standard cryptographic assumptions and having more practical requirements [17, 16, 57].

While FHE is similar to the GES in many respects, there are also significant differences. For starters, FHE protocols have only one round of interaction between the client and the server, whereas a GES allows for polynomially many rounds. Additionally, the GES assumes the server is computationally unbounded and hence requires information-theoretic security. In contrast, FHE relies on computational security. More precisely FHE schemes have semantic security against polynomial-time (quantum) algorithms [29].

The problem of *quantum* computing on encrypted data was introduced by Childs [21] and Arrighi and Salvail [12]. Further development eventually led to UBQC [19, 9] and a scheme of Broadbent [18]. The latter was followed by the construction of the first schemes for quantum fully homomorphic encryption (QFHE) [20, 24]. For a review of blind quantum computing and related protocols see [26].

In the QFHE schemes of [20, 24], the server is a polynomial-time quantum computer and the client has some quantum capabilities of its own, although it is not able to perform universal quantum computations. Both the size of the exchanged messages and the number of operations of the client are polynomial in the size of the input. More recently, QFHE schemes have been proposed in which the client is completely classical [43, 15]. Similar to FHE, these protocols rely on computational assumptions for security [10] and involve one round of back and forth interaction between the client and the server. QFHE with information-theoretic security (and a computationally unbounded server) has been considered by Yu et al. in [59], where it is shown that it is impossible to have such a scheme for arbitrary unitary operations (or even arbitrary reversible classical computations). This result was later reproved by Newmann and Shi using quantum random-access codes [49]. In relation to our work, QFHE with information-theoretic security can be viewed as a one-round QGES in which the server responds with a quantum message. The complexity-theoretic upper bound we prove for QGES computable functions would then apply to QFHE as well (provided that in QFHE we only leak the size of the input to the server), since our proof allows a quantum message from the server just as well as a classical message.

The possibility of a classical client delegating a blind computation to a quantum server was considered by Morimae and Koshiba [48]. They showed that such a protocol in which the client leaks no information about its input to the server and there is only one round of interaction leads to $\mathsf{BQP} \subseteq \mathsf{NP}$, considered an unlikely containment. We consider the more general setting of a GES for BQP functions, where the number of rounds can be polynomial

in the size of the input and we allow the encryption to leak the size of the input. In fact, the question of whether a GES, as defined in Abadi et al. [8], can exist for quantum computations was raised before by Dunjko and Kashefi [25].

1.3 Future work

As we remarked in Section 1.1, in the case of decision problems, the existence of a GES with bounded communication, for polynomial-time quantum computations, leads to the inclusion $\mathsf{BQP} \subset \mathsf{MA}/\mathsf{O}(n^d)$. We argue that this containment is unlikely based on the existence of an oracle separating the two complexity classes. A natural extension of this result would be to prove an oracle separation between BQP and $\mathsf{NP}/\mathsf{poly}$. This would provide more compelling evidence that a GES for quantum computations cannot exist.

In the case of sampling problems, we showed that a GES for BosonSampling implies the existence of circuits of size $2^{n-\Omega\left(\frac{n}{\log n}\right)}$, making polynomially-sized queries to an $\mathsf{NP}^{\mathsf{NP}}$ oracle, for computing matrix permanents. Can this result be strengthened so as to provide circuits for computing matrix permanents that would be ruled out by the *strong exponential-time hypothesis*? Alternatively, could one use other quantum sampling problems (such as random circuit sampling or IQP problems [35]) to show that having a GES for such a problem leads to a collapse of the polynomial hierarchy?

We also defined the QGES, which extends the GES by allowing the client to send one quantum message to the server, and gave an upper bound for the set of functions that can be delegated using an offline version of such a scheme. The immediate question one could ask is: what upper bound can we give for an online QGES? A related question is: what upper bound can we give for a QGES that allows all of the communication between the client and the server to be quantum? The difficulty in answering both of these questions is that the offline property of the QGES is what allowed us to relate the set of functions that can be delegated to advice classes. Without this property, it seems that a different approach would be needed to provide a complexity-theoretic upper bound.

Another direction that can be explored has to do with the size of the quantum communication between the client and the server. In a QGES in which the client's quantum message is logarithmic or poly-logarithmic in the size of the input (while the classical communication is still polynomial), is it still possible to delegate BQP functions to the server? Of course, this question only makes sense if we assume that the client is not able to perform BQP computations itself.

Abstract

The All-Pairs Min-Cut problem (aka All-Pairs Max-Flow) asks to compute a minimum s-t cut (or just its value) for all pairs of vertices s, t. We study this problem in *directed graphs* with *unit* edge/vertex capacities (corresponding to edge/vertex connectivity). Our focus is on the *k-bounded* case, where the algorithm has to find all pairs with min-cut value less than k, and report only those. The most basic case $k = 1$ is the Transitive Closure (TC) problem, which can be solved in graphs with n vertices and m edges in time $O(mn)$ combinatorially, and in time $O(n^\omega)$ where $\omega < 2.38$ is the matrix-multiplication exponent. These time bounds are conjectured to be optimal.

We present new algorithms and conditional lower bounds that advance the frontier for larger k, as follows:

- A randomized algorithm for *vertex capacities* that runs in time $O((nk)^\omega)$. This is only a factor k^ω away from the TC bound, and nearly matches it for all $k = n^{o(1)}$.
- Two deterministic algorithms for *edge capacities* (which is more general) that work in DAGs and further reports a minimum cut for each pair. The first algorithm is combinatorial (does not involve matrix multiplication) and runs in time $O(2^{O(k^2)} \cdot mn)$. The second algorithm can be faster on dense DAGs and runs in time $O((k \log n)^{4^{k+o(k)}} \cdot n^\omega)$. Previously, Georgiadis et al. [ICALP 2017], could match the TC bound (up to $n^{o(1)}$ factors) only when $k = 2$, and now our two algorithms match it for all $k = o(\sqrt{\log n})$ and $k = o(\log \log n)$.
- The first super-cubic lower bound of $n^{\omega-1-o(1)}k^2$ time under the 4-Clique conjecture, which holds even in the simplest case of DAGs with unit vertex capacities. It improves on the previous (SETH-based) lower bounds even in the unbounded setting $k = n$. For combinatorial algorithms, our reduction implies an $n^{2-o(1)}k^2$ conditional lower bound. Thus, we identify new settings where the complexity of the problem is (conditionally) higher than that of TC.

Our three sets of results are obtained via different techniques. The first one adapts the network coding method of Cheung, Lau, and Leung [SICOMP 2013] to vertex-capacitated digraphs. The second set exploits new insights on the structure of latest cuts together with suitable algebraic tools. The lower bounds arise from a novel reduction of a different structure than the SETH-based constructions.

1 Introduction

Connectivity-related problems are some of the most well-studied problems in graph theory and algorithms, and have been thoroughly investigated in the literature. Given a directed graph $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges,[1] perhaps the most fundamental such problem is to compute a *minimum s-t cut*, i.e., a set of edges E' of minimum-cardinality such that t is not reachable from s in $G \setminus E'$. This minimum s-t cut problem is well-known to be equivalent to maximum s-t flow, as they have the exact same value [17]. Currently, the fastest algorithms for this problem run in time $\tilde{O}(m\sqrt{n}\log^{O(1)} U)$ [24] and $\tilde{O}(m^{10/7}U^{1/7})$ (faster for sparse graphs) [26], where U is the maximum edge capacity (aka weight).[2]

The central problem of study in this paper is All-Pairs Min-Cut (also known as All-Pairs Max-Flow), where the input is a digraph $G = (V, E)$ and the goal is to compute the minimum s-t cut value for all $s, t \in V$. All our graphs will have *unit* edge/vertex capacities, in which case the value of the minimum s-t cut is just the maximum number of disjoint paths from s to t (aka edge/vertex connectivity), by [28]. We will consider a few variants: vertex capacities vs. edge capacities,[3] reporting only the value vs. the cut itself (a witness), or a general digraph vs. a directed acyclic graph (DAG). For all these variants, we will be interested in the *k-bounded* version (aka *bounded min-cuts*, hence the title of the paper) where the algorithm needs to find which minimum s-t cuts have value less than a given parameter k, and report

[1] We sometimes use arcs when referring to directed edges, or use nodes instead of vertices.
[2] The notation $\tilde{O}(\cdot)$ hides polylogarithmic factors.
[3] The folklore reduction where each vertex v is replaced by two vertices connected by an edge $v_{in} \to v_{out}$ shows that in all our problems, vertex capacities are no harder (and perhaps easier) than edge capacities. Notice that this is only true for directed graphs.

only those. Put differently, the goal is to compute, for every $s, t \in V$, the minimum between k and the actual minimum s-t cut value. Nonetheless, some of our results (the lower bounds) are of interest even without this restriction.

The time complexity of these problems should be compared against the fundamental special case that lies at their core – the Transitive Closure problem (aka All-Pairs Reachability), which is known to be time-equivalent to Boolean Matrix Multiplication, and in some sense, to Triangle Detection [34]. This is the case $k = 1$, and it can be solved in time $O(\min\{mn/\log n, n^\omega\})$, where $\omega < 2.38$ is the matrix-multiplication exponent [14, 23, 33, 11]; the latter term is asymptotically better for dense graphs, but it is not *combinatorial*.[4] This time bound is conjectured to be optimal for Transitive Closure, which can be viewed as a conditional lower bound for All-Pairs Min-Cut; but can we achieve this time bound algorithmically, or is All-Pairs Min-Cut a harder problem?

The naive strategy for solving All-Pairs Min-Cut is to execute a minimum s-t cut algorithm $O(n^2)$ times, with total running time $\tilde{O}(n^2 m^{10/7})$ [26] or $\tilde{O}(n^{2.5}m)$ [24]. For not-too-dense graphs, there is a faster randomized algorithm of Cheung, Lau, and Leung [13] that runs in time $O(m^\omega)$. For smaller k, some better bounds are known. First, observe that a minimum s-t cut can be found via k iterations of the Ford-Fulkerson algorithm [17] in time $O(km)$, which gives a total bound of $O(n^2mk)$. Another randomized algorithm of [13] runs in better time $O(mnk^{\omega-1})$ but it works only in DAGs. Notice that the latter bound matches the running time of Transitive Closure if the graphs are sparse enough. For the case $k = 2$, Georgiadis et al. [18] achieved the same running time as Transitive Closure up to sub-polynomial factor $n^{o(1)}$ in all settings, by devising two deterministic algorithms, whose running times are $\tilde{O}(mn)$ and $\tilde{O}(n^\omega)$.

Other than the lower bound from Transitive Closure, the main previously known result is from [21], which showed that under the Strong Exponential Time Hypothesis (SETH),[5] All-Pairs Min-Cut requires, up to sub-polynomial factors, time $\Omega(mn)$ in unit edge capacitated digraphs of any edge density, and even in the simpler case of (unit) vertex capacities and of DAGs. As a function of k their lower bound becomes $\Omega(n^{2-o(1)}k)$ [21]. Combining the two, we have a conditional lower bound of $(n^2k + n^\omega)^{1-o(1)}$.

Related Work. There are many other results related to the edge capacitated All-Pairs Min-Cut problem, let us mention a few. Other than DAGs, the problem has also been considered in the special cases of planar digraphs [6, 22], sparse digraphs and digraphs with bounded treewidth [6].

In *undirected* graphs, the problem was studied extensively following the seminal work of Gomory and Hu [19] in 1961, which introduced a representation of All-Pairs Min-Cuts via a weighted tree, commonly called a Gomory-Hu tree, and further showed how to compute it using $n - 1$ executions of maximum s-t flow. Bhalgat et al. [8] designed an algorithm that computes a Gomory-Hu tree in unit edge capacitated undirected graphs in $\tilde{O}(mn)$ time, and this upper bound was recently improved [4]. The case of bounded min-cuts (small k) in undirected graphs was studied by Hariharan et al. [20], motivated in part by applications in practical scenarios. The fastest running time for this problem is $\tilde{O}(mk)$ [31], achieved by combining results from [20] and [8]. On the negative side, there is an $n^{3-o(1)}$ lower bound for All-Pairs Min-Cut in sparse *capacitated* digraphs [21], and very recently, a similar lower bound was shown for *undirected* graphs with vertex capacities [4].

[4] Combinatorial is an informal term to describe algorithms that do not rely on fast matrix-multiplication algorithms, which are infamous for being impractical. See [1, 3] for further discussions.

[5] These lower bounds hold even under the weaker assumption that the 3-Orthogonal Vectors problem requires $n^{3-o(1)}$ time.

1.1 Our Contribution

The goal of this work is to reduce the gaps in our understanding of the All-Pairs Min-Cut problem (see Table 1 for a list of known and new results). In particular, we are motivated by three high-level questions. First, how large can k be while keeping the time complexity the same as Transitive Closure? Second, could the problem be solved in cubic time (or faster) in all settings? Currently no $\Omega(n^{3+\varepsilon})$ lower bound is known even in the hardest settings of the problem (capacitated, dense, general graphs). And third, can the actual cuts (witnesses) be reported in the same amount of time it takes to only report their values? Some of the previous techniques, such as those of [13], cannot do that.

New Algorithms. Our first result is a randomized algorithm that solves the k-bounded version of All-Pairs Min-Cut in a digraph with *unit vertex capacities* in time $O((nk)^\omega)$. This upper bound is only a factor k^ω away from that of Transitive Closure, and thus matches it up to polynomial factors for any $k = n^{o(1)}$. Moreover, any poly(n)-factor improvement over our upper bound would imply a breakthrough for Transitive Closure (and many other problems). Our algorithm builds on the network-coding method of [13], and in effect adapts this method to the easier setting of vertex capacities, to achieve a better running time than what is known for unit edge capacities. This algorithm is actually more general: Given a digraph $G = (V, E)$ with unit vertex capacities, two subsets $S, T \subseteq V$ and $k > 0$, it computes for all $s \in S, t \in T$ the minimum s-t cut value if this value is less than k, all in time $O((n + (|S| + |T|)k)^\omega + |S||T|k^\omega)$. Due to space constraints, we overview these results in Section 3.1, with full details in the full version.

Three weaknesses of this algorithm and the ones by Cheung et al. [13] are that they do not return the actual cuts, they are randomized, and they are not combinatorial. Our next set of algorithmic results deals with these issues. More specifically, we present two deterministic algorithms for DAGs with unit edge (or vertex) capacities that compute, for every $s, t \in V$, an actual minimum s-t cut if its value is less than k. The first algorithm is *combinatorial* (i.e., it does not involve matrix multiplication) and runs in time $O(2^{O(k^2)} \cdot mn)$. The second algorithm can be faster on dense DAGs and runs in time $O((k \log n)^{4^k + o(k)} \cdot n^\omega)$. These algorithms extend the results of Georgiadis et al. [18], which matched the running time of Transitive Closure up to $n^{o(1)}$ factors, from just $k = 2$ to any $k = o(\sqrt{\log n})$ (in the first case) and $k = o(\log \log n)$ (in the second case). We give an overview of these algorithms in Section 3.2, and the formal results are in the full version.

New Lower Bounds. Finally, we present conditional lower bounds for our problem, the k-bounded version of All-Pairs Min-Cut. As a result, we identify new settings where the problem is harder than Transitive Closure, and provide the first evidence that the problem cannot be solved in cubic time. Technically, the main novelty here is a reduction from the 4-Clique problem. It implies lower bounds that apply to the basic setting of DAGs with unit vertex capacities, and therefore immediately apply also to more general settings, such as edge capacities, capacitated inputs, and general digraphs, and they in fact improve over previous lower bounds [5, 21] in all these settings.[6] We prove the following theorem in Section 4.

▶ **Theorem 1.1.** *If for some fixed $\varepsilon > 0$ and any $k \in [n^{1/2}, n]$, the k-bounded version of All-Pairs Min-Cut can be solved on DAGs with unit vertex capacities in time $O((n^{\omega-1}k^2)^{1-\varepsilon})$, then 4-Clique can be solved in time $O(n^{\omega+1-\delta})$ for some $\delta = \delta(\varepsilon) > 0$.*

[6] It is unclear if our new reduction can be combined with the ideas in [4] to improve the lower bounds in the seemingly easier case of undirected graphs with vertex capacities.

Moreover, if for some fixed $\varepsilon > 0$ and any $k \in [n^{1/2}, n]$ that version of All-Pairs Min-Cut can be solved combinatorially in time $O((n^2k^2)^{1-\varepsilon})$, then 4-Clique can be solved combinatorially in time $O(n^{4-\delta})$ for some $\delta = \delta(\varepsilon) > 0$.

To appreciate the new bounds, consider first the case $k = n$, which is equivalent to not restricting k. The previous lower bound, under SETH, is $n^{3-o(1)}$ and ours is larger by a factor of $n^{\omega-2}$. For combinatorial algorithms, our lower bound is $n^{4-o(1)}$, which is essentially the largest possible lower bound one can prove without a major breakthrough in fine-grained complexity. This is because the naive algorithm for All-Pairs Min-Cuts is to invoke an algorithm for Max-Flow $O(n^2)$ times, hence a lower bound larger than $\Omega(n^4)$ for our problem would imply the first non-trivial lower bound for minimum s-t cut. The latter is perhaps the biggest open question in fine-grained complexity, and in fact many experts believe that near-linear time algorithms for minimum s-t cut do exist, and can even be considered "combinatorial" in the sense that they do not involve the infamous inefficiencies of fast matrix multiplication. If such algorithms for minimum s-t cut do exist, then our lower bound is tight.

Our lower bound shows that as k exceeds $n^{1/2-o(1)}$, the time complexity of k-bounded of All-Pairs Min-Cut exceeds that of Transitive Closure by polynomial factors. The lower bound is super-cubic whenever $k \geq n^{2-\omega/2+\varepsilon}$.

Table 1 Summary of new and known results. Unless mentioned otherwise, all upper and lower bounds hold both for unit edge capacities and for unit vertex capacitities.

2 Preliminaries

We start with some terminology and well-known results on graphs and cuts. Next we will briefly introduce the main algebraic tools that will be used throughout the paper. We note that although we are interested in solving the k-bounded All-Pairs Min-Cut problem, where we wish to find the all-pairs min-cuts of size at most $k-1$, for the sake of using simpler notation we compute the min-cuts of size at most k (instead of less than k) solving this way the $(k+1)$-bounded All-Pairs Min-Cut problem.

Directed graphs. The input of our problem consists of an integer $k \geq 1$ and a *directed graph*, digraph for short, $G = (V, A)$ with $n := |V|$ *vertices* and $m := |A|$ *arcs*. Every arc $a = (u, v) \in A$ consists of a tail $u \in V$ and a head $v \in V$. By $G[S]$, we denote the subgraph of G *induced* by the set of vertices S, formally $G[S] = (S, A \cap (S \times S))$. By $N^+(v)$, we denote

the *out-neighborhood* of v consisting of all the heads of the arcs leaving v. We denote by $\text{outdeg}(v)$ the number of outgoing arcs from v. All our results extend to multi-digraphs, where each pair of vertices can be connected with multiple (*parallel*) arcs. For parallel arcs, we always refer to each arc individually, as if each arc had a unique identifier. So whenever we refer to a set of arcs, we refer to the set of their unique identifiers, i.e., without collapsing parallel arcs, like in a multi-set.

Flows and cuts. We follow the notation used by Ford and Fulkerson [17]. Let $G = (V, A)$ be a digraph, where each arc a has a nonnegative capacity $c(a)$. For a pair of vertices s and t, an s-t flow of G is a function f on A such that $0 \leq f(a) \leq c(a)$, and for every vertex $v \neq s, t$ the incoming flow is equal to outgoing flow, i.e., $\sum_{(u,v)\in A} f(u, v) = \sum_{(v,u)\in A} f(v, u)$. If G has vertex capacities as well, then f must also satisfy $\sum_{(u,v)\in A} f(u, v) \leq c(v)$ for every $v \neq s, t$, where $c(v)$ is the capacity of v. The value of the flow is defined as $|f| = \sum_{(s,v)\in A} f(s, v)$. We denote the existence of a path from s to t by $s \rightsquigarrow t$ and by $s \not\rightsquigarrow t$ the lack of such a path. Any set $M \subseteq A$ is an *s-t-cut* if $s \not\rightsquigarrow t$ in $G \setminus M$. M is a *minimal* s-t-cut if no proper subset of M is s-t-cut. For an s-t-cut M, we say that its *source side* is $S_M = \{x \mid s \rightsquigarrow x \text{ in } G \setminus M\}$ and its *target side* is $T_M = \{x \mid x \rightsquigarrow t \text{ in } G \setminus M\}$. We also refer to the source side and the target side as *s-reachable* and *t-reaching*, respectively. An s-t k-cut is a minimal cut of size k. A set $\mathcal{M}$ of s-t cuts of size at most k is called a set of s-t $\leq k$-cuts. We can define vertex cuts analogously.

Order of cuts. An s-t cut M is *later* (respectively *earlier*) than an s-t cut M' if and only if $T_M \subseteq T_{M'}$ (resp. $S_M \subseteq S_{M'}$), and we denote it $M \geq M'$ (resp. $M \leq M'$). Note that those relations are not necessarily complementary if the cuts are not minimal (see Figure 1 for an example).

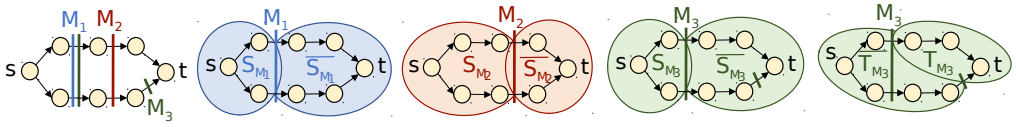

Figure 1 A digraph with three s-t-cuts M_1, M_2, M_3. While M_1 and M_2 are minimal, M_3 is not. Hence, the source side and target side differ only for M_3. This illustrates that the earlier and later orders might not be symmetric for non-minimal cuts. We have $M_3 < M_2$ yet $M_2 \not> M_3$ (and also $M_3 \leq M_2$ yet $M_2 \not\geq M_3$). Additionally, $M_1 \not< M_3$ yet $M_3 > M_1$ (yet both $M_1 \leq M_3$ and $M_3 \geq M_1$).

We make these inequalities strict (i.e., '$>$' or '$<$') whenever the inclusions are proper. We compare a cut M and an arc a by defining $a > M$ whenever both endpoints of a are in T_M. Additionally, $a \geq M$ includes the case where $a \in M$. Definitions of the relations '$\leq$' and '$<$' follow by symmetry. We refer to Figure 2 for illustrations.

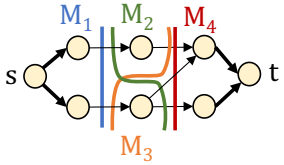

Figure 2 A digraph with several s-t cuts. Bold arcs represent parallel arcs which are too expensive to cut. M_1 is the earliest s-t min-cut and M_3 is the latest s-t min-cut. M_2 is later than M_1, but M_2 is not s-t-latest, as M_4 is later and not larger than M_2.

This partial order of cuts also allows us to define cuts that are extremal with respect to all other s-t cuts in the following sense:

▶ **Definition 2.1** (s-t-latest cuts [27]). *An s-t cut is s-t-*latest *(resp. s-t-*earliest*) if and only if there is no later (resp. earlier) s-t cut of smaller or equal size.*

Informally speaking, a cut is s-t-latest if we would have to cut through more arcs whenever we would like to cut off fewer vertices. This naturally extends the definition of an s-t-latest *min*-cut as used by Ford and Fulkerson [17, Section 5]. The notion of latest cuts has first been introduced by Marx [27] (under the name of *important* cuts) in the context of fixed-parameter tractable algorithms for multi(way) cut problems, but has been independently studied (or its equivalent formulations), [7, 29]. Since we need both earliest and latest cuts, we do not refer to latest cuts as important cuts. Additionally, we use the term *s-t-extremal* cuts to refer to the union of s-t-earliest and s-t-latest cuts.

3 Overview of Our Algorithmic Approach

3.1 Randomized Algorithms on General Graphs

We will now briefly recap the framework of Cheung et al. [13] as we will modify them later for our purposes. In this framework, edges are encoded as vectors, so that the vector of each edge $e = (u, v)$ is a randomized linear combination of the vectors correspond to edges incoming to u, the source of e. One can compute all these vectors for the whole graph, simultaneously, using some matrix manipulations. The bottleneck is that one has to invert a certain $m \times m$ matrix with an entry for each pair of edges. Just reading the matrix that is output by the inversion requires $\Omega(m^2)$ time, since most entries in the inverted matrix are expected to be nonzero even if the graph is sparse.

To overcome this barrier, while using the same framework, we define the encoding vectors on the nodes rather than the edges. We show that this is sufficient for the vertex-capacitated setting. Then, instead of inverting a large matrix, we need to compute the rank of certain submatrices which becomes the new bottleneck. When k is small enough, this turns out to lead to a significant speed up compared to the running time in [13].

3.2 Deterministic Algorithms with Witnesses on DAGs

Here we deal with the problem of computing certificates for the k-bounded All-Pairs Min-Cut problem. Our contribution here is twofold. We first prove some properties of the structure of the s-t-latest k-cuts and of the s-t-latest $\leq k$-cuts, which might be of independent interest. This gives us some crucial insights on the structure of the cuts, and allows us to develop an algorithmic framework which is used to solve the k-bounded All-Pairs Min-Cut problem. As a second contribution, we exploit our new algorithmic framework in two different ways, leading to two new algorithms which run in $O(mn^{1+o(1)})$ time for $k = o(\sqrt{\log n})$ and in $O(n^{\omega+o(1)})$ time for $k = o(\log \log n)$.

Let $G = (V, A)$ be a DAG. Consider some arbitrary pair of vertices s and t, and any s-t-cut M. For every intermediate vertex v, M must be either a s-v-cut, or a v-t-cut. The knowledge of all s-v and all v-t min-cuts does not allow us to convey enough information for computing an s-t min-cut of size at most k quickly, as illustrated in Figure 3.

However, we are able to compute an s-t min-cut by processing all the *s-v-earliest* cuts and all the *v-t-latest* cuts, of size at most k. We build our approach around this insight. We note that the characterization that we develop is particularly useful, as it has been shown that the number of all earliest/latest u-v $\leq k$-cuts can be upper bounded by $2^{O(k)}$, independently of the size of the graph.

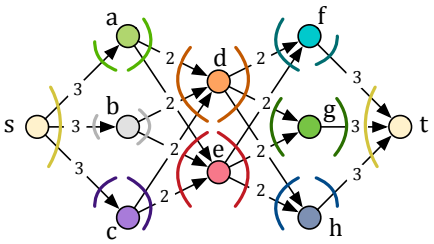

Figure 3 A digraph where each arc appears in at least one s-v or one v-t min-cut. The numbers on the arcs denote the number of parallel arcs. Note that neither of the two s-t min-cuts of size 9 (marked in yellow) are contained within the union of any two s-v or v-t min-cuts. Thus, finding all those min-cuts and trying to combine them in pairs in a divide-and-conquer-style approach is not sufficient to find an s-t min-cut.

For a more precise formulation on how to recover a min-cut (or extremal $\leq k$-cuts) from cuts to and from intermediate vertices, consider the following. Let A_1, A_2 be an *arc split*, that is a partition of the arc set A with the property that any path in G consists of a (possibly empty) sequence of arcs from A_1 followed by a (possibly empty) sequence of arcs from A_2. Assume that for each vertex v we know all the s-v-earliest $\leq k$-cuts in $G_1 = (V, A_1)$ and all the v-t-latest $\leq k$-cuts in $G_2 = (V, A_2)$. We show that a set of arcs M that contains as a subset one s-v-earliest $\leq k$-cut in G_1, or one v-t-latest $\leq k$-cut in G_2 for every v, is a s-t-cut. Moreover, we show that all the s-t-cuts of arcs with the above property include all the s-t-latest $\leq k$-cuts. Hence, in order to identify all s-t-latest $\leq k$ cuts, it is sufficient to identify all sets M with that property. We next describe how we use these structural properties to compute all s-t-extremal $\leq k$-cuts.

We formulate the following combinatorial problem over families of sets, which is independent of graphs and cuts, that we can use to compute all s-t-extremal $\leq k$-cuts. The input to our problem is c families of sets $\mathcal{F}_1, \mathcal{F}_2, \ldots, \mathcal{F}_c$, where each family $\mathcal{F}_i$ consists of at most K sets, and each set $F \in \mathcal{F}_i$ contains at most k elements from a universe U. The goal is to compute all minimal subsets $F^* \subset U, |F^*| \leq k$, for which there exists a set $F \in \mathcal{F}_i$ such that $F \subseteq F^*$, for all $1 \leq i \leq c$. We refer to this problem as Witness Superset. To create an instance (s, t, A_1, A_2) of the Witness Superset problem, we set $c = |V|$ and $\mathcal{F}_v$ to be all s-v-earliest $\leq k$-cuts in G_1 and all v-t-latest $\leq k$-cuts in G_2. Informally speaking, the solution to the instance (s, t, A_1, A_2) of the Witness Superset problem picks all sets of arcs that cover at least one earliest or one latest cut for every vertex. In a post-processing step, we filter the solution to the Witness Superset problem on the instance (s, t, A_1, A_2) in order to extract all the s-t-latest $\leq k$-cuts. We follow an analogous process to compute all the s-t-earliest $\leq k$-cuts.

Algorithmic framework. We next define a common algorithmic framework for solving the k-bounded All-Pairs Min-Cut problem, as follows. We pick a partition of the vertices V_1, V_2, such that there is no arc in $V_2 \times V_1$. Such a partition can be trivially computed from a topological order of the input DAG. Let $A_1, A_2, A_{1,2}$ be the sets of arcs in $G[V_1]$, in $G[V_2]$, and $A \cap (V_1 \times V_2)$.

- First, we recursively solve the problem in $G[V_1]$ and in $G[V_2]$. The recursion returns without doing any work whenever the graph is a singleton vertex.

- Second, for each pair of vertices (s,t), such that $s \in V_1$ has an outgoing arc from $A_{1,2}$ and $t \in V_2$, we solve the instance $(s,t,A_{1,2},A_2)$ of Witness Superset. Notice that the only non-empty earliest cuts in $(V,A_{1,2})$ for the pair (x,y) are the arcs $(x,y) \in A_{1,2}$.
- Finally, for each pair of vertices (s,t), such that $s \in V_1, t \in V_2$, we solve the instance $(s,t,A_1,A_{1,2} \cup A_2)$ of Witness Superset.

The Witness Superset problem can be solved naively as follows. Let $\mathcal{F}_v$ be the set of all s-v-earliest $\leq k$-cuts and all v-t-latest $\leq k$-cuts. Assume we have $\mathcal{F}_{v_1}, \mathcal{F}_{v_2}, \ldots, \mathcal{F}_{v_c}$, for all vertices $v_1, v_2, \ldots, v_c$ that are both reachable from s in $(V,A_{1,2})$ and that reach t in (V,A_2). Each of these sets contains $2^{O(k)}$ cuts. We can identify all sets M of arcs that contain at least one cut from each $\mathcal{F}_i$, in time $O(k \cdot (2^{O(k)})^c)$. This yields an algorithm with super-polynomial running time. However, we speed up this naive procedure by applying some judicious pruning, achieving a better running time of $O(c \cdot 2^{O(k^2)} \cdot \text{poly}(k))$, which is polynomial for $k = o(\sqrt{\log n})$. In the following, we sketch the two algorithms that we develop for solving efficiently the k-bounded All-Pairs Min-Cut problem.

Iterative division. For the first algorithm, we process the vertices in reverse topological order. When processing a vertex v, we define $V_1 = \{v\}$ and V_2 to be the set of vertices that appear after v in the topological order. Notice that V_1 has a trivial structure, and we already know all s-t-latest $\leq k$-cuts in $G[V_2]$. In this case, we present an algorithm for solving the instance $(v,t,A_{1,2},A_2)$ of the Witness Superset problem in time $O(2^{O(k^2)} \cdot c \cdot \text{poly}(k))$, where $c = |A_{1,2}|$ is the number of arcs leaving v. We invoke this algorithm for each v-w pair such that $w \in V_2$. For $k = o(\sqrt{\log n})$ this gives an algorithm that runs in time $O(\text{outdeg}(v) \cdot n^{1+o(1)})$ for processing v, and $O(mn^{1+o(1)})$ in total.

Recursive division. For the second algorithm, we recursively partition the set of vertices evenly into sets V_1 and V_2 at each level of the recursion. We first recursively solve the problem in $G[V_1]$ and in $G[V_2]$. Second, we solve the instances $(s,t,A_{1,2},A_2)$ and $(s,t,A_1,A_{1,2} \cup A_2)$ of Witness Superset for all pairs of vertices from $V_1 \times V_2$. Notice that the number of vertices that are both reachable from s in (V,A_1) and reach t in $(V,A_{1,2} \cup A_2)$ can be as high as $O(n)$. This implies that even constructing all $\Theta(n^2)$ instances of the Witness Superset problem, for all s,t, takes $\Omega(n^3)$ time. To overcome this barrier, we take advantage of the power of fast matrix multiplications by applying it into suitably defined matrices of binary codes (codewords). At a very high-level, this approach was used by Fischer and Meyer [16] in their $O(n^\omega)$ time algorithm for transitive closure in DAGs – there the binary codes where of size 1 indicating whether there exists an arc between two vertices.

Algebraic framework. In order to use coordinate-wise boolean matrix multiplication with the entries of the matrices being codewords we first encode all s-t-earliest and all s-t-latest $\leq k$-cuts using binary codes. The bitwise boolean multiplication of such matrices with binary codes in its entries allows a serial combination of both s-v cuts and v-t cuts based on AND operations, and thus allows us to construct a solution based on the OR operation of pairwise AND operations. We show that *superimposed codes* are suitable in our case, i.e., binary codes where sets are represented as bitwise-OR of codewords of objects, and small sets are guaranteed to be encoded uniquely. Superimposed codes provide a unique representation for sets of k elements from a universe of size $\text{poly}(n)$ with codewords of length $\text{poly}(k \log n)$. In this setting, the union of sets translates naturally to bitwise-OR of their codewords.

Tensor product of codes. To achieve our bounds, we compose several identical superimposed codes into a new binary code, so that encoding *set families* with it enables us to solve the corresponding instances of Witness Superset. Our composition has the cost of an exponential increase in the length of the code. Let $\mathcal{F} = F_1, \ldots, F_c$ be the set family that we wish to encode, and let $S_1, \ldots, S_c$ be their superimposed codes in the form of vectors. We construct a c-dimensional array M where $M[i_1, \ldots, i_c] = 1$ iff $S_j[i_j] = 1$, for each $1 \leq j \leq c$. In other words, the resulting code is the tensor product of all superimposed codes. This construction creates enough redundancy so that enough information on the structure of the set families is preserved. Furthermore, we can extract the encoded information from the bitwise-OR of several codewords. The resulting code is of length $O((k \log n)^{O(K)})$, where K is the upperbound on the allowed number of sets in each encoded set family. In our case $K \approx 4^k$, which results to only a logarithmic dependency on n at the price of a doubly-exponential dependency on k, thus making the problem tractable for small values of k.

From slices to Witness Superset. Finally, we show how the Witness Superset can be solved using tensor product of superimposed codes. Consider the notion of cutting the code of dimension K with an axis-parallel hyperplane of dimension $K - 1$. We call this resulting shorter codeword a *slice* of the original codeword. A slice of a tensor product is a tensor product of one dimension less, or an empty set, and a slice of a bitwise-OR of tensor products is as well a bitwise-OR of tensor products (of one dimension less). Thus, taking a slice of the bitwise-OR of the encoding of families of sets is equivalent to removing a particular set from some families and to dropping some other families completely and then encoding these remaining, reduced families. Thus, we can design a non-deterministic algorithm, which at each step of the recursion picks k slices, one slice for each element of the solution we want to output, and then recurses on the bitwise-OR of those slices, reducing the dimension by one in the process. This is always possible, since each element that belongs to a particular solution of Witness Superset satisfies one of the following: it either has a witnessing slice and thus it is preserved in the solution to the recursive call; or it is dense enough in the input so that it is a member of each solution and we can detect this situation from scanning the diagonal of the input codeword. This described nondeterministic approach is then made deterministic by simply considering every possible choice of k slices at each of the K steps of the recursion. This does not increase substantially the complexity of the decoding procedure, since $O(((K \cdot \text{poly}(k \log n))^k)^K)$ for $K \approx 4^k$ is still only doubly-exponential in k.

4 Reducing 4-Clique to All-Pairs Min-Cut

In this section we prove Theorem 1.1 by showing new reductions from the 4-Clique problem to k-bounded All-Pairs Min-Cut with unit vertex capacities. These reductions yield conditional lower bounds that are much higher than previous ones, which are based on SETH, in addition to always producing DAGs. Throughout this section, we will often use the term nodes for vertices.

▶ **Definition 4.1** (The 4-Clique Problem). *Given a 4-partite graph G, where $V(G) = A \cup B \cup C \cup D$ with $|A| = |B| = |C| = |D| = n$, decide whether there are four nodes $a \in A$, $b \in B$, $c \in C$, $d \in D$ that form a clique.*

This problem is equivalent to the standard formulation of 4-Clique (without the restriction to 4-partite graphs). The currently known running times are $O(n^{\omega+1})$ using matrix multiplication [15], and $O(n^4/\operatorname{polylog} n)$ combinatorially [35]. The k-Clique Conjecture

[3] hypothesizes that current clique algorithms are optimal. Usually when the k-Clique Conjecture is used, it is enough to assume that the current algorithms are optimal for every k that is a multiple of 3, where the known running times are $O(n^{\omega k/3})$ [30] and $O(n^k/\operatorname{polylog} n)$ combinatorially [32], see e.g. [2, 3, 10, 12, 25]. However, we will need the stronger assumption that one cannot improve the current algorithms for $k = 4$ by any polynomial factor. This stronger form was previously used by Bringmann, Grønlund, and Larsen [9].

4.1 Reduction to the Unbounded Case

We start with a reduction to the unbounded case (equivalent to $k = n$), that is, we reduce to All-Pairs Min-Cut with unit node capacities (abbreviated APMVC, for All-Pairs Minimum Vertex-Cut). Later (in Section 4.1) we will enhance the construction in order to bound k.

▶ **Lemma 4.2.** *Suppose APMVC on n-node DAGs with unit node capacities can be solved in time $T(n)$. Then 4-Clique on n-node graphs can be solved in time $O(T(n) + MM(n))$, where $MM(n)$ is the time to multiply two matrices from $\{0,1\}^{n\times n}$.*

To illustrate the usage of this lemma, observe that an $O(n^{3.99})$-time combinatorial algorithm for APMVC would imply a combinatorial algorithm with similar running time for 4-Clique.

Proof. Given a 4-partite graph G as input for the 4-Clique problem, the graph H is constructed as follows. The node set of H is the same as G, and we abuse notation and refer also to $V(H)$ as if it is partitioned into A,B,C, and D. Thinking of A as the set of sources and D as the set of sinks, the proof will focus on the number of node-disjoint paths from nodes $a \in A$ to nodes $d \in D$. The edges of H are defined in a more special way, see also Figure 4 for illustration.

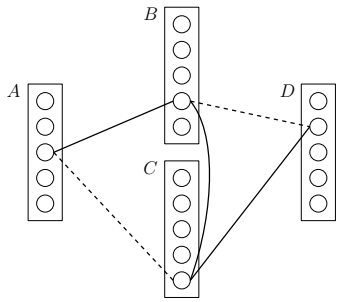

Figure 4 An illustration of H in the reduction. Solid lines between nodes represent the existence of an edge in the input graph G, and dashed lines represent the lack thereof.

- (A to B) For every $a \in A, b \in B$ such that $\{a, b\} \in E(G)$, add to $E(H)$ a directed edge (a, b).
- (B to C) For every $b \in B, c \in C$ such that $\{b, c\} \in E(G)$, add to $E(H)$ a directed edge (b, c).
- (C to D) For every $c \in C, d \in D$ such that $\{c, d\} \in E(G)$, add to $E(H)$ a directed edge (c, d).

The definition of the edges of H will continue shortly. So far, edges in H correspond to edges in G, and there is a (directed) path $a \to b \to c \to d$ if and only if the three (undirected) edges $\{a, b\}, \{b, c\}, \{c, d\}$ exist in G. In the rest of the construction, our goal is to make this 3-hop path contribute to the final $a \to d$ flow *if and only if* (a, b, c, d) is a 4-clique in G (i.e.,

all six edges exist, not only those three). Towards this end, additional edges are introduced, that make this 3-hop path useless in case $\{a, c\}$ or $\{b, d\}$ are not also edges in G. This allows "checking" for five of the six edges in the clique, rather than just three. The sixth edge is easy to "check".

- (A to C) For every $a \in A, c \in C$ such that $\{a, c\} \notin E(G)$, add to $E(H)$ a directed edge (a, c).
- (B to D) For every $b \in B, d \in D$ such that $\{b, d\} \notin E(G)$ in G, add to $E(H)$ a directed edge (b, d).

This completes the construction of H. Note that these additional edges imply that there is a path $a \to b \to d$ in H iff $\{a, b\} \in E(G)$ and $\{b, d\} \notin E(G)$, and similarly, there is a path $a \to c \to d$ in H iff $\{a, c\} \notin E(G)$ and $\{c, d\} \in E(G)$. Let us introduce notations to capture these paths. For nodes $a \in A, d \in D$ denote:

$$B'_{a,d} = \{b \in B \mid \{a, b\} \in E(G) \text{ and } \{b, d\} \notin E(G)\},$$
$$C'_{a,d} = \{c \in C \mid \{a, c\} \notin E(G) \text{ and } \{c, d\} \in E(G)\}.$$

We now argue that if an APMVC algorithm is run on H, enough information is received to be able to solve 4-Clique on G by spending only an additional post-processing stage of $O(n^3)$ time.

▷ Claim 4.3. Let $a \in A, d \in D$ be nodes with $\{a, d\} \in E(G)$. If the edge $\{a, d\}$ does not participate in a 4-clique in G, then the node connectivity from a to d in H, denoted $NC(a, d)$, is exactly

$$NC(a, d) = |B'_{a,d}| + |C'_{a,d}|,$$

and otherwise $NC(a, d)$ is strictly larger.

Proof of Claim 4.3. We start by observing that all paths from a to d in H have either two or three hops.

Assume now that there is a 4-clique (a, b^*, c^*, d) in G, and let us exhibit a set P of node-disjoint paths from a to d of size $|B'_{a,d}| + |C'_{a,d}| + 1$. For all nodes $b \in B'_{a,d}$, add to P the 2-hop path $a \to b \to d$. For all nodes $c \in C'_{a,d}$, add to P the 2-hop path $a \to c \to d$. So far, all these paths are clearly node-disjoint. Then, add the 3-hop path $a \to b^* \to c^* \to d$ to P. This path is node-disjoint from the rest because $b^* \notin B'_{a,d}$ (because $\{b^*, d\} \in E(G)$) and $c^* \notin C'_{a,d}$ (because $\{a, c^*\} \in E(G)$).

Next, assume that no nodes $b \in B, c \in C$ complete a 4-clique with a, d. Then for every set P of node-disjoint paths from a to d, there is a set P' of 2-hop node-disjoint paths from a to d that has the same size. To see this, let $a \to b \to c \to d$ be some 3-hop path in P. Since (a, b, c, d) is not a 4-clique in G and $\{a, d\}, \{a, b\}, \{b, c\}, \{c, d\}$ are edges in G, we conclude that either $\{a, c\} \notin E(G)$ or $\{b, d\} \notin E(G)$. If $\{a, c\} \notin E(G)$ then $a \to c$ is an edge in H and the 3-hop path can be replaced with the 2-hop path $a \to c \to d$ (by skipping b) and one is remained with a set of node-disjoint paths of the same size. Similarly, if $\{b, d\} \notin E(G)$ then $b \to d$ is an edge in H and the 3-hop path can be replaced with the 2-hop path $a \to b \to d$. This can be done for all 3-hop paths and result in P'. Finally, note that the number of 2-hop paths from a to d is exactly $|B'_{a,d}| + |C'_{a,d}|$, and this completes the proof of Claim 4.3. ◁

Computing the estimates. To complete the reduction, observe that the values $|B'_{a,d}|+|C'_{a,d}|$ can be computed for all pairs $a \in A, d \in D$ using two matrix multiplications. To compute the $|B'_{a,d}|$ values, multiply the two matrices M, M' which have entries from $\{0,1\}$, with $M_{a,b} = 1$ iff $\{a,b\} \in E(G) \cap A \times B$ and $M'_{b,d} = 1$ iff $\{b,d\} \notin E(G) \cap B \times D$. Observe that $|B'_{a,d}|$ is exactly $(M \cdot M')_{a,d}$. To compute $|C'_{a,d}|$, multiply M, M' over $\{0,1\}$ where $M_{a,c} = 1$ iff $\{a,c\} \notin E(G) \cap A \times C$ and $M'_{c,d} = 1$ iff $\{c,d\} \in E(G) \cap C \times D$.

After having these estimates and computing APMVC on H, it can be decided whether G contains a 4-clique in $O(n^2)$ time as follows. Go through all edges $\{a,d\} \in E(G) \cap A \times D$ and decide whether the edge participates in a 4-clique by comparing $|B'_{a,d}| + |C'_{a,d}|$ to the node connectivity $NC(a,d)$ in H. By the above claim, an edge $\{a,d\}$ with $NC(a,d) > |B'_{a,d}| + |C'_{a,d}|$ is found if and only if there is a 4-clique in G. The total running time is $O(T(n) + MM(n))$, which completes the proof of Lemma 4.2. ◀

4.2 Reduction to the *k*-Bounded Case

Next, we exploit a certain versatility of the reduction and adapt it to ask only about min-cut values (aka node connectivities) that are smaller than k. In other words, we will reduce to the k-bounded version of All-Pairs Min-Cut with unit node capacities (abbreviated kAPMVC, for k-bounded All-Pairs Minimum Vertex-Cut). Our lower bound improves on the $\Omega(n^\omega)$ conjectured lower bound for Transitive Closure as long as $k = \omega(n^{1/2})$.

▶ **Lemma 4.4.** *Suppose kAPMVC on n-node DAGs with unit node capacities can be solved in time $T(n,k)$. Then 4-Clique on n-node graphs can be solved in time $O(\frac{n^2}{k^2} \cdot T(n,k) + MM(n))$, where $MM(n)$ is the time to multiply two matrices from $\{0,1\}^{n \times n}$.*

Due to space constraints, the proof appears in the full version.

Proof of Theorem 1.1. Assume there is an algorithm that solves kAPMVC in time $O((n^{\omega-1}k^2)^{1-\varepsilon})$. Then by Lemma 4.4 there is an algorithm that solves 4-Clique in time $= O(\frac{n^2}{k^2} \cdot (n^{\omega-1}k^2)^{1-\varepsilon} + MM(n)) \leq O(n^{\omega+1-\varepsilon'})$, for some $\varepsilon' > 0$. The bound for combinatorial algorithms is achieved similarly. ◀

Fine-Grained Reductions and Quantum Speedups for Dynamic Programming

Amir Abboud

amir.abboud@ibm.com

Abstract

This paper points at a connection between certain (classical) fine-grained reductions and the question: Do quantum algorithms offer an advantage for problems whose (classical) best solution is via dynamic programming?

A remarkable recent result of Ambainis et al. [SODA 2019] indicates that the answer is positive for some fundamental problems such as Set-Cover and Travelling Salesman. They design a quantum $O^*(1.728^n)$ time algorithm whereas the dynamic programming $O^*(2^n)$ time algorithms are conjectured to be classically optimal. In this paper, fine-grained reductions are extracted from their algorithms giving the first lower bounds for problems in P that are based on the intriguing Set-Cover Conjecture (SeCoCo) of Cygan et al. [CCC 2010].

In particular, the SeCoCo implies:

- a super-linear $\Omega(n^{1.08})$ lower bound for 3-SUM on n integers,
- an $\Omega(n^{\frac{k}{c_k}-\varepsilon})$ lower bound for k-SUM on n integers and k-Clique on n-node graphs, for *any* integer $k \geq 3$, where $c_k \leq \log_2 k + 1.4427$.

While far from being tight, these lower bounds are significantly stronger than what is known to follow from the Strong Exponential Time Hypothesis (SETH); the well-known $n^{\Omega(k)}$ ETH-based lower bounds for k-Clique and k-SUM are vacuous when k is constant.

Going in the opposite direction, this paper observes that some "sequential" problems with previously known fine-grained reductions to a "parallelizable" core also enjoy quantum speedups over their classical dynamic programming solutions. Examples include RNA Folding and Least-Weight Subsequence.

1 Introduction

An increasing amount of effort is being dedicated to the question: When and by how much can quantum algorithms beat classical ones? Perhaps the most successful approach for getting quantum speedups is using Grover's search [22], which offers a quadratic improvement over classical exhaustive search, which is the bottleneck in the best-known algorithms for a long list of problems. This list includes nearly all problems studied in fine-grained complexity such as SAT, Orthogonal Vectors, 3-SUM, All-Pairs Shortest Paths, and so on. In fact, none

of the popular conjectures in fine-grained complexity (e.g. SETH) remain plausible when Grover's quantum search is allowed (with one exception, to be discussed shortly). It gives magical capabilities such as the following theorem.

▶ **Theorem 1** (Quantum Minimum Finding [17]). *Let $a_1, \ldots, a_n$ be integers accessed by a procedure $\mathcal{P}$. There exists a quantum algorithm that finds $\min_{i=1}^{n}\{a_i\}$ with success probability at least $2/3$ using $O(\sqrt{n})$ applications of $\mathcal{P}$.*

But what about problems whose best known algorithm is via dynamic programming, not exhaustive search? Could those problems be resilient to quantum speedups? A famous open question in this context is whether we can solve sequence alignment problems such Edit Distance and Longest Common Subsequence in truly-subquadratic quantum time. Such an algorithm could lead to important progress in bioinformatics in the future. The main challenge is the sequential nature of dynamic programming, which prevents us from using a Grover-like approach; one first solves the problem on small instances and then combines them to solve larger and larger instances. None of the steps involve an expensive exhaustive search. Another example is the Set-Cover problem, which can be solved in $O^*(2^n)$ time[1] with classical dynamic programming [19], and is conjectured by Cygan et al. [15] to have an $\Omega((2-\delta)^n)$ lower bound, for all $\delta > 0$. This is the so-called Set-Cover Conjecture (SeCoCo). Would this popular conjecture remain plausible in a quantum world?

A recent breakthrough of Ambainis et al. [5] shows otherwise. The authors give quantum $O^*(1.728^n)$ time algorithms for Set-Cover and Traveling Salesman, as well as other exponential speedups for problems such as Graph Bandwidth and Feedback Arc Set. These are problems where the best known classical algorithm is via dynamic programming. (It is unclear if their techniques will lead to solving Edit Distance in truly subquadratic quantum time.)

Ambainis et al. find a way to use the quantum minimum finding theorem above to solve Set-Cover. This can be viewed as a *reduction* from Set-Cover to a "parallelizable" core, and for the final algorithm to be fast the reduction should be efficient, qualifying it as a *fine-grained reduction* from Set-Cover to some minimum-finding problem. The main observation here is that the parallelizable-nature of the latter problem allows for further reductions to the popular problems in fine-grained complexity such as 3-SUM and k-Clique. Previously, no interesting reductions from Set-Cover to natural problems in P were known, and this gives a partial resolution to an open question in fine-grained complexity (see Section 5.1 in [39] and the discussion at the end of this paper). The sequential nature of Set-Cover had been a barrier for reductions as well, and the ideas of Ambainis et al. overcome it. The next subsection states the results and elaborates on their importance to the landscape of fine-grained complexity.

Section 3 suggests that this connection between quantum speedups for sequential problems and fine-grained reductions could be interesting also in the other direction.

1.1 The Consequences to Fine-Grained Complexity

The goal of fine-grained complexity and algorithms is to achieve upper and lower bounds that are as tight as possible for the computational problems of interest. The lower bounds are obtained via reductions and are based on a small set of popular conjectures, such as the Strong Exponential Time Hypothesis (SETH)[2] [23, 24], regarding the hardness of certain

[1] The notation $O^*(\cdot)$ hides polynomial factors.

[2] ETH states that 3-SAT cannot be solved in $2^{o(n)}$ time. The stronger version, SETH, states that we cannot solve k-SAT in $O((2-\varepsilon)^n)$ time for all k.

core problems, e.g. CNF-SAT. By now, there is a very long and evergrowing list of lower bounds that are tight up to $n^{o(1)}$ factors. See the recent surveys [40, 37]. One of the main gaps in knowledge, when it comes to this framework, is regarding the connections between the conjectures. For example, the k-SUM and k-Clique conjectures were used to prove many lower bound results that SETH (or any other conjectures) seem incapable of proving. Many conjectures have their own "hardness-class" and the whole theory would be much better if these conjectures can be supported by SETH or other (but different) conjectures.

k-SUM and k-Clique

The k-SUM problem asks to find k among n given numbers that sum to zero. It can be solved in $O(n^{\lceil k/2 \rceil})$ time which is conjectured to be optimal up to $n^{o(1)}$ factors [3]. The $k = 3$ case is the 3-SUM conjecture which is an old and famous conjecture in computational geometry [20]. This conjecture, for an even k, is supported by the hypothesis that Subset-Sum cannot be solved in $O(2^{(1/2-\varepsilon)n})$ for some $\varepsilon > 0$. A reduction of Patrascu and Williams [33] gives an $n^{\Omega(k)}$ lower bound for k-SUM assuming the ETH, when k is super-constant.

The k-Clique problem asks to find k among n nodes that form a clique. It can be solved in $O(n^{\frac{\omega}{3} \cdot k})$ time[3] [32, 18], where ω is the matrix multiplication exponent [38, 21], and this is conjectured to be optimal (and that $\omega = 2 + o(1)$) [1]. This conjecture, for k divisible by 3, is supported by the hypothesis that Max-Cut cannot be solved exponentially faster than its current runtime, since the current-best algorithm by Williams reduces Max-Cut to k-Clique [36]. The k-SUM conjecture implies an $n^{\lceil k/2 \rceil - o(1)}$ lower bound for k-Clique [4], and the ETH implies an $n^{\Omega(k)}$ lower bound for super-constant k [12, 13].

The aforementioned ETH lower bounds do not imply anything for these two problems when k is constant. No nontrivial SETH-based lower bounds are known, for any constant k.

SeCoCo vs. SETH

In a seminal paper on fine-grained reductions among NP-complete problems, Cygan et al. [15] introduced SeCoCo and used it to prove tight lower bounds for problems with dynamic programming solutions. It states that Set-Cover on n elements cannot be solved in $(2 - \delta)^n$ time, even when the sets have constant size (more formally defined in Section 2). Since then SeCoCo has been utilized for lower bounds for other NP-hard problems [6, 9, 26, 28].

Currently, SETH and SeCoCo seem incomparable and each of them has some advantages over the other as a hardness assumption. However, it is likely that SeCoCo will turn out to be a strictly safer (weaker, more believable) conjecture; there is no known barrier for (tightly) reducing SAT to Set-Cover and, at least back in 2010, Cygan et al. conjectured that such a reduction exists. On the other hand, a (tight) reduction in the other way, from Set-Cover to SAT, would be much more surprising. Unless the reduction is unusual, it would allow one to use the trivial 2^n algorithm for SAT to solve Set-Cover in 2^n time in a way that is simpler (no dynamic programming) and better in some ways (e.g. parallelizable). Even with today's knowledge, the latter point demonstrates an advantage of SeCoCo as a basis for reductions: it gives barriers for (e.g.) solving the end problem without dynamic programming. Meanwhile, SETH enjoys other benefits: First, it is much more popular. Second, SAT has been more extensively studied than Set-Cover in many areas such as complexity theory and verification. And third, refuting it implies some (weak) circuit lower bounds; this does not make it more believable, but it does "raise the stakes" in a way that is not known for SeCoCo. The reader is referred to [15, 31, 2, 27] for other discussions on the matter.

[3] The bound is slightly more complicated bound when k is not divisible by 3.

New Results

The main result of this paper is an extraction of fine-grained reductions from the quantum algorithms of Ambainis et al. leading to the first nontrivial lower bounds in P that are based on the Set-Cover Conjecture. The lower bounds can be based on a weaker form of the conjecture (discussed in Section 2) where sets are allowed to have size up to $n^{o(1)}$. The full version of the paper shows the same lower bound for the k-Orthogonal Vectors problem, via a minor modification to the reductions.

▶ **Theorem 2.** *Let $k \geq 3$ and[4] $c_k = k \cdot H(k^{-1}) = \log_2(k-1) + k \cdot \log \frac{k}{k-1}$. If for some $\varepsilon > 0$, either*

- *the k-Sum problem on n integers, or*
- *the k-Clique problem on n node graphs and $n^{2-\varepsilon}$ edges,*

can be solved in $O(n^{\frac{k}{c_k}-\varepsilon})$ time, then the (weak) SeCoCo is false.

Recall that the conjectured lower bounds are $1/c_k = 1/2$ for k-SUM and $1/c_k = 2/3$ for k-Clique. Whereas here, as k grows, the function c_k approaches $\log_2 k + 1.4427$, which means that the lower bound is approximately $\Omega(n^{\frac{k}{\log k}})$. It is non-trivial for k-Clique for all $k \geq 9$, while for k-SUM (where the input size is smaller) it is meaningful already in the most famous case of $k = 3$.

▶ **Corollary 3.** *If 3-SUM on n integers can be solved in $O(n^{1/H(1/3)-\varepsilon}) = O(n^{1.089-\varepsilon})$ time, for some $\varepsilon > 0$, then the (weak) SeCoCo is false.*

Perhaps the most exciting aspect of these results is that one can finally have a concrete lower bound for k-Clique and k-SUM for constant k. For instance, it implies an n^{10} lower bound for 2^{11}-Clique and 2^{11}-Sum. These two problems are canonical in parameterized complexity as they can be reduced to many other problems while preserving the boundedness of the natural parameter. Thus, the SeCoCo conjecture implies concrete lower bounds for all those other problems as well, when the parameter is a fixed constant. It is still an important open question to prove such lower bounds with a fixed $c_k > 0$ that is independent of k.

Replacing SeCoCo with SETH is a big open question. It is likely to be possible; in particular, it would follow if a reduction from SAT to Set-Cover is found. Such a reduction was conjectured to exist by Cygan et al. [15]. Notably, this suggests a barrier for proving much higher lower bounds for 3-SUM. It is known that the nondeterministic version of SETH (NSETH) rules out a SETH lower bound for 3-SUM of $\Omega(n^{1.5+\varepsilon})$ [11], and by the conjecture of Cygan et al. this is also a barrier for SeCoCo-based lower bounds.

Further open questions are discussed at the end of the paper. Since the algorithms of Ambainis et al. [5] for Set-Cover and for TSP are very similar, the exact same lower bounds above can be based on a corresponding assumption about the hardness of TSP. The modified proofs are deferred to the full version of the paper.

Less-Fine-Grained Complexity: Linear vs. Super-Linear

Traditional complexity theory classifies problems into polynomial (efficient) vs. super-polynomial (inefficient). Due, in part, to the increase in the data sizes this classification is now viewed as often being too coarse. Fine-Grained complexity's goal is to get a more exact classification that will be more relevant in many scenarios. It is natural to view the

[4] Let $H(p)$ be the binary entropy function on $p \in [0,1]$. See Section 2.

first-order goal of such a theory as: classifying problems into near-linear time solvable ones, those that can be solved "efficiently" even in "Big-Data" settings, vs. the ones that require super-linear time to solve. The latter set of problems will have to be relaxed before they can be solved at large scales. The more valuable and pleasing exact classification can be viewed as the next-step after this *less-fine-grained* classification is achieved.

This less-fine-grained classification has been conditionally achieved for a long list of problems, and the results of this paper strengthen the foundations for some of these results. For example, many problems in computational geometry are 3-SUM-hard in the sense that there is a linear-time reduction from 3-SUM to them. If these problems can be solved in near-linear time, then 3-SUM can, which is conjectured to be impossible (by a much weaker version of the 3-SUM conjecture). But what are other justifications for these "lower bounds"? Corollary3 gives a new one: such near-linear time algorithms would refute SeCoCo.

1.2 Other Related Work

Another connection between fine-grained complexity and quantum computing was recently demonstrated by Chen and Wang [14]. The authors show that a fast and communication-efficient *quantum* protocol for a function f implies a fast classical approximate counting algorithm for a related pair counting problem. They instantiate this connection in order to show a new approximate counting algorithm for the #-Orthogonal-Vectors problem.

A very recent paper by Khadiev [25] suggests a new quantum dynamic programming approach for problems on DAGs. It will be interesting to see if fine-grained reductions can be extracted.

2 Fine-Grained Reductions

Preliminaries

The standard notation $[n] = \{1, \ldots, n\}$ will be used throughout the paper. The starting point of the reductions in this paper is Set-Cover.

▶ **Definition 4** (The Set-Cover Problem). *Given m sets over the universe $U = [n]$, return the minimum number of sets required to cover U.*

The Set-Cover Conjecture (SeCoCo) of Cygan et al. states that the problem requires $2^{n-o(n)}$ time, even when all sets have constant size. Krauthgamer and Trabelsi [27] demonstrate that the Log-Set-Cover Conjecture, where the sets can have size up to $O(\log n)$, is equally useful but potentially more believable. They show that refuting it implies a breakthrough algorithm for Directed Hamiltonicity and Directed n-Tree. For the lower bounds in this paper, an even more relaxed conjecture is sufficient[5], where the sets are allowed to be of any size $n^{o(1)}$. Note that this automatically bounds the number of sets by $m = 2^{o(n)}$ which will be negligible.

The Weak Set-Cover Conjecture. No algorithm can solve Set-Cover over the universe $[n]$ with sets of size $n^{o(1)}$ in time $O((2-\delta)^n)$ where $\delta > 0$.

The main idea in the reductions, which is the crux of the quantum algorithms in [5], is an unusual split-and-list where all subsets of $[n]$ of size up to $d = n/k$ are enumerated. The analysis will rely on the following approximation of binomial coefficients, bounding the number of such sets:

[5] Although the stronger assumption would allow to extend the lower bound for larger values of k beyond $n^{1-\Omega(1)}$.

▶ **Lemma 5** (Entropy Approximation). *For all* $1 \leq d \leq n/2$,

$$\binom{n}{\leq d} = \sum_{i=1}^{d} \binom{n}{d} \leq 2^{H(d/n)\cdot n},$$

where $H(\epsilon) = -(\epsilon \log_2 \epsilon + (1-\epsilon)\log_2(1-\epsilon))$ *is the binary entropy of* $0 \leq \epsilon \leq 1$.

Observe that $H(1/k) = \frac{\log_2 k + O(1)}{k}$. In the proofs, the following bounds will be used for any $1 \leq k \leq n^{\varepsilon}$ where $\varepsilon < 1$: $\binom{n}{\leq n/k} \leq 2^{H(1/k)\cdot n}$ and when $t = n^{o(1)}$ then $\binom{n}{\leq n/k+t} \leq 2^{(H(1/k)+o(1))\cdot n}$. The last inequality follows because $\binom{n}{\leq n/k+t} \leq n^{o(1)} \cdot \binom{n}{n/k+t} \leq n^{o(1)} \cdot \binom{n}{(1+o(1))\cdot n/k} \leq 2^{H((1+o(1))/k)\cdot n + o(n)} \leq 2^{(1+o(1))\cdot H(1/k)\cdot n + o(n)} \leq 2^{(H(1/k)+o(1))\cdot n}$.

Key Observation

Following the notation in Ambainis et al., for a set system $\mathcal{S}$ over a universe U we denote the size of the minimum set-cover by $f(U, \mathcal{S})$. By definition, it follows that for any k sets $U_1, \ldots, U_k$ with union equal to U and any $\mathcal{S}$:

$$\sum_{i=1} f(U_i, \mathcal{S}) \geq f(U, \mathcal{S})$$

The central claim for all the reductions in this paper (and the quantum algorithm of Ambainis et al.) states that the above will be an equality in some cases.

▷ Claim 6. If all sets in a set system $\mathcal{S}$ over a universe U have size at most t then for all integers $k \geq 2$ such that $t < n/k$ there exist k disjoint subsets $U_1, \ldots, U_k \subseteq U$ each of size between $n/k - t$ and $n/k + t$ such that their union is equal to U and:

$$\sum_{i=1}^{k} f(U_i, \mathcal{S}) \leq f(U, \mathcal{S}).$$

Proof. Let $\mathcal{C} \subseteq \mathcal{S}$ be a minimum set-cover of U of size $\ell = f(U, \mathcal{S})$. To define a partition of U we consider this process: Start from an empty set X and add to it elements from U in the following way. Pick an arbitrary ordering of the sets in $\mathcal{C} = \{S_1, \ldots, S_\ell\}$ and go through them in order, at the i^{th} step we add all elements of S_i to X, unless they were already present.

Two observations about this process: (i) Since $\mathcal{C}$ is a Set-Cover we will end up with $X = U$. And (ii) all sets in $\mathcal{S}$ have size at most t and therefore each step can add up to t elements to X.

Define the sets $U_1, \ldots, U_k$ as follows. U_1 contains all elements added to X up until the earliest step in which $|X|$ became n/k or greater. Due to observation (ii) this guarantees that U_1 contains at most $n/k + t - 1$ elements. U_2 contains "the next" about n/k elements, and so on. More formally, U_i contains all elements added to X after the step in which its size became $\geq i \cdot n/k$ and up until the step in which its size became $\geq (i+1) \cdot n/k$. Again, due to observation (ii) the size of each U_i is upper bounded by $n/k + t$ and lower bounded by $n/k - t$. The sets are disjoint by definition and their union is equal to U.

Finally, we prove the inequality by arguing that each U_i can be covered separately using only the sets from $\mathcal{C}$. This is because one can choose exactly the sets that are responsible for adding the elements to U_i in the process in order to cover U_i. This is a cover by construction and thus $f(U_i, \mathcal{S})$ is upper bounded by this number of sets. And since the sets responsible for each U_i are different, the total number we choose for all the U_i's is exactly $|\mathcal{C}|$. Thus, $\sum_{i=1}^{k} f(U_i, \mathcal{S}) \leq |\mathcal{C}| = f(U, \mathcal{S})$. ◁

Intermediate Problems

This now allows for two preliminary reductions from Set-Cover to a parameterizd version of Exact Cover and to a simpler version of the k-Orthogonal-Vectors problem.

▶ **Definition 7** (The k-Exact-Cover Problem). *Given k lists of sets, each containing N subsets of the same universe U, decide if there are k subsets, one from each list, that are an exact cover of U, that is, they are disjoint and their union is equal to U.*

The following reduction from Set-Cover to this problem is a combination of existing tricks with the core idea of the algorithm by Ambainis et al. which is the enumeration of all subsets of $[n]$ of size equal to n/k up to plus-or-minus the size of a set in the instance, and the preprocessing of their solutions. The correctness will follow from the above key claim.

▶ **Lemma 8.** *For all $2 \leq k \leq n^{\varepsilon}$ where $\varepsilon < 1$, the Set-Cover problem on n elements and m sets of size $n^{o(1)}$ can be reduced to $2^{o(n)}$ instances of the k-Exact-Cover problem on k lists of $N \leq 2^{H(1/k)\cdot n+o(n)}$ subsets over a universe U of size n. The reduction runs in time $2^{H(1/k)\cdot n+o(n)}$.*

Proof. First, reduce Set-Cover to the decision version: is there a set-cover of size exactly ℓ? This can be done simply with an overhead of n in the number of instances by trying all possible values for $1 \leq \ell \leq n$, and returning the smallest one with a positive answer. Thus, it is enough to only consider the decision version.

The goal is to look for a partition of U into k sets that can be covered separately at no extra cost, as promised by Claim 6. Let $U_1, \ldots, U_k$ be such sets, and let $\alpha' = (f(U_1, \mathcal{S}), \ldots, f(U_k, \mathcal{S}))$ be the k-tuple of the sizes of their minimum covers. Note that for all i: $f(U_i, \mathcal{S}) \leq |U_i| \leq n/k + t$ where $t = n^{o(1)}$ is an upper bound on the size of the given sets. As a second preliminary step, we enumerate all tuples α of k numbers in $[n/k + t]$ that sum to ℓ, in an attempt to guess α', and for each tuple there will be an instance of k-Exact-Cover. The total number of tuples is at most $(n/k + t)^k = 2^{o(n)}$. From now on fix a tuple $\alpha = (\alpha_1, \ldots, \alpha_k)$.

Enumerate all subsets of U that are of size up to $n/k + t$, call this collection $\mathcal{P}$. In a preprocessing step, compute the minimum set-cover $f(P, \mathcal{S})$ for all sets $P \in \mathcal{P}$. This can be done in $O(|\mathcal{P}| \cdot m)$ time: In the classical dynamic programming algorithm we compute $f(X, \mathcal{S})$ for increasingly larger sets via the formula $f(X, \mathcal{S}) = \min_{S \in \mathcal{S}}\{f(X \setminus S, \mathcal{S}) + 1\}$. Do the same, but do not process sets such that $|X| > n/k + t$. Thus, the total running time for this step, which is the most expensive in the reduction, is $O(\binom{n}{\leq n/k+t} \cdot m) \leq 2^{H(1/k)\cdot n+o(n)}$.

For all $i \in [k]$, the i^{th} list $\mathcal{L}_i$ in the k-Exact-Cover instance contains all sets $P \in \mathcal{P}$ whose minimum set-cover size matches the guess in α, that is,

$$\mathcal{L}_i = \{P \in \mathcal{P} \mid f(P, \mathcal{S}) = \alpha_i\}.$$

This completes the reduction: at least one of the k-Exact-Cover instances (for some tuple α) is a yes-instance, if and only if there is a set-cover of size ℓ.

For the correctness, observe that for any α and any k sets $X_1 \in \mathcal{L}_1, \ldots, X_k \in \mathcal{L}_k$ whose union is equal to U we have that $f(U, \mathcal{S}) \leq \sum_{i=1}^{k} f(X_i, \mathcal{S}) = \ell$. Thus, if one of the k-Exact-Cover instances is a yes, then $f(U, \mathcal{S}) \leq \ell$. For the other direction, assume that there is a set-cover of size ℓ and consider the partition $U_1, \ldots, U_k$ promised by Claim 6 and let $\alpha = \alpha'$ above be the tuple of minimum set-cover sizes for the k sets in that partition. The instance corresponding to this α is a yes-instance because each U_i will exist in $\mathcal{L}_i$ and their union is equal to U and, moreover, they are disjoint. ◀

The second intermediate problem superficially looks like the k-Orthogonal-Vectors problem (which is the canonical problem for SETH-based lower bounds) but it is in fact easier and is more closely related to k-Clique.

▶ **Definition 9** (The k-Pairwise-Disjoint-Sets Problem, or k-Pairwise-Orthogonal-Vectors)**.** *Given k lists of sets, each containing N subsets of the same universe U, decide if there are k subsets, one from each list, that are pairwise disjoint.*

The reduction is also by a combination of existing tricks with the key claim.

▶ **Lemma 10.** *For all $2 \leq k \leq n^{\varepsilon}$ where $\varepsilon < 1$, the Set-Cover problem on n elements and m sets of size $n^{o(1)}$ can be reduced to $2^{o(n)}$ instances of the k-Pairwise-Disjoint-Sets problem on k lists of $N \leq 2^{H(1/k)\cdot n+o(n)}$ subsets over a universe U of size n. The reduction runs in time $2^{(1/k+H(1/k))\cdot n+o(n)}$.*

Moreover, in all instances, each subset can be disjoint to at most $2^{(1-1/k)\cdot H(\frac{1}{k-1})\cdot n+o(n)}$ others.

The last sentence of the lemma will be helpful in reducing the sparsity of the k-Clique instances later on.

Proof. The proof is similar to the one of Lemma 8 with a bit more. The additional challenge here is that the end problem does not check that the union of the sets is equal to U, only that they are disjoint. The trick to handle this is yet another guessing step making sure that the sizes of the sets we are choosing sums up to n (before, we only checked that the sum of their *min covers* is equal to ℓ).

First, as before, we reduce to the decision version, and also enumerate k-tuples $\alpha \in [n/k + t]^k$ with sum ℓ, that try to guess the values $f(U_i, \mathcal{S})$ in the partition $U_1, \ldots, U_k$ promised by Claim 6. The additional step here is to also enumerate all k-tuples $\beta \in [n/k+t]^k$ with sum equal to $|U| = n$, that try to guess the values $|U_i|$. The number of β's is also upper bounded by $2^{o(n)}$. From now on fix both an $\alpha = (\alpha_1, \ldots, \alpha_k)$ and a $\beta = (\beta_1, \ldots, \beta_k)$.

Then, as before, we enumerate the collection $\mathcal{P}$ of all subsets of U of size up to $n/k + t$, and compute $f(P, \mathcal{S})$ for each $P \in \mathcal{P}$. These computations can be done with dynamic programming in a total of $2^{H(1/k)\cdot n+o(n)}$ time.

For all $i \in [k]$, the i^{th} list $\mathcal{L}_i$ in the k-Pairwise-Disjoint-Sets instance contains all sets $P \in \mathcal{P}$ whose minimum set-cover size matches the guess in α *and* their size matches the guess in β, that is,

$$\mathcal{L}_i = \{P \in \mathcal{P} \mid f(P, \mathcal{S}) = \alpha_i \text{ and } |U_i| = \beta_i\}.$$

This completes the reduction: at least one of the k-Pairwise-Disjoint-Sets instances (for some tuples α, β) is a yes-instance, if and only if there is a Set-Cover of size ℓ.

For the correctness, observe that for any α, β and any k sets $X_1 \in \mathcal{L}_1, \ldots, X_k \in \mathcal{L}_k$ that are disjoint, we have that $f(U, \mathcal{S}) \leq \sum_{i=1}^{k} f(X_i, \mathcal{S}) = \ell$ and $|X_1 \cup \cdots \cup X_k| = \sum_{i=1}^{k} |X_i| = \sum_i \beta_i = n$. The latter implies that the sets cover the entire U. Thus, if one of the k-Exact-Cover instances is a yes, then $f(U, \mathcal{S}) \leq \ell$. For the other direction, assume that there is a set-cover of size ℓ and consider the partition $U_1, \ldots, U_k$ promised by Claim 6 and let α be the tuple of minimum set-cover sizes for the k sets in that partition, and β be the tuple of their sizes. The instance corresponding to this α, β pair is a yes-instance because each U_i will exist in $\mathcal{L}_i$ and they are disjoint.

Finally, observe that each subset in our instances has size at least n/k, and therefore it can be disjoint to at most

$$\binom{n - n/k}{n/k + t} = 2^{(1-1/k)\cdot H(\frac{1}{k-1})\cdot n+o(n)}$$

other sets in every instance. ◀

2.1 The Reduction to k-SUM

The following version of k-SUM is convenient for reductions.

▶ **Definition 11** (The k-SUM Problem). *Given k lists of N numbers in $[M]$ and a target number $t \in [M]$, decide if there are k numbers, one from each list, that sum to t.*

This "list" or "colored" version is equivalent to the more natural version (where we only have one list and/or where the target is fixed to $t = 0$) up to a k factor in the number of numbers and a k factor in their size.

The reduction to k-SUM is by a simple encoding of the k-Exact-Cover problem.

▶ **Theorem 12.** *For all $2 \leq k \leq n^{\varepsilon}$ where $\varepsilon < 1$, the Set-Cover problem on n elements and m sets of size $n^{o(1)}$ can be reduced to $2^{o(n)}$ instances of the k-SUM problem on k lists of $N = 2^{H(1/k)\cdot n+o(n)}$ integers and a target, where the numbers are $n \cdot \lceil \log_2 k \rceil = O(k \log N)$ bits long. The reduction runs in time $2^{H(1/k)\cdot n+o(n)}$.*

Proof. First, reduce Set-Cover instance to $2^{o(n)}$ instance of k-Exact-Cover, as in Lemma 8, and then reduce each instance to an equivalent k-SUM instance. The k-Exact-Cover instances have k lists of $N \leq 2^{H(1/k)\cdot n+o(n)}$ subsets over the universe $U = [n]$.

The following is a natural mapping g from sets $X \subseteq [n]$ to $(n \cdot \log_2 k)$ bit integers: for all $i \in [n]$, the bit number $(i-1) \cdot \lceil \log_2 k \rceil + 1$ in $g(X)$ is set to 1 if $i \in X$ and to 0 otherwise. All other bits are set to 0, and these are just "buffers" of length $\log_2 k$ that prevent the sum of k numbers to carry over from one "interesting" location to another. Another way to think of the mapping is as writing a number in base k where the i^{th} digit is 1 if $i \in X$ and 0 otherwise.

Let $\mathcal{L}_i$ be the i-th list in the k-Exact-Cover, and we will map it into a list of integers L_i by encoding each set $X \in \mathcal{L}_i$ with the integer $g(X)$. The target sum t for the k-SUM instance is the number $g(U)$, or in other words, the number that is all 1 in base k. This completes the reduction.

For the correctness, one can check that for any k sets $X_1, \ldots, X_k$: $\sum_{i=1}^{k} g(X_i) = g(U)$ if and only if the X_i's are disjoint and $X_1 \cup \cdots \cup X_k = U$. ◀

This proves the k-SUM part of the main theorem, and the lower bound for 3-SUM.

2.2 The Reduction to k-Clique

A reduction from k-SUM on n numbers to $n^{o(1)}$ instances of k-Clique on n nodes is known [4], and it can be used directly to get the desired result. However, the instances generated by that reduction could be dense ($m = n^2$ edges), whereas the following direct reduction from Set-Cover gives the same result but on sparser graphs.

The following version of k-Clique is most convenient for reductions and is equivalent up to a factor k.

▶ **Definition 13** (The k-Clique Problem). *Given a k-partite graph with N nodes in each part and M edges, decide if there is a k-clique (with one node in each part).*

The reduction to k-Clique is almost immediate after one goes though the k-Pairwise-Disjoint-Sets problem.

▶ **Theorem 14.** *For all $2 \leq k \leq n^{\varepsilon}$ where $\varepsilon < 1$, the Set-Cover problem on n elements and m sets of size $n^{o(1)}$ can be reduced to $2^{o(n)}$ instances of the k-Clique problem on k partite graphs of $N = 2^{H(1/k)\cdot n+o(n)}$ nodes and $M = 2^{(H(1/k)+(1-1/k)\cdot H(\frac{1}{k-1}))\cdot n+o(n)}$ edges. The reduction runs in time $2^{H(1/k)\cdot n+o(n)}$.*

Proof. First, reduce Set-Cover instance to $2^{o(n)}$ instance of k-Pairwise-Disjoint-Sets, as in Lemma 10, and then reduce each instance to an equivalent k-Clique instance. The nodes correspond to the sets and two nodes are connected by an edge iff the corresponding sets are disjoint. A k-clique corresponds directly to k pairwise-disjoint sets, and the correctness of the reduction is immediate. The parameters in the statement follow from the parameters in Lemma 10, including the bound on the number of edges which is:

$$M = N \cdot 2^{(1-1/k)\cdot H(\frac{1}{k-1})\cdot n + o(n)}.$$ ◀

This proves the k-Clique part of the main theorem. A corollary of this reduction is an $\Omega(M^{1.01-\varepsilon})$ lower bound for 9-Clique on M edge graphs under the Set-Cover Conjecture.

3 Quantum Algorithms

This section goes in the other direction and discusses a few examples where previously known fine-grained reductions from a "sequential problem" to a "parallelizable core" can be used to obtain quantum speedups. While these arguments are not the simplest way to obtain such quantum speedup, they may still be interesting conceptually.

The first example is from the work of Künnemann et al. [29] who investigated the fine-grained complexity of *one-dimensional dynamic programming*. Their results center around instantiations of a generic Least-Weight Subsequence (LWS) problem where: Given an ordered sequence of n data items, with a succinctly represented function that assigns a weight to each pair, find a (non-contiguous) subsequence of the data points that minimizes the total weight of pairs adjacent in the subsequence. The problem can be instantiated by fixing a weight function, and it can model basic questions such as the coin change problem and finding the longest chain of nested boxes. The authors prove subquadratic-equivalences between these problems and a parallelizable core such as the $(\min, +)$-Convolution problem or vector domination. Thus, classically these problems are unlikely to be solvable in subquadratic time. However, since the parallelizable core problems are easy to solve in $O(n^{2-\varepsilon})$ time for some $\varepsilon > 0$ (and even linear time) for Grover's search, their reductions lead to $O(n^{2-\varepsilon})$ quantum time algorithms for coin change, finding the longest chain of nested boxes, and many other problems as well.

Another example is the RNA Folding problem from bioinformatics and the related problems of Language Edit Distance and Stochastic Context-Free Grammar Parsing. These problems can be solved in cubic time with dynamic programming, and a reduction *a la* Valiant's Parser [35] shows that each of these problems can be solved in the same time as the $(\min, +)$-matrix multiplication problem, or distance product, which is equivalent to All Pairs Shortest Paths and many other problems [41]. In fact, this reduction was recently used by Bringmann et al. [10] to improve the upper bound to $O(n^{2.8244})$ by utilizing a special structure in the $(\min, +)$-matrix multiplication instances produced by the reduction. This is the fastest classical algorithm to date for each of these problems. Can it be improved with a quantum algorithm? Yes, even without any special structure, the $(\min, +)$-matrix multiplication problem is parallelizable and can be solved in $O(n^{2.5})$ time, and via Valiant's reduction, so can these problems. A detailed exposition of these reductions can be found in [10], and related examples on how to incorporate such quantum matrix multiplication algorithm to solve combinatorial problems can be found in [30].

4 Open Questions

The results in this paper lead to the following thoughts.

- From a technical perspective, the reductions in this paper and the quantum algorithms of Ambainis et al. are via an unusual split-and-list approach: it is less efficient, increasing the search space size from 2^n to $2^{\frac{k}{H(1/k)}\cdot n}$, but it can simplify the structure of the space. Is this approach fruitful in other settings, not only when the problems are hard to parallelize? Can it be applied to SAT to get SETH-based lower bounds, that may not be tight, but could have a whole new flavor?
- The efficiency of the reductions does not exactly match that of the quantum algorithm for Set-Cover, since the algorithm benefits from more asymmetry in the splitting[6]. However, it is plausible that better quantum algorithms will lead to better reductions (and lower bounds), and vice versa. Intuitively, the best result one can hope for, without refuting conjectures, is to solve Set-Cover in $\sqrt{2^n}$ quantum time and extract an $n^{k/2}$ (classical) lower bound for k-SUM (which would be tight, for an even k) and for k-Clique (which would be tight if proven for sparse enough graphs). Perhaps this can be achieved by incorporating some of the ideas from the more technically involved works on Set-Cover, e.g. [8, 31, 7, 34], into the currently simple reduction/algorithm. This would be an exciting finding.
- Proving an $\Omega(n^{\varepsilon k})$ lower bound for k-Clique for a fixed $\varepsilon > 0$ (ideally $\varepsilon = 2/3$) under SETH (or even under SeCoCo) is still an important open question. The results here give a qualitatively similar results for k that is a small constant, but one would hope for more. This issue is often considered related to the frequently raised question: Does SETH (or SeCoCo) imply an $(1+\varepsilon)^n$ lower bound for 3-SAT or 100-SAT for any fixed $\varepsilon > 0$?
- The open question of whether SeCoCo implies lower bounds for problems in P was only answered in a limited sense here. Yes, interesting lower bounds for k-Clique and k-SUM can be derived, but the real intent behind the question is: Can SeCoCo give interesting lower bounds in P that other "established" or popular conjectures are incapable of proving? The results here do not qualify, but perhaps they will lead to such results. Can the structure of Set-Cover be utilized further in order to prove similar lower bounds for easier problems? A natural candidate is the $(\min,+)$-Convolution problem which is considered to be the easiest problem without a truly subquadratic time algorithm [16].
- In [5], the quantum speedup over classical dynamic programming for the Graph Bandwidth problem is more substantial than it is for Set-Cover and TSP. The best classical algorithm has $O^*(5^n)$ complexity while the quantum one runs in time $O^*(2.945^n)$, which is quite close to $\sqrt{5^n}$. This suggests that if one reduces the Graph Bandwidth problem to problems in P, e.g. 3-SUM, a tighter relationship could be established, leading to higher "conditional lower bounds". This is more challenging than reducing from Set-Cover due to the more complicated nature of their quantum algorithm.

Abstract

We study the following separation problem: Given a collection of colored objects in the plane, compute a shortest "fence" F, i.e., a union of curves of minimum total length, that separates every two objects of different colors. Two objects are separated if F contains a simple closed curve that has one object in the interior and the other in the exterior. We refer to the problem as GEOMETRIC k-CUT, where k is the number of different colors, as it can be seen as a geometric analogue to the well-studied multicut problem on graphs. We first give an $O(n^4 \log^3 n)$-time algorithm that computes an optimal fence for the case where the input consists of polygons of two colors and n corners in total. We then show that the problem is NP-hard for the case of three colors. Finally, we give a $(2 - 4/3k)$-approximation algorithm.

1 Introduction

Problem Definition. We are given k pairwise interior-disjoint, not necessarily connected, sets $B_1, B_2, \ldots, B_k$ in the plane. We want to find a covering of the plane $\mathbb{R}^2 = \bar{B}_1 \cup \bar{B}_2 \cup \cdots \cup \bar{B}_k$ such that the sets $\bar{B}_i$ are closed and interior-disjoint, $B_i \subseteq \bar{B}_i$ and the total length of the boundary $F = \bigcup_{i=1}^{k} \partial \bar{B}_i$ between the different sets $\bar{B}_i$ is minimized.

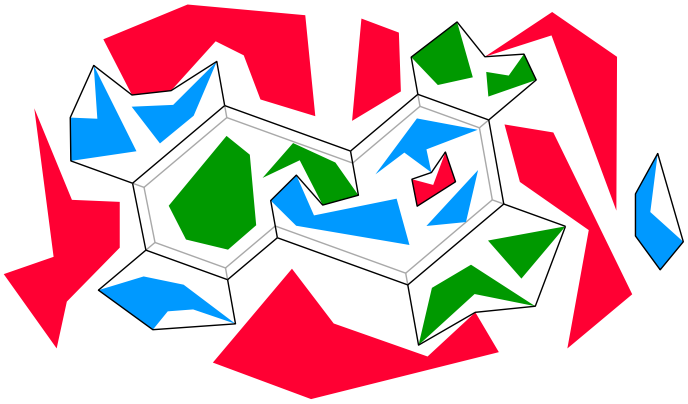

Figure 1 An instance of GEOMETRIC 3-CUT and an optimal fence in black. The fence contains a cycle that does not touch any object. The grey fence shows how the cycle can be shrunk without changing the total length of the fence.

We think of the k sets B_i as having k different *colors* and each set B_i as a union of simple geometric objects like circular disks and simple polygons. An example is shown in Figure 1. We call $\bar{B}_i$ the *territory* of color i. The "fence" F is the set of points that separates the territories. (Alternatively, F is the set of points belonging to more than one territory.) As we can see, a territory can have more than one connected component.

An alternative view of the problem concentrates on the *fence*: A fence is defined as a union of curves F such that each connected component of $\mathbb{R}^2 \setminus F$ intersects at most one set B_i. An interior-disjoint covering as defined above gives, by definition, such a fence. Likewise, a fence F induces such a covering, by assigning each connected component of $\mathbb{R}^2 \setminus F$ to an appropriate territory $\bar{B}_i$. The total length of a fence F is also called the *cost* of F and is denoted as $|F|$.

In our paper, we will focus on the case where the input consists of simple polygons (with disjoint interiors). We refer to this problem as *GEOMETRIC k-CUT*. Each input polygon is called an *object*. We use n to denote the total number of corners of the input polygons, counted with multiplicity.

Even in this simple setting, the problem poses both geometric and combinatorial difficulties. A set B_i can consist of disconnected pieces, and the combinatorial challenge is to choose which of the pieces should be grouped into the same component of $\bar{B}_i$. The geometric task is to construct a network of curves that surrounds the given groups of objects and thus separates the groups from each other. For $k = 2$ colors, optimal fences consist of geodesic curves around obstacles, which are well understood. As soon as the number k of colors exceeds 2, the geometry becomes more complicated, and the problem acquires traits of the geometric Steiner tree problem, as shown by the example in Figure 1.

The problem of enclosing a set of objects by a shortest system of fences has been considered with a single set B_1 by Abrahamsen et al. [1]. The task is to "enclose" the components of B_1 by a shortest system of fences. This can be formulated as a special case of our problem with $k = 2$ colors: We add an additional set B_2, far away from B_1 and large enough so that it is never optimal to enclose B_2. Thus, we have to enclose all components of B_1 and separate them from the unbounded region. In this setting, there will be no nested fences. Abrahamsen et al. gave an algorithm with running time $O(n \text{ polylog } n)$ for the case where the input consists of n unit disks.

Applications. Besides being a natural problem in its own right, the geometric multicut problem may well find applications in image processing and computer vision. As we describe in Section 3, a problem closely related to the case $k = 2$ has been studied from the perspective of image segmentation. Simplified slightly, we are given a picture with some pixels known to be black or white, and we have to choose colors for the remaining pixels so as to minimize the boundary between black and white regions. The problem for $k > 2$ is equally well-motivated in this context, although we have not found any explicit references to it (perhaps because of the NP-hardness that we will prove in this case).

Our Results. In Section 3, we show how to solve the case with $k = 2$ colors in time $O(n^4 \log^3 n)$. The algorithm works by reducing the problem to the multiple-source multiple-sink maximum flow problem in a planar graph. In Section 4, we show that already the case with $k = 3$ colors is NP-hard by a reduction from PLANAR POSITIVE 1-IN-3-SAT.

In Section 5, we discuss approximation algorithms. We first compare the optimal fence $F_{\mathcal{A}}$ consisting of line segments between corners of input polygons to the unrestricted optimal fence F^*. We show that $|F_{\mathcal{A}}| \leq 4/3 \cdot |F^*|$. After applying a $(3/2 - 1/k)$-approximation algorithm for the k-terminal multiway cut problem [6], we obtain a polynomial-time $(2 - \frac{4}{3k})$-approximation algorithm for GEOMETRIC k-CUT (Theorem 11).

Due to restricted space, many details and proofs have been removed and can be found in the full version [2].

2 Structure of Optimal Fences

▶ **Lemma 1.** *An optimal fence F^* is a union of (not necessarily disjoint) closed curves, disjoint from the interior of the objects. Furthermore, F^* is the union of straight line segments of positive length. Consider two non-collinear line segments $\ell_1, \ell_2 \subset F^*$ with a common endpoint p. If p is not a corner of an object, then exactly three line segments meet at p and form angles of $2\pi/3$.*

Proof. It is clear that an optimal fence F^* never enters the interior of an object.

We next show that F^* is the union of a set of closed curves. Suppose not. Let $F' \subset F^*$ be the union of all closed curves contained in F^* and let π be a connected component in $F^* \setminus F'$. Then π is the (not necessarily disjoint) union of a set of open curves, which do not contribute to the separation of any objects. Hence, $F^* \setminus \pi$ is a fence of smaller length than F^*, so F^* is not optimal.

In a similar way, one can consider the union L of all line segments of positive length contained in F^*, and if $F^* \setminus L$ is non-empty, a curve π in $F^* \setminus L$ can be replaced by a shortest path homotopic to it, which consists of a sequence of line segments. (See the proof of Lemma 13 in the full version.)

The last claimed property is shared with the Euclidean Steiner minimal tree on a set of points in the plane, and it can be proved in the same easy way by local optimality arguments, see for example Gilbert and Pollak [10]. ◀

As it can be seen in Figure 1, optimal fences may contain cycles that do not touch any object. As is also indicated in the figure, such a cycle can be shrunk until it eventually hits an object and is eliminated. This does not increase the length, so there is always an optimal fence with no cycle disjoint from all objects. See the full version for the details.

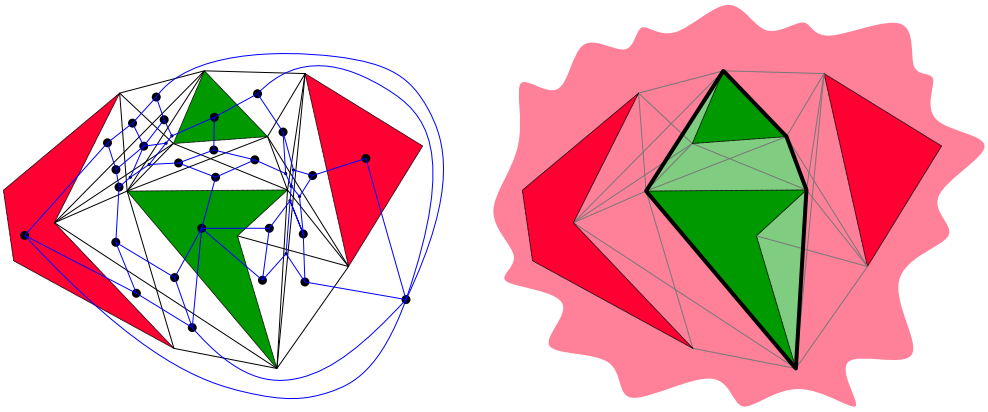

Figure 2 Left: The arrangement $\mathcal{A}$ induced by an instance of GEOMETRIC 2-CUT with two green and two red objects. The edges of the dual graph G are blue. Right: The optimal solution.

3 The Bicolored Case

In this section we consider the case of $k = 2$ different colors. Let N be the set of all corners of the objects. A line segment is said to be *free* if it is disjoint from the interior of every object. A vertex v of an optimal fence cannot have degree 3 or more unless $v \in N$, as otherwise two of the regions meeting at v would be part of the same territory and could be merged, thus reducing the length. We therefore get the following consequence of Lemma 1.

▶ **Lemma 2.** *An optimal fence consists of free line segments with endpoints in N.* ◀

Let S be the set of all free segments with endpoints in N. S includes all edges of the objects. Let $\mathcal{A}$ be the arrangement induced by S, see Figure 2. Consider an optimal fence F^* and the associated territories $\bar{B}_1$ and $\bar{B}_2$. Lemma 2 implies that F^* is contained in $\mathcal{A}$. Thus, each cell of $\mathcal{A}$ belongs entirely either to $\bar{B}_1$ or $\bar{B}_2$. The objects are cells of $\mathcal{A}$ whose classification (i.e., membership of $\bar{B}_1$ versus $\bar{B}_2$) is fixed. In order to find F^*, we need to select the territory that each of the other cells belongs to. Since $|S| = O(n^2)$, $\mathcal{A}$ has size $O(|S|^2) = O(n^4)$ and can be computed in $O(|\mathcal{A}|) = O(n^4)$ time [7]. For simplicity, we stick with the worst-case bounds. In practice, set S can be pruned by observing that the edges of an optimal fence must be *bitangents* that touch the objects in a certain way, because the curves of the fence are locally shortest.

Finding an optimal fence amounts to minimizing the boundary between $\bar{B}_1$ and $\bar{B}_2$. This can be formulated as a minimum-cut problem in the dual graph $G(V, E)$ of the arrangement $\mathcal{A}$. There is a node in V for each cell and a weighted edge in E for each pair of adjacent cells: the weight of the edge is the length of the cells' common boundary. Let $S_1, S_2 \subset V$ be the sets of cells that contain the objects of B_1, B_2, respectively. We need to find the minimum cut that separates S_1 from S_2. This can be obtained by finding the maximum flow in G from the sources S_1 to the sinks S_2, where the capacities are the weights. As G is a planar graph, we can use the algorithm by Borradaile et al. [5] with running time $O(|V| \log^3 |V|)$. The running time has since then been improved to $O(\frac{|V| \log^3 |V|}{\log^2 \log |V|})$ [9]. As $|V| = O(|S|^2) = O(n^4)$, we obtain the following theorem.

▶ **Theorem 3.** *GEOMETRIC 2-CUT can be solved in time $O(\frac{n^4 \log^3 n}{\log^2 \log n})$, where n is the total number of corners of the objects.*

A similar algorithm has been described before in a slightly different context: image segmentation [11], see also [5]. Here, we have a rectangular grid of pixels, each having a given gray-scale value. Some pixels are known to be either black or white. The remaining pixels have to be assigned either the black or the white color. Each pixel has edges to its (at most four) neighbors. The weights of these edges can be chosen in such a way that the minimum cut problem corresponds to minimizing a cost function consisting of two parts: One part, the *data component*, has a term for each pixel, and it measures the discrepancy between the gray-value of the pixel and the assigned value. The other part, the *smoothing component*, penalizes neighboring pixels with similar gray-values that are assigned different colors.

4 Hardness of the Tricolored Case

We show how to construct an instance I of GEOMETRIC 3-CUT from an instance Φ of PLANAR POSITIVE 1-IN-3-SAT. For ease of presentation, we first describe the reduction geometrically, allowing irrational coordinates. We prove that if Φ is satisfiable, then I has a fence of cost M^*, whereas if Φ is not satisfiable, then the cost is at least $M^* + 1/50$. We then argue that the corners can be slightly moved to make a new instance I' with rational coordinates while still being able to distinguish whether Φ is satisfiable or not, based on the cost of an optimal fence.

In order to make the proof as simple as possible, we introduce a new specialized problem COLORED TRIGRID POSITIVE 1-IN-3-SAT in the following.

4.1 Auxiliary NP-complete problems

▶ **Definition 4.** *In the POSITIVE 1-IN-3-SAT problem, we are given a collection Φ of clauses containing exactly three distinct variables (none of which are negated). The problem is to decide whether there exists an assignment of truth values to the variables of Φ such that exactly one variable in each clause is true.*

▶ **Definition 5.** *In the TRIGRID POSITIVE 1-IN-3-SAT problem, we are given an instance Φ of POSITIVE 1-IN-3-SAT together with a planar embedding of an associated graph $G(\Phi)$ with the following properties:*

- *$G(\Phi)$ is a subgraph of a regular triangular grid,*
- *for each variable x, there is a simple cycle v_x,*
- *for each clause $C = \{x, y, z\}$, there is a path c_C and three vertical paths $\ell_x^C, \ell_y^C, \ell_z^C$ with one endpoint at a vertex of c_C and one at a vertex of each of v_x, v_y, v_z,*
- *except for the described incidences, no edges share a vertex,*
- *all vertices have degree 2 or 3,*
- *any two adjacent edges form an angle of π or $2\pi/3$,*
- *the number of vertices is bounded by a quadratic function of the size of Φ.*

The problem is to decide whether Φ has a satisfying assignment (see Definition 4).

Mulzer and Rote [13] showed that another problem, PLANAR POSITIVE 1-IN-3-SAT, is NP-complete, which is similar but uses a slightly different embedding with axis-parallel segments. It trivially follows that TRIGRID POSITIVE 1-IN-3-SAT is also NP-complete, see Figure 3.

Consider an instance $(\Phi, G(\Phi))$ of TRIGRID POSITIVE 1-IN-3-SAT. There are some vertices of degree three on the cycles v_x corresponding to each variable x in Φ, and these we denote as *branch vertices* of $G(\Phi)$. There is also one vertex of degree three on the path c_C corresponding to each clause C in Φ, which we denote as a *clause vertex*. Except for branch and clause vertices, at most two edges meet at each vertex.

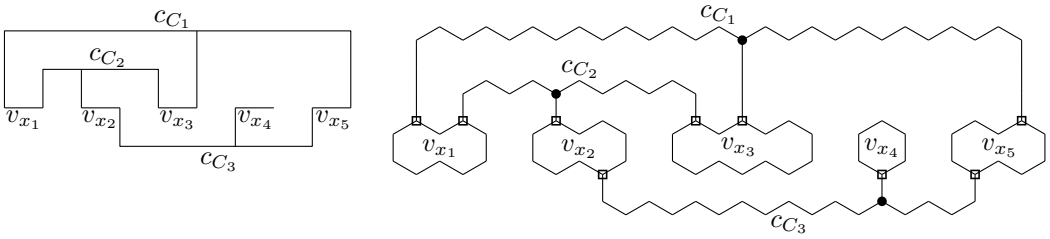

Figure 3 Left: An instance of PLANAR POSITIVE 1-IN-3-SAT for the formula $\Phi = C_1 \wedge C_2 \wedge C_3$ for $C_1 = x_1 \vee x_3 \vee x_5$, $C_2 = x_1 \vee x_2 \vee x_3$, and $C_3 = x_2 \vee x_4 \vee x_5$. Right: A corresponding instance of TRIGRID POSITIVE 1-IN-3-SAT. Clause vertices are drawn as dots and branch vertices as boxes.

Let $\mathcal{C}$ be the set of all clause vertices (considered as geometric points). Removing $\mathcal{C}$ from $G(\Phi)$ (considered as a subset of $\mathbb{R}^2$) splits $G(\Phi)$ into one connected component E_x for each variable x of Φ. The idea of our reduction to GEOMETRIC 3-CUT is to build a *channel* on top of E_x for each variable x. The channel has constant width $1/2$ and contains E_x in the center. The channel contains small *inner* objects and is bounded by larger *outer objects* of another color. There will be two equally good ways to separate the inner and outer objects, namely taking an individual fence around each inner object and taking long fences along the boundaries of the channel that enclose as many inner objects as possible. As it will turn out, any other way of separating the inner from the outer objects will require more fence. These two optimal fences play the roles of x being true and false, respectively.

At the clause vertices where three regions E_x, E_y, E_z meet, we make a clause gadget that connects the three channels corresponding to x, y, z. The objects in the clause gadget can be separated using the least amount of fence if and only if one of the channels is in the state corresponding to true and the other two are in the false state. Therefore, this corresponds to the clause in Φ being satisfied.

In order to make this idea work, we first assign every edge of $G(\Phi)$ an *inner* and an *outer* color among $\{\text{red}, \text{green}, \text{blue}\}$. These will be used as the colors of the inner and outer objects of the channel later on. We require the following of the coloring:

1. The inner and outer colors of any edge are distinct.
2. Any two adjacent collinear edges have the same inner or outer color.
3. Any two adjacent edges that meet at an angle of $2\pi/3$ at a non-clause vertex have the same inner and the same outer color.
4. The inner colors of the three edges meeting at a clause vertex are red, green, blue in clockwise order, while the outer colors of the same edges are blue, red, green, respectively.

We now introduce the problem COLORED TRIGRID POSITIVE 1-IN-3-SAT, which we will reduce to GEOMETRIC 3-CUT, see Figure 4. The problem is NP-complete, as shown in the full version.

▶ **Definition 6.** *In COLORED TRIGRID POSITIVE 1-IN-3-SAT, we are given an instance* $(\Phi, G(\Phi))$ *of TRIGRID POSITIVE 1-IN-3-SAT together with a coloring of the edges of* $G(\Phi)$ *satisfying the above requirements. We want to decide whether* Φ *has a satisfying assignment.*

4.2 Building a GEOMETRIC 3-SAT instance from tiles

Consider an instance $(\Phi, G(\Phi))$ of COLORED TRIGRID POSITIVE 1-IN-3-SAT that we will reduce to GEOMETRIC 3-CUT. We make the construction using hexagonal *tiles* of six different types, namely *straight*, *inner color change*, *outer color change*, *bend*, *branch*, and *clause* tiles. Each tile is a regular hexagon with side length $1/\sqrt{3}$ and hence has width 1. The tiles are rotated such that they have two horizontal edges.

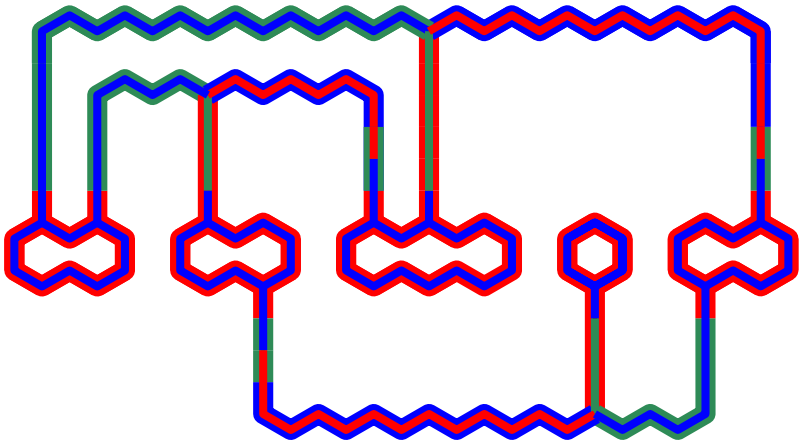

Figure 4 An instance of COLORED TRIGRID POSITIVE 1-IN-3-SAT based on the instance from Figure 3.

The tiles are placed so that each tile is centered at a vertex p of $G(\Phi)$. Let G_p be the part of $G(\Phi)$ within distance $1/2$ from p (recall that each edge of $G(\Phi)$ has length 1). Figure 5 shows the tiles and how they are placed according to the shape and colors of G_p.

In order to define the outer objects of a tile, we consider the straight skeleton offset [3, 4] of G_p at distance $1/4$. With the exception of the bend tile, this offset is the same as the Euclidean offset. By the *outer* and *inner region*, we mean the region of the tile outside, resp. inside, this offset. The outer objects cover the outer region, and every point is colored with the outer color of a closest edge in G_p. The inner region is empty except for the inner objects described in each case below. We suppose that $p = (0, 0)$.

The straight tile. If two collinear edges meet at p with the same inner and outer color, we use a straight tile. Suppose in this and the following two cases that G_p is the vertical line segment from $(0, -1/2)$ to $(0, 1/2)$ – tiles for edges of other slopes are obtained by rotation of the ones described here. There are four axis-parallel squares of the inner color of G_p with side length $1/8$ centered at $(\pm(1/4 - 1/16), \pm 1/4)$. This size is chosen so their total perimeter is 2, which is the length of the common boundary of the inner and outer regions.

The inner color change tile. If two collinear edges meet at p with different inner colors, we use an inner color change tile. There are again four squares colored in the inner color of the closest point in G_p. There are also four smaller axis-parallel squares with side length $1/28$ centered at $(\pm(1/4 - 1/56), \pm 1/56)$, likewise colored in the inner color of the closest point in G_p. The size of these small squares is chosen so that they can be individually enclosed using fences of total length $14 \cdot 1/28 = 1/2$, which is the width of the inner region.

The outer color change tile. If two collinear edges meet at p with different outer colors, we use an outer color change tile. There are four axis-parallel squares of the inner color of G_p with side length $3/32$. Their centers are $(\pm(1/4 - 3/64), \pm 1/4)$. The size of these squares is chosen so that their total perimeter is $2 - 1/2 = 3/2$.

The bend tile. If two non-collinear edges meet at p, we use a bend tile. Consider the case where G_p is the vertical line segment from p to $(0, 1/2)$ and the segment of length $1/2$ from p with direction $(\cos \pi/6, -\sin \pi/6)$. The other cases are obtained by a suitable rotation of this

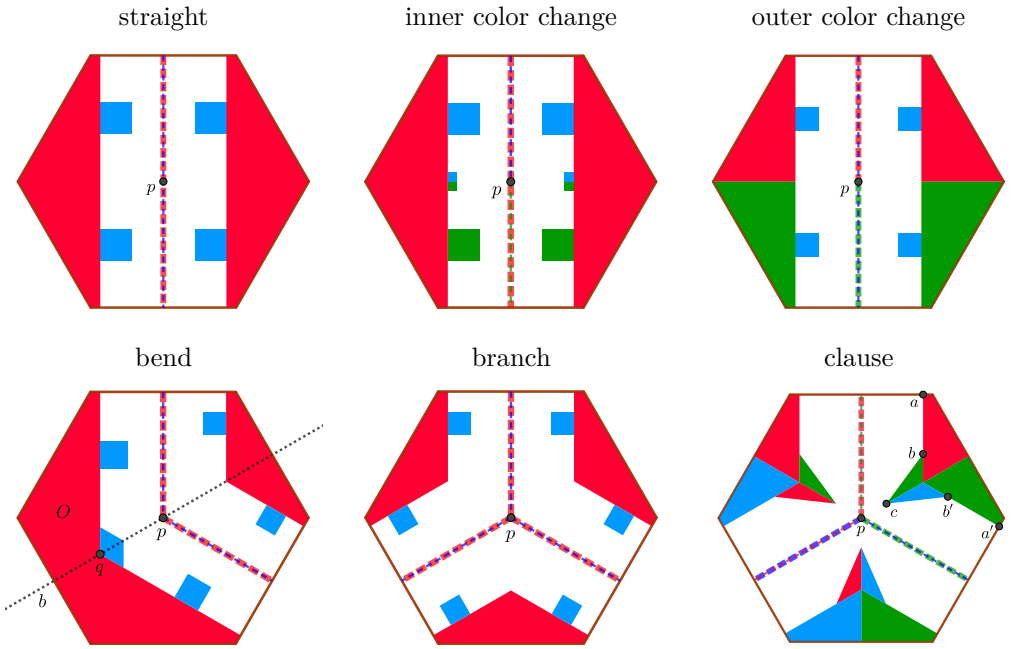

Figure 5 Different kinds of tiles used in the reduction to GEOMETRIC 3-CUT. The dashed colored segments show G_p and the inner and outer color of G_p. The tiles are colored accordingly. The points in the clause tile are defined so that $\|ab\| = \|a'b'\| = 6/25 = 0.24$ and $\|bc\| = \|b'c\| = 1/4 = 0.25$. Point c has coordinates $(x, x/\sqrt{3})$, where $x = \frac{13\sqrt{3}}{200} + 3/16 - \frac{\sqrt{-459+3900\sqrt{3}}}{400}$ is a solution to $10000x^2 + (-1300\sqrt{3} - 3750)x + 507 = 0$. The remaining points in the tile are given by rotations by angles $2\pi/3$ and $4\pi/3$ around p.

tile. There is an axis parallel square of side length $x = \frac{6+\sqrt{3}}{72}$ with center $(-(1/4 - x/2), 1/4)$ and another with side length $y = \frac{6-\sqrt{3}}{48}$ centered at $(1/4 - y/2, 3/8)$. The tile is symmetric with respect to the angular bisector b of G_p, and so the reflections of the described squares with respect to b are also inner objects. Note that there are two outer objects, one of which, O, has a concave corner q with exterior angle $2\pi/3$. We place a parallelogram with side length x, a corner at q, and two edges contained in the edges of O incident at q. It is easy to verify that the common boundary of the inner and outer regions has a total length of 2; the inner objects are chosen such that their total perimeter is also 2.

The branch tile. If p is a branch vertex, we use the branch tile. There are two cases: G_p either contains the vertical segment from p to $(0, 1/2)$ or that from p to $(0, -1/2)$. We specify the tile in the first case – the other can be obtained by a rotation of π. There are axis-parallel squares of side length $y = \frac{6-\sqrt{3}}{48}$ centered at $(\pm(1/4 - y/2), 3/8)$ and their rotations around p by angles $2\pi/3$ and $4\pi/3$. The common boundary of the inner and outer regions has a total length of $\frac{6-\sqrt{3}}{2}$, and the total perimeter of the inner objects is also $\frac{6-\sqrt{3}}{2}$.

The clause tile. If p is a clause vertex, we use the clause tile (defined in Figure 5). The other clause tiles are given by rotations of the described tile by angles $k\pi/3$ for $k = 1, \ldots, 5$.

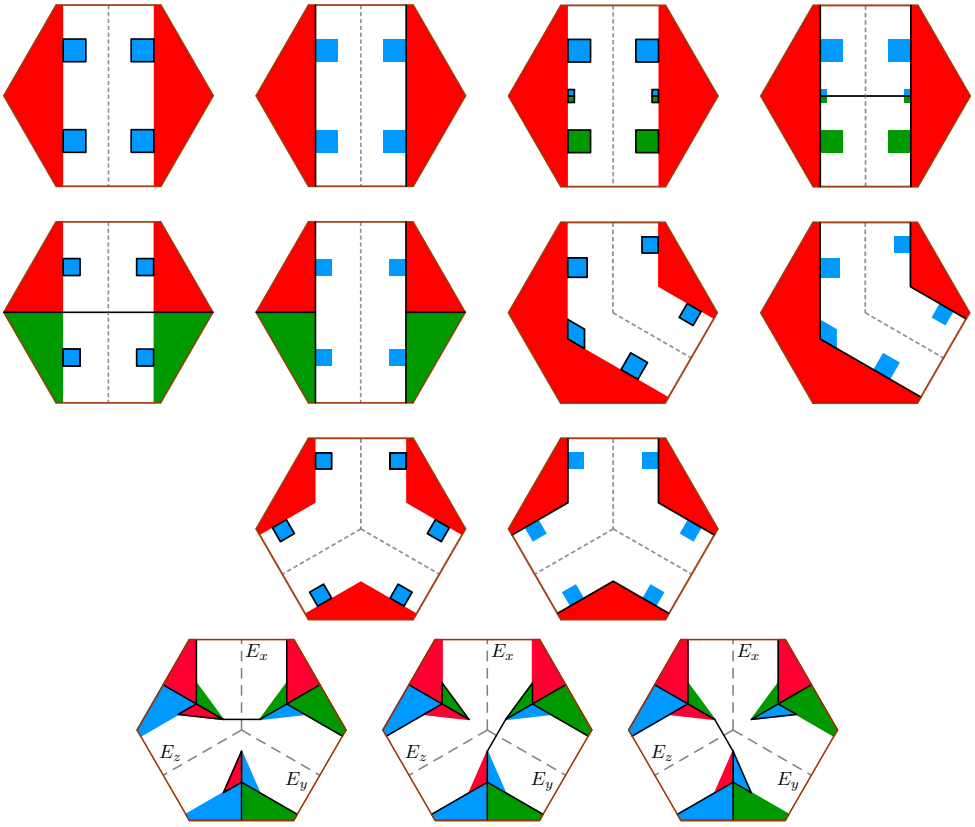

Figure 6 The optimal solutions to each type of tile. The edges in G_p are shown in dashed grey. We denote the left solution of each of the first five types of tiles as the *outer* solution and the other as the *inner* solution. For the clause tile, we define the solution as the *z-outer*, *x-outer*, and *y-outer* solution in order from left to right, respectively.

4.3 Solving the tiles

Let an instance I of GEOMETRIC 3-SAT be given together with an associated fence $\mathcal{F}$. Consider the restriction of I to a convex polygon P and the part of the fence $\mathcal{F} \cap P$ inside P. Note that $\mathcal{F} \cap P$ consists of (not necessarily disjoint) closed curves and open curves with endpoints on the boundary ∂P, such that no two objects in P of different color can be connected by a path $\pi \subset P$ unless π intersects $\mathcal{F}$. (An open curve is a subset of a larger closed curve of $\mathcal{F}$ that continues outside P.) We say that a set of closed and open curves in P with that property is a *solution* to $I \cap P$. In the following, we analyze the solutions to the tiles defined in Section 4.2 in order to characterize the solutions of minimum cost. We say that two closed curves (disjoint from the interiors of the objects) are *homotopic* if one can be continuously deformed into the other without entering the interiors of the objects. Two open curves with endpoints on the boundary of the tile are homotopic if they are subsets of two homotopic closed curves (that extend outside the tile).

The following lemma characterizes the optimal solutions to each type of tile. The statement is that if a solution is not too much more expensive than the solutions shown in Figure 6, then it will contain curves homotopic to each curve in one of the solutions in the figure. The proof is deferred to the full version.

▶ **Lemma 7.** *Figure 6 shows optimal solutions to each kind of tile. The cost in each case is: Straight tile:* 2*. Inner color change tile:* 5/2*. Outer color change tile:* $\left(\frac{2}{\sqrt{3}} - \frac{1}{2}\right) + 2 \approx 2.65$*. Bend tile:* 2*. Branch tile:* $\frac{6-\sqrt{3}}{2} \approx 2.13$*. Clause tile:* ≈ 3.51 *(the exact value is complicated due to the coordinates and of no use).*

If the cost of a solution $\mathcal{F}$ to a tile T exceeds the optimum by less than 1/50*, then $\mathcal{F}$ is homotopic to one of the optimal solutions $\mathcal{F}^*$ of T in the following sense: For each curve π^* in $\mathcal{F}^*$, there is a curve π in $\mathcal{F}$ homotopic to π^*. If π is closed, the distance from any point on π to the closest point on π^* is less than $\sqrt{(1/8 + 1/100)^2 - (1/8)^2} < 0.06$. If π is open and π^* has an endpoint f^*, there is a corresponding endpoint f of π with $\|f^* f\| < 1/10$.*

▶ **Theorem 8.** *The problem GEOMETRIC* 3*-CUT is NP-hard.*

Proof. Let an instance $(\Phi, G(\Phi))$ of COLORED TRIGRID POSITIVE 1-IN-3-SAT be given and construct the tiles on top of $G(\Phi)$ as described. Let $\mathcal{T}$ be the set of tiles and $\mathcal{A}$ the area that the tiles cover (i.e., $\mathcal{A}$ is a union of the hexagons). We will cover any holes in $\mathcal{A}$ with completely red tiles, and place red tiles all the way along the exterior boundary of $\mathcal{A}$. Let $\mathcal{R}$ be the set of these added red tiles and let I be the resulting instance of GEOMETRIC 3-CUT. It is now trivial how to place the fences in I everywhere except in the interior of $\mathcal{A}$.

Consider a fence $\mathcal{F}$ to the obtained instance with cost M. Let M^* be the sum of the cost of an optimal solution to each tile in $\mathcal{T}$ plus the cost of the fence that must be placed along the boundaries of the added red tiles in $\mathcal{R}$. We claim that if Φ is satisfiable, then a solution realizing the minimum M^* exists. Furthermore, if $M < M^* + 1/50$, then Φ is satisfiable.

Suppose that Φ is satisfiable and fix a satisfying assignment. Consider a clause tile where E_x, E_y, and E_z meet. Now, we choose the v-outer state, where $v \in \{x, y, z\}$ is the variable that is satisfied. For each non-clause tile that covers a part of E_w for a variable w of Φ, we choose the outer state if w is true and the inner otherwise. It is now easy to see that the curves form a fence of the desired cost.

On the other hand, suppose that $M < M^* + 1/50$. It follows that in each tile in $\mathcal{T}$, the cost exceeds the optimum by at most 1/50. Hence, the solution in each tile is homotopic to one of the optimal states as described in Lemma 7. We now claim that the states of all tiles representing one variable must agree on either the inner or outer state. Consider two adjacent tiles where one is in the inner state. There are open curves with endpoints on the shared edge of the two tiles with a distance of more than $1/2 - 2 \cdot 1/10 = 3/10$. The other tile cannot be in the outer state, because then there would have to be an extra open curve of length at least 3/10 to connect those endpoints. It follows that the other tile must also be in the inner state. Thus, both tiles are either in the inner or in the outer state, as desired.

We now describe how to obtain a satisfying assignment of Φ. Consider a clause tile where E_x, E_y, and E_z meet and suppose the tile is in the x-outer state. It follows from the above that each tile covering E_x is in the outer state or, in the case of the clause tile, in the x-outer state. Similarly, each non-clause tile covering only E_y (resp. E_z) is in the inner state and each clause tile covering a part of E_y (resp. E_z) is not in the y-outer (resp. z-outer) state. We now set x to true and y and z to false and do similarly with the other clause tiles, and it follows that we get a solution to Φ.

The proof that we can avoid the use of irrational corners is deferred to the full version. The basic idea is as follows. For each object O with corner v with an irrational coordinate, we choose a substitute $v' \in O$ with rational coordinates such that $\|vv'\| < \frac{1/50}{4n}$ and such that v' only requires polynomially many bits to represent. This results in a modified instance I', and we prove that I' has a solution of cost $M' := \frac{\lceil 100 M^* \rceil}{100}$ if and only if Φ is satisfiable. ◀

5 Approximation

The approach for $k = 2$ from Section 3 does not extend to $k \geq 3$ because Lemma 2 does not apply: The arrangement $\mathcal{A}$ (formed by the free segments between the corners N of the input objects) is no longer guaranteed to contain an optimal fence, see Figure 1. However, we can still search for an approximate solution in $\mathcal{A}$: We show that the optimal fence $F_{\mathcal{A}}$ contained in $\mathcal{A}$ has a cost which is at most 4/3 times higher than the true optimal fence $F^\star$ (Theorem 9). In the full version, we construct a corresponding lower-bound example with $|F_{\mathcal{A}}| > 1.15 \cdot |F^\star|$.

The graph-theoretic problem that we then have to solve in the weighted dual graph $G = (V, E)$ of $\mathcal{A}$ is the *colored multiterminal cut problem*: We have terminals of $k \geq 3$ different colors and want to make a cut that separates every pair of terminals of different colors. This problem is NP-hard, but we can use approximation algorithms, see Section 5.1.

▶ **Theorem 9.** $|F_{\mathcal{A}}| \leq 4/3 \cdot |F^\star|$.

Proof. From Section 2, we know that after cutting an optimal fence $F^\star$ at all points of N, the remaining components are Steiner minimal trees with leaves in N and internal *Steiner vertices* of degree 3, where three segments make angles of $2\pi/3$.

Consider such a Steiner tree T (Figure 7a). Since T is embedded in the plane, the leaves can be enumerated in cyclic order as $v_1, \ldots, v_m$. We will replace T by a connected system $\bar{T}$ of fences that connects the same set of leaves $v_1, \ldots, v_m$, but contains only segments from the arrangement $\mathcal{A}$. Furthermore, we prove that the total length of $\bar{T}$ is bounded as $|\bar{T}| \leq \frac{4}{3}|T|$. Thus, carrying out this replacement for every Steiner tree leads to the fence $F_{\mathcal{A}}$ of the desired cost. If T consists of a single segment, we define $\bar{T}$ to be the same segment, in which case trivially $|\bar{T}| \leq \frac{4}{3}|T|$. Assume therefore that T has at least one Steiner vertex.

Let T_{ij} be the path in T from v_i to v_j. For each pair $\{i, j\}$, we define the path $\bar{T}_{ij}$ as the shortest path with the properties that

a) $\bar{T}_{ij}$ has endpoints v_i and v_j, and
b) $\bar{T}_{ij}$ is *homotopic* to T_{ij}: this means that T_{ij} can be continuously deformed into $\bar{T}_{ij}$ while keeping the endpoints fixed at v_i and v_j, without entering the interiors of the objects.

It is clear that

c) $\bar{T}_{ij}$ is contained in the arrangement $\mathcal{A}$, and
d) $\bar{T}_{ij}$ is at most as long as T_{ij}.

We will construct $\bar{T}$ as the union of paths $\bar{T}_{ij}$ that are specified by a certain set S of leaf pairs $\{i, j\}$, and we will show that its total length is bounded $|\bar{T}| \leq \frac{4}{3}|T|$. The fact that $F_{\mathcal{A}}$ is a valid fence is ensured by our choice of the set S, which we will now discuss.

If we overlay all paths T_{ij} for $\{i, j\} \in S$, we get a multigraph $\widetilde{T}$, which has the same vertices as T and uses the edges of T, some of them multiple times. We require these three properties:

1. Every edge of T is used once or twice in $\widetilde{T}$.
2. Every Steiner vertex of T has even degree (4 or 6) in $\widetilde{T}$. (By contrast, the degree in T is always 3.)
3. Any two paths T_{ij} and $T_{i'j'}$ that have a point of T in common must *cross* in the following sense: If we assume, by relabeling if necessary, that $i < j$ and $i' < j'$, then $i \leq i' \leq j \leq j'$ or $i' \leq i \leq j' \leq j$.

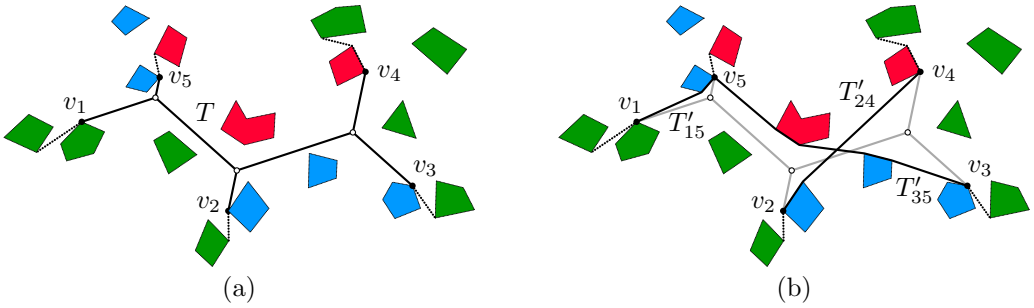

Figure 7 (a) a single Steiner tree T with 5 terminals $v_1, \ldots, v_5$, part of a larger fence system $F^\star$. Steiner vertices are white, leaves are black. (b) The transformed graph $\bar{T}$, formed as the union of three shortest homotopic paths $\bar{T}_{15}$, $\bar{T}_{24}$, and $\bar{T}_{35}$.

The last property is important to ensure that $\bar{T}$ is connected.

As we prove in the full version, Properties 1 and 3 imply that for any two leaves v_i and v_j (where the pair $\{i, j\}$ is not necessarily in S), the set $\bar{T}$ contains a path from v_i to v_j that is homotopic to the path T_{ij}. This means that after replacing T by $\bar{T}$ in $F^\star$, we get a system of fences F' that encloses and separates the same objects as $F^\star$, and thus we have indeed produced a valid fence.

To bound the length of $\bar{T}$, we bound each path $\bar{T}_{ij}$, $\{i, j\} \in S$, by the corresponding path T_{ij} in T. This upper estimate is simply the total length of T plus the length of the duplicated edges of T.

Our first task is to construct the multigraph $\widetilde{T}$. By Property 1, this boils down to selecting which edges of T to duplicate. In order to fulfill Property 2, we require that the degree of every inner vertex of $\widetilde{T}$ becomes even. (We show later that this is sufficient to ensure that the edges of $\widetilde{T}$ can be partitioned into paths T_{ij} subject to Property 3.)

▶ **Lemma 10.** *The edges that should be duplicated can be chosen such that their total length is at most* $|T|/3$.

Proof. For a particular tree, the optimum can be computed easily by dynamic programming, as follows. We root T at some arbitrary leaf. Consider a subtree U rooted at some vertex u of T such that u has one child v in U. We define U_1 and U_2 as the cost of the optimal set of duplicated edges in U, under the constraint that the multiplicity of the edge uv in $\widetilde{T}$ is 1 and 2, respectively.

By induction, we will establish that

$$2U_1 + U_2 \leq |U|. \tag{1}$$

This gives $\min\{U_1, U_2\} \leq |U|/3$ and proves the lemma, since this also holds for $U = T$. In the base case U has only one edge. Then $U_1 = 0$ and $U_2 = \|uv\| = |U|$, and (1) holds.

If U is larger, v has degree 3, and two subtrees L and R are attached there. If uv is not duplicated, then exactly one of the other edges incident to v has to be duplicated in order for v to get even degree in $\widetilde{T}$. On the other hand, if uv is duplicated, then either both or none of the other edges should be duplicated. Hence, we can compute U_1 and U_2 by the following recursion:

$$U_1 = \min\{L_1 + R_2, L_2 + R_1\} \tag{2}$$

$$U_2 = \min\{L_1 + R_1, L_2 + R_2\} + \|uv\| \tag{3}$$

We therefore get

$$U_1 \leq L_2 + R_1 \tag{4}$$
$$U_1 \leq L_1 + R_2 \tag{5}$$

from (2) and

$$U_2 \leq L_1 + R_1 + \|uv\| \tag{6}$$

from (3).

Adding inequalities (4–6) and using the inductive hypothesis (1) for L and R gives

$$2U_1 + U_2 \leq 2L_1 + L_2 + 2R_1 + R_2 + \|uv\| \leq |L| + |R| + \|uv\| = |U|. \quad \blacktriangleleft$$

We now have a multigraph $\widetilde{T}$ where every internal vertex has even degree. It follows that the edges of $\widetilde{T}$ can be partitioned into leaf-to-leaf paths, much like when creating an Eulerian tour in a graph where all vertices have even degree.

We still need to satisfy Property 3. Whenever two paths P_1 and P_2 violate this property, we repair this by swapping parts of the paths, without changing the number of remaining violating pairs, as follows: The paths P_1 and P_2 must have a common vertex, and thus also a common edge uv, because the maximum degree in T is 3. Orient P_1 and P_2 so that they use this edge in the direction uv, and cut them at v into $P_1 = Q_1 \cdot R_1$ and $P_2 = Q_2 \cdot R_2$. We now make a cross-over at v, forming the new paths $Q_1 \cdot R_2$ and $Q_2 \cdot R_1$. These new paths satisfy Property 3. To check that we did not create any new violations, we observe that, by Property 1, no other path can use the edge uv, because the capacity of 2 is already taken by P_1 and P_2. Thus, all other paths can either interact with Q_1 and Q_2, or with R_1 and R_2. Thus, swapping the parts of P_1 and P_2 in the other half of the tree T does not affect Property 3.

We have thus established Theorem 9. ◀

5.1 Finding a good fence in $\mathcal{A}$

The problem of finding a small cut in a planar graph $G = (V, E)$ that separates k different classes $T_1, \ldots, T_k \subset V$ of terminals was mentioned as a suggestion for future work by Dahlhaus et al. [8], but we have not found any subsequent work on that except for the case $k = 2$ [5]. We can, however, reduce the problem to the multiway cut problem in general graphs (also known as the multiterminal cut problem): For each class T_i, we add an "apex vertex" t_i which is connected to all vertices in T_i by edges of infinite weight. We then ask for the cut of minimum total weight that separates each pair t_i, t_j. Dahlhaus et al. gave a $(2 - 2/k)$-approximation algorithm for the problem. In our setup, the running time will be $O(kn^8 \log n)$. The approximation ratio was since then improved to $3/2 - 1/k$ by Călinescu et al. [6]. Finally, a randomized algorithm with approximation factor 1.3438 was given by Karger et al. [12], who also gave the best known bounds for various specific values of k. Together with Theorem 9, we obtain the following result.

▶ **Theorem 11.** *There is a randomized* $4/3 \cdot 1.3438$*-approximation algorithm and a deterministic* $(2 - \frac{4}{3k})$*-approximation algorithm for GEOMETRIC k-CUT, each of which runs in polynomial time.*

6 Concluding Remarks

We have initiated the study of the geometric multicut problem. As our NP-hardness reduction does not imply APX-hardness, an interesting open question is whether there exists a $(1+\varepsilon)$-approximation algorithm for any $\varepsilon > 0$.

There are other versions of the problem that could also be interesting to study. For example, apart from considering shortest paths in the plane, much attention has also been paid to minimum-link paths, i.e., paths connecting two points and consisting of a minimum number of line segments. The analogous problem in our setup is likewise interesting: Compute a simplest possible fence, i.e., one that is the union of as few line segments as possible. The fence can be required to be disjoint from the object interiors, or it can be allowed to pass through the objects, leading to two different problems.

Abstract

Multiplication is one of the most fundamental computational problems, yet its true complexity remains elusive. The best known upper bound, very recently proved by Harvey and van der Hoeven (2019), shows that two n-bit numbers can be multiplied via a boolean circuit of size $O(n \lg n)$. In this work, we prove that if a central conjecture in the area of network coding is true, then any constant degree boolean circuit for multiplication must have size $\Omega(n \lg n)$, thus almost completely settling the complexity of multiplication circuits. We additionally revisit classic conjectures in circuit complexity, due to Valiant, and show that the network coding conjecture also implies one of Valiant's conjectures.

1 Introduction

Multiplication is one of the most fundamental computational problems and the simple "long multiplication" $O(n^2)$-time algorithm for multiplying two n-digit numbers is taught to elementary school pupils around the world. Despite its centrality, the true complexity of multiplication remains elusive. In 1960, Kolmogorov conjectured that the thousands of years old $O(n^2)$-time algorithm is optimal and he arranged a seminar at Moscow State University with the goal of proving this conjecture. However only a week into the seminar, the student Karatsuba came up with an $O(n^{\lg_2 3}) \approx O(n^{1.585})$ time algorithm [9]. The algorithm was presented at the next seminar meeting and the seminar was terminated. This sparked a sequence of improved algorithm such as the Toom-Cook algorithm [15, 4] and

the Schönhage-Strassen algorithm [14]. The Schönhage-Strassen algorithm, as well as the current fastest algorithm by Fürer [6], are both based on the Fast Fourier Transform (FFT). Fürer's algorithm can be shown to run in time $O(n \lg n \cdot 4^{\lg^* n})$ when multiplying two n-bit numbers [8]. It can even be implemented as a constant degree Boolean circuit of the same size. Here $\lg^* n$ is the very slowly growing iterated logarithm. A very recent and exciting result by Harvey and van der Hoeven [7] removes the extra $4^{\lg^* n}$ term, and presents an algorithm for integer multiplication that runs in time $O(n \lg n)$. But what is the true complexity of multiplying two n-bit numbers? Can it be done via e.g. a Boolean circuit of size $O(n)$ like addition? Or is multiplication strictly harder? Our main contribution is to show a connection between multiplication and a central conjecture by Li and Li [10] in the area of *network coding*. Our results show that if the conjecture by Li and Li [10] is true, then any constant degree Boolean circuit for computing the product of two n-bit numbers must have size $\Omega(n \lg n)$. This establishes a conditional lower bound for multiplication that is tight with respect to the upper bound presented by Harvey and van der Hoeven, and implies that multiplication is strictly harder than addition.

Before diving into the details of our results, we first give a brief introduction to network coding.

Network Coding. Network coding studies communication problems in graphs. Given a graph G with capacity constraints on the edges and k data streams, each with a designated source-sink pair of nodes (s_i, t_i) in G, what is the maximum rate at which data can be transmitted concurrently between the source-sink pairs? One solution is to just forward the data, which reduces the problem to a *multicommodity flow* problem. The central question in network coding is whether one can achieve a higher rate by using coding/bit tricks. This question is known to have a positive answer in directed graphs, where the rate increase may be as high as a factor $\Omega(|G|)$ (by sending XOR's of carefully chosen input bits), see e.g. [1]. However the question remains wide open for undirected graphs where there are no known examples for which network coding can do better than the multicommodity flow rate. A central conjecture in network coding, due to Li an Li [10], says that coding yields no advantage in undirected graphs.

▶ **Conjecture 1** (Undirected k-pairs Conjecture [10]). *The coding rate is equal to the Multi-commodity-Flow rate in undirected graphs.*

Despite the centrality of this conjecture, it has heretofore resisted all attempts at either proving or refuting it. Conjecture 1 has been used twice before for proving lower bounds for computational problems. Adler et al. [1] were the first to initiate this line of study. They presented conditional lower bounds for computing the transpose of a matrix via an *oblivious algorithm*. Here oblivious means that the memory access pattern is fixed and independent of the input. Very recently Farhadi et al. [5] showed how to remove the *obliviousness* assumption for external memory problems. Their main result was a tight lower bound for external memory integer sorting, conditioned on Conjecture 1 being true.

1.1 Our Results

Our main result is an exciting new connection between network coding and the complexity of multiplication. Formally, we prove the following theorem:

▶ **Theorem 1.** *Assuming Conjecture 1, every boolean circuit with arbitrary gates and bounded in and out degrees that computes the product of two numbers given as two n-bit strings has size $\Omega(n \lg n)$.*

In fact, we prove our $\Omega(n \lg n)$ lower bound for an even simpler problem than multiplication, namely the *shift problem*: In the shift problem, we are given an n-bit string x and an index $j \in [n]$. The goal is to construct a circuit that outputs the $2n$-bit string y whose ith bit equals the $(i - j + 1)$th bit of x for every $j \leq i \leq j + n - 1$. Here we think of the index j as being given in binary using $\lceil \lg n \rceil$ bits. We prove the following result:

▶ **Theorem 2.** *Assuming Conjecture 1, every boolean circuit with arbitrary gates and bounded in and out degrees that computes the shift problem has size* $\Omega(n \lg n)$.

Theorem 1 follows as a corollary of Theorem 2 by observing that shifting x by j positions is equivalent to multiplication by 2^j. Moreover, it is not hard to see that there is a linear sized circuit that has $\lceil \lg n \rceil$ input gates and n output gates, where on an index $j \in [n]$, it outputs the number 2^j in binary (i.e. a single 1-bit at position j).

We find it quite fascinating that even a simple instruction such as shifting requires circuits of size $\Omega(n \lg n)$, at least if we believe Conjecture 1.

Valiant's Depth Reduction and Circuit Complexity Lower Bounds. In addition to our main lower bound results for multiplication, we also demonstrate that the network coding conjecture sheds new light on some fundamental conjectures by Valiant. In a 1977 survey Valiant [16] outlined potentially plausible attacks on the problem of proving a lower bound for the size of any circuit that can compute a permutation or even shifts of a given input. The goal was to prove that achieving both $O(n)$ size and $O(\lg n)$ depth for such circuits is impossible. While most of his attacks were rebuffed due to existence of complex and highly connected graphs that only had $O(n)$ edges (superconcentrators), Valiant outlined one last potential approach that could still be fruitful. His main brilliant idea was to start with a circuit of some depth and by applying graph theoretical approaches reducing the depth of the circuit while eliminating only a small number of edges. The hope was that information theoretical approaches could finish the job once the depth of the circuit was very low and once the (graph theoretical) complexity of the circuit was peeled away.

More formally, Valiant showed that for every circuit C with n input and output gates, of size $O(n)$, depth $O(\lg n)$ and fan-in 2, and for every $\varepsilon > 0$, the function computed by C can be computed by a boolean circuit with arbitrary gates C' of depth 3 with n input and output gates and εn extra nodes. Moreover, the number of input gates directly connected to an output gate is bounded. That is, if we denote the set of input and output gates by X and Y respectively, then for every $y \in Y$, there are at most $O(n^\varepsilon)$ wires connecting y and X.

In turn, this reduction shows that it is enough to prove lower bounds on such depth 3 circuits. Almost 20 years later and based on these ideas, Valiant [17] put forward several conjectures that if resolved could open the way for proving circuit complexity lower bounds. Loosely speaking, Valiant conjectured that if $\varepsilon \leq 1/2$ then such depth 3 circuits cannot compute cyclic-shift permutation. Before discussing Valiant's conjectures more formally, we first state our second main result, which essentially shows that Conjecture 1 implies one of Valiant's conjectures, albeit with a smaller (but still constant) bound on ε.

▶ **Theorem 3.** *Let C be a depth 3 circuit that computes multiplication such that the following holds.*

1. *The number of gates in the second layer of C is at most εn for $\varepsilon \leq 1/300$; and*
2. *for every output gate y of C, the number of input gates directly connected to y is at most c.*

Then assuming Conjecture 1, $c = \Omega\left(\frac{\lg n}{\lg \lg n}\right)$.

As with Theorem 1, we prove Theorem 3 on an even restricted set of circuits, namely circuits that compute the shift function. We now turn to give a formal description of Valiant's Conjectures, and demonstrate how Theorem 3 brings us closer to settling them.

Valiant's Conjectures. Let Γ be a bipartite graph on two independent sets X and Y such that $X = \{x_1, \ldots, x_n\}$ denotes a set of inputs and $Y = \{y_1, \ldots, y_n\}$ denotes a set of outputs. Furthermore assume, let $f_1, \ldots f_{\varepsilon n}$ be εn extra nodes and connect them by edges to all the nodes in Γ. Denoting the resulting graph by G consider all possible boolean circuits with arbitrary gates whose underlying topology is G. We say such a circuit computes a permutation $\pi \colon Y \to X$ if for every assignment $x_1, \ldots, x_n \in \{0,1\}^n$ to the input gates, after the evaluation of the circuit y_j is assigned $\pi(y_j)$ for every $j \in [n]$. Valiant conjectured that this should be impossible if ε is too small or if Γ has too few edges. In particular, he proposed the following.

▶ **Conjecture 2.** *If Γ has maximum degree at most 3 and if $\varepsilon \leq 1/2$, then there exists a permutation π such that no circuit that has G as its underlying topology can compute the permutation π. Moreover, there exists such π that is a cyclic shift.*

Theorem 3 shows that conditioned on Conjecture 1, if $\varepsilon \leq 1/300$ then Valiant's first conjecture holds. We note that our proof for Theorem 3 continues to hold even if the gates' boolean functions are fixed after the shift offset is given. That is, if only the topology is fixed in advance. This coincides exactly with the formulation of Valiant's conjecture. Valiant further conjectured the following.

▶ **Conjecture 3.** *If Γ has at most $n^{2-\delta}$ edges for some constant $\delta > 0$, and if $\varepsilon \leq 1/2$, then there exists a permutation π such that no circuit that has G as its underlying topology can compute the permutation π. Moreover, there exists such π that is a cyclic shift.*

1.2 Related Work

Lower Bounds for Multiplication. There are a number of previous lower bounds for multiplication in various restricted models of computation. Clifford and Jalsenius [3] considered a streaming variant of multiplication, where one number is fixed and the other is revealed one digit at a time. They require that a digit of the output is reported before the next digit of the input is revealed. In this streaming setting, they prove an $\Omega((\delta/w)n \lg n)$ lower bound, where δ is the number of bits in a digit and w is the word size. For $\delta = 1$ and $w = O(1)$, this is $\Omega(n \lg n)$. Ponzio [12] considered multiplication via read-once branching programs, i.e. programs that have bounded working memory and may only read each input bit exactly once. He proved that any read-once branching program for computing the middle bit of the product of two n-bit numbers, must use $\Omega(\sqrt{n})$ bits of working memory. Finally, we also mention the work of Morgenstern [11] who proved lower bounds for computing the related FFT. Morgenstern proved an $\Omega(n \lg n)$ lower bound for computing the *unnormalied* FFT via an arithmetic circuit when all constants used in the circuit are bounded. Unfortunately this doesn't say anything about the complexity of multiplying two n-bit numbers.

Valiant's Conjectures. Despite their importance, Valiant's conjectures are still mostly open. One interesting development by Riis [13], shows that Conjecture 3 as stated is incorrect. Riis proved that all cyclic shifts are realizable for $\varepsilon = \frac{1}{2} - \frac{1}{2n^{1-\delta}}$ where $n^{1+\delta}$ is the total number of edges of Γ. Riis further conjectured that replacing the bound on ε by a slightly stricter bound should result in a correct conjecture. Specifically, Riis suggest bounding $\varepsilon = \Theta\left(\frac{1}{\lg \lg n}\right)$.

2 Preliminaries

We now give a formal definition of Boolean circuits with arbitrary gates, followed by definitions of the k-pairs communication problem, the multicommodity flow problem. In the two latter problems we reuse some of the definitions used by Farhadi et al. [5], which have been simplified a bit compared to the more general definition by Adler et al. [1]. In particular, we have forced communication networks to be directed acyclic graphs. This is sufficient to prove our lower bounds and simplifies the definitions considerably.

Boolean Circuits with Arbitrary Gates. A *Boolean Circuit with Arbitrary Gates* with n source or input nodes and m target or output nodes is a directed acyclic graph C with n nodes of in-degree 0, which are called *input gates*, and are labeled with input variables $X = \{x_i\}_{i\in[n]}$ and m nodes out-degree 0, which are called *output gates* and are labeled with output variables $Y = \{y_i\}_{i\in[m]}$. All other nodes are simply called *gates*. For every gate u of in-degree $k \geq 1$, u is labeled with an arbitrary function $f_u : \{0,1\}^k \to \{0,1\}$. The circuit is also equipped with a topological ordering $v_1, \ldots, v_t$ of C, in which $v_i = x_i$ for $i \in [n]$ and $v_{t-i+1} = y_{m-i+1}$ for all $i \in [m]$. The *depth* of a circuit C is the length of the longest path between an input and an output node in C. An *evaluation* of a circuit on an n bit input $x = (x_1, \ldots, x_n) \in \{0,1\}^n$ is conducted as follows. For every $i \in [n]$, assign x_j to v_j. For every $j \geq n+1$, assign to v_j the value $f_{v_j}(u_1, \ldots, u_k)$, where $u_1, \ldots, u_k$ are the nodes of C with edges going into v_j in the order induced by the topological ordering. The *output* of C on an n bit input $x = (x_1, \ldots, x_n)$, denoted $C(x_1, \ldots, x_n)$ is the value assigned to $(y_1, \ldots, y_m)$ in the evaluation. We say a circuit computes a function $f : \{0,1\}^n \to \{0,1\}^m$ if for every $x = (x_1, \ldots, x_n) \in \{0,1\}^n$, $f(x_1, \ldots, x_n) = C(x_1, \ldots, x_n)$.

For every $j \in [t]$ and $b \in \{0,1\}$, we *hardwire* b for v_j in C by removing v_j and all adjacent edges from C, and replacing v_j for b in the evaluation of f_{v_i} for every $i > j$ such that $v_j v_i$ is an edge in C.

k-Pairs Communication Problem. The input to the k-pairs communication problem is a directed acyclic graph $G = (V, E)$ where each edge $e \in E$ has a capacity $c(e) \in \mathbb{R}^+$. There are k sources $s_1, \ldots, s_k \in V$ and k sinks $t_1, \ldots, t_k \in V$.

Each source s_i receives a message A_i from a predefined set of messages $A(i)$. It will be convenient to think of this message as arriving on an in-edge. Hence we add an extra node S_i for each source, which has a single out-edge to s_i. The edge has infinite capacity.

A network coding solution specifies for each edge $e \in E$ an alphabet $\Gamma(e)$ representing the set of possible messages that can be sent along the edge. For a node $v \in V$, define $\mathrm{In}(u)$ as the set of in-edges at u. A network coding solution also specifies, for each edge $e = (u, v) \in E$, a function $f_e : \prod_{e' \in \mathrm{In}(u)} \Gamma(e') \to \Gamma(e)$ which determines the message to be sent along the edge e as a function of all incoming messages at node u. Finally, a network coding solution specifies for each sink t_i a decoding function $\sigma_i : \prod_{e \in \mathrm{In}(t_i)} \Gamma(e) \to A(i)$. The network coding solution is correct if, for all inputs $A_1, \ldots, A_k \in \prod_i A(i)$, it holds that σ_i applied to the incoming messages at t_i equals A_i, i.e. each source must receive the intended message.

In an execution of a network coding solution, each of the extra nodes S_i starts by transmitting the message A_i to s_i along the edge (S_i, s_i). Then, whenever a node u has received a message a_e along all incoming edges $e = (v, u)$, it evaluates $f_{e'}(\prod_{e \in \mathrm{In}(u)} a_e)$ on all out-edges and forwards the message along the edge e'.

We define the *rate* of a network coding solution as follows: Let each source receive a uniform random and independently chosen message A_i from $A(i)$. For each edge e, let A_e

denote the random variable giving the message sent on the edge e when executing the network coding solution with the given inputs. Let $H(\cdot)$ denote the binary Shannon entropy. The network coding solution achieves rate r if:

- $H(A_i) \geq r$ for all i.
- For each edge $e \in E$, we have $H(A_e) \leq c(e)$.

The intuition is that the rate is r, if the solution can handle sending a message of entropy r bits between every source-sink pair.

Multicommodity Flow. A multicommodity flow problem in an undirected graph $G = (V, E)$ is specified by a set of k source-sink pairs (s_i, t_i) of nodes in G. We say that s_i is the source of commodity i and t_i is the sink of commodity i. Each edge $e \in E$ has an associated capacity $c(e) \in \mathbb{R}^+$. A (fractional) solution to the multicommodity flow problem specifies for each pair of nodes (u, v) and commodity i, a flow $f^i(u, v) \in [0, 1]$. Intuitively $f^i(u, v)$ specifies how much of commodity i that is to be sent from u to v. The flow satisfies *flow conservation*, meaning that:

- For all nodes u that is not a source or sink, we have $\sum_{w \in V} f^i(u, w) - \sum_{w \in V} f^i(w, u) = 0$.
- For all sources s_i, we have $\sum_{w \in V} f^i(s_i, w) - \sum_{w \in V} f^i(w, s_i) = 1$.
- For all sinks we have $\sum_{w \in V} f^i(w, t_i) - \sum_{w \in V} f^i(t_i, w) = 1$.

The flow also satisfies that for any pair of nodes (u, v) and commodity i, there is only flow in one direction, i.e. either $f^i(u, v) = 0$ or $f^i(v, u) = 0$. Furthermore, if (u, v) is not an edge in E, then $f^i(u, v) = f^i(v, u) = 0$. A solution to the multicommodity flow problem achieves a rate of r if:

- For all edges $e = (u, v) \in E$, we have $r \cdot \sum_i (f^i(u, v) + f^i(v, u)) \leq c(e)$.

Intuitively, the rate is r if we can handle a demand of r for every commodity.

The Undirected k-Pairs Conjecture. Conjecture 1 implies the following for our setting: Given an input to the k-pairs communication problem, specified by a directed acyclic graph G with edge capacities and a set of k source-sink pairs, let r be the best achievable network coding rate for G. Similarly, let G' denote the undirected graph resulting from making each directed edge in G undirected (and keeping the capacities and source-sink pairs). Let r' be the best achievable flow rate in G'. Conjecture 1 implies that $r \leq r'$.

Having defined coding rate and flow rate formally, we also mention that a result of Braverman et al. [2] implies that if there exists a graph G where the network coding rate r, and the flow rate r' in the corresponding undirected graph G', satisfies $r \geq (1 + \varepsilon)r'$ for a constant $\varepsilon > 0$, then there exists an infinite family of graphs $\{G^*\}$ for which the corresponding gap is at least $(\lg |G^*|)^c$ for a constant $c > 0$. So far, all evidence suggest that no such gap exists, as formalized in Conjecture 1.

3 Key Tools and Techniques

The main idea in the heart of both proofs is the simple fact that in a graph with t vertices and maximum degree at most c, most node pairs lie far away from one another. Specifically, for every node u in G, at least $t - \sqrt{t}$ nodes have distance $\geq \frac{1}{2} \log_c t$ from u. While this key observation is almost enough to prove Theorem 2, the proof of Theorem 3 requires a much more subtle approach, as there is no bound on the maximum degree in the circuits in question. The only bound we have is on the number of wires going directly between from input gates into output gates. Specifically, every two nodes in the underlying undirected graph are at distance ≤ 3 (see Figure 1).

In order to overcome this obstacle, we present a construction of a communication network based on the circuit C that essentially eliminates the middle layer in the depth-3 circuit C, thus leaving a bipartite graph with bounded maximum degree. To this end, we observe that since the size of the middle layer is bounded by εn, then there exists a large set $\mathcal{F}$ of inputs in $\{0,1\}^n$ such that on all inputs from $\mathcal{F}$, the gates $f_1, \ldots, f_{\varepsilon n}$ attain the same values. By hardwiring these values to the circuit, we can evaluate the circuit for all inputs in $\mathcal{F}$ on a depth-2 circuit Γ obtained from C by removing $f_1, \ldots, f_{\varepsilon n}$. We next turn to construct the communication network. Employing ideas recently presented by Farhadi et al. [5], we "wrap" the depth-2 circuit by adding source and target nodes. In order to cope with inputs that do not belong to $\mathcal{F}$, we add a designated *supervisor* node u (see figure 2). Loosely speaking, the source nodes transmit their input to u, and u sends back the information needed to "edit" the input string x and construct an input string $x' \in \mathcal{F}$, which is then transferred to the circuit Γ as blackbox.

The Correction Game. In order to bound the edge capacities of the network G in a way that the supervisor node can transmit enough information to achieve a high communication rate, but then again not allow to much flow to go through the supervisor when considering G as a multicommodity flow instance, Farhadi et al. [5] defined a game between a set of m players and a supervisor, where given a fixed set $\mathcal{F} \subseteq \{0,1\}^n$ and a random string $\beta \in \{0,1\}^n$ given as a concatenation of m strings $\beta_1, \ldots, \beta_m$ of length n/m each, the goal is to "correct" β and produce a string $\chi \in \{0,1\}^n$ such that $\beta \oplus \chi \in \mathcal{F}$. The caveat is that the only communication allowed is between the players and the supervisor. That is, no communication, and thus no cooperation, is allowed between the m players. Formally, the game is defined as follows.

▶ **Definition 4.** *Let $\mathcal{F} \subseteq \{0,1\}^n$. The* $\mathcal{F}$-correction game *with $m+1$ players is defined as follows. The game is played by m ordinary players $p_1, \ldots, p_m$ and one designated* supervisor *player u. The supervisor u receives m strings $\beta_1, \ldots, \beta_m \in \{0,1\}^{n/m}$ chosen independently at random. For every $\ell \in [m]$, u then sends p_ℓ a message R_ℓ. Given R_ℓ, the player p_ℓ produces a string $\chi_\ell \in \{0,1\}^{n/m}$ such that $(\beta_1 \oplus \chi_1) \circ (\beta_2 \oplus \chi_2) \circ (\beta_m \oplus \chi_m) \in \mathcal{F}$.*

Farhadi et al. additionally present a protocol for the $\mathcal{F}$-correction game in which the supervisor player sends prefix-free messages to the m players, and moreover, they give a bound on the amount of communication needed as a function of the number of players and the size of $\mathcal{F}$.

▶ **Lemma 5** ([5]). *If $|\mathcal{F}| \geq 2^{(1-\varepsilon)n}$, then there exists a protocol for the $\mathcal{F}$-correction game with $m+1$ players such that the messages $\{R_\ell\}_{\ell \in [m]}$ are prefix-free and*

$$\sum_{\ell \in [m]} \mathbb{E}[|R_\ell|] \leq 3m + 2m \lg \left(\sqrt{\frac{\varepsilon}{2}} \cdot \frac{n}{m} + 1 \right) + \sqrt{\frac{\varepsilon}{8}} \cdot n \lg \frac{2}{\varepsilon} ,$$

4 A Lower Bound for Boolean Circuits Computing Multiplication

In this section we show that conditioned on Conjecture 1, every bounded degree circuit computing multiplication must have size at least $\Omega(n \lg n)$, thus proving Theorems 1 and 2. In fact, we will prove something slightly stronger. Define the shift function $s : \{0,1\}^n \times [n] \to \{0,1\}^{2n}$ as follows. For every $x = (x_1, \ldots, x_n) \in \{0,1\}^n$ and $\ell \in [n]$, $s(x, \ell) = (y_1, \ldots, y_{2n})$ where $y_j = x_{j-\ell+1}$ if $\ell \leq j \leq \ell + n - 1$ and $y_j = 0$ otherwise. We will show that every circuit with bounded in and out degrees that computes the shift function on n-bit numbers has size

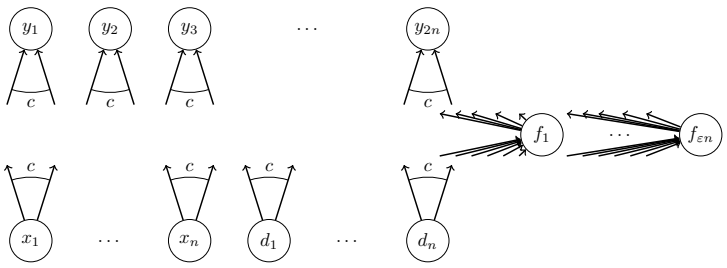

Figure 1 The depth 3 circuit C.

$\Omega(n \lg n)$. Clearly, a circuit that can compute the product of two n-bit numbers can also compute the shift function. Let c denote the maximum in and out degree in C, and let $j \in [n]$. Then in the undirected graph induced by C, there are at most $\sqrt{n}$ nodes whose distance from x_j is at most $\frac{1}{2}\log_{2c} n$. Therefore among $y_j, \ldots, y_{j+n-1}$, at least $n - \sqrt{n} - 1 \geq n - 2\sqrt{n}$ are at distance at least $\frac{1}{2}\log_{2c} n$. In other words, $\Pr_{\ell \in [n]}[d_{\bar{C}}(x_j, y_{j+\ell-1}) \geq \frac{1}{2}\log_{2c} n] \geq 1 - \frac{2}{\sqrt{n}}$, where $\bar{C}$ denotes the undirected graph induced by C (by removing edge directions). Therefore there exists a shift $\ell_0 \in [n]$ such that $|\{j \in [n] : d_{\bar{C}}(x_j, y_{j+\ell_0-1}) \geq \frac{1}{2}\log_{2c} n\}| \geq n - 2\sqrt{n} \geq n/2$.

Fixing ℓ_0, consider the following communication problem. For each $j \in [n]$, let $s_j = x_j$ and $t_j = y_{j+\ell_0-1}$ be a source-sink pair, and let $A_j = \{0,1\}$ be the set of possible messages. The circuit C equipped with 1-uniform edge capacities is a network coding solution to this problem with rate $r \geq 1$. By the undirected n-pairs conjecture, there is a multicommodity flow in $\bar{C}$ that transfers one unit of flow from each source to its corresponding sink. For every j, let $f^j : E \to [0,1]$ be the flow associated with commodity j. Then

$$|E| = \sum_{e \in E} c_e \geq \sum_{e \in E} \sum_{j \in [n]} f^j(e) \geq \Omega(n \log_c n) .$$

5 A Lower Bound for Depth 3 Boolean Circuits Computing Multiplication

Let C be a depth 3 circuit that computes multiplication such that the number of gates in the second layer of C is at most εn for some small $\varepsilon \in (0,1)$ and for every $u \in Y$, $deg_{\bar{C}[X \cup Y]}(u) \leq c$, where once again $\bar{C}$ denotes the undirected graph induced by C, and $\bar{C}[X \cup Y]$ is the subgraph of $\bar{C}$ induced by $X \cup Y$. By slightly increasing c and ε (by a small constant factor) and without loss of generality, we can assume that this applies for all $u \in X$ as well. To see this, note that by the assumption on Y, the total number of edges in $\bar{C}[X \cup Y]$ is at most cn. Therefore there are at most $n/10$ nodes in X whose degree in $\bar{C}[X \cup Y]$ is more than $10c$. For each such node $u \in X$, we can replace all edges adjacent to u in $\bar{C}[X \cup Y]$ by an extra second-layer node f_u connected to u and its neighbors in $\bar{C}[X \cup Y]$. Denote the input and output gates of C by $X = \{x_1, \ldots, x_n, \hat{x}_1, \ldots, \hat{x}_n\}$ and $Y = \{y_1, \ldots, y_{2n}\}$ respectively, and denote the set of the middle-layer gates by $F = \{f_1, \ldots, f_{\varepsilon n}\}$ (see Figure 1).

As before, we focus on computing the shift function, thus limiting the input to $(\hat{x}_1, \ldots, \hat{x}_n)$ to have exactly one 1-entry. We next partition $(x_1, \ldots, x_n)$ into consecutive blocks of size $k = 20$ bits each. For every $\ell \in [n/k]$ let $B_\ell = \{k(\ell-1)+1, \ldots, k\ell\}$ be the set of indices belonging to the ℓth block.

▶ **Definition 6.** *For every $\alpha \in [n]$ and $\ell \in [n/k]$, we say B_ℓ is* far from all targets *(with respect to α) if for all sources in the block are at distance at least $\frac{1}{2}\log_{2c} n$ from all respective destinations in $\bar{C}[X \cup Y]$. That is for every $u, v \in B_\ell$, $d_{\bar{C}[X \cup Y]}(x_u, y_{v+\alpha-1}) \geq \frac{1}{2}\log_{2c} n$.*

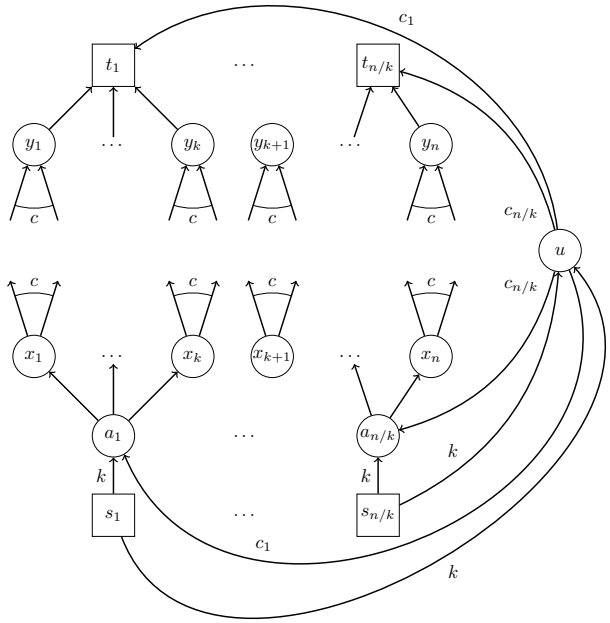

Figure 2 Given the 2-layer circuit Γ spanned by $x_1, \ldots, x_n, y_1, \ldots, y_n$, we construct the communication network graph G.

Let $\alpha \in_R [n]$. By the constraint on the degrees, for every $j \in [n]$, there are at most $\sqrt{n}$ nodes whose distance from x_j is at most $\frac{1}{2}\log_{2c} n$ in $\bar{C}[X \cup Y]$. Therefore for every $\ell \in [n/k]$,

$$\Pr_{\alpha \in_R [n]}[B_\ell \text{ is far from all targets}] \geq 1 - \frac{k^2}{\sqrt{n}}.$$

By averaging we get that for large enough n there is some $\alpha_0 \in [n]$ such that there are at least $\frac{n}{k} - k\sqrt{n} \geq \frac{9n}{10k}$ blocks which are far from all targets. Without loss of generality, we may assume for ease of notation that $\alpha_0 = 1$. By hardwiring 1 for α_0 into the circuit C, the circuit now simply transfers $(x_1, \ldots, x_n)$ to $(y_1, \ldots, y_n)$.

Reduction to Network Coding. Let $x = (x_1, \ldots, x_n)$ and $i \in [\varepsilon n]$. By slightly abusing notation, we denote the value of the gate f_i when evaluating the circuit by $f_i(x_1, \ldots, x_n)$. By averaging, there exist a string $(\hat{f}_1, \ldots, \hat{f}_{\varepsilon n})$ and a set $\mathcal{F} \subseteq \{0,1\}^n$ such that $|\mathcal{F}| \geq 2^{(1-\varepsilon)n}$ and such that for every $x = (x_1, \ldots, x_n) \in \mathcal{F}$ and $i \in [\varepsilon n]$, $f_i(x_1, \ldots, x_n) = \hat{f}_i$. By hardwiring $(\hat{f}_1, \ldots, \hat{f}_{\varepsilon n})$ for $(f_1, \ldots, f_n)$ into the circuit C, we get a new circuit denoted Γ that contains only the input and output gates of C, and transfers $(x_1, \ldots, x_n)$ to $(y_1, \ldots, y_n)$ for every $(x_1, \ldots, x_n) \in \mathcal{F}$. Moreover, the set of edges between X and Y in Γ is equal to the set of edges between X and Y in C.

Next, we construct a communication network G by adding some nodes and edges to Γ, as demonstrated also in Figure 2. We add a new set of nodes $\{s_j, a_j, t_j\}_{j=1}^{n/k} \cup \{u\}$. For every $\ell \in [n/k]$, add edges $s_\ell a_\ell$ and $s_\ell u$ of capacity k and edges ua_ℓ and ut_ℓ of capacity $c_\ell = \mathbb{E}[|R_\ell|]$,

where R_ℓ is the message sent to player p_ℓ by the supervisor player in the $\mathcal{F}$-correction game protocol for $n/k+1$ players guaranteed in Lemma 5. In addition, for every $\ell \in [n/k]$ and every $j \in B_\ell$ add edges $a_\ell x_j$ and $y_j t_\ell$ of capacity 1. All edges of Γ are assigned capacity of 1.

Transmitting Data. In what follows, we will lower bound the communication rate of the newly constructed network G.

▶ **Lemma 7.** *There exists a network coding solution on G that achieves rate k.*

To this end, let $A_1, \ldots, A_{n/k} \in \{0,1\}^k$ be independent uniform random variables. We next give a protocol by which the sources $s_1, \ldots, s_{n/k}$ transmit $A_1, \ldots, A_{n/k}$ to the targets $t_1, \ldots, t_{n/k}$. The protocol employs as an intermediate step the correction game protocol guaranteed by Lemma 5.

1. For every $\ell \in [n/k]$, s_ℓ sends A_ℓ to a_ℓ over the edge $s_\ell a_\ell$ and to u over the edge $s_\ell u$.
2. Employing the $\mathcal{F}$-correction game protocol with $n/k+1$ players, for every $\ell \in [n/k]$, u sends a message R_ℓ to a_ℓ over the edge ua_ℓ and to t_ℓ over the edge ut_ℓ. Following the correction game protocol, for every ℓ, given R_ℓ, a_ℓ and t_ℓ produce a string χ_ℓ satisfying that $(A_1 \oplus \chi_1) \circ \ldots \circ (A_{n/k} \oplus \chi_{n/k}) \in \mathcal{F}$.
3. For every $\ell \in [n/k]$ and every $i \in [k]$, a_ℓ transmits the ith bit of $A_\ell \oplus \chi_\ell$ to the ith gate in the ℓth block, namely $x_{(\ell-1)k+i}$. Note that $(x_1, \ldots, x_n) = (A_1 \oplus \chi_1) \circ \ldots \circ (A_{n/k} \oplus \chi_{n/k}) \in \mathcal{F}$.
4. Next, the communication network employs the circuit Γ and transmits $(x_1, \ldots, x_n)$ to $(y_1, \ldots, y_n)$. For every $\ell \in [n/k]$ and every $i \in B_\ell$, y_i transmits x_i to t_ℓ.
5. Finally, for every $\ell \in [n/k]$, t_ℓ now holds both $A_\ell \oplus \chi_\ell$ and χ_ℓ. Therefore t_ℓ can recover A_ℓ.

By invoking the protocol described above, every one of the n/k sources sends k bits to the corresponding target. For every edge $e \in G$, let A_e denote the random variable giving the message sent on the edge e when executing the protocol.

▷ Claim 8. For every $e \in G$, $H(A_e) \leq c_e$.

Proof. First note that for every $\ell \in [n/k]$, every edge e leaving s_ℓ has capacity k and transmits A_ℓ. Therefore $H(A_\ell) = k \leq c_e$. Every edge e that is not leaving any source nor u has capacity 1 and transmits exactly one bit (not necessarily uniformly random) of information. Therefore $c_e = 1 \geq H(A_e)$. Finally, let e be an edge leaving u. Then there exists some $\ell \in [n/k]$ such that $e = ua_\ell$ or $e = ut_\ell$. In both cases the message transmitted on e is R_ℓ and the capacity c_e of e satisfies $c_e = c_\ell = \mathbb{E}[|R_\ell|] \geq H(R_\ell)$, where the last inequality follows from Shannon's Source Coding theorem, as all messages are prefix-free. ◁

We can therefore conclude that the network G achieves rate $\geq k$, and the proof of Lemma 7 is complete.

Deriving the Lower Bound. By Conjecture 1, the underlying undirected graph $\bar{G}$ achieves a multicommodity-flow rate $\geq k$. Therefore there exists a multicommodity flow $\{f^\ell\}_{\ell \in [n/k]} \subseteq [0,1]^{E(\bar{G})}$ that achieves rate k. We first observe that at most a constant fraction of the flow can go through the supervisor node u. To see this, we note that as $|\mathcal{F}| \geq 2^{(1-\varepsilon)n}$, then by Lemma 5, for small enough (constant) ε, the expected total information sent by the supervisor in the $\mathcal{F}$-correction game with n/k players is at most

$$\frac{3n}{k} + \frac{2n}{k} \lg\left(k\sqrt{\frac{\varepsilon}{2}} + 1\right) + \sqrt{\frac{\varepsilon}{8}} \cdot n \lg \frac{2}{\varepsilon} \leq \frac{5n}{k} \tag{1}$$

Therefore by the definition of the capacities $\{c_\ell\}_{\ell\in[n/k]}$ we get that

$$\sum_{\ell\in[n/k]} c_{ua_\ell} = \sum_{\ell\in[n/k]} c_{ut_\ell} = \sum_{\ell\in[n/k]} c_\ell \leq \frac{5n}{k} \tag{2}$$

Since $\{f^\ell\}_{\ell\in[n/k]}$ achieves rate k we conclude that for every $v \in V(\bar{G})$ adjacent to u we have $k\sum_{\ell\in[n/k]}(f^\ell(u,v)+f^\ell(v,u)) \leq c_{uv}$. Therefore

$$\begin{aligned} k\cdot \sum_{v\in V(\bar{G}):uv\in E(\bar{G})} \sum_{\ell\in[n/k]} (f^\ell(u,v)+f^\ell(v,u)) &\leq \sum_{v\in V(\bar{G}):uv\in E(\bar{G})} c_{uv} \\ &= \sum_{\ell\in[n/k]} c_{us_\ell} + \sum_{\ell\in[n/k]} (c_{ua_\ell}+c_{ut_\ell}) \leq n + \frac{10n}{k}\,. \end{aligned}$$

Rearranging we get that

$$\sum_{v\in V(\bar{G}):uv\in E(\bar{G})} \sum_{\ell\in[n/k]} (f^\ell(u,v)+f^\ell(v,u)) \leq \frac{n}{k} + \frac{10n}{k^2} \leq 1.5\frac{n}{k}\,. \tag{3}$$

By the flow-conservation constraint, we know that therefore the total amount of flow that can go through u is $\leq 0.75\frac{n}{k}$. By averaging, at least a $1/6$ fraction of the sources send at least $1/10$ units of flow through $\bar{G}-u$. By the choice of α_0, in $\bar{G}-u$, at least a $1/15$ of the sources are at least $\frac{1}{2}\log_{2c}(n)$ away from their targets. Without loss of generality, assume these are the first $\frac{n}{15k}$ sources. We conclude that

$$\begin{aligned} cn \geq |E[X\cup Y]| = \sum_{e\in E[X\cup Y]} c_e &\geq k\cdot \sum_{e=vw\in E[X\cup Y]} \sum_{\ell\in[n/k]} f^\ell(v,w)+f^\ell(w,v) \\ &\geq k\cdot \sum_{\ell\in[n/15k]} \sum_{e=vw\in E[X\cup Y]} f^\ell(v,w)+f^\ell(w,v) \geq \frac{n}{30}\log_{2c}(n)\,, \end{aligned} \tag{4}$$

and therefore $c \geq \Omega\left(\frac{\lg n}{\lg\lg n}\right)$, and the proof of Theorem 3 is now complete.

5.1 Remarks and Extensions

For sake of fluency, some minor remarks and extensions were intentionally left out of the text, and will be discussed now.

Circuits with Bounded Average Degree. Our results still hold if we relax the second requirement of Theorem 3 and require instead that the number of edges in $\bar{C}[X\cup Y]$ is at most cn. That is, the average degree in $\bar{C}[X\cup Y]$ is at most c. To see this, note that under this assumption, there are at most $0.001n$ gates in $X\cup Y$ whose degree in $\bar{C}[X\cup Y]$ is larger than $1000c$. For each such gate v, add a new node f in the middle layer, and connect v and all the neighbors of v in $\bar{C}[X\cup Y]$ to f. Then delete all the edges adjacent to v in $\bar{C}[X\cup Y]$. The number of nodes added to the middle layer is at most $0.001n$, and the degree of all nodes in $\bar{C}[X\cup Y]$ is now bounded by $1000c$. The rest of our proof continues as before.

Shifts vs. Cyclic Shifts. In order to prove lower bounds for circuits computing multiplication, our results are stated in terms of shifts (which are a special case of products, as mentioned). This is in contrast to Valiant's conjectures, which are stated in terms of cyclic shifts. However, we draw the readers attention to the fact that our proofs work for cyclic shifts as well. The exact same arguments apply, and the proofs remain unchanged.

Abstract

A graph G is contractible to a graph H if there is a set $X \subseteq E(G)$, such that G/X is isomorphic to H. Here, G/X is the graph obtained from G by contracting all the edges in X. For a family of graphs $\mathcal{F}$, the $\mathcal{F}$-Contraction problem takes as input a graph G on n vertices, and the objective is to output the largest integer t, such that G is contractible to a graph $H \in \mathcal{F}$, where $|V(H)| = t$. When $\mathcal{F}$ is the family of paths, then the corresponding $\mathcal{F}$-Contraction problem is called Path Contraction. The problem Path Contraction admits a simple algorithm running in time $2^n \cdot n^{\mathcal{O}(1)}$. In spite of the deceptive simplicity of the problem, beating the $2^n \cdot n^{\mathcal{O}(1)}$ bound for Path Contraction seems quite challenging. In this paper, we design an exact exponential time algorithm for Path Contraction that runs in time $1.99987^n \cdot n^{\mathcal{O}(1)}$. We also define a problem called 3-Disjoint Connected Subgraphs, and design an algorithm for it that runs in time $1.88^n \cdot n^{\mathcal{O}(1)}$. The above algorithm is used as a sub-routine in our algorithm for Path Contraction.

1 Introduction

Graph editing problems are one of the central problems in graph theory that have received a lot of attention in algorithm design. Some of the natural graph editing operations are vertex/edge deletion, edge addition, and edge contraction. For a family of graphs $\mathcal{F}$, the

$\mathcal{F}$-Editing problem takes as input a graph G, and the objective is to find the minimum number of operations required to transform G into a graph from $\mathcal{F}$. In fact, the $\mathcal{F}$-Editing problem, where the edit operations are restricted to one of vertex deletion, edge deletion, edge addition, or edge contraction have also received a lot of attention in algorithm design. The $\mathcal{F}$-Editing problems encompass several classical NP-hard problems like Vertex Cover, Feedback Vertex Set, Odd Cycle Transversal, etc.

The $\mathcal{F}$-Editing problem where the only allowed edit operation is edge contraction, is called $\mathcal{F}$-Contraction. For a graph G and an edge $e = uv \in E(G)$, *contraction* of an edge uv in G results in a graph G/e, which is obtained by deleting u and v from G, adding a new vertex w_e and making w_e adjacent to the neighbors of u or v (other than u, v). A graph G is *contractible* to a graph H, if there exists a subset $X \subseteq E(G)$, such that if we contract each edge from X, then the resulting graph is isomorphic to H. For several families of graphs $\mathcal{F}$, early papers by Watanabe et al. [18, 19] and Asano and Hirata [1] showed that $\mathcal{F}$-Contraction is NP-hard. The NP-hardness of problems like Tree Contraction and Path Contraction, which are the $\mathcal{F}$-Contraction problems for the family of trees and paths, respectively, follows easily from [1, 3]. A restricted version of Path Contraction, is the problem P_t Contraction, where t is a fixed constant. P_t-Contraction is shown to be NP-hard even for $t = 4$, while for $t \leq 3$, the problem is polynomial time solvable [3]. P_t-Contraction alone had received lot of attention for smaller values of t, even when the input graph is from a very structured family of graphs (for instance, see [3, 17, 10, 6, 8, 13], and the references therein).

Several NP-hard problem like SAT, k-SAT, Vertex Cover, Hamiltonian Path, etc. are known to admit an algorithm running in time $\mathcal{O}^\star(2^n)$[1]. These results are obtained by techniques like brute force search, dynamic programming over subsets, etc. One of the main questions that arise in this context is: can we break the $\mathcal{O}^\star(2^n)$ barrier for these problems. In fact, the hardness of SAT gives rise to the Strong Exponential Time Hypothesis (SETH) of Impagliazzo and Paturi [12, 11], which rules out existence of $\mathcal{O}^\star((2-\epsilon)^n)$-time algorithm for SAT, for any $\epsilon > 0$. SETH has been used to obtain such algorithmic lower bounds for many other NP-hard problems (see for example, [4, 14]). Not all NP-hard problems seem to be as "hard" as SAT. For many NP-hard problems, it is possible to break the $\mathcal{O}^\star(2^n)$ barrier. For instance problems like Vertex Cover and (undirected) Hamiltonian Path are known to admit algorithms running in time $\mathcal{O}^\star((2-\epsilon)^n)$, for some $\epsilon > 0$ [2, 15]. Thus, one of the natural question is for which NP-hard problems can we avoid the "brute force search", and say obtain algorithms that are better than $\mathcal{O}^\star(2^n)$.

In this article, we focus on the problem Path Contraction, which is formally defined below.

Path Contraction
Input: Graph G.
Output: Largest integer t, such that G is contractible to P_t.

Path Contraction is known to admit a simple algorithm that runs in time $\mathcal{O}^\star(2^n)$. Such an algorithm can be obtained by coloring the input graph with two colors and contracting connected components in the colored subgraphs. For a deceptively simple problem like Path Contraction, it seems quite challenging to break the $\mathcal{O}^\star(2^n)$ barrier. The problem 2-Disjoint Connected Subgraphs (2-DCS), can be "roughly" interpreted as solving P_4-Contraction. (We can use the algorithm for 2-DCS to solve P_4-Contraction.) There

[1] The $\mathcal{O}^\star$ notation hides polynomial factors in the running time expression.

have been studies, which break the $\mathcal{O}^\star(2^n)$ brute force barrier, for 2-DCS. In particular, Cygan et al. [5] designed a $\mathcal{O}^\star(1.933^n)$ algorithm for 2-DCS. This result was improved by Telle and Villanger, who designed an algorithm running in time $\mathcal{O}^\star(1.7804^n)$, for the problem [16]. The main goal of this article is to break the $\mathcal{O}^\star(2^n)$ barrier for Path Contraction. Obtaining such an algorithm for Path Contraction was stated as an open problem in [17].

Our Results. We design an algorithm for Path Contraction running in time $\mathcal{O}^\star(1.99987^n)$, where n is the number of vertices in the input graph. To the best of our knowledge, this is the first non-trivial algorithm for the problem, which breaks the $\mathcal{O}^\star(2^n)$ barrier. To obtain our main algorithm for Path Contraction, we design four different algorithms for the problem, which are used as subroutines to the main algorithm. We exploit the property that certain types of algorithms are better for certain instance, but may be inefficient for certain other instances. Roughly speaking, we look for solutions using different algorithms, and then the best suited algorithm for the instance is used to return the solution. When one of the four algorithms is called as a subroutine, it does not necessarily return an optimum solution for the instance, rather it only looks for solutions that satisfy certain conditions. These conditions are quantified by fractions associated with the input graph. We note that for appropriate values of these "fractions", each of our subroutine still serve as an algorithm for Path Contraction (and thus, can compute the optimal solution). We argue that there is always a solution which satisfies the conditions for one of the subroutines, by setting the values of the fractions appropriately. A saving over $\mathcal{O}^\star(2^n)$, in the running time achieved by our algorithm, also exploits the property that "small" connected sets with bounded neighborhood can be enumerated "efficiently".

In the following we very briefly explain the type of solutions we look for, in our subroutines. Consider a path P_t, such that G can be contracted to P_t, where t is the largest such integer. The solution t, can be "witnessed" by a partition $\mathcal{W} = \{W_1, W_2, \cdots, W_t\}$ of $V(G)$, where the vertices from W_i "merge" to the ith vertex of P_t (a formal definition for it can be found in Section 2). Such a "witness" is called a *P_t-witness structure*. The first (subroutine) algorithm for Path Contraction searches for a solution where the P_t-witness structure can be "split" into two connected disjoint parts which are "small". Then, it exploits the "smallness" of the parts to compute solutions efficiently, and combines them to compute the solution for whole graph. The second subroutine searches for a pair of sets in the P_t-witness structure which are very dense. Then it exploit the sparseness of the remaining graph to efficiently compute partial solutions for them. Moreover, the pair of dense parts are resolved using the algorithm of Telle and Villanger for 2-Disjoint Connected Subgraph [16]. The third routine works with a hope that the total number of vertices in one of odd/even sets from $\mathcal{W}$ can be bounded. Finally, the fourth subroutine work by exploiting a similar odd/even property as the third subroutine, but it relaxes the condition to "nearly" small odd/even set.

To design our algorithm, we also define a problem called 3-Disjoint Connected Subgraphs (3-DCS), which is a generalization of the 2-Disjoint Connected Subgraphs (2-DCS) problem. 3-DCS takes as input a graph G and disjoint sets $Z_1, Z_2 \subseteq V(G)$, and the goal is to partition $V(G)$ into three sets (V_1, U, V_2), such that graphs induced on each of the parts is connected and $Z_i \subseteq V_i$, for $i \in [2]$. We design an algorithm for 3-DCS running in time $\mathcal{O}^\star(1.88^n)$. The fourth subroutine of our algorithm uses the algorithm for 3-DCS as a subroutine. As a corollary to our $\mathcal{O}^\star(1.88^n)$-time algorithm for 3-DCS, we obtain that P_5-Contraction admits an algorithm running in time $\mathcal{O}^\star(1.88^n)$.

Due to space limitation, most proofs appear in full version of the paper.

2 Preliminaries

In this section, we state some basic definitions and introduce terminologies from graph theory. We use standard terminology from the book of Diestel [7] for the graph related terminologies which are not explicitly defined here. We also establish some notations that will be used throughout. We note that all graphs considered in this article are connected graphs on at least two vertices (unless stated otherwise).

We denote the set of natural numbers by $\mathbb{N}$ (including 0). For $k \in \mathbb{N}$, $[k]$ denotes the set $\{1, 2, \ldots, k\}$. A graph G is *isomorphic* to a graph H if there exists a bijective function $\phi : V(G) \to V(H)$, such that for $v, u \in V(G)$, $uv \in E(G)$ if and only if $(\phi(v), \phi(u)) \in E(H)$. A graph G is *contractible* to a graph H if there exists $F \subseteq E(G)$, such that G/F is isomorphic to H. In other words, G is contractible to H if there is a surjective function $\varphi : V(G) \to V(H)$, with $W(h) = \{v \in V(G) \mid \varphi(v) = h\}$, for $h \in V(H)$, with the following properties:

- for any $h \in V(H)$, the graph $G[W(h)]$ is connected, and
- for any two vertices $h, h' \in V(H)$, $hh' \in E(H)$ if and only if $W(h)$ and $W(h')$ are adjacent in G.

Let $\mathcal{W} = \{W(h) \mid h \in V(H)\}$. The sets in $\mathcal{W}$ are called *witness sets*, and $\mathcal{W}$ is an *H-witness structure* of G.

In this paper, we will restrict ourselves to contraction to paths. This allows us to use an ordered notation for witness sets, rather than just the set notation. This ordering of the sets in witness set is given by the ordering of vertices in the path. That is, for a $P_t = (h_1, h_2, \cdots, h_t)$-witness structure, $\mathcal{W} = \{W(h_1), W(h_2), \cdots, W(h_t)\}$ of a graph G, we use the ordered witness structure notation, $(W(h_1), W(h_2), \cdots, W(h_t))$, or simply, $(W_1, W_2, \cdots, W_t)$. We note that we use both unordered and ordered notation, as per the convenience.

In the following, we give some useful observations regarding contraction to paths.

▶ **Observation 2.1.** *Let G be a graph contractible to P_t. Then, there is a P_t-witness structure, $\mathcal{W} = (W_1, \ldots, W_t)$, of G such that W_1 is a singleton set. Moreover, if $t \geq 3$, then there is a P_t-witness structure, $\mathcal{W} = (W_1, \ldots, W_t)$, of G such that both W_1 and W_t are singleton set.*

▶ **Observation 2.2.** *For a set U with n elements and a constant $\delta < 1/2$, the number of subsets of U of size at most δn is bounded by $\mathcal{O}^\star([g(\delta)]^n)$, where $g(\delta) = \frac{1}{\delta^\delta \cdot (1-\delta)^{(1-\delta)}}$. Moreover, all such subsets can be enumerated in the same time.*

For a graph G, a non-empty set $Q \subseteq V(G)$, and integers $a, b \in \mathbb{N}$, a connected set A in G is a *(Q, a, b)-connected set* if $Q \subseteq A$, $|A| = a$, and $|N(A)| \leq b$. Moreover, a connected set A in G is an *(a, b)-connected set* if $|A| \leq a$ and $|N(A)| \leq b$. Next, we state results regarding (Q, a, b)-connected sets and connected sets, which follow from Lemma 3.1 of [9]. (We note that their result give slightly better bounds, but for simplicity, we only use the bounds stated in the following lemmas.)

▶ **Lemma 1.** *For a graph G, a non-empty set $Q \subseteq V(G)$, and integers $a, b \in \mathbb{N}$, the number of (Q, a, b)-connected sets in G is at most $2^{a+b-|Q|}$. Moreover, we can enumerate all (Q, a, b)-connected sets in G in time $2^{a+b-|Q|} \cdot n^{\mathcal{O}(1)}$.*

▶ **Lemma 2.** *For a graph G and integers $a, b \in \mathbb{N}$ the number of (a, b)-connected sets in G is at most $2^{a+b} \cdot n^{\mathcal{O}(1)}$. Moreover, we can enumerate all such sets in $2^{a+b} \cdot n^{\mathcal{O}(1)}$ time.*

3 3-Disjoint Connected Subgraph

In this section, we define a generalization of 2-Disjoint Connected Subgraphs (2-DCS), called 3-Disjoint Connected Subgraphs (3-DCS). We design an algorithm for 3-DCS

running in time $\mathcal{O}^\star(1.88^n)$, where n is number of vertices in input graph. This algorithm will be useful in designing our algorithm for Path Contraction.

In the following, we formally define the problem 2-DCS which is studied in [5, 16].

2-Disjoint Connected Subgraphs (2-DCS)
Input: A connected graph G and two disjoint sets Z_1 and Z_2.
Question: Does there exist a partition (V_1, V_2) of $V(G)$, such that for each $i \in [2]$, $Z_i \subseteq V_i$ and $G[V_i]$ is connected?

In the following we state a result regarding 2-DCS which will be useful later sections.

▶ **Proposition 3** ([16] Theorem 3). *There exists an algorithm that solves* 2-Disjoint Connected Subgraphs *problem in* $\mathcal{O}^\star(1.7804^n)$ *time where* n *is number of vertices in input graph.*

In the 3-DCS problem, the input is same as that of 2-DCS, but we are interested in a partition of $V(G)$ into three sets, rather than two. We formally define the problem below.

3-Disjoint Connected Subgraphs (3-DCS)
Input: A connected graph G and two disjoint sets Z_1 and Z_2.
Question: Does there exist a partition (V_1, U, V_2) of $V(G)$, such that 1) for each $i \in [2]$, $Z_i \subseteq V_i$ and $G[V_i]$ is connected, 2) $G[U]$ is connected, and 3) $G - U$ has exactly two connected components, namely, $G[V_1]$ and $G[V_2]$?

We note that the problem definitions for 2-DCS and 3-DCS do not require the sets Z_1, Z_2 to be non-empty. If either of this set is empty, we can guess a vertex for each of the non-empty sets. Since there are at most n^2 such guesses, it will not affect the running time of our algorithm. Thus, here after we assume that both Z_1 and Z_2 are non-empty sets.

In the following theorem, we state our result regarding 3-DCS.

▶ **Theorem 4.** 3-DCS *admits an algorithm running in time* $\mathcal{O}^\star(1.88^n)$*, where* n *is number of vertices in the input graph.*

4 Exact Algorithm for Path Contraction

In this section we design our algorithm for Path Contraction running in time $\mathcal{O}^\star(1.99987^n)$, where n is the number of vertices in the input graph. To design our algorithm, we design four different subroutines each solving the problem Path Contraction. Each of these subroutines are better than the other when a specific "type" of solution exists for the input instance. Thus the main algorithm will use these subroutines to search for solutions of the type they are the best for. We also design a sub-routine for enumerating special types of partial solution, which will be used in some of our algorithms for Path Contraction.

In the following we briefly explain the four subroutines and describe when they are useful. Let G be an instance for Path Contraction, where G is a graph on n vertices. Let t be the largest integer (which we do not know a priori), such that G is contractible to P_t with $(W_1, W_2, \cdots, W_t)$ as a P_t-witness structure of G. We let $\mathtt{OS}$ and $\mathtt{ES}$ be the union of vertices in odd and even witness sets, respectively. That is, $\mathtt{OS} = \cup_{x=1}^{\lceil t/2 \rceil} W_{2x-1}$ and $\mathtt{ES} = \bigcup_{x=1}^{\lfloor t/2 \rfloor} W_{2x}$.

We now give an intuitive idea of the purposes of each of our subroutines in the main algorithm, while deferring their implementations to the subsequent sections. We also describe a subroutine which will help us build "partial solutions", and this subroutine will be used in two of our subroutines for Path Contraction. (We refer the reader to Figure 1 for an illustration of it.)

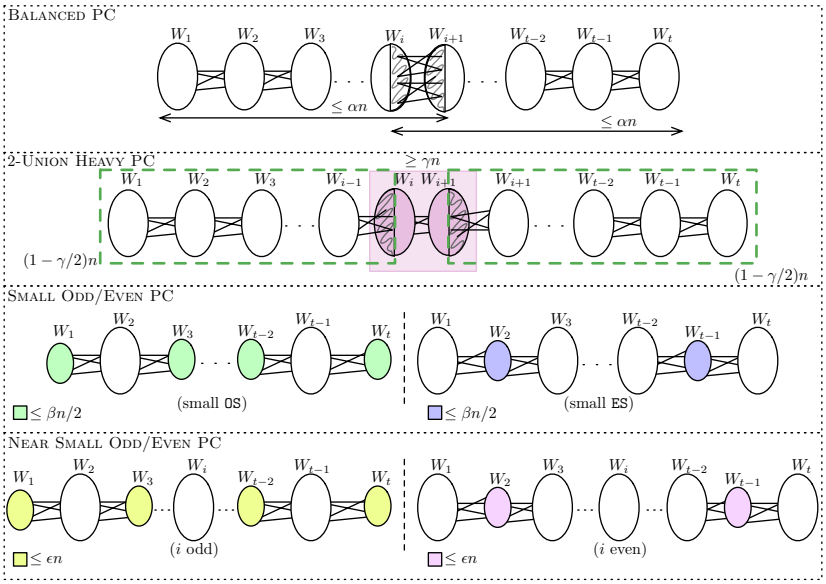

Figure 1 Various subroutines for the algorithm and their usage.

Balanced PC. This subroutine is useful when we can "break" the graph into two parts after a witness set, such that the closed neighborhood for each of the parts have small size, or in other words, the parts are "balanced". The quantification of the "balancedness" after a witness set will be done with the help of a rational number $0 < \alpha \leq 1$, which will be part of the input for the subroutine. The subroutine will only look for those P_t-witness structures for G for which there is an integer $i \in [t]$, such that the sizes of both $N[\cup_{j\in[i]}W_j]$ and $N[\cup_{j\in[t]\setminus[i]}W_j]$ are bounded by αn. Moreover, the algorithm will return the largest such t. Our algorithm for Balanced PC will run in time $\mathcal{O}^\star(2^{\alpha n})$. Note that when $\alpha = 1$, Balanced PC is an algorithm for Path Contraction running in time $\mathcal{O}^\star(2^n)$.

2-Union Heavy PC. This subroutine will be used when "large" part of the graph is concentrated in two consecutive witness sets and the neighborhood of the rest of the graph into them is "small". The quantification of term "large/small" will be done by a a fraction $0 < \gamma < 1$, which will be part of the input. The algorithm will only search for those P_t-witness structure of G where there is an integer $i \in [t-1]$, such that $|W_i \cup W_{i+1}| \geq \gamma n$, and $|N[\cup_{j\in[i-1]}W_j]|, |N[\cup_{j\in[t]\setminus[i+1]}W_j]| \leq (1-\gamma/2)n$. Moreover, the algorithm will return largest such t.

Small Odd/Even PC. Roughly speaking, this subroutine is particularly useful when one of OS or ES is "small". The "smallness" of OS/ES is quantified by a rational number $0 < \beta \leq 1$, which will be part of the input. The subroutine will only look for those P_t-witness structures for G where one of $|\texttt{OS}| \leq \beta n/2$ or $|\texttt{ES}| \leq \beta n/2$ holds. Moreover, the algorithm will return the largest integer $t \geq 1$, for which such a P_t-witness structure for G exists. Small Odd/Even PC will run in time $\mathcal{O}^\star(c^n)$, where $c = g(\beta/2)$. We note that when $\beta = 1$, then one of $|\texttt{OS}| \leq \beta n/2$ or $|\texttt{ES}| \leq \beta n/2$ definitely holds. Thus, for $\beta = 1$, Small Odd/Even PC is an algorithm for Path Contraction running in time $\mathcal{O}^\star(2^n)$ (see Observation 2.2).

Near Small Odd/Even PC. In the case when both OS and ES are "large", it may be the case that for one of OS/ES, there is just one witness set which is large. That is, when we remove this large witness set, then one of OS/ES becomes "small". The "smallness" of the remaining OS/ES (after removing a witness set) will be quantified by a rational number $0 < \epsilon \leq 1$, which will be part of the input. The subroutine will only look for those P_t-witness structures for G where the size of one of $|\texttt{OS}|$ or $|\texttt{ES}|$ after removal of a witness set is bounded by ϵn. Moreover, the algorithm will return the largest such t.

Our subroutines Balanced PC and 2-Union Heavy PC use a subroutine called Enum-Partial-PC for enumerating solutions for "small" subgraphs. The efficiency of the algorithm for Enum-Partial-PC is centered around the bounds for (Q, a, b)-connected sets. In Section 4.1 we (define and) design an algorithm for Enum-Partial-PC. In Section 4.2, 4.3, 4.4 and 4.5 we present our algorithms for Balanced PC, 2-Union Heavy PC, Small Odd/Even PC, and Near Small Odd/Even PC, respectively. Finally, in Section 4.6 we show how we can use the above algorithms to obtain an algorithm for Path Contraction, running in time $\mathcal{O}^\star(1.99987^n)$.

4.1 Algorithm for Enum-Partial-PC

In this section, we describe an algorithm which computes "nice solution" for all "ρ-small" subset of vertices of an input graph. In an input graph G, for a set $S \subseteq V(G)$, by $\Phi(S)$ we denote the set of vertices in S that have a neighbor outside S. That is, $\Phi(S) = \{s \in S \mid N(s) \setminus S \neq \emptyset\}$. A set $S \subseteq V(G)$ is *ρ-small* if $N[S] \leq \rho n$. For an ρ-small set $S \subseteq V(G)$, the largest integer t_S is called the *nice solution* if $G[S]$ is contractible to P_{t_S} with all the vertices in $\Phi(S)$ in the end bag. That is, there is a P_{t_S}-witness structure $(W_1, W_2, \cdots W_{t_S})$ of $G[S]$, such that $\Phi(S) \subseteq W_{t_S}$. We formally define the problem Enum-Partial-PC in the following way.

Enum-Partial-PC
Input: A graph G on n vertices and a fraction $0 < \rho \leq 1$.
Output: A table Γ which is indexed by *ρ-small* sets. For any *ρ-small* set S, $\Gamma[S]$ is the largest integer t for which $G[S]$ has a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$, such that $\Phi(S) \subseteq W_t$.

We design an algorithm for Enum-Partial-PC running in time $\mathcal{O}^\star(2^{\rho n})$. We briefly explain how we can compute nice solutions for ρ-small set. Consider an ρ-small set S. Note that $|S| \leq \rho n$. Thus, by the method of 2-coloring (as was explained in the introduction), we can obtain the nice solution in time $2^{\rho n}$. This would lead us to an algorithm running in time $\mathcal{O}^\star(2^{\rho n} g(\rho)^n)$. By doing a simple dynamic programming we can also obtain an algorithm running in time $\mathcal{O}^\star(3^n)$. We will improve upon these algorithms by a dynamic programming algorithm where we update the values "forward" instead of looking "backward".

The Algorithm. We start by defining the tables entries for our dynamic programming routine, which is used for computation of nice solutions. Let $\mathcal{S}$ be the set of all connected sets S in G, such that $|N[S]| \leq \rho n$. That is, $\mathcal{S} = \{S \subseteq V(G) \mid G[S] \text{ is connected and } |N[S]| \leq \rho n\}$. For each $S \in \mathcal{S}$, we have an entry denoted by $\Gamma[S]$. $\Gamma[S]$ is the largest integer $q \geq 1$ for which $G[S]$ can be contracted to P_q with a P_q-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_q)$ of $G[S]$, such that $\Phi(S) \subseteq W_q$. The algorithm starts by initializing $\Gamma[S] = 1$, for each $S \in \mathcal{S}$.

In the following we introduce some notations that will be useful in stating the algorithm. Consider $S \in \mathcal{S}$. We will define a set $\mathcal{A}[S]$, which will be the set of all "potential extenders bags" for S, when we look at contraction to paths for larger graphs (containing S). For the

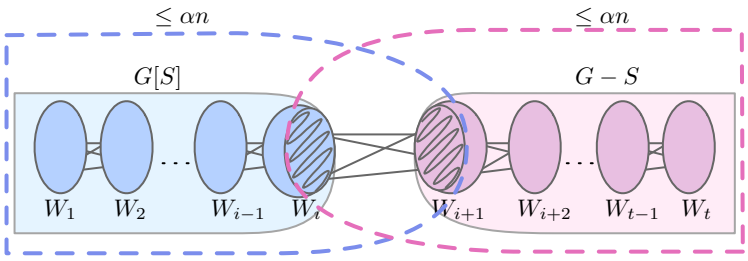

Figure 2 An illustration of construction of the solution using solutions for instances of smaller sizes.

sake of notational simplicity, we will define $\mathcal{A}_{a,b}[S] \subseteq \mathcal{A}[S]$, where the sets in $\mathcal{A}_{a,b}[S]$ will be of size exactly a and will have exactly b neighbors outside S. We will define the above sets only for "relevant" as and bs. We now move to the formal description of these sets. Consider $S \in \mathcal{S}$ and integers a, b, such that $|S| + a + b \leq \rho n$ and $|N(S)| \leq b$. We let $\mathcal{A}_{a,b}[S] = \{A \subseteq V(G - S) \mid G - S[A]$ is connected, $N_G(S) \subseteq A, |A| = a,$ and $|N_{G-S}(A)| = b\}$.

The algorithm now computes nice solutions. The algorithm considers sets from $S \in \mathcal{S}$, in increasing order of their sizes and does the following. (Two sets that have the same size can be considered in any order.) For every pair of integer a, b, such that $|S| + a + b \leq \rho n$ and $|N(S)| \leq b$, it computes the set $\mathcal{A}_{a,b}[S]$. Note that $\mathcal{A}_{a,b}[S]$ can be computed in time $\mathcal{O}^\star(2^{a+b-|S|})$, using Lemma 1. Now the algorithm considers $A \in \mathcal{A}_{a,b}[S]$. Intuitively speaking, A is the "new" witness set to be "appended" to the witness structure of $G[S]$, to obtain a witness structure for $G[S \cup A]$. Thus, the algorithm sets $\Gamma[S \cup A] = \max\{\Gamma[S \cup A], \Gamma[S] + 1\}$. This finishes the description of our algorithm.

In the following few lemmas we establish the correctness and runtime analysis of the algorithm.

▶ **Lemma 5.** *For each $S \in \mathcal{S}$, the algorithm computes $\Gamma[S]$ correctly.*

▶ **Lemma 6.** *The algorithm presented for* Enum-Partial-PC *runs in time $\mathcal{O}^\star(2^{\rho n})$.*

4.2 Algorithm for Balanced PC

We formally define the problem Balanced PC in the following.

Balanced PC
Input: A graph G on n vertices and a fraction $0 < \alpha \leq 1$.
Output: Largest integer $t \geq 2$ for which G has a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$, such that there is $i \in [t]$ with $N[\cup_{j \in [i]} W_j] \leq \alpha n$ and $N[\cup_{j \in [t] \setminus [i]} W_j] \leq \alpha n$. Moreover, if no such t exists, then output 1.

We design an algorithm for Balanced PC running in time $\mathcal{O}^\star(2^{\alpha n})$. Let (G, α) be an instance of Balanced PC.

We begin by explaining the intuition behind the algorithm. Recall that for a α-small set $S \subseteq V(G)$, integer t_S is called the *nice solution* if $G[S]$ is contractible to P_{t_S} with all the vertices in $\Phi(S)$ in the end bag. That is, there is a P_{t_S}-witness structure $(W_1, W_2, \cdots W_{t_S})$ of $G[S]$, such that $\Phi(S) \subseteq W_{t_S}$. Suppose that we know the value of t_S for every α-small set S. Now we see how we can use these nice solutions for α-small sets to solve our problem (see Figure 2). Recall that we are looking for the largest integer t, such that G is contractible to P_t, with $\mathcal{W} = (W_1, W_2, \cdots, W_t)$ as a P_t-witness structure of G, such that there is $i \in [t]$ with

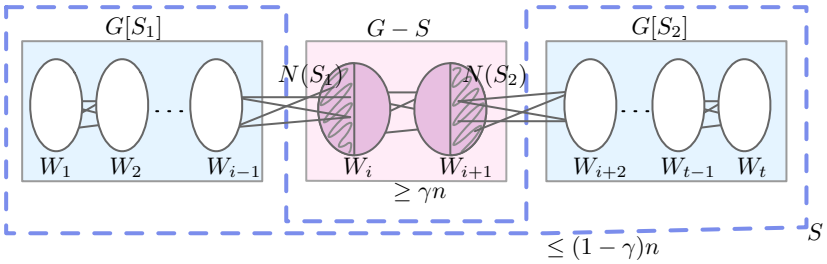

Figure 3 An intuitive illustration of the algorithm for 2-Union Heavy PC.

$|\cup_{j\in[i+1]} W_j| \leq \alpha n$ and $|\cup_{j\in[t]\setminus[i-1]} W_j| \leq \alpha n$. Let $S = \cup_{j\in[i]} W_j$. As $|\cup_{j\in[i+1]} W_j| \leq \alpha n$ and $N(S) \subseteq W_{i+1}$, the set S is an α-small set. Similarly, we can argue that $V(G) \setminus S$ is an α-small set. Thus, for S and $V(G) \setminus S$, we know the nice solutions t_S and $t_{V(G)\setminus S}$, respectively. Notice that the solution to the whole graph is actually $t_S + t_{V(G)\setminus S}$.

The Algorithm. The algorithm initializes $t = 1$. (At the end, t will be the output of the algorithm.) The algorithm computes table $\Gamma =$Enum-Partial-PC(G, α) using algorithm from Section 4.1. Let $\mathcal{S}$ be the set of all connected sets S in G, such that $|N[S]| \leq \alpha n$. That is, $\mathcal{S} = \{S \subseteq V(G) \mid G[S]$ is connected and $|N[S]| \leq \alpha n\}$. For each $S \in \mathcal{S}$, we have an entry denoted by $\Gamma[S]$. The algorithm considers each $S \in \mathcal{S}$ for which $V(G) \setminus S \in \mathcal{S}$. It sets $t = \max\{t, \Gamma[S] + \Gamma[V(G) \setminus S]\}$. Finally, the algorithm returns t as the output. This completes the description of the algorithm.

▶ **Lemma 7.** *The algorithm presented for* Balanced PC *is correct.*

▶ **Lemma 8.** *The algorithm presented for* Balanced PC *runs in time* $\mathcal{O}^\star(2^{\alpha n})$.

4.3 Algorithm for 2-Union Heavy PC

We formally define the problem 2-Union Heavy PC in the following (also see Figure 1).

2-Union Heavy PC
Input: A graph G on n vertices and a fraction $0 < \gamma \leq 1$.
Output: Largest integer $t \geq 3$ for which G has a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$, such that there is $i \in [t-1]$ for which the following conditions hold: 1) $|W_i \cup W_{i+1}| \geq \gamma n$ and 2) $|N[\cup_{j\in[i-1]} W_j]|, |N[\cup_{j\in[t]\setminus[i+1]} W_j]| \leq (1-\gamma/2)n$. Moreover, if no such t exists, then output 2.

We design an algorithm for 2-Union Heavy PC running in time $\mathcal{O}^\star(2^{(1-\gamma/2)n} + c^n)$, where $c = \max_{\gamma\leq\delta\leq 1}\{1.7804^\delta \cdot g(1-\delta)\}$. The first term in the running time expression will be due to a call made to Enum-Partial-PC with $\rho = (1-\gamma/2)$, and the second term will be due to enumerating sets of size at most $(1-\gamma)n$ and running the algorithm for solving 2-Disjoint Connected Subgraphs for an instance created for each of them, using the algorithm of Telle and Villanger [16].

Let (G, γ) be an instance of 2-Union Heavy PC. We start by explaining the intuitive idea behind our algorithm (see Figure 3). Consider a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$ of G, such that there is $i \in [t-1]$ for which the following conditions hold: 1) $|W_i \cup W_{i+1}| \geq \gamma n$ and 2) $|N[\cup_{j\in[i-1]} W_j]|, |N[\cup_{j\in[t]\setminus[i+1]} W_j]| \leq (1-\gamma/2)n$. Let $S = W_i \cup W_{i+1}$. As $W_i \cup W_{i+1}$ is "large", the number of vertices in $S = V(G) \setminus (W_i \cup W_{i+1})$ is "small". That is, we can bound $|S|$ by $(1-\gamma)n$. Note that $G[S]$ has exactly two connected components, which we

denote by $G[S_1]$ and $G[S_2]$. Also note that $N[S_1], N[S_2] \leq (1-\gamma/2)n$. The algorithm starts by enumerating all such "potential candidates" for S. As for each of the two components of $G[S]$, the sizes of $N[S_1]$ and $N[S_2]$ can be bounded, the algorithm computes the "optimum solution" for them using the algorithm for Enum-Partial-PC. In the above we use the algorithm for Enum-Partial-PC because we are only interested in those solutions where the vertices of $\Phi(S_1)$ and $\Phi(S_2)$ are contained in one of the "end bags" of their respective solutions. Now we see how we can use these solutions to obtain the solution for the whole graph. Note that we have to "split" vertices in $V(G) \setminus S$ into two "connected sets", where the first set must contain all the vertices from $N(S_1)$ and the second set must contain all the vertices from $N(S_1)$. For the above we employ the algorithm for 2-Disjoint Connected Subgraphs (see Section 3 for its definition) by Telle and Villanger [16].

We now formally describe our algorithm. The algorithm will output an integer t, which is initially set to 2. Let $\mathcal{S} = \{S \subseteq V(G) \mid |S| \leq (1-\gamma)n$ and $G[S]$ has exactly two connected components $G[S_1], G[S_2]$, s.t. $|N[S_1]|, |N[S_2]| \leq (1-\gamma/2)n\}$. Let $\widehat{\mathcal{S}} = \{\widehat{S} \subseteq V(G) \mid |N[\widehat{S}]| \leq (1-\gamma/2)n$ and $G[\widehat{S}]$ is connected$\}$. The algorithm will now computes a table Γ, which has an entry $\Gamma[\widehat{S}]$, for each $\widehat{S} \in \widehat{\mathcal{S}}$. The definition of Γ is the same as that in Section 4.2, where $\rho = 1-\gamma/2$. That is, for $\widehat{S} \in \widehat{\mathcal{S}}$, $\Gamma[\widehat{S}]$ is the largest integer $q \geq 1$ for which $G[\widehat{S}]$ can be contracted to P_q with a P_q-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_q)$ of $G[\widehat{S}]$, such that $\Phi(\widehat{S}) \subseteq W_q$. Compute the value of $\Gamma[\widehat{S}]$, for each $\widehat{S} \in \widehat{\mathcal{S}}$, by using Enum-Partial-PC$(G, 1-\gamma/2)$. For each $S \in \mathcal{S}$, the algorithm does the following. Recall that $G[S]$ has exactly two connected components. Let the two connected components in $G[S]$ be $G[S_1]$ and $G[S_2]$, where $S_1 \cup S_2 = S$. Recall that $|N[S_1]|, N[S_1]| \leq (1-\gamma/2)n$. Thus, $S_1, S_2 \in \widehat{\mathcal{S}}$. If $(G - S, N_G(S_1), N_G(S_2))$ is a yes-instance of 2-DCS, then the algorithm sets $t = \max\{t, \Gamma[S_1] + \Gamma[S_2] + 2\}$, and otherwise, it moves to the next set in $\mathcal{S}$. Finally, the algorithm outputs t. This completes the description of the algorithm.

In the following two lemmas we present the correctness and runtime analysis of the algorithm, respectively.

▶ **Lemma 9.** *The algorithm presented for* 2-Union Heavy PC *is correct.*

▶ **Lemma 10.** *The algorithm presented for* 2-Union Heavy PC *runs in time* $\mathcal{O}^\star(2^{(1-\gamma/2)n} + c^n)$*, where* $c = \max_{\gamma \leq \delta \leq 1}\{1.7804^\delta \cdot g(1-\delta)\}$.

4.4 Algorithm for Small Odd/Even PC

We formally define the problem Small Odd/Even PC in the following.

Small Odd/Even PC
Input: A graph G on n vertices and a fraction $0 < \beta \leq 1$.
Output: Largest integer t for which G can be contracted to P_t, with $\mathcal{W} = (W_1, W_2, \cdots, W_t)$ as a P_t-witness structure of G, such that $|\mathtt{OS}_\mathcal{W}| \leq \beta n/2$ or $|\mathtt{ES}_\mathcal{W}| \leq \beta n/2$, where $\mathtt{OS}_\mathcal{W} = \cup_{i \in [\lceil t/2 \rceil]} W_{2i-1}$ and $\mathtt{ES}_\mathcal{W} = \cup_{i \in [\lfloor t/2 \rfloor]} W_{2i}$.

In this section, we design an algorithm for Small Odd/Even PC running in time $\mathcal{O}^\star(c^n)$, where $c = g(\beta/2)$.

Let (G, β) be an instance of Small Odd/Even PC. The algorithm is fairly simple. It starts by enumerating all "potential candidates" for $\mathtt{OS}_\mathcal{W}$ (resp. $\mathtt{ES}_\mathcal{W}$), i.e., the set of all subsets of $V(G)$ of size at most $\beta n/2$. Then, for each such "potential set", it contracts G appropriately, and finds the length of the path to which G is contracted (and stores 0, if the contracted graph is not a path). Finally, it returns the maximum over such path lengths.

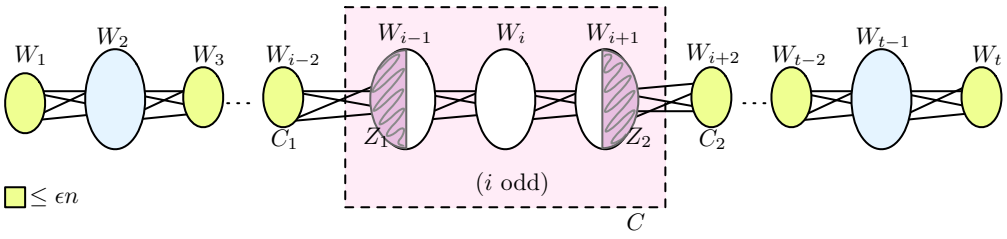

Figure 4 An intuitive illustration of the algorithm for Near Small Odd/Even PC.

We now move to formal description of the algorithm. We start by enumerating the set of all subsets of $V(G)$ of size at most $\beta n/2$. That is, $\mathcal{S} = \{S \subseteq V(G) \mid |S| \leq \beta n/2\}$. Note that $\mathcal{S}$ can be computed in time $\mathcal{O}^\star(g(\beta/2)^n)$, using Observation 2.2. For each $S \in \mathcal{S}$ the algorithm does the following. Let $\mathcal{C}_S$ and $\overline{\mathcal{C}}_S$ be the set of connected components of $G[S]$ and $G - S$, respectively. Let G_S be the graph obtained from G by contracting each $C \in \mathcal{C}_S \cup \overline{\mathcal{C}}_S$ to a single vertex. Set $\mathsf{len}_S = |V(G_S)|$, if G_S is a path, and $\mathsf{len}_S = 0$, otherwise. Finally, the algorithm returns $\max_{S \in \mathcal{S}} \mathsf{len}_S$.

In the following lemma we prove the correctness and runtime analysis of the algorithm.

▶ **Lemma 11.** *The algorithm presented for* Small Odd/Even PC *is correct and runs in time* $\mathcal{O}^\star(g(\beta/2)^n)$.

4.5 Algorithm for Near Small Odd/Even PC

We formally define the problem Near Small Odd/Even PC in the following (also see Figure 1).

Near Small Odd/Even PC
Input: A graph G on n vertices and a fraction $0 < \epsilon \leq 1$.
Output: Largest integer $t \geq 3$ for which there is a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$ of G, for which there is $i \in \{2, 3, \cdots, t-1\}$, such that if i is odd, then $|\mathtt{OS}_{\mathcal{W}} \setminus W_i| \leq \epsilon n$ and otherwise, $|\mathtt{ES}_{\mathcal{W}} \setminus W_i| \leq \epsilon n$. Here, $\mathtt{OS}_{\mathcal{W}} = \cup_{i \in [\lceil t/2 \rceil]} W_{2i-1}$ and $\mathtt{ES}_{\mathcal{W}} = \cup_{i \in [\lfloor t/2 \rfloor]} W_{2i}$. If no such $t \geq 3$ exists, then output 2.

We design an algorithm for Near Small Odd/Even PC running in time $\mathcal{O}^\star(c^n)$ where $c = \max_{0 \leq \delta \leq \epsilon}\{1.88^{(1-\delta)} \cdot g(\delta)\}$. The second term in multiplicative factor will be due enumeration of sets, and the first term will be due to calls made to the algorithm for 3-Disjoint Connected Subgraphs, from Section 3.

Let (G, ϵ) be an instance of Near Small Odd/Even PC. We start by explaining the intuitive idea behind our algorithm (see Figure 4). Consider a P_t-witness structure $\mathcal{W} = (W_1, W_2, \cdots, W_t)$ of G, for which there is $i \in \{2, 3, \cdots, t-2\}$, such that if i is odd, then $|\mathtt{OS}_{\mathcal{W}} \setminus W_i| \leq \epsilon n$ and otherwise, $|\mathtt{ES}_{\mathcal{W}} \setminus W_i| \leq \epsilon n$. In the above, $\mathtt{OS}_{\mathcal{W}} = \cup_{i \in [\lceil t/2 \rceil]} W_{2i-1}$ and $\mathtt{ES}_{\mathcal{W}} = \cup_{i \in [\lfloor t/2 \rfloor]} W_{2i}$. Let us consider the case when i is odd (the other case is symmetric). Let $S = \mathtt{OS}_{\mathcal{W}} \setminus W_i$. (The union of vertices from yellow sets in Figure 4 is the set S.) As $|S| \leq \epsilon n$, the algorithm starts by enumerating all "potential candidates" for the set S. All the components of $G - S$, except for the component C, containing W_i, must each be contracted to a single vertex. Similarly, the components of $G[S]$ must each be contracted to a single vertex. Moreover, the component containing W_i must be "split" into three sets. The first and the last sets in the "split" must contain the neighbors of W_{i-2} and W_{i+2} in C, respectively. To obtain such a "split", we use the algorithm for 3-Disjoint Connected Subgraphs that we designed in Section 3.

We now formally describe our algorithm. The algorithm will output an integer t, which is initially set to 2. Let $\mathcal{S} = \{S \subset V(G) \mid |S| \leq \epsilon n\}$. For each $S \in \mathcal{S}$, the algorithm does the following. Let $\mathcal{C}_S$ and $\overline{\mathcal{C}}_S$ be the sets of connected components in $G[S]$ and $G - S$, respectively. Let H_S be obtained from G by contracting component in $\mathcal{C}_S \cup \overline{\mathcal{C}}_S$ to single vertices. That is, H_S has a vertex v_C for each $C \in \mathcal{C}_S \cup \overline{\mathcal{C}}_S$, and two vertices $v_C, v_{C'} \in V(H_S)$ are adjacent in H_S if and only if C and C' are adjacent in G. If H_S is not a path, then the algorithm moves to the next set in $\mathcal{S}$. Otherwise, for each $C^* \in \overline{\mathcal{C}}_S$ it does the following. Intuitively speaking, C^* is the current guess for the component containing vertices from W_i for the witness structure that we are looking for. Note that C^* can be adjacent to at most two components from $\mathcal{C}_S$, as H_S is a path. Moreover, C^* must be adjacent to at least one component from $\mathcal{C}_S$, as G is connected and S is a strict subset of $V(G)$, i.e., $S \neq V(G)$. Let C_1 be a component from $\mathcal{C}_S$ that is adjacent to C^* in G, and $Z_1 = N(C_1) \cap V(C^*)$. Let $C_2 \in \mathcal{C}_S \setminus \{C_1\}$ be a component of $G[S]$ that is adjacent to C^*, and $Z_2 = N(C_2) \cap V(C^*)$. If such a C_2 does not exist, then we set $Z_2 = \emptyset$. If $(G[C^*], Z_1, Z_2)$ is a yes-instance of 3-DCS, then the algorithm updates $t = \max\{t, |V(H_S)| + 2\}$. After finishing the processing for each $S \in \mathcal{S}$, the algorithm outputs t. This finishes the description of our algorithm.

In the following two lemmas we present the correctness and runtime analysis of the algorithm, respectively.

▶ **Lemma 12.** *The algorithm presented for* Near Small Odd/Even PC *is correct.*

▶ **Lemma 13.** *The algorithm presented for* Near Small Odd/Even PC *runs in time* $\mathcal{O}^\star(c^n)$*, where* $c = \max_{0 \leq \delta \leq \epsilon}\{1.88^{(1-\delta)} \cdot g(\delta)\}$.

4.6 Algorithm for Path Contraction

We are now ready to present our algorithm for Path Contraction. The algorithm calls four of the subroutines Small Odd/Even PC, Balanced PC, 2-Union Heavy PC, and Near Small Odd/Even PC for appropriate instances, and returns the maximum of their outputs. In the following theorem, we present the algorithm, which is the main result of this paper.

▶ **Theorem 14.** Path Contraction *admits an algorithm running in time* $\mathcal{O}^\star(1.99987^n)$*, where* n *is the number of vertices in the input graph.*

5 Conclusion

We generalized the 2-Disjoint Connected Subgraphs problem, to a problem called 3-Disjoint Connected Subgraphs, where instead of partitioning the vertex set into two connected sets, we are required to partition it into three connected sets. We gave an algorithm for 3-Disjoint Connected Subgraphs running in time $\mathcal{O}^\star(1.88^n)$. We believe that this algorithm can be of independent interest and may find other algorithmic applications. We designed an algorithm for Path Contraction which breaks the $\mathcal{O}^\star(2^n)$ barrier. It was surprising that even for a simple problem like Path Contraction, there was no known algorithm that solves it faster than $\mathcal{O}^\star(2^n)$. Our algorithm for Path Contraction relied the fact that the number of (Q, a, b)-connected sets can be bounded by $\mathcal{O}^\star(2^{a+b-|Q|})$. This gives us savings in the number of states that we consider, in our dynamic programming routine (for enumerating partial solutions). We designed four different algorithms for Path Contraction and used them for appropriate instances, to obtain the main algorithm for Path Contraction.

Abstract

In this work we derandomize two central results in graph algorithms, replacement paths and distance sensitivity oracles (DSOs) matching in both cases the running time of the randomized algorithms.

For the replacement paths problem, let $G = (V, E)$ be a directed unweighted graph with n vertices and m edges and let P be a shortest path from s to t in G. The *replacement paths* problem is to find for every edge $e \in P$ the shortest path from s to t avoiding e. Roditty and Zwick [ICALP 2005] obtained a randomized algorithm with running time of $\widetilde{O}(m\sqrt{n})$. Here we provide the first deterministic algorithm for this problem, with the same $\widetilde{O}(m\sqrt{n})$ time. Due to matching conditional lower bounds of Williams et al. [FOCS 2010], our deterministic combinatorial algorithm for the replacement paths problem is optimal up to polylogarithmic factors (unless the long standing bound of $\widetilde{O}(mn)$ for the combinatorial boolean matrix multiplication can be improved). This also implies a deterministic algorithm for the second simple shortest path problem in $\widetilde{O}(m\sqrt{n})$ time, and a deterministic algorithm for the k-simple shortest paths problem in $\widetilde{O}(km\sqrt{n})$ time (for any integer constant $k > 0$).

For the problem of distance sensitivity oracles, let $G = (V, E)$ be a directed graph with real-edge weights. An f-Sensitivity Distance Oracle (f-DSO) gets as input the graph $G = (V, E)$ and a parameter f, preprocesses it into a data-structure, such that given a query (s, t, F) with $s, t \in V$ and $F \subseteq E \cup V, |F| \leq f$ being a set of at most f edges or vertices (failures), the query algorithm efficiently computes the distance from s to t in the graph $G \setminus F$ (i.e., the distance from s to t in the graph G after removing from it the failing edges and vertices F).

For weighted graphs with real edge weights, Weimann and Yuster [FOCS 2010] presented several randomized f-DSOs. In particular, they presented a combinatorial f-DSO with $\widetilde{O}(mn^{4-\alpha})$ preprocessing time and subquadratic $\widetilde{O}(n^{2-2(1-\alpha)/f})$ query time, giving a tradeoff between preprocessing and query time for every value of $0 < \alpha < 1$. We derandomize this result and present a combinatorial deterministic f-DSO with the same asymptotic preprocessing and query time.

1 Introduction

In many algorithms used in computing environments such as massive storage devices, large scale parallel computation, and communication networks, recovering from failures must be an integral part. Therefore, designing algorithms and data structures whose running time is efficient even in the presence of failures is an important task. In this paper we study variants of shortest path queries in setting with failures.

The computation of shortest paths and distances in the presence of failures was extensively studied. Two central problems researched in this field are the Replacement Paths problem and Distance Sensitivity Oracles, we define these problems hereinafter.

The Replacement Paths problem. (See, e.g., [26, 28, 16, 14, 21, 27, 6, 30, 22, 23, 24, 25, 29, 15].) Let $G = (V, E)$ be a graph (directed or undirected, weighted or unweighted) with n vertices and m edges and let $P_G(s, t)$ be a shortest path from s to t. For every edge $e \in P_G(s, t)$ a replacement path $P_G(s, t, e)$ is a shortest path from s to t in the graph $G \setminus \{e\}$ (which is the graph G after removing the edge e). Let $d_G(s, t, e)$ be the length of the path $P_G(s, t, e)$. The replacement paths problem is as follows: given a shortest path $P_G(s, t)$ from s to t in G, compute $d_G(s, t, e)$ (or an approximation of it) for every $e \in P_G(s, t)$.

Distance Sensitivity Oracles. (See, e.g., [9, 17, 7, 8, 10, 11, 12, 13, 19].) An f-Sensitivity Distance Oracle (f-DSO) gets as input a graph $G = (V, E)$ and a parameter f, preprocesses it into a data-structure, such that given a query (s, t, F) with $s, t \in V$ and $F \subseteq E \cup V, |F| \leq f$ being a set of at most f edges or vertices (failures), the query algorithm efficiently computes (exactly or approximately) $d_G(s, t, F)$ which is the distance from s to t in the graph $G \setminus F$ (i.e., in the graph G after removing from it the failing edges and vertices F). Here we would like to optimize several parameters of the data-structure: minimize the size of the oracle, support many failures f, have efficient preprocessing and query algorithms, and if the output is an approximation of the distance then optimize the approximation-ratio.

An important line of research in the theory of computer science is derandomization. In many algorithms and data-structures there exists a gap between the best known randomized algorithms and the best known deterministic algorithms. There has been extensive research on closing the gaps between the best known randomized and deterministic algorithms in many problems or proving that no deterministic algorithm can perform as good as its randomized counterpart. There also has been a long line of work on developing derandomization techniques, in order to obtain deterministic versions of randomized algorithms (e.g., Chapter 16 in [2]).

In this paper we derandomize algorithms and data-structures for computing distances and shortest paths in the presence of failures. Many randomized algorithms for computing shortest paths and distances use variants of the following sampling lemma (see Lemma 1 in Roditty and Zwick [26]).

▶ **Lemma 1** (Lemma 1 in [26]). *Let $D_1, D_2, \ldots, D_q \subseteq V$ satisfy $|D_i| > L$ for $1 \leq i \leq q$ and $|V| = n$. If $R \subseteq V$ is a random subset obtained by selecting each vertex, independently, with probability $(c \ln n)/L$, for some $c > 0$, then with probability of at least $1 - q \cdot n^{-c}$ we have $D_i \cap R \neq \emptyset$ for every $1 \leq i \leq q$.*

Our derandomization step of Lemma 1 is very simple, as described in Section 1.3, we use the folklore greedy approach to prove the following lemma, which is a deterministic version of Lemma 1.

▶ **Lemma 2** (See also Section 1.3). *Let $D_1, D_2, \ldots, D_q \subseteq V$ satisfy $|D_i| > L$ for $1 \leq i \leq q$ and $|V| = n$. One can deterministically find in $\widetilde{O}(qL)$ time a set $R \subset V$ such that $|R| = \widetilde{O}(n/L)$ and $D_i \cap R \neq \emptyset$ for every $1 \leq i \leq q$.*

We emphasize that the use of Lemma 2 is very standard and is not our main contribution. The main technical challenge is how to efficiently and deterministically compute a small number of sets $D_1, D_2, \ldots, D_q \subseteq V$ so that the invocation of Lemma 2 is fast.

1.1 Derandomizing the Replacment Paths Algorithm of Roditty and Zwick [26]

We derandomize the algorithm of Roditty and Zwick [26] and obtain a near optimal deterministic algorithm for the replacement paths problem in directed unweighed graphs (a problem which was open for more than a decade since the randomized algorithm was published) as stated in the following theorem.

▶ **Theorem 3.** *There exists a deterministic algorithm for the replacement paths problem in unweighted directed graphs whose runtime is $\widetilde{O}(m\sqrt{n})$. This algorithm is near optimal assuming the conditional lower bound of combinatorial boolean matrix multiplication of [29].*

The term "combinatorial algorithms" is not well-defined, and it is often interpreted as non-Strassen-like algorithms [4], or more intuitively, algorithms that do not use any matrix multiplication tricks. Arguably, in practice, combinatorial algorithms are to some extent considered more efficient since the constants hidden in the matrix multiplication bounds are high. On the other hand, there has been research done to make fast matrix multiplication practical, *e.g.*, [18, 5].

Vassilevska Williams and Williams [29] proved a subcubic equivalence between $\sqrt{n}$ occurrences of the combinatorial replacement paths problem in unweighted directed graphs and the combinatorial boolean multiplication (BMM) problem. More precisely, they proved that there exists some fixed $\epsilon > 0$ such that the combinatorial replacement paths problem can be solved in $O(mn^{1/2-\epsilon})$ time if and only if there exists some fixed $\delta > 0$ such that the combinatorial boolean matrix multiplication (BMM) can be solved in subcubic $O(n^{3-\delta})$ time. Giving a subcubic combinatorial algorithm to the BMM problem, or proving that no such algorithm exists, is a long standing open problem. This implies that either both problems can be polynomially improved, or neither of them does. Hence, assuming the conditional lower bound of combinatorial BMM, our combinatorial $\widetilde{O}(m\sqrt{n})$ algorithm for the replacement paths problem in unweighted directed graphs is essentially optimal (up to $n^{o(1)}$ factors).

The replacement paths problem is related to the k simple shortest paths problem, where the goal is to find the k simple shortest paths between two vertices. Using known reductions from the replacement paths problem to the k simple shortest paths problem, we close this gap as the following Corollary states.

▶ **Corollary 4.** *There exists a deterministic algorithm for computing k simple shortest paths in unweighted directed graphs whose runtime is $\widetilde{O}(km\sqrt{n})$.*

The trivial $\widetilde{O}(mn)$ time algorithm for solving the replacement paths problem in directed weighted graphs (simply, for every edge $e \in P_G(s,t)$ run Dijkstra in the graph $G \setminus \{e\}$) is deterministic and near optimal (according to a conditional lower bound by [29]). To the best of our knowledge the only deterministic combinatorial algorithms known for directed unweighted graphs are the algorithms for general directed weighted graphs whose runtime is $\widetilde{O}(mn)$ leaving a significant gap between the randomized and deterministic algorithms. As mentioned above, in this paper we derandomize the $\widetilde{O}(m\sqrt{n})$ algorithm of Roditty and Zwick [26] and close this gap. More related work can be found in the full version.

1.2 Derandomizing the Combinatorial Distance Sensitivity Oracle of Weimann and Yuster [27]

Our second result is derandomizing the combinatorial distance sensitivity oracle of Weimann and Yuster [27] and obtaining the following theorem.

▶ **Theorem 5.** *Let $G = (V, E)$ be a directed graph with real edge weights, let $|V| = n$ and $|E| = m$. There exists a deterministic algorithm that given G and parameters $f = O(\frac{\log n}{\log \log n})$ and $0 < \alpha < 1$ constructs an f-sensitivity distance oracle in $\widetilde{O}(mn^{4-\alpha})$ time. Given a query (s, t, F) with $s, t \in V$ and $F \subseteq E \cup V, |F| \leq f$ being a set of at most f edges or vertices (failures), the deterministic query algorithm computes in $\widetilde{O}(n^{2-2(1-\alpha)/f})$ time the distance from s to t in the graph $G \setminus F$.*

We remark that while our focus in this paper is in computing distances, one may obtain the actual shortest path in time proportional to the number of edges of the shortest paths, using the same algorithm for obtaining the shortest paths in the replacement paths problem [26], and in the distance sensitivity oracles case [27].

1.3 Technical Contribution and Our Derandomization Framework

Let $\mathcal{A}$ be a random algorithm that uses Lemma 1 for sampling a subset of vertices $R \subseteq V$. We say that $\mathcal{P} = \{D_1, \ldots, D_q\}$ is a set of *critical* paths for the randomized algorithm $\mathcal{A}$ if $\mathcal{A}$ uses the sampling Lemma 1 and it is sufficient for the correctness of algorithm $\mathcal{A}$ that R is a hitting set for $\mathcal{P}$ (i.e., every path in $\mathcal{P}$ contains at least one vertex of R). According to Lemma 2 one can derandomize the random selection of the hitting set R in time that depends on the number of paths in $\mathcal{P}$. Therefore, in order to obtain an efficient derandomization procedure, we want to find a small set $\mathcal{P}$ of critical paths for the randomized algorithms.

Our main technical contribution is to show how to compute a small set of critical paths that is sufficient to be used as input for the greedy algorithm stated in Lemma 2.

Our framework for derandomizing algorithms and data-structures that use the sampling Lemma 1 is given in Figure 1.

1. **Step 1**: Prove the existence of a small set of critical paths $\{D_1, \ldots, D_q\}$ such that $|D_i| > L$ and show that it is sufficient for the correctness of the randomized algorithm that the set R obtained by Lemma 1 hits all the paths $D_1, \ldots, D_q$.
2. **Step 2**: Find an efficient algorithm to compute the paths $D_1, \ldots, D_q$.
3. **Step 3**: Use a deterministic algorithm to compute a small subset $R \subseteq V$ of vertices such that $D_i \cap R \neq \emptyset$ for every $1 \leq i \leq q$. For example, one can use the greedy algorithm of Lemma 2 or the blocker set algorithm of [20] to find a subset $R \subset V$ of $\widetilde{O}(n/L)$ vertices.

Figure 1 Our derandomization framework to derandomize algorithms that use the sampling Lemma 1.

Our first main technical contribution, denoted as Step 1 in Figure 1, is proving the existence of small sets of critical paths for the randomized replacement path algorithm of Roditty and Zwick [26] and for the distance sensitivity oracles of Weimann and Yuster [27]. Our second main technical contribution, denoted as Step 2 in Figure 1, is developing algorithms to efficiently compute these small sets of critical paths.

For the replacement paths problem, Roditty and Zwick [26] proved the existence of a critical set of $O(n^2)$ paths, each path containing at least $\lceil\sqrt{n}\rceil$ edges. Simply applying Lemma 2 on this set of paths requires $\widetilde{O}(n^{2.5})$ time which is too much, and it is also not clear from their algorithm how to efficiently compute this set of critical paths. As for Step 1, we prove the existence of a small set of $O(n)$ critical paths, each path contains $\lceil\sqrt{n}\rceil$ edges, and for Step 2, we develop an efficient algorithm that computes this set of critical paths in $\widetilde{O}(m\sqrt{n})$ time.

For the problem of distance sensitivity oracles, Weimann and Yuster [27] proved the existence of a critical set of $O(n^{2f+3})$ paths, each path containing $n^{(1-\alpha)/f}$ edges (where $0 < \alpha < 1$). Simply applying Lemma 2 on this set of paths requires $\widetilde{O}(n^{2f+3+(1-\alpha)/f})$ time which is too much, and here too, it is also not clear from their algorithm how to efficiently and deterministically compute this set of critical paths. As for Step 1, we prove the existence of a small set of $O(n^{2+\epsilon})$ critical paths, each path contains $n^{(1-\alpha)/f}$ edges, and for Step 2, we develop an efficient deterministic algorithm that computes this set of critical paths in $\widetilde{O}(mn^{1+\epsilon})$ time.

For Step 3, we use the folklore greedy deterministic algorithm denoted here by GreedyPivotsSelection($\{D_1, \ldots, D_q\}$). Given as input the paths $D_1, \ldots, D_q$, each path contains at least L vertices, the algorithm chooses a set of pivots $R \subseteq V$ such that for every $1 \leq i \leq q$ it holds that $D_i \cap R \neq \emptyset$. In addition, it holds that $|R| = \widetilde{O}(\frac{n}{L})$ and the runtime of the algorithm is $\widetilde{O}(qL)$.

The GreedyPivotsSelection algorithm works as follows. Let $\mathcal{P} = \{D_1, \ldots, D_q\}$. Starting with $R \leftarrow \emptyset$, find a vertex $v \in V$ which is contained in the maximum number of sets of $\mathcal{P}$, add it to R and remove all the sets that contain v from $\mathcal{P}$. Repeat this process until $\mathcal{P} = \emptyset$.

The following greedy selection lemma is folklore and we prove it in the full version.

▶ **Lemma 6.** *Let $1 \leq L \leq n$ and $1 \leq q < poly(n)$ be two integers. Let $D_1, \ldots, D_q \subseteq V$ be paths satisfying $|D_i| \geq L$ for every $1 \leq i \leq q$. The algorithm GreedyPivotsSelection($\{D_1, \ldots, D_q\}$) finds in $\widetilde{O}(qL)$ time a set $R \subset V$ such that for every $1 \leq i \leq q$ it holds that $R \cap D_i \neq \emptyset$ and $|R| = O(\frac{n \log q}{L}) = \widetilde{O}(n/L)$.*

Related Work - the Blocker Set Algorithm of King. We remark that the GreedyPivotsSelection algorithm is similar to the blocker set algorithm described in [20] for finding a hitting set for a set of paths. The blocker set algorithm was used in [20] to develop sequential dynamic algorithms for the APSP problem. Additional related work is that of Agarwal et al. [1]. They presented a deterministic distributed algorithm to compute APSP in an edge-weighted directed or undirected graph in $\widetilde{O}(n^{3/2})$ rounds in the Congest model by incorporating a deterministic distributed version of the blocker set algorithm.

While our derandomization framework uses the greedy algorithm (or the blocker set algorithm) to find a hitting set of vertices for a critical set of paths $D_1, \ldots, D_q$, we stress that our main contribution are the techniques to reduce the number of sets q the greedy algorithm must hit (Step 1), and the algorithms to efficiently compute the sets $D_1, \ldots, D_q$ (Step 2). These techniques are our main contribution, which enable us to use the greedy algorithm (or the blocker set algorithm) for a wider range of problems. Specifically, these techniques allow us to derandomize the best known random algorithms for the replacement paths problem and distance sensitivity oracles. We believe that our techniques can also be leveraged for additional related problems which use a sampling lemma similar to Lemma 1.

Outline. The structure of the paper is as follows. In Section 1.4 we describe some preliminaries and notations. In Section 2 we apply our framework to the replacement paths algorithm of Roditty and Zwick [26]. In Section 3 we apply our framework to the DSO of Weimann and Yuster for graphs with real-edge weights [27].

1.4 Preliminaries

Let $G = (V, E)$ be a directed weighted graph with n vertices and m edges with real edge weights $\omega(\cdot)$. Given a path P in G we define its weight $\omega(P) = \Sigma_{e \in E(P)} \omega(e)$.

Given $s, t \in V$, let $P_G(s,t)$ be a shortest path from s to t in G and let $d_G(s,t) = \omega(P_G(s,t))$ be its length, which is the sum of its edge weights. Let $|P_G(s,t)|$ denote the number of edges along $P_G(s,t)$. Note that for unweighted graphs we have $|P_G(s,t)| = d_G(s,t)$. When G is known from the context we sometimes abbreviate $P_G(s,t), d_G(s,t)$ with $P(s,t), d(s,t)$ respectively.

We define the path concatenation operator $\circ$ as follows. Let $P_1 = (x_1, x_2, \ldots, x_r)$ and $P_2 = (y_1, y_2, \ldots, y_t)$ be two paths. Then $P = P_1 \circ P_2$ is defined as the path $P = (x_1, x_2, \ldots, x_r, y_1, y_2, \ldots, y_t)$, and it is well defined if either $x_r = y_1$ or $(x_r, y_1) \in E$.

For a graph H we denote by $V(H)$ the set of its vertices, and by $E(H)$ the set of its edges. When it is clear from the context, we abbreviate $e \in E(H)$ by $e \in H$ and $v \in V(H)$ by $v \in H$.

Let P be a path which contains the vertices $u, v \in V(P)$ such that u appears before v along P. We denote by $P[u..v]$ the subpath of P from u to v.

For every edge $e \in P_G(s,t)$ a replacement path $P_G(s,t,e)$ for the triple (s,t,e) is a shortest path from s to t avoiding e. Let $d_G(s,t,e) = \omega(P_G(s,t,e))$ be the length of the replacement path $P_G(s,t,e)$.

We will assume, without loss of generality, that every replacement path $P_G(s,t,e)$ can be decomposed into a common prefix $\text{CommonPref}_{s,t,e}$ with the shortest path $P_G(s,t)$, a detour $\text{Detour}_{s,t,e}$ which is disjoint from the shortest path $P_G(s,t)$ (except for its first vertex and last vertex), and finally a common suffix $\text{CommonSuff}_{s,t,e}$ which is common with the shortest path $P_G(s,t)$. Therefore, for every edge $e \in P_G(s,t)$ it holds that $P_G(s,t,e) = \text{CommonPref}_{s,t,e} \circ \text{Detour}_{s,t,e} \circ \text{CommonSuff}_{s,t,e}$ (the prefix and/or suffix may be empty).

Let $F \subseteq V \cup E$ be a set of vertices and edges. We define the graph $G \setminus F = (V \setminus F, E \setminus F)$ as the graph obtained from G by removing the vertices and edges F. We define a replacement path $P_G(s,t,F)$ as a shortest path from s to t in the graph $G \setminus F$, and let $d_G(s,t,F) = w(P_G(s,t,e))$ be its length.

2 Deterministic Replacement Paths in $\widetilde{O}(m\sqrt{n})$ Time

In this section we apply our framework from Section 1.3 to the replacement paths algorithm of Roditty and Zwick [26].

The randomized algorithm by Roddity and Zwick as described in [26] takes $\widetilde{O}(m\sqrt{n})$ expected time. They handle separately the case that a replacement path has a short detour containing at most $\lceil \sqrt{n} \rceil$ edges, and the case that a replacement path has a long detour containing more than $\lceil \sqrt{n} \rceil$ edges. The first case is solved deterministically. The second case is solved by first sampling a subset of vertices R according to Lemma 1, where each vertex is sampled uniformly independently at random with probability $c \ln n / \sqrt{n}$ for large enough constant $c > 0$. Using this uniform sampling, it holds with high probability (of at least $1 - n^{-c+2}$) that for every long triple (s,t,e) (as defined hereinafter), the detour $\text{Detour}_{s,t,e}$ of the replacement path $P_G(s,t,e)$ contains at least one vertex of R.

▶ **Definition 7.** *Let $s,t \in V, e \in P_G(s,t)$. The triple (s,t,e) is a long triple if every replacement path from s to t avoiding e has its detour part containing more than $\lceil\sqrt{n}\rceil$ edges.*

Note that in Definition 7 we defined (s,t,e) to be a long triple if **every** replacement path from s to t avoiding e has a long detour (containing more than $\lceil\sqrt{n}\rceil$ edges). We could have defined (s,t,e) to be a long triple even if at least one replacement path from s to t avoiding e has a long detour (perhaps more similar to the definitions in [26]), however we find Definition 7 more convenient for the following reason. If (s,t,e) has a replacement path whose detour part contains at most $\lceil\sqrt{n}\rceil$ edges, then the algorithm of [26] for handling short detours finds deterministically a replacement path for (s,t,e). Hence, we only need to find the replacement paths for triples (s,t,e) for which every replacement path from s to t avoiding e has a long detour, and this is the case for which we define (s,t,e) as a long triple.

It is sufficient for the correctness of the replacement paths algorithm that the following condition holds; For every long triple (s,t,e) the detour $\text{Detour}_{s,t,e}$ of the replacement path $P_G(s,t,e)$ contains at least one vertex of R. As the authors of [26] write, the choice of the random set R is the only randomization used in their algorithm. To obtain a deterministic algorithm for the replacement paths problem and to prove Theorem 3, we prove the following deterministic alternative of Lemma 2.

▶ **Lemma 8** (Our derandomized version of Lemma 2 for the replacement paths algorithm)**.** *There exists an $\widetilde{O}(m\sqrt{n})$ time deterministic algorithm that computes a set $R \subseteq V$ of $\widetilde{O}(\sqrt{n})$ vertices, such that for every long triple (s,t,e) there exists a replacement path $P_G(s,t,e)$ whose detour part contains at least one of the vertices of R.*

Following the above description, in order to prove Theorem 3, that there exists an $\widetilde{O}(m\sqrt{n})$ deterministic replacement paths algorithm, it is sufficient to prove the derandomization Lemma 8, we do so in the following sections.

2.1 Step 1: the Method of Reusing Common Subpaths - Defining the Set $\mathcal{D}_n$

In this section we prove the following lemma.

▶ **Lemma 9.** *There exists a set $\mathcal{D}_n$ of at most n paths, each path of length exactly $\lceil\sqrt{n}\rceil$ with the following property; for every long triple (s,t,e) there exists a path $D \in \mathcal{D}_n$ and a replacement path $P_G(s,t,e)$ such that D is contained in the detour part of $P_G(s,t,e)$.*

In order to define the set of paths $\mathcal{D}_n$ and prove Lemma 9 we need the following definitions. Let $G' = G \setminus E(P_G(s,t))$ be the graph obtained by removing the edges of the path $P_G(s,t)$ from G. For two vertices u and v, let $d_{G'}(u,v)$ be the distance from u to v in G'.

We use the following definitions of the index $\rho(x)$, the set of vertices $V_{\sqrt{n}}$ and the set of paths $\mathcal{D}_n$.

▶ **Definition 10** (The index $\rho(x)$)**.** *Let $P_G(s,t) =< v_0,\ldots,v_k >$ and let $X = \{x \in V \mid \exists_{0\le i\le k}\ d_{G'}(v_i,x) = \lceil\sqrt{n}\rceil\}$ be the subset of all the vertices $x \in V$ such that there exists at least one index $0 \le i \le k$ with $d_{G'}(v_i,x) = \lceil\sqrt{n}\rceil$.*

For every vertex $x \in X$ we define the index $0 \le \rho(x) \le k$ to be the minimum index such that $d_{G'}(v_{\rho(x)},x) = \lceil\sqrt{n}\rceil$.

▶ **Definition 11** (The set of vertices $V_{\sqrt{n}}$)**.** *We define the set of vertices $V_{\sqrt{n}} = \{x \in X | \forall_{i<\rho(x)} d_{G'}(v_i,x) > \lceil\sqrt{n}\rceil\}$. In other words, $V_{\sqrt{n}}$ is the set of all vertices $x \in X$ such that for all the vertices v_i before $v_{\rho(x)}$ along $P_G(s,t)$ it holds that $d_{G'}(v_i,x) > \lceil\sqrt{n}\rceil$.*

▶ **Definition 12** (A set of paths $\mathcal{D}_n$). *For every vertex $x \in V_{\sqrt{n}}$, let $D(x)$ be an arbitrary shortest path from $v_{\rho(x)}$ to x in G' (whose length is $\lceil\sqrt{n}\rceil$ as $d_{G'}(v_{\rho(x)}, x) = \lceil\sqrt{n}\rceil$). We define $\mathcal{D}_n = \{D(x) | x \in V_{\sqrt{n}}\}$.*

Note that while $V_{\sqrt{n}}$ is uniquely defined (as it is defined according to distances between vertices) the set of paths $\mathcal{D}_n$ is not unique, as there may be many shortest paths from $v_{\rho(x)}$ to x in G', and we take $D(x) = P_{G'}(v_{\rho(x)}, x)$ to be an arbitrary such shortest path.

The basic intuition for the method of reusing common subpaths is as follows. Let $P_G(s,t,e_1), \ldots, P_G(s,t,e_r)$ be arbitrary replacement paths such that x is the $(\lceil\sqrt{n}\rceil + 1)^{\text{th}}$ vertex along the detours of all the replacement path $P_G(s,t,e_1), \ldots, P_G(s,t,e_r)$. Then one can construct replacement paths $P'_G(s,t,e_1), \ldots, P'_G(s,t,e_r)$ such that the subpath $D(x) \in \mathcal{D}_n$ is contained in all these replacement paths. Therefore, the subpath $D(x)$ is reused as a common subpath in many replacement paths. We utilize this observation in the following proof of Lemma 9.

Proof of Lemma 9. Obviously, the set $\mathcal{D}_n$ described in Definition 12 contains at most n paths, each path is of length exactly $\lceil\sqrt{n}\rceil$.

We prove that for every long triple (s,t,e) there exists a path $D \in \mathcal{D}_n$ and a replacement path $P'(s,t,e)$ *s.t.* D is contained in the detour part of $P'(s,t,e)$.

Let $P_G(s,t,e)$ be a replacement path for (s,t,e). Since (s,t,e) is a long triple then the detour part $\text{Detour}_{s,t,e}$ of $P_G(s,t,e)$ contains more than $\lceil\sqrt{n}\rceil$ edges. Let $x \in \text{Detour}_{s,t,e}$ be the $(\lceil\sqrt{n}\rceil + 1)^{\text{th}}$ vertex along $\text{Detour}_{s,t,e}$, and let v_j be the first vertex of $\text{Detour}_{s,t,e}$. Let P_1 be the subpath of $\text{Detour}_{s,t,e}$ from v_j to x and let P_2 be the subpath of $P_G(s,t,e)$ from x to t. In other words, $P_G(s,t,e) =< v_0, \ldots, v_j > \circ P_1 \circ P_2$. Since $\text{Detour}_{s,t,e}$ contains more than $\lceil\sqrt{n}\rceil$ edges and is disjoint from $P_G(s,t)$ except for the first and last vertices of $\text{Detour}_{s,t,e}$ and $P_1 \subset \text{Detour}_{s,t,e}$ it follows that P_1 is disjoint from $P_G(s,t)$ (except for the vertex v_j). In particular, since P_1 is a shortest path in $G \setminus \{e\}$ that is edge-disjoint from $P_G(s,t)$, then P_1 is also a shortest path in $G' = G \setminus E(P_G(s,t))$. We get that $d_{G'}(v_j, x) = |P_1| = \lceil\sqrt{n}\rceil$.

We prove that $j = \rho(x)$ and $x \in V_{\sqrt{n}}$. As we have already proved that $d_{G'}(v_j, x) = \lceil\sqrt{n}\rceil$, we need to prove that for every $0 \leq i < j$ it holds that $d_{G'}(v_i, x) > \lceil\sqrt{n}\rceil$. Assume by contradiction that there exists an index $0 \leq i < j$ such that $d_{G'}(v_i, x) \leq \lceil\sqrt{n}\rceil$. Then the path $\hat{P} =< v_0, \ldots, v_i > \circ P_{G'}(v_i, x) \circ P_2$ is a path from s to t that avoids e and its length is:

$$\begin{aligned} |\hat{P}| &= |< v_0, \ldots, v_i > \circ P_{G'}(v_i, x) \circ P_2| \\ &\leq i + \lceil\sqrt{n}\rceil + |P_2| \\ &< j + \lceil\sqrt{n}\rceil + |P_2| \\ &= |P_G(s, v_j) \circ P_1 \circ P_2| \\ &= |P_G(s,t,e)| \end{aligned}$$

This means that the path $\hat{P}$ is a path from s to t in $G \setminus \{e\}$ and its length is shorter than the length of the shortest path $P_G(s,t,e)$ from s to t in $G \setminus \{e\}$, which is a contradiction. We get that $d_{G'}(v_j, x) = \lceil\sqrt{n}\rceil$ and for every $0 \leq i < j$ it holds that $d_{G'}(v_i, x) > \lceil\sqrt{n}\rceil$. Therefore, according to Definitions 10 and 11 it holds that $j = \rho(x)$ and $x \in V_{\sqrt{n}}$.

Let $D(x) \in \mathcal{D}_n$, then according to Definition 12, $D(x)$ is a shortest path from $v_{\rho(x)}$ to x in G'. We define the path $P'(s,t,e) =< v_0, \ldots, v_{\rho(x)} > \circ D(x) \circ P_2$. It follows that $P'(s,t,e)$ is a path from s to t that avoids e and $|P'(s,t,e)| = |< v_0, \ldots, v_{\rho(x)} > \circ D(x) \circ P_2| = \rho(x) + \lceil\sqrt{n}\rceil + |P_2| = |P_G(s,t,e)| = d_G(s,t,e)$. Hence, $P'(s,t,e)$ is a replacement path for (s,t,e) such that $D(x) \subset P'(s,t,e)$ so the lemma follows. ◀

2.2 Step 2: the Method of Decremental Distances from a Path - Computing the Set $\mathcal{D}_n$

In this section we describe a decremental algorithm that enables us to compute the set of paths $\mathcal{D}_n$ in $\widetilde{O}(m\sqrt{n})$ time, proving the following lemma.

▶ **Lemma 13.** *There exists a deterministic algorithm for computing the set of paths $\mathcal{D}_n$ in $\widetilde{O}(m\sqrt{n})$ time.*

Our algorithm for computing the set of path $\mathcal{D}_n$ is a variant of the decremental SSSP (single source shortest paths) algorithm of King [20]. Our variant of the algorithm is used to find distances of vertices from a path rather than from a single source vertex as we define below.

Overview of the Deterministic Algorithm for Computing $\mathcal{D}_n$ in $\widetilde{O}(m\sqrt{n})$ Time. In the following description let $P = P_G(s,t)$. Consider the following assignment of weights ω to edges of G. We assign weight ϵ for every edge e on the path P, and weight 1 for all the other edges where ϵ is a small number such that $0 < \epsilon < 1/n$. We define a graph $G^w = (G, w)$ as the weighted graph G with edge weights ω. We define for every $0 \leq i \leq k$ the graph $G_i = G \setminus \{v_{i+1}, \ldots, v_k\}$ and the path $P_i = P \setminus \{v_{i+1}, \ldots, v_k\}$. We define the graph $G_i^w = (G_i, w)$ as the weighted graph G_i with edge weights ω.

The algorithm computes the graph G^w by simply taking G and setting all edge weights of $P_G(s,t)$ to be ϵ (for some small ϵ such that $\epsilon < 1/n$) and all other edge weights to be 1. The algorithm then removes the vertices of $P_G(s,t)$ from G^w one after the other (starting from the vertex that is closest to t). Loosely speaking after each vertex is removed, the algorithm computes the distances from s in the current graph. In each such iteration, the algorithm adds to $V^w_{\sqrt{n}}$ all vertices such that their distance from s in the current graph is between $\lceil\sqrt{n}\rceil$ and $\lceil\sqrt{n}\rceil + 1$. We will later show that at the end of the algorithm we have $V^w_{\sqrt{n}} = V_{\sqrt{n}}$. Unfortunately, we cannot afford running Dijkstra after the removal of every vertex of $P_G(s,t)$ as there might be n vertices on $P_G(s,t)$. To overcome this issue, the algorithm only maintains nodes at distance at most $\lceil\sqrt{n}\rceil + 1$ from s. In addition, we observe that to compute the SSSP from s in the graph after the removal of a vertex v_i we only need to spend time on nodes such that their shortest path from s uses the removed vertex. Roughly speaking, for these nodes we show that their distance from s rounded down to the closest integer must increase by at least 1 as a result of the removal of the vertex. Hence, for every node we spend time on it in at most $\lceil\sqrt{n}\rceil + 1$ iterations until its distance from s is bigger than $\lceil\sqrt{n}\rceil + 1$. As we will show later this will yield our desired running time.

In the full version we analyse the algorithm and prove Lemma 13.

Proof of Theorem 3. We summarize the $\widetilde{O}(m\sqrt{n})$ deterministic replacement paths algorithm and outline the proof of Theorem 3. First, compute in $\widetilde{O}(m\sqrt{n})$ time the set of paths $\mathcal{D}_n$ as in Lemma 13. Given $\mathcal{D}_n$, the deterministic greedy selection algorithm GreedyPivotsSelection($\mathcal{D}_n$) (as described in Lemma 2) computes a set $R \subset V$ of $\widetilde{O}(\sqrt{n})$ vertices in $\widetilde{O}(n\sqrt{n})$ time with the following property; every path $D \in \mathcal{D}_n$ contains at least one of the vertices of R. Theorem 3 follows from Lemmas 8, 9 and 13.

3 Deterministic Distance Sensitivity Oracles

Let $0 < \epsilon < 1$ and $1 \leq f = O(\frac{\log n}{\log\log n})$ be two parameters. In [27], Weimann and Yuster considered the following notion of intervals (note that in [27] they use a parameter $0 < \alpha < 1$ and we use a parameter $0 < \epsilon < 1$ such that $\epsilon = 1 - \alpha$). They define an interval of a long

simple path P as a subpath of P consisting of $n^{\epsilon/f}$ consecutive vertices, so every simple path induces less than n (overlapping) intervals. For every subset $F \subset E$ of at most f edges, and for every pair of vertices $u, v \in V$, let $P_G(u, v, F)$ be a shortest path from u to v in $G \setminus F$. The path $P_G(u, v, F)$ induces less than n (overlapping) intervals. The total number of possible intervals is less than $O(n^{2f+3})$ as each one of the (at most) $O(n^{2f+2})$ possible queries (u, v, F) corresponds to a shortest path $P_G(u, v, F)$ that induces less than n intervals.

▶ **Definition 14.** *Let $\mathcal{D}_f$ be defined as all the intervals (subpaths containing $n^{\epsilon/f}$ edges) of all the replacement paths $P_G(s, t, F)$ for every $s, t \in V, F \subseteq E \cup V$ with $|F| \leq f$.*

Weimann and Yuster apply Lemma 1 to find a set $R \subseteq V$ of $\widetilde{O}(n^{1-\epsilon/f})$ vertices that hit w.h.p. all the intervals $\mathcal{D}_f$. According to these bounds (that $\mathcal{D}_f$ contains $O(n^{2f+3})$ paths, each containing exactly $n^{\epsilon/f}$ edges) applying the greedy algorithm to obtain the set R deterministically according to Lemma 2 takes $\widetilde{O}(n^{2f+3+\epsilon/f})$ time, which is very inefficient.

In this section we assume that all weights are non-negative (so we can run Dijkstra's algorithm) and that shortest paths are unique, we justify these assumptions in the full version.

3.1 Step 1: the Method of Using Fault-Tolerant Trees to Significantly Reduce the Number of Intervals

In Lemma 15 we prove that the set of intervals $\mathcal{D}_f$ actually contains at most $O(n^{2+\epsilon})$ unique intervals, rather than the $O(n^{2f+3})$ naive upper bound mentioned above. From Lemmas 15 and 2 it follows that the GreedyPivotsSelection($\mathcal{D}_f$) finds in $\widetilde{O}(n^{2+\epsilon+\epsilon/f})$ time the subset $R \subseteq V$ of $\widetilde{O}(n^{1-\epsilon/f})$ vertices that hit all the intervals $\mathcal{D}_f$. In the full version we further reduce the time it takes for the greedy algorithm to compute the set of pivots R to $\widetilde{O}(n^{2+\epsilon})$.

▶ **Lemma 15.** $|\mathcal{D}_f| = O(n^{2+\epsilon})$.

In order to prove Lemma 15 we describe the fault-tolerant trees data-structure, which is a variant of the trees which appear in Appendix A of [9].

▶ **Definition 16.** *Let $P^L_G(s, t, F)$ be the shortest among the s-to-t paths in $G \setminus F$ that contain at most L edges and let $d^L_G(s, t, F) = \omega(P^L_G(s, t, F))$. In other words, $d^L_G(s, t, F) = \min\{\omega(P) \mid P \text{ is an } s-to-t \text{ path on at most } L \text{ edges}\}$. If there is no path from s to t in $G \setminus F$ containing at most L edges then we define $P^L_G(s, t, F) = \emptyset$ and $d^L_G(s, t, F) = \infty$. For $F = \emptyset$ we abbreviate $P^L_G(s, t, \emptyset) = P^L_G(s, t)$ as the shortest path from s to t that contains at most L edges, and $d^L_G(s, t) = d^L_G(s, t, \emptyset)$ as its length.*

Let $s, t \in V$ be vertices and let $L, f \geq 1$ be fixed integer parameters, we define the trees $FT^{L,f}(s, t)$ as follows.

- In the root of $FT^{L,f}(s, t)$ we store the path $P^L_G(s, t)$ (and its length $d^L_G(s, t)$), and also store the vertices and edges of $P^L_G(s, t)$ in a binary search tree $BST^L(s, t)$; If $P^L_G(s, t) = \emptyset$ then we terminate the construction of $FT^{L,f}(s, t)$.
- For every edge or vertex a_1 of $P^L_G(s, t)$ we recursively build a subtree $FT^{L,f}(s, t, a_1)$ as follows. Let $P^L_G(s, t, \{a_1\})$ be the shortest path from s to t that contains at most L edges in the graph $G \setminus \{a_1\}$. Then in the subtree $FT^{L,f}(s, t, a_1)$ we store the path $P^L_G(s, t, \{a_1\})$ (and its length $d^L_G(s, t, \{a_1\})$) and we also store the vertices and edges of $P^L_G(s, t, \{a_1\})$ in a binary search tree $BST^L(s, t, a_1)$; If $P^L_G(s, t, \{a_1\}) = \emptyset$ we terminate the construction of $FT^{L,f}(s, t, a_1)$. If $f > 1$ then for every vertex or edge a_2 in $P^L_G(s, t, \{a_1\})$ we recursively build the subtree $FT^{L,f}(s, t, a_1, a_2)$ as follows.

- For the recursive step, assume we want to construct the subtree $FT^{L,f}(s,t,a_1,\ldots,a_i)$. In the root of $FT^{L,f}(s,t,a_1,\ldots,a_i)$ we store the path $P^L_G(s,t,\{a_1,\ldots,a_i\})$ (and its length $d^L_G(s,t,\{a_1,\ldots,a_i\})$) and we also store the vertices and edges of $P^L_G(s,t,\{a_1,\ldots,a_i\})$ in a binary search tree $BST^L(s,t,a_1,\ldots,a_i)$. If $P^L_G(s,t,\{a_1,\ldots,a_i\})=\emptyset$ then we terminate the construction of $FT^{L,f}(s,t,a_1,\ldots,a_i)$. If $i<f$ then for every vertex or edge a_{i+1} in $P^L_G(s,t,\{a_1,\ldots,a_i\}))$ we recursively build the subtree $FT^{L,f}(s,t,a_1,\ldots,a_i,a_{i+1})$.

Observe that there are two conditions in which we terminate the recursive construction of $FT^{L,f}(s,t,a_1,\ldots,a_i)$:

- Either $i=f$ in which case $FT^{L,f}(s,t,a_1,\ldots,a_f)$ is a leaf node of $FT^{L,f}(s,t)$ and we store in the leaf node $FT^{L,f}(s,t,a_1,\ldots,a_f)$ the path $P^L_G(s,t,\{a_1,\ldots,a_f\})$.
- Or there is no path from s to t in $G\setminus\{a_1,\ldots,a_i\}$ that contains at most L edges and then $FT^{L,f}(s,t,a_1,\ldots,a_i)$ is a leaf vertex of $FT^{L,f}(s,v)$ and we store in it $P^L_G(s,t,\{a_1,\ldots,a_i\})=\emptyset$.

Querying the tree $FT^{L,f}(s,t)$. Given a query (s,t,F) such that $F\subset V\cup E$ with $|F|=f$ we would like to compute $d^L_G(s,t,F)$ using the tree $FT^{L,f}(s,t)$.

The query procedure is as follows. Let $P^L_G(s,t)$ be the path stored in the root of $FT^{L,f}(s,t)$ (if the root of $FT^{L,f}(s,t)$ contains $\emptyset$ then we output that $d^L_G(s,t,F)=\infty$). First we check if $P^L_G(s,t)\cap F=\emptyset$ by checking if any of the elements $a_1\in F$ appear in $BST^L(s,t)$ (which takes $O(\log L)$ time for each element $a_1\in F$). If $P^L_G(s,t)\cap F=\emptyset$ we output $d^L_G(s,t,F)=d^L_G(s,t)$ (as $P^L_G(s,t)$ does not contain any of the vertices or edges in F). Otherwise, let $a_1\in P^L_G(s,t)\cap F$.

We continue the search similarly in the subtree $FT^{L,f}(s,t,a_1)$ as follows. Let $P^L_G(s,t,\{a_1\})$ be the path stored in the root of $FT^{L,f}(s,t,a_1)$ (if the root of $FT^{L,f}(s,t,a_1)$ contains $\emptyset$ then we output that $d^L_G(s,t,F)=\infty$). First we check if $P^L_G(s,t,\{a_1\})\cap F=\emptyset$ by checking if any of the elements $a_2\in F$ appear in $BST^L(s,t,a_1)$ (which takes $O(\log L)$ time for each element $a_2\in F$). If $P^L_G(s,t,\{a_1\})\cap F=\emptyset$ we output $d^L_G(s,t,F)=d^L_G(s,t,\{a_1\})$ (as $P^L_G(s,t,\{a_1\})$ does not contain any of the vertices or edges in F). Otherwise, let $a_2\in P^L_G(s,t,\{a_1\})\cap F$. We continue the search similarly in the subtrees $FT^{L,f}(s,t,a_1,a_2)$, $FT^{L,f}(s,t,a_1,a_2,\ldots,a_i)$ until we either reach a leaf node which contains $\emptyset$ (and in this case we output that $d^L_G(s,t,F)=\infty$) or we find a path $P^L_G(s,t,\{a_1,\ldots,a_i\})$ such that $P^L_G(s,t,\{a_1,\ldots,a_i\})\cap F=\emptyset$ and then we output $d^L_G(s,t,F)=d^L_G(s,t,\{a_1,\ldots,a_i\})$.

In the full version we prove the following lemma.

▶ **Lemma 17.** *Given the tree $FT^{L,f}(s,t)$ and a set of failures $F\subset V\cup E$ with $|F|\le f$, the query procedure computes the distance $d^L_G(s,t,F)$ in $O(f^2\log L)$ time.*

We are now ready to prove lemma 15 asserting that $|\mathcal{D}_f|=O(n^{2+\epsilon})$.

Proof of Lemma 15. Let $L=n^{\epsilon/f}$ and let $\mathcal{D}$ be the set of all the unique shortest paths $P^L_G(s,t,\{a_1,\ldots,a_i\})$ stored in all the nodes of all the trees $\{FT^{L,f}(s,t)\}_{s,t\in V}$. Since the number of nodes in every tree $FT^{L,f}(s,t)$ is at most $L^f=(n^{\epsilon/f})^f=n^\epsilon$, and there are $O(n^2)$ trees (one tree for every pair of vertices $s,t\in V$) we get that the number of nodes in all the trees $\{FT^{L,f}(s,t)\}_{s,t\in V}$ is $O(n^{2+\epsilon})$ and hence $|\mathcal{D}|=O(n^{2+\epsilon})$.

We prove that $\mathcal{D}_f\subseteq\mathcal{D}$. By definition, $\mathcal{D}_f$ contains all the intervals (subpaths containing $n^{\epsilon/f}$ edges) of all the replacement paths $P_G(s,t,F)$ for every $s,t\in V, F\subseteq E\cup V$ with $|F|\le f$. Let $P\in\mathcal{D}_f$ be the unique shortest path, then P is a subpath containing $n^{\epsilon/f}$ edges of the replacement paths $P_G(s,t,F)$. Let u be the first vertex of P, and let v be the last vertex of P. Then P is a shortest path from u to v in $G\setminus F$, and since we assume

that the shortest paths our algorithms compute are unique then $P = P_G(u, v, F)$ is the unique shortest path from u to v in $G \setminus F$. Since P is assumed to be a path on exactly $L = n^{\epsilon/f}$ edges, then $P = P_G(u, v, F) = P_G^L(u, v, F)$. According to the query procedure in the tree $FT^{L,f}(u, v)$ and Lemma 17, if we query the tree $FT^{L,f}(u, v)$ with (u, v, F) then we reach a node $FT^{L,f}(u, v, a_1, \ldots, a_i)$ which contains the path $P_G^L(u, v, \{a_1, \ldots, a_i\})$ with $\{a_1, \ldots, a_i\} \subseteq F$ such that $P_G^L(u, v, \{a_1, \ldots, a_i\}) = P_G^L(u, v, F) = P$ is the shortest u-to-v path in $G \setminus F$. Hence, $P \in \mathcal{D}$ and thus $\mathcal{D}_f \subseteq \mathcal{D}$ and $|\mathcal{D}_f| \leq |\mathcal{D}| = O(n^{2+\epsilon})$ ◀

3.2 Step 2: Efficient Construction of the Fault-Tolerant Trees – Computing the Paths $\mathcal{D}_f$

Recall that we defined the trees $FT^{L,f}(u, v)$ with respect the parameters f (the maximum number of failures) and L (where we search for shortest paths among paths of at most L edges). The idea is to build the trees $FT^{L,f}(u, v)$ using dynamic programming having the trees $FT^{L-1,f}(u, v)$ with parameters $f, L-1$ as subproblems.

Assume we have already built the trees $FT^{i,f}(u, v)$, where $u, v \in V, 1 \leq i < L$, we describe how to build the trees $FT^{i+1,f}(u, v)$. Let (u, v, F) be a query for which we want to compute the distance $d^{i+1}(u, v, F)$ (as part of the construction of the tree $FT^{i+1,f}(u, v)$). Scan all the edges $(u, z) \in E$ and query the tree $FT^{i,f}(z, v)$ with the set F to find the distance $d^i(z, v, F)$. Querying the tree $FT^{i,f}(z, v)$ takes $O(f^2 \log i) = O(f^2 \log L)$ time as described in Lemma 17 (note that $f^2 \log L = \widetilde{O}(1)$ for $f \leq \log n$ as $L \leq n$), and we run $O(\text{out-degree(u)})$ such queries and take the minimum of the following equation.

$$d^{i+1}(u, v, F) = \min_z \{\omega(u, z) + d^i(z, v, F) \mid (u, z) \in E \;\; AND \;\; u, z, (u, z) \notin F\} \tag{1}$$

$$\text{parent}^{i+1}(u, v, F) = \arg\min_z \{\omega(u, z) + d^i(z, v, F) \mid (u, z) \in E \;\; AND \;\; u, z, (u, z) \notin F\} \tag{2}$$

Note that in Equation 1 we assume that for every vertex $u \in V$ it holds that G contains the self loops $(u, u) \in E$ such that $\omega(u, u) = 0$.

So the time to compute $d^{i+1}(u, v, F)$ is $\widetilde{O}(\text{out-degree(u)})$. Next, we describe how to reconstruct the path $P^{i+1}(u, v, F)$ in $O(L)$ additional time. We reconstruct the shortest path $P^{i+1}(u, v, F)$ by simply following the (at most L) parent pointers. In more details, let $z = \text{parent}^{i+1}(u, v, F)$ be the vertex defined according to Equation 2. We reconstruct the shortest path $P^{i+1}(u, v, F)$ by concatenating (u, z) with the shortest path $P^i(z, v, F)$ (which we reconstruct in the same way), thus we can reconstruct $P^{i+1}(u, v, F)$ edge by edge in constant time per edge, and hence it takes $O(L)$ time to reconstruct the path $P^{i+1}(u, v, F)$ that contains at most L edges.

The tree $FT^{i,f}(u, v)$ contains $i^f \leq L^f$ nodes, and thus all the trees $\{FT^{i,f}(u, v)\}$ for all $i \leq L, u, v \in V$ contain $O(n^2 L^{f+1})$ nodes together.

In each such node we compute the distance $d^i(u, v, \{a_1, \ldots, a_j\})$ in $\widetilde{O}(\text{out-degree(u)})$ time and reconstruct the path $P^i(u, v, \{a_1, \ldots, a_j\})$ in additional $O(L)$ time. Theretofore, computing all the distances $d^i(u, v, \{a_1, \ldots, a_j\})$ and all the paths $P^i(u, v, \{a_1, \ldots, a_j\})$ in all the nodes of all the trees $\{FT^{i,f}(u, v)\}_{u,v \in V, 1 \leq i \leq L}$ takes $\widetilde{O}(\sum_{i \leq L, u, v \in V} L^f(\text{out-degree(u)} + L)) = \widetilde{O}(mnL^{f+1} + n^2 L^{f+2})$ time. substituting $L = \widetilde{O}(n^{\epsilon/f})$ we get an algorithm to compute the trees $\{FT^{L,f}(u, v)\}_{u,v \in V}$ in $\widetilde{O}(mn^{1+\epsilon+\epsilon/f} + n^{2+\epsilon+2\epsilon/f})$ time.

This proves the following Lemma.

▶ **Lemma 18.** *One can deterministically construct the trees $FT^{L,f}(s, t)$ for every $s, t \in V$ in $\widetilde{O}(mn^{1+\epsilon+\epsilon/f} + n^{2+\epsilon+2\epsilon/f})$ time.*

In the full version we further reduce the runtime to $\widetilde{O}(mn^{1+\epsilon})$ by using dynamic programming only for computing the first $f-1$ levels of the trees $FT^{L,f}(s,t)$ and then applying Dijkstra in a sophisticated manner to compute the last layer of the trees $FT^{L,f}(s,t)$. In addition, we also boost-up the runtime of the greedy pivots selection algorithm from $\widetilde{O}(n^{2+\epsilon+\epsilon/f})$ to $\widetilde{O}(n^{2+\epsilon})$ time.

Abstract

The diameter, radius and eccentricities are natural graph parameters. While these problems have been studied extensively, there are no known *dynamic* algorithms for them beyond the ones that follow from trivial recomputation after each update or from solving dynamic All-Pairs Shortest Paths (APSP), which is very computationally intensive. This is the situation for dynamic *approximation* algorithms as well, and even if only edge insertions or edge deletions need to be supported.

This paper provides a comprehensive study of the dynamic approximation of Diameter, Radius and Eccentricities, providing both conditional lower bounds, and new algorithms whose bounds are optimal under popular hypotheses in fine-grained complexity. Some of the highlights include:

- Under popular hardness hypotheses, there can be no significantly better *fully dynamic approximation* algorithms than recomputing the answer after each update, or maintaining full APSP.
- Nearly optimal *partially dynamic* (incremental/decremental) algorithms can be achieved via efficient reductions to (incremental/decremental) maintenance of Single-Source Shortest Paths. For instance, a nearly $(3/2+\epsilon)$-approximation to Diameter in directed or undirected n-vertex, m-edge graphs can be maintained decrementally in total time $m^{1+o(1)}\sqrt{n}/\epsilon^2$. This nearly matches the static 3/2-approximation algorithm for the problem that is known to be conditionally optimal.

1 Introduction

Computing the shortest paths distances between all pairs of vertices in a graph, the All-Pairs Shortest Paths (APSP) problem, has been studied since the beginning of computer science as a field. Nevertheless, the fastest known algorithms [26, 20, 19] for APSP in n-vertex m-edge graphs are only slightly faster (by $n^{o(1)}$ factors) than the simple $\tilde{O}(mn)$ time[1] algorithm running Dijkstra's algorithm from every vertex[2]. For dense graphs with small integer weights there are improved algorithms [22, 28] using fast matrix multiplication [23, 17], but these algorithms are not faster than mn for sparser graphs or when the weights can be large.

There are many important graph parameters that can be easily computed when all the distances are known. These include the *eccentricity* of each vertex (the maximum length of a shortest path from the vertex to another vertex), the graph *diameter* (the maximum over all eccentricities), the *radius* (the minimum over all eccentricities) and many more. These parameters are of particular importance in the analysis of social networks (e.g. [3]), but also in graphs generated for entities such as images and search queries (and web pages).

Unfortunately, there are no significantly faster algorithms to compute these parameters than just solving APSP, and this is far from practical. In many cases the analyzed networks are so large that even enumerating all pairs of vertices is prohibitively expensive. Thus, obtaining all pairwise distances is essentially impossible. For graph parameters, on the other hand, the output is a single number; in principle looking at all vertex pairs might not be necessary, and subquadratic time algorithms (in the number of vertices) might exist for sparse graphs (whereas quadratic time is necessary for APSP as this is the size of the output). The existence of such fast algorithms is an important, practically motivated question.

In recent years, much progress has been made in understanding the complexity of graph parameter computation. Results from fine-grained complexity give that even obtaining a $(3/2-\epsilon)$-approximation for graph diameter [21] or radius [2], or a $(5/3-\epsilon)$-approximation of all eccentricities [8] (for $\epsilon > 0$) requires $n^{2-o(1)}$ time even in very sparse graphs, assuming the Strong Exponential Time Hypothesis (SETH) and related conjectures. Even stronger hardness results were obtained by Backurs et al. [6], altogether showing that most of the known algorithms for diameter, radius and eccentricities are conditionally optimal.

In addition to computing graph parameters in a static graph, a very natural goal is to maintain estimates of these parameters in a *dynamic* graph, where edges are inserted and deleted. In this setting, we would like to have a fast algorithm which preprocesses the given graph, and builds a data structure which can support edge updates efficiently and can answer queries about the parameter of interest in the current state of the data structure. This dynamic version of the problems is even more practically motivated, as real networks are naturally dynamic.

Unfortunately, the state of the art of dynamic algorithms for graph parameters such as Diameter is somewhat disappointing. The best known dynamic algorithms either just use the best known dynamic algorithms for APSP, or recompute the parameter estimate from scratch after each update. This leads to the following bounds:

(1) Demetrescu and Italiano [10] obtained a fully dynamic exact APSP algorithm with an amortized update time of $\tilde{O}(n^2)$ and $O(1)$ query time; this is the best exact dynamic algorithm for the graph parameters as well. Abboud and Vassilevska W. [1] showed that under SETH, any $(4/3-\epsilon)$-approximation fully dynamic algorithm for diameter (for $\epsilon > 0$) requires

[1] $\tilde{O}$ notation supresses polylogarithmic factors.
[2] after Johnson's trick to make the weights nonnegative

$n^{2-o(1)}$ amortized update or query time even in sparse graphs. Thus the APSP approach is conditionally optimal for fully dynamic $(4/3-\epsilon)$-approximate diameter algorithms. It is unclear however whether a 4/3-approximation with better update time is possible, and whether the APSP bounds are best for Radius.

(2) By recomputing the parameter estimates after each query, one can maintain a 2-approximation for Diameter in directed graphs and Radius in undirected graphs in worst case $O(m+n)$ time per update, and a $(2+\epsilon)$-approximation for all Eccentricities in directed graphs for all ϵ in $\tilde{O}(m/\epsilon)$ time per update using the algorithm of Backurs et al. [6]. One can also maintain a 3/2-approximation for Diameter and Radius, and a 5/3-approximation of all Eccentricities in worst case time $\tilde{O}(m^{3/2})$ per update using the algorithms of [21, 8] . More algorithms follow from the static results of Cairo, Grossi and Rizzi [7]. Can any of these algorithms be improved or are they conditionally optimal? The only related lower bounds here are (a) by Henzinger et al. [14] which showed that under the Online Matrix Vector hypothesis (OMv), any fully dynamic Diameter algorithm that achieves a $(2-\epsilon)$-approximation for undirected *weighted* graphs, or any finite approximation in directed graphs needs $n^{0.5-o(1)}$ amortized update time and (b) by Henzinger et al. [15] which proved under the combinatorial Boolean Matrix Multiplication conjecture any fully dynamic Diameter or Eccentricity algorithm that achieves a $(4/3-\epsilon)$-approximation in undirected *unweighted* graphs with $n^{3-o(1)}$ preprocessing time requires $n^{2-o(1)}$ update or query time (and the same result for undirected *weighted* graph using the APSP conjecture). While these results give some limitation, they are far from tight.

The first contributions of our paper are strong conditional lower bounds for fully dynamic graph parameter estimation. Our first result is a strengthening of the conditional lower bound for Diameter of [1]: we increase the approximation ratio from $(4/3-\epsilon)$ to $(3/2-\epsilon)$.

▶ **Theorem 1.** *Under SETH, every fully dynamic $(3/2-\epsilon)$-approximation algorithm for Diameter with polynomial preprocessing time requires $n^{2-o(1)}$ amortized update or query time in the word-RAM model of computation with $O(\log n)$ bit words, even for dynamic undirected unweighted graphs that are always sparse.*

The same limitation applies for fully dynamic $(5/3-\epsilon)$-approximation algorithms for Eccentricities with polynomial preprocessing time, and for fully dynamic $(3/2-\epsilon)$-approximation algorithms for Radius with polynomial preprocessing time, under the related Hitting Set hypothesis.

These conditional lower bounds imply that the $\tilde{O}(m^{3/2})$ time estimation algorithms that recompute the answer from scratch are optimal in the sense that any improvement of the approximation factor causes the update time to grow to n^2, and Demetrescu and Italiano's algorithm achieves $\tilde{O}(n^2)$ update time even for the exact maintenance of APSP.

We also show that recomputing a 2-approximation from scratch in linear time is close to optimal under SETH.

▶ **Theorem 2.** *Under SETH, any fully dynamic algorithm with polynomial preprocessing time that can maintain for $\epsilon > 0$ any of the following in an n node, m-edge undirected unweighted graph requires either $m^{1-o(1)}$ amortized update or query time, even when $m = \tilde{O}(n)$:*

- *a $(2-\epsilon)$-approximation of the eccentricity of a fixed vertex, or*
- *a $(2-\epsilon)$-approximation of the Radius, or*
- *a $(2-\epsilon)$-approximation of the Diameter.*

This result significantly strengthens the OMv based lower bound of [14]: the update time lower bound is now linear as opposed to $\sqrt{n}$, the result holds for unweighted graphs as well, it also holds for Radius and single-node eccentricity, and it has implications for partially dynamic algorithms with worst case time bounds, unlike the one of [14]. Furthermore, the lower bound for the eccentricity of a fixed vertex is tight in the sense that one can simply recompute the answer exactly from scratch in time $O(m)$.

Much stronger lower bounds are possible for *directed* graphs. Our first hardness result for directed graphs is that under SETH and the Hitting Set hypothesis, respectively, nearly quadratic time is needed for Eccentricities and Radius, even for $(2-\epsilon)$-approximation. (Recall that for undirected graphs we could only show this for $(3/2-\epsilon)$-approximate Radius and $(5/3-\epsilon)$-approximate Eccentricities.) This means that for directed graphs, recomputing a 2-approximation from scratch (in linear time) after each update is very much optimal – for any better approximation one might as well use the exact dynamic APSP algorithms.

▶ **Theorem 3.** *Every fully dynamic algorithm with polynomial preprocessing time for $(2-\epsilon)$-approximate (for $\epsilon > 0$) Eccentricities (under SETH) or Radius (under a version of the Hitting Set Hypothesis) in directed, unweighted graphs with n vertices and $m = \tilde{O}(n)$ edges requires amortized update or query time $m^{2-o(1)}$.*

Surprisingly, we also show conditionally that no *finite* approximation can be maintained in *sublinear* time. Henzinger et al. [14], building upon [1], showed that any finite approximation for Diameter in directed graphs requires $m^{0.5-o(1)}$ time under the OMv Hypothesis. We strengthen the lower bound to linear, using a very natural hypothesis on the complexity of k-Cycle.

All known algorithms for detecting k-cycles in sparse directed graphs with m edges run at best in time $m^{2-c/k}$ for various small constants c [27, 4, 9], even if you use powerful tools such as fast matrix multiplication. A natural hypothesis completely consistent with the state of the art of cycle detection is that one needs $m^{2-f(k)-o(1)}$ time to find a k-cycle, for some continuous (over the reals) $f(k)$ that goes to 0 as k goes to infinity. Let us call this the k-Cycle Hypothesis. We obtain:

▶ **Theorem 4.** *Under the k-Cycle Hypothesis, any fully dynamic algorithm with polynomial preprocessing time that can maintain a* finite *approximation for any of the following in an n node, $m = \tilde{O}(n)$-edge directed unweighted graph requires either $m^{1-o(1)}$ amortized update or query time:*

- *the eccentricity of a fixed vertex, or*
- *the Radius, or*
- *the Diameter.*

All known approaches to estimating graph proximity parameters such as the Diameter, at the very least require maintaining approximate distances from a single node, up to some distance. The conditional lower bounds above say that even if we only want to maintain an estimate of the largest distance from a fixed node, and even if that distance is never more than a constant, we still need linear update time. Thus, to have better than 2 approximations of our undirected distance parameters or any finite approximation in the directed case that can be maintained in sublinear time we probably need to abandon our need for fully dynamic algorithms. We thus turn to *partially* dynamic algorithms that handle either only edge insertions (incremental) or only edge deletions (decremental).

Our conditional lower bounds for the fully dynamic setting also apply to incremental and decremental algorithms that have *worst case* update and query time guarantees. This is due to the nature of our reductions: they all produce an initial graph on which we perform update

stages that only insert or only delete (we can choose which) a small batch of edges, ask a query and undo the changes just made, returning to the initial graph. An incremental/decremental algorithm can be used to implement such reductions by performing the deletions/insertions by rolling back the data structure. Because of this, we have very strong worst case lower bounds, and it makes sense to focus on amortized guarantees instead.

The strong conditional lower bounds in the static case, imply strong limitations for partially dynamic algorithms as well. For *undirected* graphs, these limitations are as follows: Due to [21, 6, 8], under SETH, every incremental and decremental algorithm for Diameter in n node undirected unweighted graphs requires total time at least $m^{3/2-o(1)}$ to maintain a $(8/5-\epsilon)$-approximation, and at least $m^{2-o(1)}$ total time to maintain a $(3/2-\epsilon)$-approximation for $\epsilon > 0$ under $m = \tilde{O}(n)$ insertions or deletions. For Eccentricities, the static conditional lower bounds are slightly stronger. For partially dynamic algorithms they imply that under SETH, for every $k \geq 1$, maintaining a $((3k+2)/(k+2)-\epsilon)$-approximation for $\epsilon > 0$ requires total time $m^{1+1/k}$ for $m = \tilde{O}(n)$ insertions or deletions. For Radius, they just imply that under the Hitting Set hypothesis [24, 2] maintaining a $(3/2-\epsilon)$-approximation requires total time $m^{2-o(1)}$ even in a sparse graph.

For *directed* graphs, there are stronger lower bounds: maintaining a $(2-\epsilon)$-approximation for Radius and Eccentricities requires total time $m^{2-o(1)}$ under Hitting Set and SETH, respectively [2, 6].

The incremental lower bounds directly follow from the static ones by starting from an empty graph and inserting edges until we reach the graph from the static construction. The decremental lower bounds hold since the static lower bound instances are all subgraphs of the same global graph, independent of the SAT/Hitting Set instance that the reduction is trying to solve; thus we start with the global graph and delete edges until reaching the graph from the static construction.

A natural question is, are these conditional lower bounds tight? Can one create partially dynamic algorithms that can achieve the same total runtime as the known static approximation algorithms? We give positive answers to these questions by developing new partially dynamic algorithms that are essentially optimal. Our algorithms are actually very efficient reductions to incremental and decremental single source shortest paths (SSSP), so that any improvement over dynamic SSSP would improve our parameter estimation algorithms.

Let D_0 and D_f be the initial and final values of the diameter, respectively. Let $T_{inc}(n, m, k, \epsilon)$ (resp., $T_{dec}(n, m, k, \epsilon)$) be the total time of an incremental (decremental) approximate SSSP algorithm from source u that maintains an estimate $d'(u, v)$ for all v such that if $d(u, v) \leq k$ then $(1-\epsilon)d(u, v) \leq d'(u, v) \leq d(u, v)$. For directed graphs we assume that the approximate SSSP algorithm works in directed graphs, and for undirected graphs, the SSSP algorithm only needs to work in undirected graphs. Our black-box reductions can be summarized in the theorem below.

▶ **Theorem 5.** *There is a Las Vegas randomized algorithm for incremental (resp., decremental) diameter in unweighted, directed graphs against an oblivious (resp., adaptive) adversary that given $\epsilon > 0$, runs in total time $\tilde{O}(\max_{D_f \leq D' \leq D_0}\{T_{inc}(n, m, D', \epsilon)\frac{\sqrt{n/D'}}{\epsilon^2}\})$ (resp., $\tilde{O}(\max_{D_0 \leq D' \leq D_f}\{T_{dec}(n, m, D', \epsilon)\frac{\sqrt{n/D'}}{\epsilon^2}\})$) with high probability, and maintains an estimate $\hat{D}$ such that $\frac{2(1-\epsilon)}{3}D - \frac{2}{3} \leq \hat{D} \leq D$ where D is the diameter of the current graph.*

We obtain similar black-box reductions for nearly $(5/3+\epsilon)$-approximate Eccentricities and $(3/2+\epsilon)$-approximate Radius in undirected graphs.

Henzinger et al. [13] obtained a randomized $(1+\epsilon)$-approximate decremental algorithm for SSSP in undirected unweighted graphs against an oblivious adversary with total expected update time $m^{1+o(1/\epsilon)}$. As an immediate corollary we obtain:

▶ **Corollary 6.** *There is a Las Vegas randomized algorithm for decremental diameter in unweighted, undirected graphs against an oblivious adversary that given $\epsilon > 0$, runs in total time $m^{1+o(1/\epsilon)}\sqrt{n}/\epsilon^2$ in expectation, and maintains an estimate $\frac{2(1-\epsilon)}{3}D - \frac{2}{3} \leq \hat{D} \leq D$, where D is the diameter of the current graph.*

Due to lower bounds in the static setting described above, this result is conditionally optimal in terms of both running time and approximation factor except for a small loss in the approximation factor. A similar result hold for decremental undirected Radius with a conditionally essentially optimal approximation factor. A similar result also holds for Eccentricities, which is conditionally essentially optimal in terms of both running time and approximation factor.

For decremental algorithms in directed graphs and for incremental algorithms in undirected or directed graphs, the best known algorithms for SSSP up to distance k are achieved by the Even and Shiloach Trees data structure [11], giving amortized update time $O(k)$. Henzinger and King recognized that this data structure can be extended to directed graphs [12]. As a corollary we obtain:

▶ **Corollary 7.** *There is a Las Vegas randomized algorithm for incremental/decremental diameter in unweighted, directed graphs that given $\epsilon > 0$, runs in total time $\tilde{O}(m\sqrt{nD_{\max}}/\epsilon^2)$ with high probability where $D_{\max}$ is the maximum diameter throughout the algorithm, and maintains an estimate $\hat{D}$ such that $\frac{2(1-\epsilon)}{3}D - 1 \leq \hat{D} \leq D$, where D is the diameter of the current graph. The incremental algorithm works against an oblivious adversary and the decremental algorithm works against an adaptive adversary.*

Similar results hold for Radius and Eccentricities but only for undirected graphs. Recall that static conditional lower bounds rule out such algorithms in directed graphs.

The algorithms so far are all randomized. We present some deterministic incremental algorithms as well, again via a reduction to incremental SSSP. Let D_0, D_f and $T_{inc}(n, m, k, \epsilon)$ be as before.

▶ **Theorem 8.** *There is a deterministic algorithm for incremental diameter in unweighted, directed graphs that, for any ϵ with $0 < \epsilon < 2$, runs in total time $\tilde{O}(\max_{D_f \leq D' \leq D_0}\{(T_{inc}(n, m, D', \epsilon) + m)n/(\epsilon^2 D')\})$, and maintains an estimate $\hat{D}$ such that $(1-\epsilon)D \leq \hat{D} \leq D$, where D is the diameter of the current graph.*

Using Even and Shiloach trees we obtain as a corollary a deterministic incremental $(1+\epsilon)$-approximation algorithm for diameter with total update time $\tilde{O}(mn/\epsilon^2)$. The running time is essentially tight for $\epsilon < 1/2$ by the SETH based quadratic lower bound for $(3/2-\delta)$-approximate static diameter [21]. Similar algorithms with essentially tight running times hold for radius in directed graphs and eccentricities in directed, strongly connected graphs.

1.1 Our techniques for partially dynamic algorithms

Our partially dynamic nearly 3/2-approximation algorithms for diameter and radius and our nearly 5/3-approximation algorithm for eccentricities are based on known algorithms in the static setting [21, 8]. These static algorithms work by carefully choosing a set U of vertices, performing SSSP from every vertex in U, and showing that at least one of these SSSP instantiations yields a good estimate for the parameter of interest. The set U is chosen as follows. We pick a random sample S of $\tilde{\Theta}(\sqrt{n})$ vertices and let w^* be the vertex that is farthest from S; that is, w^* is the vertex that maximizes $\min_{s \in S} d(w^*, s)$. Then, letting $N(w, \sqrt{n})$ be the closest $\sqrt{n}$ vertices to w, we set $U = S \cup \{w^*\} \cup N(w^*, \sqrt{n})$.

Adapting these static algorithms to the dynamic setting presents two main challenges:

(1) Firstly, given a set S of vertices, the farthest vertex w^* from S can change over time. We wish to minimize the total number of vertices that we ever run dynamic SSSP from, as reinitializing dynamic SSSP from a new vertex is expensive. Suppose we run dynamic SSSP from every vertex in $N(w^*, \sqrt{n})$ at all times. Then, every time w^* changes, we must reinitialize the dynamic SSSP data structure from $\sqrt{n}$ new vertices. If w^* changes frequently, this is prohibitively slow. To overcome this issue, we show that it suffices to choose a vertex w that *approximates* w^* (for a careful notion of approximation); and furthermore, by doing so we can limit the number of times we choose a new w.

Due to inherent differences between the incremental and decremental settings, we choose w in different ways in the different settings. In the decremental setting, distances can only increase, so our current choice of w can only become a poor approximation for w^* if $d(w^*, S)$ increases. Then, we use the fact that $d(w^*, S)$ is monotonically increasing to bound the number of times we need to choose a new w.

The incremental setting is more involved. Since distances can only decrease, our current choice of w becomes a poor approximation of w^* if $d(w, S)$ decreases. A challenge arises because unlike $d(w^*, S)$, the distance $d(w, S)$ does not change monotonically. One can imagine a scenario in which whenever we choose a new w, an edge is added causing $d(w, S)$ to immediately decrease to 1, which mandates that we choose a new w. We address this challenge by carefully employing randomness against an oblivious adversary. We argue that by randomly sampling w from a specifically chosen set of vertices, in expectation it will take a long time for w to become a poor approximation for w^*.

(2) Secondly, we wish to apply a partially dynamic SSSP algorithm as a subroutine, however the state of such algorithms is much better for undirected graphs than directed graphs. For instance, for *undirected* decremental graphs, there is a randomized $(1+\epsilon)$-approximate SSSP algorithm that runs amortized $m^{o(1)}$ time [13] (and it is believed, but not published, than a similar result is possible for incremental graphs), while for incremental/decremental *directed* graphs the best known algorithms for SSSP up to distance k run in amortized time $O(k)$ [11]. To address this discrepancy, we carefully exploit the fact that longer paths are easier to hit by randomly sampling: we augment the algorithm with an additional subsampling routine that quadratically decreases the time dependence on the diameter D.

2 Preliminaries

Let $G = (V, E)$ be a graph, where $|V| = n$ and $|E| = m$. For every $u, v \in V$ let $d_G(u, v)$ be the length of the shortest path from u to v. We omit the subscript when G is clear from context. Let $N_{out}(v, s)$ (resp., $N_{in}(v, s)$) be the set of the s closest outgoing (incoming) vertices of v, where ties are broken by taking the vertex with the smaller ID. The eccentricity $\varepsilon(v)$ of a vertex v is defined as $\max_{u \in V} d(v, u)$. The diameter D of a graph is $\max_{v \in V} \varepsilon(v)$. The radius R of a graph is $\min_{v \in V} \varepsilon(v)$.

2.1 Algorithms

For all of our algorithms for diameter, radius, and eccentricities in undirected graphs as well as diameter in directed graphs, we assume that the diameter is finite. One can easily check if this is the case by running a dynamic reachability algorithm from a single vertex. For our partially dynamic algorithms, we let D_0 and D_f be the initial and final values of the diameter, respectively. Similarly, R_0 and R_f are the initial and final values of the radius, respectively.

The running times of our randomized algorithms are with high probability, which we take to mean with probability at least $1 - 1/n^c$ for all constants c. The running times of our algorithms is written in terms of n and m, which refer to an upper bound on the number of vertices and edges, respectively, over the entire sequence of updates. That is, for incremental algorithms, the running time is written in terms of the final values of n and m and for decremental algorithms the running time written is in terms of the initial values of n and m.

Each of our algorithms is written as a reduction to a black-box incremental or decremental approximation algorithm for *truncated SSSP*; that is, SSSP which provides a distance estimate for all nodes whose distance from the source is at most a given value k. For generality, our algorithms are written for directed graphs and use directed SSSP algorithms, however if the graph is undirected one can simply run an undirected SSSP algorithm instead. Let *out*-$\mathcal{A}_{inc}(u, k, \delta)$ (resp., *out*-$\mathcal{A}_{dec}(u, k, \delta)$) be an incremental (resp., decremental) algorithm that maintains for all v an estimate $d'(u, v)$ such that if $d(u, v) \leq k$ then $(1 - \delta)d(u, v) \leq d'(u, v) \leq d(u, v)$. Analogously, let *in*-$\mathcal{A}_{inc}(u, k, \delta)$ (resp., *in*-$\mathcal{A}_{dec}(u, k, \delta)$) be an incremental (decremental) algorithm that maintains an estimate $d'(v, u)$ for all v such that if $d(u, v) \leq k$ then $(1 - \delta)d(v, u) \leq d'(v, u) \leq d(v, u)$. We assume that after every update, these algorithms output all nodes whose distance estimate has changed. Let $T_{inc}(n, m, k, \delta)$ (resp., $T_{dec}(n, m, k, \delta)$) be the total time of out-$\mathcal{A}_{inc}(u, k, \delta)$ and in-$\mathcal{A}_{inc}(u, k, \delta)$ (resp., out-$\mathcal{A}_{inc}(u, k, \delta)$ and in-$\mathcal{A}_{inc}(u, k, \delta)$) (or the corresponding undirected algorithms).

The running times of our algorithms are written as the maximum of an expression over all values of the diameter D (or radius R) throughout the entire sequence of updates. Although the maximum value of D and R in a partially dynamic graph either occurs at the beginning or end of the update sequence, the maximum value of the running time expression could occur for any value of D or R.

Suppose we run in-$\mathcal{A}_{inc}$, in-$\mathcal{A}_{dec}$, out-$\mathcal{A}_{inc}$, or out-$\mathcal{A}_{dec}$ from a vertex v. Then, let $B_{out}(v, r)$ be the set of vertices u with $d'(v, u) \leq r$.

For a subset $S \subseteq V$ of vertices and a vertex $v \in V$ we define $d(S, v) := \min_{s \in S} d(s, v)$. Similarly, $d(v, S) := \min_{s \in S} d(v, s)$. When the algorithms call for an approximation $d'(S, v)$ of $d(S, v)$, we add a dummy vertex x with an edge to every vertex in S and run out-$\mathcal{A}_{inc}$ (or out-$\mathcal{A}_{dec}$) from x; let $d'(S, v) = d'(x, v) - 1$. We define and maintain $d'(v, S)$ analogously by adding a dummy vertex with an edge from every vertex in S.

▷ Claim 9. For all $u \notin S$, $(1 - 2\delta)d(u, S) \leq d'(u, S) \leq d(u, S)$.

Proof. $(1 - 2\delta)d(u, S) = (1 - 2\delta)(d(u, x) - 1) = d(u, x) - \delta d(u, x) - 1 + \delta(2 - d(u, x)) \leq d(u, x) - \delta d(u, x) - 1 = (1 - \delta)d(u, x) - 1 \leq d'(u, x) - 1 = d'(u, S)$ and $d'(u, S) = d'(u, x) - 1 \leq d(u, x) - 1 = d(u, S)$. ◁

For all of our algorithms for diameter and eccentricities, the bulk of the argument is to prove a lemma of the following form: if one is given values P' and ϵ such that P' is at most the true value P of the parameter of interest, then there is an algorithm that outputs an estimate $\hat{P}$ such that $\alpha(1 - \epsilon)P' - \beta \leq \hat{P} \leq P$ for appropriate α and β. Lemma 10, whose proof we defer to the full version [5], states that a lemma of the above form suffices to prove our theorems. (In Lemma 10, the number k of parameters is 1 for the case of diameter and n for the case of eccentricities.) Lemma 10 also requires a fast constant-factor approximation for the parameter of interest in the static setting. Such algorithms exist for directed diameter and eccentricities in near-linear time.

Lemma 10 does not apply to radius since radius is a minimization problem, however an analogous lemma holds for radius; we defer it to the full version [5].

▶ **Lemma 10.** *Let $\pi_1, \pi_2, \ldots, \pi_k$ be a set of graph parameters (e.g. eccentricities). Suppose there is a static $\tilde{O}(T'(n,m))$ time algorithm that gives a constant-factor approximation for all π_i. Let $P_1, P_2, \ldots, P_k$ be the dynamically changing values of $\pi_1, \pi_2, \ldots, \pi_k$, respectively. Suppose there is an algorithm $\mathcal{P}$ that given a partially dynamic graph and values P' and $\epsilon > 0$, runs in total time $T(n,m,P',\epsilon)$ where T is a polynomial, and maintains a set of estimates $\hat{P}_1 \leq P_1, \ldots, \hat{P}_k \leq P_k$ such that for all i, if $P' \leq P_i$, then $\hat{P}_i \geq \alpha(1-\epsilon)P' - \beta$ for constants α and β.*

Let P_{min} and P_{max} be the minimum and maximum respectively over all P_i over the entire sequence of updates. Then there is an algorithm $\mathcal{P}'$ that given a partially dynamic graph and $\epsilon > 0$, runs in total time $\tilde{O}(T'(n,m) + \max_{P_{min} \leq P' \leq P_{max}} T(n,m,P',\epsilon)/\epsilon)$ and maintains estimates $\hat{P}_1, \ldots, \hat{P}_k$ such that for all i, $\alpha(1-\epsilon)P_i - \beta \leq \hat{P}_i \leq P_i$.

2.2 Lower bounds

Let $k \geq 2$. The k-Orthogonal Vectors Problem (k-OV) is as follows: given k sets $S_1, \ldots, S_k$, where each S_i contains n vectors in $\{0,1\}^d$, determine whether there exist $v_1 \in S_1, \ldots, v_k \in S_k$ so that their generalized inner product is 0, i.e. $\sum_{i=1}^{d} \prod_{j=1}^{k} v_j[i] = 0$. The k-OV Hypothesis is that k-OV requires $n^{k-o(1)}$ time in the word-RAM model of computation with $O(\log n)$ bit words, even for randomized algorithms.

The *unbalanced* version of k-OV has the sets S_i potentially have different sizes, $|S_i| = n_i$. The unbalanced k-OV Hypothesis is that unbalanced k-OV requires $(\prod_i n_i)^{1-o(1)}$ time. When each n_i is polynomial in n, the unbalanced k-OV Hypothesis is known to be equivalent to the k-OV Hypothesis.

R. Williams [25] (see also [24]) showed that if for some $\epsilon > 0$ there is an $n^{k-\epsilon}\text{poly}\,(d)$ time algorithm for k-OV, then CNF-SAT on formulas with N variables and m clauses can be solved in $2^{N(1-\epsilon/k)}\text{poly}\,(m)$ time. In particular, such an algorithm would contradict the Strong Exponential Time Hypothesis (SETH) of Impagliazzo, Paturi and Zane [16] which states that for every $\epsilon > 0$ there is a K such that K-SAT on N variables cannot be solved in $2^{(1-\epsilon)N}\text{poly}\,N$ time (on a word-RAM with $O(\log N)$ bit words) even by randomized algorithms. Thus SETH implies the k-OV Hypothesis for all constants k. Each of our lower bounds conditional upon SETH is a reduction from either unbalanced 2 or 3-OV

The Hitting Set (HS) problem [2] is: given two sets U and V of n vectors each in $\{0,1\}^d$, is there $u \in U$ so that for all $v \in V$, $u \cdot v \neq 0$? The HS Hypothesis states that HS requires $n^{2-o(1)}$ time in the word-RAM model with $O(\log n)$ bit words, even for randomized algorithms.

We introduce the unbalanced version of HS, for three unbalanced sets. Unbalanced 3-HS is the problem, given $U, V, W \subseteq \{0,1\}^d$ with $|U| = n, |V| = n^a, |W| = n^b$ for constants $a, b > 0$, are there $u \in U, w \in W$ so that for all $v \in V$, $u \cdot v \cdot w \neq 0$? This is in similar spirit to unbalanced 3-OV. The unbalanced 3-HS Hypothesis is that unbalanced 3-HS requires $(|U| \cdot |V| \cdot |W|)^{1-o(1)} = n^{1+a+b-o(1)}$ time in the word-RAM model with $O(\log n)$ bit words, even for randomized algorithms. Due to its similarity to 3-OV and the lack of good algorithms, the 3-HS Hypothesis is believable. Refuting it would imply some very interesting improved algorithms for a balanced variant of Quantified Boolean Formulas with 2 quantifiers [18].

As mentioned in the introduction, the k-Cycle Hypothesis is that in the word-RAM model with $O(\log n)$ bit words, any possibly randomized algorithm needs $m^{2-f(k)-o(1)}$ time to find a k-cycle in an m-edge graph, for some continuous (over the reals) $f(k)$ that goes to 0 as k goes to infinity. The Hypothesis is completely consistent with the state of the art k-Cycle algorithms (e.g. [27, 4, 9]).

3 Nearly 3/2-approximation of Diameter

In this section we present a nearly 3/2-approximation for incremental/decremental diameter, given access to a black-box incremental/decremental approximate SSSP algorithm as specified in the preliminaries. We defer the remaining algorithms to the full version [5].

▶ **Theorem 11.** *There is a Las Vegas randomized algorithm for incremental (resp., decremental) diameter in unweighted, directed graphs against an oblivious (resp., adaptive) adversary that given $\epsilon > 0$, runs in $\tilde{O}(\max_{D_f \le D' \le D_0}\{T_{inc}(n,m,D',\epsilon)\frac{\sqrt{n/D'}}{\epsilon^2}\})$ (resp., $\tilde{O}(\max_{D_0 \le D' \le D_f}\{T_{dec}(n,m,D',\epsilon)\frac{\sqrt{n/D'}}{\epsilon^2}\})$) total time with high probability, and maintains an estimate $\hat{D}$ such that $\frac{2(1-\epsilon)}{3}D - \frac{2}{3} \le \hat{D} \le D$ where D is the diameter of the current graph.*

By Lemma 10, the following lemma implies Theorem 11.

▶ **Lemma 12.** *There is a Las Vegas algorithm for incremental (resp., decremental) diameter in unweighted, directed graphs against an oblivious (resp., adaptive) adversary that given $D', \epsilon > 0$, runs in $\tilde{O}\left(T_{inc}(n,m,D',\epsilon)\frac{\sqrt{n/D'}}{\epsilon}\right)$ (resp., $\tilde{O}\left(T_{dec}(n,m,D',\epsilon)\frac{\sqrt{n/D'}}{\epsilon}\right)$) total time with high probability, and maintains an estimate $\hat{D} \le D$ such that if $D' \le D$ then $\hat{D} \ge \frac{2(1-\epsilon)}{3}D' - \frac{2}{3}$ where D is the diameter of the current graph.*

Algorithm

Here we give the algorithm for Lemma 12. We defer the proof to the full version [5]. Let $\delta = 2\epsilon/11$. Throughout the incremental (resp., decremental) algorithm we will run in-$\mathcal{A}_{inc}$ (in-$\mathcal{A}_{dec}$) and out-$\mathcal{A}_{inc}$ (out-$\mathcal{A}_{dec}$) from certain sets of vertices. For ease of notation, we let in-$\mathcal{A}$ denote either in-$\mathcal{A}_{inc}$ or in-$\mathcal{A}_{dec}$, depending on the setting, and similarly we let out-$\mathcal{A}$ denote either out-$\mathcal{A}_{inc}$ or out-$\mathcal{A}_{dec}$.

Initialization. Let α be such that $D' = \Theta(n^{1-2\alpha})$. We randomly sample a set S of size $\Theta(n^\alpha \log^2 n)$ so that with high probability, for every vertex v, after every update, S hits $N_{out}(v, n^{1-\alpha})$. Throughout the entire execution of the algorithm, for all $s \in S$ we run in-$\mathcal{A}(s, D', \delta)$. Additionally, we maintain the approximate distance $d'(v, S)$ from every vertex v to S as described in the preliminaries. Let W be the dynamically changing set of vertices v that satisfy $d'(v, S) > D'/3$.

Phases. In the incremental setting on the other hand, distances can decrease so vertices can leave W. The incremental algorithm may have many phases, and at the beginning of each phase, we choose $w \in W$ uniformly at random. The beginning of a new phase is triggered when w leaves the set W.

Throughout the phase, we run out-$\mathcal{A}(w, D', \delta)$. Also, we will define a subset $S' \subseteq B_{out}(w, \frac{D'}{3})$ and for all $s' \in S'$, we run in-$\mathcal{A}(s', D', \delta)$. S' is initially empty and we independently add each vertex in $B_{out}(w, \frac{D'}{3})$ to S' with probability $\min\{1, \frac{\log^2 n}{\delta D'}\}$. In the incremental setting (but not the decremental setting), $B_{out}(w, \frac{D'}{3})$ can grow, and whenever a vertex u joins $B_{out}(w, \frac{D'}{3})$ we add u to S' with probability $\min\{1, \frac{\log^2 n}{\delta D'}\}$.

Reinitialization. We reinitialize the entire algorithm if at any point during the execution of the algorithm, any of the following occur: (1) $|B_{out}(w, \frac{D'}{3})| > n^{1-\alpha}$, (2) $|S'| > \frac{n^{1-\alpha}\log^4 n}{\delta D'}$, or (3) there is a vertex $v \in B_{out}(w, \frac{D'}{3})$ such that $d'(v, S') > \delta D'$. We will show in the analysis that with high probability we never reinitialize the algorithm.

Query. Following each update, the return value $\hat{D}$ is the maximum distance estimate found over all instantiations of out-$\mathcal{A}$ and in-$\mathcal{A}$. That is,
$\hat{D} = \max\{\max_{v\in V} d'(w, v), \max_{v\in V, s\in S\cup S'} d'(v, s)\}$.

To maintain this value, we maintain the following heaps. For every vertex v that we run out-$\mathcal{A}$ (resp., out-$\mathcal{A}$) from, we keep a max-heap $\mathcal{H}(v)$ that stores for each other vertex u the estimate $d'(v, u)$ (resp., $d'(u, v)$). Let $\hat{d}_{out}(v)$ be the value that $\mathcal{H}(v)$ outputs. Additionally we keep a max-heap $\mathcal{H}$ which stores each $\hat{d}_{out}(v)$.

4 $(2-\epsilon)$-approximation requires linear update time

In this section we give a linear lower bound per update for $(2-\epsilon)$-approximation for diameter, radius, and fixed-vertex eccentricity of undirected graphs. We defer the remaining proofs to the full version [5].

▶ **Theorem 13.** *Let t, ϵ, and ϵ' be positive constants. SETH implies that there exists no fully dynamic algorithm for $(2-\epsilon)$-approximate Diameter, Radius, or fixed-vertex Eccentricity on undirected, unweighted graphs with n vertices and $\tilde{O}(n)$ edges, which has preprocessing time $p(n) = O(n^t)$, amortized update time $u(n) = O(n^{1-\epsilon'})$, and amortized query time $q(n) = O(n^{1-\epsilon'})$. The same holds for the incremental/ decremental settings, for worst-case update and query times.*

Proof of Theorem 13.

Initialization

Let $a = \lceil \frac{2-\epsilon}{2\epsilon} \rceil + 1$ and $\delta = \frac{1-\epsilon'}{t}$. We begin with an instance of 2-OV with vector sets U and V of vectors, with $|U| = N^{\delta}$ and $|V| = N^{1-\delta}$. We create a graph G as follows. Add a node s and for each coordinate c, create two paths of length $2a$ beginning at s, and denote the endpoints of the paths by c_{left} and c_{right}.

Next, create two paths of length a for each vector $u \in U$. Denote the endpoints of one path by u^0_{left} and u^a_{left}, and the endpoints of the other by u^0_{right} and u^a_{right}. Finally, we encode each vector $u \in U$ in the graph by connecting u^a_{left} to c_{left} with a path of length a if $u[c] = 1$, and doing the same on the right side of G. If u has no coordinates equal to 1, then we may report that there is an orthogonal pair and halt; thus there will be no disconnected nodes in G.

Dynamic stages

We proceed in $N^{1-\delta}$ stages, one for each element $v \in V$. For the current v, for each coordinate c where $v[c] = 1$, we add edges (s, c_{left}) and (s, c_{right}). We then query the diameter or radius of G or the eccentricity of s. We will show that the eccentricity of s is always equal to the radius, and that if the diameter is least $8a$ or the radius is at least $4a$, then there is an orthogonal pair u, v; otherwise, the diameter is at most $4a+2$ or the radius is at most $2a+1$. We have set a so that a $(2-\epsilon)$-approximation algorithm for diameter, radius or eccentricity of s distinguishes between these two cases and thus detects an orthogonal pair. If the query

does not detect an orthogonal pair, we undo the edge additions for the stage and continue to the next v. We can modify the stage to be decremental by beginning with edges from s to all nodes c_{left} and c_{right}, and removing the excess edges each stage.

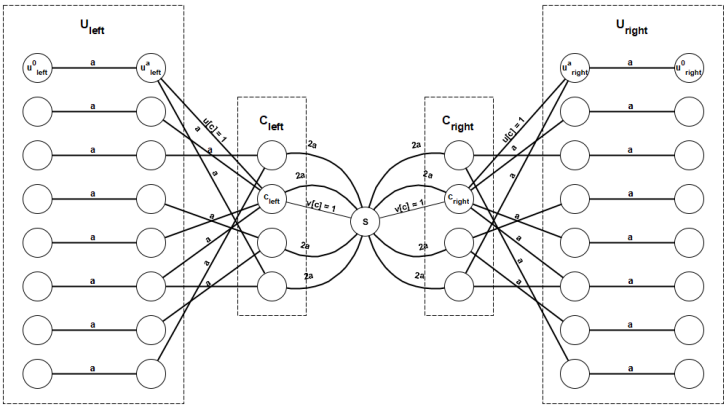

Figure 1 Sketch of Theorem 13 Construction. Bold edges represent paths, whose labels denote their length.

Correctness

We claim that the node s is always the center of G, so the eccentricity of s is always the radius of G. Let x_{right} be the node farthest from s on the right side of G. Since the graph is symmetrical, the counterpart x_{left} of x_{right} is such that $d(s, x_{right}) = d(s, x_{left})$. Any node y to the left of s must pass through s to reach x_{right}, so y has a higher eccentricity than s because it is farther from the node farthest from s. Symmetrically, any node y to the right of s must pass through s to reach x_{left}, so y has a higher eccentricity than s because it is farther from the node farthest from s.

If for the current stage, for all u, $u \cdot v \neq 0$, then for each u there must be some coordinate c such that $u[c] = v[c] = 1$. Then there is a path of length 1 from s to c_{left}, and a path of length a from c_{left} to u^a_{left}, for all u. The same is true on the right side. Then since all nodes except s are of distance at most a from a node u'^a_{left} or u'^a_{right} for some $u' \in U$, all nodes are accessible in at most $2a + 1$ steps from s. This means that the radius and eccentricity of s is $2a + 1$, and the diameter is at most $4a + 2$.

If for the current stage there is some u such that $u \cdot v = 0$, then there is no direct path from s to u^0 on either side via a vector coordinate c and u^a. A path via a different u'_a would be of length at least $4a+1$, because returning to a c' where $u[c'] = 1$ would cost an additional $2a$ from the direct path. The shortest path would thus be along the length-$2a$ path from s to c', giving $d(s, u^0) = 4a$. The radius and eccentricity of s must be at least $4a$ and diameter must be at least $8a$, because $d(u^0_{left}, u^0_{right}) = d(s, u^0_{left}) + d(s, u^0_{right}) = 4a + 4a = 8a$.

Running time

We assume for the sake of contradiction that the algorithm of Theorem 13 exists. Let $n = N^\delta$ be the size of G. We have that $u(n) = q(n) = O((N^\delta)^{1-\epsilon'})$. After initialization and $|V| = N^{1-\delta}$ stages, the total update and query time is then at most $\tilde{O}(N^{1-\delta\epsilon'})$. The preprocessing time $p(n)$ for the algorithm on G is $O((N^\delta)^t) = O(N^{1-\epsilon'})$. Thus the total time of the algorithm is $\tilde{O}(N^{1-\epsilon'} + N^{1-\delta\epsilon'})$. This contradicts SETH, because SETH implies that no algorithm exists for 2-OV in $O((|U| \cdot |V|)^{1-\epsilon''}) = O(N^{1-\epsilon''})$ time for any $\epsilon'' > 0$. ◀

Abstract

Many modern parallel systems, such as MapReduce, Hadoop and Spark, can be modeled well by the MPC model. The MPC model captures well coarse-grained computation on large data – data is distributed to processors, each of which has a sublinear (in the input data) amount of memory and we alternate between rounds of computation and rounds of communication, where each machine can communicate an amount of data as large as the size of its memory. This model is stronger than the classical PRAM model, and it is an intriguing question to design algorithms whose running time is smaller than in the PRAM model.

In this paper, we study two fundamental problems, 2-edge connectivity and 2-vertex connectivity (biconnectivity). PRAM algorithms which run in $O(\log n)$ time have been known for many years. We give algorithms using roughly log diameter rounds in the MPC model. Our main results are, for an n-vertex, m-edge graph of diameter D and bi-diameter D', 1) a $O(\log D \log\log_{m/n} n)$ parallel time 2-edge connectivity algorithm, 2) a $O(\log D \log^2 \log_{m/n} n + \log D' \log\log_{m/n} n)$ parallel time biconnectivity algorithm, where the bi-diameter D' is the largest cycle length over all the vertex pairs in the same biconnected component. Our results are fully scalable, meaning that the memory per processor can be $O(n^\delta)$ for arbitrary constant $\delta > 0$, and the total memory used is linear in the problem size. Our 2-edge connectivity algorithm achieves the same parallel time as the connectivity algorithm of [4]. We also show an $\Omega(\log D')$ conditional lower bound for the biconnectivity problem.

1 Introduction

The success of modern parallel and distributed systems such as MapReduce [16, 17], Spark [41], Hadoop [39], Dryad [23], together with the need to solve problems on massive data, is driving the development of new algorithms which are more efficient and scalable in these large-scale systems. An important theoretical problem is to develop models which are good abstractions of these computational frameworks. The *Massively Parallel Computation (MPC)* model [25, 21, 11, 3, 9, 15, 4] captures the capabilities of these computational systems while keeping the description of the model itself simple. In the MPC model, there are machines (processors), each with $\Theta(N^\delta)$ local memory, where N denotes the size of the input and $\delta \in (0, 1)$. The computation proceeds in rounds, where each machine can perform unlimited local computation in a round and exchange $O(N^\delta)$ data at the end of the round. The parallel time of an algorithm is measured by the total number of computation-communication rounds. The MPC model is a variant of the Bulk Synchronous Parallel (BSP) model [38]. It is also a more powerful model than the PRAM since any PRAM algorithm can be simulated in the MPC model [25, 21] while some problem can be solved in a faster parallel time in the MPC model. For example, computing the XOR of N bits takes $O(1/\delta)$ parallel time in the MPC model but needs near-logarithmic parallel time on the most powerful CRCW PRAM [10].

A natural question to ask is: which problems can be solved in faster parallel time in the MPC model than on a PRAM? This question has been studied by a line of recent papers [25, 19, 29, 3, 1, 6, 22, 15, 7, 14, 13, 32, 20]. Most of these results studied the graph problems, which are the usual benchmarks of parallel/distributed models. Many graph problems such as graph connectivity [35, 33, 30], graph biconnectivity [37, 36], maximal matching [26], minimum spanning tree [27] and maximal independent set [31, 2] can be solved in the standard logarithmic time in the PRAM model, but these problems have been shown to have a better parallel time in the MPC model.

In addition, we hope to develop *fully scalable* algorithms for the graph problems, i.e., the algorithm should work for any constant $\delta > 0$. The previous literatures show that a graph problem in the MPC model with large local memory size may be much easier than the same problem in the MPC model but with a smaller local memory size. In particular, when the local memory size per machine is close to the number of vertices n, many graph problems have efficient algorithms. For example, if the local memory size per machine is $n/\log^{O(1)} n$, the connectivity problem [7] and the approximate matching problem [5] can be solved in $O(\log \log n)$ parallel time. If the local memory size per machine is $\Omega(n)$, then the MPC model meets the congested clique model [12]. In this setting, the connectivity problem and the minimum spanning tree problem can be solved in $O(1)$ parallel time [24]. If the local memory size per machine is $n^{1+\Omega(1)}$, many graph problems such as maximal matching, approximate weighted matchings, approximate vertex and edge covers, minimum cuts, and the biconnectivity problem can be solved in $O(1)$ parallel time [29, 8]. The landscape of graph algorithms in the MPC model with small local memory is more nuanced and challenging for algorithm designers. If the local memory size per machine is $n^{1-\Omega(1)}$, then the best connectivity algorithm takes parallel time $O(\log D \log \log n)$ where D is the diameter of the graph [4], and the best approximate maximum matching algorithm takes parallel time $\widetilde{O}(\sqrt{\log n})$ [32].

Therefore, the main open question is: which kind of the graph problems can have faster fully scalable MPC algorithms than the standard logarithmic PRAM algorithms?

Two fundamental graph problems in graph theory are 2-edge connectivity and 2-vertex connectivity (biconnectivity). In this work, we studied these two problems in the MPC model. Consider an n-vertex, m-edge undirected graph G. A bridge of G is an edge whose removal

increases the number of connected components of G. In the 2-edge connectivity problem, the goal is to find all the bridges of G. For any two different edges e, e' of G, e, e' are in the same biconnected component (block) of G if and only if there is a simple cycle which contains both e, e'. If we define a relation R such that eRe' if and only if $e = e'$ or e, e' are contained by a simple cycle, then R is an equivalence relation [18]. Thus, a biconnected component is an induced graph of an equivalence class of R. In the biconnectivity problem, the goal is to output all the biconnected components of G. We proposed faster, fully scalable algorithms for the both 2-edge connectivity problem and the biconnectivity problem by parameterizing the running time as a function of the *diameter* and the *bi-diameter* of the graph. The diameter D of G is the largest diameter of its connected components. The definition of bi-diameter is a natural generalization of the definition of diameter. If vertices u, v are in the same biconnected component, then the cycle length of (u, v) is defined as the minimum length of a simple cycle which contains both u and v. The bi-diameter D' of G is the largest cycle length over all the vertex pairs (u, v) where both u and v are in the same biconnected component. Our main results are 1) a fully scalable $O(\log D \log \log_{m/n} n)$ parallel time 2-edge connectivity algorithm, 2) a fully scalable $O(\log D \log^2 \log_{m/n} n + \log D' \log \log_{m/n} n)$ parallel time biconnectivity algorithm. Our 2-edge connectivity algorithm achieves the same parallel time as the connectivity algorithm of [4]. We also show an $\Omega(\log D')$ conditional lower bound for the biconnectivity problem.

1.1 The Model

Our model of computation is the Massively Parallel Computation (MPC) model [25, 21, 11].

Consider two non-negative parameters $\gamma \geq 0, \delta > 0$. In the (γ, δ)-MPC model [4], there are p machines (processors) each with local memory size s, where $p \cdot s = \Theta(N^{1+\gamma}), s = \Theta(N^{\delta})$ and N denotes the size of the input data. Thus, the space per machine is sublinear in N, and the total space is only an $O(N^{\gamma})$ factor more than the input size. In particular, if $\gamma = 0$, the total space available in the system is linear in the input size N. The space size is measured by words each containing $\Theta(\log(s \cdot p))$ bits. Before the computation starts, the input data is distributed on $\Theta(N/s)$ input machines. The computation proceeds in rounds. In each round, each machine can perform local computation on its local data, and send messages to other machines at the end of the round. In a round, the total size of messages sent/received by a machine should be bounded by its local memory size $s = \Theta(N^{\delta})$. For example, a machine can send s size 1 messages to s machines or send a size s message to 1 machine in a single round. However, it cannot broadcast a size s message to every machine. In the next round, each machine only holds the received messages in its local memory. At the end of the computation, the output data is distributed on the output machines. An algorithm in this model is called a (γ, δ)-MPC algorithm. The parallel time of an algorithm is the total number of rounds needed to finish its computation. In this paper, we consider δ an arbitrary constant in $(0, 1)$.

1.2 Our Results

Our main results are efficient MPC algorithms for 2-edge connectivity and biconnectivity problems. In our algorithms, one important subroutine is computing the Depth-First-Search (DFS) sequence [4] which is a variant of the Euler tour representation proposed by [37, 36] in 1984. We show how to efficiently compute the DFS sequence in the MPC model with linear total space. Conditioned on the hardness of the connectivity problem in the MPC model, we prove a hardness result on the biconnectivity problem.

For 2-edge connectivity and biconnectivity, the input is an undirected graph $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges. $N = n + m$ denotes the size of the representation of G, D denotes the diameter of G, and D' denotes the bi-diameter of G. We state our results in the following.

Biconnectivity. In the biconnectivity problem, we want to find all the biconnected components (blocks) of the input graph G. Since the biconnected components of G define a partition on E, we just need to color each edge, i.e., at the end of the computation, $\forall e \in E$, there is a unique tuple (x, c) with $x = e$ stored on an output machine, where c is called the color of e, such that the edges e_1, e_2 are in the same biconnected components if and only if they have the same color.

▶ **Theorem 1** (Biconnectivity in MPC). *For any $\gamma \in [0, 2]$ and any constant $\delta \in (0, 1)$, there is a randomized (γ, δ)-MPC algorithm which outputs all the biconnected components of the graph G in $O\left(\log D \cdot \log^2 \frac{\log n}{\log(N^{1+\gamma}/n)} + \log D' \cdot \log \frac{\log n}{\log(N^{1+\gamma}/n)}\right)$ parallel time. The success probability is at least 0.95. If the algorithm fails, then it returns FAIL.*

The worst case is when the input graph is sparse and the total space available is linear in the input size, i.e., $N = n + m = O(n)$ and $\gamma = 0$. In this case, the parallel running time of our algorithm is $O(\log D \cdot \log^2 \log n + \log D' \cdot \log \log n)$. If the graph is slightly denser ($m = n^{1+c}$ for some constant $c > 0$), or the total space is slightly larger ($\gamma > 0$ is a constant), then we obtain $O(\log D + \log D')$ time.

A cut vertex (articulation point) in the graph G is a vertex whose removal increases the number of connected components of G. Since a vertex v is a cut vertex if and only if there are two edges e_1, e_2 which share the endpoint v and e_1, e_2 are not in the same biconnected component, our algorithm can also find all the cut vertices of G.

2-Edge connectivity. In the 2-edge connectivity problem, we want to output all the bridges of the input graph G. Since an edge is a bridge if and only if each of its endpoints is either a cut vertex or a vertex with degree 1, the 2-edge connectivity problem should be easier than the biconnectivity problem. We show how to solve 2-edge connectivity in the same parallel time as the algorithm proposed by [4] for solving connectivity.

▶ **Theorem 2** (2-Edge connectivity in MPC). *For any $\gamma \in [0, 2]$ and any constant $\delta \in (0, 1)$, there is a randomized (γ, δ)-MPC algorithm which outputs all the bridges of the graph G in $O\left(\log D \cdot \log \frac{\log n}{\log(N^{1+\gamma}/n)}\right)$ parallel time. The success probability is at least 0.97. If the algorithm fails, then it returns FAIL.*

DFS sequence. A rooted tree with a vertex set V can be represented by $n = |V|$ pairs $(v_1, \text{par}(v_1)), (v_2, \text{par}(v_2)), \cdots, (v_n, \text{par}(v_n))$ where $\text{par} : V \to V$ is a set of parent pointers, i.e., for a non-root vertex v, $\text{par}(v)$ denotes the parent of v, and for the root vertex v, $\text{par}(v) = v$. We show an algorithm which can compute the DFS sequence (Definition 6) of the rooted tree in the MPC model with linear total space.

▶ **Theorem 3** (DFS sequence of a tree in MPC). *Given a rooted tree represented by a set of parent pointers $\text{par} : V \to V$, there is a randomized $(0, \delta)$-MPC algorithm which outputs the DFS sequence in $O(\log D)$ parallel time, where $\delta \in (0, 1)$ is an arbitrary constant, D is the depth of the tree. The success probability is at least 0.99. If the algorithm fails, then it returns FAIL.*

Conditional hardness for biconnectivity. A conjectured hardness for the connectivity problem is the *one cycle vs. two cycles* conjecture: for any $\gamma \geq 0$ and any constant $\delta \in (0,1)$, any (γ,δ)-MPC algorithm requires $\Omega(\log n)$ parallel time to determine whether the input n-vertex graph is a single cycle or contains two disjoint length $n/2$ cycles. This conjectured hardness result is widely used in the MPC literature [25, 11, 28, 34, 40]. Under this conjecture, we show that $\Omega(\log D')$ parallel time is necessary for the biconnectivity problem, and this is true even when $D = O(1)$, i.e., the diameter of the graph is a constant.

▶ **Theorem 4** (Hardness of biconnectivity in MPC). *For any $\gamma \geq 0$ and any constant $\delta \in (0,1)$, unless there is a (γ,δ)-MPC algorithm which can distinguish the following two instances: 1) a single cycle with n vertices, 2) two disjoint cycles each contains $n/2$ vertices, in $o(\log n)$ parallel time, any (γ,δ)-MPC algorithm requires $\Omega(\log D')$ parallel time for testing whether a graph G with a constant diameter is biconnected.*

1.3 Our Techniques

Biconnectivity. At a high level our biconnectivity algorithm is based on a framework proposed by [36]. The main idea is to construct a new graph and reduce the problem of finding biconnected components of G to the problem of finding connected components of the new graph G'. At first glance, it should be efficiently solved by the connectivity algorithm [4]. However, there are two main issues: 1) since the parallel time of the MPC connectivity algorithm of [4] depends on the diameter of the input graph, we need to make the diameter of G' small, 2) we need to construct G' efficiently. Let us first consider the first issue, and we will discuss the second issue later.

We give an analysis of the diameter of $G' = (V', E')$ constructed by [36]. Without loss of generality, we can suppose the input $G = (V, E)$ is connected. Each vertex in G' corresponds to an edge of G. Let T be an arbitrary spanning tree of G with depth d. Each non-tree edge e can define a simple cycle C_e which contains the edge e and the unique path between the endpoints of e in the tree T. Thus, the length of C_e is at most $2d + 1$. If there is a such cycle containing any two tree edges $(u, v), (v, w)$, vertices $(u, v), (v, w)$ are connected in G'. For each non-tree edge e, we connect the vertex e to the vertex e' in graph G' where e' is an arbitrary tree edge in the cycle C_e. By the construction of G', any e, e' from the same connected components of G' should be in the same biconnected components of G. Now consider arbitrary two edges e, e' in the same biconnected component of G. There must be a simple cycle C which contains both edges e, e' in G. Since all the simple cycles defined by the non-tree edges are a cycle basis of G [18], the edge set of C can be represented by the xor sum of all the edge sets of k basis cycles $C_1, C_2, \cdots, C_k$ where C_i is a simple cycle defined by a non-tree edge e_i on the cycle C. k is upper bounded by the bi-diameter of G. Furthermore, we can assume C_i intersects C_{i+1}. There should be a path between e, e' in G', and the length of the path is at most $\sum_{i=1}^{k} |C_i| \leq O(k \cdot d)$. So, the diameter of G' is upper bounded by $O(k \cdot d)$. Thus, according to [4], we can find the connected components of G' in $\sim (\log k + \log d)$ parallel time, where d and k are upper bounded by the diameter and the bi-diameter of G respectively.

Now let us consider how to construct G' efficiently. The bottleneck is to determine whether the tree edges $(u, v), (v, w)$ should be connected in G' or not. Suppose w is the parent of v and v is the parent of u. The vertex (u, v) should connect to the vertex (v, w) in G' if and only if there is a non-tree edge that connects a vertex x in the subtree of u and a vertex y which is on the outside of the subtree of v. For each vertex x, let $\mathrm{lev}(x)$ be the minimum depth of the least common ancestor (LCA) of (x, y) over all the non-tree edges

(x, y). Then (u, v) should be connected to (v, w) in G' if and only if there is a vertex x in the subtree of u in G such that $\text{lev}(x)$ is smaller than the depth of v. Since the vertices in a subtree should appear consecutively in the DFS sequence, this question can be solved by some range queries over the DFS sequence. Next, we will discuss how to compute the DFS sequence of a tree.

DFS sequence. The DFS sequence of a tree is a variant of the Euler tour representation of the tree. For an n-vertex tree T, [36] gives an $O(\log n)$ parallel time PRAM algorithm for the Euler tour representation of T. However, since their construction method will destroy the tree structure, it is hard to get a faster MPC algorithm based on this framework. Instead, we follow the leaf sampling framework proposed by [4]. Although the DFS sequence algorithm proposed by [4] takes $O(\log d)$ time where d is the depth of T, it needs $\Omega(n \log d)$ total space. The bottleneck is the subroutine which needs to solve the least common ancestors problem and generate multiple path sequences. The previous algorithm uses the doubling algorithm for the subroutine, i,e., for each vertex v, they store the 2^i-th ancestor of v for every $i \in [\lceil \log d \rceil]$. This is the reason why [4] cannot achieve the linear total space. We show how to compress the tree T into a new tree T' which only contains at most $n/\lceil \log d \rceil$ vertices. We argue that applying the doubling algorithm on T' is sufficient for us to find the DFS sequence of T.

2-Edge connectivity. Without loss of generality, we can assume the input graph G is connected. Consider a rooted spanning tree T and an edge $e = (u, v)$ in G. Suppose the depth of u is at least the depth of v in T, i.e., v cannot be a child of u. The edge e is not a bridge if and only if either e is a non-tree edge or there is a non-tree edge (x, y) connecting the subtree of u and a vertex on the outside of the subtree of u. Similarly, the second case can be solved by some range queries over the DFS sequence of T.

Conditional hardness for biconnectivity. We want to reduce the connectivity problem to the biconnectivity problem. For an undirected graph G, if we add an additional vertex v^* and connects v^* to every vertex of G, then the diameter of the resulting graph G' is at most 2 and each biconnected components of G' corresponds to a connected component of G. Furthermore, the bi-diameter of G' is upper bounded by the diameter of G plus 2. Therefore, if the parallel time of an algorithm $\mathcal{A}'$ for finding the biconnected components of G' depends on the bi-diameter of G', there exists an algorithm $\mathcal{A}$ which can find all the connected components of G in the parallel time which has the same dependence on the diameter of G.

1.4 A Roadmap

Section 2 introduces the notation and some useful definitions. Section 3 describes the offline algorithms for 2-edge connectivity and biconnectivity. It also includes some crucial properties of the algorithms. In Section 4, we show an linear space offline algorithm to find the DFS sequence of a tree. All of these offline algorithms can be implemented in the MPC model efficiently. Section 5 contains the conditional hardness result for the biconnectivity problem in the MPC model. For the MPC implementations and all the missing technical proofs, we refer readers to the full version of the paper.

2 Preliminaries

2.1 Notation

We follow the notation of [4]. $[n]$ denotes the set of integers $\{1, 2, \cdots, n\}$.

Diameter and bi-diameter. Consider an undirected graph G with a vertex set V and an edge set E. For any two vertices u, v, we use $\text{dist}_G(u, v)$ to denote the distance between u and v in graph G. If u, v are not in the same (connected) component of G, then $\text{dist}_G(u, v) = \infty$. The diameter $\text{diam}(G)$ of G is the largest diameter of its connected components, i.e., $\text{diam}(G) = \max_{u,v \in V: \text{dist}_G(u,v) \neq \infty} \text{dist}_G(u, v)$. $(v_1, v_2, \cdots, v_k) \in V^k$ is a cycle of length $k - 1$ if $v_1 = v_k$ and $\forall i \in [k - 1], (v_i, v_{i+1}) \in E$. We say a cycle $(v_1, v_2, \cdots, v_k)$ is simple if $k \geq 4$ and each vertex only appears once in the cycle except v_1 (v_k). Consider two different vertices $u, v \in V$. We use $\text{cyclen}_G(u, v)$ to denote the minimum length of a simple cycle which contains both vertices u and v. If there is no simple cycle which contains both u and v, $\text{cyclen}_G(u, v) = \infty$. $\text{cyclen}_G(u, u)$ is defined as 0. The bi-diameter of G, $\text{bi-diam}(G)$, is defined as $\max_{u,v \in V: \text{cyclen}_G(u,v) \neq \infty} \text{cyclen}_G(u, v)$.

Representation of a rooted forest. Let V denote a set of vertices. We represent a rooted forest in the same manner as [4]. Consider a mapping $\text{par} : V \to V$. For $i \in \mathbb{N}_{>0}$ and $v \in V$, we define $\text{par}^{(i)}(v)$ as $\text{par}(\text{par}^{(i-1)}(v))$, and $\text{par}^{(0)}(v)$ is defined as v itself. If $\forall v \in V, \exists i > 0$ such that $\text{par}^{(i)}(v) = \text{par}^{(i+1)}(v)$, then we call par a set of parent pointers on V. For $v \in V$, if $\text{par}(v) = v$, then we say v is a root of par. Notice that par actually can represent a rooted forest, thus par can have more than one root. The depth of $v \in V$, $\text{dep}_{\text{par}(v)}$ is the smallest $i \in \mathbb{N}$ such that $\text{par}^{(i)}(v)$ is the same as $\text{par}^{(i+1)}(v)$. The root of $v \in V$, $\text{par}^{(\infty)}(v)$ is defined as $\text{par}^{(\text{dep}_{\text{par}}(v))}(v)$. The depth of par, $\text{dep}(\text{par})$ is defined as $\max_{v \in V} \text{dep}_{\text{par}}(v)$.

Ancestor and path. For two vertices $u, v \in V$, if $\exists i \in \mathbb{N}$ such that $u = \text{par}^{(i)}(v)$, then u is an ancestor of v (in par). If u is an ancestor of v, then the path $P(v, u)$ (in par) from v to u is a sequence $(v, \text{par}(v), \text{par}^{(2)}(v), \cdots, u)$ and the path $P(u, v)$ is the reverse of $P(v, u)$, i.e., $P(u, v) = (u, \cdots, \text{par}^{(2)}(v), \text{par}(v), v)$. If an ancestor u of v is also an ancestor of w, then u is a common ancestor of (v, w). Furthermore, if a common ancestor u of (v, w) satisfies $\text{dep}_{\text{par}}(u) \geq \text{dep}_{\text{par}}(x)$ for any common ancestor x of (v, w), then u is the lowest common ancestor (LCA) of (v, w).

Children and leaves. For any non-root vertex u of par, u is a child of $\text{par}(u)$. For any vertex $v \in V$, $\text{child}_{\text{par}}(v)$ denotes the set of all the children of v, i.e., $\text{child}_{\text{par}}(v) = \{u \in V \mid u \neq v, \text{par}(u) = v\}$. If u is the k^{th} smallest vertex in the set $\text{child}_{\text{par}}(v)$, then we define $\text{rank}_{\text{par}}(u) = k$, or in other words, u is the k^{th} child of v. If v is a root vertex of par, then $\text{rank}_{\text{par}}(v)$ is defined as 1. $\text{child}_{\text{par}}(v, k)$ denotes the k^{th} child of v. For simplicity, if par is clear in the context, we just use $\text{child}(v)$, $\text{rank}(v)$ and $\text{child}(v, k)$ to denote $\text{child}_{\text{par}}(v)$, $\text{rank}_{\text{par}}(v)$ and $\text{child}_{\text{par}}(v, k)$ for short. If $\text{child}(v) = \emptyset$, then v is a leaf of par. We denote $\text{leaves}(\text{par})$ as the set of all the leaves of par, i.e., $\text{leaves}(\text{par}) = \{v \mid \text{child}(v) = \emptyset\}$.

2.2 Depth-First-Search Sequence

The Euler tour representation of a tree is proposed by [37, 36]. It is a crucial building block in many graph algorithms including biconnectivity algorithms. The Depth-First-Search (DFS) sequence [4] of a rooted tree is a variant of the Euler tour representation. Let us first introduce some relevant concepts of the DFS sequence.

▶ **Definition 5** (Subtree [4]). *Consider a set of parent pointers* $\text{par} : V \to V$ *on a vertex set* V*. Let* v *be a vertex in* V*, and let* $V' = \{u \in V \mid v \text{ is an ancestor of } u\}$*.* $\text{par}' : V' \to V'$ *is a set of parent pointers on* V'*. If* $\forall u \in V' \setminus \{v\}$*,* $\text{par}'(u) = \text{par}(u)$ *and* $\text{par}'(v) = v$*, then* par′ *is a subtree of* v *in* par*. For* $u \in V'$*, we say* u *is in the subtree of* v*.*

The definition of the DFS sequence is the following:

▶ **Definition 6** (DFS sequence [4]). *Consider a set of parent pointers* $\text{par} : V \to V$ *on a vertex set* V*. Let* v *be a vertex in* V*. If* v *is a leaf in* par*, then the DFS sequence of the subtree of* v *is* (v)*. Otherwise, the DFS sequence of the subtree of* v *is defined recursively as*

$$(v, a_{1,1}, a_{1,2}, \cdots, a_{1,n_1}, v, a_{2,1}, a_{2,2}, \cdots, a_{2,n_2}, v, \cdots, a_{k,1}, a_{k,2}, \cdots, a_{k,n_k}, v),$$

where $k = |\text{child}(v)|$ *and* $\forall i \in [k]$*,* $(a_{i,1}, a_{i,2}, \cdots, a_{i,n_i})$ *is the DFS sequence of the subtree of* $\text{child}(v, i)$*, i.e., the* i^{th} *child of* v*.*

If $\text{par} : V \to V$ has a unique root v, then we define the DFS sequence of par as the DFS sequence of the subtree of v. By the definition of the DFS sequence, for any two consecutive elements a_i and a_{i+1} in the sequence, a_i is either a parent of a_{i+1} or a_i is a child of a_{i+1}. Furthermore, for any vertex v, if both elements a_i and a_j $(i < j)$ in the DFS sequence A are v, any element a_k between a_i and a_j (i.e., $i \leq k \leq j$) should be a vertex in the subtree of v.

3 2-Edge Connectivity and Biconnectivity

Consider a connected undirected graph G with a vertex set V and an edge set E. In the 2-edge connectivity problem, the goal is to find all the bridges of G, where an edge $e \in E$ is called a bridge if its removal disconnects G. In the biconnectivity problem, the goal is to partition the edges into several groups $E_1, E_2, \cdots, E_k$, i.e., $E = \bigcup_{i=1}^{k} E_i, \forall i \neq j, E_i \cap E_j = \emptyset$, such that $\forall e \neq e' \in E$, e and e' are in the same group if and only if there is a simple cycle in G which contains both e and e'. A subgraph induced by an edge group E_i is called a biconnected component (block). In other words, the goal of the biconnectivity problem is to find all the blocks of G.

In this section, we describe the algorithms for both the 2-edge connectivity problem and the biconnectivity problem in the offline setting.

3.1 2-Edge Connectivity

The 2-edge connectivity problem is much simpler than the biconnectivity problem. We first compute a spanning tree of the graph. Only a tree edge can be a bridge. Then for any non-root vertex v, if there is no non-tree edge which crosses between the subtree of v and the outside of the subtree of v, then the tree edge which connects v to its parent is a bridge.

▶ **Lemma 7** (2-Edge connectivity). *Consider an undirected graph* $G = (V, E)$*. Let* B *be the output of* Bridges(G)*. Then* B *is the set of all the bridges of* G*.*

3.2 Biconnectivity

In this section, we will show a biconnectivity algorithm. It is a modification of the algorithm proposed by [36]. The high level idea is to construct a new graph G' based on the input graph G, and reduce the biconnectivity problem of G to the connectivity problem of G'. Since the running time of the connectivity algorithm [4] depends on the diameter of the graph, we also give an analysis of the diameter of the graph G'.

Algorithm 1 2-Edge Connectivity Algorithm.

- **Input**:
  - A connected undirected graph $G = (V, E)$.
- **Output**:
  - A subset of edges $B \subseteq E$.
- **Finding bridges** (BRIDGES($G = (V, E)$)):
  1. Compute a rooted spanning tree of G. The spanning tree is represented by a set of parent pointers $\text{par} : V \to V$.
  2. Compute $\text{lev} : V \to \mathbb{Z}_{\geq 0}$: for each $v \in V$,
  $$\text{lev}(v) \leftarrow \min\left(\text{dep}_{\text{par}}(v), \min_{w \in V \setminus \{\text{par}(v)\} : (v,w) \in E} \text{dep}_{\text{par}}(\text{the LCA of } (v, w))\right).$$
  3. Compute the DFS sequence A of par.
  4. Initialize $B \leftarrow \emptyset$. For each non-root vertex v, let a_i, a_j be the first and the last appearance of v in A respectively. If $\min_{k:i \leq k \leq j} \text{lev}(a_k) \geq \text{dep}_{\text{par}}(v)$, $B \leftarrow B \cup \{(v, \text{par}(v))\}$. Output B.

Algorithm 2 Biconnectivity Algorithm.

- **Input**:
  - A connected undirected graph $G = (V, E)$.
- **Output**:
  - A coloring $\text{col} : E \to V$ of the edges.
- **Finding blocks** (BICONN($G = (V, E)$)):
  1. Compute a rooted spanning tree of G. The spanning tree is represented by a set of parent pointers $\text{par} : V \to V$.
  2. Compute $\text{lev} : V \to \mathbb{Z}_{\geq 0}$: for each $v \in V$,
  $$\text{lev}(v) \leftarrow \min\left(\text{dep}_{\text{par}}(v), \min_{w \in V \setminus \{\text{par}(v)\} : (v,w) \in E} \text{dep}_{\text{par}}(\text{the LCA of } (v, w))\right).$$
  3. Compute the DFS sequence A of par.
  4. Let r be the root of par. Initialize $V' \leftarrow V \setminus \{r\}, E' \leftarrow \emptyset$.
  5. For each $v \in V'$, let a_i, a_j be the first and the last appearance of v in A respectively. If $\min_{k \in \{i, i+1, \cdots, j\}} \text{lev}(a_k) < \text{dep}_{\text{par}}(\text{par}(v))$, $E' \leftarrow E' \cup \{(v, \text{par}(v))\}$.
  6. For each $(u, v) \in E$, if neither u nor v is the LCA of (u, v) in par, $E' \leftarrow E' \cup \{(u, v)\}$.
  7. Compute the connected components of $G' = (V', E')$. Let $\text{col}' : V' \to V'$ be the coloring of the vertices in V' such that $\forall u', v' \in V'$, u', v' are in the same connected component in $G' \Leftrightarrow \text{col}'(u') = \text{col}'(v')$.
  8. Initialize $\text{col} : E \to V$. For each $e = (u, v) \in E$, if $\text{dep}_{\text{par}}(u) \geq \text{dep}_{\text{par}}(v)$, set $\text{col}(e) \leftarrow \text{col}'(u)$; otherwise, set $\text{col}(e) \leftarrow \text{col}'(v)$. Output $\text{col} : E \to V$.

▶ **Lemma 8** (Biconnectivity). *Consider an undirected graph $G = (V, E)$. Let* $\mathrm{col} : E \to V$ *be the output of* $\textsc{Biconn}(G)$. *Then* $\forall e, e' \in E, e \neq e'$, col *satisfies* $\mathrm{col}(e) = \mathrm{col}(e') \Leftrightarrow$ *there is a simple cycle in G which contains both e and e'. Furthermore, the diameter of the graph G' constructed by* $\textsc{Biconn}(G)$ *is at most* $O(\mathrm{dep}(\mathrm{par}) \cdot \text{bi-diam}(G))$, *the number of vertices of G' is at most $|V|$, and the number of edges of G' is at most $|E|$.*

Algorithm 3 Leaf Sampling Algorithm for DFS Sequence.

- **Pre-determined**:
  - A threshold value s. //s will be the local memory size in the MPC model.
- **Input**:
  - A rooted tree represented by a set of parent pointers $\mathrm{par} : V \to V$ on a set V of n vertices (i.e., par has a unique root r).
- **Output**:
  - The DFS sequence of the rooted tree represented by par.
- **Leaf sampling algorithm** ($\textsc{LeafSampling}(s, \mathrm{par} : V \to V)$):

1. If $n \leq s$, return the DFS sequence of par directly.
2. Set $t \leftarrow \Theta(s^{1/3} \log n)$, $L \leftarrow \mathrm{leaves}(\mathrm{par})$.
3. Each $v \in L$ is independently chosen with probability $p = \min(1, t/|L|)$, and let $S = \{l_1, l_2, \cdots, l_k\}$ be the set of samples. If $|S|^2 > s$, output FAIL.
4. For every pair of sampled leaves $x, y \in S$ with $x \neq y$, find the least common ancestor $p_{x,y}$ of (x, y), and set $p_{xy,x}$, $p_{xy,y}$ to be two children of $p_{x,y}$ such that $p_{xy,x}$ is an ancestor of x and $p_{xy,y}$ is an ancestor of y.
5. Sort $l_1, l_2, \cdots, l_k \in S$ such that $\forall i < j \in [k]$, $\mathrm{rank}(p_{l_i l_j, l_i}) < \mathrm{rank}(p_{l_i l_j, l_j})$.
6. Find the paths $A'_1 = P(r, l_1), A'_2 = P(\mathrm{par}(l_1), p_{l_1,l_2}), A'_3 = P(p_{l_1 l_2, l_2}, l_2), \cdots, A'_{2k-2} = P(\mathrm{par}(l_{k-1}), p_{l_{k-1} l_k}), A'_{2k-1} = P(p_{l_{k-1} l_k, l_k}, l_k), A'_{2k} = P(l_{2k}, r)$, i.e., the paths: $r \to l_1 \to$ the LCA of $(l_1, l_2) \to l_2 \to \cdots \to l_{k-1} \to$ the LCA of $(l_{k-1}, l_k) \to l_k \to r$.
7. Set $A' \leftarrow A'_1 A'_2 \cdots A'_{2k}$, i.e., A' is the concatenation of $A'_1, A'_2, \cdots, A'_{2k}$.
8. For each element a'_i in the i^{th} $(i > 1)$ position of the sequence A',
   - if the vertex a'_i is a leaf, keep a'_i as a single copy;
   - Otherwise,
     - if $a'_{i-1} = \mathrm{par}(a'_i)$, i.e., i is the first position that the vertex a'_i appears in A', split a'_i into $\mathrm{rank}(a'_{i+1})$ copies; //a'_{i+1} is a child of a'_i.
     - if $a'_{i-1}, a'_{i+1} \in \mathrm{child}(a'_i)$, split a'_i into $\mathrm{rank}(a'_{i+1}) - \mathrm{rank}(a'_{i-1})$ copies;
     - if $a'_{i+1} = \mathrm{par}(a'_i)$, i.e., i is the last position that the vertex a'_i appears in A', split a'_i into $|\mathrm{child}(a'_i)| - \mathrm{rank}(a'_{i-1})$ copies. //a'_{i-1} is a child of a'_i.

   Let A'' be the result sequence.
9. For each $v \in V$, if $\mathrm{par}(v)$ appears in A'' but v does not appear in A'', recursively find the DFS sequence of the subtree of v, and insert the such sequence into the position after the $\mathrm{rank}(v)^{\text{th}}$ appearance of $\mathrm{par}(v)$ in A''. Output the final result sequence A.

4 An Offline DFS Sequence Algorithm in Linear Space

In Section 4.1, we will review an algorithmic framework proposed by [4] for the DFS sequence. In Section 4.2, 4.3, 4.4, we will discuss the subroutines needed for our DFS sequence algorithm in the offline setting.

4.1 DFS Sequence via Leaf Sampling

In the following, we review the leaf sampling algorithmic framework proposed by [4] for finding the DFS sequence of a rooted tree.

▶ **Theorem 9** (Leaf sampling algorithm [4]). *Consider a set of parent pointers* $\text{par} : V \to V$ *on a set* V *of* n *vertices. Suppose* par *has a unique root. For any* $\gamma \geq 0$ *and any constant* $\delta \in (0, 1)$*, if both of step 4 and step 6 in* LeafSampling(n^δ, par) *can be implemented in the* (γ, δ)*-MPC model with* $O(\log(\text{dep}(\text{par})))$ *parallel time, then the leaf sampling algorithm with parameter* $s = n^\delta$ *on input* $\text{par} : V \to V$ *can be implemented in the* (γ, δ)*-MPC model. Furthermore, with probability at least* 0.99*,* LeafSampling(n^δ, par) *can output the DFS sequence of* par *in* $O(\log(\text{dep}(\text{par})))$ *parallel time. If the algorithm fails, then it returns FAIL.*

By Theorem 9, we only need to give a linear total space MPC algorithm for the LCA problem and the path generation problem to design an efficient DFS sequence algorithm in the $(0, \delta)$-MPC model.

In [4], they proposed to use doubling algorithms to compute the LCA and generate the paths. Since they need to store the every 2^i-th ancestor for each vertex, the total space needed is $\Theta(n \cdot \log(\text{the depth of the tree}))$. We show that we only need to apply the doubling algorithm for a compressed tree, instead of applying it for the original tree.

Algorithm 4 Construction of a Compressed Rooted Tree.

- **Input**:
  - A rooted tree represented by a set of parent pointers $\text{par} : V \to V$ on a set V of n vertices (par has a unique root r).
- **Output**:
  - A vertex set $V' \subseteq V$, a set of parent pointers $\text{par}' : V' \to V'$ on V'.
- **Tree compression** (Compress$(\text{par} : V \to V)$):
  1. Compute the depth of par, the depth of each vertex and set $d \leftarrow \text{dep}(\text{par})$, $t \leftarrow \lceil \log d \rceil$.
  2. $V' \leftarrow \{v \in V \mid \text{dep}_{\text{par}}(v) \mod t = 0, \text{dep}_{\text{par}}(v) + t \leq d\}$.
  3. Initialize $\text{par}' : V' \to V'$. For each $v \in V'$, $\text{par}'(v) \leftarrow \text{par}^{(t)}(v)$.
  4. Output V', par′.

4.2 Compressed Rooted Tree

Given a set of parent pointers $\text{par} : V \to V$, we will show how to compress the rooted tree represented by par.

▶ **Lemma 10** (Properties of a compressed rooted tree). *Let* $\text{par} : V \to V$ *be a set of parent pointers on a vertex set* V *with* $|V| > 1$*, and* par *has a unique root. Let* $t = \lceil \log(\text{dep}(\text{par})) \rceil$ *and let* $(V', \text{par}') =$Compress(par)*. Then it has the following properties:*

1. $|V'| \leq |V| / \log(\text{dep}(\text{par}))$.
2. $\forall v \in V', i \in \mathbb{N}$, $\text{par}'^{(i)}(v) = \text{par}^{(i \cdot t)}(v) \in V'$.
3. $\forall v \in V$, $\exists i \in \{0, 1, \cdots, 2t\}$, *such that* $\text{par}^{(i)}(v) \in V'$.

4.3 Least Common Ancestor

Given a rooted tree represented by a set of parent pointers $\text{par} : V \to V$ on a vertex set V, and a set of q queries $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\}$ where $\forall i \in [q], u_i \neq v_i, u_i, v_i \in \text{leaves}(\text{par})$, we show a space efficient algorithm which can output the LCA of each queried

Algorithm 5 Lowest Common Ancestor.

- **Input**:
  - A rooted tree represented by a set of parent pointers $\text{par} : V \to V$ on a set V of n vertices (par has a unique root r), and a set of q queries $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\}$ where $\forall i \in [q], u_i \neq v_i, u_i, v_i \in \text{leaves(par)}$.
- **Output**:
  - $\text{lca} : Q \to V \times V \times V$.
- **Finding LCA** ($\text{LCA}(\text{par} : V \to V, Q)$):
  1. $(V', \text{par}') \leftarrow$COMPRESS(par). //(see Lemma 10).
  2. Set $d \leftarrow \text{dep(par)}, t \leftarrow \lceil \log d \rceil$ and compute mappings $g_0, g_1, \cdots g_t : V' \to V'$ such that $\forall v \in V', j \in \{0, 1, \cdots, t\}$, $g_j(v) = \text{par}'^{(2^j)}(v)$.
  3. For each query $(u_i, v_i) \in Q$: //Suppose $\text{dep}_{\text{par}}(u_i) \geq \text{dep}_{\text{par}}(v_i)$.
     - **a.** If $\text{dep}_{\text{par}}(u_i) > \text{dep}_{\text{par}}(v_i) + 2t$, find an ancestor $\widehat{u}_i$ of u_i in par such that $\text{dep}_{\text{par}}(\widehat{u}_i) \leq \text{dep}_{\text{par}}(v_i) + 2t$ and $\text{dep}_{\text{par}}(\widehat{u}_i) \geq \text{dep}_{\text{par}}(v_i)$. Otherwise, $\widehat{u}_i \leftarrow u_i$.
     - **b.** If $\exists j \in [4t]$ $\text{par}^{(j)}(\widehat{u}_i)$ is the LCA of $(\widehat{u}_i, v_i)$ in par, set $\text{lca}(u_i, v_i) = (\text{par}^{(j)}(\widehat{u}_i), x, y)$ where x, y are children of $\text{par}^{(j)}(\widehat{u}_i)$ and x, y are ancestors of $\widehat{u}_i, v_i$ respectively. The query of (u_i, v_i) is finished.
     - **c.** Find an ancestor u_i' of $\widehat{u}_i$ in par such that u_i' is the closest vertex to $\widehat{u}_i$ in V', i.e., $\text{dep}_{\text{par}}(\widehat{u}_i) - \text{dep}_{\text{par}}(u_i')$ is minimized. Similarly, find an ancestor v_i' of v_i in par such that v_i' is the closest vertex to v_i in V', i.e., $\text{dep}_{\text{par}}(v_i) - \text{dep}_{\text{par}}(v_i')$ is minimized.
     - **d.** Find $u_i'' \neq v_i'' \in V'$ such that they are ancestors of u_i' and v_i' respectively, and $\text{par}'(u_i'') = \text{par}'(v_i'')$ is the LCA of (u_i', v_i') in par'.
     - **e.** Find the smallest $j \in [2t]$ such that $\text{par}^{(j)}(u_i'') = \text{par}^{(j)}(v_i'')$. Set $\text{lca}(u_i, v_i) = (\text{par}^{(j)}(u_i''), \text{par}^{(j-1)}(u_i''), \text{par}^{(j-1)}(v_i''))$.

pair of vertices. Notice that the assumption that queries only contain leaves is without loss of generality: we can attach an additional child vertex v to each non-leaf vertex u. Thus, v is a leaf vertex. When a query contains u, we can use v to replace u in the query, and the result will not change.

Before we analyze the algorithm $\text{LCA}(\text{par}, Q)$, let us discuss some details of the algorithm.

1. We pre-compute $\text{dep}_{\text{par}}(v)$ and $\text{dep}_{\text{par}'}(u)$ for every $v \in V$ and $u \in V'$.
2. To implement step 3a, we firstly check whether $\text{dep}_{\text{par}}(u_i) > \text{dep}_{\text{par}}(v_i) + 2t$. If it is not true, we can set $\widehat{u}_i$ to be u_i directly. Otherwise, according to Lemma 10, there is a $j \in \{0, 1, \cdots, 2t\}$ such that $\text{par}^{(j)}(u_i) \in V'$. Since $\text{dep}_{\text{par}}(u_i) > \text{dep}_{\text{par}}(v_i) + 2t$, $\text{dep}_{\text{par}}(\text{par}^{(j)}(u_i)) > \text{dep}_{\text{par}}(v_i)$. We initialize $\widehat{u}_i$ to be $\text{par}^{(j)}(u_i) \in V'$. For $k = t \to 0$, if $\text{dep}_{\text{par}}(g_k(\widehat{u}_i)) > \text{dep}_{\text{par}}(v_i)$ (i.e., $\text{dep}_{\text{par}}(\text{par}'^{(2^k)}(\widehat{u}_i)) > \text{dep}_{\text{par}}(v_i)$), we set $\widehat{u}_i \leftarrow g_k(\widehat{u}_i) = \text{par}'^{(2^k)}(\widehat{u}_i)$. Due to Lemma 10 again, the final $\widehat{u}_i$ must satisfy $\text{dep}_{\text{par}}(\widehat{u}_i) \geq \text{dep}_{\text{par}}(v_i)$ and $\text{dep}_{\text{par}}(\widehat{u}_i) \leq \text{dep}_{\text{par}}(v_i) + 2t$. This step takes time $O(t)$.

▶ **Lemma 11** (LCA algorithm). *Let* $\text{par} : V \to V$ *be a set of parent pointers on a vertex set* V. par *has a unique root. Let* $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\}$ *be a set of* q *pairs of vertices where* $\forall i \in [q], u_i \neq v_i, u_i, v_i \in \text{leaves(par)}$. *Let* $\text{lca} : Q \to V \times V \times V$ *be the output of* $\text{LCA}(\text{par}, Q)$. *For* $(u_i, v_i) \in Q$, $(p_i, p_{i,u_i}, p_{i,v_i}) = \text{lca}(u_i, v_i)$ *satisfies that* p_i *is the LCA of* (u_i, v_i), p_{i,u_i}, p_{i,v_i} *are ancestors of* u_i, v_i *respectively, and* p_{i,u_i}, p_{i,v_i} *are children of* p_i. *Furthermore, the space used by the algorithm is at most* $O(|Q| + |V|)$.

4.4 Multi-Paths Generation

Consider a rooted tree represented by a set of parent pointers $\text{par} : V \to V$ on a vertex set V and a set of q vertex-ancestor pairs $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\}$ where $\forall i \in [q]$, v_i is an ancestor of u_i. We show a space efficient algorithm MultiPaths(par, Q) which can generate all the paths $P(u_1, v_1), P(u_2, v_2), \cdots, P(u_q, v_q)$.

Algorithm 6 Multi-Paths Generation.

- **Input**:
  - A rooted tree represented by a set of parent pointers $\text{par} : V \to V$ on a set V of n vertices (par has a unique root r), and a set of q vertex-ancestor pairs $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\}$ where $\forall i \in [q], v_i$ is an ancestor of u_i.
- **Output**:
  - $P_1, P_2, \cdots, P_q$.
- **Generating multiple path sequences** (MultiPaths$(\text{par} : V \to V, Q)$):
  1. $(V', \text{par}') \leftarrow$Compress(par). //(see Lemma 10).
  2. Set $d \leftarrow \text{dep}(\text{par}), t \leftarrow \lceil \log d \rceil$ and compute mappings $g_0, g_1, \cdots g_t : V' \to V'$ such that $\forall v \in V', j \in \{0, 1, \cdots, t\}$, $g_j(v) = \text{par}'^{(2^j)}(v)$.
  3. For each vertex-ancestor pair $(u_i, v_i) \in Q$:
     a. If $\text{dep}_{\text{par}}(u_i) - \text{dep}_{\text{par}}(v_i) \leq 2t$, generate the path sequence $P_i = (u_i, \text{par}^{(1)}(u_i), \text{par}^{(2)}(u_i), \cdots, v_i)$ directly.
     b. Otherwise, find the minimum $j \in [2t]$ such that $\text{par}^{(j)}(u_i) \in V'$. Set $u'_i \leftarrow \text{par}^{(j)}(u_i)$. Find an ancestor v'_i of u'_i in par$'$ such that $\text{dep}_{\text{par}}(v'_i) \geq \text{dep}_{\text{par}}(v_i)$ and $\text{dep}_{\text{par}}(v'_i) - 2t \leq \text{dep}_{\text{par}}(v_i)$.
     c. Generate the path $P'(u'_i, v'_i)$ in par$'$.
     d. Initialize a sequence A as the concatenation of (u_i), $P'(u'_i, v'_i)$ and (v_i).
     e. Repeat: for each element a_i in A, if a_i is not the last element and $a_{i+1} \neq \text{par}(a_i)$, insert $\text{par}(a_i)$ between a_i and a_{i+1}; until A does not change. Output the final sequence A as the path sequence P_i.

Before we analyze the correctness of the algorithm, let us discuss some details.

1. In step 3a, if the length of the path is at most $2t$, then we can generate the path in $O(t)$ rounds. In the j-th round, we can find the vertex $\text{par}^{(j)}(u_i) = \text{par}(\text{par}^{(j-1)}(u_i))$.
2. In step 3b, we want to find v'_i. We initialize v'_i as u'_i. For $k = t \to 0$, if $\text{dep}_{\text{par}}(g_k(v'_i)) > \text{dep}_{\text{par}}(v_i)$ (i.e., $\text{dep}_{\text{par}}(\text{par}'^{(2^k)}(v'_i)) > \text{dep}_{\text{par}}(v_i)$), we set $v'_i \leftarrow g_k(v'_i) = \text{par}'^{(2^k)}(v'_i)$.

▶ **Lemma 12** (Generation of multiple paths). *Let* $\text{par} : V \to V$ *be a set of parent pointers on a vertex set* V. par *has a unique root. Let* $Q = \{(u_1, v_1), (u_2, v_2), \cdots, (u_q, v_q)\} \subseteq V \times V$ *be a set of pairs of vertices where* $\forall j \in [q]$, v_j *is an ancestor of* u_j *in* par. *Let* $P_1, P_2, \cdots, P_q$ *be the output of* MultiPaths(par, Q). *Then* $\forall j \in [q], P_j = P(u_j, v_j)$, *i.e.,* P_j *is a sequence which denotes a path from* u_j *to* v_j *in* par. *Furthermore, the space used by the algorithm is at most* $O(|V| + \sum_{j \in [q]} |P_j|)$.

5 Hardness of Biconnectivity in MPC

There is a conjectured hardness which is widely used in the MPC literature [25, 11, 28, 34, 40].

▷ Conjecture 1 (1-cycle vs. 2-cycles). For any $\gamma \geq 0$ and any constant $\delta \in (0, 1)$, distinguishing the following two instances in the (γ, δ)-MPC model requires $\Omega(\log n)$ parallel time:

1. a single cycle contains n vertices,
2. two disjoint cycles, each contains $n/2$ vertices.

Under the above conjecture, we show that $\Omega(\log \text{bi-diam}(G))$ parallel time is necessary to compute the biconnected components of G. This claim is true even for the constant diameter graph G, i.e., $\text{diam}(G) = O(1)$.

▶ **Theorem 13** (Hardness of biconnectivity in MPC). *For any $\gamma \geq 0$ and any constant $\delta \in (0, 1)$, unless the one cycle vs. two cycles conjecture (Conjecture 1) is false, any (γ, δ)-MPC algorithm requires $\Omega(\log \text{bi-diam}(G))$ parallel time for testing whether a graph G with a constant diameter is biconnected.*

Proof. For $\gamma \geq 0$ and an arbitrary constant $\delta \in (0, 1)$, suppose there is a (γ, δ)-MPC algorithm $\mathcal{A}$ which can determine whether an arbitrary constant diameter graph G is biconnected in $o(\log \text{bi-diam}(G))$ parallel time. Then we give a (γ, δ)-MPC algorithm for solving one cycle vs. two cycles problem as the following:

1. For a one cycle vs. two cycles instance n-vertex graph $G' = (V', E')$, construct a new graph $G = (V, E)$: $V = V' \cup \{v^*\}, E = E' \cup \{(v, v^*) \mid v \in V'\}$.
2. Run $\mathcal{A}$ on G. If G is not biconnected, G' has two cycles. Otherwise G' is a single cycle.

It is easy to see that the diameter of G is 2. If G' is a single cycle, then G is biconnected and $\text{bi-diam}(G) = \Theta(n)$. If G' contains two cycles, then G contains two biconnected components and $\text{bi-diam}(G) = \Theta(n)$.

The first step of the above algorithm takes $O(1)$ parallel time and only requires linear total space. The graph G has $n + 1$ vertices and $2n$ edges. Thus, the above algorithm is also a (γ, δ)-MPC algorithm. The parallel time of the above algorithm is the same as the time needed for running $\mathcal{A}$ on G which is $o(\log \text{bi-diam}(G)) = o(\log n)$. Thus the existence of the algorithm $\mathcal{A}$ implies that the one cycle vs. two cycles conjecture (Conjecture 1) is false. ◀

Abstract

We study the problem of discrete distribution testing in the *two-party setting*. For example, in the standard closeness testing problem, Alice and Bob each have t samples from, respectively, distributions a and b over $[n]$, and they need to test whether $a = b$ or a, b are ϵ-far (in the ℓ_1 distance). This is in contrast to the well-studied one-party case, where the tester has unrestricted access to samples of both distributions. Despite being a natural constraint in applications, the two-party setting has previously evaded attention.

We address two fundamental aspects of the two-party setting: 1) what is the communication complexity, and 2) can it be accomplished securely, without Alice and Bob learning extra information about each other's input. Besides closeness testing, we also study the independence testing problem, where Alice and Bob have t samples from distributions a and b respectively, which may be correlated; the question is whether a, b are independent or ϵ-far from being independent. Our contribution is three-fold: 1) We show how to gain **communication efficiency** given more samples, beyond the information-theoretic bound on t. The gain is polynomially better than what one would obtain via adapting one-party algorithms. 2) We prove *tightness* of our trade-off for the closeness testing, as well as that the independence testing requires tight $\Omega(\sqrt{m})$ communication for unbounded number of samples. These **lower bounds** are of independent interest as, to the best of our knowledge, these are the first 2-party communication lower bounds for testing problems, where the inputs are a set of *i.i.d. samples*. 3) We define the concept of **secure distribution testing**, and provide secure versions of the above protocols with an overhead that is only polynomial in the security parameter.

1 Introduction

Distribution property testing is a sub-area of statistical hypothesis testing, which has enjoyed continuously growing interest in the theoretical computer science community, especially since the 2000 papers [36, 12]. One of the most basic problems is closeness testing, also known as the *homogeneity testing* ; see [37, 55, 58]. Here, given two distributions a, b and t

samples from each of them, distinguish between the cases where $a = b$ versus a and b are ϵ-far, which usually means $\|a - b\|_1 > \epsilon$.[1] For this specific problem, the extensive research led to algorithms with optimal sample complexity [12, 59, 13, 24, 31, 29], including when the number of samples from the two distributions is unequal [5, 16, 31]. Further research directions of interest include obtaining instance-optimal algorithms, which depend on further properties of the distributions a, b [3, 4, 31], quantum algorithms [20], as well as algorithms whose output is differentially-private [30, 21, 6, 8]. An even larger body of work studied numerous other related problems; see, e.g., surveys [35, 22, 53, 52].

Focusing on testing two distributions, such as in the closeness problem, a very natural aspect has, surprisingly, evaded attention so far: such a task would often be run by two players, each with access to their own distribution. Specifically, Alice has samples from distribution a, Bob has samples from distribution b, and they need to jointly solve a distribution testing problem on (a, b). This setting models many of the envisioned usage scenarios of distribution testing, where different parties wish to jointly perform a statistical hypothesis testing task on their distributions. For example, [55] describes the scenario where two distinct sensors need to test whether they sample from the same distribution ("noise") or not.

This 2-party setting raises the following standard theoretical challenges, neither of which has been previously studied in the context of distribution testing:

- What is the *communication complexity* of the testing problem? In particular, can we do better than the straightforward approach, where Alice sends her samples to Bob who then runs an offline algorithm? Can we prove matching lower bounds?
  This aspect parallels the quest for low memory or communication usage for hypothesis testing on a *single distribution*, initiated in the statistics community [25, 41] and [7, 40, 10]. In fact, very recent, independent work has considered this aspect for binary sources [54, 38].
- Is it possible to design a distribution testing protocol that is *secure*, i.e., where Alice and Bob learn nothing about each other's samples, besides testing result? This question is highly relevant in today's push for doing statistics in a privacy-respecting manner.

1.1 Our Contributions

In this paper, we initiate the study of testing problems in the two-party model, and design protocols which are both communication-efficient and secure. We do so for two basic problems on pairs of distributions (i.e., where the two-party setting is natural): 1) closeness testing, and 2) independence testing.

Our main finding is that, once the number of samples exceeds the information-theoretic minimum, we can obtain protocols with polynomially smaller communication than the naïve adaptation of existing algorithms. We complement our protocols with lower bounds on the communication complexity of such problems that are near-optimal for closeness testing, as well as for independence for an unbounded number of samples. Our upper and lower bounds on communication are novel even without any security considerations.

To argue security, we also put forth a definition for secure distribution testing in the multi-party model. Our definition differs from the standard secure computation setting due to two unique features of the considered setting. First, this is "testing" (a promise problem) and not "computing"; second, the function of interest is defined with respect to distributions, while the parties' inputs are samples. These features do not come into play if the distributions satisfy the promise (e.g., they are either identical or ϵ-far), in which case

[1] This is equivalent to saying that the total variation distance is more than $\epsilon/2$.

the security guarantee matches the standard cryptographic one (no information is leaked beyond the output). However, when the promise is not satisfied, we need to allow for some information on the parties' samples to be leaked by the protocol. Our definition permits leakage of at most one bit in this case, and leaks nothing when the promise is satisfied.

▶ **Definition 1** (Security Definition). *Let D be the set of input distributions over $\bigtimes_{i=1}^{d}[n_i]$, and let $g : D \to \{0,1\}$ be a partial boolean function, defined on $P \subseteq D$.*

Let π be a d-party protocol, and let k be a security parameter. We say that π is a t-sample secure distribution testing protocol *(for the testing task defined by g), if there exists a boolean function $f : \{\bigtimes_{i=1}^{d}[n_i]\}^t \to \{0,1\}$ such that the following holds:*

Correctness: *for any $p \in P$, $\Pr_{\zeta_1 \dots \zeta_t \sim_{i.i.d} p}[f(\zeta) = g(p)] = 1 - neg(k)$*

Security: *For any $\zeta \in \{\bigtimes_{i=1}^{d}[n_i]\}^t$, if we give each player $i \in [d]$ the input $\left(1^k, \zeta_1(i), \dots, \zeta_t(i)\right)$, then protocol π is a secure computation of the function $f(\zeta)$.*

We provide a detailed discussion of the above definition in the full version of this paper.

Closeness Testing. In the *2-party closeness testing* problem $2\text{PCT}_{n,t,\epsilon}$, Alice and Bob each have access to t samples from some distributions respectively a, b over alphabet $[n]$. Their goal is to distinguish between $a = b$ and $\|a - b\|_1 \geq \epsilon$ with probability $\geq 2/3$.

We first give a non-secure near-optimal communication protocol, and then show how to make it secure with only a small overhead (polynomial in the security parameter). Our secure version is based on the existence of a PRG that stretches from $\text{polylog}(m)$ bits to m bits, and of an OT protocol with polylog communication. Overall, we prove the following.

▶ **Theorem** (Closeness, Secure). *Fix a security parameter $k > 1$. Fix $n > 1$ and $\epsilon \in (0, 2)$, and let t be such that $t \geq C \cdot k \cdot \max\left(n^{2/3} \cdot \epsilon^{-4/3}, \sqrt{n} \cdot \epsilon^{-2}\right)$ for some (universal) constant $C > 0$. Then, assuming PRG and OT as above, there exists a* secure distribution testing protocol *for $2\text{PCT}_{n,t,\epsilon}$ which uses $\tilde{O}_k\left(\frac{n^2}{t^2\epsilon^4} + 1\right)$ communication.*

To contrast the communication bounds of our protocol to the classic 1-party setting, consider what happens in the extreme settings of the parameters s, t, for a fixed ϵ. When $t \approx \Theta(n^{2/3})$, the communication is $\tilde{O}(n^{2/3})$ as well, i.e., Alice may as well just send all the samples over to Bob. However the communication decreases as the players have more samples. This may not be surprising given the testing results with unequal number of samples [16, 31]: indeed, Alice can send $\approx \max\{n/\sqrt{t}, \sqrt{n}\}$ samples to Bob, and Bob can run the tester. In contrast, our protocol obtains a *polynomially smaller* complexity, $\approx n^2/t^2$, whenever $t \gg n^{2/3}$. Intuitively, considering the extreme of $t \gg n$, we can obtain near-constant communication: with so many samples, we can *learn* the distribution, and then use *sketching* tools [9, 42].

We prove a *near-tight* lower bound on the above trade-off (even without security considerations) in Section 4. We note that our lower bound differs from the common communication complexity lower bounds as the players' inputs are *i.i.d. samples* and not worst-case.

▶ **Theorem** (Closeness lower bound). *Any two-way communication protocol for $2\text{PCT}_{n,t,1/2}$ requires $\tilde{\Omega}\left(n^2/t^2\right)$ communication.*

Independence Testing. Our second problem is the independence testing problem in the 2-party model, denoted $2\text{PIT}_{n,m,t,\epsilon}$. Let $p = (a, b)$ be some joint distribution over $[n] \times [m]$, where $n \geq m$, and for $i \in [t]$, let ζ_i be a sample drawn from p. Now we provide Alice with the first coordinates of ζ_i's and Bob with the second coordinates. Alice and Bob's goal is to test whether distributions a and b are independent (p is a product distribution) or p is ϵ-far from any product distribution. We prove the following:

▶ **Theorem** (Independence, Secure). *Fix a security parameter $k > 1$. Fix $\epsilon \in (0, 2)$, $1 \leq m \leq n$, and let t be such that $t \geq C \cdot k \cdot \left(n^{2/3}m^{1/3}\epsilon^{-4/3} + \sqrt{nm}/\epsilon^2\right)$, for some (universal) constant C, and assuming OT, there is a secure distribution testing protocol for $2\text{PIT}_{n,m,t,\epsilon}$ using $\tilde{O}_k\left(\frac{n^2 \cdot m}{t^2\epsilon^4} + \frac{n \cdot m}{t\epsilon^4} + \frac{\sqrt{m}}{\epsilon^3}\right)$ bits of communication.*

We note that the lower bound on t from the above theorem is necessary as it is the information-theoretic bound, as proven in [31]. An important qualitative aspect of the communication complexity for 2PIT is that, when the number of samples $t \to \infty$, the protocol uses $\tilde{\Theta}_\epsilon(\sqrt{m})$ bits of communication. This is in contrast to 2PCT, where the communication becomes $\tilde{O}(1)$ for $t \to \infty$. Indeed, we show that $\Omega(\sqrt{m})$ is necessary for one-way protocols for 2PIT. Since our protocol can easily be converted to a one-way (non-secure) protocol, this lower bound is tight for one-way protocols. We conjecture that the bound from the above theorem is near-tight in n, m, t for two-way communication protocols, even without security.

▶ **Theorem** (Independence lower bound). *For $n, t \in \mathbf{N}$, any one-way protocol for $2\text{PIT}_{n,n,t,1}$ requires $\Omega(\sqrt{n})$ bits of communication.*

1.2 Related work

Our work bridges three separate areas and models: distribution testing, streaming/sketching, and secure computation. There's a large body of work in each of these areas. We mention work most relevant to us.

Testing and learning with memory or space constraints. Two-party communication model is tightly connected to the streaming and distributed models, which have received lots of focus in the context of testing and learning questions. As early as in 1960s, [25, 41] considered the hypothesis testing (of one distribution) in the streaming model, where samples are streamed over while keeping small extra space. More recently, much attention has been drawn to streaming (memory) lower bounds for learning problems, such as parity learning [50, 51, 46, 48, 33]. Another direction was to consider *stochastic streaming* problems [26], where the input is generated from a distribution. All these results apply to samples from *one distribution*, and show a (tight) trade-off between number of samples and space complexity.

Another recent avenue is to study such problems in the distributed model, where there are many symmetric players, each with a number of i.i.d. samples from the same distribution. For learning problems (e.g., parameter or density estimation), see, e.g., [19, 28, 27]. We note that since learning is a much harder problem, typically proving lower bounds is easier (e.g., as shown in [28], merely communicating the output requires $\Omega(n)$ communication). In contrast, for testing problems, the output is just one bit. For testing problems (of one distribution), see also the recent (independent) manuscript [2].

None of the lower bounds from the above papers are relevant here as they become vacuous for a 2-party setting. Indeed, when two players have two sets of samples from the *same* distribution, then purely doubling the sample set of a player trivializes the question (she can solve it without communication).

Finally, a very recent, independent works of [54, 38] consider a problem very similar to 2PIT: estimating the correlation of two binary sources ($n = m = 2$) in the two-party model.

Secure approximations. Our results on secure distribution testing can also be seen in the context of the area of secure computation of approximations. This is a framework introduced by [32], allowing to combine the benefits of approximation algorithms and secure computation.

This was considered in different settings [32, 39, 14, 43, 15, 44, 45], but the most relevant to us is private approximation of distance between two input vectors. In particular, for ℓ_2 distance, Alice and Bob each have a vector $a, b \in \mathbb{R}^n$ and want to estimate $\|a - b\|_2$, without revealing any information that does not follow from the ℓ_2 distance itself. For this problem, [43] show that secure protocols are possible with only poly-logarithmic communication complexity.We use some of their techniques in our secure protocols.

Approximation and testing have a similar flavor in that they both trade accuracy for efficiency, in different ways. The security goals are also similar (prevent leakage beyond the intended output). One important difference is that the intended output in secure testing is just the single bit of whether or not the test passed. Thus, for example, when approximating a distance function, even a secure protocol can leak any information that follows from the distance. In contrast, when testing for closeness, if the inputs are either identical or far, the protocol may only reveal this fact, but no other information about what the distance is.

Security and privacy of testing. While we are not aware of any work on secure testing, several recent papers address *differentially-private distribution testing* [30, 21, 6, 8]. Here the privacy guarantee relates to the value of the output after the computation is concluded, requiring it to be differentially-private with respect to the inputs. Our notion of security for distribution testing is different, in the same way that secure computation is different from differentially private computation. While differential privacy (DP) is concerned with what the intended output may leak about the inputs (even if the input came from a single party or the computation is done by a trusted curator), secure 2-party computation is concerned with how to compute an intended output without leaking any information beyond the output itself. The difference in goals is also reflected in the privacy guarantees, which are typically statistical in nature (for DP testing) and provide a non-negligible adversarial advantage. Secure testing protocols rely on cryptographic assumptions and provide negligible advantage.

Even more recently, a stringent model of Locally Differentially Private Testing was proposed [56, 1]. This model provides a stronger notion of differential privacy, where users send noisy samples to an untrusted curator, and the goal is to allow the curator to test the distribution of user inputs (for some property) without learning "too much" about the individual samples. For LDP, the main goal is to optimize the sample complexity as a function of the privacy guarantees. While this notion of privacy also incorporates some privacy of the individual inputs, it is much closer to DP than to our security notion. In addition, both DP and LDP do not provide sub-linear communication (in the sample size, as we achieve here). In fact, their goal is to allow $O(1)$ communication per sample, with minimal sample overhead. In contrast, our protocols provide security "nearly for free" while allowing for faster communication with more samples. Finally, in the case of independence testing, our work assumes samples are *distributed* between the parties who need to test the joint distribution, while in the above work, each data point contains full sample information.

1.3 Our Techniques

We now outline the techniques used to establish our main results. Since our overall contribution is painting a big picture of the 2-party complexity of distribution testing problems, we appeal to a number of diverse tools. First, we design communication-efficient protocols. Second, we argue optimality of our protocols by proving communication complexity lower bounds on the considered problems, which are near-tight in some of the parameter regimes. Third, we show how to transform our protocols into secure protocols, under standard cryptographic assumptions, without further loss in efficiency. All three of these contributions are independently first-of-a-kind, to the best of our knowledge.

Communication-efficient protocols. We start by reducing the testing problem under the ℓ_1 distance to the same problem under the ℓ_2 distance, using now-standard methods of [31, 24]. Here, our main challenge is actually testing under the ℓ_2 distance.

Closeness testing (2pCT) is technically the simpler problem, but it already illustrates some phenomena, how to leverage a larger number of samples to improve communication. To estimate the ℓ_2 distance between the 2 unknown distributions, we compute the ℓ_2 distance approximation between the given *samples* of these distributions. In order to approximate the latter in the 2-party setting, we use the ℓ_2 *sketching* tools [9]. The crux is to show that we can tolerate a cruder ℓ_2 approximation if we are given a larger sample size. Since the complexity of $(1+\alpha)$-approximating the ℓ_2 distance is $\Theta(1/\alpha^2)$, we obtain an improvement in communication that is quadratic in the number of samples.

Independence Testing (2pIT) is more challenging since any distance approximation would need to be established based on the distribution(s) implicitly defined via the *joint samples*, split between Alice and Bob, and hence our approximation techniques above are not sufficient. Instead, we develop a reduction from a large, $[n] \times [m]$, alphabet problem, to a smaller alphabet problem, which can be efficiently solved by communicating fewer samples. This is accomplished by sampling a rectangle of the joint alphabet, and showing that such a process, when combined with the *split-set* technique from [31], generates *sub-distributions* (defined later) which satisfy some nice properties. We then show one can test the original distribution $p = (a, b)$ over a "large" domain of size $[n]\times[m]$ for independence by distinguishing closeness of 2 simulated distributions $\hat{p}, \hat{q}$, defined on a smaller domain of size $[l] \times [m]$, where $l = \tilde{\Theta}_\epsilon(n^3m/t^3 + n^2m/t^2 + 1)$. We show it is possible for Alice and Bob to simulate joint samples from $\hat{p}$ and $\hat{q}$ using $O(1)$ communication per sample, after they have down-sampled letters from one of the marginals.

The trade-off on communication–vs–samples emerges from two compounding effects: 1) balancing the size of the target rectangle with the expected number of available samples over such rectangle; and 2) the additional advantage from a tighter bound on the ℓ_2 norm of $\hat{q}$. Each of the above independently generates linear improvement in communication with more samples. The latter advantage, however, is helpful only while $t = O(n)$, and therefore we benefit from quadratic improvement in that regime, and linear improvement thereafter.

Lower bounds on communication. We note that the lower bounds on communication of testing problems present a particular technical challenge: for testing problems, the inputs are i.i.d. samples from some distributions. This is more akin to the average-case complexity setup, as opposed to "worst case" complexity as is standard for communication lower bounds.

We manage to prove such testing lower bounds for the *Closeness Testing* problem (2pCT). While our lower bound is, at its core, a reduction from some "hard 2-party communication problem", our main contribution is dealing with the above challenge. One may observe that a "hard 2-party communication problem" is hard under a certain input distribution (by Yao's minimax theorem), and hence a reduction algorithm would also produce a hard distribution on the inputs to our problem. However, a priori, it is hard to ensure that the resulting input distribution resembles anything like a set of samples from distributions a, b. For example, the inputs may have statistical quirks that actually depend on whether it is a "close" or "ϵ-far" instance, which a reduction is not able to generate without knowing the output.

At a high level, the role of the "hard problem" is played by a variant of the well-known two-way Gap Hamming Distance (GHD) problem [23, 57]. The known GHD lower-bound variants are insufficient for us precisely because of the above challenge – we need a better control over the actual hard distribution.Therefore, we study the following *Exact GHD*

variant: given $x, y \in \{0,1\}^n$, with $\|x\|_1 = \|y\|_1 = n/2$, distinguish between $\|x-y\|_1 = n/2$ versus $\|x-y\|_1 \in [n/2+\beta, n/2+2\beta]$. We show there exists some $\beta \in [\Omega(\sqrt{n}), O(\sqrt{n \log n})]$ for which communication complexity must be $\tilde{\Omega}(n)$, by adapting the proof of [57].

Using one instance of *Exact GHD*, our reduction performs a careful embedding of this hard instance into the samples from distributions a, b, while patching the set of samples to look like i.i.d. samples from the two distributions. While we don't manage to get the output of the reduction to look precisely like i.i.d. samples from a, b, our reduction produces two sets of size $\mathrm{Poi}(t)$ whose distribution is within a small statistical distance from the distribution of two set of samples that would be drawn from two distributions a and b which are either "equal" (when $\|x-y\|_1 = n/2$) or "far" (when $\|x-y\|_1 \in [n/2+\beta, n/2+2\beta]$).

Note that our proof recovers the standard lower bound of $\tilde{\Omega}(n^{2/3})$ on samples necessary to solve closeness testing (in the vanilla setting), albeit not a tight bound [24, 31].

For *Independence testing* (2pIT), we focus on the lower bound for unbounded number of samples. We argue such a hardness result under one-way communication only. Our $\Omega(\sqrt{m})$ lower bound uses the Boolean Hidden Hypermatching (BHH) problem [60]. We conjecture our entire trade-off for the Independence problem is tight. The proof of this conjecture would have to overcome the challenge of lower bounds for statistical inputs.

Securing the communication protocols. Once low-communication insecure protocols have been designed, one may try to convert the protocols to secure ones using generic cryptographic techniques. The latter includes various techniques for secure computation ([61] and followup work), fully homomorphic encryption ([34] and followup work), or homomorphic secret sharing ([17, 18]). However, a naïve application of such techniques will blow up the communication to be at least linear in the input size, possibly requiring strong assumptions, a high computation complexity, or not being applicable to arbitrary computations. The constraint of low-overhead, among other considerations, requires design of custom protocols.

Our starting point is a technique that falls into the latter category: secure circuits with ROM [49], a technique that can transform an insecure 2-party protocol to a secure one with a minimal blow-up in communication, and uses a weak assumption only (OT). In order to obtain an efficient protocol, however, it only applies to computations expressible via a very small circuit, whose size is proportional to the target communication, with access to a larger read-only-memory (ROM) table. Thus, the main challenge becomes to design two-party testing protocols that fit this required format.

For *Closeness Testing* (2pCT), we begin with our low-communication non-secure protocol, and adapt it to be secure by designing a small circuit. One of the main difficulties in designing such a circuit is that, in the ℓ_1- to ℓ_2-testing reduction, Alice and Bob need to agree on an alphabet, which depends on their inputs, without compromising the inputs themselves. To bypass this, and other issues, we allow Alice and Bob to perform some off-line work and prepare some polynomial-size inputs (in ROM). First, we devise a method for Alice and Bob to generate a combined split set S (discussed later) by having each of Alice and Bob contribute sampled letters to S. Second, we securely estimate the ℓ_2 distance of Alice and Bob's original, un-splitted samples using techniques from [43]. Finally, we adjust our approximation by accounting for a few letters which differ from the original alphabet or which cannot be estimated efficiently. The main focus of our analysis goes into proving our construction adds only poly-logarithmic communication over the insecure protocol.

We describe the details of our secure protocols, as well as our results on independence testing, in the full version of this paper.

2 Preliminaries

Notation. Throughout this paper we denote distributions in small letters, and distribution samples in capital letters. Unless stated otherwise, any distribution is on alphabet $[n]$, and domain elements of $[n]$ are addressed as letters.

We also denote any multiplicative error arising from approximation as $1+\alpha$, and any error or distance of/between distributions as ϵ. Unless stated otherwise, distance and norms are referring to the Euclidean distance and ℓ_2 norms.

We denote Poisson Random variables with parameter $\lambda > 0$ as $\mathrm{Poi}(\lambda)$.

Split Distributions. We use the concept of split distributions from [31] to essentially reduce testing under ℓ_1 distance to testing under ℓ_2 distance.

▶ **Definition 2.** *Given a probability distribution p on $[n]$ and a multiset S of items from $[n]$, define the* split distribution p_S *on $[n+|S|]$ as follows. For $i \in [n]$, let a_i be equal to 1 plus the number of occurrences of i in S; note that $\sum_{i=1}^{n} a_i = n + |S|$. We associate the elements of $[n+|S|]$ to elements of the set $E = \{(i,j) : i \in [n], 1 \le j \le a_i\}$. Now the distribution p_S has support E and a random draw (i,j) from p_S is sampled by picking i randomly from p and j uniformly at random from $[a_i]$.*

Recall from [31] that split distributions are used to upper bound the ℓ_2 norm of an underlying distribution while maintaining its ℓ_1 distance to other distributions:

▶ **Fact 3** ([31]). *Let p and q be probability distributions on $[n]$, and S a given multiset of $[n]$. Then, (1) We can simulate a sample from p_S or q_S by taking a single sample from p or q, respectively; and (2) $\|p_S - q_S\|_1 = \|p - q\|_1$.*

▶ **Lemma 4** ([31]). *Let p be a distribution on $[n]$. Then: (i) For any multisets $S \subseteq S'$ of $[n]$, $\|p_{S'}\|_2 \le \|p_S\|_2$, and (ii) If S is obtained by taking $\mathrm{Poi}(m)$ samples from p, then $\mathbb{E}[\|p_S\|_2^2] \le 1/m$.*

3 Closeness Testing: Communication-Efficient Protocol

In this section we consider the closeness testing problem 2PCT, focusing on the 2-party communication complexity only. In the full version of this paper, we show how to modify the protocol to make it secure.

As mentioned in the introduction, one way to obtain a protocol is to use unequal-size closeness testing, where Alice has s samples and Bob has t samples: Alice just sends her s samples to Bob, and Bob invokes a standard algorithm for closeness testing. Using the optimal bounds from, say, [31], we get the following trade-off for fixed ϵ: $s = \tilde{O}(n/\sqrt{t})$, with the condition that $s, t \ge \sqrt{n}$. Here we obtain a *polynomially smaller* communication complexity, $s = \tilde{O}_\epsilon(n^2/t^2)$, whenever t is above the information-theoretic minimum on the number of samples. In Section 4, we show a nearly-matching lower bound.

3.1 Tool: approximation via occurrence vectors

Our protocol uses the framework introduced in [31], allowing us to focus on the ℓ_2 testing problem. For ℓ_2 testing, we show that we can approximate the ℓ_2 distance of two discrete distributions p, q by approximating the ℓ_2 distance of their respective sample occurrence vectors, defined as follows.

▶ **Definition 5.** *Given t samples of distribution p over $[n]$, we define the* occurrence vector *$X \in [t]^n$ such that X_i represent the count of occurrences of element $i \in [n]$ in the sample set.*

The following lemma bounds how well we need to estimate the ℓ_2 distance between occurrence vectors to distinguish between $p = q$ vs. $\|p - q\|_1 \geq \epsilon$. It shows that the more samples we have, the less accurate the ℓ_2 estimation needs to be. Using the framework from [31], for now it is enough to assume that the ℓ_2 norm of both p and q is bounded by $U < 1$.

▶ **Lemma 6.** *Let p, q be distributions over $[n]$ with $\|p\|_2, \|q\|_2 \leq U$ for some $U < 1$. There exists $t = O(U \cdot n \cdot \epsilon^{-2})$, and $\alpha = \Omega(U)$, such that given Δ which is $(1 \pm \alpha)$-factor approximation of $\|X - Y\|_2^2$ where X, Y represent the occurrence vectors of t samples drawn from p, q respectively, then, using Δ, it is possible to distinguish whether $p = q$ versus $\|p - q\|_1 > \epsilon$ with 0.8 probability.*

The actual distinguishing algorithm is simple: for fixed $\alpha = \Omega(U)$, we merely compare Δ to some fixed threshold τ (fixed in the proof below). The intuition is that for a given number of samples, we have some gap between the range of possible distances $\|X - Y\|_2^2$ for each of the cases. If the number of samples is close to the information-theoretic minimum [24], then the gap is minimal and we need to calculate almost exactly the distance, hence estimating the distance between occurrence vectors doesn't help. However, as the number of samples t increases, so does the gap between the ranges, allowing for a looser distance approximation.

Proof of Lemma 6. Given $t = O(U/\epsilon'^2)$ samples from each p, q, according to [24, Proposition 3.1], the estimator $Z = \sqrt{\sum_i (X_i - Y_i)^2 - X_i - Y_i}/t$ is a $\max\{\epsilon', \|p - q\|_2 /8\}$ additive approximation of $\|p - q\|_2$ with 0.9 probability. Setting $\epsilon' = \epsilon/(8\sqrt{n})$, we obtain: (1) $\|p - q\|_2 = 0 \Rightarrow \|X - Y\|_2^2 \leq \frac{\epsilon^2 t^2}{4n} + 2t$; and (2) $\|p - q\|_2 > \epsilon/\sqrt{n} \Rightarrow \|X - Y\|_2^2 \geq \frac{3\epsilon^2 t^2}{4n} + 2t$ Now, suppose Δ is such that $\frac{\Delta}{\|X-Y\|_2^2} \in (1 - \alpha, 1 + \alpha)$. If $\|p - q\|_1 = 0$, then $\|p - q\|_2 = 0$ and hence $\Delta \leq (1+\alpha)(\frac{\epsilon^2 t^2}{4n} + 2t) \leq t(\frac{\epsilon^2 t}{4n} + 2 + 2\alpha + \frac{\alpha\epsilon^2 t}{4n})$. On the other hand, if $\|p - q\|_1 > \epsilon$, then $\|p - q\|_2 > \epsilon/\sqrt{n}$ and hence $\Delta \geq (1 - \alpha)(\frac{3\epsilon^2 t^2}{4n} + 2t) \geq t(\frac{3\epsilon^2 t}{4n} + 2 - 2\alpha - \frac{3\alpha\epsilon^2 t}{4n})$.

We distinguish the two cases, by comparing Δ to $\tau = \frac{\epsilon^2 t^2}{2n} + 2t$: namely $p = q$ iff $\Delta \leq \tau$. Indeed we argue that $t(\frac{3\epsilon^2 t}{4n} + 2 - 2\alpha - \frac{3\alpha\epsilon^2 t}{4n}) - \tau \geq \tau - t(\frac{\epsilon^2 t}{4n} + 2 + 2\alpha + \frac{\alpha\epsilon^2 t}{4n})$. We have that $\frac{\epsilon^2 t}{4n} - 2\alpha - \frac{3\alpha\epsilon^2 t}{4n} \geq 0$, or $\alpha \leq \frac{\epsilon^2 t}{4n \cdot (2 + 3\epsilon^2 t/4n)}$. Since $t = O(Un\epsilon^{-2})$, the conclusion follows. ◀

3.2 Communication vs number of samples

We now provide a (non-secure) protocol for 2PCT with a trade-off between communication and number of samples.

▶ **Theorem 7** (Closeness, insecure)**.** *Fix $n > 1$ and $\epsilon \leq 2$. There exists some constant $C > 0$ such that for all $t \geq C \cdot \max\left(n^{2/3} \cdot \epsilon^{-4/3}, \sqrt{n} \cdot \epsilon^{-2}\right)$, the problem $2\text{PCT}_{n,t,\epsilon}$ can be solved using $\tilde{O}\left(\frac{n^2}{t^2\epsilon^4} + 1\right)$ bits of communication.*

The protocol uses Lemma 6 as the main algorithmic tool and proceeds as follows. Bob generates multi-set S using samples from b and sends S to Alice. Then, Alice and Bob each simulate samples from a_S and b_S respectively, and together approximate the ℓ_2 difference of the resulting occurrence vectors using sketching methods [9].

Proof of Theorem 7. We note that, according to Lemma 4, $\mathbb{E}[\|b_S\|_2^2] \leq t^2\epsilon^4/n^2$ and hence $\|b_S\|_2^2 = O(t^2\epsilon^4/n^2)$ with at least 90% probability. Furthermore, since $t = \Omega(\sqrt{n}/\epsilon^2)$, we have that $|S| = O(n)$ with high probability. From now on, we condition on these two events.

Non-Secure 2pCT(a, b, t)
Alice's input: t samples from a
Bob's input: t samples from b
1. Fix $\alpha = \Omega(t \cdot \epsilon^2/n)$.
2. Bob generates multi-set S using $\mathrm{Poi}(\frac{n^2}{t^2\epsilon^4})$ samples from b.
3. Bob sends S to Alice.
4. Alice and Bob recast their samples as being from distributions a_S, b_S (see Def. 2), and set A_S, B_S to be the respective occurrence vectors.
5. Alice and Bob each estimate $\|a_S\|_2$ and $\|b_S\|_2$ up to factor 2; if the two estimates are not within factor 4, output "ϵ-FAR";
6. Alice and Bob approximate $\Delta = \|A_S - B_S\|_2^2$ up to $(1+\alpha)$ factor, using, say, [9].
7. If Δ is less than $\tau = \frac{\epsilon^2 t^2}{2n} + 2t$ output "SAME", and, otherwise, output "ϵ-FAR".

If $\|a_S\|_2 \neq \Theta(\|b_S\|_2)$ then distributions are different and we output "ϵ-far" is step 5. Otherwise, we have that $\|a_S\|_2^2 = O(\|b_S\|_2^2) = O(t^2\epsilon^4/n^2)$. Hence we can use Lemma 6, where $U = O(t\epsilon^2/n)$ and $\alpha = \Omega(U)$, to claim the correctness of the protocol.

In terms of communication complexity, first, communicating S takes $|S| \log n = \tilde{O}(n^2/t^2\epsilon^4)$ bits with high probability. Second, estimating Δ up to approximation $1+\alpha$ takes $\tilde{O}(1/\alpha^2) = \tilde{O}(n^2/t^2\epsilon^4)$ bits, using standard ℓ_2 estimation algorithms [9, 47]. ◀

▶ Remark 8. Another application of this protocol is that it can be simulated by a *single party* to obtain a space bounded *streaming algorithm* with the same space/sample trade-offs. While we are not formalizing this argument in this paper, this can essentially be done by storing S and sketching $\|A_S - B_S\|_2^2$.

4 Closeness Testing: Communication Lower Bounds

We now prove that the protocol for 2pCT from Section 3 is near-tight, showing the following:

▶ **Theorem 9.** *Let a, b be some distributions over alphabet $[n]$, where Alice and Bob each receive $\mathrm{Poi}(t)$ samples from a, b respectively, for $t \leq n/\log^c n$ for some large enough $c > 1$. Then any (two-way) communication protocol Π that distinguishes between $a = b$ and $\|a - b\|_1 \geq 1/2$ requires $s = \tilde{\Omega}(n^2/t^2)$ communication.*

Intuitively, our proof formalizes the concept that in testing distributions for closeness, "collisions is all that matters", *even in the communication model*. This is similar to the intuition from the "canonical tester" from [59], which shows a similar principle when all the samples are accessible. Our result can be seen to extending it to saying that the canonical tester is still the best even if we have more-than-strictly-necessary number of samples that we could potentially compress in a communication protocol.

To prove the theorem, we rely on the following communication complexity lower bound, which is a variant of the Gap-Hamming-Distance (GHD) lower bound [23, 57]. Somewhat surprisingly, there does not seem to be a proof in the *one-way communication* model, which would be simpler than the two-way proof from the lemma below.

▶ **Lemma 10.** *Let $n \geq 1$ be even. There exists some $\beta = \beta(n) \in [\Theta(\sqrt{n}), \Theta(\sqrt{n \log n})]$, satisfying the following. Consider a two-way communication protocol $\mathcal{A}$ that, with probability at least 0.9, for $x, y \in \{0,1\}^n$ with $\|x\|_1 = \|y\|_1 = n/2$, can distinguish between the case when $\|x - y\|_1 = n/2$ versus $\|x - y\|_1 - n/2 \in [\beta, 2\beta]$. Then $\mathcal{A}$ must exchange at least $\Omega(\frac{n}{\log n \cdot \log\log n \cdot \log\log\log n})$ bits of communication.*

The proof of this lemma is presented in the full version of this paper.

Proof of Theorem 9. The idea is to reduce an instance of the GHD problem from Lemma 10 to an instance of closeness testing by carefully molding the input (x, y) into a couple of related occurrence vectors $(A, B) \in \mathbf{N}^n \times \mathbf{N}^n$ (recall that an occurrence vector precisely describes a set of samples).

Fix input vectors x, y, of length $m = \frac{n^2}{t^2 \log^3 n}$, to the above GHD problem. Let $\Delta = \beta(m) = \Omega(\sqrt{m})$, and $\delta = \frac{1}{2}(\|x - y\|_1 - m/2) \in \{0\} \cup [\Delta/2, \Delta]$. The case of $\delta = 0$ will correspond to "same" case (i.e. $a = b$), and $\delta \in [\Delta/2, \Delta]$ – to "far" case (i.e. $\|a - b\|_1 \in [1/2, 1]$).

Fix $d = n/10$ and $l = C \cdot t \cdot \log n$ (where C is some constant that we shall fix later), which have the following meaning: each distribution a, b has half mass over $[d]$ items uniformly (called *dense items*), and the other half on $[l]$ items uniformly (called *large items*). When $a = b$, these are the same items, and when $a \neq b$, the large items are the same while the dense items have supports with a large difference. In particular, the dense items are supported on sets S_A, S_B respectively, with $|S_A| = |S_B| = d$, and $S_A \cap S_B = d \cdot \frac{\Delta - \delta}{\Delta}$; we hence also have that $|S_A \setminus S_B| = d \cdot \frac{\delta}{\Delta}$.

Now for $i \geq 0$, let $D(i) = \Pr[\mathrm{Poi}(t/2d) = i]$, i.e., probability a dense number is sampled i times (when sampling $\mathrm{Poi}(t)$ items from one of the distributions). For simplicity, we write $D(i, j) = D(i) \cdot D(j)$. Similarly we define $L(i) = \Pr[\mathrm{Poi}(t/2l) = i]$ and $L(i, j) = L(i) \cdot L(j)$. We also set $k = \Theta(\log n)$, which should be thought of as an upper bound on the count of any fixed item (whp). The algorithm constructs the occurrence vectors A, B iteratively coordinate by coordinate. Let $m_c = m/4 - \Delta$.

2pCT Lower Bound Reduction
Input: (x, y) size m input bits for the Exact GHD problem
Output: (A, B) occurrence vectors for $\mathrm{Poi}(t)$ samples for the 2pCT Problem.

1. For each $i, j \in \{1, \dots k\}$, and for each $c \in [m]$ (corresponding to a coordinate of x, y), we take $z_c = \mathrm{Poi}(\frac{d}{\Delta} \cdot D(i, j))$, and generate z_c pairs $(i \cdot x_c, j \cdot y_c)$ (i.e., we set the corresponding coordinate of A or B to i or j iff $x_c = 1$ or $y_c = 1$ respectively);
2. For each $i \in \{1, \dots k\}$, generate $\mathrm{Poi}(d \cdot D(i, 0))$ pairs $(i, 0)$, and similarly-distributed number of pairs $(0, i)$;
3. For each $i, j \in \{1, \dots k\}$, generate $\mathrm{Poi}(l \cdot L(i, j) - m_c \cdot \frac{d}{\Delta} D(i, j))$ pairs (i, j);
4. For each $i \in \{1, \dots k\}$, generate $\mathrm{Poi}(l \cdot L(i, 0) - \frac{m}{4} \cdot \frac{d}{\Delta} \sum_{j=1}^{k} D(i, j))$ pairs $(i, 0)$, and similarly-distributed number of pairs $(0, i)$.
5. Generate the required number of $(0, 0)$ pairs so that A, B have length precisely n;
6. Permute the coordinates of A, B using a common randomly picked permutation over $[n]$.

In each of steps (1)-(5) above, we say we "generate a pair (i, j)" which corresponds to setting the next coordinate of A and B to i and j respectively. We only use the input vectors (x, y) in step (1). We note that all random variables are chosen using shared randomness.

We first claim that the above reduction is well-defined, and in particular all arguments of the Poisson variables are positive.

▷ Claim 11. All the Poisson random variables from above have positive argument.

Proof. We only need to prove this for steps 3 and 4 as the other ones are obvious. Indeed, for $i, j \geq 1$, we get that $l \cdot L(i, j) = t \log n \cdot (\Omega(1/\log n))^{i+j} = t/\log n \cdot (\Omega(1/\log n))^{i+j-2}$, whereas, $m_c \cdot \frac{d}{\Delta} D(i, j) = O(\sqrt{m} \cdot n \cdot (t/2d)^{i+j}) \leq \frac{n^2}{t \log^{1.5} n} \cdot O(t^2/n^2) \cdot (O(t/n))^{i+j-2} \leq \frac{t}{\log^{1.5} n} (O(t/n))^{i+j-2}$. Thus $l \cdot L(i, j) - m_c \cdot \frac{d}{\Delta} D(i, j) \geq 0$ for all $i, j \geq 1$.

Similarly, for step 5, for $i \geq 1$, we have, $l \cdot L(i,0) = \Omega(t \cdot (O(1/\log n))^{i-1})$, whereas, $m/4 \cdot \frac{d}{\Delta} \sum_{j \geq 1} D(i,j) \leq O(\sqrt{m} \cdot n \cdot \sum_{j \geq 1} (O(t/n))^{i+j}) \leq O(\frac{n^2}{t \log^{1.5} n} \cdot (O(t/n))^{i+1}) \leq O(\frac{t}{\log^{1.5} n} \cdot (O(t/n))^{i-1})$. We again have $l \cdot L(i,0) - m/4 \cdot \frac{d}{\Delta} \sum_{j \geq 1} D(i,j) \geq 0$ as required. ◁

We now prove the core of the reduction: that the distribution of (A, B) (denoted $\hat{\mathcal{D}}$) is close to the distribution $\mathcal{D}$ of occurrence vectors of $\mathrm{Poi}(t)$ i.i.d. samples from (a, b), such that $a = b$ if $\|x - y\|_1 = m/2$, and similarly, $\|a - b\|_1 \geq 1/2$ when $\|x - y\|_1 \geq m/2 + \beta$. We will prove that, for distribution of (co-)occurrences of large items is nearly same in the two instances; and similarly for the dense items. We partition the coordinates of (x, y) in the following four groups, each corresponding to either occurrences of dense or large items:

- large: $m_c = m/4 - \Delta$ coordinates for each of $(1,1)$ and $(0,0)$ coordinate pairs (i.e., coordinates $i \in [m]$ where $(x_i, y_i) = (1,1)$ or $(x_i, y_i) = (0,0)$);
- large: $m/4$ coordinates for each of $(1,0)$ and $(0,1)$ pairs;
- dense: $\Delta - \delta$ coordinates for each of $(1,1)$ and $(0,0)$ pairs;
- dense: δ coordinates for each of $(1,0)$ and $(0,1)$ pairs.

Note that this accounts for all coordinates for a pair x, y such that $\|x - y\|_1 = m/2 + 2\delta$.

Next, we compare the distributions of occurrences for large and dense items in the generated vectors (A, B) as opposed to occurrences of items coming from distributions a, b defined above. In particular, we consider the distribution of counts $c_{i,j}$, where $i + j > 0$, where $c_{i,j}$ is the number of large items which where sampled i times on Alice's side and j times on the Bob's side; we will refer to them as (i, j) occurrence pairs.

We denote by $\hat{\mathcal{D}}^L, \hat{\mathcal{D}}^D$ the distribution of, respectively, large and dense $\{c_{i,j}\}_{i+j>0}$ occurrence pairs in (A, B). Similarly, we denote $\mathcal{D}^L, \mathcal{D}^D$ the distribution of, respectively, large and dense $\{c_{i,j}\}_{i+j>0}$ occurrence pairs randomly drawn from (a, b). Note that $\mathcal{D}^L, \mathcal{D}^D$ are multinomial distributions, formally defined as follows:

▶ **Definition 12.** *Fix $n, k \geq 1$, vector $\vec{p} \in \mathbb{R}_+^k$, where $\sum_{i=1}^k p_i \leq 1$. The k-dimensional random variable $(M_1, \ldots M_k) = \mathrm{Mult}_{-0}(n; \vec{p})$ is obtained by drawing a Multinomial r.v. with parameters n and probability vector $(1 - \sum_{i=1}^k p_i, \vec{p})$, and dropping the first coordinate.*

In particular, $\mathcal{D}^L = \mathrm{Mult}_{-0}(l; \vec{p}_L)$ where $\vec{p}_L = (L(i,j))_{i,j \geq 0; i+j>0}$; $\mathcal{D}^D$ will be clarified later. We now deduce $\hat{\mathcal{D}}^L$ and $\hat{\mathcal{D}}^D$. Below we use the fact that the sum of Poisson random variables is also Poisson.

▷ Claim 13. $\hat{\mathcal{D}}^L$ is distributed as $\mathrm{Poi}(l \cdot \vec{p}_L)$. Also $\hat{\mathcal{D}}^D$ is distributed as $\mathrm{Poi}(\frac{\Delta - \delta}{\Delta} \cdot d \cdot \vec{p}_D) + \mathrm{Poi}(\frac{\delta}{\Delta} \cdot d \cdot \vec{p}_{D^0})$ where $\vec{p}_D = (D(i,j))_{i,j \geq 0; i+j>0}$ and $\vec{p}_{D^0} = (D(i) \cdot \mathbb{1}[j=0] + D(j) \cdot \mathbb{1}[i=0])_{i,j \geq 0; i+j>0}$.

Proof. For $i, j \in \{1, \ldots k\}$, $\hat{\mathcal{D}}^L_{i,j}$ is distributed as $\mathrm{Poi}(l \cdot L(i,j))$, which is composed of $\mathrm{Poi}(m_c \cdot \frac{d}{\Delta} D(i,j))$ (from the first step: there are m_c coordinate pairs $(1,1)$), plus $\mathrm{Poi}(l \cdot L(i,j) - m_c \cdot \frac{d}{\Delta} \cdot D(i,j))$ (from the third step).

Similarly, $\hat{\mathcal{D}}^L_{i,0}$ (and by symmetric argument also $\hat{\mathcal{D}}^L_{0,i}$) is distributed as $\mathrm{Poi}(l \cdot L(i,0))$, composed of $\mathrm{Poi}(m/4 \cdot \frac{d}{\Delta} \sum_{j=1}^k D(i,j))$ (from the first step: there are $m/4$ coordinate pairs $(1,0)$), plus $\mathrm{Poi}(l \cdot L(i,0) - m/4 \cdot \frac{d}{\Delta} \sum_{j=1}^k D(i,j))$ (from step 4).

For $i, j \geq 1$, $\hat{\mathcal{D}}^D_{i,j}$ are distributed as $\mathrm{Poi}((\Delta - \delta) \cdot \frac{d}{\Delta} D(i,j))$ since there are $\Delta - \delta$ coordinate pairs $(1,1)$. For $\hat{\mathcal{D}}^D_{i,0}$ (and similarly $\hat{\mathcal{D}}^L_{0,i}$), the distribution is $\mathrm{Poi}(\delta \cdot \frac{d}{\Delta} \sum_{j=1}^k D(i,j))$ (from the first step: there are δ coordinate pairs $(1,0)$), plus $\mathrm{Poi}(d \cdot D(i,0))$ (from the second step). This amounts to $\mathrm{Poi}(d \cdot \frac{\delta}{\Delta} \sum_{j=1}^k D(i,j) + d \cdot D(i,0)) = \mathrm{Poi}(d \frac{\Delta - \delta}{\Delta} \cdot D(i,0) + d \frac{\delta}{\Delta} \cdot (D(i,0) + \sum_{j=1}^k D(i,j))) = \mathrm{Poi}(d \cdot \frac{\Delta - \delta}{\Delta} \cdot D(i,0) + d \cdot \frac{\delta}{\Delta} \cdot D(i))$. ◁

We prove $\left\|\hat{\mathcal{D}} - \mathcal{D}\right\|_{TV} \leq 0.01 + o(1)$ by showing (i) $\left\|\hat{\mathcal{D}}^L - \mathcal{D}^L\right\|_{TV} \leq 0.01 + o(1)$ and (ii) $\left\|\hat{\mathcal{D}}^D - \mathcal{D}^D\right\|_{TV} = o(1)$. We compare $\hat{\mathcal{D}}^L$ and $\hat{\mathcal{D}}^D$ versus $\mathcal{D}^L$ and $\mathcal{D}^D$ using the following estimate on the TV distance between Multinomial and Poisson random variables. Note that the identity of items is not important, as the items are randomly permuted inside the domain, for both A, B as well as in distributions a, b.

▶ **Theorem 14** ([11]). *Let $n, k \geq 1$, as well as a vector $\vec{p} \in \mathbb{R}_+^k$, where $p = \sum_{i=1}^k p_i \leq 1$. Consider the random variable $(M_1, \ldots M_k)$ drawn from the Multinomial $\mathrm{Mult}_{-0}(n; \vec{p})$. Also consider the Poisson random variable $P = (P_1, \ldots, P_k)$ where $P_i \sim \mathrm{Poi}(np_i)$. Then the variables $M = (M_1, \ldots M_k)$ and $(P_1, \ldots P_k)$ are at a statistical distance of $O(p \log n)$.*

By Theorem 14, the TV-distance between $\mathcal{D}^L = \mathrm{Mult}_{-0}(l; \vec{p}_L)$ and $\hat{\mathcal{D}}^L = \mathrm{Poi}(l \cdot \vec{p}_L)$ is bounded by: $O(\log n) \cdot \sum_{i,j \geq 0; i+j>0} L(i,j) \leq O(\log n) \cdot \sum_{i,j \geq 0; i+j>0} (t/2l)^{i+j} \leq O(1)/C \leq 0.01$ (for sufficiently large constant C).

For (ii), we note $\mathcal{D}^D$ can be thought of as two distributions, corresponding to: (1) items in $S_A \cap S_B$, (2) items in $S_A \triangle S_B$. The occurrence counts for (1) are distributed as a Multinomial M^D with parameters $|S_A \cap S_B| = d \cdot \frac{\Delta - \delta}{\Delta}$ and probability vector $\vec{p}_D = (D(i,j))_{i,j \geq 0; i+j>0}$. By Theorem 14, the TV-distance between M^D and the distribution $\mathrm{Poi}(d \cdot \frac{\Delta - \delta}{\Delta} \cdot \vec{p}_D)$ is bounded by: $O(\log n) \cdot \sum_{i,j \geq 0; i+j>0} D(i,j) \leq O(\log n) \cdot \sum_{i,j \geq 0; i+j>0} (t/2d)^{i+j} \leq O(1/\log n)$.

For (2), we can only have $(i, 0)$ and $(0, j)$ pairs, and the occurrence counts are distributed as a Multinomial $M^{D^0} = \mathrm{Mult}_{-0}(|S_A \triangle S_B|/2; \vec{p}_{D^0})$. By Theorem 14, the TV-distance between M^{D^0} and $\mathrm{Poi}(\frac{\delta}{\Delta} \cdot d \cdot \vec{p}_{D^0})$ is at most $O(\log n) \cdot \sum_{i \geq 1} D(i) \leq O(1/\log n)$.

Thus we conclude that the distributions $\hat{\mathcal{D}}$ and $\mathcal{D}$ are at a small TV distance. ◀

Abstract

We present two new results about exact learning by quantum computers. First, we show how to exactly learn a k-Fourier-sparse n-bit Boolean function from $O(k^{1.5}(\log k)^2)$ uniform quantum examples for that function. This improves over the bound of $\widetilde{\Theta}(kn)$ uniformly random *classical* examples (Haviv and Regev, CCC'15). Our main tool is an improvement of Chang's lemma for sparse Boolean functions. Second, we show that if a concept class $\mathcal{C}$ can be exactly learned using Q quantum membership queries, then it can also be learned using $O\left(\frac{Q^2}{\log Q}\log|\mathcal{C}|\right)$ *classical* membership queries. This improves the previous-best simulation result (Servedio-Gortler, SICOMP'04) by a $\log Q$-factor.

1 Introduction

1.1 Quantum learning theory

Both quantum computing and machine learning are hot topics at the moment, and their intersection has been receiving growing attention in recent years as well. On the one hand there are particular approaches that use quantum algorithms like Grover search [18] and the Harrow-Hassidim-Lloyd linear-systems solver [19] to speed up learning algorithms for specific machine learning tasks (see [34, 29, 1, 9, 16] for recent surveys of this line of work). On the other hand there have been a number of more general results about the sample and/or time complexity of learning various concept classes using a quantum computer (see [4] for a survey). This paper presents two new results in the latter line of work. In both cases the goal is to *exactly* learn an unknown target function with high probability; for the first result our access to the target function is through quantum examples for the function, and for the second result our access is through membership queries to the function.

1.2 Exact learning of sparse functions from uniform quantum examples

Let us first explain the setting of distribution-dependent learning from examples. Let $\mathcal{C}$ be a class of functions, a.k.a. *concept class*. For concreteness assume they are ± 1-valued functions on a domain of size N; if $N = 2^n$, then the domain may be identified with $\{0,1\}^n$. Suppose $c \in \mathcal{C}$ is an unknown function (the *target* function or concept) that we want to learn. A learning algorithm is given *examples* of the form $(x, c(x))$, where x is distributed according to some probability distribution D on $[N]$. An (ε, δ)-learner for $\mathcal{C}$ w.r.t. D is an algorithm that, for every possible target concept $c \in \mathcal{C}$, produces a hypothesis $h : [N] \to \{-1, 1\}$ such that with probability at least $1 - \delta$ (over the randomness of the learner and the examples for the target concept c), h's generalization error is at most ε:

$$\Pr_{x \sim D}[c(x) \neq h(x)] \leq \varepsilon.$$

In other words, from D-distributed examples the learner has to construct a hypothesis that mostly agrees with the target concept *under the same* D.

In the early days of quantum computing, Bshouty and Jackson [11] generalized this learning setting by allowing coherent *quantum* examples. A quantum example for concept c w.r.t. distribution D, is the following $(\lceil \log N \rceil + 1)$-qubit state:

$$\sum_{x \in [N]} \sqrt{D(x)} |x, c(x)\rangle.$$

Clearly such a quantum example is at least as useful as a classical example, because measuring this state yields a pair $(x, c(x))$ where $x \sim D$. Bshouty and Jackson gave examples of concept classes that can be learned more efficiently from quantum examples than from classical random examples under specific D. In particular, they showed that the concept class of DNF-formulas can be learned in polynomial time from quantum examples under the *uniform* distribution, something we do not know how to do classically (the best classical upper bound is quasi-polynomial time [33]). The key to this improvement is the ability to obtain, from a uniform quantum example, a sample $S \sim \widehat{c}(S)^2$ distributed according to the squared *Fourier coefficients* of c.[1] This *Fourier sampling*, originally due to Bernstein and Vazirani [8], is very

[1] Parseval's identity implies $\sum_{S \in \{0,1\}^n} \widehat{f}(S)^2 = 1$, so this is indeed a probability distribution.

powerful. For example, if $\mathcal{C}$ is the class of $\mathbb{F}_2$-linear functions on $\{0,1\}^n$, then the unknown target concept c is a character function $\chi_S(x) = (-1)^{x \cdot S}$; its only non-zero Fourier coefficient is $\widehat{c}(S)$ hence one Fourier sample gives us the unknown S with certainty. In contrast, learning linear functions from classical uniform examples requires $\Theta(n)$ examples. Another example where Fourier sampling is proven powerful is in learning the class of ℓ-juntas on n bits.[2] Atıcı and Servedio [6] showed that $(\log n)$-juntas can be exactly learned under the uniform distribution in time polynomial in n. Classically it is a long-standing open question if a similar result holds when the learner is given uniform classical examples (the best known algorithm runs in quasi-polynomial time [24]). These cases (and others surveyed in [4]) show that uniform quantum examples (and in particular Fourier sampling) can be more useful than classical examples.[3]

In this paper we consider the concept class of n-bit Boolean functions that are *k-sparse in the Fourier domain*: $\widehat{c}(S) \neq 0$ for at most k different S's. This is a natural generalization of the above-mentioned case of learning linear functions, which corresponds to $k = 1$. It also generalizes the case of learning ℓ-juntas on n bits, which are functions of sparsity $k = 2^\ell$. Variants of the class of k-Fourier-sparse functions have been well-studied in the area of *sparse recovery*, where the goal is to recover a k-sparse vector $x \in \mathbb{R}^N$ given a low-dimensional linear sketch Ax for a so-called "measurement matrix" matrix $A \in \mathbb{R}^{m \times N}$. See [20, 23] for some upper bounds on the size of the measurement matrix that suffice for sparse recovery. Closer to the setting of this paper, there has also been extensive work on learning the concept class of n-bit *real-valued* functions that are k-sparse in the Fourier domain. In this direction Cheraghchi et al. [14] showed that $O(nk(\log k)^3)$ uniform examples suffice to learn this concept class, improving upon the works of Bourgain [10], Rudelson and Vershynin [27] and Candés and Tao [12].

In this paper we focus on *exactly* learning the target concept from uniform examples, with high success probability. So $D(x) = 1/2^n$ for all x, $\varepsilon = 0$, and $\delta = 1/3$. Haviv and Regev [21] showed that for classical learners $O(nk \log k)$ uniform examples suffice to learn k-Fourier-sparse functions, and $\Omega(nk)$ uniform examples are necessary. In Section 3 we study the number of uniform *quantum* examples needed to learn k-Fourier-sparse Boolean functions, and show that it is upper bounded by $O(k^{1.5}(\log k)^2)$. For $k \ll n^2$ this quantum bound is much better than the number of uniform examples used in the classical case. Proving the upper bound combines the fact that a uniform quantum example allows us to Fourier-sample the target concept, with some Fourier analysis of k-Fourier-sparse functions. In particular, we significantly strengthen "Chang's lemma" for the special case of k-Fourier-sparse Boolean functions. This lemma upper bounds the dimension of the span of the large-weight part of the Fourier support of a Boolean function, and our Theorem 13 improves this bound almost quadratically for the special case of k-Fourier-sparse functions. Our learner has two phases. In the first phase, using Chang's lemma, we show that the span of the Fourier support of the target function can be learned from $O(k(\log k)^2)$ Fourier samples. In the second phase, we reduce the number of variables to the dimension r of the Fourier support, and then invoke the classical learner of Haviv and Regev to learn the target function from $O(rk \log k)$ classical examples. Since it is known that $r = O(\sqrt{k} \log k)$ [28], the two phases together imply that $O(k^{1.5}(\log k)^2)$ uniform quantum examples suffice to exactly learn the target with high probability.

[2] We say $f : \{0,1\}^n \to \{-1,1\}$ is an *ℓ-junta* if there exists a set $S \subseteq [n]$ of size $|S| \leq \ell$ such that f depends only on the variables whose indices are in S.

[3] This is not the case in Valiant's *PAC-learning* model [32] of distribution-independent learning. There we require the same learner to be an (ε, δ)-learner for $\mathcal{C}$ w.r.t. *every* possible distribution D. One can show in this model (and also in the broader model of *agnostic* learning) that the quantum and classical sample complexities are equal up to a constant factor [5].

Since $r \geq \log k$, the second phase of our learner is always at least as expensive as the first phase. It might be possible to improve the upper bound to $O(k \cdot \text{polylog}(k))$ quantum examples, but that would require additional ideas to improve phase 2. We also prove a (non-matching) lower bound of $\Omega(k \log k)$ uniform quantum examples, using techniques from quantum information theory. We omitted some proofs due to space limitations; these may be found in [3].

1.3 Exact learning from quantum membership queries

Our second result is in a model of active learning. The learner still wants to exactly learn an unknown target concept $c : [N] \to \{-1, 1\}$ from a known concept class $\mathcal{C}$, but now the learner can choose which points of the truth-table of the target it sees, rather than those points being chosen randomly. More precisely, the learner can query $c(x)$ for any x of its choice. This is called a *membership query*.[4] Quantum algorithms have the following query operation available:

$$O_c : |x, b\rangle \mapsto |x, b \cdot c(x)\rangle,$$

where $b \in \{-1, 1\}$. For some concept classes, quantum membership queries can be much more useful than classical. Consider again the class $\mathcal{C}$ of $\mathbb{F}_2$-linear functions on $\{0, 1\}^n$. Using one query to a uniform superposition over all x and doing a Hadamard transform, we can Fourier-sample and hence learn the target concept exactly. In contrast, $\Theta(n)$ classical membership queries are necessary and sufficient for classical learners. As another example, consider the concept class $\mathcal{C} = \{\delta_i \mid i \in [N]\}$ of the N point functions, where $\delta_i(x) = 1$ iff $i = x$. Elements from this class can be learned using $O(\sqrt{N})$ quantum membership queries by Grover's algorithm, while every classical algorithm needs to make $\Omega(N)$ membership queries.

For a given concept class $\mathcal{C}$ of ± 1-valued function on $[N]$, let $D(\mathcal{C})$ denote the minimal number of classical membership queries needed for learners that can exactly identify every $c \in \mathcal{C}$ with success probability 1 (such learners are deterministic without loss of generality). Let $R(\mathcal{C})$ and $Q(\mathcal{C})$ denote the minimal number of classical and quantum membership queries, respectively, needed for learners that can exactly identify every $c \in \mathcal{C}$ with error probability $\leq 1/3$.[5] Servedio and Gortler [30] showed that these quantum and classical measures cannot be too far apart. First, using an information-theoretic argument they showed

$$Q(\mathcal{C}) \geq \Omega\left(\frac{\log |\mathcal{C}|}{\log N}\right).$$

Intuitively, this holds because a learner recovers roughly $\log |\mathcal{C}|$ bits of information, while every quantum membership query can give at most $O(\log N)$ bits of information. Note that this is tight for the class of linear functions, where the left- and right-hand sides are both constant. Second, using the so-called hybrid method they showed

$$Q(\mathcal{C}) \geq \Omega(1/\sqrt{\gamma(\mathcal{C})}),$$

[4] Think of the set $\{x \mid c(x) = 1\}$ corresponding to the target concept: a membership query asks whether x is a member of this set or not.

[5] We can identify each concept with a string $c \in \{-1, 1\}^N$, and hence $\mathcal{C} \subseteq \{-1, 1\}^N$. The goal is to learn the unknown $c \in \mathcal{C}$ with high probability using few queries to the corresponding N-bit string. This setting is also sometimes called "oracle identification" in the literature; see [4, Section 4.1] for more.

for some combinatorial parameter $\gamma(\mathcal{C})$ that we will not define here (but which is $1/N$ for the class $\mathcal{C}$ of point functions, hence this inequality is tight for that $\mathcal{C}$). They also noted the following upper bound:

$$D(\mathcal{C}) = O\left(\frac{\log|\mathcal{C}|}{\gamma(\mathcal{C})}\right).$$

Combining these three inequalities yields the following relation between $D(\mathcal{C})$ and $Q(\mathcal{C})$

$$D(\mathcal{C}) \leq O(Q(\mathcal{C})^2 \log|\mathcal{C}|) \leq O(Q(\mathcal{C})^3 \log N). \tag{1}$$

This shows that, up to a $\log N$-factor, quantum and classical membership query complexities of exact learning are polynomially close. While each of the three inequalities that together imply (1) can be individually tight (for different $\mathcal{C}$), this does not imply (1) itself is tight.

Note that Eq. (1) upper bounds the membership query complexity of *deterministic* classical learners. We are not aware of a stronger upper bound on *bounded-error* classical learners. However, in Section 4 we tighten that bound further by a $\log Q(\mathcal{C})$-factor:

$$R(\mathcal{C}) \leq O\left(\frac{Q(\mathcal{C})^2}{\log Q(\mathcal{C})}\log|\mathcal{C}|\right) \leq O\left(\frac{Q(\mathcal{C})^3}{\log Q(\mathcal{C})}\log N\right).$$

Note that this inequality is tight both for the class of linear functions and for the class of point functions.

Our proof combines the quantum adversary method [2, 7, 31] with an entropic argument to show that we can always find a query whose outcome (no matter whether it's 0 or 1) will shrink the concept class by a factor $\leq 1 - \frac{\log Q(\mathcal{C})}{Q(\mathcal{C})^2}$. While our improvement over the earlier bounds is not very large, we feel our usage of entropy to save a log-factor is new and may have applications elsewhere.

2 Preliminaries

Notation. Let $[n] = \{1, \ldots, n\}$. For an n-dimensional vector space, the standard basis vectors are $\{e_i \in \{0,1\}^n \mid i \in [n]\}$, where e_i is the vector with a 1 in the ith coordinate and 0s elsewhere. For $x \in \{0,1\}^n$, $i \in [n]$, let x^i be the input obtained by flipping the ith bit in x.

For $f : \{0,1\}^n \to \{-1,1\}$ and $B \in \mathbb{F}_2^{n\times n}$, define $f \circ B : \{0,1\}^n \to \{-1,1\}$ as $(f \circ B)(x) := f(Bx)$, where the matrix-vector product Bx is over $\mathbb{F}_2$. Throughout this paper, the rank of a matrix $B \in \mathbb{F}_2^{n\times n}$ will be taken over $\mathbb{F}_2$. Let $B_1, \ldots, B_n$ be the columns of B.

Fourier analysis on the Boolean cube. We introduce the basics of Fourier analysis here, referring to [26, 35] for more. Define the inner product between functions $f, g : \{0,1\}^n \to \mathbb{R}$ as

$$\langle f, g\rangle = \mathbb{E}_{x\in\{0,1\}^n}[f(x)\cdot g(x)],$$

where the expectation is uniform over all $x \in \{0,1\}^n$. For $S \in \{0,1\}^n$, the character function corresponding to S is given by $\chi_S(x) := (-1)^{S\cdot x}$, where the dot product $S \cdot x$ is $\sum_{i=1}^n S_i x_i$. Observe that the set of functions $\{\chi_S\}_{S\in\{0,1\}^n}$ forms an orthonormal basis for the space of real-valued functions over the Boolean cube. Hence every $f : \{0,1\}^n \to \mathbb{R}$ can be written uniquely as

$$f(x) = \sum_{S\in\{0,1\}^n} \widehat{f}(S)(-1)^{S\cdot x} \qquad \text{for all } x \in \{0,1\}^n,$$

where $\widehat{f}(S) = \langle f, \chi_S \rangle = \mathbb{E}_x[f(x)\chi_S(x)]$ is called a *Fourier coefficient* of f. For $i \in [n]$, we write $\widehat{f}(e_i)$ as $\widehat{f}(i)$ for notational convenience. Parseval's identity states that $\sum_{S\in\{0,1\}^n} \widehat{f}(S)^2 = \mathbb{E}_x[f(x)^2]$. If f has domain $\{-1,1\}$, then Parseval gives $\sum_{S\in\{0,1\}^n} \widehat{f}(S)^2 = 1$, so $\{\widehat{f}(S)^2\}_{S\in\{0,1\}^n}$ forms a probability distribution. The *Fourier weight* of function f on $\mathcal{S} \subseteq \{0,1\}^n$ is defined as $\sum_{S\in\mathcal{S}} \widehat{f}(S)^2$.

For $f : \{0,1\}^n \to \mathbb{R}$, the *Fourier support* of f is $\mathrm{supp}(\widehat{f}) = \{S : \widehat{f}(S) \neq 0\}$. The *Fourier sparsity* of f is $|\mathrm{supp}(\widehat{f})|$. The *Fourier span* of f, denoted $\mathrm{Fspan}(f)$, is the span of $\mathrm{supp}(\widehat{f})$. The *Fourier dimension* of f, denoted $\mathrm{Fdim}(f)$, is the dimension of the Fourier span. We say f is *k-Fourier-sparse* if $|\mathrm{supp}(\widehat{f})| \leq k$.

We now state a few structural results about Fourier coefficients and dimension.

▶ **Theorem 1** ([28]). *The Fourier dimension of a k-Fourier-sparse $f : \{0,1\}^n \to \{-1,1\}$ is $O(\sqrt{k}\log k)$.*

▶ **Lemma 2** ([17, Theorem 12]). *Let $k \geq 2$. The Fourier coefficients of a k-Fourier-sparse Boolean function $f : \{0,1\}^n \to \{-1,1\}$ are integer multiples of $2^{1-\lfloor \log k \rfloor}$.*

▶ **Definition 3.** *Let $f : \{0,1\}^n \to \{-1,1\}$ and suppose $B \in \mathbb{F}_2^{n\times n}$ is invertible. Define f_B as $f_B(x) = f((B^{-1})^{\mathsf{T}}x)$.*

▶ **Lemma 4.** *Let $f : \{0,1\}^n \to \mathbb{R}$ and suppose $B \in \mathbb{F}_2^{n\times n}$ is invertible. Then the Fourier coefficients of f_B are $\widehat{f_B}(Q) = \widehat{f}(BQ)$ for all $Q \in \{0,1\}^n$.*

Proof. Write out the Fourier expansion of f_B:

$$f_B(x) = f((B^{-1})^{\mathsf{T}}x) = \sum_{S\in\{0,1\}^n} \widehat{f}(S)(-1)^{S\cdot((B^{-1})^{\mathsf{T}}x)}$$
$$= \sum_{S\in\{0,1\}^n} \widehat{f}(S)(-1)^{(B^{-1}S)\cdot x} = \sum_{Q\in\{0,1\}^n} \widehat{f}(BQ)(-1)^{Q\cdot x},$$

where the third equality used $\langle S, (B^{-1})^{\mathsf{T}}x\rangle = \langle B^{-1}S, x\rangle$ and the last used the substitution $S = BQ$. ◀

An easy consequence is the next lemma:

▶ **Lemma 5.** *Let $f : \{0,1\}^n \to \{-1,1\}$, and $B \in \mathbb{F}_2^{n\times n}$ be an invertible matrix such that the first r columns of B are a basis of $\mathrm{Fspan}(f)$, and $\widehat{f}(B_1), \ldots, \widehat{f}(B_r)$ are non-zero. Then the Fourier span of f_B is spanned by $\{e_1, \ldots, e_r\}$, i.e., f_B has only r influential variables. Additionally, for every $i \in [r]$, $\widehat{f_B}(i) \neq 0$.*

Here is the well-known fact, already mentioned in the introduction, that one can Fourier-sample from uniform quantum examples:

▶ **Lemma 6.** *Let $f : \{0,1\}^n \to \{-1,1\}$. There exists a procedure that uses one uniform quantum example and satisfies the following: with probability $1/2$ it outputs an S drawn from the distribution $\{\widehat{f}(S)^2\}_{S\in\{0,1\}^n}$, otherwise it rejects.*

Information theory. We refer to [15] for a comprehensive introduction to classical information theory, and here just remind the reader of the basic definitions. A random variable $\mathbf{A}$ with probabilities $\Pr[\mathbf{A} = a] = p_a$ has *entropy* $H(\mathbf{A}) := -\sum_a p_a \log(p_a)$. For a pair of (possibly correlated) random variables $\mathbf{A}, \mathbf{B}$, the *conditional entropy* of $\mathbf{A}$ given $\mathbf{B}$, is $H(\mathbf{A} \mid \mathbf{B}) := H(\mathbf{A}, \mathbf{B}) - H(\mathbf{B})$. This equals $\mathbb{E}_{b\sim\mathbf{B}}[H(\mathbf{A} \mid \mathbf{B} = b)]$. The *mutual information*

between $\mathbf{A}$ and $\mathbf{B}$ is $I(\mathbf{A}:\mathbf{B}) := H(\mathbf{A}) + H(\mathbf{B}) - H(\mathbf{A},\mathbf{B}) = H(\mathbf{A}) - H(\mathbf{A} \mid \mathbf{B})$. The *binary entropy* $H(p)$ is the entropy of a bit with distribution $(p, 1-p)$. If ρ is a density matrix (i.e., a trace-1 positive semi-definite matrix), then its singular values form a probability distribution P, and the *von Neumann entropy* of ρ is $S(\rho) := H(P)$. We refer to [25, Part III] for a more extensive introduction to quantum information theory.

3 Exact learning of k-Fourier-sparse functions

In this section we consider exactly learning the concept class $\mathcal{C}$ of k-Fourier-sparse Boolean functions:

$$\mathcal{C} = \{f : \{0,1\}^n \to \{-1,1\} : |\mathrm{supp}(\widehat{f})| \leq k\}.$$

The goal is to exactly learn $c \in \mathcal{C}$ given *uniform examples* from c of the form $(x, c(x))$ where x is drawn from the uniform distribution on $\{0,1\}^n$. Haviv and Regev [21] considered learning this concept class and showed the following results.

▶ **Theorem 7** (Corollary 3.6 of [21]). *For every $n > 0$ and $k \leq 2^n$, the number of uniform examples that suffice to learn $\mathcal{C}$ with probability $1 - 2^{-\Omega(n \log k)}$ is $O(nk \log k)$.*

▶ **Theorem 8** (Theorem 3.7 of [21]). *For every $n > 0$ and $k \leq 2^n$, the number of uniform examples necessary to learn $\mathcal{C}$ with constant success probability is $\Omega(k(n - \log k))$.*

Our main results in this section are about the number of uniform *quantum* examples that are necessary and sufficient to exactly learn the class $\mathcal{C}$ of k-Fourier-sparse functions. A uniform quantum example for a concept $c \in \mathcal{C}$ is the quantum state

$$\frac{1}{\sqrt{2^n}} \sum_{x \in \{0,1\}^n} |x, c(x)\rangle.$$

We prove the following two theorems here.

▶ **Theorem 9.** *For every $n > 0$ and $k \leq 2^n$, the number of uniform quantum examples that suffice to learn $\mathcal{C}$ with probability $\geq 2/3$ is $O(k^{1.5}(\log k)^2)$.*

In the theorem below we prove the following (non-matching) lower bound on the number of uniform quantum examples necessary to learn $\mathcal{C}$.

▶ **Theorem 10.** *For every $n > 0$, constant $c \in (0,1)$ and $k \leq 2^{cn}$, the number of uniform quantum examples necessary to learn $\mathcal{C}$ with constant success probability is $\Omega(k \log k)$.*

3.1 Upper bound on learning k-Fourier-sparse Boolean functions

We split our quantum learning algorithm into two phases. Suppose $c \in \mathcal{C}$ is the unknown concept, with Fourier dimension r. In the first phase the learner uses samples from the distribution $\{\widehat{c}(S)^2\}_{S \in \{0,1\}^n}$ to learn the Fourier span of c. In the second phase the learner uses uniform *classical* examples to learn c exactly, knowing its Fourier span. Phase 1 uses $O(k(\log k)^2)$ uniform quantum examples (for Fourier-sampling) and phase 2 uses $O(rk \log k)$ uniform *classical* examples. Note that since $r \geq \log k$, phase 2 of our learner is always at least as expensive as phase 1.

▶ **Theorem 11.** *Let $k, r > 0$. There exists a quantum learner that exactly learns (with high probability) an unknown k-Fourier-sparse $c : \{0,1\}^n \to \{-1,1\}$ with Fourier dimension upper bounded by some known r, from $O(rk \log k)$ uniform quantum examples.*

The learner may not know the exact Fourier dimension r in advance, but Theorem 1 gives an upper bound $r = O(\sqrt{k} \log k)$, so our Theorem 9 follows immediately from Theorem 11.

3.1.1 Phase 1: Learning the Fourier span

A crucial ingredient that we use in phase 1 of our quantum learning algorithm is an improvement of Chang's lemma [13, 22] for k-Fourier-sparse Boolean functions. The original lemma upper bounds the dimension of the span of the "large" Fourier coefficients as follows.

▶ **Lemma 12** (Chang's lemma). *Let $\alpha \in (0,1)$ and $\rho > 0$. For every $f : \{0,1\}^n \to \{-1,1\}$ that satisfies $\widehat{f}(0^n) = 1 - 2\alpha$, we have*

$$\dim(\mathrm{span}\{S : |\widehat{f}(S)| \geq \rho\alpha\}) \leq \frac{2\log(1/\alpha)}{\rho^2}. \tag{2}$$

Let us consider Chang's lemma for k-Fourier-sparse Boolean functions. In particular, consider the case $\rho\alpha = 1/k$. In that case, since all elements of the Fourier support satisfy $|\widehat{f}(S)| \geq 1/k$ by Lemma 2, the left-hand side of Eq. (2) equals the Fourier dimension r of f. Chang's lemma gives

$$r \leq 2\alpha^2 k^2 \log k.$$

We now improve this upper bound on r nearly quadratically:

▶ **Theorem 13.** *Let $\alpha \in (0,1)$ and $k \geq 2$. For every k-Fourier-sparse $f : \{0,1\}^n \to \{-1,1\}$ that satisfies $\widehat{f}(0^n) = 1 - 2\alpha$ and $\mathrm{Fdim}(f) = r$, we have*

$$r \leq 2\alpha k \log k.$$

For a proof of this theorem, see the full version of the paper. We now illustrate how this theorem improves over Lemma 12. First, observe that $\alpha \geq 1/k$ (by Lemma 2), so $\alpha k \leq \alpha^2 k^2$. Second, consider a Boolean function f which satisfies $\alpha = 1/k^{3/4}$. Then, Chang's lemma (with $\rho = 1/k^{1/4}$) upper bounds the Fourier dimension of f as $r \leq O(\sqrt{k}\log k)$, which already follows from Theorem 1. Our Theorem 13 gives the much better upper bound $r \leq O(k^{1/4}\log k)$ in this case.

Now that we have a better understanding of the Fourier dimension of k-Fourier-sparse Boolean functions, we would like to understand how many Fourier samples suffice to obtain the Fourier span of f (in fact this will be our quantum learning algorithm for phase 1). Since the $\leq k$ squared non-zero Fourier coefficients of a k-Fourier-sparse function are each at least $1/k^2$, it is easy to see that after $O(k^2 \log k)$ Fourier samples we are likely to have seen every element in the Fourier support, and hence know the full Fourier support as well. We will improve on this easy bound below. The main idea is to show that if the span of the Fourier samples seen at a certain point has some dimension $r' < r$, then there is significant Fourier weight on elements outside of this span, so after a few more Fourier samples we will have grown the span. We now state this formally and prove the lemma.

▶ **Lemma 14.** *Let $n > 0$ and $1 \leq k \leq 2^n$. For every k-Fourier-sparse $f : \{0,1\}^n \to \{-1,1\}$ with Fourier span $\mathcal{V}$ and Fourier dimension r, the following holds: for every $r' > 0$ and $\mathcal{S} \subset \mathcal{V}$ satisfying $\dim(\mathrm{span}(\mathcal{S})) = r'$, we have*

$$\sum_{S \in \mathrm{span}(\mathcal{S})} \widehat{f}(S)^2 \leq 1 - \frac{r - r'}{k \log k}.$$

Proof. Let $B \in \mathbb{F}_2^{r \times r}$ be an invertible matrix such that the first $r' < r$ columns of B form a basis for $\mathrm{span}(\mathcal{S})$. By Lemma 5, f_B depends only on r bits, so we write $f_B : \{0,1\}^r \to \{-1,1\}$. Let $\mathcal{W} = \mathrm{span}\{e_1, \ldots, e_{r'}\} \subseteq \{0,1\}^r$. Then

$$\sum_{S \in \mathrm{span}(\mathcal{S})} \widehat{f}(S)^2 = \sum_{S \in \mathcal{W}} \widehat{f_B}(S)^2. \tag{3}$$

Let us decompose f_B as follows: $f_B(x_1,\ldots,x_r) = g(x_1,\ldots,x_{r'}) + g'(x_1,\ldots,x_r)$, where

$$g(y) = \sum_{T\in\{0,1\}^{r'}} \widehat{f_B}(T,0^{r-r'})\chi_T(y,0^{r-r'}) \quad \text{for every } y\in\{0,1\}^{r'}, \tag{4}$$

and

$$g'(x) = \sum_{S\notin\mathcal{W}} \widehat{f_B}(S)\chi_S(x) \quad \text{for every } x\in\{0,1\}^r.$$

Now by Parseval's identity we have

$$\mathbb{E}_{y\in\{0,1\}^{r'}}[g(y)^2] = \sum_{T\in\{0,1\}^{r'}} \widehat{g}(T)^2 = \sum_{S\in\mathcal{W}} \widehat{f_B}(S)^2, \tag{5}$$

where the second equality used Eq. (4). Combining Eq. (5) with an averaging argument, there exists an assignment of $a=(a_1,\ldots,a_{r'})\in\{0,1\}^{r'}$ to $(y_1,\ldots,y_{r'})$ such that

$$g(a_1,\ldots,a_{r'})^2 \geq \sum_{S\in\mathcal{W}} \widehat{f_B}(S)^2, \tag{6}$$

Consider the function h defined as

$$h(z_1,\ldots,z_{r-r'}) = f_B(a_1,\ldots,a_{r'},z_1,\ldots,z_{r-r'}) \quad \text{for every } z_1,\ldots,z_{r-r'}\in\{0,1\}. \tag{7}$$

Note that h has Fourier sparsity at most the Fourier sparsity of f_B, hence at most k. Also, the Fourier dimension of h is at most $r-r'$. Finally note that

$$\begin{aligned}
\widehat{h}(0^{r-r'}) &= \mathbb{E}_{z\in\{0,1\}^{r-r'}}[h(z)] \\
&= \mathbb{E}_{z\in\{0,1\}^{r-r'}}[f_B(a,z)] && \text{(by Eq. (7))} \\
&= \mathbb{E}_{z\in\{0,1\}^{r-r'}}\Big[\sum_{S_1\in\{0,1\}^{r'}}\sum_{S_2\in\{0,1\}^{r-r'}} \widehat{f_B}(S_1,S_2)\chi_{S_1}(a)\chi_{S_2}(z)\Big] \\
& && \text{(Fourier expansion of } f_B) \\
&= \sum_{S_1\in\{0,1\}^{r'}} \widehat{f_B}(S_1,0^{r-r'})\chi_{S_1}(a,0^{r-r'}) && \text{(using } \mathbb{E}_{z\in\{0,1\}^{r-r'}}\chi_S(z)=\delta_{S,0^{r-r'}}) \\
&= g(a_1,\ldots,a_{r'}) && \text{(by definition of } g \text{ in Eq. (4))} \\
&\geq \Big(\sum_{S\in\mathcal{W}} \widehat{f_B}(S)^2\Big)^{1/2}. && \text{(by Eq. (6))}
\end{aligned}$$

Using Theorem 13 for the function h, it follows that $\widehat{h}(0^{r-r'}) \leq 1-(r-r')/(k\log k)$, which in particular implies

$$\sum_{S\in\mathrm{span}(\mathcal{S})} \widehat{f}(S)^2 = \sum_{S\in\mathcal{W}} \widehat{f_B}(S)^2 \leq \widehat{h}(0^{r-r'})^2 \leq 1-\frac{r-r'}{k\log k},$$

where the first equality used Eq. (3). ◀

▶ **Theorem 15.** *For every k-Fourier-sparse Boolean function $f:\{-1,1\}^n\to\{-1,1\}$ with Fourier dimension r, its Fourier span can be learned using an expected number of $O(k\log k\log r)$ quantum examples.*

Proof. We only use the quantum examples for Fourier sampling; an expected number of two quantum examples suffices to get one Fourier sample. At any point of time let $\mathcal{S}$ be the set of samples we have received. Let the dimension of the span of $\mathcal{S}$ be r'. Now if we receive a new sample S such that $S \notin \text{span}(\mathcal{S})$, then the dimension of the samples we have seen increases by 1. By Lemma 14

$$\sum_{S \notin \text{span}(\mathcal{S})} \widehat{f}(S)^2 \geq \frac{r - r'}{k \log k}.$$

So the expected number of samples to increase the dimension by 1 is $\leq \frac{k \log k}{r - r'}$. Hence, the expected number of Fourier samples needed to learn the whole Fourier span of f is at most

$$\sum_{i=1}^{r} \frac{k \log k}{i} \leq O(k \log k \log r),$$

where the final inequality used $\sum_{i=1}^{r} \frac{1}{i} = O(\log r)$. ◀

3.1.2 Phase 2: Learning the function completely

In the above phase 1, the quantum learner obtains the Fourier span of c, which we will denote by $\mathcal{T}$. Using this, the learner can restrict to the following concept class

$$\mathcal{C}' = \{c : \{0,1\}^n \to \{-1,1\} \mid c \text{ is } k\text{-Fourier-sparse with Fourier span } \mathcal{T}\}$$

Let $\dim(\mathcal{T}) = r$. Let $B \in \mathbb{F}_2^{n \times n}$ be an invertible matrix whose first r columns of B form a basis for $\mathcal{T}$. Consider $c_B = c \circ (B^{-1})^{\mathsf{T}}$ for $c \in \mathcal{C}'$. By Lemma 5 it follows that c_B depends on only its first r bits, and we can write $c_B : \{0,1\}^r \to \{-1,1\}$. Hence the learner can apply the transformation $c \mapsto c \circ (B^{-1})^{\mathsf{T}}$ for every $c \in \mathcal{C}'$ and restrict to the concept class

$$\mathcal{C}'_r = \{c' : \{0,1\}^r \to \{-1,1\} \mid c' = c \circ (B^{-1})^{\mathsf{T}} \text{ for some } c \in \mathcal{C}' \text{ and invertible } B\}.$$

We now conclude phase 2 of the algorithm by invoking the classical upper bound of Haviv-Regev (Theorem 7) which says that $O(rk \log k)$ uniform classical examples of the form $(z, c'(z)) \in \{0,1\}^{r+1}$ suffice to learn $\mathcal{C}'_r$. Although we assume our learning algorithm has access to uniform examples of the form $(x, c(x))$ for $x \in \{0,1\}^n$, the quantum learner knows B and hence can obtain a uniform example $(z, c'(z))$ for c' by letting z be the first r bits of $B^{\mathsf{T}}x$ and $c'(z) = c(x)$.

3.2 Lower bound on learning k-Fourier-sparse Boolean functions

We show that $\Omega(k \log k)$ uniform quantum examples are necessary to learn the concept class of k-Fourier-sparse Boolean functions. See the full version of the paper for the proof.

▶ **Theorem 16.** *For every n, constant $c \in (0,1)$ and $k \leq 2^{cn}$, the number of uniform quantum examples necessary to learn the class of k-Fourier-sparse Boolean functions, with success probability $\geq 2/3$, is $\Omega(k \log k)$.*

4 Quantum vs classical membership queries

In this section we assume we can access the target function using membership queries rather than examples. Our goal is to simulate quantum exact learners for a concept class $\mathcal{C}$ by classical exact learners, without using many more membership queries. A key tool here

will be the ("nonnegative" or "positive-weights") adversary method. This was introduced by Ambainis [2]; here we will use the formulation of Barnum et al. [7], which is called the "spectral adversary" in the survey [31].

Let $\mathcal{C} \subseteq \{0,1\}^N$ be a set of strings. If $N = 2^n$ then we may view such a string $c \in \mathcal{C}$ as (the truth-table of) an n-bit Boolean function, but in this section we do not need the additional structure of functions on the Boolean cube and may consider any positive integer N. Suppose we want to identify an unknown $c \in \mathcal{C}$ with success probability at least $2/3$ (i.e., we want to compute the identity function on $\mathcal{C}$). The required number of quantum queries to c can be lower bounded as follows. Let Γ be a $|\mathcal{C}| \times |\mathcal{C}|$ matrix with real, nonnegative entries and 0s on the diagonal (called an "adversary matrix"). Let D_i denote the $|\mathcal{C}| \times |\mathcal{C}|$ 0/1-matrix whose (c,c')-entry is $[c_i \neq c'_i]$.[6] Then it is known that at least (a constant factor times) $\| \Gamma \| / \max_{i \in [N]} \| \Gamma \circ D_i \|$ quantum queries are needed, where $\| \cdot \|$ denotes operator norm (largest singular value) and '$\circ$' denotes entrywise product of matrices. Let

$$\mathrm{ADV}(\mathcal{C}) = \max_{\Gamma \geq 0} \frac{\| \Gamma \|}{\max_{i \in [N]} \| \Gamma \circ D_i \|}$$

denote the best-possible lower bound on $Q(\mathcal{C})$ that can be achieved this way.

The key to our classical simulation is the next lemma. It shows that if $Q(\mathcal{C})$ (and hence $\mathrm{ADV}(\mathcal{C})$) is small, then there is a query that splits the concept class in a "mildly balanced" way.

▶ **Lemma 17.** *For $N \geq 1$, let $\mathcal{C} \subseteq \{0,1\}^N$ be a concept class and suppose $\mathrm{ADV}(\mathcal{C}) = \max_{\Gamma \geq 0} \| \Gamma \| / \max_{i \in [N]} \| \Gamma \circ D_i \|$ is the nonnegative adversary bound for the exact learning problem corresponding to $\mathcal{C}$. Let μ be a distribution on $\mathcal{C}$ such that $\max_{c \in \mathcal{C}} \mu(c) \leq 5/6$, and let $\mathbf{C}$ be a random variable distributed according to μ. Then there exists an $i \in [N]$ such that*

$$\min(\mu(\mathbf{C}_i = 0), \mu(\mathbf{C}_i = 1)) \geq \frac{1}{36 \mathrm{ADV}(\mathcal{C})^2}.$$

Proof. Define unit vector $v \in \mathbb{R}_+^{|\mathcal{C}|}$ by $v_c = \sqrt{\mu(c)}$, and adversary matrix

$$\Gamma = vv^* - \mathrm{diag}(\mu),$$

where $\mathrm{diag}(\mu)$ is the diagonal matrix that has the entries of μ on its diagonal. This Γ is a nonnegative matrix with 0 diagonal (and hence a valid adversary matrix for the exact learning problem), and $\| \Gamma \| \geq \| vv^* \| - \| \mathrm{diag}(\mu) \| \geq 1 - 5/6 = 1/6$. Abbreviate $A = \mathrm{ADV}(\mathcal{C})$. By definition of A, we have for this particular Γ

$$A \geq \frac{\| \Gamma \|}{\max_i \| \Gamma \circ D_i \|} \geq \frac{1}{6 \max_i \| \Gamma \circ D_i \|},$$

hence there exists an $i \in [N]$ such that $\| \Gamma \circ D_i \| \geq \frac{1}{6A}$. We can write $v = \begin{pmatrix} v_0 \\ v_1 \end{pmatrix}$ where the entries of v_0 are the ones corresponding to cs where $c_i = 0$, and the entries of v_1 are the ones where $c_i = 1$. Then

$$\Gamma = \begin{pmatrix} v_0 v_0^* & v_0 v_1^* \\ v_1 v_0^* & v_1 v_1^* \end{pmatrix} - \mathrm{diag}(\mu) \quad \text{and} \quad \Gamma \circ D_i = \begin{pmatrix} 0 & v_0 v_1^* \\ v_1 v_0^* & 0 \end{pmatrix}.$$

[6] The bracket-notation $[P]$ denotes the truth-value of proposition P.

It is easy to see that $\| \Gamma \circ D_i \| = \| v_0 \| \cdot \| v_1 \|$. Hence

$$\frac{1}{36A^2} \leq \| \Gamma \circ D_i \|^2 = \| v_0 \|^2 \| v_1 \|^2 = \mu(\mathbf{C}_i = 0)\mu(\mathbf{C}_i = 1) \leq \min(\mu(\mathbf{C}_i = 0), \mu(\mathbf{C}_i = 1)),$$

where the last inequality used $\max(\mu(\mathbf{C}_i = 0), \mu(\mathbf{C}_i = 1)) \leq 1$. ◀

Note that if we query the index i given by this lemma and remove from $\mathcal{C}$ the strings that are inconsistent with the query outcome, then we reduce the size of $\mathcal{C}$ by a factor $\leq 1 - \Omega(1/\mathrm{ADV}(\mathcal{C})^2)$. Repeating this $O(\mathrm{ADV}(\mathcal{C})^2 \log |\mathcal{C}|)$ times would reduce the size of $\mathcal{C}$ to 1, completing the learning task. However, we will see below that analyzing the same approach in terms of entropy gives a somewhat better upper bound on the number of queries.

▶ **Theorem 18.** *For $N \geq 1$, let $\mathcal{C} \subseteq \{0,1\}^N$ be a concept class and suppose $\mathrm{ADV}(\mathcal{C}) = \max_{\Gamma \geq 0} \| \Gamma \| / \max_{i \in [N]} \| \Gamma \circ D_i \|$ is the nonnegative adversary bound for the exact learning problem corresponding to $\mathcal{C}$. Then there exists a classical learner for the concept class $\mathcal{C}$ using $O\left(\frac{\mathrm{ADV}(\mathcal{C})^2}{\log \mathrm{ADV}(\mathcal{C})} \log |\mathcal{C}|\right)$ membership queries that identifies the target concept with probability $\geq 2/3$.*

Proof. Fix an arbitrary distribution μ on $\mathcal{C}$. We will construct a deterministic classical learner for $\mathcal{C}$ with success probability $\geq 2/3$ under μ. Since we can do this for every μ, the "Yao principle" [36] then implies the existence of a randomized learner that has success probability $\geq 2/3$ for every $c \in \mathcal{C}$.

Consider the following algorithm, whose input is an N-bit random variable $\mathbf{C} \sim \mu$:

1. Choose an i that maximizes $H(\mathbf{C}_i)$ and query that i.[7]
2. Update $\mathcal{C}$ and μ by restricting to the concepts that are consistent with the query outcome.
3. Goto 1.

The queried indices are themselves random variables, and we denote them by $\mathbf{I}_1, \mathbf{I}_2, \ldots$. We can think of t steps of this algorithm as generating a binary tree of depth t, where the different paths correspond to the different queries made by the algorithm and their binary outcomes.

Let P_t be the probability that, after t queries, our algorithm has reduced μ to a distribution that has weight $\geq 5/6$ on one particular c:

$$P_t = \sum_{i_1,\ldots,i_t \in [N],\ b \in \{0,1\}^t} \Pr[\mathbf{I}_1 = i_1, \ldots, \mathbf{I}_t = i_t, \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b] \cdot [\exists c \in \mathcal{C} \text{ s.t. } \mu(c \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b) \geq 5/6].$$

Because restricting μ to a subset $\mathcal{C}' \subseteq \mathcal{C}$ cannot decrease probabilities of individual $c \in \mathcal{C}'$, this probability P_t is non-decreasing in t. Because N queries give us the target concept completely, we have $P_N = 1$. Let T be the smallest integer t for which $P_t \geq 5/6$. We will run our algorithm for T queries, and then output the c with highest probability under the restricted version of μ we now have. With μ-probability at least $5/6$, that c will have probability at least $5/6$ (under μ conditioned on the query-results). The overall error probability under μ is therefore $\leq 1/6 + 1/6 = 1/3$.

[7] Querying this i will give a fairly "balanced" reduction of the size of $\mathcal{C}$ irrespective of the outcome of the query. If there are several maximizing is, then choose the smallest i to make the algorithm deterministic.

It remains to upper bound T. To this end, define the following "energy function" in terms of conditional entropy:

$$\begin{aligned} E_t &= H(\mathbf{C} \mid \mathbf{C}_{\mathbf{I}_1}, \ldots, \mathbf{C}_{\mathbf{I}_t}) \\ &= \sum_{i_1,\ldots,i_t \in [N],\ b \in \{0,1\}^t} \Pr[\mathbf{I}_1 = i_1, \ldots, \mathbf{I}_t = i_t, \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b] \cdot H(\mathbf{C} \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b). \end{aligned}$$

Because conditioning on a random variable cannot increase entropy, E_t is non-increasing in t. We now show that as long as $P_t < 5/6$, the energy shrinks significantly with each new query.

Let $i_1, ..., i_t$ and b be such that there is no c in $\mathcal{C}$ s.t. $\mu(c \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b) \geq 5/6$ (note that the μ-probability of getting such an $i_1, ..., i_t$ and b, is $1 - P_t$). Let μ' be μ restricted to the class $\mathcal{C}'$ of concepts c where $c_{i_1} \ldots c_{i_t} = b$. The nonnegative adversary bound for this restricted concept class is $A' = \mathrm{ADV}(\mathcal{C}') \leq \mathrm{ADV}(\mathcal{C}) = A$. Applying Lemma 17 to μ', there is an $i_{t+1} \in [N]$ with $p := \min(\mu'(\mathbf{C}_{i_{t+1}} = 0), \mu'(\mathbf{C}_{i_{t+1}} = 1)) \geq \frac{1}{36A'^2} \geq \frac{1}{36A^2}$. Note that $H(p) \geq \Omega(\log(A)/A^2)$. Hence

$$\begin{aligned} H(\mathbf{C} \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b) - H(C \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b, \mathbf{C}_{i_{t+1}}) &= H(\mathbf{C}_{i_{t+1}} \mid \mathbf{C}_{i_1} \ldots \mathbf{C}_{i_t} = b) \\ &\geq \Omega(\log(A)/A^2). \end{aligned}$$

This implies $E_t - E_{t+1} \geq (1-P_t) \cdot \Omega(\log(A)/A^2)$. In particular, as long as $P_t < 5/6$, the $(t+1)$st query shrinks E_t by at least $\frac{1}{6}\Omega(\log(A)/A^2) = \Omega(\log(A)/A^2)$. Since $E_0 = H(\mathbf{C}) \leq \log|\mathcal{C}|$ and E_t cannot shrink below 0, there can be at most $O\left(\frac{A^2}{\log A} \log|\mathcal{C}|\right)$ queries before P_t grows to $\geq 5/6$. ◀

Since $\mathrm{ADV}(\mathcal{C})$ lower bounds $Q(\mathcal{C})$, Theorem 18 implies the bound $R(\mathcal{C}) \leq O\left(\frac{Q(\mathcal{C})^2}{\log Q(\mathcal{C})} \log|\mathcal{C}|\right)$ claimed in our introduction. Note that this bound is tight up to a constant factor for the class of N-bit point functions, where $A = \Theta(\sqrt{N})$, $|\mathcal{C}| = N$, and $R(\mathcal{C}) = \Theta(N)$ classical queries are necessary and sufficient.

5 Future work

Neither of our two results is tight. As directions for future work, let us state two conjectures, one for each model:

- k-Fourier-sparse functions can be learned from $O(k \cdot \mathrm{polylog}(k))$ uniform quantum examples.
- For all concept classes $\mathcal{C}$ of Boolean-valued functions on a domain of size N we have: $R(\mathcal{C}) = O(Q(\mathcal{C})^2 + Q(\mathcal{C}) \log N)$.

Abstract

Maximal independent set (MIS), maximal matching (MM), and $(\Delta+1)$-(vertex) coloring in graphs of maximum degree Δ are among the most prominent algorithmic graph theory problems. They are all solvable by a simple linear-time greedy algorithm and up until very recently this constituted the state-of-the-art. In SODA 2019, Assadi, Chen, and Khanna gave a randomized algorithm for $(\Delta+1)$-coloring that runs in $\widetilde{O}(n\sqrt{n})$ time[1], which even for moderately dense graphs is sublinear in the input size. The work of Assadi et al. however contained a spoiler for MIS and MM: neither problems provably admits a sublinear-time algorithm in general graphs. In this work, we dig deeper into the possibility of achieving sublinear-time algorithms for MIS and MM.

The neighborhood independence number of a graph G, denoted by $\beta(G)$, is the size of the largest independent set in the neighborhood of any vertex. We identify $\beta(G)$ as the "right" parameter to measure the runtime of MIS and MM algorithms: Although graphs of bounded neighborhood independence may be very dense (clique is one example), we prove that carefully chosen variants of greedy algorithms for MIS and MM run in $O(n\beta(G))$ and $O(n\log n\cdot\beta(G))$ time respectively on any n-vertex graph G. We complement this positive result by observing that a simple extension of the lower bound of Assadi et al. implies that $\Omega(n\beta(G))$ time is also necessary for any algorithm to either problem for all values of $\beta(G)$ from 1 to $\Theta(n)$. We note that our algorithm for MIS is deterministic while for MM we use randomization which we prove is unavoidable: any deterministic algorithm for MM requires $\Omega(n^2)$ time even for $\beta(G)=2$.

Graphs with bounded neighborhood independence, already for constant $\beta=\beta(G)$, constitute a rich family of possibly dense graphs, including line graphs, proper interval graphs, unit-disk graphs, claw-free graphs, and graphs of bounded growth. Our results suggest that even though MIS and MM do not admit sublinear-time algorithms in general graphs, one can still solve both problems in sublinear time for a wide range of $\beta(G)\ll n$.

Finally, by observing that the lower bound of $\Omega(n\sqrt{n})$ time for $(\Delta+1)$-coloring due to Assadi et al. applies to graphs of (small) constant neighborhood independence, we unveil an intriguing separation between the time complexity of MIS and MM, and that of $(\Delta+1)$-coloring: while the time complexity of MIS and MM is strictly higher than that of $(\Delta+1)$ coloring in general graphs, the exact opposite relation holds for graphs with small neighborhood independence.

1 Introduction

Maximal independent set (MIS) and maximal matching (MM) are two of the most prominent graph problems with a wide range of applications in particular to symmetry breaking. Algorithmic study of these problems can be traced back to at least four decades ago in the pioneering work of [33, 41, 1, 32] on PRAM algorithms. These problems have since been studied extensively in various models including distributed algorithms [40, 46, 31, 34, 38, 10, 9, 21, 19], dynamic algorithms [43, 11, 50, 45, 5, 6], streaming algorithms [18, 27, 15, 4], massively parallel computation (MPC) algorithms [37, 22, 12], local computation algorithms (LCA) [48, 2, 21, 20, 39, 23], and numerous others.

In this paper, we consider the **time complexity** of MIS and MM (in the centralized setting) and focus on one of the most basic questions regarding these two problems:

How fast can we solve maximal independent set and maximal matching problems?

At first glance, the answer to this question may sound obvious: there are text-book greedy algorithms for both problems that run in linear time and "of course" one cannot solve these problems faster as just reading the input takes linear time. This answer however is not quite warranted: for the closely related problem of $(\Delta+1)$-(vertex) coloring, very recently Assadi, Chen, and Khanna [4] gave a randomized algorithm that runs in only $\widetilde{O}(n\sqrt{n})$ time on any n-vertex graph with high probability[2]. This means that even for moderately dense graphs, one can indeed color the graph faster than reading the entire input, i.e., in sublinear time.

The Assadi-Chen-Khanna algorithm hints that one could perhaps hope for sublinear-time algorithms for MIS and MM as well. Unfortunately however, the work of [4] already contained a spoiler: neither MIS nor MM admits a sublinear-time algorithm in general graphs.

In this work, we show that despite the negative result of [4] for MIS and MM, the hope for obtaining sublinear-time algorithms for these problems need not be short lived. In particular, we identify a key parameter of the graph, namely the *neighborhood independence number*, that provides a more nuanced measure of runtime for these problems and show that both problems can be solved much faster when neighborhood independence is small. This in turn gives rise to sublinear-time algorithms for MIS and MM on a rich family of graphs with bounded neighborhood independence. In the following, we elaborate more on our results.

1.1 Our Contributions

For a graph $G(V,E)$, the neighborhood independence number of G, denoted by $\beta(G)$, is defined as the size of the largest independent set in the graph in which all vertices of the independent set are incident on some shared vertex $v \in V$. Our main result is as follows:

▷ Result 1. There exist algorithms that given a graph $G(V,E)$ find (i) a maximal independent set of G deterministically in $O(n \cdot \beta(G))$ time, and (ii) a maximal matching of G randomly in $O(n \log n \cdot \beta(G))$ time in expectation and with high probability.

When considering sublinear-time algorithms, specifying the exact data model is important as the algorithm cannot even read the entire input once. We assume that the input graph is presented in the adjacency array representation, i.e., for each vertex $v \in V$, we are given degree $\mathsf{deg}(v)$ of v followed by an array of length $\mathsf{deg}(v)$ containing all neighbors of v in

[2] We say an event happens with high probability if it happens with probability at least $1 - 1/\text{poly}(n)$.

arbitrary order. This way, we can access the degree of any vertex v or its i-th neighbor for $i \in [\mathsf{deg}(v)]$ in $O(1)$ time. We also make the common assumption that a random number from 1 to n can be generated in $O(1)$ time. This is a standard input representation for graph problems and is commonly used in the area of sublinear-time algorithms (see, e.g. [25, 26, 44]). We elaborate on several aspects of Result 1 in the following.

Optimality of Our Bounds. Assadi et al. [4] proved that any algorithm for MIS or MM requires $\Omega(n^2)$ time in general[3]. These lower bounds can be extended in an easy way to prove that $\Omega(n \cdot \beta)$ time is also necessary for both problems on graphs with neighborhood independence $\beta(G) = \beta$. Indeed, independently sample $t := n/\beta$ graphs $G_1, \ldots, G_t$ each on β vertices from the hard distribution of graphs in [4] and let G be the union of these graphs. Clearly, $\beta(G) \leq \beta$ and it follows that since solving MIS or MM on each graph G_i requires $\Omega(\beta^2)$ time by the lower bound of [4], solving t independent copies requires $\Omega(t \cdot \beta^2) = \Omega(n\beta)$ time. As such, our Result 1 is optimal for every β ranging from a constant to $\Theta(n)$ (up to a constant factor for MIS and $O(\log n)$ for MM).

Our Algorithms. Both our algorithms for MIS and MM in Result 1 are similar to the standard greedy algorithms, though they require careful adjustments and implementation. Specifically, the algorithm for MIS is the standard deterministic greedy algorithm (with minimal modification) and for MM we use a careful implementation of the (modified) randomized greedy algorithm (see, e.g. [16, 3, 42, 47]). The novelty of our work mainly lies in the analysis of these algorithms. We show, perhaps surprisingly, that already-known algorithms can in fact achieve an improved performance and run in sublinear-time for graphs with bounded neighborhood independence *even* when the value of $\beta(G)$ is unknown to the algorithms. Combined with the optimality of our bounds mentioned earlier, we believe that this makes neighborhood independence number an ideal parameter for measuring the runtime of MIS and MM algorithms.

Determinism and Randomization. Our MIS algorithm in Result 1 is deterministic which is a rare occurrence in the realm of sublinear-time algorithms. But for MM, we again fall back on randomization to achieve sublinear-time performance. This is not a coincidence however: we prove in Theorem 11 that any deterministic algorithm for MM requires $\Omega(n^2)$ time even on graphs with constant neighborhood independence number. This also suggests a separation in the time complexity of MIS and MM for deterministic algorithms.

Bounded Neighborhood Independence. Our Result 1 is particularly interesting for graphs with constant neighborhood independence as we obtain quite fast algorithms with running time $O(n)$ and $O(n \log n)$ for MIS and MM, respectively. Graphs with constant neighborhood independence capture a rich family of graphs; several illustrative examples are as follows:

- *Line graphs:* For any arbitrary graph G, the neighborhood independence number of its line graph $L(G)$ is at most 2. More generally, for any r-hyper graph $\mathcal{H}$ in which each hyper-edge connects at most r vertices, $\beta(L(\mathcal{H})) \leq r$.

[3] We note that the lower bound for MIS only appears in the full version of [4].

- *Bounded-growth graphs:* A graph $G(V, E)$ is said to be of bounded growth iff there exists a function such that for every vertex $v \in V$ and integer $r \geq 1$, the size of the largest independent set in the r-neighborhood of v is bounded by $f(r)$. Bounded-growth graphs in turn capture several intersection graphs of geometrical objects such as proper interval graphs [30], unit-disk graphs [28], quasi-unit-disk graphs [36], and general disc graphs [29].
- *Claw-free graphs:* Graphs with neighborhood independence β can be alternatively defined as β-claw-free graphs, i.e., graphs that do not contain $K_{1,\beta}$ as an induced subgraph. Claw-free graphs have been subject of extensive study in structural graph theory; see the series of papers by Chudnovsky and Seymour, starting with [14], and the survey by Faudree et al. [17].

Above graphs appear naturally in the context of symmetry breaking problems (for instance in the study of wireless networks), and there have been numerous works on MIS and MM in graphs with bounded neighborhood independence and their special cases (see, e.g. [36, 49, 28, 7, 8, 29, 19] and references therein).

1.2 Other Implications

Despite the simplicity of our algorithms in Result 1, they lead to several interesting implications, when combined with some known results and/or techniques:

(a) *Approximate vertex cover and matching:* Our MM algorithm in Result 1 combined with well-known properties of maximal matchings implies an $O(n \log n \cdot \beta(G))$ time 2-approximation algorithm to both maximum matching and minimum vertex cover. For graphs with constant neighborhood independence, our results improve upon the sublinear-time algorithms of [44] that achieve $(2+\varepsilon)$-approximation to the *size* of the optimal solution to both problems but did not find the actual edges or vertices in $\widetilde{O}_\varepsilon(n)$ time on general graphs.

(b) *Caro-Wei bound and approximation of maximum independent set:* The Caro-Wei bound [13, 51] states that any graph $G(V, E)$ contains an independent set of size at least $\sum_{v \in V} \frac{1}{\mathsf{deg}(v)+1}$, and there is a substantial interest in obtaining independent sets of this size (see, e.g. [27, 29, 15] and references therein). One standard way of obtaining such independent set is to run the greedy MIS algorithm on the vertices of the graph in the increasing order of their degrees. As our Result 1 implies that one can implement the greedy MIS algorithm for *any* ordering of vertices, we can sort the vertices in $O(n)$ time and then run our deterministic algorithm with this order to obtain an independent set with Caro-Wei bound size in $O(n\beta(G))$ time. Additionally, it is easy to see that on graphs with $\beta(G) = \beta$, any MIS is a β-approximation to the *maximum* independent set (see, e.g. [35, 49]). We hence also obtain a constant factor approximation in $O(n)$ time for maximum independent set on graphs with bounded neighborhood independence.

(c) *Separation of $(\Delta+1)$-coloring with MIS and MM:* Assadi et al. [4] gave an $\widetilde{O}(n\sqrt{n})$ time algorithm for $(\Delta+1)$ coloring and an $\Omega(n^2)$ time lower bound for MIS and MM on general graphs. It is also shown in [4] that $(\Delta+1)$ coloring requires $\Omega(n\sqrt{n})$ time and in fact the lower bound holds for graphs with constant neighborhood independence. Together with our Result 1, this implies an interesting separation between the time-complexity of MIS and MM, and that of $(\Delta+1)$-coloring: while the time complexity of MIS and MM is strictly higher than that of $(\Delta+1)$ coloring in general graphs, the exact opposite relation holds for graphs with small neighborhood independence number.

(d) *Efficient MM computation via MIS on line graphs:* The line graph $L(G)$ of a graph G contains m vertices corresponding to edges of G and up to $O(mn)$ edges. Moreover, for any graph G, $\beta(L(G)) \leq 2$. As an MIS in $L(G)$ corresponds to an MM in G, our results suggest that despite the larger size of $L(G)$, perhaps surprisingly, computing an MM of G through computing an MIS for $L(G)$ is just as efficient as directly computing an MM of G (assuming direct access to $L(G)$). This observation may come into play in real-life situations where there is no direct access to the graph but rather only to its line graph.

Preliminaries and Notation

For a graph $G(V, E)$ and vertex $v \in V$, $N(v)$ and $\mathsf{deg}(v)$ denote the neighbor-set and degree of a vertex v, respectively. For a subset $U \subseteq V$, $\mathsf{deg}_U(v)$ denotes the degree of v to vertices in U. Denote by $\beta(G)$ the neighborhood independence number of graph G.

2 Technical and Conceptual Highlights

Our first (non-technical) contribution is in identifying the neighborhood independence number as the "right" measure of time-complexity for both MIS and MM. We then show that surprisingly simple algorithms for these problems run in sublinear-time on graphs with bounded $\beta(G)$.

The textbook greedy algorithm for MIS works as follows: scan the vertices in an arbitrary order and add each scanned vertex to a set $\mathcal{M}$ iff it does not already have a neighbor in $\mathcal{M}$. Clearly the runtime of this algorithm is $\Theta(\sum_{v \in V} \mathsf{deg}(v)) = \Theta(m)$ and this bound does not improve for graphs with small β. We can slightly tweak this algorithm by making every vertex that joins $\mathcal{M}$ to *mark* all its neighbors and simply ignore scanning the already marked vertices. This tweak however is not useful in general graphs as the algorithm may waste time by repeatedly marking the same vertices over and over again without making much further progress (the complete bipartite graph is an extreme example). The same problem manifests itself in other algorithms, including those for MM, and is at the root of the lower bounds in [4] for sublinear-time computation of MIS and MM.

We prove that this issue cannot arise in graphs with bounded neighborhood independence. Noting that the runtime of the greedy MIS algorithm that uses "marks" is $\Theta(m_{\mathcal{M}})$, where we define $m_{\mathcal{M}} := \sum_{v \in \mathcal{M}} \mathsf{deg}(v)$, a key observation is that $m_{\mathcal{M}}$ is much smaller than m when β is small. Indeed, as the vertices of $\mathcal{M}$ form an independent set, all the edges incident on $\mathcal{M}$ lead to $V \setminus \mathcal{M}$, and so if $m_{\mathcal{M}}$ is large, then the *average* degree of $V \setminus \mathcal{M}$ *to* $\mathcal{M}$ cannot be "too small"; however, the latter average degree cannot be larger than β as otherwise there is some vertex in $V \setminus \mathcal{M}$ that is incident to more than β independent vertices, a contradiction. This is all we need to conclude that the runtime of the greedy MIS algorithm that uses marks is bounded by $O(n \cdot \beta)$.

Both the MIS algorithm and its analysis are remarkably simple, and *in hindsight*, this is not surprising since this parameter β is in a sense "tailored" to the MIS problem. Although MM and MIS problems are intimately connected to each other, the MM problem appears to be much more intricate for graphs with bounded neighborhood independence. Indeed, while the set U of unmatched vertices in any MM forms an independent set and hence total number m_U of edges incident on U cannot be too large by the above argument, the runtime of greedy or any other algorithm cannot be bounded in terms of m_U (as m_U can simply be zero). In fact, it is provably impossible to adjust our argument for MIS to the MM problem due to our lower bound for deterministic MM algorithms (Theorem 11) that shows that any such algorithm must incur a runtime of $\Omega(n^2)$ even for $\beta = 2$.

The main technical contribution of this paper is thus in obtaining a fast randomized MM algorithm for graphs with bounded β. Our starting point is the modified randomized greedy (MRG) algorithm of [16, 3] that finds an MM by iteratively picking an *unmatched* vertex u uniformly at random and matching it to a uniformly at random chosen *unmatched* neighbor $v \in N(u)$. On its own, this standard algorithm does not benefit from small values of β: while picking an unmatched vertex u is easy, finding an unmatched neighbor v for u is too time consuming in general. We instead make the following simple but crucial modification: instead of picking v from unmatched neighbors of u, we simply sample v from the set of *all* neighbors of u and only match it to u if it is also unmatched; otherwise we sample another vertex u and continue like this (additional care is needed to ensure that this process even terminates but we postpone the details to Section 4).

To analyze the runtime of this modified algorithm, we leverage the above argument for MIS and take it to the next step to prove a basic structural property of graphs with bounded neighborhood independence: for any set P of vertices, a constant fraction of vertices are such that their inner degree inside P is "not much smaller" than their total degree (depending both on β and size of P). Letting P to be the set of unmatched vertices in the above algorithm allows us to bound the number of iterations made by the algorithm before finding the next matching edge, and ultimately bounding the overall runtime of the algorithm by $O(n \log n \cdot \beta)$ both in expectation and with high probability.

Technical Comparison with Prior Work

Our work is most closely related to the $\widetilde{O}(n\sqrt{n})$-time $(\Delta+1)$-coloring algorithm of Assadi, Chen, and Khanna [4] (and their $\Omega(n^2)$ time lower bounds for MIS and MM on general graphs), as well as the series of work by Goel, Kapralov, and Khanna [25, 24, 26] on finding perfect matchings in regular bipartite graphs that culminated in an $O(n \log n)$ time algorithm.

The coloring algorithm of [4] works by *non-adaptively sparsifying* the graph into $O(n \log^2(n))$ edges in $\widetilde{O}(n\sqrt{n})$ time in such a way that a $(\Delta+1)$ coloring of the original graph can be found quickly from this sparsifier. The algorithms in [25, 24] were also based on the high-level idea of sparsification but the final work in this series [26] instead used a *(truncated) random walk* approach to speedup augmenting path computations in regular graphs. The sparsification methods used in [4, 25, 24] as well as the random walk approach of [26] are all quite different from our techniques in this paper that are tailored to graphs with bounded neighborhood independence. Moreover, even though every perfect matching is clearly maximal, our results and [25, 24, 26] are incomparable as d-regular bipartite graphs and graphs with bounded neighborhood independence are in a sense the exact opposite of each other: for a d-regular bipartite graph, $\beta(G) = d$ which is the largest possible for graphs with maximum degree d.

3 Maximal Independent Set

The standard greedy algorithm for MIS works as follows: Iterate over vertices of the graph in an arbitrary order and insert each one to an initially empty set $\mathcal{M}$ if none of its neighbors have already been inserted to $\mathcal{M}$. By the time all vertices have been processed, $\mathcal{M}$ clearly provides an MIS of the input graph. See Algorithm 1 for a pseudo-code.

We prove that this algorithm is fast on graphs with bounded neighborhood independence.

▶ **Theorem 1.** *The greedy MIS algorithm (as specified by Algorithm 1) computes a maximal independent set of a graph G given in adjacency array representation in $O(n \cdot \beta(G))$ time.*

Algorithm 1: The (Deterministic) Greedy Algorithm for Maximal Independent Set.

Input: An n-vertex graph $G(V, E)$ given in adjacency array representation.
Output: An MIS $\mathcal{M}$ of G.
Initialize $\mathcal{M} = \emptyset$ and $\texttt{mark}[v_i] = \text{FALSE}$ for all vertices $v_i \in V$ where $V := \{v_1, \ldots, v_n\}$.
for $i = 1$ ***to*** n **do**
  if $\texttt{mark}[v_i] = \text{FALSE}$ **then**
    add v_i to $\mathcal{M}$ and set $\texttt{mark}[u] = \text{TRUE}$ for all $u \in N(v_i)$.
  end
end
Return $\mathcal{M}$.

Proof. Let $G(V, E)$ be an arbitrary graph. Suppose we run Algorithm 1 on G and obtain $\mathcal{M}$ as the resulting MIS. To prove Theorem 1, we use the following two simple claims.

▷ Claim 2. The time spent by Algorithm 1 on a graph $G(V, E)$ is $O(n + \sum_{v \in \mathcal{M}} \mathsf{deg}(v))$.

Proof. Iterating over vertices in the **for** loop takes $O(n)$ time. Beyond that, for each vertex joining the MIS $\mathcal{M}$, we spend time that is linear in its degree to mark all its neighbors. ◁

▷ Claim 3. For any independent set $I \subseteq V$ in G, $\sum_{v \in I} \mathsf{deg}(v) \leq n \cdot \beta(G)$.

Proof. Let $E(I)$ denote the edges incident on vertices in the independent set I. Since I is an independent set, these edges connect vertices of I with vertices of $V \setminus I$. Suppose towards a contradiction that $|E(I)| = \sum_{v \in I} \mathsf{deg}(v) > n \cdot \beta(G)$. By a double counting argument, there must exist a vertex v in $V \setminus I$ with at least $|E(I)| / |V \setminus I| > \beta(G)$ neighbors in I. But since I is an independent set, this means that there exists an independent set of size $> \beta(G)$ in the neighborhood of v, which contradicts the fact that $\beta(G)$ is the neighborhood independence number of G. ◁

Theorem 1 now follows from Claims 2 and 3 as $\mathcal{M}$ is an independent set of G. ◀

4 Maximal Matching

We now consider the maximal matching (MM) problem. Similar to MIS, a standard greedy algorithm for MM is to iterate over the vertices in arbitrary order and match each vertex to one of their unmatched neighbors (if any). However, as we show in Section 5 this and any other *deterministic* algorithm for MM, cannot run in sublinear-time even when $\beta(G) = 2$.

We instead consider the following variant of the greedy algorithm, referred to as the *(modified) randomized greedy algorithm*, put forward by [16, 3] and extensively studied in the literature primarily with respect to its approximation ratio for the maximum matching problem (see, e.g. [42, 47] and the references therein). Pick an unmatched vertex u uniformly at random; pick an unmatched vertex v incident on u uniformly at random and add (u, v) to the matching M; repeat as long as there is an unmatched edge left in the graph. It is easy to see that at the end of the algorithm M will be an MM of G.

As it is, this algorithm is not suitable for our purpose as finding an unmatched vertex v incident on u is too costly. We thus instead consider the following variant which samples the set v from all neighbors of u and only match it to u if v is also unmatched (we also change the final check of the algorithm for maximality of M with a faster computation). See Algorithm 2 for a pseudo-code after proper modifications.

Algorithm 2: The (Modified) Randomized Greedy Algorithm for Maximal Matching.

Input: An n-vertex graph $G(V, E)$ given in adjacency array representation.
Output: A maximal matching M of G.
Initialize $M = \emptyset$ and $U = V$.
while $U \neq \emptyset$ **do**
  Define the threshold $\tau := \tau(U) = \frac{4n \cdot \beta(G)}{|U|}$.
  Sample a vertex u uniformly at random from U.
  if $\mathsf{deg}(u) < \tau$ **then**
    Choose a random vertex v from $N(u) \cap U$ (if non-empty), add (u, v) to M and set $U \leftarrow U \setminus \{u, v\}$. If $N(u) \cap U = \emptyset$, set $U \leftarrow U \setminus \{u\}$.
  else
    Sample a vertex v uniformly at random from $N(v)$.
    if $v \in U$ **then**
      add (u, v) to M and set $U \leftarrow U \setminus \{u, v\}$.
  end
end
Return M.

We remark that the first **if** condition in Algorithm 2 is used to remove the costly operation of checking if any unmatched edge is left in the graph. It is easy to see that this algorithm always output an MM.

We prove that Algorithm 2 is fast both in expectation and with high probability on graphs with bounded neighborhood independence. We also note that as stated, Algorithm 2 actually assumes knowledge of $\beta(G)$ (needed for the definition of the threshold parameter τ). However, we show at the end of this section that this assumption can be lifted easily and obtain a slight modification of Algorithm 2 with the same asymptotic runtime that does *not* require any knowledge of $\beta(G)$.

▶ **Theorem 4.** *The modified randomized greedy MM algorithm (as specified by Algorithm 2) computes a maximal matching of a graph G given in adjacency array representation in $O(n \log n \cdot \beta(G))$ time in expectation and with high probability.*

Let t denote the number of iterations of the **while** loop in Algorithm 2. We can bound the runtime of this algorithm based on t as follows.

▷ Claim 5. Algorithm 2 can be implemented in $O(n \log n \cdot \beta(G) + t)$ time.

Proof. First, we would like to store the set U in a data structure that supports random sampling and deletion of a vertex from U, as well as determining whether a vertex is currently in U or not, in constant time. This data structure can be easily implemented using two

arrays A_1 and A_2; we provide the rather tedious details for completeness. The arrays are initialized as $A_1[i] = A_2[i] = i$ for all $i = 1, \ldots, n$, where $A_2[i]$ holds the index of the cell in A_1 where v_i is stored, or -1 if v_i is not in U, while A_1 stores the vertices of U in its first $|U|$ cells, identifying each v_i with index i. When any unmatched vertex v_i is removed from U, we first use $A_2[i]$ to determine the cell where v_i is stored in A_1, then we move the unmatched vertex stored at the last cell in A_1, $A_1[|U|]$, to the cell currently occupied by v_i by setting $A_1[A_2[i]] = A_1[|U|]$, and finally set $A_2[A_1[|U|] = A_2[i], A_2[i] = -1$. Randomly sampling a vertex from U and determining whether a vertex belongs to U can now be done in $O(1)$ time.

Using these arrays each iteration of the **while** loop in which $\mathsf{deg}(u) \geq \tau$ can be carried out within $O(1)$ time. Iterations for which $\mathsf{deg}(u) < \tau$ are more costly, due to the need to determine $N(u) \cap U$. Nonetheless, in each such iteration we spend at most $O(\tau)$ time while at least one vertex is removed from U, hence the time required by all such iterations is bounded by $\sum_{k=1}^{n} O(\frac{n \cdot \beta(G)}{k}) = O(n \log n \cdot \beta(G))$. It follows that the total runtime of the algorithm is $O(n \log n \cdot \beta(G) + t)$. ◁

The main ingredient of the analysis is thus to bound the number t of iterations. Before proceeding we introduce some definition. We say that an iteration of the **while** loop *succeeds* iff we remove at least one vertex from U in this iteration. Clearly, there can be at most n successful iterations. We prove that each iteration of the algorithm is successful with a sufficiently large probability, using which we bound the total number of iterations.

To bound the success probability, we shall argue that for sufficiently many vertices u in U, the number of its neighbors in U, referred to as its *internal* degree, is proportionate to the number of its neighbors outside U, referred to as its *external* degree; for any such vertex u, a random neighbor v of u has a good chance of belonging to U. This is captured by the following definition.

▶ **Definition 6** (Good vertices). *For a parameter $\delta \in (0, 1)$, we say a vertex $u \in U$ is* δ-good *iff $\mathsf{deg}_U(u) \geq \delta \cdot \mathsf{deg}_{V \setminus U}(u)$ or $\mathsf{deg}(u) < 1/\delta$.*

Clearly, if we sample a δ-good vertex $u \in U$ in some iteration, then with probability $\geq \delta$ that iteration succeeds. It thus remains to show that many vertices in U are good for an appropriate choice of δ. We use the bounded neighborhood independence property (in a more sophisticated way than it was used in the proof of Theorem 1) to prove the following lemma, which lies at the core of the analysis.

▶ **Lemma 7.** *Fix any choice of U in some iteration and let $\delta := \delta(U) = 1/\tau(U)$ (for the parameter $\tau(U)$ defined in Algorithm 2). Then at least half the vertices in U are δ-good in this iteration.*

Proof. Let us say that a vertex $u \in U$ is *bad* iff it is not δ-good (for the parameter δ in the lemma statement). Let B denote the set of bad vertices and let $b := |B|$.

▷ Claim 8. There exists an independent set $I \subseteq B$ with at least $\frac{b}{2\delta}$ edges leading to $V \setminus U$.

Proof. We prove this claim using a probabilistic argument. Pick a random permutation σ of vertices in B and add each vertex $v \in B$ to an initially empty independent set $I = I_\sigma$ iff v appears before all its neighbors in B according to σ. Clearly, the resulting set I is an independent set inside B.

Let $E(I)$ denote the set of edges that connect vertices of I with vertices of $V \setminus U$. For any vertex $v \in B$, define a random variable $D_v \in \left\{0, \mathsf{deg}_{V \setminus U}(v)\right\}$ which takes value equal to

the external degree of v iff v is added to I. Clearly, $|E(I)| = \sum_{v \in V} D_v$. We have,

$$\begin{aligned}\mathbb{E}\,|E(I)| &= \sum_{v \in B} \mathbb{E}\,[D_v] = \sum_{v \in B} \mathbf{Pr}\,(v \in I) \cdot \mathsf{deg}_{V \setminus U}(v) \\ &= \sum_{v \in B} \frac{1}{\mathsf{deg}_B(v)+1} \cdot \mathsf{deg}_{V \setminus U}(v) \\ &\quad (v \text{ is only chosen in } I \text{ iff it is ranked first by } \sigma \text{ among itself and its } \mathsf{deg}_B(v) \text{ neighbors}) \\ &\geq \sum_{v \in B} \frac{1}{\delta \cdot \mathsf{deg}_{V \setminus U}(v)+1} \cdot \mathsf{deg}_{V \setminus U}(v) \qquad (\text{as } B \subseteq U \text{ and vertices in } B \text{ are all bad}) \\ &\geq \sum_{v \in B} \frac{1}{2\delta \cdot \mathsf{deg}_{V \setminus U}(v)} \cdot \mathsf{deg}_{V \setminus U}(v) = \frac{b}{2\delta}. \\ &\qquad\qquad (\text{as } \mathsf{deg}(v) \geq \tfrac{1}{\delta} \text{ and hence } \delta \cdot \mathsf{deg}_{V \setminus U}(v) \geq 1)\end{aligned}$$

It follows that there exists a permutation σ for which the corresponding independent set $I = I_\sigma \subseteq B$ has at least $\frac{b}{2\delta}$ edges leading to $V \setminus U$, finalizing the proof. ◁

We next prove Lemma 7 using an argument akin to Claim 3 in the proof of Theorem 1. Let I be the independent set guaranteed by Claim 8. As at least $\frac{b}{2\delta}$ edges are going from I to $V \setminus U$, a double counting argument implies that there exists a vertex $v \in V \setminus U$ with degree to I satisfying:

$$\mathsf{deg}_I(v) \geq \frac{b}{2\delta \cdot |V \setminus U|} \geq \frac{b \cdot \tau(U)}{2n} = \frac{2b \cdot \beta(G)}{|U|}, \tag{1}$$

where the equality is by the choice of $\tau(U)$. Suppose towards a contradiction that $b > |U|/2$. This combined with Eq (1) implies that $\mathsf{deg}_I(v) > \beta(G)$. Since I is an independent set, it follows that $N(v)$ contains an independent set of size larger than $\beta(G)$, a contradiction. Hence $b \leq |U|/2$, and so at least half the vertices in U are δ-good, as required. ◀

We now use Lemma 7 to bound the expected number of iterations t in Algorithm 2. Let us define the random variables $X_1, \ldots, X_n$, where X_k denotes the number of iterations spent by the algorithm when $|U| = k$. Clearly, the total number of iterations $t = \sum_{k=1}^{n} X_k$. We use these random variables to bound the expected value of t in the following claim. The next claim then proves a concentration bound for t to obtain the high probability result.

▷ Claim 9. The number of iterations in Algorithm 2 is in expectation $\mathbb{E}\,[t] \leq 8\beta(G) \cdot n \log n$.

Proof. As stated above, $\mathbb{E}\,[t] = \sum_{k=1}^{n} \mathbb{E}\,[X_k]$ and hence it suffices to bound each $\mathbb{E}\,[X_k]$. Fix some $k \in [n]$ and consider the case when $|U| = k$. Recall the function $\delta(U)$ in Lemma 7. As $\delta(U)$ is only a function of size of k, we slightly abuse the notation and write $\delta(k)$ instead of $\delta(U)$ where k is the size of U.

By Lemma 7, at least half the vertices in U are $\delta(k)$-good. Hence, in each iteration, with probability at least half, we sample a $\delta(k)$-good vertex u from U. Conditioned on this event, either $\mathsf{deg}(u) < 1/\delta(k)$ which means this iteration succeeds with probability 1 or $\mathsf{deg}_U(u) \geq \delta(k) \cdot \mathsf{deg}_{V \setminus U}(u)$, and hence with probability at least $\delta(k)$ the sampled vertex v belongs to U and again this iteration succeeds. As a result, as long as U has not changed, each iteration has probability at least $\delta(k)/2$ to succeed.

By the above argument, X_k statistically dominates a Poisson distribution with parameter $\delta(k)/2$ and hence $\mathbb{E}[X_k] \leq 2/\delta(k)$. To conclude,

$$\mathbb{E}[t] = \sum_{k=1}^{n} \mathbb{E}[X_k] \leq \sum_{k=1}^{n} 2/\delta(k) = 8\beta(G) \cdot n \cdot \sum_{k=1}^{n} \frac{1}{k} \leq 8\beta(G) \cdot n \log n.$$

which finalizes the proof. ◁

Claim 9 combined with Claim 5 is already enough to prove the expected runtime bound in Theorem 4. We now prove a concentration bound for t to obtain the high probability bound. We note that it seems possible to prove the following claim by using standard concentration inequalities; however doing so requires taking care of several boundary cases for the case when $|U|$ become $o(\log n)$, and hence we instead prefer to use the following direct and more transparent proof.

▷ Claim 10. The number of iterations in Algorithm 2 is $t = O(\beta(G) \cdot n \log n)$ with high probability.

Proof. Recall from the proof of Claim 9 that $t = \sum_{k=1}^{n} X_k$ and that each X_k statistically dominates a Poisson distribution with parameter $\delta(k)/2$ (as defined in Claim 9). Define $Y_1, \ldots, Y_n$ as independent random variables where Y_k is distributed according to exponential distribution with mean $\mu_k := \frac{2}{\delta(k)}$. For any $x \in \mathbb{R}^+$,

$$\mathbf{Pr}(X_k \geq x) \leq \left(\frac{\delta(k)}{2}\right)^x = \mathbf{Pr}(Y_k \geq x).$$

As such, the random variable $Y := \sum_{k=1}^{n} Y_k$ statistically dominates the random variable t for number of iterations. Moreover by Claim 9, $\mu := \mathbb{E}[Y] = 8\beta(G) \cdot n \log n$ (the equality for Y follows directly from the proof).

In the following, we prove that with high probability Y does not deviate from its expectation by much. The proof follows the standard moment generating function idea (used for instance in the proof of Chernoff-Hoeffding bound). Let $y \in \mathbb{R}^+$. For any $s > 0$,

$$\mathbf{Pr}(Y \geq y) = \mathbf{Pr}\left(e^{sY} \geq e^{sy}\right) \leq \frac{\mathbb{E}\left[e^{sY}\right]}{e^{sy}}, \tag{2}$$

where the inequality is simply by Markov bound. Additionally, since $Y = \sum_{k=1}^{n} Y_k$ and and Y_k's are independent, we have for any $s > 0$,

$$\frac{\mathbb{E}\left[e^{sY}\right]}{e^{sy}} = \frac{\mathbb{E}\left[e^{s \cdot \sum_{k=1}^{n} Y_k}\right]}{e^{sy}} = \frac{\prod_{k=1}^{n} \mathbb{E}\left[e^{s \cdot Y_k}\right]}{e^{sy}}. \tag{3}$$

Recall that for every $i \in [n]$, $\mathbb{E}[Y_k] = \mu_k$ and Y_k is distributed according to exponential distribution. Thus, for any $s < 1/\mu_k$,

$$\mathbb{E}\left[e^{sY_k}\right] = \int_{y=0}^{\infty} e^{sy} \cdot \mathbf{Pr}(Y_k = y)\, dy = \frac{1}{\mu_k} \int_{y=0}^{\infty} e^{sy} \cdot e^{-y/\mu_k} dy = \frac{1}{1 - s\mu_k}. \tag{4}$$

Recall that $\mu_k = 2/\delta(k)$ for every $k \in [n]$ and $\delta(1) < \delta(2) < \ldots < \delta(n)$ by definition. Pick $s^* = 1/2\mu_1$ and so $s^* < 1/\mu_k$ for all $k \in [n]$. By plugging in the bounds in Eq (4) for $s = s^*$

into Eq (3), we have,

$$\frac{\mathbb{E}\left[e^{s^*Y}\right]}{e^{s^*y}} = \frac{\prod_{k=1}^{n}\mathbb{E}\left[e^{s^*\cdot Y_k}\right]}{e^{s^*y}} = \prod_{k=1}^{n}\frac{e^{-s^*y}}{1-s^*\mu_k} \leq e^{-s^*y}\cdot\exp\left(2\sum_{k=1}^{n}s^*\mu_k\right)$$

(as $1-x \geq e^{-2x}$ for $x \in (0,1/2]$)

$$= \exp\left(-s^*y + 2s^*\mu\right) = \exp\left(-y/2\mu_1 + \mu/\mu_1\right).$$

We now plug in this bound into Eq (2) with the choice of $y = 4\mu$ to obtain that,

$$\mathbf{Pr}\left(Y \geq 4\mu\right) \leq \exp\left(-4\mu/2\mu_1 + \mu/\mu_1\right) = \exp\left(-\mu/\mu_1\right) = \exp\left(-\log n\right) = 1/n,$$

where we used the fact that $\mu/\mu_1 \geq \log n$. This means that with high probability, Y is only 4 times larger than its expectation, finalizing the proof. ◁

The high probability bound in Theorem 4 now follows from Claim 5 and Claim 10, concluding the whole proof of this theorem.

Unknown $\beta(G)$

We next show that our algorithm can be easily adjusted to the case when $\beta(G)$ is unknown. The idea is simply to "guess" $\beta(G)$ in powers of two, starting from $\beta = 2$ and ending at $\beta = n$, and each time to (sequentially) run Algorithm 2 under the assumption that $\beta(G) = \beta$. For each choice of β, we shall only run the algorithm for at most $t = O(n\log n\cdot\beta(G))$ iterations (where the constant hiding in the O-notation should be sufficiently large, in accordance with that in the proof of Claim 10) and if at the end of a run the set U in the algorithm has not become empty, we start a new run from scratch with the next (doubled) value of β. (For $\beta = n$, we do not terminate the algorithm prematurely and instead run it until U is empty.)

By Theorem 4, for the *first* choice of β for which $\beta \geq \beta(G)$, the algorithm must terminate with high probability within $O(n\log n\cdot\beta(G))$ time (as $\beta \leq 2\beta(G)$ also). Moreover, the runtime of every previous run is bounded *deterministically* by $O(n\log n\cdot\beta(G))$. Consequently, the total runtime is

$$O(n\log n)\cdot\sum_{\{2^i\,|\,2^i\leq 2\beta(G)\}}2^i = O(n\log n\cdot\beta(G)),$$

where this bound holds with high probability. In this way we get an algorithm that uses no prior knowledge of $\beta(G)$ and achieves the same asymptotic performance as Algorithm 2.

5 A Lower Bound for Deterministic Maximal Matching

We prove that randomization is necessary to obtain a sublinear time algorithm for MM even on graphs with bounded neighborhood independence.

▶ **Theorem 11.** *Any deterministic algorithm that finds a maximal matching in every given graph G with neighborhood independence $\beta(G) = 2$ (known to the algorithm) presented in the adjacency array representation requires $\Omega(n^2)$ time.*

For every integer $n = 8k$ for $k \in \mathbb{N}$, we define $\mathcal{G}_n$ as the family of all graphs obtained by removing a perfect matching from a clique K_n on n vertices. For a graph G in $\mathcal{G}_n$ we refer to the removed perfect matching of size $5k$ as the *non-edge matching* of G and denote it by $\overline{M}(G)$. Clearly, every graph in $\mathcal{G}_n$ has neighborhood independence $\beta(G) = 2$. Moreover, any MM in G can have at most 2 unmatched vertices.

Let $\mathcal{A}$ be a deterministic algorithm for computing an MM on every graph in $\mathcal{G}_n$. We prove Theorem 11 by analyzing a game between $\mathcal{A}$ and an adaptive adversary that answers the probes of $\mathcal{A}$ to the adjacency array of the graph. In particular, whenever $\mathcal{A}$ probes a *new* entry of the adjacency array for some vertex $v \in V$, we can think of $\mathcal{A}$ making a *query* $Q(v)$ to the adversary, and the adversary outputs a vertex v that had not been so far revealed in the neighborhood of u (as degree of all vertices in G is exactly $n-1$, $\mathcal{A}$ knows the degree of all vertices and we assume it never queries a vertex u more than $n-1$ times).

We now show that there is a strategy for the adversary to answer the queries of $\mathcal{A}$ in a way that ensures $\mathcal{A}$ needs to make $\Omega(n^2)$ queries before it can output an MM of the graph.

Adversary's Strategy. The adversary picks an arbitrary set of $2k$ vertices D referred to as *dummy* vertices. We refer to remaining vertices as *core* vertices and denote them by $C := V \setminus D$. The adversary also fixes a non-edge matching of size k between vertices in D, denoted by $\overline{M}_D$. The non-edge matching of G consists of $\overline{M}_D$ and a non-edge matching of size $4k$ between vertices in C, denoted by $\overline{M}_C$, which unlike $\overline{M}_D$ is constructed adaptively by the adversary. We assume $\mathcal{A}$ knows the partitioning of V into D and C, as well as the non-edge matching $\overline{M}_D$. Hence, the only missing information to $\mathcal{A}$ is identity of $\overline{M}_C$.

To answer a query $Q(u)$ for a dummy vertex $u \in D$, the adversary simply returns any arbitrary vertex in V (not returned so far as an answer to $Q(u)$) except for the pair of u in $\overline{M}_D$ which cannot be neighbor to u. To answer the queries $Q(w)$ for core vertices $w \in C$, the adversary maintains a partitioning of C into C_{used} and C_{free}. Initially all core vertices belong to C_{free} and hence C_{used} is empty. Throughout we only move vertices from C_{free} to C_{used}. The adversary also maintains a counter for every vertex in C_{free} on how many times they have been queried so far. Whenever a vertex $w \in C_{\mathsf{free}}$ is queried, as long as this vertex has been queried at most k times, the adversary returns an arbitrary dummy vertex u from D as the answer to $Q(w)$ (which is possible because of size of D is k). Once a vertex $w \in C_{\mathsf{free}}$ is queried for its $(k+1)$-th time, we pick another vertex w' from C_{free} also, add the pair (w, w') to the non-edge matching $\overline{M}_C$ and move both w and w' to C_{used}, and then answer $Q(w)$ for the case $w \in C_{\mathsf{used}}$ as described below.

Recall that for any vertex $w \in C_{\mathsf{used}}$, by construction, there is another fixed vertex w' in C_{used} (joined at the same time with w) where $(w, w') \in \overline{M}_C$. For any query for $w \in C_{\mathsf{used}}$, the adversary answers $Q(w)$ by returning an arbitrary vertex from $C \setminus \{w'\}$. This concludes the description of the strategy of the adversary.

We have the following basic claim regarding the correctness of the adversary's strategy.

▷ Claim 12. The answers returned by the adversary for any sequence of queries are always consistent with at least one graph G in $\mathcal{G}_n$.

Proof. We can append the current sequence of queries by the sequence that ensures all vertices are queried $n-1$ times. Thus, the adversary would eventually construct the whole non-edge matching $\overline{M}_C$ also. There exists a unique graph G in $\mathcal{G}_n$ where $\overline{M}(G) = \overline{M}_D \cup \overline{M}_C$, hence proving the claim (note that before appending the sequence, there can be more than one graph consistent with the original sequence). ◁

We now prove the following lemma which is the key step in the proof of Theorem 11.

▶ **Lemma 13.** *Suppose $\mathcal{A}$ makes at most k^2 queries to the adversary and outputs a matching M using only these queries. Then, there exists some graph G in $\mathcal{G}_n$ where G is consistent with the answers returned by the adversary to $\mathcal{A}$ and $\overline{M}(G) \cap M \neq \emptyset$.*

Proof. Since $\mathcal{A}$ makes at most k^2 queries, there can only be $2k$ vertices in C_{used} by the time the algorithm finishes its queries (as each pair of vertices in C_{used} consumed k queries). Consider the maximal matching M. There are at most $2k$ edges of M that are incident on C_{used} and k more edges incident on D. This implies that at most $3k$ vertices in C_{free} are matched to vertices outside C_{free}. As $|C_{\mathsf{free}}| \geq 5k$, it means that there are at least $2k$ vertices in C_{free} that are not matched by M to vertices outside C_{free}. However, as M is maximal, and since G is in $\mathcal{G}_n$, there should be at least $k-1$ edges in M between these vertices in C_{free}. As the adversary has not committed to the non-edge matching $\overline{M}_C$ entirely at this point and this non-edge matching pairs vertices in C_{free} to each other, the adversary can simply let $\overline{M}_C$ contains M and still obtain a graph G in $\mathcal{G}_n$. For this graph, $\overline{M}(G) \cap M \neq \emptyset$, finalizing the proof. ◀

Theorem 11 now follows immediately from Lemma 13, as it state that unless the algorithm makes $\Omega(n^2)$ queries, there always exists at least one graph in $\mathcal{G}_n$ for which the output matching of the algorithm is not feasible. As graphs in $\mathcal{G}_n$ all have $\beta(G) = 2$, we obtain the final result.

Abstract

In this work, we study the k-median and k-means clustering problems when the data is distributed across many servers and can contain outliers. While there has been a lot of work on these problems for worst-case instances, we focus on gaining a finer understanding through the lens of beyond worst-case analysis. Our main motivation is the following: for many applications such as clustering proteins by function or clustering communities in a social network, there is some unknown target clustering, and the hope is that running a k-median or k-means algorithm will produce clusterings which are close to matching the target clustering. Worst-case results can guarantee constant factor approximations to the optimal k-median or k-means objective value, but not closeness to the target clustering.

Our first result is a distributed algorithm which returns a near-optimal clustering assuming a natural notion of stability, namely, *approximation stability* [12], even when a constant fraction of the data are outliers. The communication complexity is $\tilde{O}(sk+z)$ where s is the number of machines, k is the number of clusters, and z is the number of outliers. Next, we show this amount of communication cannot be improved even in the setting when the input satisfies various non-worst-case assumptions. We give a matching $\Omega(sk + z)$ lower bound on the communication required both for approximating the optimal k-means or k-median cost up to any constant, and for returning a clustering that is close to the target clustering in Hamming distance. These lower bounds hold even when the data satisfies approximation stability or other common notions of stability, and the cluster sizes are balanced. Therefore, $\Omega(sk + z)$ is a communication bottleneck, even for real-world instances.

1 Introduction

Clustering is a fundamental problem in machine learning with applications in many areas including computer vision, text analysis, bioinformatics, and so on. The underlying goal is to group a given set of points to maximize similarity inside a group and dissimilarity among groups. A common approach to clustering is to set up an objective function and then approximately find the optimal solution according to the objective. Common examples of these objective functions include k-median and k-means, in which the goal is to find k centers to minimize the sum of the distances (or sum of the squared distances) from each point to its closest center. Motivated by real-world constraints, further variants of clustering have been studied. For instance, in k-clustering with outliers, the goal is to find the best clustering (according to one of the above objectives) after removing a specified number of data points, which is useful for noisy data. Finding approximation algorithms to different clustering objectives and variants has attracted significant attention in the computer science community [7, 23, 24, 25, 28, 31, 41].

As datasets become larger, sequential algorithms designed to run on a single machine are no longer feasible for real-world applications. Additionally, in many cases data is naturally spread out among multiple locations. For example, hospitals may keep records of their patients locally, but may want to cluster the entire spread of patients across all hospitals in order to do better data analysis and inference. Therefore, distributed clustering algorithms have gained popularity in recent years [18, 20, 42, 32, 40, 29, 27]. In the distributed setting, it is assumed that the data is partitioned arbitrarily across s machines, and the goal is to find a clustering which approximates the optimal solution over the entire dataset while minimizing communication among machines. Recent work in the theoretical machine learning community establishes guarantees on the clusterings produced in distributed settings for certain problems [18, 20, 42]. For example, [42] provides distributed algorithms for k-center and k-center with outliers, and [20] introduces distributed algorithms for capacitated k-clustering under any ℓ_p objective. Along similar lines, the recent work of [32] provides constant-factor approximation algorithms for k-median and k-means with z outliers in the distributed setting. The work of Guha et al. also provides the best known communication complexity bound of $O(sk + z)$ where s is the number of machines, and z is the number of outliers.

Although the above results provide a constant-factor approximation to k-median or k-means objectives, many real-world applications desire a clustering that is close to a 'ground truth' clustering in terms of the structure, i.e., the way the points are clustered rather than in terms of cost. For example, for applications such as clustering proteins by function or clustering communities in a social network, there is some unknown target clustering, and the hope is that running a k-median or k-means algorithm will produce clusterings which are close to matching the target clustering. While in general having a constant factor approximation provides no guarantees on the closeness to the optimal clustering, a series of recent works has established that this is possible if the data has certain structural properties [10, 11, 12, 16, 21, 30, 39, 46]. For example, the $(1 + \alpha, \epsilon)$-*approximation stability* condition defined by [12] states that any $(1 + \alpha)$-approximation to the clustering objective is ϵ-close to the target clustering. For such instances, it is indeed possible to output a clustering close to the ground truth in polynomial time, even for values of α such that computing a $(1+\alpha)$-approximation is NP-hard. We follow this line of research and ask whether distributed clustering is possible for non worst-case instances, in the presence of outliers.

1.1 Our contributions

A distributed clustering instance consists of a set of n points in a metric space partitioned arbitrarily across s machines. The problem is to optimize the k-median/k-means objective while minimizing the amount of communication across the machines. We consider algorithms that approximate the optimal cost as well as computing a clustering close to the target clustering in Hamming distance. Our contributions are as follows:

1. In Section 3, we give a centralized clustering algorithm whose output is ϵ-close to the target clustering, in the presence of z outliers, assuming the data satisfies $(1+\alpha, \epsilon)$-approximation stability and assuming a lower bound on the size of the optimal clusters. To the best of our knowledge, this is the first polynomial time algorithm for clustering approximation stable instances in the presence of outliers. Our results hold for arbitrary values of z, including when a constant fraction of the points are outliers, as long as there is a lower bound on the minimum cluster size.
2. We then give a distributed algorithm whose output is close to the target clustering, assuming the data satisfies $(1+\alpha, \epsilon)$-approximation stability. The communication complexity is $\widetilde{O}(sk)$, where s is the number of servers and k is the number of clusters. We also extend this to handle z outliers, with a communication complexity $\widetilde{O}(sk+z)$. This matches the worst-case communication of [32], while outputting a near-optimal clustering by taking advantage of new structural guarantees specific to approximation stability with outliers.
3. While the above algorithms improve over worst-case distributed clustering algorithms in terms of quality of the returned clustering, our algorithms use the same amount of communication as the worst case protocols. In Section 4, we show that the $\Omega(sk)$ and $\Omega(sk+z)$ communication costs for clustering without and with outliers are unavoidable even if data satisfies many types of stability assumptions that have been studied in the literature. Our lower bound of $\Omega(sk+z)$ for obtaining a c-approximation (for any $c \geq 1$) holds even when the data is arbitrarily stable, e.g., $(1+\alpha, \epsilon)$-approximation stable for all $\alpha \geq 0$ and $0 \leq \epsilon < 1$.
4. We also give an $\Omega(sk+z)$ lower bound for the problem of computing a clustering whose Hamming distance is close to the optimal clustering, even when the data is approximation-stable. Finally, we prove that our above $\Omega(sk+z)$ lower bounds hold for finding a clustering close to the optimal in Hamming distance even when it is guaranteed that the optimal clusters are completely balanced, i.e., each cluster is of size $\frac{n-z}{k}$ (in addition to the guarantee that the clustering satisfies approximation stability), implying our algorithms from Section 3 are optimal. Therefore, $\Omega(sk+z)$ is a fundamental communication bottleneck, even for real-world clustering instances.

1.2 Related Work

There is a long line of work on approximation algorithms for k-median and k-means clustering [24, 36, 41], and the current best approximation ratios are 2.675 [23] and 6.357 [4], respectively. The first constant-factor approximation algorithm for k-median with z outliers was given by Chen [28], and the current best approximation ratios for k-median and k-means with outliers are $7.081+\epsilon$ and $53.002+\epsilon$, respectively, given by Krishnaswamy et al. [38]. There is also a line of work on clustering with balance constraints on the clusters [5, 3, 30]. For k-median and k-means clustering in distributed settings, the work of Balcan et al. showed a coreset construction for k-median and k-means, which leads to a clustering algorithm with $\tilde{O}(skd)$ communication, where d is the dimension, and also studied more general graph topologies for distributed computing [18]. Huang et al. [34] showed a coreset construction for

doubling metrics. Malkomes et al. showed a distributed 13- and 4- approximation algorithm for k-center with and without outliers, respectively [42]. Chen et al. studied clustering under the broadcast model of distributed computing, and also proved a communication complexity lower bound of $\Omega(sk)$ for distributed clustering [27], building on a recent lower bound for set-disjointness in the message-passing model [22]. Recently, [32] showed a distributed algorithm with $\tilde{O}(sk + z)$ communication for computing a constant-factor approximation to k-median clustering with z outliers. They also provide bicriteria approximations that remove $(1 + \epsilon)z$ outliers to get a clustering of cost $O\left(1 + \frac{1}{\epsilon}\right)$ times the cost of the optimal k-median clustering with z outliers, for any $\epsilon > 0$. Even more recently, [40] showed that there exists a bi-criteria algorithm with communication independent of z that achieves a constant approximation to the cost. In particular, their algorithm outputs $(1 + \epsilon)z$ outliers and achieves a $(24 + \epsilon)$-approximation with $O\left(\frac{sk}{\epsilon} + \frac{s \log \Delta}{\epsilon}\right)$ communication, where Δ is the aspect ratio of the metric.

In recent years, there has also been a focused effort towards understanding clustering for non worst-case models [43, 1, 21, 39]. The work of Balcan et al. defined the notion of approximation stability and showed an algorithm which utilizes the structure to output a nearly optimal clustering [12]. Approximation stability has been studied in a wide range of contexts, including clustering [15, 17, 14], the k-means++ heuristic [2], social networks [33], and computing Nash-equilibria [9]. A recent paper by Chekuri and Gupta introduces the model of clustering with outliers under perturbation resilience, a notion of stability which is related to approximation stability [26].

2 Preliminaries

Given a set V of points of size n, a distance metric d, and an integer k, let $\mathcal{C}$ denote a clustering of V, which we define as a partition of V into k subsets $C_1, \ldots, C_k$. Each cluster C_i contains a center c_i. When d is an arbitrary distance metric, we must choose the centers from the point set. If $V \subseteq \mathbb{R}^d$ and the distance metric is the Euclidean distance, then the centers can be any k points in $\mathbb{R}^d$. In fact, this distinction only changes the cost of the optimal clustering by at most a factor of 2 by the triangle inequality for any p (see, e.g., [8]).

The k-median and the k-means costs are $\sum_i \sum_{v \in C_i} d(c_i, v)$, and $\sum_i \sum_{v \in C_i} d(c_i, v)^2$ respectively. For k clustering with z outliers, the problem is to compute the minimum cost clustering over $n - z$ points, e.g., we must decide which z points to remove, and how to cluster the remaining points, to minimize the cost. We will denote the optimal k-clustering with z outliers by $\mathcal{OPT}$, and we denote the set of outliers for $\mathcal{OPT}$ by Z. We often overload notation and let $\mathcal{OPT}$ denote the objective value of the optimal clustering as well. We denote the optimal clusters as $C_1^*, \ldots, C_k^*$, with centers $c_1, \ldots, c_k$. We say that two clusterings $\mathcal{C}$ and $\mathcal{C}'$ are δ-close if they differ by only $\delta(n - z)$ points, i.e., $\min_\sigma \sum_{i=1}^k |C_i \setminus C'_{\sigma(i)}| < \delta(n - z)$. Let $C^*_{\min} = \min_{j \in [k]} |C_j^*|$, i.e., the minimum cluster size. Given a point $c \in V$, we define $V_c \subset V$ to be the closest set of $C^*_{\min}$ points to c.

We study a notion of stability called approximation stability. Intuitively, a clustering instance satisfies this assumption if all clusterings close in *value* to $\mathcal{OPT}$ are also close in terms of the clusters themselves. This is a desirable property when running an approximation algorithm, since in many applications, the k-means or k-median costs are proxies for the final goal of recovering a clustering that is close to the desired "target" clustering. Approximation stability makes this assumption explicit. This was first defined for clustering with $z = 0$ [12], however, we generalize the definition to the setting with outliers.

▶ **Definition 1** (approximation stability). *A clustering instance satisfies* $(1+\alpha, \epsilon)$-approximation stability *for k-median or k-means with z outliers if for all k-clusterings with z outliers, denoted by $\mathcal{C}$, if cost$(\mathcal{C}) \leq (1+\alpha) \cdot \mathcal{OPT}$, then $\mathcal{C}$ is ϵ-close to $\mathcal{OPT}$.*

This definition implies that all clusterings close in cost to $\mathcal{OPT}$ must have nearly the same set of outliers, because if $\mathcal{C}$ contains more than $\epsilon(n-z)$ points from Z, then $\mathcal{C}$ and $\mathcal{OPT}$ cannot be ϵ-close. This is similar to related models of stability for clustering with outliers, e.g. [26]. Note it is standard in this line of work to assume the value of α is known [12].

We will study distributed algorithms under the standard framework of the *coordinator model*. There are s servers, and a designated coordinator. Each server can send messages back and forth with the coordinator. This model is very similar to the *message-passing model*, also known as the *point-to-point* model, in which any pair of machines can send messages back and forth. In fact, the two models are equivalent up to constant factors in the communication complexity [22]. Most of our algorithms can be applied to the mapreduce framework with a constant number of rounds. For more details, see [20, 42].

For our communication lower bounds, we work in the multi-party message passing model, where there are s players, $P_1, P_2, \ldots, P_s$, who receive inputs X^1, X^2, $\ldots X^s$ respectively. They have access to private randomness as well as a common publicly shared random string R, and the objective is to communicate with a central coordinator who computes a function $f : X^1 \times X^2 \ldots \times X^s \to \{0,1\}$ on the joint inputs of the players. The communication has multiple rounds and each player is allowed to send messages to the coordinator. Note, we can simulate communication between the players by blowing up the rounds by a factor of 2. Given X^i as an input to player i, let Π be the random variable that denotes the transcript between the players and the referee when they execute a protocol Π. For $i \in [s]$, let Π_i denote the messages sent by P_i to the referee.

A protocol Π is called a δ-error protocol for function f if there exists a function Π_{out} such that for every input, $Pr\left[\Pi_{out} = f(X^1, X^2, \ldots X^s)\right] \geq 1-\delta$. The communication cost of a protocol, denoted by $|\Pi|$, is the maximum length of Π over all possible inputs and random coin flips of all the s players and the referee. The randomized communication complexity of a function f, $R_\delta(f)$, is the communication cost of the best δ-error protocol for computing f. For our lower bounds, we also consider that the data satisfies a very strong, general notion of stability which we call c-separation.

▶ **Definition 2** (separation). *Given $c \geq 1$ and a clustering objective, a clustering instance satisfies* c-separation *if $c \cdot \max_i \max_{u,v \in C_i^*} d(u,v) < \min_i \min_{u' \in C_i^*, v' \notin C_i^*} d(u',v')$.*

Intuitively, this definition implies the maximum distance between any two points in one cluster is a factor c smaller than the minimum distance across clusters. This assumption has been used in several papers (for clustering with no outliers) to show guarantees for various algorithms [13, 44, 37]. We note that this notion of stability captures a wide class of previously studied notions including perturbation resilience [21, 10, 16, 6] and approximation stability.

▶ **Definition 3** (perturbation resilience). *For $\beta > 0$, a clustering instance (V,d) satisfies $1+\alpha$-perturbation resilience for the k-means objective, if for any function $d' : V \times V \to \mathbb{R}_{\geq 0}$, such that for all $p, q \in V$, $d(p,q) \leq d'(p,q) \leq (1+\beta)d(p,q)$, and the optimal clustering under d' is unique and equal to the optimal clustering under d, for the k-means objective.*

We note we can replace the objective with any center based objective such as k-median or k-center. Next, we show that *separation* implies *approximation stability* and *perturbation resilience*. We defer the proof to the Appendix.

▶ **Lemma 4.** *Given $\alpha, \epsilon > 0$, and a clustering objective such as k-median, let (V, d) be a clustering instance which satisfies c-separation, for $c > (1+\alpha)n$, where $n = |V|$. Then (V, d) satisfies $(1+\alpha, \epsilon)$-approximation stability and $(1+\alpha)$-perturbation resilience.*

3 Approximation Stability with Outliers

In this section, we give a centralized algorithm for clustering with z outliers under approximation stability, and then extend it to a distributed algorithm for the same problem. To the best of our knowledge, this is the first result for clustering with outliers under approximation stability, as well as the first distributed algorithm for clustering under approximation stability even without outliers. We defer the details to the Appendix. Our algorithm can handle any fraction of outliers, even when the set of outliers makes up a constant fraction of the input points. For simplicity, we focus on k-median.

▶ **Theorem 5** (Centralized Clustering)**.** *Algorithm 1 runs in poly$\left(n, \left(\frac{\alpha}{\epsilon}\left(k + \frac{1}{\alpha}\right)\right)^{\frac{1}{\alpha}}\right)$ time and outputs a clustering that is ϵ-close to $\mathcal{OPT}$ for k-median with z outliers under $(1+\alpha, \epsilon)$-approximation stability, assuming for all i, $|C_i^*| \geq 2\left(1 + \frac{5}{\alpha}\right)\epsilon(n-z)$.*

Note that the runtime is at most poly$\left(n^{\frac{1}{\alpha}}\right)$, and if $\frac{\alpha}{\epsilon} \in \Theta(k)$, the runtime is poly$\left(n, k^{\frac{1}{\alpha}}\right)$. The algorithm has two high-level steps. First, we use standard techniques from approximation stability without outliers to find a list of clusters $\mathcal{X}$, which contains clusters from the optimal solution (with $\leq \left(1 + \frac{1}{\alpha}\right)\epsilon(n-z)$ mistakes), and clusters made up mostly of outlier points. We show how all but $1/\alpha$ of the outlier clusters must have high cost if their size were to be extended to the minimum optimal cluster size, and can thus be removed from our list $\mathcal{X}$. Finally, we use brute force enumeration to remove the final $\frac{1}{\alpha}$ outlier clusters, and after another cluster purifying step, we are left with a k clustering which $(1+\alpha)$-approximates the cost and thus is guaranteed to be ϵ-close to optimal.

We begin by outlining the key properties of $(1+\alpha, \epsilon)$-approximation stability. Let w_{avg} denote the average distance from each point to its optimal center, so $w_{avg} \cdot (n-z) = \mathcal{OPT}$. The following lemma is the first of its kind for clustering with outliers and establishes two key properties for approximation stable instances. Intuitively, the first property bounds the number of points that are far away from their optimal center, and follows from Markov's inequality. The second property bounds the number of points that are either closer on average to the center of a non-optimal cluster that the optimal one or are outliers that are close to some optimal center as compared to a point belonging to that cluster.

▶ **Lemma 6.** *Given a $(1+\alpha, \epsilon)$-approximation stable clustering instance (V, d) for k-median such that for all i, $|C_i^*| > 2\epsilon(n-z)$, then **Property 1:** For all $y > 0$, there exist at most $\frac{y\epsilon}{\alpha}(n-z)$ points, v, such that $d(v, c_v) \geq \frac{\alpha w_{avg}}{y\epsilon}$. **Property 2:** There are fewer than $\epsilon(n-z)$ total points with one of the following two properties: the point v is in an optimal cluster C_i^*, and there exists $j \neq i$ such that $d(v, c_j) - d(v, c_i) \leq \frac{\alpha w_{avg}}{\epsilon}$, or, the point v is in Z, and there exists i and $v' \in C_i^*$ such that $d(v, c_i) \leq d(v', c_i) + \frac{\alpha w_{avg}}{\epsilon}$ (recall that Z denotes the set of outliers from the optimal clustering).*

We define a point as *bad* if it falls into the bad case of either Property 1 (with $y = 5$) or Property 2, and we denote the set of bad points by B. Otherwise, a point is *good*. From Properties 1 and 2, $|B| \leq \left(1 + \frac{5}{\alpha}\right)\epsilon(n-z)$. For each i, let G_i denote the good points from the optimal cluster C_i^*. We consider the graph $G' = (V, E')$ called the *neighborhood graph*, constructed by adding an edge (u, v) iff there are at least $|B| + 2$ points w such that $d(u, w), d(v, w) \leq \tau = \frac{2w_{avg}}{5}$. Under approximation stability, the graph G' has the following

structure: there is an edge between all pairs of good points from C_i^* and there is no edge between any pair of good points belonging to distinct clusters, C_i^*, C_j^*. Further, these points do not have any common neighbors. Since the set of good points in each cluster, denoted by G_i, form cliques of size $> |B|$ and are far away from one another, and there are $\leq |B|$ bad points, it follows that each G_i is in a unique connected component C_i' of G'.

In the setting without outliers, the list of connected components of size greater than $\left(1+\frac{5}{\alpha}\right)\epsilon n$ is exactly $\{C_1', \ldots, C_k'\}$. However, in the setting with outliers, we can only return a set $\mathcal{X}$ which includes $\{C_1', \ldots, C_k'\}$ but also may include many other outlier clusters which are hard to distinguish from the optimal clusters. Although approximation stability tells us that any set Z' of outliers must have a much higher cost than any optimal cluster C_i^* (since we can arrive at a contradiction by replacing the cluster C_i^* with the cluster Z'), this is not true when the size of Z' is even slightly smaller than C_i^*. Since the good clusters returned are only $O\left(\frac{\epsilon}{\alpha}\right)$-close to optimal, many good clusters may be smaller than outlier clusters, and so a key challenge is to distinguish outlier clusters Z' from good clusters C_i'.

To accomplish this task, we compute the minimum cost of each cluster, pretending that its size is at least $C^*_{\min}$ (the size of the minimum optimal cluster, which we can guess in polynomial time). In our key structural lemma (Lemma 7), we show that nearly all outlier components will have large cost. Given a set of points Q, we define $\text{cost}_{\min}(Q)$ to be the minimum cost of Q if it were extended to $C^*_{\min}$ points. Note, $\text{cost}_{\min}(Q)$ can be computed in polynomial time by iterating over all points $c \in Q$, for each such point constructing V_c by adding the the $C^*_{\min} - |Q|$ points closest to c, computing the resulting cost, and taking the minimum over all such costs.

Algorithm 1 k-median with z-outliers under Approximation Stability.

`Input`: Clustering instance (V, d), cost w_{avg}, value C^*_{min}, integer $x > 0$.

1. Create the neighborhood graph on V with parameters $\tau = \frac{2w_{avg}}{5\epsilon}$ and $b = C^*_{min} - (1 + \frac{5}{\alpha})\epsilon(n-z)$ as follows: for each $u, v \in V$, add an edge (u, v) iff there exist $\geq b$ points $w \in V$ such that $d(u, w), d(w, v) \leq \tau$. Denote the connected components by $\mathcal{X} = \{Q_1, \ldots, Q_d\}$.
2. For each Q_i, compute $\text{cost}_{\min}(Q_i) = \min_{c \in Q_i} \min_{V_c} \sum_{v \in V_c} d(c, v)$, where V_c must satisfy $|V_c| \geq C^*_{min}$ and $Q_i \subseteq V_c$. Create a new set $\mathcal{X}' = \{Q_i \mid \text{cost}_{min}(Q_i) < \left(3 + \frac{2\alpha}{5}\right)\frac{1}{x} \cdot \mathcal{OPT}\}$. .
3. For all $0 \leq t \leq x$, for each size t subset $\mathcal{X}_t' \subseteq \mathcal{X}'$ and size $(k - |\mathcal{X}'| - t)$ subset $\mathcal{X}_t \subseteq (\mathcal{X} \setminus \mathcal{X}')$,
   a. Create a new clustering $\mathcal{C} = \mathcal{X}' \cup \mathcal{X}_t \setminus \mathcal{X}_t'$.
   b. For each point $v \in V$, define $I(v)$ as the index of the cluster in $\mathcal{C}$ with minimum median distance to v, e.g., $I(v) = \text{argmin}_i\left(d_{\text{med}}(v, Q_i)\right)$ where $d_{\text{med}}(v, Q_i)$ denotes the median distance from v to Q_i.
   c. Let $V' \subseteq V$ denote the $n - z$ points with the smallest values of $d(v, c_{I(v)})$. For all i, set $Q_i' = \{v \in V' \mid I(v) = i\}$.
   d. If $\sum_i \text{cost}(Q_i') \leq (1+\alpha)\mathcal{OPT}$, return $\{Q_1, \ldots, Q_k\}$.

▶ **Lemma 7.** *Given an instance of k-median clustering with z outliers such that each optimal cluster $|C_i^*| > 2\left(1+\frac{5}{\alpha}\right)\epsilon(n-z)$, for any $x \in \mathbb{N}$, the instance satisfies $(1+\alpha, \epsilon)$-approximation stability for $\alpha > \frac{35}{5x-4}$, and there are at most x disjoint sets of outliers Z' such that $|Z'| > \min_i |C_i^*| - \left(1+\frac{5}{\alpha}\right)\epsilon(n-z)$ and $\text{cost}_{\min}(Z') \leq \left(3+\frac{2\alpha}{5}\right)\frac{1}{x}\mathcal{OPT}$.*

The key ideas behind the proof are as follows. If there are two sets of outliers Z_1 and Z_2 both with fewer than $C^*_{\min}$ points, then we can obtain a contradiction by taking into account both sets of outliers. Set $1 \leq z_1, z_2 \leq \left(1+\frac{5}{\alpha}\right)\epsilon(n-z)$ such that $|Z_1| = C^*_{\min} - z_1$ and

$|Z_2| = C^*_{\min} - z_2$, and assume without loss of generality that $z_1 < z_2$. We design a different clustering $\mathcal{C}'$ by first replacing the minimum-sized cluster in the optimal clustering with Z_1. The cost of the points in Z_2 is low by assumption. However, we have now potentially assigned more than z points to be outliers by an additive z_1 amount. Hence, in order to create a valid clustering that is far from $\mathcal{OPT}$ we need to add back at least z_1 more outlier points. We do this by choosing z_1 outlier points from Z_2 that are closest to an optimal center in $\mathcal{OPT}$. To bound the additional cost incurred, we use the fact that Z_2 must be close to at least z_2 points from $V \setminus Z$, by the assumption that $\text{cost}_{\min}(Z_2)$ is low, and use these points to bound the distance from centers in $\mathcal{OPT}$ to the z_1 points that were added back. In the full proof, we extend this idea to x sets $Z_1, \ldots, Z_x$ to achieve a tradeoff between x and α.

From Lemma 7, we show a threshold of $\text{cost}_{\min}$ for the components of $\mathcal{X}$, such that all but x optimal clusters are below the cost threshold, and all but x outlier clusters are above the cost threshold. Then we can brute force over all ways of excluding x low-cost sets and including x high-cost sets, and we will be guaranteed that one combination contains a clustering which is $O\left(\frac{\epsilon}{\alpha}\right)$-close to the optimal. However, we still need to recognize the right clustering when we see it. To do this, we show that after performing one more cluster purifying step which is inspired by arguments in [12] - reassigning all points to the component with the minimum median distance - we will reduce our error to $\epsilon(n-z)$ in Hamming distance and we show how to bound the total cost of these mistakes by $\frac{4\alpha}{5}\mathcal{OPT}$. Therefore, during brute force enumeration, we return immediately when we find a clustering with cost at most $(1+\alpha)\mathcal{OPT}$ (and thus must be ϵ-close to $\mathcal{OPT}$). Then we can try all possible values of C^*_{min} while only incurring a polynomial increase in the runtime of the algorithm. For w_{avg}, we first run an approximation algorithm for k-median with z outliers to obtain a constant approximation to w_{avg} (e.g., [38]). The constant in the minimum allowed optimal cluster size then increases by a factor of 7. This is because we need to use a smaller value of τ when constructing the neighborhood graph G', and so the number of "bad" points increases. In order to show all the good connected components from G' contain a majority of good points, we merely increase the bound on the minimum cluster size.

Distributed Setting. Next, we give a distributed algorithm for approximation stability with outliers using $\tilde{O}(sk+z)$ communication. However, as opposed to worst case, we can get close to the ground truth (target) clustering. In Section 4, we show a matching lower bound.

▶ **Theorem 8** (Distributed Clustering). *Given a $(1+\alpha, \epsilon)$-approximation stable clustering instance, there exists an algorithm that runs in poly$\left(n^{\frac{1}{\alpha}}\right)$ time and with high probability outputs a clustering that is $O(\epsilon)$-close to $\mathcal{OPT}$ for k-median with $\tilde{O}(sk+z)$ communication if each optimal cluster C^*_i has cardinality at least* $\max\left\{2\left(1+\frac{22}{\alpha}\right)\epsilon(n-z), \Omega\left(\frac{(n-z)}{sk}\right)\right\}$.

We start by giving intuition for our algorithm where there are no outliers. The high-level structure of the algorithm can be thought of as a two-round version of the centralized algorithm from approximation stability with no outliers [12]. Each machine effectively creates a coreset of its input, consisting of a weighted set of points, and sends these weighted points to the coordinator. The coordinator runs the same algorithm on these sets of weighted centers, to output the final solution.

In the analysis, we define good and bad points using Property *(1)* above with $y = 20$ as opposed to $y = 5$, so that there are more bad points than in the non-distributed setting, $|B| = \left(1+\frac{1}{20}\right)\epsilon(n-z)$, but for each optimal cluster C^*_i, the good points G_i are even more tightly concentrated. In the first round, each machine computes the neighborhood graph described above with parameter $\tau = \frac{w_{avg}}{10}$. This more stringent definition of τ ensures that

Claims *(1)* and *(2)* above are not only true for the input point set, but also true for a summarized version of the point set, where each point represents a ball of data points within a radius of τ. Therefore, there is still enough structure present such that the coordinator can compute a near-optimal clustering, and finally the coordinator sends the k resulting (near optimal) centers to each machine.

Now we expand this approach to the case with outliers. The starting point of the algorithm is the same: we perform two rounds of the sequential approximation stability algorithm with no outliers, so that each machine computes a summary of its point set, and the coordinator clusters the points it receives. Recall that in the centralized setting, running the non-outlier algorithm produces a list of clusters $\mathcal{X}$, some of which are near-optimal and some of which are outlier clusters, and then we crucially computed the $\text{cost}_{\min}$ of each potential cluster to distinguish the near-optimal clusters from the outlier clusters. In the distributed setting, we can construct the set $\mathcal{X}$ using the two-round approach.

However, the $\text{cost}_{\min}$ computation is sensitive to small sets of input points, and, as a result, the coresets will not give the coordinator enough information to perform this step correctly. In particular, this involves finding the closest points to a component that increase the cardinality to $C^*_{\min}$, and these points may be arbitrarily partitioned across the machines. Furthermore, the centralized algorithm can easily try all possible centers to compute the minimum cost of a given component Q, but it is much harder in the distributed setting to even find an approximately optimal center. Even with a center c chosen, the coordinator needs a near-exact estimate of the minimum cost of Q, however, it does not know the $C^*_{\min}$ closest points to c. Therefore our distributed algorithm must balance accuracy with communication.

For each component Q, the coordinator simulates $\log n$ random draws from Q by querying its own weighted points, and then querying the machine of the corresponding point. This allows the coordinator to find a center c whose cost is only a constant factor away from the best center. To compute $\text{cost}_{\min}(c)$, the coordinator runs a binary-search procedure with all machines to find the minimum distance t such that $B_t(c)$ contains more than $C^*_{\min}$ points.

Given a random point v from Q, by a Markov inequality, there is a $1/2$ chance that the cost of center v on V_c is at most twice the cost with center c. From a Chernoff bound, by sampling $10 \log n$ points for each component, each component will find a good center with high probability. Therefore, the coordinator can evaluate the cost of each component up to a factor of 2, which is sufficient to (nearly) distinguish the outlier clusters from the near-optimal clusters. The rest of the algorithm is similar to the centralized setting. We brute-force all combinations of removing x low-cost clusters from $\mathcal{X}$ and adding back x high-cost clusters from x. We perform one more cluster purifying step, and then check the cost of the resulting clustering. If the cost is smaller than $(1+\alpha)w_{avg}(n-z)$, then we return this clustering.

Similar to the centralized setting, we can use existing algorithms (e.g. [32]) to approximate w_{avg}, and we can use binary search to find $C^*_{\min}$. The algorithm communicates $\tilde{O}(sk+z)$ bits to approximate w_{avg}. The communication in the first step is $O(sk \log n)$, since there are at most $\min\left\{\frac{s}{\epsilon}, O(sk)\right\}$ sets of size at least $\max\left\{\frac{\epsilon n}{s}, \frac{n}{sk}\right\}$, each of which are communicated to the coordinator. The total communication to compute $\text{cost}_{\min}$ for every component is $\tilde{O}(sk)$. The binary search wrapper to find $C^*_{\min}$ adds a $\log n$ multiplicative factor. Therefore, the total communication is $\tilde{O}(sk+z)$.

4 Communication Complexity Lower Bounds

In this section, we show lower bounds for the communication complexity of distributed clustering with and without outliers. We prove $\Omega(sk + z)$ lower bounds for two types of clustering problems: computing a clustering whose cost is at most a c-approximation to the optimal (or even just to determine the cost up to a factor of c) for any $c \geq 1$, and computing a clustering which is δ-close to $\mathcal{OPT}$, for any $\delta < \frac{1}{4}$. This shows prior work of [32] is tight.

Our lower bounds hold even under c-separation (Definition 2). Furthermore, our lower bounds for δ-close clustering hold even under a weaker version of clustering, which we call *locally-consistent clustering*. In this problem, instead of assigning a globally consistent index in $\{1, \ldots, k\}$ for each point, each player only needs to assign indices to its points that is consistent in a local manner, e.g., the assignment of index set $\{1, \ldots, k\}$ to clusters $\{C_1, \ldots, C_k\}$ chosen by player 1 might be a permutation of the assignment chosen by player 2. We work in the communication model described in Section 2.

▶ **Definition 9** (Multi-party set disjointness ($\mathsf{DISJ}_{s,\ell}$)). *Given s players, denoted by P_1, P_2, $\ldots P_s$, player P_j receives as input a bit vector X^j of length ℓ. Let X denote the a binary matrix such that each X^j is a column of X. Let X_i denote the i-th row of X and $X^j[i]$ denote the (i, j)-th entry of X. Then, $\mathsf{DISJ}_{s,\ell} = \bigvee_{i\in[\ell]} \bigwedge_{j\in[s]} X^j[i]$, i.e., $\mathsf{DISJ}_{s,\ell} = 0$ if at least one row of X corresponds to the all ones vector and 1 otherwise.*

We note that set disjointness is a fundamental problem in communication complexity and we use the following lower bound for $\mathsf{DISJ}_{s,\ell}$ in the message-passing model by [22]:

▶ **Theorem 10** (Communication complexity of $\mathsf{DISJ}_{s,\ell}$ [22]). *For any $\delta > 0$, $s = \Omega(\log(n))$ and $\ell \geq 1$, the randomized communication complexity of multi-party set disjointness, $R_\delta(\mathsf{DISJ}_{s,\ell})$, is $\Omega(s\ell)$.*

We use the above theorem to show a lower bound of $\Omega(sk + z)$ for distributed clustering algorithms that attain an approximation to the cost of the optimal clustering under center-based clustering objectives such as k- median and k-means even if the instance satisfies strong beyond-worse case stability assumptions. We note that our first reduction is a slight modification of the reduction that appears in [27] and we show how to extend the reduction to stable instances and to account for outliers. Intuitively, the parameters of the reduction are carefully chosen so that the clustering instance created either has k or $k + 1$ distinct locations, toggled by the disjointness instance being yes or no. The lower bound for outliers requires starting with a two player, balanced instance of set disjointness, introduced by [45].

▶ **Theorem 11.** *Given $c_1 \geq 1$, $c_2 \geq 0$, the communication complexity for computing a c_1-approximation for k-median, k-means, or k-center clustering is $\Omega(sk)$, even when promised that the instance satisfies c_2-separation. Further, for the case of clustering with z outliers, computing a c_1-approximation to k-median, k-means, or k-center cost, given the promise that the instance satisfies c_2-separation requires $\Omega(sk + z)$ bits of communication.*

We note that thus far we have ruled out a distributed clustering algorithm that has communication complexity less than $\Omega(sk + z)$ to output the exact clustering under strong stability assumptions. Next, we show an $\Omega(sk + z)$ lower bound when the goal is to return a clustering that is $\delta < \frac{1}{4}$-close to optimal in Hamming distance, i.e., outputting a clustering that differs from the optimal clustering in a δ-fraction of the points, given that the instance is $(1 + \alpha, \epsilon)$-stable for any setting of these parameters.

We show that our lower bounds hold even when the algorithm outputs a c-approximate solution to the clustering cost of a $\frac{1}{4}$-close clustering. Intuitively, the proof is again a reduction from $\mathsf{DISJ}_{s,\ell}$, similar to the proof of Theorem 11. The main difference is that the

coordinator now adds roughly $\frac{n}{2}$ copies of a subset of points in our construction, to make the optimal clustering stand out from the rest. The main technical challenge is to figure out how to add these points such that the optimal clustering stands out in both yes and no instances. Therefore, recovering an approximation to the optimal clustering in Hamming distance provides enough information to solve set disjointness.

▶ **Theorem 12.** *Given $c_1 \geq 1$, $c_2 \geq 0$, and $0 < \delta < \frac{1}{4}$, the communication complexity for computing a c_1-approximation to the k-median, k-means, or k-center objective with z outliers and outputting a clustering that is δ-close to the optimal, $\Omega(sk + z)$, even when promised that the instance satisfies c_2-separation.*

Though the above lower bounds are quite general, it is possible that the hard instances may have the optimal clusters to be very different in cardinality if sk is large. The smallest cluster may be size $O\left(\frac{n}{sk}\right)$, while the largest cluster may be size $\Omega(n)$. Often, real-world instances have roughly balanced clusters. There is a line of work on clustering with balance constraints on the clusters [5, 3, 30], and some of our algorithmic results assume a lower bound on the minimum cluster size.

We note that our previous reduction for proving a lower bound against δ-close clustering algorithms fundamentally relies on testing the cardinality of the clusters. Therefore, we extend our previous lower bounds to the setting where we are promised that the input clusters are well balanced, i.e., have roughly the same cardinality. We still consider algorithms that only get δ-close to the optimal clustering. We begin by defining the following basic notions from information theory:

▶ **Definition 13** (Entropy and conditional entropy)**.** *The entropy of a random variable X drawn from distribution μ, denoted as $X \sim \mu$, with support χ, is given by $H(X) = \sum_{x \in \chi} \Pr_\mu[X = x] \log \frac{1}{\Pr_\mu[X=x]}$. Given two random variable X and Y with joint distribution μ, the entropy of X conditioned on Y is given by $H(X \mid Y) = \mathbb{E}_{y \sim \mu(Y)} \left[\sum_{x \in \chi} \Pr_{\mu(X|Y=y)}[X = x] \log \frac{1}{\Pr_{\mu(X|Y=y)}[X=x]}\right]$.*

Note, the binary entropy function $H_2(X)$ is the entropy function for the distribution $\mu(X)$ supported on $\{0, 1\}$ such that $\mu(X) = 1$ with probability p and $\mu(X) = 0$ otherwise.

▶ **Definition 14** (Mutual information and conditional mutual information)**.** *Given random variables X and Y, the mutual information between X and Y is given by $I(X;Y) = H(X) - H(X \mid Y) = H(Y) - H(Y \mid X)$. The conditional mutual information between X and Y, conditioned on a random variable Z is given by $I(X;Y \mid Z) = H(X \mid Z) - H(X \mid Y, Z) = H(Y \mid Z) - H(Y \mid X, Z)$.*

Recall, the δ-error randomized communication complexity of $\mathcal{A}$, $R_\delta(\mathcal{A})$, in the message passing model is communication complexity of any randomized protocol Π that solves $\mathcal{A}$ with error at most δ. Let μ be a distribution over $X^1, X^2, \ldots X^s$. We call a deterministic protocol (δ, μ)-error if it gives the correct answer for $\mathcal{A}$ on at least a $1-\delta$ fraction of the input, weighted by the distribution μ. Let $D_{\mu,\delta}(\mathcal{A})$ denote the cost of the minimum communication (δ, μ)-error protocol. By Yao's minimax lemma, $R_\delta(\mathcal{A}) \geq \max_\mu D_{\mu,\delta}(\mathcal{A})$. Therefore, in order to lower bound the randomized communication complexity of $\mathcal{A}$, it suffices to construct a distribution μ over the input such that any deterministic protocol that is correct on $1 - \delta$ fraction of any input can be analyzed easily. The communication complexity of a protocol Π is also lower bounded by its information complexity.

▶ **Definition 15** (Information complexity of $\mathcal{A}$)**.** *For $i \in [s]$, let Π_i be a random variable that denotes the transcript of the messages sent by player P_i to the coordinator. We overload notation by letting Π denote the concatenation of Π_1 to Π_s. Then, the information complexity of $\mathcal{A}$ is given by $IC_{\mu,\delta}(\mathcal{A}) = \min_{(\delta,\mu)\text{-error } \Pi} I(X_1, X_2, \ldots X_s; \Pi)$.*

Since information lower bounds communication (see, e.g., [35]), $R_\delta(\mathcal{A}) \geq \mathsf{IC}_{\mu,\delta}(\mathcal{A})$ in the message passing model. So our proof strategy is to construct a distributed protocol for solving the above problem using an algorithm that obtains a δ-close clustering for balanced clusters. We then design a distribution μ over the input and lower bound the information complexity of the resulting problem by $\Omega(k)$. We then amplify the bound by introducing $s/2$ copies of Alice and Bob (as before). Next, we describe this proof strategy in detail.

We begin with a two-player communication problem, where Alice and Bob receive length ℓ bit vectors, and the objective is to compute the AND function on each index in $[\ell]$. We then construct a gadget that reduces computing AND on any particular index to solving a 2-clustering problem, where each cluster has 2 points (and thus the instance is balanced). The gadget is such that Alice and Bob insert 2 points each, at a fixed set of locations determined by their input, and the optimal 2-clustering places Alice's points in different clusters iff the AND evaluates to true. The same holds for Bob. Therefore, Alice and Bob learn each other's bit simply looking at the output of the clustering algorithm. The players then create this gadget for each index in their input, and place the gadgets sufficiently far from each other.

Observe, a δ-close clustering algorithm must output a $(1-2\delta)$-fraction of the clusters correctly. Using such an algorithm as a distributed protocol enables the players to learn the AND function on a $(1-2\delta)$-fraction of the coordinates. Note the underlying communication problem here does not correspond to well-studied problems such as set disjointness. However, some proofs of the lower bound for multi-party set disjointness do reduce to computing the AND function on every index [19]. Therefore, we relate the communication complexity of the above problem to the amount of information revealed by any protocol that is correct on a large fraction of the input.

We define a distribution μ over the input such that each bit for Alice and Bob is set to be 1 with probability 1/2 independently and 0 otherwise. Here, we observe that the δ-close clustering algorithm implies a $(2\delta, \mu)$-protocol for computing AND on each index. Therefore, we prove that the information complexity of a $(2\delta, \mu)$-protocol is $\Omega(\ell)$. Intuitively, this says any correct deterministic protocol that is correct on a $1-2\delta$ fraction of the input, for the given input distribution μ, must reveal $\Omega(1)$ information on every index that has at least one 1, which amounts to communicating the bit. Since our gadget has 2 clusters for each index, setting $\ell = \Theta(k)$ obtains an $\Omega(k)$ communication lower bound. Using our previous strategy of duplicating the Alice and Bob players $s/2$ times, we obtain the following theorem:

▶ **Theorem 16.** *Given $\delta < \frac{1}{4}$ and the promise that the optimal clusters are balanced, i.e., the cardinality of each cluster is $\frac{n}{k}$, the communication complexity for computing a clustering that is δ-close to the optimal k-means or k-median clustering is $\Omega(sk)$.*

Finally, we extend the above lower bound to clustering instances that are balanced and also satisfy $(1+\alpha, \epsilon)$-approximation stability, again obtaining an $\Omega(sk+z)$ lower bound. Perhaps surprisingly, we show that there is no trade-off between the stability parameters and the communication lower bound even if the clusters are balanced and the algorithm outputs a clustering that is $\delta < \epsilon/4$ close to the optimal clustering. In contrast, our previous result can handle all $\delta < 1/4$. Intuitively, to obtain a clustering instance that is $(1+\alpha, \epsilon)$-approximation stable, we restrict the number of indices on which AND evaluates to 1 to be $O(\epsilon n)$. Therefore we start with a promise version of the multi-party set disjointness problem, where the promise states if the sets intersect, they intersect on exactly one element. Formally,

▶ **Definition 17** (Promise multi-party set disjointness ($\mathsf{PDISJ}_{s,\ell}$))**.** *Given s players denoted by $P_1, \ldots, P_s$, each player receives a bit vector X^j of length ℓ. Let X denote a binary matrix such that each X^j is a column of X. Let X_i denote the i-th row of X and X_i^j denote*

the (i, j)-th entry of X. We are promised that at most one row of X has all ones. Then, $\mathsf{PDISJ}_{s,\ell} = \bigvee_{i\in[\ell]} \bigwedge_{j\in[s]} X_i^j$, i.e., $\mathsf{PDISJ}_{s,\ell} = 0$ if any row of X corresponds to the all ones vector and 1 otherwise.

We use a result of [19] to lower bound the communication complexity of set-disjointness in the multi-party communication model.

▶ **Theorem 18** (Communication complexity of $\mathsf{PDISJ}_{s,\ell}$ [19]). *For any $\delta > 0$, $s, \ell \in \mathbb{N}$, the randomized communication complexity of promise multi-party set disjointness, $R_\delta(\mathsf{PDISJ}_{s,\ell})$, is $\Omega(\ell/s^2)$.*

We show any algorithm obtaining a δ-close clustering, given the clusters are balanced and the clustering instance is $(1+\alpha, \epsilon)$-stable can be converted into a randomized communication protocol that solves $\mathsf{PDISJ}_{s,\ell}$. At a high level, Alice and Bob receive length ℓ bit vectors and create a gadget for each index in $[\ell]$. If the number of indices on which the bit vectors intersect is at most ϵk, the instance is $(1+\alpha, \epsilon)$-stable. We ensure this by constructing gadgets that incur an arbitrarily high cost in all other cases (see the Appendix for details).

We note that if our clustering instance has exactly one index on which AND evaluates to 1, it is easy for a randomized protocol to be incorrect with good probability. In order to circumvent this issue and maintain $(1+\alpha, \epsilon)$-stability, Alice and Bob create $\epsilon n - 1 = 2\epsilon k - 1$ dummy indices that are set to 1 for both players. Further, Alice and Bob use public randomness to agree on a uniform permutation of the padded input and apply this permutation before constructing the gadgets and running the clustering algorithm. Intuitively, permuting the indices ensures that the δ-close clustering gets a typical cluster right with reasonable probability, by being oblivious to the dummy clusters that were used as padding.

Since we uniformly permute the indices of the input before running the protocol, for any given index, the corresponding cluster has Hamming distance 0 from the optimal clustering with probability at least $1-\epsilon$. This implies at most an ϵ-fraction of the clusters are incorrect. The protocol outputs a clustering that is known to both Alice and Bob. For each index of their input, they know whether their pair of points lie in the same cluster or different clusters. Let $\mathcal{I}$ be the set of indices for which Alice and Bob's points lie in different clusters. If $\mathcal{I} > 4\epsilon k$, the protocol outputs fail. Otherwise, Alice communicates her input on the set $\mathcal{I}$ to Bob. Bob applies an inverse random permutation to indices in set $\mathcal{I}$, and verifies if the indices correspond to the dummy indices that were added or indeed the sets are not disjoint. Note the verification step requires additional communication. Since $\mathcal{I} \leq 4\epsilon k$, and ϵ is at most a small constant, the total additional communication is $O(k/c)$ for some large constant c.

Consider the case where the sets are not disjoint. Then there is an index i^* such that AND on this index evaluates to 1, and with probability at least $1-\epsilon$, the clustering algorithm correctly clusters the corresponding 2-means gadget. This implies that Alice and Bob know that their pair of points lie in different clusters, thus i^* is in the set $\mathcal{I}$ and Alice communicates her input on index i^* to Bob. Bob can then verify that i^* is not a dummy index and indeed the sets are not disjoint.

The case where the sets are disjoint is more subtle. Now the clustering algorithm may return $4\epsilon k$ indices such that Alice's points belong to separate clusters, i.e., they correspond to a $(1,1)$ input, therefore leading to false positives. However, we observe that we can verify if the sets are disjoint by Alice sending over her input bits on the set $\mathcal{I}$ to Bob. Bob can verify if they correspond to the dummy indices and the sets are indeed disjoint. This increases the over all communication by $O(k/c)$. We recall that the promise problem requires $\Omega(\ell) = \Omega(k)$ communication and thus the communication of the above protocol is $\Omega(k - \epsilon k) = \Omega(k)$. We use the technique of cloning Alice and Bob $s/2$ times, so communicating the solution to each player requires $\Omega(sk)$ bits of communication. Finally, we show how to extend this lower bound to the case of outliers to get an overall $\Omega(sk + z)$ lower bound:

▶ **Theorem 19.** *Given a* $(1+\alpha, \epsilon)$*-approximation stable instance with* z *outliers such that* $\epsilon = o(1)$ *and* $\delta < \frac{\epsilon}{4}$*, and the promise that the optimal clusters are balanced, i.e., the cardinality of each cluster is* $\frac{n-z}{k}$*, the communication complexity for computing a clustering that is* δ*-close to the optimal* k*-means or* k*-median clustering is* $\Omega(sk + z)$*.*

Capacitated Dynamic Programming: Faster Knapsack and Graph Algorithms

Abstract

One of the most fundamental problems in Computer Science is the *Knapsack* problem. Given a set of n items with different weights and values, it asks to pick the most valuable subset whose total weight is below a capacity threshold T. Despite its wide applicability in various areas in Computer Science, Operations Research, and Finance, the best known running time for the problem is $O(Tn)$. The main result of our work is an improved algorithm running in time $O(TD)$, where D is the number of distinct weights. Previously, faster runtimes for Knapsack were only possible when both weights and values are bounded by M and V respectively, running in time $O(nMV)$ [17]. In comparison, our algorithm implies a bound of $O(nM^2)$ without any dependence on V, or $O(nV^2)$ without any dependence on M. Additionally, for the unbounded Knapsack problem, we provide an algorithm running in time $O(M^2)$ or $O(V^2)$. Both our algorithms match recent conditional lower bounds shown for the Knapsack problem [10, 15].

We also initiate a systematic study of general *capacitated dynamic programming*, of which Knapsack is a core problem. This problem asks to compute the maximum weight path of length k in an edge- or node-weighted directed acyclic graph. In a graph with m edges, these problems are solvable by dynamic programming in time $O(km)$, and we explore under which conditions the dependence on k can be eliminated. We identify large classes of graphs where this is possible and apply our results to obtain linear time algorithms for the problem of k-sparse Δ-separated sequences. The main technical innovation behind our results is identifying and exploiting concavity that appears in relaxations and subproblems of the tasks we consider.

1 Introduction

A large number of problems in Computer Science can be formulated as finding the optimal subset of items to pick in order to maximize a given objective subject to capacity constraints.

A core problem in this class is the *Knapsack problem*: In this problem, each of the n items has a value and a weight and the objective is to maximize the total value of the selected items while having total weight at most T.

A standard approach for solving such capacitated problems is to use dynamic programming. Specifically, the dynamic programming algorithm keeps a state that tracks how much of the available capacity has already been exhausted. The runtime of these algorithms typically

incurs a multiplicative factor equal to the total capacity. In particular, in the case of the Knapsack problem the classical dynamic programming algorithm due to Bellman [6] has a runtime of $O(Tn)$.

In contrast, uncapacitated problems do not restrict the number of elements to be selected, but charge an extra cost for each one of them (i.e. they have a *soft* as opposed to a *hard* capacity constraint). The best known algorithms for these problems are usually much faster than the ones for their capacitated counterparts, i.e. for the uncapacitated version of knapsack one would need to pick all items whose value is larger than their cost. Therefore a natural question that arises is whether or when the additional dependence of the runtime on the capacity is really necessary.

In this work, we make progress towards answering this question by exploring when this dependence can be improved or completely eliminated.

Knapsack. We first revisit the Knapsack problem and explore under which conditions we can obtain faster algorithms than the standard dynamic programming algorithm.

Despite being a fundamental problem in Computer Science, no better algorithms are known in the general case for over 60 years and it is known to be notoriously hard to improve upon. The best known algorithm for the special case where both the weights and the values of the items are small and bounded by M and V respectively, is a result by Pisinger [17] who presents an algorithm with runtime $O(nMV)$.

Even for the subset sum problem, which is a more restricted special case of knapsack where the value of every item is equal to its weight, the best known algorithm beyond the textbook algorithm by Bellman [6] was also an algorithm by Pisinger [17] which runs in time $O(nM)$ until significant recent progress by Bringmann [7] and Koiliaris and Xu [14] was able to bring its the complexity down to $\widetilde{O}(n+T)$.

However, recent evidence shows that devising a more efficient algorithm for the general Knapsack problem is much harder. Specifically, [10, 15] reduce the $(\max,+)$-convolution problem to Knapsack, proving that any truly subquadratic algorithm for Knapsack (i.e. $O((n+T)^{2-\epsilon})$) would imply a truly subquadratic algorithm for the $(\max,+)$-convolution problem. The problem of $(\max,+)$-convolution is a fundamental primitive inherently embedded into a lot of problems and has been used as evidence for hardness for various problems in the last few years (e.g. [10, 15, 3]). However, an important open question remains here: *Can we get faster algorithms that circumvent this conditional lower bound?*

We answer this question affirmatively by providing an algorithm running in time $O(TD)$, where D is the number of *distinct* weights. Our algorithm is deterministic and computes the optimal Knapsack value for *all* capacities t from 1 to T. Since $D \leq n$, its runtime either matches (for $D = \Theta(n)$) or yields an improvement (for $D = o(n)$) over Bellman's algorithm [6], for all parameter regimes. It also directly implies runtimes of $O(TM)$[1], $O(nM^2)$[2], and $O(nV^2)$, and therefore also yields an improvement over the $O(nMV)$ algorithm of Pisinger [17].

---

[1] Concurrent and independent work by Bateni, Hajiaghayi, Seddighin, and Stein [4] also obtains an algorithm running in time $\widetilde{O}(TM)$, as well as an algorithm running in time $\widetilde{O}(TV)$. In comparison to ours, their $\widetilde{O}(TM)$ algorithm is randomized and computes the answer only for a single capacity T.

[2] Eisenbrand and Weismantel [11] develop fast algorithms for Integer Programming. Concurrently and independently, they also obtain an algorithm for Knapsack that runs in time $O(nM^2)$. They provide a structural property of Knapsack using the Steinitz Lemma that enables us to remove logarithmic factors in T from our results for Unbounded Knapsack (Theorem 13), as they reduce to the case $T = \Theta(M^2)$. Combined with Theorem 8, this also implies an $O(M^3)$ algorithm for Knapsack.

Table 1 Summary of our deterministic pseudopolynomial time results on the Knapsack problem with the corresponding known conditional lower bounds based on $(\min, +)$-convolution.

Setting	Our Results	Conditional Lower bounds
Knapsack		
No bounds on weights or values	$O(TD)$ **[Theorem 8]**	$\Omega((TD)^{1-o(1)})$ [10, 15]
Weights bounded by M	$O(TM)$ **[Corollary 11]**	$\Omega((TM)^{1-o(1)})$ [10, 15]
Values bounded by V	$O(nV^2)$ **[Corollary 12]**	–
Unbounded Knapsack		
Weights bounded by M	$O(M^2)$ **[Corollary 14]**	$\Omega(M^{2-o(1)})$ [10, 15]
Values bounded by V	$O(V^2)$ **[Corollary 15]**	–

Our algorithm can be summarized as follows: First, it partitions the items into D sets according to their weights and solves the knapsack problem in each set of the partition for every possible capacity up to T. This can be done efficiently in $O(T)$ time as all items in each set have the same weight and thus knapsack can be greedily solved in those instances. Having a sequence of solutions for every capacity level for each set of items allows us to obtain the overall solution by performing $(\max, +)$-convolutions among them. Even though it is not known whether computing general $(\max, +)$-convolutions in truly sub-quadratic time is possible, we exploit the inherent concavity of the specific family of sequences produced by our algorithm to perform this in linear time. We present our results in Section 3.1.

In addition to the general Knapsack problem studied above, we also consider the *Unbounded Knapsack* problem where there are infinite copies of every item. In Section 3.2, we present novel algorithms for Unbounded Knapsack with running times $O(M^2)$[3] and $O(V^2)$, where M is the maximum weight and V is the maximum value of any item. Our algorithm again utilizes $(\max, +)$-convolutions of short sequences to compute the answer and interestingly is only pseudo-polynomial with respect to the maximum weight M or the maximum value V and not the capacity T.

Our results are summarized in Table 1.

It follows from the results of [10, 15] that, under the $(\min, +)$-convolution hardness assumption, it is not possible to obtain faster runtimes for Knapsack under most of the parameterizations that we consider. This is because, even though the lower bound claimed in these results is $\Omega((n+T)^{2-o(1)})$, the hardness construction uses a Knapsack instance where T, M, and D are $\Theta(n)$.

Capacitated Dynamic Programming. In addition to our results on the knapsack problem, we move on to study capacitated problems in a more general setting. Specifically, we consider the problem of computing a path of maximum reward between a pair of nodes in a weighted Directed Acyclic Graph, where the capacity constraint corresponds to an upper bound on the length of the path.

This model has successfully been used for uncapacitated problems [19, 15], as well as capacitated problems with weighted adjacency matrices that satisfy a specific condition, namely the *Monge property* [2, 18, 5]. In [5], it is shown that under this condition, the

[3] Jansen and Rohwedder [13] extend the results of [11] for Integer Programming and also concurrently and independently obtain an algorithm for Unbounded Knapsack running in time $O(M^2)$.

maximum weight of a path of length k is *concave* in k. Whenever such a concavity property is true, one can always solve the capacitated problem by replacing the capacity constraint with an "equivalent" cost per edge. This cost can be identified through a binary search procedure that checks whether the solution for the uncapacitated problem with this cost corresponds to a path of length k.

Our second main result, Theorem 18, gives a complete characterization of such a concavity property for transitive node-weighted graphs. We show that this holds if and only if the following graph theoretic condition is satisfied:
For every path $a \to b \to c$ of length 2, and every node v, at least one of the edges (a, v) and (v, c) exists.

To illustrate the power of our characterization, we show that a linear algorithm can be easily obtained for the problem of k-sparse Δ-separated subsequences [12] recovering recent results of [8, 16].

To complement our positive result which allows us to obtain fast algorithms for finding maximum weight paths of length k, we provide strong evidence of hardness for transitive node-weighted graphs which do not satisfy the conditions of our characterization. We base our hardness results on computational assumptions for the $(\max, +)$-convolution problem we described above.

Beyond node-weighted graphs, when there are weights on the edges, no non-trivial algorithms are known other than for Monge graphs. Even in that case, we show that linear time solutions exist only if one is interested in finding the max-weight path of length k between only one pair of nodes. If one is interested in computing the solution in Monge graphs for a single source but all possible destinations, we provide an algorithm that computes this in near-linear time in the number of edges in the graph.

2 Preliminaries

We first describe the problems of Knapsack and Unbounded Knapsack:

▶ **Definition 1** (Knapsack). *Given N items with weights $w_1, \ldots, w_N \in [M]$ and values $v_1, \ldots, v_N \in [V]$, and a parameter T, our goal is to find a set of items $S \subseteq [N]$ of total weight at most T (i.e. $\sum_{i \in S} w_i \leq T$) that maximizes the total value $\sum_{i \in S} v_i$. We will denote the number of distinct weights by D.*

▶ **Definition 2** (Unbounded Knapsack). *Given N items with weights $w_1, \ldots, w_N \in [M]$ and values $v_1, \ldots, v_N \in [V]$, and a parameter T, our goal is to find a multiset of items $S \subseteq [N]$ of total weight at most T (i.e. $\sum_{i \in S} w_i \leq T$) that maximizes the total value $\sum_{i \in S} v_i$. We will denote the number of distinct weights by D.*

Throughout the paper we make use of the following operation between two sequences called $(\max, +)$-convolution.

▶ **Definition 3** ($(\max, +)$-convolution). *Given two sequences $a_0, \ldots, a_n$ and $b_0, \ldots, b_m$, the $(\max, +)$-convolution $a \oplus b$ between a and b is a sequence $c_0, \ldots, c_{n+m}$ such that for any i*

$$c_i = \max_{0 \leq j \leq i} \{a_j + b_{i-j}\}$$

This operation is commutative, so it is also true that

$$c_i = \max_{0 \leq j \leq i} \{a_{i-j} + b_j\}$$

Our algorithms rely on uncovering and exploiting discrete concavity that is inherent in the problems we consider.

▶ **Definition 4** (Concave, k-step concave). *A sequence $b_0, \dots, b_n$ is* concave *if for all $i \in [n-1]$ we have $b_i - b_{i-1} \geq b_{i+1} - b_i$. A sequence is called k-*step concave *if its subsequence $b_0, b_k, b_{2k}, \dots$ is concave and for all i such that $i \mod k \neq 0$, we have that $b_i = b_{i-1}$.*

For the problems defined on graphs with edge weights, we typically assume that their weighted adjacency matrix is given by a Monge matrix.

▶ **Definition 5** (Monge matrices). *A matrix $A \in \mathbb{R}^{n \times m}$ is called Monge if for any $i \in [n-1]$ and $j \in [m-1]$*

$$A_{i,j} + A_{i+1,j+1} \geq A_{i+1,j} + A_{i,j+1}$$

▶ **Definition 6** (Monge weights). *We will say that a Directed Acyclic Graph has* Monge weights *if its weighted adjacency matrix is a Monge matrix.*

In addition to our positive results, we present evidence of computational hardness assuming for $(\max, +)$-convolution problem.

▶ **Definition 7** ($(\max, +)$-convolution hardness). *The $(\max, +)$-convolution hardness hypothesis states that any algorithm that computes the $(\max, +)$-convolution of two sequences of size n requires time $\Omega(n^{2-o(1)})$.*

A result of [3] shows that the $(\max, +)$-convolution problem is equivalent to the following problem: Given an integer n and three sequences $a_0, \dots, a_n$, $b_0, \dots, b_n$, and $c_0, \dots, c_n$, compute $\max_{i+j+k=n} \{a_i + b_j + c_k\}$. In our conditional lower bounds, we will be using this equivalent form of the conjecture.

3 Knapsack

In this section we present two novel pseudo-polynomial deterministic algorithms, one for Knapsack and one for Unbounded Knapsack. The running times of these algorithms significantly improve upon the best known running times in the small-weight regime. In essence, the main improvements stem from a more principled understanding and systematic use of $(\max, +)$-convolutions. Thus, we show that devising faster algorithms for special cases of $(\max, +)$-convolution lies in the core of improving algorithms for the Knapsack problem. In Theorem 8, we present an algorithm for Knapsack that runs in time $O(TD)$, where T is the size of the knapsack and D is the number of distinct item weights. Then, in Theorem 13, we present algorithms for Unbounded Knapsack with runtimes $O(M^2)$ and $O(V^2)$, where M is the maximum weight and V the maximum value of some item.

3.1 Knapsack

Given N items with weights $w_1, \dots, w_N \in [M]$ and values $v_1, \dots, v_N \in [V]$, and a parameter T, our goal is to find a set of items $S \subseteq [N]$ of total weight at most T (i.e. $\sum_{i \in S} w_i \leq T$) that maximizes the total value $\sum_{i \in S} v_i$. We will denote the number of distinct weights by D.

The following is the main theorem of this section.

▶ **Theorem 8.** *Algorithm 1 solves* Knapsack *in time $O(TD)$.*

Algorithm 1 Knapsack.

Given items with weights in $\{w_1^\#, \dots, w_D^\#\}$
Partition items into sets $S_1, \dots, S_D$, so that $S_i = \{j \mid w_j = w_i^\#\}$
for $i \in [D]$ and $t \in [T]$ **do**
    $b_t^{(i)} \leftarrow$ solution for S_i with knapsack size t
$s \leftarrow$ empty sequence
for $i \in [D]$ **do**
    $s \leftarrow s \oplus b^{(i)}$ using Lemma 10
    Truncate s after the T-th entry
Output s_T

Overview. The main ingredient of this result is an algorithm for fast $(\max, +)$-convolution in the case that one of the two sequences is *k-step concave*. Using the SMAWK algorithm [1] it is not hard to see how to do this in linear time for $k = 1$. For the general case, we show that computing the $(\max, +)$-convolution of the two sequences can be decomposed into $\frac{n}{k}$ subproblems of computing the $(\max, +)$-convolution between two size-k subsequences of the two sequences. Furthermore, the subsequence that came from the k-step concave sequence is concave and so each subproblem can be solved in time $O(k)$ and the total time spent in the subproblems will be $O(\frac{n}{k}k) = O(n)$.

▶ **Lemma 9.** *Given an arbitrary sequence $a_0, \dots, a_m$ and a concave sequence $b_0, \dots, b_n$ we can compute the $(\max, +)$ convolution between a and b in time $O(m + n)$.*

Proof. Consider a (zero-indexed) $(n + 1) \times (m + 1)$ matrix A with $A_{ij} = a_j + b_{i-j}$ for $(i, j) \in \{0, \dots, n\} \times \{0, \dots, m\}$, where we suppose that elements of the sequences with out-of-bounds indices have value $-\infty$. Note now that $(a \oplus b)_i$ is by definition equal to the maximum value of row i of A. Therefore computing $a \oplus b$ corresponds to finding the row maxima of A. Now note that for any $(i, j) \in \{0, 1, \dots, n-1\} \times \{0, 1, \dots, m-1\}$, we have

$$\begin{aligned} A_{i,j} - A_{i,j+1} &= a_j + b_{i-j} - a_{j+1} - b_{i-j-1} \\ &\overset{concavity}{\geq} a_j + b_{i+1-j} - a_{j+1} - b_{i-j} \\ &= A_{i+1,j} - A_{i+1,j+1} \end{aligned}$$

therefore A is Monge. The main result of [1] is that given an $(n+1) \times (m+1)$ Monge matrix A, one can compute all its row maxima in time $O(m + n)$, which implies the Lemma. ◀

▶ **Lemma 10.** *Given an arbitrary sequence $a_0, \dots, a_m$ and a k-step concave sequence $b_0, \dots, b_n$ we can compute the $(\max, +)$ convolution of a and b in time $O(m + n)$.*

Proof. We use the fact that we can compute the $(\max, +)$ convolutions of an arbitrary sequence with a concave sequence in linear time (Lemma 9). Since b is a k-step concave sequence, taking every k-th term of it one gets a concave sequence of size $O(n/k)$. Then, we do the same for a, taking k subsequences of size m/k each. Therefore we can compute the convolution between the concave sequence and all of these subsequences of a in linear time. The results of these convolutions can be used to compute the final sequence. We now describe this in detail.

For ease of notation, we will again assume that our sequences take value $-\infty$ in out-of-bounds indices. Let $x^{(i)} := (a_i, a_{k+i}, a_{2k+i}, \dots)$ denote the subsequence of a with indices whose remainder is i when divided by k, and $y := (b_0, b_k, b_{2k}, \dots)$. Furthermore, define

$$f_i = \max_{q=0}^{\infty} \{b_{qk} + a_{i-qk}\}$$

Now, for any j we have

$$\begin{aligned}\max_{i=j-k+1}^{j} f_i &= \max_{i=j-k+1}^{j} \max_{q=0}^{\infty}\{b_{qk} + a_{i-qk}\}\\ &= \max_{i=j-k+1}^{j} \max_{q=0}^{\infty}\{b_{qk+j-i} + a_{i-qk}\}\\ &= \max_{z=0}^{\infty}\{b_z + a_{j-z}\}\end{aligned}$$

where the second equality follows from the fact that $b_{qk+t} = b_{qk}$ for any $t \in [k-1]$ and the third from the fact that $z = qk + j - i$ can take any value in $[0, \infty)$.

This is the j-th element of the $(\max, +)$-convolution between a and b, so the elements of this convolution are exactly the maxima of size-k segments of f.

In order to compute f, note that for some p, the convolution between $x^{(p)}$ and y gives us all values of f of the form f_{qk+p}, for any q. This is because from the definition of f,

$$\begin{aligned}f_{qk+p} &= \max_{z=0}^{\infty}\{b_{zk} + a_{qk+p-zk}\}\\ &= \max_{z=0}^{\infty}\{y_z + x^{(p)}_{q-z}\}\\ &= (x^{(p)} \oplus y)_q\end{aligned}$$

Furthermore, y is a concave sequence and by Lemma 9 we can compute such a convolution in time $O((m+n)/k)$. Doing this for all $p \in \{0, \dots, k-1\}$, we can compute all values of f in time $O(m+n)$.

Now, in order to compute the target sequence, we have to compute the maxima of all size-k segments of f. We can do that using a simple sliding window technique. Specifically, suppose that for some segment $[i, i+k-1]$ we have an increasing subsequence of $f_{[i,\dots,i+k-1]}$, containing all the potentially useful elements. The first element of this subsequence is the maximum value of f in the segment $[i, i+k-1]$. Now, to move to $[i+1, i+k]$, we remove f_i if it is in the subsequence, and then we compare f_{i+k} with the last element in the subsequence. Note that if that last element has value $\leq f_{i+k}$, it will never be the maximum element in any segment. Therefore we can remove it and repeat until the last element has value greater than f_{i+k}, at which point we just insert f_{i+k} in the end of the subsequence. Note that by construction, this subsequence will always be decreasing, and the first element will be the maximum of the respective segment. The total runtime is linear if implemented with a standard queue. ◀

Now that we have these tools we can use them to prove the main result of this section:

Proof of Theorem 8. Consider any knapsack instance where D is the number of distinct item weights $w^{\#}_1, \dots, w^{\#}_D$. Now for each $i \in [D]$ let c_i be the number of items with weight $w^{\#}_i$ and $v^{(i)}_1 \geq v^{(i)}_2 \cdots \geq v^{(i)}_{c_i}$ their respective values.

If we only consider items with weights $w^{\#}_i$, the knapsack problem is easy to solve, since we will just greedily pick the most valuable items until the knapsack fills up. More specifically, if b_s is the maximum value obtainable with a knapsack of size s, we have that $b_0 = 0, b_{w_i} = v^{(i)}_1, b_{2w_i} = v^{(i)}_1 + v^{(i)}_2, \dots$, and also $b_j = b_{j-1}$ for any j not divisible by $w^{\#}_i$. Therefore b is a $w^{\#}_i$-step concave sequence.

In order to compute the full solution, we have to compute the $(\max, +)$ convolution of D such sequences. Since by Lemma 10 each convolution takes linear time and we only care about the first T values of the resulting sequence (i.e. we will only ever keep the first T values of the result of a convolution), the total runtime is $O(TD)$, where T is the size of the knapsack. ◀

▶ **Corollary 11.** *Knapsack can be solved in $O(TM)$ time.*

▶ **Corollary 12.** *Knapsack can be solved in time $O(nM^2)$ or $O(nV^2)$.*

Proof. The first bound directly follows by Corollary 11 and the fact that $T \leq nM$. For the second bound, note that by swapping the role of the weights and the values in Algorithm 1, replacing all $(\max, +)$-convolutions by $(\min, +)$-convolutions, and setting the knapsack capacity to nV as opposed to T, this algorithm runs in time $O(nV^2)$ and outputs for every possible value, the minimum weight of items that can achieve this value. The answer can then be recovered by finding the minimum value that gives a corresponding weight of at most T. ◀

3.2 Unbounded Knapsack

Given N items with weights $w_1, \ldots, w_N$ and values $v_1, \ldots, v_N$, and a parameter T, our goal is to find a multiset of items $S \subseteq [N]$ of total weight at most T (i.e. $\sum_{i \in S} w_i \leq T$) that maximizes the total value $\sum_{i \in S} v_i$. We will denote the largest item weight by M.

Note that this problem is identical to Knapsack except for the fact that there is no limit on the number of times each item can be picked. This means that we can assume that there are no two items with the same weight, since we would only ever pick the most valuable of the two.

Algorithm 2 Unbounded Knapsack.

Let $v^{(0)}$ be a sequence where $v^{(0)}_x$ is the value of the element with weight x or $-\infty$ if no such element exists
for $z = 1, \ldots, \lceil \log M \rceil$ **do**
  $v^{(z)} \leftarrow v^{(z-1)} \oplus v^{(z-1)}$
$a_{[0,M]} \leftarrow v^{(\lceil \log M \rceil)}$
for $i = \lceil \log \frac{T}{M} \rceil, \ldots, 1$ **do**
  $a_{\left[\frac{T}{2^i} - M, \frac{T}{2^i} + M\right]} \leftarrow a_{\left[\frac{T}{2^i} - M, \frac{T}{2^i}\right]} \oplus a_{[0,M]}$
  $a_{\left[\frac{T}{2^{i-1}} - M, \frac{T}{2^{i-1}}\right]} \leftarrow a_{\left[\frac{T}{2^i} - M, \frac{T}{2^i} + M\right]} \oplus a_{\left[\frac{T}{2^i} - M, \frac{T}{2^i} + M\right]}$
Output a_T

The following is the main theorem of this section:

▶ **Theorem 13.** *Algorithm 2 solves* Unbounded knapsack *in time $O(M^2 \log T)$.*

Overview. As in the algorithm for Knapsack our algorithm utilizes $(\max, +)$-convolutions, but with a different strategy. We aren't using any concavity arguments here, but in fact we will use the straightforward quadratic-time algorithm for computing $(\max, +)$-convolutions. The main argument here is that if all the weights are relatively small, one can always partition any solution in two, so that the weights of the two parts are relatively close to each other. Therefore, for any knapsack size we only have to compute the optimal values for a few knapsack sizes around its half, and not for all possible knapsack sizes.

We can now proceed to the proof of this result.

Proof of Theorem 13. Consider any valid solution to the unbounded knapsack instance. Since every item has weight at most M, we can partition the items of that solution into two multisets with respective weights W_1 and W_2, so that $|W_1 - W_2| < M$ (one can obtain

this by repeatedly moving any item from the larger part to the smaller one). This implies the following, which is the main fact used in our algorithm: If a_s is the maximum value obtainable with a knapsack of size s, then we have that

$$a_s = \left[\left(a_{s/2-M/2}, \dots, a_{s/2+M/2}\right)^{\oplus 2}\right]_s$$

where $^{\oplus 2}$ denotes $(\max,+)$-convolution squaring, i.e. applying $(\max,+)$-convolution between a sequence and itself.

First, we compute the values $a_1, \dots, a_M$ in $O(M^2 \log M)$ time as follows: We start with the sequence $v^{(0)}$, where $v_x^{(0)}$ is the value of the element with weight x, or $-\infty$ if such an item does not exist. Now define $v^{(i+1)} = (v^{(i)} \oplus v^{(i)})_{[0,M]}$. This convolution can be applied in time $O(M^2)$ for any i, since we are always only keeping the first M entries. By induction, it is immediate that $v^{(i)}$ contains the optimal values achievable for all knapsack sizes in $[M]$ using at most 2^i items. Therefore $a_{0,\dots,M} \equiv v_{0,\dots,M}^{(\lceil \log M \rceil)}$, which as we argued can be computed in time $O(M^2 \log M)$.

Now, suppose that we have computed the values $a_{\frac{T}{2^i}-M}, \dots, a_{\frac{T}{2^i}}$ for some i. By convolving this sequence with $a_0, \dots, a_M$ we can compute in time $O(M^2)$ the values $a_{\frac{T}{2^i}+1}, \dots, a_{\frac{T}{2^i}+M}$. Now, convolving the sequence $a_{\frac{T}{2^i}-M}, \dots, a_{\frac{T}{2^i}+M}$ with itself gives us $a_{\frac{T}{2^{i-1}}-M}, \dots, a_{\frac{T}{2^{i-1}}}$ (here we used the fact that to compute a_{2j} we only need the values $a_{j-M/2}, \dots, a_{j+M/2}$). Doing this for $i = \lceil \log T \rceil, \dots, 2, 1$, we are able to compute the values $a_{T-M}, \dots, a_T$ in total time $O(M^2 \log T)$. The answer to the problem, i.e. the maximum value achievable, is $\max\{a_{T-M}, \dots, a_T\}$. ◀

Recent work of [11] shows, using the *Steinitz lemma*, that an optimal Knapsack solution for a capacity in $[T-M, T]$ can be turned into an optimal solution for capacity T by inserting or removing at most M elements, where M is a bound on weight of the items. In the case of Unbounded Knapsack, a solution that only uses the best item until it exceeds capacity $T - M^2$ can always be extended into an optimal solution with capacity T. Therefore the capacity can be assumed to be $O(M^2)$. Combining this with the $\frac{M^2}{2^{\Omega\left(\sqrt{\log M}\right)}}$-time randomized algorithm of [20] (or the deterministic algorithm of [9]) for $(\max,+)$-convolution implies an algorithm that runs in time $\frac{M^2}{2^{\Omega\left(\sqrt{\log M}\right)}} O(\log M) = \frac{M^2}{2^{\Omega\left(\sqrt{\log M}\right)}}$.

▶ **Corollary 14.** *Unbounded Knapsack can be solved in time $O(M^2)$.*

A similar argument can be used to get a more efficient algorithm when we have a bound on the values of the items. In particular, using the item j with the highest value-to-weight ratio v_j/w_j, $k = \lfloor \frac{T}{w_j} \rfloor + 1$ times, until we exceed the capacity we get both a lower bound of $(k-1)v_j$ and a upper bound of kv_j on the value of the optimal solution. In addition, again by the Steinitz Lemma, there exists an optimal solution that uses item j at least $k - V$ times. This allows us to start from value $(k-V)v_j$ and compute the minimum weight required to achieve values in $[(k-1)v_j, kv_j]$. This gives an algorithm that runs in $O(V^2 \log V)$ using the naive algorithm for $(\min,+)$-convolutions, and $O\frac{V^2}{2^{\Omega\left(\sqrt{\log V}\right)}}$, again using the improved algorithms in [20] or [9].

▶ **Corollary 15.** *Unbounded Knapsack can be solved in time $O(V^2)$.*

4 k-link path in Node-weighted graphs

We now move on to study more general capacitated dynamic programming settings, described by computing the maximum reward k-link path in a directed acyclic graph. This setting can capture a lot of natural capacitated problems, either directly or indirectly, such as the Knapsack problem, k-sparse Δ-separated sequences, max-weight increasing subsequence of length k, and so on. Therefore a better understanding of these special cases might lead to improved algorithms for other capacitated problems.

More specifically, we study the problem of finding maximum-reward paths in node-weighted transitive DAGs. In Lemma 16, we show that in general this problem is hard, by reducing $(\max,+)$-convolution to it. We then proceed to show our second main result, which provides a family of graphs for which the problem can be efficiently solved.

▶ **Lemma 16** ($(\max,+)$-hardness of Node-weighted graphs). *Given a transitive DAG, a pair of vertices s and t, and an integer k, the problem of computing a maximum reward path from s to t with at most k edges is $(\max,+)$-convolution hard, i.e. requires $\Omega((mk)^{1-o(1)})$ time assuming $(\max,+)$-convolution hardness.*

As we saw in the introduction, one can solve the problem if the optimal value as a function of the capacity is concave. This is made formal in the following lemma:

▶ **Lemma 17** (Concave functions). *Let G be a node-weighted transitive DAG with n vertices and m edges, whose weights' absolute values are bounded by M, and let $f(x)$ be the maximum reward obtainable in a path of length x. If f is a concave function, then one can reduce the capacitated problem (i.e. computing $f(k)$ for some k) to solving $O(\log(nM))$ uncapacitated problems with some fixed extra cost per item. Since each one of these problems can be solved in $O(m)$ time, the total runtime is $O(m\log(nM))$.*

In Lemma 18 we give a complete graph-theoretic characterization of the graphs that have this concavity property and therefore can be solved efficiently.

▶ **Lemma 18** (Concavity characterization). *The problem of finding a maximum reward path with at most k edges in a transitive DAG is concave for all choices of node weights if and only if for any path $u_1 \to u_2 \to u_3$ and any node v either $u_1 \to v$ or $v \to u_3$ (Property $\mathcal{P}$).*

Proof. Let $f(k)$ be the maximum reward obtainable with a path of exactly k edges.
$\Rightarrow$: Let G be a DAG for which property $\mathcal{P}$ doesn't hold. Let $u_1 \to u_2 \to u_3$ be the path of length 2 and v be the vertex that has no edge to or from any of u_1, u_2, u_3. We set the node values as $val(u_1) = val(u_2) = val(u_3) = 1$, $val(v) = 1+\epsilon$, and $-\infty$ for all other vertices. Then, $f(1) = 1+\epsilon$, $f(3) = 3$, but $f(2) = 2 < \frac{f(1)+f(3)}{2}$, therefore f is not concave.
$\Leftarrow$: Suppose that property $\mathcal{P}$ is true. Now, let $P = (s, p_1, p_2, \ldots, p_{k-1}, t)$ be a path of length k such that $val(P) = f(k)$ and $Q = (s, q_1, q_2, \ldots, q_{k+1}, t)$ be a path of length $k+2$ such that $val(Q) = f(k+2)$, where P and Q can potentially have common vertices other than s and t. Since property $\mathcal{P}$ is true, we know that for any $i \in [k-1]$, there is either an edge from one of q_i, q_{i+1}, q_{i+2} to p_i, or from p_i to one of q_i, q_{i+1}, q_{i+2}. By transitivity, this implies that either $q_i \to p_i$, or $p_i \to q_{i+2}$. We distinguish three cases. In all three cases we will be able to find paths P' and Q' with $k+1$ edges each, that contain all vertices of the form p_i and q_i.

Case 1: $q_1 \to p_1$
We pick $P' = (s, q_1, p_1, \ldots, p_{k-1}, t)$ and $Q' = (s, q_2, \ldots, q_{k+1}, t)$.
Case 2: $\forall i : p_i \to q_{i+2}$
We pick $P' = (s, p_1, \ldots, p_{k-1}, q_{k+1}, t)$ and $Q' = (s, q_1, \ldots, q_k, t)$
Case 3: $\exists i : p_i \to q_{i+2},\ q_{i+1} \to p_{i+1}$
We pick $P' = (s, p_1, \ldots, p_i, q_{i+2}, \ldots, q_{k+1}, t)$ and $Q' = (s, q_1, \ldots, q_{i+1}, p_{i+1}, \ldots, p_{k-1}, t)$.

Therefore we established that in any case there exist such paths P' and Q'. Now note that

$$\max\{val(P'), val(Q')\} \geq \frac{1}{2}(val(P') + val(Q')) = \frac{1}{2}(val(P) + val(Q))$$

and therefore f is a concave function. ◀

As mentioned before, even very simple special cases of the model capture a lot of important problems. In the following lemma, we show that we can solve the k-sparse Δ-separated subsequence problem [12] in near-linear time using the main result of this section, thus recovering recent results of [8, 16].

▶ **Lemma 19** (Max-weight k-sparse Δ-separated subsequence). *Given a sequence $a_1, \dots, a_n$, find indices $i_1, i_2, \dots, i_k$ such that for all $j \in [k-1]$, $i_{j+1} \geq i_j + \Delta$ and the sum $\sum_{j\in[k]} a_{i_j}$ is maximized. This problem can be solved in $O(n \log(n \max_i |a_i|))$ time.*

Proof. Let's define a simple node-weighted DAG for this problem. We define a sequence of vertices $u_1, \dots, u_n$ each one of which corresponds to picking an element from the sequence. Then, we add an edge $u_i \to u_j$ iff $j - i \geq \Delta$. Furthermore, for all i, $val(u_i) = a_i$. It remains to prove that it satisfies the property of Lemma 18. Consider any length-2 path $u_i \to u_j \to u_k$. We know that both $k - j$ and $j - i$ are at least Δ. Now, for any u_p we have that

$$\max\{|u_p - u_k|, |u_p - u_i|\} \geq \frac{1}{2}(|u_p - u_k| + |u_p - u_i|) \geq \frac{1}{2}(|u_k - u_i|) \geq \frac{1}{2}2\Delta = \Delta$$

so there is an edge between u_p and either u_i or u_k. Therefore by Lemma 17 the problem can be solved in time $O(m \log(n \max_i |a_i|)) = O(n^2 \log(n \max_i |a_i|))$.

The quadratic runtime stems from the fact that the DAG we constructed is dense. In fact, we can do better by defining some auxiliary vertices $v_1, \dots, v_n$. The values of these extra vertices will be set to $-\infty$ to ensure that they aren't used in any solution and thus don't break the concavity. Instead of edges between vertices u_i, we only add the following edges

- $u_i \to v_i$ for all i
- $v_i \to u_{i+\Delta}$ for all $i + \Delta \leq n$
- $v_i \to v_{i+1}$ for all $i + 1 \leq n$

Now, the number of edges is $O(n)$ and so the runtime becomes $O(n \log(n \max_i |a_i|))$. ◀

As another example of a problem that can be modeled as a capacitated maximum-reward path problem in a DAG, we consider the Max-Weight Increasing Subsequence of length k problem. In contrast to its uncapacitated counterpart, which is solvable in linear time, the capacitated version requires quadratic time, assuming $(\max, +)$-convolution hardness, as witnessed in the following lemma.

▶ **Lemma 20** (Max-Weight Increasing Subsequence of length k). *Given a sequence $a_1, \dots, a_n$ with respective weights $w_1, \dots, w_n$, find indices $i_1 < i_2 < \dots < i_k$ such that for all $j \in [k-1]$, $a_{i_j} \leq a_{i_{j+1}}$ and the sum $\sum_{j\in[k]} w_{i_j}$ is maximized. This problem is $(\max, +)$-convolution hard, i.e. requires $\Omega((nk)^{1-o(1)})$ time assuming $(\max, +)$-convolution hardness.*

Proof. Consider the construction used in Lemma 16. We define an instance of the Max-Weight Increasing Subsequence of length k problem which contains an element for each node of the DAG. Specifically, let's define our sequence to be

$$x_0, x'_0, x_1, x'_1, \dots, x_k, x'_k, y_0, y'_0, \dots, y_k, y'_k, z_0, z'_0, \dots, z_k, z'_k$$

$$\text{with} \quad \begin{aligned} x_i &= i & x'_i &= 2k+1-i \\ y_i &= 2k+2+i & y'_i &= 4k+3-i \\ z_i &= 4k+4+i & z'_i &= 6k+5-i \end{aligned}$$

where the weight of each element is equal to the weight of the corresponding node in the DAG (i.e. $x_\star \leftrightarrow a_\star$, $x'_\star \leftrightarrow a'_\star$, $y_\star \leftrightarrow b_\star$, $y'_\star \leftrightarrow b'_\star$, $z_\star \leftrightarrow c_\star$, $z'_\star \leftrightarrow c'_\star$)

By definition of the sequence, the fact that we are looking for increasing subsequences implies that there is a $1-1$ correspondence between length-k increasing subsequences and $(k-1)$-hop paths of the original DAG. Therefore any $O((nk)^{1-\epsilon})$ algorithm for the Max-Weight Increasing Subsequence of length k problem implies a truly subquadratic algorithm for the $(\max,+)$-convolution problem. ◀

5 k-link path in graphs with Monge Weights

In this section we study the problem of computing maximum-reward paths with at most k edges in a DAG with edge weights satisfying the Monge property. Using the elegant algorithm of [5], one can compute a single such path in $\widetilde{O}(n)$ time.

▶ **Lemma 21** (From [5]). *Given a DAG with Monge weights, with n vertices, a pair of vertices s and t, and a positive integer k, we can compute a maximum reward path from s to t that uses at most k edges, in time $\widetilde{O}(n)$.*

Given the adjacency matrix A of the DAG, one can see this equivalently as computing one element of the matrix power A^k in the tropical semiring (i.e. we replace $(+,\cdot)$ with $(\max,+)$). Therefore, an important question is whether a whole row or column of A^k can be computed efficiently rather. This corresponds to finding maximum reward paths with k edges from some vertex s to *all* other vertices, or finding maximum reward paths with k edges from some vertex s to some vertex t for all k. In Lemma 22 we show that one needs $\Omega(n^{3/2})$ time to compute a column of A^k in general.

▶ **Lemma 22.** *Given a DAG with Monge weights, with n vertices, computing the maximum weight path of length k from a given s to all other nodes t requires $\Omega(n^{1.5})$ time.*

On the positive side, by further exploiting the Monge property, in Lemma 23 we present an algorithm that can compute any row or column of A^k in $\widetilde{O}(nnz(A)) = \widetilde{O}(m)$ time.

▶ **Lemma 23.** *Let G be a DAG of n vertices and m edges equipped with Monge weights that are integers of absolute value at most M. Given a vertex s, and a positive integer k, we can compute a maximum reward path from s to t that uses at most k edges, for all t, in time $O(m \log n \log(nM))$. Furthermore, if we are given a pair of vertices s and t, we can compute as maximum reward path from s to t that uses at most k edges, for all $k \in [n]$, in time $O(m \log n \log(nM))$.*

Abstract

A *tree cover* of a metric space (X, d) is a collection of trees, so that every pair $x, y \in X$ has a low distortion path in one of the trees. If it has the stronger property that every point $x \in X$ has a single tree with low distortion paths to all other points, we call this a *Ramsey* tree cover. Tree covers and Ramsey tree covers have been studied by [15, 31, 19, 30, 38], and have found several important algorithmic applications, e.g. routing and distance oracles. The union of trees in a tree cover also serves as a special type of spanner, that can be decomposed into a few trees with low distortion paths contained in a single tree; Such spanners for Euclidean pointsets were presented by [8].

In this paper we devise efficient algorithms to construct tree covers and Ramsey tree covers for general, planar and doubling metrics. We pay particular attention to the desirable case of distortion close to 1, and study what can be achieved when the number of trees is small. In particular, our work shows a large separation between what can be achieved by tree covers vs. Ramsey tree covers.

1 Introduction

The problem of approximating metric spaces by tree metrics has been a successful research thread in the past decades, and has found numerous algorithmic applications. This is mainly due to the fact that a tree has a very simple structure that can be exploited by the algorithm designer. While a single tree cannot provide a meaningful approximation, due to a lower bound of [44] (the metric of the n point cycle requires $\Omega(n)$ distortion for embedding into a tree), several other variants have been considered in the literature. The purpose of this paper is to study the natural question whether there exists a small collection of trees (*tree cover*) such that each pair is well preserved in at least one of them. A natural stronger demand may be that for each point all of its interpoint distances to the rest of the metric are well preserved in one of the trees (*Ramsey tree covers*).

Tree covers and Ramsey tree covers have been studied by [31, 15, 19, 30, 38], and are useful ingredients in important algorithmic applications such as routing and distance oracles.

Given a metric space (X, d_X) and an edge-weighted tree T with $X \subseteq V(T)$, for $x, y \in X$ let $d_T(x, y)$ denote the length of the path in T from x to y. We say T is *dominating* if $d_T(x, y) \geq d_X(x, y)$ for all $x, y \in X$. A dominating tree T has *distortion* α for a pair $x, y \in X$, if $d_T(x, y) \leq \alpha \cdot d_X(x, y)$. In what follows, all trees we consider are always dominating (this can be assumed w.l.o.g.).

▶ **Definition 1** (Tree cover)**.** *Given a metric space (X, d_X), for $\alpha \geq 1$ and an integer k, a* tree cover *with distortion α and size k, (α, k)-tree cover in short, is a collection of k dominating trees $T_1, \ldots, T_k$, such that for any $u \neq v$ in X there is a tree T_i with distortion at most α for the pair u, v.*

If for each $u \in X$ there is a tree T_i with distortion at most α for each pair u, v with $v \in X$, we call this a Ramsey (α, k)-tree cover*.*

If the metric is a shortest path metric of some graph G, and the trees are subgraphs, we call this a *spanning* tree cover.

The notion of tree covers is closely related to the well studied notion of spanners. In the context of metric spaces, a *spanner* with distortion α for the metric (X, d_X), is a graph H with $X \subseteq V(H)$, so that for all $x, y \in X$, $d_X(x, y) \leq d_H(x, y) \leq \alpha \cdot d_X(x, y)$. It is often desired that the spanner would be a sparse graph. Note that taking H as the union of the trees in a (Ramsey) tree cover forms a sparse spanner with a special structure; that can be decomposed into a few trees, and every pair (or every point) has the distortion guarantee in one of these trees. In the context of graphs H is usually required to be a subgraph of the original graph, and then the same holds for spanning tree covers. Spanners are basic graph constructions, have been intensively studied [42, 7, 22, 20, 8, 24, 16, 47, 41] and have numerous applications in various settings, see e.g. [9, 43, 10, 22, 46, 25].

A related well-studied concept is probabilistic embedding of a metric space into tree metrics. This notion was introduced by Bartal [11], and a sequence of works by Bartal, and Fakcharoenphol et al. [12, 27, 13] culminated in obtaining a tight $O(\log n)$ bound. The result of [11] already implies a probabilistic construction of tree covers of size k with distortion $O(n^{2/k} \log n)$, for general metrics spaces. In Theorem 2 we improve this by constructing deterministic Ramsey tree covers with almost optimal distortion (nearly matching the lower bound in Theorem 27).

In the rest of the section we review known results on tree covers and Ramsey tree covers, and present the new results of this paper.

1.1 Tree Covers

In the context of Euclidean spanners, Arya et al. [8] used the so called dumbbell trees to build low distortion spanners. Rephrased in our context, they obtained a tree cover for Euclidean pointsets. More specifically, for any finite set of points in d-dimensional Euclidean space, and any parameter $\epsilon > 0$, they devised a $(1 + \epsilon)$-distortion tree cover with $O((d/\epsilon)^d \log(d/\epsilon))$ trees. We note that their trees are using Steiner points (i.e., points in Euclidean space that are not part of the input set), and it is not clear that such points can be removed from the spanner while maintaining $(1 + \epsilon)$ distortion.

Chan et al. [19] presented tree covers for doubling metrics. The *doubling constant* of a metric (X, d_X) is the minimal λ, so that every ball of radius $2r$ can be covered by λ balls of radius r. The *doubling dimension* of (X, d_X) is defined as $\log \lambda$, and a family of

metrics is called *doubling* if every metric in it has doubling dimension $O(1)$. The result of [19] used hierarchical partitioning to construct a tree cover with distortion $O(\log^2 \lambda)$ and $O(\log \lambda \cdot \log\log \lambda)$ trees.

The notion of spanning tree covers was introduced by Gupta et al. in [31], who used these for MPLS routing. They devised spanning tree covers for planar graphs: an exact (i.e. distortion 1) tree cover with $O(\sqrt{n})$ trees (more generally $O(r(n)\log n)$ trees for graphs admitting a hierarchical $r(n)$ size separators), and a spanning tree cover with distortion 3 and only $O(\log n)$ trees. They also showed the former result for planar graphs is tight, i.e., at least $\Omega(\sqrt{n})$ trees are needed for an exact tree cover.

1.1.1 Our results

As a starting point for this study, we observe, that for general metrics, the number of trees of any tree covers with distortion α must be as large as $n^{1/\alpha}$. (This bound stems from the standard example of high girth graphs and extends a previous lower bound for spanning trees of [31]). Nearly optimal upper bounds are known even for Ramsey tree covers (see next subsection). The above lower bound also implies a lower bound of $\lambda^{1/\alpha}$ in any space with doubling constant λ.

One of our main results is a tree cover for doubling metrics. We develop a novel hierarchical clustering for such metrics, built in a bottom-up manner. We then use this new clustering to show that for any $0 < \epsilon < 1$, every metric with doubling constant λ admits a tree cover with distortion $1+\epsilon$ and only $(1/\epsilon)^{O(\log \lambda)}$ trees. Since d-dimensional Euclidean space has doubling dimension $\Theta(d)$, the number of trees in the cover is therefore $(1/\epsilon)^{O(d)}$. Hence, this can be viewed as both a generalization and improvement of the result of [8]. Moreover, we improve their result in another aspect, since unlike [8] we do not require the use of Steiner points. In particular, for any $\epsilon > 0$ our result provides a $(1+\epsilon)$-spanner with $n/\epsilon^{O(\log \lambda)}$ edges, that can be decomposed to a small number of trees, and where each pair has a $1+\epsilon$ stretch path in one of the trees. We note that the number of edges in this spanner is asymptotically optimal [45], and thus so is our result.

We then turn to obtaining a distortion-size tradeoff for tree covers of doubling spaces with arbitrary distortion α. We improve and extend the result of [19]; for any parameter α, we use a more sophisticated construction of hierarchical partitions, to build a tree cover with distortion $O(\alpha)$ and $O(\lambda^{1/\alpha} \cdot \log \lambda \cdot \log \alpha)$ trees (note that setting $\alpha = \log \lambda$ yields distortion $O(\log \lambda)$ with $O(\log \lambda \cdot \log\log \lambda)$ trees). We note that the trees obtained here are in fact *ultrametrics*[1]. This result provides a special type of spanner with distortion $O(\alpha)$ and $O(n \cdot \lambda^{1/\alpha} \cdot \log \lambda \cdot \log \alpha)$ edges, which improves the recent spanner construction of [28], whose number of edges was larger by a factor of $O(\log_\lambda n)$ (though their spanner has additionally bounded lightness). The lower bound mentioned above for doubling spaces implies that our tree cover bounds cannot be substantially improved.

For planar graphs with n vertices, and more generally graphs excluding a fixed minor, we apply the path-separators framework of [48, 4], and show that for any $\epsilon > 0$, there exists a tree cover with distortion $1+\epsilon$ and $O((\log n)/\epsilon)^2$ trees. (Recall that for distortion 1, [31] used the planar separators of [37], but this requires $\Omega(\sqrt{n})$ trees.) We also observe that certain hierarchical partitions of [35] for planar (and fixed minor-free) graphs, can be used to obtain a tree cover with $O(1)$ distortion and only $O(1)$ trees (the obtained trees are ultrametrics).

[1] An ultrametric (U, d_U) is a metric satisfying a strong form of the triangle inequality, $\forall x, y, z$, $d_U(x, z) \leq \max\{d_U(x, y), d_U(y, z)\}$. An ultrametric is both a tree metric and a Euclidean metric.

See Table 1 for a succinct comparison between our and previous results on tree covers.

Table 1 Results on tree covers for general, planar (our new results also hold for fixed minor-free graphs) and doubling metrics. (The upper bound for general metrics appears in Table 2.)

1.2 Ramsey Tree Covers

Given a metric (X,d), the metric Ramsey problem asks for a large subset $S \subseteq X$ that embeds with a given distortion into a simple metric, such as a tree metric or Euclidean space. Following [15], [38] gave a probabilistic construction that finds in any n point metric (X,d) a set $S \subseteq X$ of size at least $n^{1-1/\alpha}$ that embeds into an ultrametric with distortion $O(\alpha)$. In fact, the embedding has such distortion on all pairs in $S \times X$. Applying this iteratively, [38] obtained a collection of $O(\alpha \cdot n^{1/\alpha})$ trees, so that each point $x \in X$ has a "home tree" T_x with distortion $O(\alpha)$ for every pair containing x. We call such a collection a *Ramsey tree cover*. Some further works aim at improving the leading constant in the distortion ([14, 40, 17]) and finding a deterministic construction ([14]). Recently, in the graph setting, [3] devised a *spanning* Ramsey tree cover, where the trees are subgraphs of the input graph. They obtained the same number of trees, but with slightly larger distortion $O(\alpha \cdot \log\log n)$.

We note that the number of trees in all previous works is $\alpha \cdot n^{1/\alpha} \geq \log n$ for any value of α. It seems like a natural question to understand what can be achieved in the inverse tradeoff, where the number of trees, k, is small. We remark that the lower bound via high girth graphs is rather weak, it implies that using k trees the distortion must be only $\Omega(\log_k n)$, as that is the bound on the girth of a graph with kn edges [18].

1.2.1 Our results

We focus on the regime where the number of trees is small. We first observe that a similar method as used in [38] of iteratively extracting large Ramsey subspaces can be applied in this setting as well. Given any metric space (X,d) on n points, and a parameter $k \geq 1$, there exists a Ramsey tree cover of size k (in particular, ultrametrics) and distortion $O(n^{1/k} \cdot \log^{1-1/k} n)$. We also note that the result of [3] can be translated to this setting: given a graph $G=(V,E)$ with n vertices, we find a Ramsey *spanning* tree cover with k spanning trees and distortion $O(n^{1/k} \cdot \log^{1-1/k} n \cdot \log\log n)$. The proof of this observation is given in the full version of the paper.

Next, we investigate the tightness of this bound. We find a graph on n vertices, such that any Ramsey tree cover with k trees requires distortion $\Omega(n^{1/k})$, significantly improving the $\Omega(\log_k n)$ bound obtained from high girth graphs. This also implies that our upper bound is tight, up to lower order terms.

Moreover, the graph we construct is series-parallel (in particular a planar graph) and also has $O(1)$ doubling dimension. Thus, our lower bound indicates a large separation between what can be achieved by a tree cover vs. a Ramsey tree cover; Our upper bounds give a tree cover with $O(1)$ trees and constant distortion for planar and doubling metrics (even $1+\epsilon$ distortion for the latter), as opposed to the $n^{\Omega(1)}$ distortion required with a constant number of Ramsey trees, for both planar and doubling metrics.

We also use a result of [15] to show a lower bound for planar and doubling metrics in the low distortion regime: there are n-point planar (in fact, series-parallel) doubling metrics, such that any Ramsey tree cover with distortion α must contain at least $n^{\Omega(1/(\alpha \log \alpha))}$ trees.

Overall, for general, planar and doubling metrics, our results solve the question of covering metrics by Ramsey trees, up to logarithmic terms, in every regime of parameters. See Table 2 for a concise description of previous and our results.

Table 2 Previous and our results on Ramsey trees for general, planar and doubling metrics.

General metrics	[38]	$O(\alpha \cdot n^{1/\alpha})$	$O(\alpha)$
	New	k	$O(n^{1/k} \cdot \log^{1-1/k} n)$
Planar & doubling metrics	**New**	k	$\Omega(n^{1/k})$
	New	$n^{\Omega(1/(\alpha \log \alpha))}$	α

1.3 Overview of Techniques

Tree cover for doubling metrics. The standard way to construct a $(1+\epsilon)$-spanner for doubling metrics is along the following lines [29, 32]: Choose a hierarchical collection of 2^i-nets (see Section 3 for definitions), and assign every vertex to its nearest net-point at the level i when it first leaves the net hierarchy; this creates a *net tree*. Then additional edges are added to other net-points within distance $\approx 2^i/\epsilon$. This spanner cannot be decomposed into a few trees as low distortion paths for the pairs use both the net tree and the additional edges.

We use a different approach for constructing a spanner, so that it can be decomposed to trees; We first partition the hierarchical net into a small number of well-separated sub-nets (so that in level i, distances between points in the sub-net are at least $2^i/\epsilon$). Then construct a tree for each hierarchical sub-net, by iterative clustering around the sub-net points in a bottom-up manner. In order to control the radius increase caused by the clustering of lower level sub-nets, we also take sufficiently large gaps between consecutive levels used in the same tree.

Tree cover for minor-free graphs. We apply the path separators of [4], asserting that graphs excluding a fixed minor have a separator consisting of $O(1)$ shortest paths (see Section 4 for the precise definitions). Adding for each point $O(1/\epsilon)$ edges to each shortest path guarantees small distortion for all separated pairs [48, 34]. However, since we desire trees, we can allow each point to add only 1 edge (per tree) to the path separator. Using a simple randomized algorithm to choose these edge connections, we show that w.h.p. all pairs will have a low distortion tree.

Hierarchical partitions. We construct a collection of HST spaces (a special type of ultrametric spaces, see Section 5) via a hierarchical probabilistic partitions similarly to [19]. Yet instead of using the basic probabilistic partitions (e.g. [11]) we use the probabilistic partitions

of [1], which have two main strong properties: The padding of the partition can be set as a parameter, which may also be a constant depending on distortion α; The partitions are local, i.e. the probability of being padded is not affected by the structure of the clusters that are far enough. This allows showing that intersecting a bundle of such independent partitions achieves a good tradeoff when the number of scale levels is small. Combining these with the idea of bottom-up union of clusters similar to that of [19], we are able to construct hierarchies with diameters of clusters decreasing by a *constant factor* while letting the padding parameter depend on α, obtaining more general and improved bounds.

1.4 Related Work

We note that Charikar et al. [21] studied a related question of bounding the number of trees sufficient for probabilistic embedding. The result they obtain implies an exponentially weaker cover size than those that follow from [11] and from our construction.

In [30], Gupta et al. considered a stronger version of tree covers (stronger than Ramsey tree covers), which they used to devise an oblivious algorithm for network design problems. We note that the lower bounds given in this paper show that the bound they get using this method is almost tight, even for doubling or planar metrics.

In the context of spanning trees, the problem of computing a spanning tree with low average stretch was first studied by Alon et al. [6]. Following Elkin et al. [23], Abraham et al. [2, 5] obtained a nearly tight $O(\log n \cdot \log\log n)$ bound.

2 Ramsey Tree Covers for General Metrics with Few Trees

In this section we show a deterministic Ramsey tree cover construction for general metrics. Unlike previous works, we build a cover with a small (possible constant) number of trees.

▶ **Theorem 2.** *For any n-point metric (X,d) and any $k \geq 1$, there is a deterministic algorithm that constructs a Ramsey tree cover for X of size k with distortion $O(n^{1/k} \cdot (\log n)^{1-1/k})$.*

Our deterministic construction follows directly from the following theorem on deterministic Ramsey embedding into a tree metric that was presented by Bartal [14] and later by Abraham et al. [3] (alternatively, a randomized construction can be based on [38]).

▶ **Theorem 3** ([14, 3])**.** *Let (X,d) be a metric space, fix any subset $S \subseteq X$, and let $\alpha \geq 1$ be a parameter. There is a deterministic algorithm that finds a subset $Z \subseteq S$, of size $|Z| \geq |S|^{1-\frac{1}{\alpha}}$, and an embedding f of X into an ultrametric T with distortion $O(\alpha)$ for any pair $(u,v) \in Z \times X$.*

Proof of Theorem 2. Let $S_1 = X$. For $i = 1, \ldots, k-1$ iteratively apply the algorithm of Theorem 3 on the subset S_i with parameter α (to be determined later), and obtain trees $T_1, \ldots, T_{k-1}$. The last tree T_k will be constructed separately. Let $Z_i \subseteq S_i$ be the set of size at least $|S_i|^{1-1/\alpha}$ guaranteed by Theorem 2, and define $S_{i+1} = S_i \setminus Z_i$. Note that every point $x \in X \setminus S_k$ has a tree with distortion $O(\alpha)$ for all pairs in $\{x\} \times X$. For each $i \geq 1$, we have $|S_{i+1}| = |S_i| - |Z_i| \leq |S_i| \left(1 - n^{-1/\alpha}\right)$. Therefore, after $k-1$ iterations we have $|S_k| \leq n \left(1 - n^{-1/\alpha}\right)^{k-1}$. We can embed the metric S_k into an ultrametric with distortion $|S_k| - 1$ by the embedding of [15, 32]. This embedding can be extended to all of X, with distortion $O(|S_k|)$ for pairs in $S_k \times X$ by [38, Lemma 4.1]. Therefore, α should be chosen so that $n \cdot \left(1 - n^{-1/\alpha}\right)^{k-1} \leq \alpha$. Using the inequality $e^x \geq 1 + x$ for all $x \in \mathbb{R}$ we have: $n \cdot \left(1 - n^{-1/\alpha}\right)^{k-1} = n \cdot \left(1 - e^{-\frac{\ln n}{\alpha}}\right)^{k-1} \leq n \cdot \left(\frac{\ln n}{\alpha}\right)^{k-1}$. Taking $\alpha = n^{1/k} \cdot (\ln n)^{\left(1-\frac{1}{k}\right)}$ gives a Ramsey tree cover with distortion $O(\alpha)$. ◀

3 $(1+\epsilon)$-Distortion Tree Covers for Doubling Metrics

In this section we devise a tree cover for doubling metrics with distortion arbitrarily close to 1. Let (X,d) be a metric with doubling constant λ, and fix $0<\epsilon<1/8$.

▶ **Definition 4.** *An r-net $N\subseteq X$ is a set satisfying: 1) For every $x,y\in N$, $d(x,y)>r$, and 2) For every $u\in X$ there exists $x\in N$ with $d(x,u)\le r$. We say that a collection $\{N_i\}$ of 2^i-nets is* hierarchical *if $N_{i+1}\subseteq N_i$.*

It is well-known that a simple greedy algorithm can construct (hierarchical) nets. Also, it is known that the size of an r-net of a ball of radius R is bounded by $\lambda^{O(\log(R/r))}$.

Let $\{N_i\}$ be a hierarchical collection of 2^i-nets of X. (It suffices to take the indices i from the range $[\log(\epsilon\delta),\log\Delta]$ where $\delta=\min_{x\neq y\in X}\{d(x,y)\}$ and $\Delta=\max_{x,y\in X}\{d(x,y)\}$.)

▷ Claim 5. There is a partition of N_i to $t=\lambda^{O(\log(1/\epsilon))}$ sets $N_{i1},\ldots,N_{it}$, so that for every $x,y\in N_{ij}$, $d(x,y)\ge 6/\epsilon\cdot 2^i$. It is also hierarchical: if $x\in N_{ij}$ then $x\in N_{i'j}$ for every $i'<i$.

Proof. First place in N_{ij} all the points of $N_{(i+1)j}$ for each j, and denote $N_i'=N_i\setminus(\bigcup_j N_{(i+1)j})$. Next, for $j=1,2,...,t$ complete N_{ij} by choosing greedily from the points remaining in $N_i'\setminus(N_{i1}\cup\cdots\cup N_{i(j-1)})$. Since for any $x\in N_i$ the ball of radius $6/\epsilon\cdot 2^i$ contains less than t net points of N_i, we will surely pick x to some N_{ij} in some iteration $j\le t$. ◁

Construction of trees. Assume w.l.o.g that $\log(1/\epsilon)$ is an integer, we will construct $t\cdot\log(1/\epsilon)$ trees (in fact, forests). The tree $T_{j,p}$ is indexed by the pair (j,p) with $1\le j\le t$ and $0\le p<\log(1/\epsilon)$. Fix j and p, we now describe how to build $T_{j,p}$. Let $I_p=\{i\,:\,i\equiv p\pmod{\log(1/\epsilon)}\}$. Initially all points in X are unclustered. We go over all $i\in I_p$ (from small to large in order), and for every $x\in N_{ij}$ we add an edge from x to every unclustered point $y\in X$ satisfying $d(x,y)<3/\epsilon\cdot 2^i$, of weight $d(x,y)$. These points connected to x are now clustered. (The center x is not considered clustered.)

The following observation is proved in the full version of the paper:

▶ **Observation 6.**

a. *No point $x\in N_{ij}$ is clustered when iteration i is complete.*

b. *Every $u\in X$ can be clustered by at most 1 point.*

c. *If C_x is the connected component created by the clustering of $x\in N_{ij}$ at level $i\in I_p$, then* $\mathrm{diam}(C_x)\le 8/\epsilon\cdot 2^i$.

▷ Claim 7. When the process completes we have a forest.

Proof. By Observation 6(b) every point u adds at most a single edge to $T_{j,p}$, at the time it becomes clustered. As u adds this edge to an unclustered point, it cannot close a cycle. (More formally, if we give each vertex a time stamp which is the time it becomes clustered, then the single edge every vertex adds is to a vertex with a higher time stamp.) ◁

▷ Claim 8. Let C_x be the connected component created when we clustered points to x at some level $i\in I_p$. Then for every point $y\in B(x,2/\epsilon\cdot 2^i)$ we have $d_{C_x}(x,y)\le d(x,y)+2^{i+4}$.

Proof. If y was unclustered when creating C_x then $d_{C_x}(x,y)=d(x,y)$ by definition. Otherwise, let z be the (unique) unclustered point in C_z, the connected component containing y before executing the clustering of level i. Let $i'<i$ be the level in which z created C_z, and by Observation 6(c) we have $\mathrm{diam}(C_z)\le 8/\epsilon\cdot 2^{i'}\le 8\cdot 2^i$ (recall $i'\le i-\log(1/\epsilon)$ since $i'\in I_p$). As $8\le 1/\epsilon$ it follows that $d(x,z)\le d(x,y)+d(y,z)\le 2/\epsilon\cdot 2^i+8\cdot 2^i\le 3/\epsilon\cdot 2^i$, so x will cluster z (recall that by Observation 6(b) no other center can cluster z). Furthermore, $d_{C_x}(x,y)=d_{C_x}(x,z)+d_{C_z}(z,y)=d(x,z)+d_{C_z}(z,y)\le d(x,y)+2d_{C_z}(z,y)\le d(x,y)+2^{i+4}$. ◁

▶ **Lemma 9.** *For every $u, v \in X$, there is a tree $T = T_{j,p}$ so that $d_T(u,v) \le (1+O(\epsilon))\cdot d(u,v)$.*

Proof. Choose i such that $2^{i-1}/\epsilon \le d(u,v) < 2^i/\epsilon$, and let $p = i \bmod \log(1/\epsilon)$. Let $x \in N_i$ be the nearest net point to u, so that $d(x,u) \le 2^i$, and let $1 \le j \le t$ be such that $x \in N_{ij}$.

Observe that $d(x,v) \le d(x,u) + d(u,v) \le 2^i + 2^i/\epsilon < 2/\epsilon \cdot 2^i$, so by Claim 8

$$d_{C_x}(x,v) \le d(x,v) + 2^{i+4} \le d(x,u) + d(u,v) + 2^{i+4} = (1+O(\epsilon)) \cdot d(u,v).$$

We also have by the same claim that $d_{C_x}(x,u) \le d(x,u) + 2^{i+4} = O(\epsilon) \cdot d(u,v)$. The fact that C_x is a subtree of the forest $T = T_{j,p}$ completes the proof. ◀

Since we use edge weights that are the actual distances in (X,d), clearly $d_T \ge d$. Rescaling ϵ by a constant yields the following.

▶ **Theorem 10.** *For every metric (X,d) with doubling constant λ, and any $0 < \epsilon < 1$, there is an efficient algorithm to construct a tree cover of size $\lambda^{O(\log(1/\epsilon))}$, with distortion $1+\epsilon$.*

4 $(1+\epsilon)$-Distortion Tree Covers for Planar and Minor-Free Graphs

In this section we use *path-separators* for planar [48] and more generally minor-free graphs [4], to devise tree covers with $1+\epsilon$ distortion and $O((\log n)/\epsilon)^2$ trees. We start with some preliminary definitions.

A graph G has H as a minor if one can obtain H from G by a sequence of edge deletions, vertex deletions and edge contractions. The graph G is H-minor-free if it does not contain H as a minor.

▶ **Definition 11.** *A graph $G = (V,E)$ on n vertices is* s-path separable *if there exists an integer t and a separator $S \subseteq V$ such that:*

1. *$S = V(\mathcal{P}_0) \cup V(\mathcal{P}_1) \cup \cdots \cup V(\mathcal{P}_t)$, where for each $0 \le i \le t$, $\mathcal{P}_i$ is a collection of shortest paths in the graph $G \setminus (\bigcup_{0 \le j < i} \mathcal{P}_j)$ (and $V(\mathcal{P}_i)$ is the vertex set used by the paths in $\mathcal{P}_i$).*
2. *$\sum_{i=0}^{t} |\mathcal{P}_i| \le s$, that is, the total number of paths is at most s.*
3. *Each connected component of $G \setminus S$ is s-path separable and has at most $n/2$ vertices.*

▶ **Theorem 12** ([4])**.** *Every H-minor-free graph is s-path separable for some $s = s(H)$, and an s-path separator can be computed in polynomial time.*

The following Lemma is implicit in the works of [34, 48] (for completeness a proof is included in the full version of the paper):

▶ **Lemma 13.** *Let $G = (V,E)$ be an edge-weighted graph, fix any $0 < \epsilon < 1$, and let P be a shortest path in G. Then one can find for each $x \in V$ a set of landmarks L_x on P of size $|L_x| = O(1/\epsilon)$, such that for any $x, y \in V$ whose shortest path between them intersects P, there exists $u \in L_x$ and $v \in L_y$ satisfying $d_G(x,u) + d_P(u,v) + d_G(v,y) \le (1+\epsilon) \cdot d_G(x,y)$.*

Construction. Using these tools, we are ready to describe our tree cover for minor-free graphs. Apply the path separator of Theorem 12 on the input graph $G = (V,E)$, $|V| = n$, to obtain a collection $\mathcal{P}$ of s paths, and denote $S = V(\mathcal{P})$. For each path $P \in \mathcal{P}$, apply Lemma 13 to get a set of landmarks for each vertex, and let $\ell = \max_{x \in V}\{|L_x|\} = O(1/\epsilon)$ be the maximal size of a landmark set. Let T be a tree formed by taking P, and for each $x \in V \setminus V(P)$ add a single edge to $u \in L_x$ chosen uniformly and independently at random. Let $d_G(x,u)$ be the weight of a chosen edge. We pick $(C \log n)/\epsilon^2$ such trees independently for each path P, for sufficiently large constant C.

Next, we continue recursively on each connected component of $G \setminus S$. Since the number of vertices halves at every iteration, there will be $O(\log n)$ iterations. Furthermore, the trees of different connected components can be viewed as a forest of G (which can be arbitrarily completed to a tree), thus the total number of trees is $O((\log n)/\epsilon)^2$.

Analysis. Fix some $x, y \in V$, and let P be the first path in $\mathcal{P}$ that intersects the shortest path between x, y in G. (It may be the case that $\mathcal{P}$ is a path separator in a deep level of the recursion, when we decompose some subgraph G'. Note that $d_{G'}(x,y) = d_G(x,y)$, since no path intersected the shortest path from x to y so far. So w.l.o.g. we call the current graph G.) Let $u \in L_x$ and $v \in L_y$ be such that $d_G(x,u) + d_P(u,v) + d_G(v,y) \leq (1+\epsilon) \cdot d_G(x,y)$, which are guaranteed to exist by Lemma 13. If we choose a tree T that contains P and both edges $(x,u),(y,v)$, then T will have distortion at most $1+\epsilon$ for the pair x, y. The probability that both x, y add these edges to T is at least $1/\ell^2 = \Omega(\epsilon^2)$. Thus, the probability that none of the trees created for the path P has distortion at most $1+\epsilon$ for the pair x, y is at most $(1-\Omega(\epsilon^2))^{(C \log n)/\epsilon^2} \leq e^{-3 \ln n} = 1/n^3$, whenever C is sufficiently large. By the union bound over the $\binom{n}{2}$ pairs, with high probability all pairs have a tree with distortion $1+\epsilon$ in that tree. We have proven the following.

▶ **Theorem 14.** *Let G be a graph on n vertices that is H-minor-free. For any $0 < \epsilon < 1$, there is a randomized efficient algorithm that w.h.p. constructs a tree cover for G containing $O((\log n)/\epsilon)^2$ trees with distortion $1+\epsilon$. (The constant in the O-notation depends on $|H|$.)*

5 Tree Covers for Doubling Metrics with Distortion-Size Tradeoff

In this section we prove that any metric space with doubling constant λ has a tree cover with distortion $O(\alpha)$ of size $O(\lambda^{1/\alpha} \log \lambda \log \alpha)$.

Recall that ultrametric is a metric space obeying a strong form of the triangle inequality. It is well known that any finite ultrametric (U, ρ) can be represented by a finite labeled tree T, with the points of U being the leaves of T. Each node $u \in T$ has a label $\Delta(u) \geq 0$ and the label of each leaf is 0. For any two nodes u and v, such that v is a child of u, $\Delta(u) \geq \Delta(v)$. For $u, v \in U$, the distance $\rho(u,v)$ is defined to be the label of their least common ancestor. We refer to ultrametrics by their tree representation. If the labels in an ultrametric tree T are decreasing by a factor at most $\mu > 1$, then T is called a μ-Hierarchically Separated Tree metric (μ-HST) [11]. We note that an ultrametric space can also be represented as a shortest path metric on a Steiner tree.

For a finite metric (X,d), let $d_{\max} = \max_{x \neq y \in X}\{d(x,y)\}$, and $d_{\min} = \min_{x \neq y \in X}\{d(x,y)\}$. Let $\Phi(X) := d_{\max}/d_{\min}$ denote the aspect ratio of X.

5.1 Probabilistic Hierarchical Partition Family

With start with the neceassary definitions. For any $\Delta > 0$, a Δ-bounded partition P of a finite metric space (X,d) is a collection of pairwise disjoint clusters $P_i \subseteq X$, such that $\cup P_i = X$, and for each cluster $P_i \in P$, $\mathrm{diam}(P_i) \leq \Delta$. We assume that each cluster has some point designated as its center. For a point $x \in X$, let $P(x) \in P$ denote the cluster that contains x. A Δ-bounded probabilistic partition of X is a distribution $\mathcal{P}$ over a set of Δ-bounded partitions of X.

The notion of a padding parameter of a random partition is studied in various papers [36, 33, 11, 27]. We use a stronger definition given by Abraham et al. in [1], where the padding parameter depends on the desired probability of success. The following is a rephrased version of their original definition ([1], Definition 17):

▶ **Definition 15** (Padded Probabilistic Partition). *Let $\eta(\delta)\colon (0,1] \to (0,1]$ be some function, and $(a,b] \subseteq (0,1]$ be some range. A Δ-bounded probabilistic partition $\mathcal{P}$ is $\eta(\delta)$-padded on the range $(a,b]$, if for all $x \in X$ and for all $\delta \in (a,b]$, $\Pr_{P\sim\mathcal{P}}[B(x,\eta(\delta)\cdot\Delta) \subseteq P(x)] \geq \delta$.*

In addition, the authors defined a notion of a *locally* padded probabilistic partition (on the range $(a,b]$): $\mathcal{P}$ is $\eta(\delta)$-locally padded if for all $a < \delta \leq b$ the event $B(x,\eta(\delta)\cdot\Delta) \subseteq P(x)$ occurs with probability at least δ regardless of the structure of the partition outside the ball $B(x,2\Delta)$. Formally stated, for all $x \in X$, for all subsets $C \subseteq X \setminus B(x,2\Delta)$ and all partitions P' of C, $\Pr_{P\sim\mathcal{P}}[B(x,\eta(\delta)\cdot\Delta) \subseteq P(x) \mid P[C] = P'] \geq \delta$, where $P[C]$ denotes the restriction of the partition P to C. Our construction uses their random partitions as a building block:

▶ **Lemma 16** ([1], Lemma 8). *Given a finite metric space X with doubling constant λ, and given any $0 < \Delta < \mathrm{diam}(X)$, there is a Δ-bounded, $\left(\frac{\log(1/\delta)}{2^6 \log\lambda}\right)$-locally padded probabilistic partition $\mathcal{P}$ of X, for $\delta \in \left[\lambda^{-2^{12}}, 1\right]$.*

A set of nested partitions of X forms a hierarchy:

▶ **Definition 17** (Hierarchical Partition). *For all $\mu > 1$, $\Delta \leq d_{\max}(X)$ and integer $1 \leq B \leq \log_\mu \Phi(X)$, let $\Delta_i = \Delta/\mu^i$, for all $0 \leq i \leq B$. A μ-Hierarchical Partition of X for range $[\Delta, \Delta_B]$, is a collection $H = \{P_0, \ldots, P_B\}$ of partitions of X such that: For all $0 \leq i \leq B$, P_i is a Δ_i-bounded partition of X; Each P_{i+1} is a refinement of P_i, i.e. each cluster in P_i is a union of some clusters in P_{i+1}. Let μ-$HP_B(\Delta)$ denote such a collection.*

A full range Hierarchical Partition, denoted by μ-HP, is the μ-$HP_B(\Delta)$, for $\Delta = d_{\max}(X)$ and $B = \log_\mu \Phi(X)$ (we assume this is an integer).

There is a natural way to associate a dominating μ-HST tree to a μ-HP. For each cluster of the partition P_i there is a node in the tree. The nodes associated with clusters of the partition P_{i+1} are the children of nodes associated with clusters of P_i. The label of all level i nodes in the tree is Δ/μ^i. The points of X are at the leaves.

▶ **Definition 18** (η-Padded μ-Hierarchical Partition Family). *Let $\eta < 1$ and $\mu > 1$. For a finite metric space (X,d), an η-padded μ-Hierarchical Partition Family of X, (η,μ)-HPF, is a set $\mathcal{H}$ of μ-Hierarchical Partitions $\{H^j\}_{j\geq 1}$ of X such that: For all $x \in X$ and for all scales $0 \leq i \leq \log_\mu \Phi(X)$, there is an $H^j \in \mathcal{H}$ such that $B(x,\eta\Delta_i) \subseteq P_i^{(j)}(x)$, where $P_i^{(j)}$ is a Δ_i-bounded partition of H^j. The size of $\mathcal{H}$ is the number of hierarchical partitions it has.*

The following lemma shows the connection between hierarchical family and a tree cover:

▶ **Lemma 19.** *If there is an (η,μ)-HPF of size k of X, then there is an $(\mu/\eta, k)$-tree cover of X.*

Proof. Let $H^1, \ldots, H^k$ be an (η,μ)-HPF of X. Consider an associated collection of dominating μ-HST trees $T_1, \ldots, T_k$. Given any $x \neq y \in X$, let i be the minimal index such that $d(x,y) \geq \eta\Delta_i$. If $i = 0$, then by the construction, for any tree T_j, $d_{T_j}(x,y) \leq \Delta_0$, implying $d_{T_j}(x,y)/d(x,y) \leq 1/\eta$. If $i \geq 1$, then $\eta\Delta_i \leq d(x,y) \leq \eta\Delta_{i-1}$. The padding property implies that there is H^j such that $B(x,\eta\Delta_{i-1}) \subseteq P_{i-1}^{(j)}(x)$. As $y \in B(x,\eta\Delta_{i-1})$, it holds that $d_{T^j}(x,y) \leq \Delta_{i-1}$. Therefore, $d_{T^j}(x,y)/d(x,y) \leq \Delta_{i-1}/\eta\Delta_i = \mu/\eta$. ◀

In what follows, we construct $(\Omega(1/\alpha), 2)$-HPF of X, of size $O(\lambda^{1/\alpha}\log\lambda\log\alpha)$. We note that the notion of hierarchical family also appeared in [35], where the authors constructed an $(\Omega(s^{-2})), O(s^2))$-HPF of size 3^s for any metric of a $K_{s,s}$-minor free graph. As a corollary, we conclude

▶ **Corollary 20.** *For any metric induced on a $K_{s,s}$-minor free graph, there is a tree cover with distortion $O(s^4)$, of size 3^s.*

In our proofs we will use the following version of the Lovasz Local Lemma:

▶ **Lemma 21** ([26]). *Let $\mathcal{E}_1, \ldots, \mathcal{E}_n$ be a family of events. Let $G(V, E)$ be a directed graph on n vertices with out-degree at most d, where each vertex corresponds to an event. Assume that for all $1 \leq i \leq n$, for all $Q \subseteq \{j \mid (\mathcal{E}_i, \mathcal{E}_j) \notin E\}$, $\Pr[\mathcal{E}_i \mid \bigcap_{j \in Q} \neg\mathcal{E}_j] \leq p$. If $ep(d+1) \leq 1$, then $\Pr\left[\bigcap_{i \in [1,n]} \neg\mathcal{E}_i\right] > 0$.*

5.2 Constructing Hierarchical Padded Family of Bounded Size

Our main hierarchical partitions result is:

▶ **Theorem 22.** *For any finite metric space X with doubling constant λ and for any $\alpha \geq 2$, there is an $\Omega(1/\alpha)$-padded 2-Hierarchical Partition Family of X, of size $O\left(\lambda^{1/\alpha} \log\alpha \log\lambda\right)$.*

Note that taking $\alpha = O(\log\lambda)$, we obtain a hierarchical family with padding $\Omega(1/\log\lambda)$, of size $O(\log\lambda \log\log\lambda)$, which is an improvement over the result of [19]: $O(\log\lambda)$-hierarchical partitions with padding $\Omega(1/\log\lambda)$, of the same size. They construct a family of hierarchies, where each hierarchy is constructed in a bottom-up manner: the clusters of larger diameters are the union of the clusters of lower diameters. Preserving the padding parameter requires the diameters of the clusters to increase by a factor of $O(\log\lambda)$, thus covering only $\log\log\lambda$ of all the distance scales in the metric space. This results in $O(\log^2\lambda)$ distortion. Using the Lovasz Local Lemma they were able to bound the size of this family.

In our construction, we combine the bottom-up union of clusters technique with an *intersection of clusters* procedure. Essentially, there are two steps. First, we use the locally padded partitions of Lemma 16 to create a padded hierarchy with diameters decreasing by a constant factor, by intersecting the clusters of levels of the hierarchy of larger diameter. Using the locality property and the fact that the padding parameter depends on the success probability, we show that using $\log\log\lambda$ such levels of partitions with diameters increasing by factor 2, results in a 2-hierarchy with $\Omega(1/\alpha)$ padding, thus covering the $\log\log\lambda$ scales uncovered by the construction of [19]. We apply the Lovasz Local Lemma to bound the size of the family of such hierarchies by $O\left(\lambda^{1/\alpha} \log\alpha \log\lambda\right)$. Second, we combine the hierarchies obtained by cutting clusters, in a bottom-up manner, by defining higher scales clusters as the union of lower level clusters, thus obtaining a hierarchy with diameters decreasing by a factor of 2 in all its levels, while padding is $\Omega(1/\alpha)$.

To prove Theorem 22, we consider hierarchical partitions that cover a range of scales: for any Δ and an integer B we build a family $\{H^j\}_{j \geq 1}$, where each H^j is a μ-HP$_B(\Delta)$. The padding property is then required to hold for all points $x \in X$ and for all scales $\Delta_i \in [\Delta, \Delta_B]$. We call such family as (η, μ)-HPF for range $[\Delta, \Delta_B]$.

The following lemma is used as a subroutine in the construction of the hierarchical family:

▶ **Lemma 23.** *Let X be a finite metric space with doubling constant λ . For a given $\alpha \geq 2$, $\Delta \leq \mathrm{diam}(X)$ and an integer $1 \leq B \leq \log_\mu \Phi(x)$, there exists an $(\Omega(1/\alpha), 2)$-HPF for range $[\Delta, \Delta_B]$, of size $O\left(\lambda^{1/\alpha} \log\lambda(\log\alpha + B)\right)$.*

Proof. For a given distortion $\alpha \geq 2$, let $\delta = \lambda^{-1/(2\alpha)}$. Therefore, for such δ we have $\eta(\delta) := \frac{\log(1/\delta)}{2^6 \log\lambda} = 2^{-7}/\alpha$. Also note that for any $\alpha \geq 1$, it holds that $\delta \in [\lambda^{-2^{12}}, 1]$. Thus, we will show that there exists a hierarchical family with padding $\Omega(\eta(\delta))$, of size $k := O(\left(\lambda^{1/\alpha} \log\lambda(\log\alpha + B)\right))$.

Let $N \subseteq X$ be an $(\eta(\delta)\Delta_B/4)$-net of X. We show the claim is true for N and the extension of it to X is immediate, with a constant factor loss in distortion. In the sequel, all the balls are balls of metric space N.

Let $\Delta_i = \Delta/2^i$, for all $0 \leq i \leq B$. Consider the following random process: For each scale Δ_i in the range $[\Delta, \Delta_B]$, independently generate Δ_i-bounded partitions $P_0, \ldots P_B$ of N by invoking the locally padded probabilistic decomposition of Lemma 16. To obtain a 2-Hierarchical Partition H for the scales $[\Delta_0, \Delta_B]$ we cut all the clusters of all the partitions, to get Δ_i-bounded nested partitions $\hat{P}_0, \ldots, \hat{P}_B$. Let $\hat{P}_0 = P_0$, for all $i \geq 1$, define $\hat{P}_i = \cup_{\hat{C} \in \hat{P}_{i-1}} \cup_{C \in P_i} C \cap \hat{C}$.

Now, independently repeat the above random process k times to obtain a randomly generated family $H^{(1)}, \ldots, H^{(k)}$ of 2-Hierarchical Partitions of the net N, for range $[\Delta, \Delta_B]$. Each hierarchical partition $H^{(t)}$ consists of Δ_i-bounded partitions, denoted by $\hat{P}_i^{(t)}$.

For each $x \in N$ and for each scale $\Delta_i \in [\Delta, \Delta_B]$, let $\mathcal{E}_{x,i}$ be an event that the ball $B(x, \eta(\delta)\Delta_i)$ is not padded at the i-th level partition $\hat{P}_i^{(t)}$ in any of the hierarchical partitions $H^{(1)}, \ldots, H^{(k)}$. We use the Lovasz Local Lemma (Lemma 21) to prove that for the chosen value of k, $\Pr\left[\bigcap_{\substack{x \in X, \\ 0 \leq i \leq B}} \neg\mathcal{E}_{x,i}\right] > 0$. Let $G = (V, E)$ be a directed graph with $V = \{\mathcal{E}_{x,i}\}$, for all $x \in N$ and $0 \leq j \leq B$. The vertex $\mathcal{E}_{x,i}$ is connected with an out-edge with all the verticies $\mathcal{E}_{y,j}$, such that $y \in B(x, 2\Delta)$ and $0 \leq j \leq B$. In the full version we prove the following lemma:

▶ **Lemma 24.** *For all $Q \subseteq N \setminus B(x, 2\Delta)$, for all $J \subseteq [0, B]$, $Pr[\mathcal{E}_{x,i} \mid \bigcap_{\substack{y \in Q, \\ j \in J}} \neg\mathcal{E}_{y,j}] \leq (1-\delta^2)^k$.*

Then, for $\delta = \lambda^{-1/(2\alpha)}$, and $k = O\left(\lambda^{1/\alpha} \log\lambda(\log\alpha + B)\right)$, $(1-\delta^2)^k \leq e^{-\delta^2 k} \leq \lambda^{-\Theta(\log\alpha + B)}$.

In addition, the out degree d of G is bounded by

$$d = B \cdot |N \cap B(x, 2\Delta)| = B \cdot O\left(\left(\frac{\Delta}{\eta(\delta)\Delta_B}\right)^{\log\lambda}\right) = B \cdot \lambda^{O(\log(1/\eta(\delta)) + B)} = \lambda^{O(\log(1/\eta(\delta)) + B)}.$$

Thus, the LLL can be applied to conclude the proof. ◀

Proof of Theorem 22. Let $\Phi = \Phi(X)$, $\Delta_0 = d_{\max}(X)$, and for all $1 \leq i \leq \log\Phi$, $\Delta_i = \Delta_0/2^i$. Let $\mathcal{I} = \{\Delta_i \mid 0 \leq i \leq \log\Phi\}$. We build a small family of 2-HP's, such that the padding property is satisfied for all points in X and for all scales $\Delta_i \in \mathcal{I}$, with padding parameter $\Omega(1/\alpha)$. Let $B = \lceil \log(2\alpha/c') \rceil$, where $c' < 1$ will be defined later, and let $k = O\left(\lambda^{1/\alpha} \log\alpha \log\lambda\right)$. We will build a family $\mathcal{H} \cup \mathcal{R}$ such that:

1. $\mathcal{H}$ is a collection of size k of 2-HP's. For[2] $\mathcal{I}_{\mathcal{H}} := \left\{\Delta_j \mid \Delta_j \in \bigcup_{0 \leq l \leq L} \left[\Delta_{2lB}, \Delta_{(2l+1)B}\right]\right\} \subseteq \mathcal{I}$, where $L = \log(\Phi^{1/(2B)}) - 1/2$, the following padding property holds: For all $x \in X$ and for all scale $\Delta_j \in \mathcal{I}_{\mathcal{H}}$, there is a 2-HP $H \in \mathcal{H}$ such that $B(x, \Omega(1/\alpha)\Delta_j) \subseteq P_j(x)$, for the j-th level partition $P_j \in H$.
2. $\mathcal{R}$ is a collection of size k of 2-HP's. The padding property as for $\mathcal{H}$ holds for all $x \in X$ and for all scales $\Delta_j \in \mathcal{I}_{\mathcal{R}} := \mathcal{I} \setminus \mathcal{I}_{\mathcal{H}}$.

Namely, the hierarchical partitions of $\mathcal{R}$ are padded for the scales that are not padded in the partitions of $\mathcal{H}$. Thus, together these two collections constitute an $\Omega(1/\alpha)$-padded 2-HP Family for X, of size $2k$. We describe the construction of $\mathcal{H}$, while $\mathcal{R}$ is constructed similarly.

[2] For the simplicity of representation, we assume that B is integer and that $\log\Phi$ is a multiple of B.

Let $\mathcal{H} = H^{(1)}, \ldots, H^{(k)}$ denote the set of 2-HP's. We construct it iteratively in a bottom up fashion. Assume by induction that we have already constructed a family $\hat{\mathcal{H}} = \hat{H}^{(1)}, \ldots, \hat{H}^{(k)}$ such that: Each $\hat{H}^{(t)}$ is a 2-HP for range $[\Delta_{2B}, \Delta_{(2L+1)B}]$; The padding property holds with parameter $\Omega(1/\alpha)$ for all scales $\Delta_j \in \mathcal{I}_{\mathcal{H}} \setminus \{\Delta_i \in [\Delta_0, \Delta_B]\}$.

Let $c = 1 + \frac{1}{2^{B-1}-1}$, by Lemma 23 there is $(\Omega(1/\alpha), 2)$-HPF $F^{(1)}, \ldots, F^{(k)}$ for range $[\tilde{\Delta}_0, \tilde{\Delta}_B]$, where $\tilde{\Delta}_j = \Delta_j/c$, for $0 \le j \le B$. For each $1 \le t \le k$, $H^{(t)}$ is obtained by adding the partitions of $F^{(t)}$ to $\hat{H}^{(t)}$ in the following way. Let $\hat{P}^{(t)}_{2B}$ denote the Δ_{2B}-bounded partition of $\hat{H}^{(t)}$. First, for all scale $\Delta_j \in [\Delta_{B+1}, \Delta_{2B}]$ add to $H^{(t)}$, Δ_j-bounded partition $P^{(t)}_j := \hat{P}^{(t)}_{2B}$ (these artificial partitions are added to have a well defined 2-HP family). Next, let $\{\tilde{P}^{(t)}_j\}_{0 \le j \le B}$ denote the set of $\tilde{\Delta}_j$-bounded partitions of $F^{(t)}$. For all j starting from $j = B$ down to $j = 0$, the partition $P^{(t)}_j$ is constructed a s follows: for each $\tilde{C} \in \tilde{P}^{(t)}_j$, add a cluster C to $P^{(t)}_j$, defined by $C = \cup\{C' \in P^{(t)}_{2B} \mid \text{center of } C' \in \tilde{C}\}$. Finally, the partitions of $\hat{H}^{(t)}$ are unchanged.

For all $B \le j \le 2B$, $P_j(t)$ is Δ_j-bounded, since $\Delta_{2B} \le \Delta_j$. For $0 \le j \le B$ the diameter of each cluster in partition $P^{(t)}_j$ is bounded by $\tilde{\Delta}_j + 2\Delta_{2B} = \Delta_j/c + \Delta_B/2^{B-1} \le \Delta_j\left(1/c + 1/2^{B-1}\right) = \Delta_j$, for a chosen value of c. In addition, by the construction, the partitions $P^{(t)}_j$ form a hierarchy. It is left to show that the padding property holds in $\mathcal{H}$ for the scales $[\Delta_0, \Delta_B]$. By Lemma 23, for any $x \in X$, for any $\tilde{\Delta}_j \in [\tilde{\Delta}_0, \tilde{\Delta}_B]$, there is $F^{(t)}$ such that $B(x, (c'/\alpha)\tilde{\Delta}_j) \subseteq \tilde{P}^{(t)}_j(x)$, for $\tilde{P}^{(t)}_j \in F^{(t)}$, for some constant c'. Consider some cluster $P^{(t)}_j(x)$, for some $x \in X$. In the process of constructing $P^{(t)}_j(x)$ some points from $\tilde{P}^{(t)}_j(x)$ may be removed, due to removal of some cluster $C' \in P^{(t)}_{2B}$ whose center falls outside the cluster $\tilde{P}^{(t)}_j(x)$. For B as defined above, for $r = \frac{c'}{\alpha}\tilde{\Delta}_j - \Delta_{2B} \ge \left(\frac{c'}{2\alpha}\right)\Delta_j$, we have that $B(x, r) \subseteq P^{(t)}_j(x)$. This completes the proof. ◀

▶ **Theorem 25.** *For any finite metric space (X, d) with doubling constant λ, for any $\alpha \ge 2$, there is a tree cover of X with distortion $O(\alpha)$ and of size $O\left(\lambda^{1/\alpha} \log \alpha \log \lambda\right)$.*

Proof. Apply Lemma19 on the Hierarchical Family of Theorem 22. ◀

Note that the tree cover of Theorem 25 can be deterministically constructed in polynomial time via the constructive local lemma due to [39].

6 Lower Bounds

In full version of the paper we show that there is an n-point metric (X, d) (the metric of a high girth graph) with doubling constant λ, such that any tree cover for X with distortion α requires at least $\Omega(\lambda^{1/\alpha})$ trees. Additionally, we show below a nearly tight lower bound for Ramsey tree covers of a doubling planar metric space.

6.1 Lower Bound on Ramsey Tree Cover

In this section we show an asymptotically tight lower bound on Ramsey tree covers, in the regime where the number of trees is small. The lower bound on high girth graphs mentioned above can only give distortion $\Omega(\log_k n)$ for tree covers with k trees. Here we use a different example (which is a planar metric with $O(1)$ doubling dimension) that strengthen the lower bound on the distortion to $\Omega(n^{1/k})$.

We will need the following notion of a composition of metric spaces that was introduced in [15] (we present here a simplification of the original definition).

▶ **Definition 26.** *Let (S, d_S), (T, d_T) be finite metric spaces. For $\beta \geq 1/2$, the β-composition of S with T, denoted by $Z = S_\beta[T]$, is a metric space of size $|Z| = |S| \cdot |T|$ constructed by replacing each point $u \in S$ with a copy of T, denoted by $T^{(u)}$. Let $\gamma = \frac{\max_{t \neq t' \in T}\{d_T(t,t')\}}{\min_{s \neq s' \in S}\{d_S(s,s')\}}$. For $z_i \neq z_j \in Z$ such that $z_i \in T^{(u)}$ and $z_j \in T^{(v)}$ the distance is defined as follows: if $u = v$, then $d_Z(z_i, z_j) = \frac{1}{\beta\gamma} \cdot d_T(z_i, z_j)$, otherwise (if $u \neq v$), $d_Z(z_i, z_j) = d_S(u, v)$.*

It is easily checked that the choice of the factor $1/(\beta\gamma)$ guarantees that d_Z is indeed a metric. For a finite metric space S and an integer $t \geq 1$, let $[S]^t_\beta$ denote the metric space obtained by β-composition of S with itself t times. The following theorem asserts that when the number of trees is small our upper bound on the distortion of Ramsey tree covers is tight up to a logarithmic factor. Although the example is not described as a planar and doubling metric space, in the full version of the paper we show that it can be approximated with constant distortion by a shortest path metric on a series-parallel graph with constant doubling dimension.

▶ **Theorem 27.** *For any $k \geq 1$ and large enough n, there is an n-point doubling metric space X, such that any Ramsey tree cover of X of size k, has distortion $\Omega\left(n^{\frac{1}{k}}\right)$.*

Proof. Let C_N denote the shortest path metric on the unweighted N-point cycle graph. For any integers $k, N \geq 1$ and for any $\beta \geq 1/2$, consider the metric space $Z_k(N) = [C_N]^k_\beta$. We prove by induction on k, that any Ramsey tree cover of $Z_k(N)$ with k trees has distortion at least $\frac{1}{3}|Z_k(N)|^{1/k} - 1$. The details are differed to the full version of the paper. ◀

Abstract

An elastic-degenerate (ED) string is a sequence of n sets of strings of total length N, which was recently proposed to model a set of similar sequences. The ED string matching (EDSM) problem is to find all occurrences of a pattern of length m in an ED text. The EDSM problem has recently received some attention in the combinatorial pattern matching community, and an $\mathcal{O}(nm^{1.5}\sqrt{\log m}+N)$-time algorithm is known [Aoyama et al., CPM 2018]. The standard assumption in the prior work on this question is that N is substantially larger than both n and m, and thus we would like to have a linear dependency on the former. Under this assumption, the natural open problem is whether we can decrease the 1.5 exponent in the time complexity, similarly as in the related (but, to the best of our knowledge, not equivalent) *word break* problem [Backurs and Indyk, FOCS 2016].

Our starting point is a conditional lower bound for the EDSM problem. We use the popular combinatorial Boolean matrix multiplication (BMM) conjecture stating that there is no truly subcubic *combinatorial* algorithm for BMM [Abboud and Williams, FOCS 2014]. By designing an appropriate reduction we show that a combinatorial algorithm solving the EDSM problem in $\mathcal{O}(nm^{1.5-\epsilon}+N)$ time, for any $\epsilon > 0$, refutes this conjecture. Of course, the notion of combinatorial algorithms is not clearly defined, so our reduction should be understood as an indication that decreasing the exponent requires fast matrix multiplication.

Two standard tools used in algorithms on strings are string periodicity and fast Fourier transform. Our main technical contribution is that we successfully combine these tools with fast matrix multiplication to design a non-combinatorial $\mathcal{O}(nm^{1.381}+N)$-time algorithm for EDSM. To the best of our knowledge, we are the first to do so.

1 Introduction

Boolean matrix multiplication (BMM) is one of the most fundamental computational problems. Apart from its theoretical interest, it has a wide range of applications [37, 52, 29, 27, 46]. BMM is also the core combinatorial part of integer matrix multiplication. In both problems, we are given two $\mathcal{N} \times \mathcal{N}$ matrices and we are to compute $\mathcal{N}^2$ values. Integer matrix multiplication can be performed in *truly subcubic* time, *i.e.*, in $\mathcal{O}(\mathcal{N}^{3-\epsilon})$ operations over the field, for some $\epsilon > 0$. The fastest known algorithms for this problem run in $\mathcal{O}(\mathcal{N}^{2.373})$ time [30, 54]. These algorithms are known as *algebraic*: they rely on the underlying ring structure.

There also exists a different family of algorithms for the BMM problem known as *combinatorial*. Their focus is on unveiling the combinatorial structure in the Boolean matrices to reduce redundant computations. A series of results [7, 9, 15] culminating in an $\hat{\mathcal{O}}(\mathcal{N}^3/\log^4 \mathcal{N})$-time algorithm [58] (the $\hat{\mathcal{O}}(\cdot)$ notation suppresses poly(log log) factors) has led to the popular *combinatorial BMM conjecture* stating that there is no combinatorial algorithm for BMM working in time $\mathcal{O}(\mathcal{N}^{3-\epsilon})$, for any $\epsilon > 0$ [2]. There has been ample work on applying this conjecture to obtain *BMM hardness* results: see, *e.g.*, [44, 2, 49, 33, 43, 42, 17].

String matching is another fundamental problem. The problem is to find all fragments of a string *text* of length n that match a string *pattern* of length m. This problem has several linear-time solutions [22]. In many real-world applications, it is often the case that letters at some positions are either unknown or uncertain. A way of representing these positions is with a subset of the alphabet Σ. Such a representation is called *degenerate string*. The first efficient algorithm for a degenerate text and a standard pattern was published by Fischer and Paterson in 1974 [28]. It has undergone several improvements since then [36, 39, 20, 19]. The first efficient algorithm for a degenerate pattern and a standard text was published by Abrahamson in 1987 [3], followed by several practically efficient algorithms [57, 47, 34].

Degenerate letters are used in the IUPAC notation [38] to represent a position in a DNA sequence that can have multiple possible alternatives. These are used to encode the consensus of a population of sequences [21, 4] in a multiple sequence alignment (MSA). In the presence of insertions or deletions in the MSA, we may need to consider alternative representations. Consider the following MSA of three closely-related sequences (on the left):

```
GCAACGGGTA--TT
GCAACGGGTATATT
GCACCTGG----TT
```

$$\tilde{T} = \{\ \texttt{GCA}\ \} \cdot \left\{ \begin{array}{c} \texttt{A} \\ \texttt{C} \end{array} \right\} \cdot \{\ \texttt{C}\ \} \cdot \left\{ \begin{array}{c} \texttt{G} \\ \texttt{T} \end{array} \right\} \cdot \{\ \texttt{GG}\ \} \cdot \left\{ \begin{array}{c} \texttt{TA} \\ \texttt{TATA} \\ \varepsilon \end{array} \right\} \cdot \{\ \texttt{TT}\ \}$$

These sequences can be compacted into a single sequence $\tilde{T}$ of sets of strings (on the right) containing some deterministic and some *non-deterministic* segments. A non-deterministic segment is a finite set of deterministic strings and may contain the empty string ε corresponding to a deletion. The total number of segments is the *length* of $\tilde{T}$ and the total number of letters is the *size* of $\tilde{T}$. We denote the length by $n = |\tilde{T}|$ and the size by $N = ||\tilde{T}||$.

This representation has been defined in [35] by Iliopoulos et al. as an *elastic-degenerate* (ED) string. Being a sequence of subsets of Σ^*, it can be seen as a generalization of a degenerate string. The natural problem that arises is finding all matches of a deterministic pattern P in an ED text $\tilde{T}$. This is the *elastic-degenerate string matching* (EDSM) problem. Since its introduction in 2017 [35], it has attracted some attention in the combinatorial pattern matching community, and a series of results have been published. The simple

algorithm by Iliopoulos et al. [35] for EDSM was first improved by Grossi et al. in the same year, who showed that, for a pattern of length m, the EDSM problem can be solved *on-line* in $\mathcal{O}(nm^2 + N)$ time [32]; on-line means that the text is read segment-by-segment and an occurrence is detected as soon as possible. This result was improved by Aoyama et al. [6] who presented an $\mathcal{O}(nm^{1.5}\sqrt{\log m} + N)$-time algorithm. An important feature of these bounds is their *linear dependency* on N. A different branch of on-line algorithms waiving the linear-dependency restriction exists [32, 48, 18]. Moreover, the EDSM problem has been considered under Hamming and edit distance [12].

A question with a somewhat similar flavor is the *word break* problem. We are given a dictionary $\mathcal{D}$, $m = ||\mathcal{D}||$, and a string S, $n = |S|$, and the question is whether we can split S into fragments that appear in $\mathcal{D}$ (the same element of $\mathcal{D}$ can be used multiple times). Backurs and Indyk [8] designed an $\tilde{\mathcal{O}}(nm^{1/2-1/18}+m)$-time algorithm for this problem (the $\tilde{\mathcal{O}}$ notation suppresses poly(log) factors). Bringmann et al. [14] improved this to $\tilde{\mathcal{O}}(nm^{1/3} + m)$ and showed that this is optimal for combinatorial algorithms by a reduction from k-Clique. Their algorithm uses fast Fourier transform (FFT), and so it is not clear whether it should be considered combinatorial. While this problem seems similar to EDSM, there does not seem to be a direct reduction and so their lower bound does not immediately apply.

Our Results. It is known that BMM and triangle detection in graphs either both have truly subcubic combinatorial algorithms or none of them do [56]. Recall also that the currently fastest algorithm with linear dependency on N for the EDSM problem runs in $\mathcal{O}(nm^{1.5}\sqrt{\log m} + N)$ time [6]. In this paper we prove the following two theorems.

▶ **Theorem 1.** *If the EDSM problem can be solved in $\mathcal{O}(nm^{1.5-\epsilon} + N)$ time, for any $\epsilon > 0$, with a combinatorial algorithm, then there exists a truly subcubic combinatorial algorithm for triangle detection.*

Arguably, the notion of combinatorial algorithms is not clearly defined, and Theorem 1 should be understood as an indication that in order to achieve a better complexity one should use fast matrix multiplication. Indeed, there are examples where a lower bound conditioned on BMM was helpful in constructing efficient algorithms using fast matrix multiplication [1, 16, 13, 45, 24, 55, 59]. We successfully design such a non-combinatorial algorithm by combining three ingredients: a string periodicity argument, FFT, and fast matrix multiplication. While periodicity is the usual tool in combinatorial pattern matching [40, 23, 41] and using FFT is also not unusual (for example, it often shows up in approximate string matching [3, 5, 19, 31]), to the best of our knowledge, we are the first to combine these with fast matrix multiplication. Specifically, we show the following result for the EDSM problem.

▶ **Theorem 2.** *The EDSM problem can be solved on-line in expected $\mathcal{O}(nm^{1.381} + N)$ time.*

An important building block in our solution that might find applications in other problems is a method of selecting a small set of length-ℓ substrings of the pattern, called *anchors*, so that any relevant occurrence of a string from an ED text set contains at least one but not too many such anchors inside. This is obtained by rephrasing the question in a graph-theoretical language and then generalizing the well-known fact that an instance of the *hitting set* problem with m sets over $[n]$, each of size at least k, has a solution of size $\mathcal{O}(n/k \cdot \log m)$. While the idea of carefully selecting some substrings of the same length is not new, for example Kociumaka et al. [41] used it to design a data structure for pattern matching queries on a string, our setting is different and hence so is the method of selecting these substrings.

Roadmap. Section 2 provides the necessary definitions and notation as well the algorithmic toolbox used throughout the paper. In Section 3 we prove our hardness result for the EDSM problem (Theorem 1). In Section 4 we present our algorithm for the same problem (Theorem 2); this is the most technically involved part of the paper.

2 Preliminaries

Let $T = T[1]T[2]\dots T[n]$ be a *string* of length $|T| = n$ over a finite ordered alphabet Σ of size $|\Sigma| = \sigma$. For two positions i and j on T, we denote by $T[i\,..\,j] = T[i]\dots T[j]$ the *substring* of T that starts at position i and ends at position j (it is of length 0 if $j < i$). By ε we denote the *empty string* of length 0. A *prefix* of T is a substring of the form $T[1\,..\,j]$, and a suffix of T is a substring of the form $T[i\,..\,n]$. T^r denotes the *reverse* of T, that is, $T[n]T[n-1]\dots T[1]$. We say that a string X is a *power* of a string Y if there exists an integer $k > 1$, such that X is expressed as k consecutive concatenations of Y, denoted by $X = Y^k$. A period of a string X is any integer $p \in [1, |X|]$ such that $X[i] = X[i+p]$ for every $i = 1, 2, \dots, |X| - p$, and *the period*, denoted by $\mathrm{per}(X)$, is the smallest such p. We call a string X *strongly periodic* if $\mathrm{per}(X) \le |X|/4$.

▶ **Lemma 3** ([26]). *If p and q are both periods of the same string X, and additionally $p + q \le |X| + 1$, then $\gcd(p, q)$ is also a period of X.*

A *trie* is a rooted tree in which every edge is labeled with a single letter, and every two edges outgoing from the same node have different labels. The label of a node u in such a tree T, denoted by $\mathcal{L}(u)$, is defined as the concatenation of the labels of all the edges on the path from the root of T to u. Thus, the label of the root of T is ε, and a trie is a representation of a set of strings consisting of the labels of all its leaves. By replacing each path p consisting of nodes with exactly one child by an edge labeled by the concatenation of the labels of the edges of p we obtain a *compact trie*. The nodes of the trie that are removed after this transformation are called *implicit*, while the remaining ones are referred to as *explicit*. The *suffix tree* of a string S is the compact trie representing all suffixes of $S\$$, $\$ \notin \Sigma$, where instead of explicitly storing the label $S[i\,..\,j]$ of an edge we represent it by a pair (i, j).

A *heavy path decomposition* of a tree T is obtained by selecting, for every non-leaf node $u \in T$, its child v such that the subtree rooted at v is the largest. This decomposes the nodes of T into node-disjoint paths, with each such path p (called a heavy path) starting at some node, called the *head* of p, and ending at a leaf. An important property of such a decomposition is that the number of distinct heavy paths above any leaf (that is, intersecting the path from a leaf to the root) is only logarithmic in the size of T [51].

Let $\tilde{\Sigma}$ denote the set of all finite non-empty subsets of Σ^*. Previous works (cf. [35, 32, 12, 6, 48]) define $\tilde{\Sigma}$ as the set of all finite non-empty subsets of Σ^* excluding $\{\varepsilon\}$ but we waive here the latter restriction as it has no algorithmic implications. An *elastic-degenerate string*, or ED string, over alphabet Σ, is a string over $\tilde{\Sigma}$, i.e., an ED string is an element of $\tilde{\Sigma}^*$.

Let $\tilde{T}$ denote an ED string of *length* n, i.e. $|\tilde{T}| = n$. We assume that for any $1 \le i \le n$, the set $\tilde{T}[i]$ is implemented as an array and can be accessed by an index, i.e., $\tilde{T}[i] = \{\tilde{T}[i][k] \mid k = 1, \dots, |\tilde{T}[i]|\}$. For any $\tilde{c} \in \tilde{\Sigma}$, $||\tilde{c}||$ denotes the total length of all strings in $\tilde{c}$, and for any ED string $\tilde{T}$, $||\tilde{T}||$ denotes the total length of all strings in all $\tilde{T}[i]$s or the *size* of $\tilde{T}$, i.e., $||\tilde{c}|| = \sum_{s\in\tilde{c}} |s|$ and $||\tilde{T}|| = \sum_{i=1}^{n} ||\tilde{T}[i]||$. An ED string $\tilde{T}$ can be thought of as a representation of the set of strings $\mathcal{A}(\tilde{T}) = \tilde{T}[1] \times \dots \times \tilde{T}[n]$, where $A \times B = \{xy \mid x \in A, y \in B\}$ for any sets of strings A and B. For any ED string $\tilde{X}$ and a pattern P, we say that P *matches* $\tilde{X}$ if

1. $|\tilde{X}| = 1$ and P is a substring of some string in $\tilde{X}[1]$, or,
2. $|\tilde{X}| > 1$ and $P = P_1 \dots P_{|\tilde{X}|}$, where P_1 is a suffix of some string in $\tilde{X}[1]$, $P_{|\tilde{X}|}$ is a prefix of some string in $\tilde{X}[|\tilde{X}|]$, and $P_i \in \tilde{X}[i]$, for all $1 < i < |\tilde{X}|$.

We say that an *occurrence* of a string P *ends* at position j of an ED string $\tilde{T}$ if there exists $i \leq j$ such that P matches $\tilde{T}[i] \dots \tilde{T}[j]$. We will refer to string P as the *pattern* and to ED string $\tilde{T}$ as the *text*. We define the main problem considered in this paper.

Elastic-Degenerate String Matching (EDSM)
INPUT: A string P of length m and an ED string $\tilde{T}$ of length n and size $N \geq m$.
OUTPUT: All positions in $\tilde{T}$ where at least one occurrence of P ends.

▶ **Example 4.** Pattern $P = \texttt{GTAT}$ ends at positions 2, 6, and 7 of the following text $\tilde{T}$.

$$\tilde{T} = \{\ \texttt{ATGTA}\ \} \cdot \left\{ \begin{matrix} \texttt{A} \\ \texttt{T} \end{matrix} \right\} \cdot \{\ \texttt{C}\ \} \cdot \left\{ \begin{matrix} \texttt{G} \\ \texttt{T} \end{matrix} \right\} \cdot \{\ \texttt{CG}\ \} \cdot \left\{ \begin{matrix} \texttt{TA} \\ \texttt{TATA} \\ \varepsilon \end{matrix} \right\} \cdot \left\{ \begin{matrix} \texttt{TATGC} \\ \texttt{TTTTA} \end{matrix} \right\}$$

Aoyama et al. [6] obtained an on-line $\mathcal{O}(nm^{1.5}\sqrt{\log m} + N)$-time algorithm by designing an efficient solution for the following problem.

Active Prefixes (AP)
INPUT: A string P of length m, a bit vector U of size m, a set $\mathcal{S}$ of strings of total length N.
OUTPUT: A bit vector V of size m with $V[j] = 1$ if and only if there exists $S \in \mathcal{S}$ and $i \in [1, m], U[i] = 1$, such that $P[1\,..\,i] \cdot S = P[1\,..\,i + |S|]$ and $j = i + |S|$.

In more detail, given an ED text one should consider an instance of the AP problem per segment. Hence, an $\mathcal{O}(f(m) + N_i)$ solution for AP (with N_i being the size of the i-th segment of the ED text) implies an $\mathcal{O}(n \cdot f(m) + N)$ solution for EDSM, as $N = \sum_{i=1}^{n} N_i$. We provide an example of the AP problem.

▶ **Example 5.** Let $P = \texttt{ababbababab}$ of length $m = 11$, $U = 01000100000$, and $\mathcal{S} = \{\varepsilon, \texttt{ab}, \texttt{abb}, \texttt{ba}, \texttt{baba}\}$. We have that $V = 01011101010$.

For our hardness results we rely on BMM and the following closely related problem.

Boolean Matrix Multiplication (BMM)
INPUT: Two $\mathcal{N} \times \mathcal{N}$ Boolean matrices A and B.
OUTPUT: $\mathcal{N} \times \mathcal{N}$ Boolean matrix C, where $C[i, j] = \bigvee_k (A[i, k] \wedge B[k, j])$.

Triangle Detection (TD)
INPUT: Three $\mathcal{N} \times \mathcal{N}$ Boolean matrices A, B and C.
OUTPUT: Are there i, j, k such that $A[i, j] = B[j, k] = C[k, i] = 1$?

An algorithm is called *truly subcubic* if it runs in $\mathcal{O}(\mathcal{N}^{3-\epsilon})$ time, for some $\epsilon > 0$. TD and BMM either both have truly subcubic combinatorial algorithms, or none of them do [56].

3 EDSM Conditional Lower Bound

We show a conditional lower bound for the EDSM problem. Specifically, we show that TD can be reduced to the EDSM problem. We work with the decision version: the goal is to detect whether there exists at least one occurrence of P in $\tilde{T}$.

▶ **Theorem 1.** *If the EDSM problem can be solved in $\mathcal{O}(nm^{1.5-\epsilon}+N)$ time, for any $\epsilon>0$, with a combinatorial algorithm, then there exists a truly subcubic combinatorial algorithm for triangle detection.*

Proof. Consider an instance of TD, where we are given three $\mathcal{N}\times\mathcal{N}$ Boolean matrices A, B, C, and the question is to check if there exist i, j, k such that $A[i, j] = B[j, k] = C[k, i] = 1$. Let s be a parameter to be determined later that corresponds to decomposing B into blocks of size $(\mathcal{N}/s)\times(\mathcal{N}/s)$. We reduce to an instance of EDSM over an alphabet Σ of size $\mathcal{O}(\mathcal{N})$.

Pattern P. We construct P by concatenating, in some fixed order, the following strings:

$$P(i,x,y) = v(i)xa^{\mathcal{N}/s}x\$\$ya^{\mathcal{N}/s}yv(i)$$

for every $i=1,2,\ldots,\mathcal{N}$ and $x,y=1,2,\ldots,s$, where $a\in\Sigma_1$, $\$\in\Sigma_2$, $x\in\Sigma_3$, $y\in\Sigma_4$, $v(i)\in\Sigma_5$, and $\Sigma_1,\Sigma_2,\ldots,\Sigma_5$ are disjoint subsets of Σ.

ED text $\tilde{T}$. The text $\tilde{T}$ consists of three parts. Its middle part encodes all the entries equal to 1 in matrices A, B and C, and consists of three string sets $\mathcal{X}=\mathcal{X}_1\cdot\mathcal{X}_2\cdot\mathcal{X}_3$, where:

1. $\mathcal{X}_1$ contains all strings of the form $v(i)xa^j$, for some $i=1,2,\ldots,\mathcal{N}$, $x=1,2,\ldots,s$ and $j=1,2,\ldots,\mathcal{N}/s$ such that $A[i,(x-1)\cdot(\mathcal{N}/s)+j]=1$;
2. $\mathcal{X}_2$ contains all strings of the form $a^{\mathcal{N}/s-j}\ x\$\$ya^{\mathcal{N}/s-k}$, for some $x,y=1,2,\ldots,s$ and $j,k=1,2,\ldots,\mathcal{N}/s$ such that $B[(x-1)\cdot(\mathcal{N}/s)+j,(y-1)\cdot(\mathcal{N}/s)+k]=1$, i.e., if the corresponding entry of B is 1;
3. $\mathcal{X}_3$ contains all strings of the form $a^kyv(i)$, for some $i=1,2,\ldots,\mathcal{N}$, $y=1,2,\ldots,s$ and $k=1,2,\ldots,\mathcal{N}/s$ such that $C[(y-1)\cdot(\mathcal{N}/s)+k,i]=1$.

It is easy to see that $|P(i,x,y)|=\mathcal{O}(\mathcal{N}/s)$. This implies the following:

1. The length of the pattern is $m=\mathcal{O}(\mathcal{N}\cdot s^2\cdot\mathcal{N}/s)=\mathcal{O}(\mathcal{N}^2\cdot s)$;
2. The size of $\mathcal{X}$ is $||\mathcal{X}||=\mathcal{O}(\mathcal{N}\cdot s\cdot\mathcal{N}/s\cdot\mathcal{N}/s+s^2\cdot(\mathcal{N}/s)^2\cdot\mathcal{N}/s+\mathcal{N}\cdot s\cdot\mathcal{N}/s\cdot\mathcal{N}/s)=\mathcal{O}(\mathcal{N}^3/s)$.

By the above construction, we obtain the following fact.

▶ **Fact 6.** $P(i,x,y)$ matches $\mathcal{X}$ if and only if the following holds for some $j,k=1,2,\ldots,\mathcal{N}/s$:

$$A[i,(x-1)\cdot(\mathcal{N}/s)+j]=B[(x-1)\cdot(\mathcal{N}/s)+j,(y-1)\cdot(\mathcal{N}/s)+k]=C[(y-1)\cdot(\mathcal{N}/s)+k,i]=1.$$

Solving the TD problem thus reduces to taking the disjunction of all such conditions. Let us write down all strings $P(i,x,y)$ in some arbitrary but fixed order to obtain $P=P_1P_2\ldots P_z$ with $z=\mathcal{N}s^2$, where every $P_t=P(i,x,y)$, for some i,x,y. We aim to construct a small number of sets of strings that, when considered as an ED text, match any prefix $P_1P_2\ldots P_t$ of the pattern, $1\le t\le z-1$; a similar construction can be carried on to obtain sets of strings that match any suffix $P_k\ldots P_{z-1}P_z$, $2\le k\le z$. These sets will then be added to the left and to the right of $\mathcal{X}$, respectively, to obtain the ED text $\tilde{T}$.

ED Prefix. We construct $\log z$ sets of strings as follows. The first one contains the empty string ε and $P_1P_2\ldots P_{z/2}$. The second one contains ε, $P_1P_2\ldots P_{z/4}$ and $P_{z/2+1}\ldots P_{z/2+z/4}$. The third one contains ε, $P_1P_2\ldots P_{z/8}$, $P_{z/4+1}\ldots P_{z/4+z/8}$, $P_{z/2+1}\ldots P_{z/2+z/8}$ and $P_{z/2+z/4+1}\ldots P_{z/2+z/4+z/8}$. Formally, for every $i=1,2,\ldots,\log z$, the i-th of such sets is:

$$\tilde{T}_i^p=\varepsilon\cup\{P_{j\frac{z}{2^{i-1}}+1}\ldots P_{j\frac{z}{2^{i-1}}+\frac{z}{2^i}}\mid j=0,1,\ldots,2^{i-1}-1\}.$$

ED Suffix. We similarly construct $\log z$ sets to be appended to $\mathcal{X}$:

$$\tilde{T}_i^s = \varepsilon \cup \{P_{z-j\frac{z}{2^{i-1}}-\frac{z}{2^i}+1} \dots P_{z-j\frac{z}{2^{i-1}}} \mid j = 0, 1, \dots, 2^{i-1}-1\}.$$

The total length of all the ED prefix and ED suffix strings is $\mathcal{O}(\log z \cdot \mathcal{N}^2 \cdot s) = \mathcal{O}(\mathcal{N}^2 \cdot s \cdot \log \mathcal{N})$. The whole ED text $\tilde{T}$ is: $\tilde{T} = \tilde{T}_1^p \cdot \dots \cdot \tilde{T}_{\log z}^p \cdot \mathcal{X} \cdot \tilde{T}_{\log z}^s \cdot \dots \cdot \tilde{T}_1^s$.

▶ **Lemma 7.** *The pattern P occurs in the ED text $\tilde{T}$ if and only if there exist i, j, k such that $A[i, j] = B[j, k] = C[k, i] = 1$.*

Proof. By Fact 6, if such i, j, k exist then P_t matches $\mathcal{X}$, for some $t \in \{1, \dots, z\}$. Then, by construction of the sets $\tilde{T}_i^p$ and $\tilde{T}_i^s$, the prefix $P_1 \dots P_{t-1}$ matches the ED prefix (this can be proved by induction), and similarly the suffix $P_{t+1} \dots P_z$ matches the ED suffix, so the whole P matches $\tilde{T}$, and so P occurs in $\tilde{T}$. Because of the letters \$ appearing only in the center of P_is and strings from $\mathcal{X}_2$, every P_i and a concatenation of $X_1 \in \mathcal{X}_1$, $X_2 \in \mathcal{X}_2$, $X_3 \in \mathcal{X}_3$ having the same length, and the P_is being distinct, there is an occurrence of the pattern P in $\tilde{T}$ if and only if $X_1X_2X_3 = P_t$ for some t and $X_1 \in \mathcal{X}_1$, $X_2 \in \mathcal{X}_2$, $X_3 \in \mathcal{X}_3$. But then, by Fact 6 there exists a triangle. ◀

Note that for the EDSM problem we have $m = \mathcal{N}^2 \cdot s$, $n = 1 + 2\log z$ and $N = ||\mathcal{X}|| + \mathcal{O}(\mathcal{N}^2 \cdot \dots \cdot \log \mathcal{N})$. Thus if we had a solution running in $\mathcal{O}(\log z \cdot m^{1.5-\epsilon} + ||\mathcal{X}|| + \mathcal{N}^2 \cdot s \cdot \log \mathcal{N}) = \mathcal{O}(\log \mathcal{N} \cdot (\mathcal{N}^2 \cdot s)^{1.5-\epsilon} + \mathcal{N}^3/s)$ time, for some $\epsilon > 0$, by choosing a sufficiently small $\alpha > 0$ and setting $s = \mathcal{N}^\alpha$ we would obtain an $\mathcal{O}(\mathcal{N}^{3-\delta})$-time algorithm for TD, for some $\delta > 0$. ◀

4 An $\mathcal{O}(nm^{1.381} + N)$-time Algorithm for EDSM

Our goal is to design a non-combinatorial $\mathcal{O}(nm^{1.381} + N)$-time algorithm for EDSM. It suffices to solve an instance of the AP problem in $\mathcal{O}(m^{1.381} + N)$ time. We further reduce the AP problem to a logarithmic number of restricted instances of the problem, in which the length of every string $S \in \mathcal{S}$ is in $[(10/9)^k, (10/9)^{k+1})$, for $k = 0, \dots, \log m / \log(10/9)$. If we solve every such instance in $\mathcal{O}(f(m) + N)$ time, then we can solve the original instance in $\mathcal{O}(f(m) \log m + N)$ time by taking the disjunction of results. We partition the strings in $\mathcal{S}$ into three types, compute the corresponding bit vector V for each type separately and in different ways, and, finally, take the disjunction to obtain the answer for the restricted instance.

Partitioning S. Let $\ell = 8/9 \cdot (10/9)^k$ (to avoid clutter we assume that ℓ is an integer, but this can be avoided by appropriately adjusting the constants), so that the length of every string in S belongs to $[9/8 \cdot \ell, 5/4 \cdot \ell)$. The three types of strings are as follows:

Type 1: Strings $S \in \mathcal{S}$ such that every length-ℓ substring of S is not strongly periodic.

Type 2: Strings $S \in \mathcal{S}$ containing at least one length-ℓ substring that is not strongly periodic and at least one length-ℓ substring that is strongly periodic.

Type 3: Strings $S \in \mathcal{S}$ such that every length-ℓ substring of S is strongly periodic (in Lemma 8 we show that in this case $\mathrm{per}(S) \le \ell/4$).

These three types are evidently a partition of $\mathcal{S}$ and, before we proceed with the algorithm, we need to show that we can determine the type of a string $S \in \mathcal{S}$ in $\mathcal{O}(|S|)$ time. We start with showing that, in fact, strings of type 3 are exactly strings with period at most $\ell/4$.

▶ **Lemma 8.** *Let S be a string. If $\mathrm{per}(S[j \,..\, j + \ell - 1]) \le \ell/4$ for every j then $\mathrm{per}(S) \le \ell/4$.*

▶ **Lemma 9.** *Given a string S we can determine its type in $\mathcal{O}(|S|)$ time.*

4.1 Type 1 Strings

In this section we show how to solve a restricted instance of the AP problem where every string $S \in \mathcal{S}$ is of type 1, that is, each of its length-ℓ substrings is not strongly periodic, and furthermore $|S| \in [9/8 \cdot \ell, 5/4 \cdot \ell)$ for some $\ell \leq m$. Observe that all (hence at most $1/4 \cdot \ell$) length-ℓ substrings of any $S \in \mathcal{S}$ must be distinct, as otherwise we would be able to find two occurrences of a length-ℓ substring at distance at most $1/4 \cdot \ell$ in S, making the period of the substring at most $1/4 \cdot \ell$ and contradicting the assumption that S is of type 1.

We start with constructing the suffix tree ST of P (our pattern in the EDSM problem) in $\mathcal{O}(m \log m)$ time [53] (note that we are spending $\mathcal{O}(m \log m)$ time and not just $\mathcal{O}(m)$ as to avoid any assumptions on the alphabet). For every explicit node $u \in ST$, we construct a perfect hash function mapping the first letter on every edge outgoing from u to the corresponding edge. This takes $\mathcal{O}(m \log m)$ time [50] and allows us to navigate in ST in constant time per letter. Then, for every $S \in \mathcal{S}$ we check if it occurs in P using the suffix tree in $\mathcal{O}(|S|)$ time, and if not disregard it from further consideration. We want to further partition $\mathcal{S}$ into $\mathcal{S}_0, \mathcal{S}_1, \ldots, \mathcal{S}_{\log m}$ that are processed separately. For every $\mathcal{S}_k$, we want to select a set of length-ℓ substrings of P, called the *anchors*, each represented by one of its occurrences in P, such that:

1. The total number of occurrences of all anchors in P is $\mathcal{O}(m/\ell \cdot \log^2 m)$.
2. For every $S \in \mathcal{S}_k$, at least one of its length-ℓ substrings is an anchor.
3. For every $S \in \mathcal{S}_k$, at most $\mathcal{O}(\log^2 m)$ of its length-ℓ substrings are anchors.

We formalize this using the following auxiliary problem, which is a strengthening of the *hitting set* problem: for any collection of m sets over $[n]$, each of size at least k, we can choose a subset of $[n]$ of size $\mathcal{O}(n/k \cdot \log m)$ that nontrivially intersects every set.

Node Selection (NS)
INPUT: A bipartite graph $G = (U, V, E)$ with $\deg(u) \in [d, \alpha \cdot d]$ for every $u \in U$.
OUTPUT: A set of $\mathcal{O}(|V|/d \cdot \log |U|)$ nodes from V such that every node in U has at least one selected neighbor but $\mathcal{O}(\alpha \cdot \log |U|)$ such selected neighbors.

To reduce finding anchors to an instance of the NS problem, we first build a bipartite graph G in which the nodes on the left correspond to strings $S \in \mathcal{S}$, the nodes on the right correspond to distinct length-ℓ substrings of P, and there is an edge connecting a node corresponding to a length-ℓ string H with a node corresponding to a string S when H occurs in S. Using suffix links, we can find the node of the suffix tree corresponding to every length-ℓ substring of S in $\mathcal{O}(|S|)$ total time, so the whole construction takes $\mathcal{O}(m \log m + \sum_{S \in \mathcal{S}} |S|) = \mathcal{O}(m \log m + N)$ time. The size of G is $\mathcal{O}(m + N)$, and the degree of every node on its left belongs to $[1/8 \cdot \ell, 1/4 \cdot \ell)$. We further partition G into a logarithmic number of graphs $G_0, G_1, \ldots, G_{\log m}$ where G_k contains all nodes v on the right of G such that the number of occurrences in P of the corresponding length-ℓ string belongs to $[2^k, 2^{k+1})$. For every node u on the left of G we find k such that at least $1/8 \cdot \ell / \log m$ of its neighbors exist in G_k, add u as a node on the left of G_k, and declare $\mathcal{S}_k$ to consist of all strings $S \in \mathcal{S}$ corresponding to nodes on the left of G_k. By construction, every $S \in \mathcal{S}$ corresponds to a node on the left of exactly one G_k, so we indeed obtain a partition of $\mathcal{S}$. For every $\mathcal{S}_k$ we solve the corresponding instance of the NS problem to obtain its corresponding set of anchors. We can assume that all strings in $\mathcal{S}_k$ are distinct, so there are at most m^2 nodes on the left of G_k, the degree of each such node belongs to $[1/8 \cdot \ell / \log m, 1/4 \cdot \ell]$ and, denoting by m_k the total number of occurrences in P of strings corresponding to nodes on the right of G_k, we have $\sum_k m_k \leq m$ and there are at most $m_k/2^k$ nodes on the right of G_k. At most

$\mathcal{O}((m_k/2^k)/(\ell/\log m)\cdot\log m)$ nodes on the right of G_k are designated as anchors, making the total number of occurrences of all anchors $\mathcal{O}(m/\ell\cdot\log^2 m)$. Also, every $S\in\mathcal{S}_k$ contains an occurrence of at least one anchor, and no more than $\mathcal{O}(\log^2 m)$ such occurrences.

It is not immediately clear that an instance of the NS problem always has a solution. We show that indeed it does, and that it can be efficiently found with a Las Vegas algorithm.

▶ **Lemma 10.** *A solution to an instance of the NS problem always exists and can be found in expected linear time.*

Proof. We independently choose each node of V with probability p to obtain the set X of selected nodes. Then, we check if the size of X is small enough, every node in U has at least one selected neighbor, and $\mathcal{O}(\alpha\cdot\log|U|)$ such selected neighbors. All these checks can be made in linear time in the size of the graph, so to show that a solution exists and can be found in expected linear time, it remains to show that we can adjust p to make the probability of failure equal to a constant less than 1. The expected size of X is obviously $p|V|$, so by Markov's inequality the probability that $|X|>4p|V|$ is at most $1/4$. The probability that a node in U has no neighbors in X is at most $(1-p)^d$. Thus, by union bound the probability that there exists at least one such node is at most $|U|\cdot(1-p)^d\le|U|\cdot e^{-pd}$. Consider a node in U of degree $d'\in[d,\alpha\cdot d]$. Its expected number of selected neighbors is pd'. Thus, by Chernoff's inequality the probability that its number of selected neighbors exceeds $(1+\delta)pd'$ is at most $e^{-\frac{\delta^2}{2+\delta}pd'}$. By setting $\delta=1$, we obtain that the probability of the number of selected neighbors exceeding $2p\alpha d$ is at most $e^{-\frac{1}{3}\alpha pd}$. By union bound, the probability that this happens for at least one node is at most $|U|\cdot e^{-\frac{1}{3}\alpha pd}$.

We choose $p=3\ln(4|U|)/d$. Then, the probability that the size of X exceeds $4p|V|=12\ln(4|U|)/d\cdot|V|=\mathcal{O}(\frac{|V|}{d}\cdot\log|U|)$ is at most $1/4$, the probability that there exists a node in U with no selected neighbor is at most $|U|\cdot e^{-pd}\le 1/4$, and the probability that there exists a node in U with more than $2p\alpha d=\mathcal{O}(\alpha\cdot\log|U|)$ selected neighbors is at most $|U|\cdot e^{-\frac{1}{3}\alpha pd}\le 1/4$, thus the overall probability of failure is at most $3/4$ as required. ◀

In the rest of this section we explain how to compute the bit vector V from the bit vector U after having obtained a set $\mathcal{A}$ of anchors for a set of strings $\mathcal{S}_k$ of total length N_k. For any $S\in\mathcal{S}_k$, since S contains an occurrence of at least one anchor $H\in\mathcal{A}$, for concreteness $S[j\,..\,(j+|H|-1)]=H$, any occurrence of S in P can be generated by choosing some occurrence of H in P, say $P[i\,..\,(i+|H|-1)]=H$, and then checking that $S[1\,..\,(j-1)]=P[(i-j+1)\,..\,(i-1)]$ and $S[(j+|H|)\,..\,|S|]=P[(i+|H|)\,..\,(i+|S|-j)]$. In other words, $S[1\,..\,(j-1)]$ should be a suffix of $P[1\,..\,(i-1)]$ and $S[(j+|H|)\,..\,|S|]$ should be a prefix of $P[(i+|H|)\,..\,|P|]$. In such case, we say that the occurrence of S in P is generated by H. By the properties of $\mathcal{A}$, any occurrence of $S\in\mathcal{S}_k$ is generated by at least one but no more than $\mathcal{O}(\log^2 m)$ anchors. For every $H\in\mathcal{A}$ we create a separate data structure $D(H)$ responsible for setting $V[i+|S|-1]=1$ if $U[i-1]=1$ and $P[i\,..\,(i+|S|-1)]=S$ is generated by H. We separately describe what information is used to initialize each $D(H)$ and how it is later processed to update V.

Initialization. $D(H)$ consists of two compact tries $T(H)$ and $T^r(H)$. For every occurrence of H in P, denoted by $P[i\,..\,(i+|H|-1)]=H$, $T(H)$ should contain a leaf corresponding to $P[(i+|H|)\,..\,|P|]\$$ and $T^r(H)$ should contain a leaf corresponding to $(P[1\,..\,(i-1)])^r\$$, both decorated with position i. Additionally, $D(H)$ stores a list $L(H)$ of pairs of nodes (u,v), where $u\in T^r(H)$ and $v\in T(H)$. Each such pair corresponds to an occurrence of H in a string $S\in\mathcal{S}_k$, $S[j\,..\,(j+|H|-1)]=H$, where u is the node of $T^r(H)$ corresponding to $(S[1\,..\,(j-1)])^r\$$ and v is the node of $T(H)$ corresponding to $S[(j+|H|+1)\,..\,|S|]\$$. We claim that $D(H)$, for all H, can be constructed in $\mathcal{O}(m\log m+N_k)$ total time.

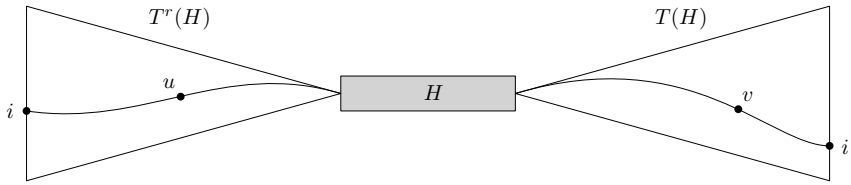

Figure 1 An occurrence of S starting at position i in P is generated by H: (u, v) corresponds to $S[j\,..\,(j+|H|-1)] = H$ and i appears in the subtree rooted at u as well as the subtree rooted at v.

We first construct the suffix tree ST of P and the suffix tree ST^r of P^r in $\mathcal{O}(m \log m)$ time. We augment both trees with a structure for answering *weighted ancestor* (WA) and *lowest common ancestor* (LCA) queries that are defined as follows. For a rooted tree T on n nodes with an integer weight $\mathcal{D}(v)$ assigned to every node u, such that the weight of the root is zero and $\mathcal{D}(u) < \mathcal{D}(v)$ if u is the parent of v, we say that a node v is a weighted ancestor of a node v at depth ℓ, denoted by $\mathrm{WA}_T(u, \ell)$, if v is the highest ancestor of u with weight of at least ℓ. Such queries can be answered in $\mathcal{O}(\log n)$ time after an $\mathcal{O}(n)$-time preprocessing [25]. For a rooted tree T, $\mathrm{LCA}_T(u, v)$ is the lowest node that is an ancestor of both u and v. Such queries can be answered in $\mathcal{O}(1)$ time after an $\mathcal{O}(n)$-time preprocessing [10]. Recall that every anchor H is represented by one of its occurrences in P. Using WA queries, we can access in $\mathcal{O}(\log m)$ time the nodes corresponding to H and H^r, respectively, and extract a lexicographically sorted list of suffixes following an occurrence of H in $P\$$ and a lexicographically sorted list of reversed prefixes preceding an occurrence of H in $P^r\$$ in time proportional to the number of such occurrences. Then, by iterating over the lexicographically sorted list of suffixes and using LCA queries on ST we can build $T(H)$ in time proportional to the length of the list, and similarly for $T^r(H)$. To construct $L(H)$ we start by computing, for every $S \in \mathcal{S}_k$ and $j = 1, \ldots, |S|$, the node of ST^r corresponding to $(S[1\,..\,j])^r$ and the node of ST corresponding to $S([(j+1)\,..\,|S|]$ (the nodes might possibly be implicit). Using suffix links this takes only $\mathcal{O}(|S|)$ time. We also find, for every length-ℓ substring $S[j\,..\,(j+\ell-1)]$ of S, an anchor $H \in \mathcal{A}$ such that $S[j\,..\,(j+\ell-1)] = H$, if any exists. This can be done by finding the nodes (implicit or explicit) of ST that correspond to the anchors, and then scanning over all length-ℓ substrings while maintaining the node of ST corresponding to the current substring using suffix links in $\mathcal{O}(|S|)$ total time. After having determined that $S[j\,..\,(j+\ell-1)] = H$ we add (u, v) to $L(H)$, where u and v are the previously found nodes of ST^r and ST corresponding to $(S[1\,..\,(j-1)])^r$ and $S[(j+\ell)\,..\,|S|]$, respectively. By construction, we have the following property, also illustrated in Figure 1.

▶ **Fact 11.** A string $S \in \mathcal{S}_k$ starts at position $i - j + 1$ in P if and only if, for some anchor $H \in \mathcal{A}$, $L(H)$ contains a pair (u, v) corresponding to $S[j\,..\,(j+|H|-1)] = H$, such that the subtree of $T^r(H)$ rooted at u and that of $T(H)$ rooted at v contain a leaf decorated with i.

Note that the overall size of all lists $L(H)$, when summed up over all $H \in \mathcal{A}$, is $\mathcal{O}(N_k/\ell \cdot \log^2 m)$, because any $S \in \mathcal{S}_k$ contains $\mathcal{O}(\log^2 m)$ occurrences of anchors, and since each S is of length at least ℓ, there are only $\mathcal{O}(N_k/\ell)$ strings in $\mathcal{S}_k$.

Processing. The goal of processing $D(H)$ is to efficiently process all occurrences generated by H. As a preliminary step, we decompose $T^r(H)$ and $T(H)$ into heavy paths. Then, for every pair of leaves $u \in T^r(H)$ and $v \in T(H)$ decorated by the same i, we consider all heavy paths above u and v. Let $p = u_1 - u_2 - \ldots$ be a heavy path above u in $T^r(H)$ and $q = v_1 - v_2 - \ldots$ be a heavy path above v in $T(H)$, where u_1 is the head of p and v_1 is the

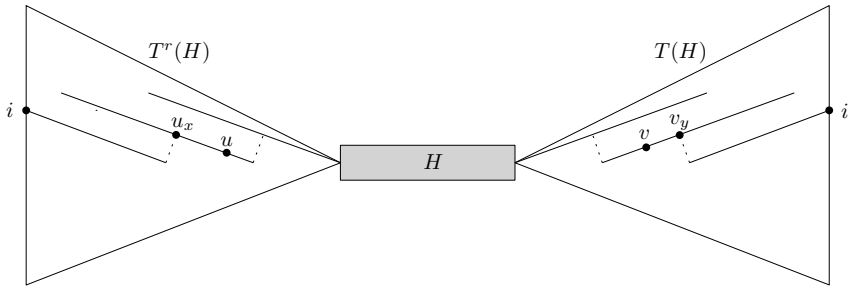

Figure 2 An occurrence of S starting at position i in P corresponds to a triple $(i, \mathcal{L}(u_x), \mathcal{L}(v_y))$ on some auxiliary list.

head of q, respectively. Further, choose the largest x such that u is in the subtree rooted at u_x, and the largest y such that v is in the subtree rooted at v_y (by the choice of p and q, u is in the subtree rooted at u_1 and v is in the subtree rooted at v_1, so this is well-defined). We add $(i, |\mathcal{L}(u_x)|, |\mathcal{L}(v_y)|)$ to an auxiliary list associated with the pair of heavy paths (p, q). In the rest of the processing we work with each such list separately. Notice that the overall size of all auxiliary lists, when summed up over all $H \in \mathcal{A}$, is $\mathcal{O}(m/\ell \cdot \log^4 m)$, because there are at most $\log^2 m$ pairs of heavy paths above u and v decorated by the same i, and the total number of leaves in all trees $T^r(H)$ and $T(H)$ is bounded by the total number of occurrences of all anchors in P, which is $\mathcal{O}(m/\ell \cdot \log^2 m)$. By Fact 11, there is an occurrence of a string $S \in \mathcal{S}_k$ generated by H and starting at position $i - j + 1$ in P if and only if $L(H)$ contains a pair (u, v) corresponding to $S[j\,..\,(j + |H| - 1)] = H$ such that, denoting by p the heavy path containing u in $T^r(H)$ and by q the heavy path containing v in $T(H)$, the auxiliary list associated with (p, q) contains a triple (i, x, y) such that $x \geq |\mathcal{L}(u)|$ and $y \geq |\mathcal{L}(v)|$. This is illustrated in Figure 2. From now on we focus on processing a single auxiliary list associated with (p, q) together with a list of pairs (u, v) such that u belongs to p and v belongs to q.

An auxiliary list can be interpreted geometrically: for every (i, x, y) we create a red point (x, y), and for every (u, v) we create a blue point $(|\mathcal{L}(u)|, |\mathcal{L}(v)|)$. Then, each occurrence of $S \in \mathcal{S}_k$ generated by H corresponds to a pair of points (p_1, p_2) such that p_1 is red, p_2 is blue, and p_1 dominates p_2. We further reduce this to a collection of simpler instances in which all red points already dominate all blue points. This can be done with a divide-and-conquer procedure which is essentially equivalent to constructing a 2D range tree [11]. The total number of points in all obtained instances increases by a factor of $\mathcal{O}(\log^2 m)$, making the total number of red points in all instances $\mathcal{O}(m/\ell \cdot \log^6 m)$, while the total number of blue points is $\mathcal{O}(N_k/\ell \cdot \log^4 m)$. There is an occurrence of a string $S \in \mathcal{S}_k$ generated by H and starting at position $i - j + 1$ in P if and only if some simpler instance contains a red point created for some (i, x, y) and a blue point created for some (u, v) corresponding to $S[j\,..\,(j + |H| - 1)] = H$. In the following we focus on processing a single simpler instance.

To process a simpler instance we need to check if $U[i - j] = 1$, for a red point created for some (i, x, y) and a blue point created for some (u, v) corresponding to $S[j\,..\,(j+|H|-1)] = H$, and if so set $V[i - j + |S|] = 1$. This has a natural interpretation as an instance of BMM: we create an $(5/4 \cdot \ell) \times (5/4 \cdot \ell)$ matrix M such that $M[|S| - j, 5/4 \cdot \ell + 1 - j] = 1$ if and only if there is a blue point created for some (u, v) corresponding to $S[j\,..\,(j+|H|-1)] = H$; then for every red point created for some (i, x, y) we construct a bit vector $U_i = U[(i - 5/4 \cdot \ell)\,..\,(i - 1)]$ (if $i < 5/4 \cdot \ell$, we pad U_i with 0s to make its length always equal to $5/4 \cdot \ell$); calculate $V_i = M \times U_i$; and finally set $V[i + j] = 1$ whenever $V_i[j] = 1$ (and $i + j \leq m$).

▶ **Lemma 12.** *$V_i[k] = 1$ if and only if there is a blue point created for some (u, v) corresponding to $S[j\,..\,(j + |H| - 1)] = H$ such that $U[i - j] = 1$ and $k = |S| - j$.*

The total length of all vectors U_i and V_i is $\mathcal{O}(m \log^6 m)$, so we can afford to extract the appropriate fragment of U and then update the appropriate fragment of V. The bottleneck is computing the matrix-vector product $V_i = M \times U_i$. Naïvely, this might take $\mathcal{O}(N_k/\ell \cdot \log^4 m)$ time, because the total number of 1s in all matrices M is bounded by the total number of blue points. We overcome this by processing together all multiplications concerning the same matrix M. Let $U_{i_1}, U_{i_2}, \ldots, U_{i_s}$ be all bit vectors that need to be multiplied with M, and z a parameter to be determined later. We distinguish between two cases: (i) If $\boldsymbol{s < z}$ we compute the products naïvely by iterating over all 1s in M, and the total computation time, when summed up over all such matrices M, is $\mathcal{O}(N_k/\ell \cdot \log^4 m \cdot z)$; (ii) If $\boldsymbol{s \geq z}$ we partition the bit vectors into $\lceil s/z \rceil \leq s/z + 1$ groups of z (padding the last group with bit vectors containing all 0s). For every group, we create a single matrix whose columns contain all the bit vectors belonging to the group. Thus, we reduce computing all matrix-vector products $M \times U_i$ to computing $\mathcal{O}(s/z)$ matrix-matrix products of the form $M \times M'$, where M' is an $(5/4 \cdot \ell) \times z$ matrix. M' is not necessarily a square matrix, but we can still apply the fast matrix multiplication algorithm to compute $M \times M'$ using the standard trick of decomposing the matrices into square blocks.

▶ **Lemma 13.** *If two $\mathcal{N} \times \mathcal{N}$ matrices can be multiplied in $\mathcal{O}(\mathcal{N}^\omega)$ time, then, for any $\mathcal{N} \geq \mathcal{N}'$, an $\mathcal{N} \times \mathcal{N}$ and an $\mathcal{N} \times \mathcal{N}'$ matrix can be multiplied in $\mathcal{O}((\mathcal{N}/\mathcal{N}')^2 \mathcal{N}'^\omega)$ time.*

By applying Lemma 13, we can compute $M \times M'$ in $\mathcal{O}(\ell^2 z^{\omega-2})$ time (as long as we later verify that $5/4 \cdot \ell \geq z$), so all products $M \times U_i$ can be computed in $\mathcal{O}(\ell^2 z^{\omega-2} \cdot (s/z + 1))$ time. Note that this case can occur only $\mathcal{O}(m/(\ell \cdot z) \cdot \log^6 m)$ times, because all values of s sum up to $\mathcal{O}(m/\ell \cdot \log^6 m)$. This makes the total computation time, when summed up over all such matrices M, $\mathcal{O}(\ell^2 z^{\omega-2} \cdot m/(\ell \cdot z) \cdot \log^6 m) = \mathcal{O}(\ell z^{\omega-3} \cdot m \log^6 m)$.

▶ **Theorem 14.** *An instance of the AP problem where all strings are of type 1 can be solved in expected $\mathcal{O}(m^{1.373} + N)$ time.*

Proof. The total time complexity is first $\mathcal{O}(m + N)$ to construct the graph G and then all graphs G_k, then expected linear time to solve their corresponding instances of the NodeSelection problem, partition $\mathcal{S}$ into $\mathcal{S}_0, \mathcal{S}_1, \ldots, \mathcal{S}_{\log m}$ and obtain their corresponding sets of anchors H. The time to initialize all structures $D(H)$ is $\mathcal{O}(m \log m + N_k)$. For every $D(H)$, we obtain in $\mathcal{O}(m/\ell \cdot \log^6 m + N_k/\ell \cdot \log^4 m)$ time a number of simpler instances, and then construct the corresponding Boolean matrices M and bit vectors U_i in additional $\mathcal{O}(m \log^6 m)$ time. Note that some M might be sparse, so we need to represent them as a list of 1s. Then, summing up over all matrices M and both cases, we spend $\mathcal{O}(N_k/\ell \cdot \log^4 m \cdot z + \ell z^{\omega-3} \cdot m \log^6 m)$ time. We would like to assume that $\ell \geq \log^4 m$ so that we can set $z = \ell/\log^4 m$. This is indeed possible, because for any t we can switch to a more naïve approach to process all strings of length at most t in $\mathcal{O}(mt^2 + N_k)$ time: for every possible length $t' \leq t$ scan P with a window of length t', in every step check if the current window $P[i\,..\,(i+t'-1)]$ corresponds to a string $S \in \mathcal{S}$, if so and $U[i-1] = 1$ then set $V[i+t'-1] = 1$. After applying this with $t = \log^4 m$ in $\mathcal{O}(m \log^8 m + N_k)$ time, we can set $z = \ell/\log^4 m$ (so that indeed $5/4 \cdot \ell \geq z$ as required in case $s \geq z$) and the overall time complexity for all matrices M and both cases becomes $\mathcal{O}(N_k + \ell^{\omega-2} \cdot m \log^{6+4(3-\omega)} m)$. Summing up over all values of k and ℓ and taking the initialization into account we obtain $\mathcal{O}(m \log^8 m + m^{\omega-1} \log^{7+4(3-\omega)} m + N) = \mathcal{O}(m^{1.373} + N)$ total time. (We hide $\log^{\mathcal{O}(1)} m$ factors using the fact that $\omega < 2.373$ [30, 54]). ◀

4.2 Wrapping Up

In the full version of the paper we design $\mathcal{O}(m^{1.373} + N)$ and $\mathcal{O}(m^{1.381} + N)$-time algorithms for an instance of the AP problem where all strings are of type 2 and 3, respectively. For type 2 strings, we follow the same ideas as for type 1 strings, except that instead of the NodeSelection problem we select the anchors by applying a periodicity-based argument. For type 3 strings, we need both fast matrix multiplication and FFT. Together with Theorem 14, this gives us Theorem 2.

Abstract

We study the problem of approximating the value of the matching polynomial on graphs with edge parameter γ, where γ takes arbitrary values in the complex plane.

When γ is a positive real, Jerrum and Sinclair showed that the problem admits an FPRAS on general graphs. For general complex values of γ, Patel and Regts, building on methods developed by Barvinok, showed that the problem admits an FPTAS on graphs of maximum degree Δ as long as γ is not a negative real number less than or equal to $-1/(4(\Delta-1))$. Our first main result completes the picture for the approximability of the matching polynomial on bounded degree graphs. We show that for all $\Delta \geq 3$ and all real γ less than $-1/(4(\Delta-1))$, the problem of approximating the value of the matching polynomial on graphs of maximum degree Δ with edge parameter γ is #P-hard.

We then explore whether the maximum degree parameter can be replaced by the connective constant. Sinclair et al. showed that for positive real γ it is possible to approximate the value of the matching polynomial using a correlation decay algorithm on graphs with bounded connective constant (and potentially unbounded maximum degree). We first show that this result does not extend in general in the complex plane; in particular, the problem is #P-hard on graphs with bounded connective constant for a dense set of γ values on the negative real axis. Nevertheless, we show that the result does extend for any complex value γ that does not lie on the negative real axis. Our analysis accounts for complex values of γ using geodesic distances in the complex plane in the metric defined by an appropriate density function.

1 Introduction

We study the problem of approximating the matching polynomial of a graph. This polynomial has a parameter γ, called the edge activity. A *matching* of a graph G is a set $M \subseteq E(G)$ such that each vertex $v \in V(G)$ is contained in at most one edge in M. We denote by $\mathcal{M}_G$ the set of all matchings of G. The matching polynomial $Z_G(\gamma)$ is given by

$$Z_G(\gamma) = \sum_{M \in \mathcal{M}_G} \gamma^{|M|}.$$

This polynomial is also referred to as the partition function of the *monomer-dimer model* in statistical physics.

Here is what is known about approximating this polynomial. We first describe the case where γ is positive and real. This is a natural case, and is the case where the first complexity-theoretic results were obtained. We next describe the more general case, where γ is a complex number. There are many reasons for considering the more general case. The parameter γ is defined to be complex, rather than real, in the classic paper of Heilmann and Lieb [8]. Furthermore, it has recently been shown [15] that the quantum evolution of a system originally in thermodynamic equilibrium is equivalent to the partition function of the system with a complex parameter. As [15] explains, recent discoveries in physics make it possible to study thermodynamics in the complex plane of physical parameters – so complex parameters are increasingly relevant. As we will see in this paper, it is beneficial to study partition functions with complex parameters even when one is most interested in the real case – the reason is that the generalisation sheds light on "what is really going on" with complexity bottlenecks, and on appropriate potential functions. Here is the summary of known results in both cases.

- **When the edge activity γ is a positive real number:** For any positive real number γ, Jerrum and Sinclair [9, Corollary 4.4] gave an FPRAS for approximating $Z_G(\gamma)$. Using the correlation decay technique, Bayati et al. [3] gave a (deterministic) FPTAS for the same problem for the case in which the degree of the input graph G is at most a constant Δ.
- **When the edge activity γ is a complex number:** Known results are restricted to the case where γ is not a real number less than or equal to $-1/(4(\Delta-1))$. In this case, there is a positive result, due to Patel and Regts [11]. Using a method of Barvinok [1, 2] for approximating a partition function by truncating its Taylor series (in a region where the partition function has no zeroes), Patel and Regts [11, Theorem 1.2] extended the positive result of Bayati et al. to the case in which γ is a complex number that is not a negative real that is less than $-1/(4(\Delta-1))$, see also [2, Section 5.1.7]). Patel and Regts obtained a polynomial time algorithm (rather than a quasi-polynomial time one) by developing clever methods for exactly computing coefficients of the Taylor series.

Our first contribution completes this picture by showing that for all $\Delta \geq 3$ and all real $\gamma < -1/(4(\Delta-1))$ it is actually #P-hard to approximate $Z_G(\gamma)$ on graphs with degree at most Δ. We use the following notation to state our result more precisely. We consider the problems of multiplicatively approximating the norm of $Z_G(\gamma)$, and of computing its sign. Our first theorem shows that, for all $\Delta \geq 3$ and all rational numbers $\gamma < -1/(4(\Delta-1))$, it is #P-hard to approximate $|Z_G(\gamma)|$ on bipartite graphs of maximum degree Δ within a constant factor.

▶ **Theorem 1.** *Let $\Delta \geq 3$ and $\gamma < -\frac{1}{4(\Delta-1)}$ be a rational number. Then, it is #P-hard to approximate $|Z_G(\gamma)|$ within a factor of 1.01 on graphs G of maximum degree Δ, even when restricted to bipartite graphs G with $Z_G(\gamma) \neq 0$.*

The number 1.01 in Theorem 1 is not important. It can be replaced with any constant greater than 1. In fact, for any fixed $\epsilon > 0$, the theorem, together with a standard powering argument, shows that it is #P-hard to approximate $Z_G(\gamma)$ within a factor of $2^{|V(G)|^{1-\epsilon}}$.

Our second theorem shows that it is #P-hard to compute the sign of $Z_G(\gamma)$ on bipartite graphs of maximum degree Δ.

▶ **Theorem 2.** *Let $\Delta \geq 3$ and $\gamma < -\frac{1}{4(\Delta-1)}$ be a rational number. Then, it is #P-hard to decide whether $Z_G(\gamma) > 0$ on graphs G of maximum degree Δ, even when restricted to bipartite graphs G with $Z_G(\gamma) \neq 0$.*

We next explore whether the bound on the maximum degree of G can be relaxed to a restriction on average degree. The notion of average degree that we use is the *connective constant*. Given a graph G, and a vertex v, let $N_G(v,k)$ be the number of k-edge paths in G that start from v. The following definition is taken almost verbatim from [13, 14].[1]

▶ **Definition 3** ([13, 14])**.** *Let $\mathcal{F}$ be a family of finite graphs and let Δ, a and c be positive real numbers. The connective constant of $\mathcal{F}$ is at most Δ with profile (a,c) if, for any graph $G=(V,E)$ in $\mathcal{F}$ and any vertex v in G, it holds that $\sum_{k=1}^{\ell} N_G(v,k) \leq c\Delta^{\ell}$ for all $\ell \geq a \log |V|$.*

Sinclair, Srivastava, Štefankovič and Yin [13, Theorem 1.3] showed that, for fixed Δ, when γ is a positive real, the correlation decay method gives an FPTAS for approximating $Z_G(\gamma)$ on graphs G with connective constant at most Δ (without any bound on the maximum degree of G). The run-time of their algorithm is $(n/\epsilon)^{\mathrm{O}(\sqrt{\gamma\Delta}\log\Delta)}$, where n is the number of vertices of G and ϵ is the relative error.

Our next result shows that, in striking contrast to the bounded-degree case, the algorithmic result of Sinclair et al. cannot be extended to negative reals, even if $\gamma \geq -1/(4(\Delta-1))$. Given positive real numbers a and c and a real number $\Delta > 1$, let $\mathcal{F}_{\Delta,a,c}$ be the set of graphs with connective constant at most Δ and profile (a,c).

▶ **Theorem 4.** *There exist a dense set of values γ on the negative real axis such that the following holds for any real numbers $\Delta > 1$ and all $a, c > 0$.*

1. *It is #P-hard to approximate $|Z_G(\gamma)|$ within a factor 1.01 on graphs $G \in \mathcal{F}_{\Delta,a,c}$,*
2. *it is #P-hard to decide whether $Z_G(\gamma) > 0$ on graphs $G \in \mathcal{F}_{\Delta,a,c}$.*

Both of these results hold even when restricted to bipartite graphs G with $Z_G(\gamma) \neq 0$.

[1] The only difference between Definition 3 and the corresponding definitions in [13, 14] is the addition of the terminology "profile (a,c)" which will be used to state our hardness results in a strong form (the results in [13, 14] were algorithmic which is why this handle on the constants a and c was not required).

The algorithmic contribution of our paper is to show that, despite the hardness result of Theorem 4, correlation decay gives a good approximation algorithm for any complex value γ that does not lie on the negative real axis when the input graph has bounded connective constant. It is interesting that we are able to use correlation decay to get a good approximation for all non-real complex values γ. Our result is the only known approximation in this setting. In particular, it is not known how to obtain such a result using the method of Patel and Regts [11]. In order to describe our result, we use the following notation. Given a complex number x, let $\arg(x)$ denote the principal value of its argument in the range $[0, 2\pi)$ and $|x|$ denote its norm. Our result is the following.

▶ **Theorem 5.** *Let Δ, a and c be positive real numbers and let $\gamma \in \mathbb{C} \setminus \mathbb{R}_{<0}$ be any fixed edge activity. Then there is an algorithm which takes as input an n-vertex graph $G \in \mathcal{F}_{\Delta,a,c}$ and a rational $\epsilon \in (0,1)$ and produces an output $\hat{Z} = Z_G(\gamma)\mathrm{e}^z$ for some complex number z with $|z| \leq \epsilon$. The running time of the algorithm is $(\hat{c}n/\epsilon)^{O\left((1+a+\sqrt{|\hat{\gamma}|\Delta})\log\Delta\right)}$ where $\hat{\gamma} = \frac{2|\gamma|}{1+\cos(\arg\gamma)}$ and $\hat{c} = \max\{1, c\}$.*

Theorem 5 gives an algorithmic result which contrasts with the hardness results of Theorems 1 and 2. It has the following corollary.

▶ **Corollary 6.** *Let Δ, a and c be positive real numbers and let $\gamma \in \mathbb{C} \setminus \mathbb{R}_{<0}$ be any fixed edge activity. Then, for any rational $K > 1$ and any positive rational ρ, there are polynomial-time algorithms to take as input a graph $G \in \mathcal{F}_{\Delta,a,c}$ and approximate $|Z_G(\gamma)|$ within a multiplicative factor of K and $\arg(Z_G(\gamma))$ within an additive error ρ.*

In order to prove Theorem 5, showing correlation decay for complex γ, we use geodesic distances in the complex plane in the metric defined by an appropriate density function. Correlation decay for complex activities has been analysed in the context of the hard-core model (see Harvey, Srivastava and Vondrák [7])[2]. The region in the complex plane in which the authors of [7] worked allowed them to measure distances using the norm instead of requiring geodesic distances. An alternative approach was given by Peters and Regts [12], again in the context of the hard-core model, where they showed contraction within the basin of an attracting fixpoint using the theory of complex dynamical systems.

2 Preliminaries

Let γ be a complex number and $G = (V, E)$ be an arbitrary graph. Recall that $\mathcal{M}_G$ is the set of matchings of G. For a matching $M \in \mathcal{M}_G$, we denote by $\mathsf{ver}(M)$ the set of matched vertices in the matching M. For a vertex u in G, we also define

$$Z_{G,u}(\gamma) := \sum_{M \in \mathcal{M}_G;\, u \in \mathsf{ver}(M)} \gamma^{|M|} \quad \text{and} \quad Z_{G,\neg u}(\gamma) := \sum_{M \in \mathcal{M}_G;\, u \notin \mathsf{ver}(M)} \gamma^{|M|}.$$

Thus, $Z_{G,u}(\gamma)$ is the contribution to the partition function $Z_G(\gamma)$ from those matchings $M \in \mathcal{M}_G$ such that u is matched in M, while $Z_{G,\neg u}(\gamma)$ is the contribution to the partition function $Z_G(\gamma)$ from those matchings $M \in \mathcal{M}_G$ such that u is not matched in M.

We will use the following result about the location of the zeroes of the matching polynomial.

[2] Note that Harvey et al were actually working with the mutivariate hard-core polynomial – this causes interesting complications which will not be relevant for this paper. They also extend their method (for the hard-core polynomial, in their region) to graphs of unbounded degree that have bounded connective constant.

▶ **Theorem 7** ([8], see, e.g., [2, Theorem 5.1.2]). *Let $\Delta \geq 3$ be an integer and G be a graph of maximum degree Δ. Then, for all complex γ that do not lie on the interval $(-\infty, -\frac{1}{4(\Delta-1)})$ of the negative real axis, it holds that $Z_G(\gamma) \neq 0$.*

▶ **Corollary 8.** *Let $\Delta \geq 3$ be an integer and $\gamma > -\frac{1}{4(\Delta-1)}$ be a real number. Then, for all graphs G of maximum degree Δ it holds that $Z_G(\gamma) > 0$.*

For our approximation algorithm of Theorem 5, given a graph $G = (V, E)$ with $Z_G(\gamma) \neq 0$ and a vertex $v \in V$, we will be interested in the quantity

$$p_v(G, \gamma) := Z_{G,\neg v}(\gamma)/Z_G(\gamma).$$

The algorithm will be based on the following result by Godsil.

▶ **Theorem 9** ([6]). *Let $\gamma \in \mathbb{C}\backslash\mathbb{R}_{<0}$. Let $G = (V, E)$ be a graph and let $v \in V$ be one of its vertices. Let $T_{SAW}(v, G)$ be the self-avoiding walk tree of G rooted at v. Then,*

$$p_v(G, \gamma) = p_v(T_{SAW}(v, G), \gamma).$$

3 FPTAS for graphs with bounded connective constant

In this section, we prove Theorem 5. Consider $\gamma \in \mathbb{C}\backslash\mathbb{R}_{<0}$.

We will use the correlation decay technique of Weitz [16], which we adapt for use with complex activities. We review the basic idea behind the technique (see, e.g., [3, 14, 13]). For a graph G (of bounded connective constant), we first express $Z_G(\gamma)$ as a telescoping product

$$Z_G(\gamma) = 1/\prod_{i=1}^{n} p_{v_j}(G_j, \gamma) \tag{1}$$

where $v_1, \ldots, v_n$ is an arbitrary enumeration of the vertices of the graph G and G_j is the graph obtained from G by deleting the vertices $v_1, \ldots, v_j$. In light of (1), we can therefore focus on approximating the value $p_v(G, \gamma)$ for a graph G and vertex v. Using Godsil's Theorem (cf. Theorem 9), it in turn suffices to approximate $p_v(T_{SAW}(v, G), \gamma)$. This might seem as a somewhat simpler task given that $T_{SAW}(v, G)$ is a tree; the caveat however is that the tree $T_{SAW}(v, G)$ is prohibitively large, so in order to be able to perform computations efficiently we need to truncate the tree. The correlation decay technique analyses the approximation error introduced by this truncation process by recursively tracking the error using tree recurrences.

In the case of matchings, for a tree T and a vertex v in T, we can write a recursion for $p_v(T, \gamma)$ as follows. If v is the only vertex in T, then $p_v(T, \gamma) = 1$ (since the only possible matching is the empty set and thus $Z_{T,\neg v}(\gamma) = Z_T(\gamma) = 1$). Otherwise, let $T_1, \ldots, T_d$ be the trees of $T\backslash\{v\}$ and let $v_1, \ldots, v_d$ be the neighbours of v in $T_1, \ldots, T_d$, respectively. Then, we have that

$$Z_{T,\neg v}(\gamma) = \prod_{i=1}^{d} Z_{T_i}(\gamma), \quad Z_T(\gamma) = \prod_{i=1}^{d} Z_{T_i}(\gamma) + \sum_{i=1}^{d} \gamma\, Z_{T_i,\neg v_i}(\gamma) \prod_{j\in\{1,\ldots,d\}, j\neq i} Z_{T_j}(\gamma)$$

and therefore

$$p_v(T, \gamma) = \frac{Z_{T,\neg v}(\gamma)}{Z_T(\gamma)} = \frac{1}{1 + \gamma \sum_{i=1}^{d} \frac{Z_{T_i,\neg v_i}(\gamma)}{Z_{T_i}(\gamma)}} = \frac{1}{1 + \gamma \sum_{i=1}^{d} p_{v_i}(T_i, \gamma)}.$$

Hence, we need to evaluate the recurrence

$$x = F(x_1, \ldots, x_d) \text{ where } F(x_1, \ldots, x_d) = \frac{1}{1 + \gamma \sum_{i=1}^{d} x_i}, \tag{2}$$

with base case $x = 1$.

To show the decay of correlations, one wants to show that after applying the recurrence starting from two different sets of values at $v_1, \ldots, v_d$, the two computed values at v will be "closer" than were the initial values at the v_i's. This leads us to define a notion of distance. Often straightforward distances do not suffice to show decay of correlations, and distances defined via a "potential" function are used. We adapt this notion to the complex plane.

3.1 Metrics for measuring the error in the complex plane

We use a distance metric based on conformal density functions (see [10] for details).

▶ **Definition 10** (Length, Distance, Metric). *Let U be a simply connected open subset of $\mathbb{C}$ and let $\Phi : U \to \mathbb{R}_{>0}$ be a function (called conformal density). The* length with respect to Φ *of a path*[3] *$\eta : [0, 1] \to U$ is defined as*

$$\int_0^1 \Phi(\eta(t)) \left| \frac{\partial}{\partial t} \eta(t) \right| dt.$$

The distance with respect to Φ *between two points $x, y \in U$, denoted $\mathrm{dist}_\Phi(x, y)$, is the infimum of the lengths of the paths η connecting x to y (that is, $\eta(0) = x$ and $\eta(1) = y$). We will refer to the metric induced by the distance function $\mathrm{dist}_\Phi(\cdot, \cdot)$ as the (conformal) metric given by Φ.*

We first quantify one-level correlation decay.

▶ **Lemma 12.** *Let U be a simply connected open subset of $\mathbb{C}$, $\Phi : U \to \mathbb{R}_{>0}$ be a conformal density function, and $\mathrm{dist}_\Phi(\cdot, \cdot)$ be the metric given by Φ. Let p and q be conjugate exponents, that is, $1/p + 1/q = 1$, where $p, q \in \mathbb{R}_{>0} \cup \{\infty\}$.*

Suppose that $d \geq 1$ is an integer and $F : U^d \to U$ is a holomorphic map. Let $x_1, \ldots, x_d \in U$ and $y_1, \ldots, y_d \in U$ and let $x = F(x_1, \ldots, x_d)$ and $y = F(y_1, \ldots, y_d)$. Assume that there exists a real $\alpha \in (0, 1)$ such that for any $z_1, \ldots, z_d \in U$

$$\sum_{i=1}^{d} \left| \Phi(F(z_1, \ldots, z_d)) \frac{\partial F}{\partial z_i}(z_1, \ldots, z_d) \frac{1}{\Phi(z_i)} \right|^p \leq \alpha^p. \tag{3}$$

Then

$$\mathrm{dist}_\Phi(x, y) \leq \alpha \left(\sum_{i=1}^{d} \mathrm{dist}_\Phi(x_i, y_i)^q \right)^{1/q}. \tag{4}$$

Proof. Let $\epsilon > 0$. For $i \in [d]$, let η_i be a path connecting x_i to y_i of length $\ell_i \leq \mathrm{dist}_\Phi(x_i, y_i) + \epsilon$. We assume w.l.o.g. that η_i is re-parameterized to uniform speed (using arc length), that is, for a.e. $t \in [0, 1]$ we have

$$\left| \frac{\partial}{\partial t} \eta_i(t) \right| \Phi(\eta_i(t)) = \ell_i. \tag{5}$$

[3] Following [10], paths are assumed to be continuous and piecewise continuously differentiable.

We now define a path η connecting x to y:

$$\eta(t) := F(\eta_1(t), \ldots, \eta_d(t)).$$

Let L denote the length of η and $F_i(x_1, \ldots, x_d)$ denote the function $\frac{\partial F}{\partial x_i}(x_1, ..., x_d)$ Then, using the triangle inequality and (5), we have

$$\begin{aligned} L &= \int_0^1 \Phi(\eta(t)) \Big| \frac{\partial}{\partial t}\eta(t) \Big| \, dt = \int_0^1 \Phi(\eta(t)) \Big| \sum_{i=1}^d F_i(\eta_1(t), \ldots, \eta_d(t)) \, \frac{\partial \eta_i}{\partial t}(t) \Big| \, dt \\ &\leq \int_0^1 \Phi(\eta(t)) \sum_{i=1}^d \Big| F_i(\eta_1(t), \ldots, \eta_d(t)) \, \frac{\partial \eta_i}{\partial t}(t) \Big| \, dt \qquad (6) \\ &= \int_0^1 \sum_{i=1}^d \Big| \Phi(\eta(t)) F_i(\eta_1(t), \ldots, \eta_d(t)) \frac{1}{\Phi(\eta_i(t))} \, \ell_i \Big| \, dt. \end{aligned}$$

By Hölder's inequality and condition (3), for any $t \in [0, 1]$, we have

$$\sum_{i=1}^d \Big| \Phi(\eta(t)) F_i(\eta_1(t), \ldots, \eta_d(t)) \frac{1}{\Phi(\eta_i(t))} \ell_i \Big| \leq$$

$$\left(\sum_{i=1}^d \Big| \Phi(\eta(t)) F_i(\eta_1(t), \ldots, \eta_d(t)) \frac{1}{\Phi(\eta_i(t))} \Big|^p \right)^{1/p} \left(\sum_{i=1}^d \ell_i^q \right)^{1/q} \leq \alpha \Big(\sum_{i=1}^d \ell_i^q \Big)^{1/q}.$$

Integrating this for t between 0 and 1 and combining with (6), we obtain

$$\mathrm{dist}_\Phi(x, y) \leq L \leq \alpha \Big(\sum_{i=1}^d \ell_i^q \Big)^{1/q}.$$

Taking $\epsilon \to 0$ we obtain

$$\mathrm{dist}_\Phi(x, y) \leq \alpha \left(\sum_{i=1}^d \mathrm{dist}_\Phi(x_i, y_i)^q \right)^{1/q}. \qquad \blacktriangleleft$$

Now, given a rooted tree, our goal will be to bound the correlation decay at the root when we truncate the tree at depth $\Theta(\log n)$. Let T be a finite tree rooted at a vertex ρ and let C be a subset of the leaves of T. Let $U \subseteq \mathbb{C}$. We will have a family of maps $\{F_d\}_{d \geq 1}$ where $F_d : U^d \mapsto U$ will be a symmetric map of arity d (which will be the recurrence applied to a vertex of the tree with d children). Let $\sigma : C \to U$ be an arbitrary assignment of values in U to the vertices of C. Let also $u_0 \in U$ be the "initial" value (u_0 corresponds to the starting point of the recurrences). For a vertex v in T and an initial value $u_0 \in U$, we define the quantity $r_v(C, \sigma, u_0)$ recursively as follows.

$$r_v(C, \sigma, u_0) = \begin{cases} u_0 & \text{if } v \text{ is a leaf of } T \text{ and } v \notin C, \\ \sigma(v) & \text{if } v \in C, \\ F_d(x_1, \ldots, x_d) & \text{otherwise, where } x_i = r_{v_i}(C, \sigma, u_0) \\ & \text{and } v_1, \ldots, v_d \text{ are } v\text{'s children in } T. \end{cases} \qquad (7)$$

We can now study the sensitivity of $r_v(C, \sigma, u_0)$ to the assignment σ. The following lemma is the analogue of [14, Lemma 3] for the complex plane and will be used to apply the correlation decay technique for graphs of bounded connective constant, the proof can be found in the full version.

▶ **Lemma 13.** *Let U be a simply connected open subset of $\mathbb{C}$ and $\Phi : U \to \mathbb{R}_{>0}$ be a conformal density function. For $d = 1, 2, \ldots$, let $F_d : U^d \mapsto U$ be symmetric holomorphic maps. Suppose that there exists a real $\alpha \in (0, 1)$ and conjugate exponents p and q such that for every integer $d \geq 1$ and all $z_1, \ldots, z_d \in U$ it holds that*

$$\sum_{i=1}^{d} \left| \Phi(F_d(z_1, \ldots, z_d)) \frac{\partial F_d}{\partial z_i}(z_1, \ldots, z_d) \frac{1}{\Phi(z_i)} \right|^p \leq \alpha^p. \tag{8}$$

Then, the following holds for any initial value $u_0 \in U$ and any finite tree T rooted at ρ.

Let C be a subset of the leaves of T and consider two arbitrary assignments $\sigma_1 : C \to U$ and $\sigma_2 : C \to U$. Then

$$|r_\rho(C, \sigma_1, u_0) - r_\rho(C, \sigma_2, u_0)| \leq \left(\frac{M}{L}\right) \left(\sum_{v \in C} \alpha^{q \cdot \mathrm{depth}(v)} \right)^{1/q},$$

where $L := \inf_{x \in U} \Phi(x)$, $M := \max_{v \in C} \mathrm{dist}_\Phi(\sigma_1(v), \sigma_2(v))$ and $\mathrm{depth}(v)$ is the distance of v from the root ρ.

3.2 Applying the method for matchings

Suppose that $\gamma \in \mathbb{C} \setminus \mathbb{R}_{\leq 0}$. We will parameterise γ as

$$\gamma = (1/Q)^2, \text{ where we choose } Q \text{ such that } \mathrm{Re}(Q) > 0. \tag{9}$$

Note that, in the choice of Q, we used the assumption that γ is not a negative real number. Let $\mathcal{H}$ be the right complex half-plane, that is, the set of complex x such that $\mathrm{Re}(x) > 0$, and note that $Q \in \mathcal{H}$. We will also transform the space in which the quantities $p_v(G, \gamma)$ live using the map $x \mapsto x/Q$. In the transformed space, the recurrence (2) becomes

$$y = F(y_1, \ldots, y_d) \text{ where } F(y_1, \ldots, y_d) = \frac{1}{Q + \sum_{i=1}^{d} y_i}, \tag{10}$$

where if y corresponds to a leaf then $y = 1/Q$ (we refer to this y as the initial y). Let

$$U = \left\{ y \in \mathbb{C} \mid \mathrm{Re}(y) > 0,\ |y| < 1/\mathrm{Re}(Q) \right\}. \tag{11}$$

The following lemma shows that the set U is closed under application of the recurrence (10).

▶ **Lemma 14.** *Suppose that $y_1, \ldots, y_d \in U$ and $\mathrm{Re}(Q) > 0$. Then, for y given by (10), we have that $y \in U$ as well. In fact, we have that $\mathrm{Re}(y) \geq \frac{\mathrm{Re}(Q)}{\left(|Q| + \frac{d}{\mathrm{Re}(Q)}\right)^2}$.*

We next go on to show the required contraction properties for an appropriate function Φ. This is largely based on arguments from [13] from the real case, which we can adapt to the complex plane to obtain the following.

▶ **Lemma 16.** *Let Δ be a positive real number, $\gamma \in \mathbb{C} \setminus \mathbb{R}_{<0}$, and Q, U be given from (9) and (11), respectively. Consider the function $\Phi : U \mapsto \mathbb{R}_{>0}$ given by $\Phi(y) = \frac{1}{\mathrm{Re}(y)(2/\mathrm{Re}(Q) - \mathrm{Re}(y))}$ and let $\hat{\gamma} = \frac{2|\gamma|}{1 + \cos(\arg\gamma)}$,*

$$D = \max\{\Delta, \frac{3}{4\hat{\gamma}}\},\ \ p = 1/(1 - \frac{1}{\sqrt{1 + 4\hat{\gamma}D}}),\ \ q = \frac{p}{p-1},\ \ \alpha = \frac{1}{D^{1/q}}\Big(1 - \frac{2}{1 + \sqrt{1 + 4\hat{\gamma}D}}\Big). \tag{12}$$

Then, the following holds for all integer $d \geq 1$.

Consider the map $F : U^d \mapsto U$ given by $F(y_1, \ldots, y_d) = \frac{1}{Q + \sum_{i=1}^{d} y_i}$. Then, for arbitrary $y_1, \ldots, y_d \in U$ we have

$$\sum_{i=1}^{d} \left| \Phi(F(y_1, \ldots, y_d)) \frac{\partial F}{\partial y_i}(y_1, \ldots, y_d) \frac{1}{\Phi(y_i)} \right|^p \leq \alpha^p. \tag{13}$$

Based on the above lemmas, we can now give a proof sketch of Theorem 5.

Proof Sketch of Theorem 5. If γ is a non-negative real number, then the result follows from [13, Theorem 1.3]. So we focus on the case where γ is not real. Using the telescoping expansion of $Z_G(\gamma)$ described in (1), it suffices to give an algorithm that on an input graph $G \in \mathcal{F}_{\Delta,a,c}$, a vertex v in G and rational $\delta > 0$ outputs in time $(\hat{c}n/\delta)^{O\left((1+a+\sqrt{|\hat{\gamma}|\Delta})\log\Delta\right)}$ a quantity $\tilde{p}$ which satisfies $\tilde{p} = p_v(G, \gamma)\mathrm{e}^z$ for some complex number z with $|z| \leq \delta$.

Let $T = T_{SAW}(v, G)$ be the self-avoiding walk tree rooted at v, then by Theorem 9 we have that $p_v(G, \gamma) = p_v(T, \gamma)$, so it suffices to approximate $p_v(T, \gamma)$. For this, we apply the general framework of Lemma 13 to the recurrence in (10) using the contraction properties proved in Lemma 16. More precisely, we first truncate the tree T at logarithmic depth ℓ to obtain a tree T' and we output $\hat{p} = p_v(T', \gamma)$ as our approximation to $p_v(T, \gamma)$. Note that T' has size at most $c\Delta^\ell$ since G has connective constant at most Δ. We then invoke Lemmas 13 and 16 to show that the absolute error between $p_v(T, \gamma)$ and $p_v(T', \gamma)$ decays as $(\Delta^{1/q}\alpha)^\ell$ where $\alpha < 1/\Delta^{1/q}$ is the constant in Lemma 16. By taking $\ell = \Theta(\log n)$, we can therefore make the absolute error as small as an inverse polynomial in n. The absolute error can then be translated to the desired relative error between $\hat{p}$ and $p_v(G, \gamma)$ using the bound in Lemma 14. ◀

4 Proof of hardness results

Let $\gamma_0 = -1/10$ and $\mathcal{G}$ be the set of graphs of maximum degree 3. It is well-known [5, Theorem 3] that the problem of *exactly* computing $Z_G(\gamma_0)$ given an input graph $G \in \mathcal{G}$ is #P-hard. Moreover, by Corollary 8 we have that $Z_G(\gamma_0) > 0$ for all graphs $G \in \mathcal{G}$.

Using an oracle on graphs H of maximum degree Δ for either approximating $Z_H(\gamma)$ multiplicatively or deciding the sign of $Z_H(\gamma)$, we will design a polynomial time algorithm to exactly compute the ratio $\frac{Z_G(\gamma_0)}{Z_{G-e^*}(\gamma_0)}$ for an arbitrary graph $G \in \mathcal{G}$ and an arbitrary edge e^* of G; note that this ratio is well-defined since $Z_{G-e^*}(\gamma_0) > 0$. With such a subroutine at hand, we can compute $Z_G(\gamma_0)$ using self-reducibility techniques; namely, let $e_1, e_2, \ldots, e_m$ be an enumeration of the edges of G and let G_i be the graph where the edges $e_i, \ldots, e_m$ are deleted (note that $G_{m+1} = G$ and G_1 is the empty graph). Then, we have that $Z_G(\gamma_0) = \prod_{i=1}^{m} \frac{Z_{G_{i+1}}(\gamma_0)}{Z_{G_i}(\gamma_0)}$. This yields the #P-hardness results of Theorems 1 and 2.

The most difficult part of designing the subroutine is constructing graph gadgets that have the effect of "changing" the edge activity γ to any desired activity, perhaps with some small error. It is actually important to make the error exponentially small relative to the size of the graph. To formalise these gadget constructions, we will need some definitions. Let $G = (V, E)$ be a graph and $u, v \in V$. Analogously to the notation $Z_{G,u}(\gamma)$ and $Z_{G,\neg u}(\gamma)$ of Section 2, we let $Z_{G,u,v}(\gamma)$ be the contribution to the partition function $Z_G(\gamma)$ from those matchings $M \in \mathcal{M}_G$ such that both u, v are matched in M, and we define $Z_{G,u,\neg v}(\gamma), Z_{G,\neg u,v}(\gamma), Z_{G,\neg u,\neg v}(\gamma)$ similarly.

▶ **Definition 17.** *Fix a real number γ. Given γ, the graph $G = (V, E)$ is said to* implement *the edge activity $\gamma' \in \mathbb{R}$ with* accuracy $\epsilon > 0$ *if there are vertices u, v in G such that $Z_{G,\neg u,\neg v}(\gamma) \neq 0$ and*

1. *u, v have degree one in G and $(u, v) \notin E$,*
2. $\left|\frac{Z_{G,u,\neg v}(\gamma)}{Z_{G,\neg u,\neg v}(\gamma)}\right| \leq \epsilon$, $\left|\frac{Z_{G,\neg u,v}(\gamma)}{Z_{G,\neg u,\neg v}(\gamma)}\right| \leq \epsilon$,
3. $\left|\frac{Z_{G,u,v}(\gamma)}{Z_{G,\neg u,\neg v}(\gamma)} - \gamma'\right| \leq \epsilon$.

We call u, v the terminals of G. If both of Items 2 and 3 hold with $\epsilon = 0$, we say that G implements the edge activity γ' (perfectly).

▶ **Definition 18.** *Let α be a rational number and write $\alpha = p/q$, where p, q are integers such that $\gcd(p, q) = 1$. Then, the* size *of α, denoted by $\text{size}(\alpha)$, is given by $1 + \log(|p| + |q|)$. For $\alpha_1, \ldots, \alpha_t \in \mathbb{Q}$, we denote by $\text{size}(\alpha_1, \ldots, \alpha_t)$ the total of the sizes of $\alpha_1, \ldots, \alpha_t$.*

Our key lemma for designing the subroutine is the following.

▶ **Lemma 19.** *Let $\Delta \geq 3$ be an integer and $\gamma < -\frac{1}{4(\Delta-1)}$ be a rational number.*

There is an algorithm which, on input rational $\gamma' \leq 0$ and $\epsilon > 0$, outputs in $poly(\text{size}(\gamma', \epsilon))$ time a bipartite graph G of maximum degree at most Δ with terminals u, v in the same part of the vertex partition of G so that G implements γ' with accuracy ϵ.

In turn, to prove Lemma 19 it will be simpler to first construct graph gadgets that implement "vertex" activities.

▶ **Definition 22.** *Fix a real number γ. Given γ, the graph $G = (V, E)$ is said to* implement the vertex activity $\lambda \in \mathbb{R}$ *with* accuracy $\epsilon > 0$ *if there is vertex u in G such that*

1. *u has degree one in G,*
2. *$Z_G(\gamma) \neq 0$ and $\left|\frac{Z_{G,\neg u}(\gamma)}{Z_G(\gamma)} - \lambda\right| \leq \epsilon$.*

We call u the terminal of G. If Item 2 holds with $\epsilon = 0$, we say that G implements λ (perfectly).

Our main lemma about implementing vertex activities is as follows.

▶ **Lemma 23.** *Let $\Delta \geq 3$ be an integer and $\gamma < -\frac{1}{4(\Delta-1)}$ be a rational number.*

There is an algorithm which, on input a rational number λ and $\epsilon > 0$, outputs in $poly(\text{size}(\lambda, \epsilon))$ time a bipartite graph G of maximum degree at most Δ that implements the vertex activity λ with accuracy ϵ.

In order to obtain the exponential precision of Lemma 23, we will first show how to implement vertex activities with arbitrarily small constant precision, as formalised in the following lemma.

▶ **Lemma 24.** *Let $\Delta \geq 3$ be an integer and $\gamma < -\frac{1}{4(\Delta-1)}$ be a real number.*

For every $\lambda \in \mathbb{R}$ and $\epsilon > 0$, there is a bipartite graph G of maximum degree at most Δ that implements the vertex activity λ with accuracy ϵ.

To prove Lemma 24, we will need to consider two cases for the value of γ. Namely, for an integer $\Delta \geq 3$, the following subset of the negative reals will be relevant:

$$\mathcal{B}_\Delta = \left\{\gamma \in \mathbb{R} \mid \gamma = -\tfrac{1}{4(\Delta-1)(\cos\theta)^2} \text{ for some } \theta \in (0, \pi/2) \text{ that is a rational multiple of } \pi\right\}. \tag{14}$$

If $\gamma \notin \mathcal{B}_\Delta$ then we show that we can use $(\Delta-1)$-ary trees of appropriate height to obtain the constant accuracy of Lemma 24. The situation is more complicated for $\gamma \in \mathcal{B}_\Delta$ since the $(\Delta-1)$-ary tree is not as effective; neverthless, it can still be used to show that we can implement perfectly the edge activity $\gamma' = -1$ (though in some cases we have to work a bit harder, cf. Lemmas 25 and 27 of the full version). To make use of $\gamma' = -1$, we show in Lemma 26 of the full version that for every rational number λ, there exists a tree of maximum degree $\Delta = 3$ that implements the vertex activity λ and this can then be propagated to get the constant accuracy of Lemma 24 for $\gamma \in \mathcal{B}_\Delta$.

We then bootstrap Lemma 24 to obtain the exponential precision required in Lemma 23, based on the "contracting maps that cover" technique of [4]. The key is to build a finite collection of maps $\Phi_i : x \mapsto \frac{1}{1+\gamma(\lambda_i+x)}$ for different values of λ_i (obtained from Lemma 24) and to apply these iteratively to amplify precision on an appropriately chosen interval of the real axis; the details of the construction as well as the choice of the λ_i's (see Lemma 30 below) depend heavily on the fact that we are working with the matching polynomial. Using the maps Φ_i, Lemma 23 can then be proved using a careful analysis depending on the value of λ (relative to the interval) and, once this is in place, we have everything we need to prove Lemma 19, see the full version for details.

The proof of the hardness results for graphs with bounded connective constant (Theorem 4) can be obtained by adapting our arguments above. Namely, we let $S = \bigcup_{d\geq 3} \mathcal{B}_d$. Then, for $\gamma \in S$, as we discussed earlier, there exists a tree that implements the edge activity $\gamma' = -1$. We can then modify the tree so that the terminals of the final tree are at distance ℓ, for arbitrarily large ℓ. The key now is that we can attach the new tree to the edges of a target graph to modify the edge activity and at the same time reduce its connective constant (since there is just one path connecting the terminals of the tree gadget). Since S is dense on the negative real axis, we therefore obtain Theorem 4 by applying the hardness results of Theorems 1 and 2.

We conclude by giving the deferred construction of the maps Φ_i which are used to obtain the exponential precision of Lemma 23. The proof of the following lemma establishes important properties of the maps that enable them to bootstrap precision. The lemma also gives an algorithm that can be used to implement any "target" y with exponential precision.[4]

▶ **Lemma 30.** *Let $\gamma < 0$ be a rational number. Then, there exist rationals x_0 and $r, \delta > 0$ and reals $\lambda_1^*, \ldots, \lambda_t^*$ (for some positive integer t) such that the following holds for all rational $\lambda_1, \ldots, \lambda_t$ satisfying $|\lambda_i - \lambda_i^*| \leq \delta$ for $i \in [t]$.*

Let $I := [x_0 - r, x_0 + r]$ and, for $i \in [t]$, consider the map $\Phi_i : x \mapsto \frac{1}{1+\gamma(\lambda_i+x)}$ for $x \neq -(1+\gamma\lambda_i)/\gamma$. There is an algorithm which, on input (i) a starting point $y_0 \in I \cap \mathbb{Q}$, (ii) a target $y \in I \cap \mathbb{Q}$, and (iii) a rational $\epsilon > 0$, outputs in poly$(\text{size}(y_0, y, \epsilon))$ time a number $\hat{y} \in I \cap \mathbb{Q}$ and a sequence $i_1, i_2, \ldots, i_k \in [t]$ such that

$$\hat{y} = \Phi_{i_k}(\Phi_{i_{k-1}}(\cdots \Phi_{i_1}(y_0)\cdots)) \text{ and } |\hat{y} - y| \leq \epsilon.$$

Proof. Let x_1, x_2 be rationals such that $\gamma x_1 x_2 = -1$ and $x_1 \neq \pm x_2$. Let λ be such that $1 + \gamma\lambda = -\gamma(x_1 + x_2)$. Then, the fixpoints of the map $\Phi : x \mapsto \frac{1}{1+\gamma(\lambda+x)}$ are x_1 and x_2, and at least one of the two points is attracting.[5] Denote by x_0 the attracting fixpoint of Φ, so

[4] The "target" y corresponds to a vertex activity λ – the only difference is that a transformation between them has been applied for technical reasons, see proof of Lemma 23 in the full version for details.

[5] To see this, note that $\Phi(x) = x$ is equivalent to $x(1+\gamma\lambda) + \gamma x^2 = 1$ and therefore x_1 and x_2 are (the only) fixpoints of Φ. Moreover, we have that $\Phi'(x) = -\frac{\gamma}{(1+\gamma(\lambda+x))^2}$ and hence $\Phi'(x_1) = -\gamma x_1^2$,

that x_0 satisfies $\Phi(x_0) = x_0$ and $0 < |\Phi'(x_0)| < 1$. By Lemma 21 of the full version, we can compute $\eta > 0$ such that for all $x \in [x_0 - \eta, x_0 + \eta]$ and all $\lambda' \in [\lambda - \eta, \lambda + \eta]$ it holds that

$$1 + \gamma(\lambda' + x) \neq 0 \text{ and } \left| \frac{\gamma}{\big(1+\gamma(\lambda'+x)\big)^2} - \frac{\gamma}{\big(1+\gamma(\lambda+x_0)\big)^2} \right| \leq \frac{1}{2} \min\big\{|\Phi'(x_0)|, 1 - |\Phi'(x_0)|\big\}. \quad (15)$$

Let $r := \frac{|\Phi'(x_0)|}{4}\eta$, $\delta := (r/4)$ and let $\lambda_1^*, \ldots, \lambda_t^*$ form a δ-covering of the interval $[\lambda - \eta/2, \lambda + \eta/2]$. Let $\lambda_1, \ldots, \lambda_t$ be arbitrary rationals satisfying $|\lambda_i - \lambda_i^*| \leq \delta$. For $i \in [t]$ consider the maps $\Phi_i : x \mapsto \frac{1}{1+\gamma(\lambda_i+x)}$. Finally, let I be the interval $[x_0 - r, x_0 + r]$. We will show
Property 1: The maps $\{\Phi_i\}_{i\in[t]}$ are contracting on the interval I, and
Property 2: $I \subseteq \Phi_1(I) \cup \cdots \cup \Phi_t(I)$.
Once these two properties of the maps $\{\Phi_i\}_{i\in[t]}$ are proved, the algorithm in the statement of the lemma and its analysis are almost identical to those in [4, Proof of Lemmas 12 & 26]. The only difference here is that the maps $\{\Phi_i\}_{i\in[t]}$ have different expressions. The fact that we need about the expression of the maps is that, for $i \in [t]$ and for every rational x, $\Phi_i^{-1}(x)$ can be computed in time $poly(\text{size}(x, \lambda_i, \gamma))$. This is clear since $\Phi_i^{-1}(x) = \frac{1}{\gamma}(\frac{1}{x} - 1) - \lambda_i$.

Proof of Property 1. Fix $i \in [t]$. We will show that Φ_i is contracting on the interval I. Observe that $r < \eta/4$ since $|\Phi'(x_0)| < 1$ and therefore $\delta < \eta/4$ as well. Then, we have by the triangle inequality that

$$|\lambda_i - \lambda| \leq |\lambda_i - \lambda_i^*| + |\lambda_i^* - \lambda| \leq \delta + \eta/2 < \eta.$$

Therefore, we can apply (15) to $\lambda' = \lambda_i$ and $x \in I$. Observe that $\Phi'(x) = -\gamma/\big(1+\gamma(\lambda_i+x)\big)^2$ and $\Phi'(x_0) = -\gamma/\big(1+\gamma(\lambda_i+x_0)\big)^2$ and hence we obtain that for all $x \in I$ it holds that

$$|\Phi_i'(x)| \leq \frac{1}{2}(1 + |\Phi'(x_0)|) < 1.$$

It follows that the maps Φ_i are contracting on the interval I for all $i \in [t]$. ◀

Proof of Property 2. It suffices to consider an arbitrary $y \in I$ and show that there exists $j \in [t]$ such that $\Phi_j^{-1}(y) \in I$. To do this, we set J to be the interval $[x_0 - \eta/2, x_0 + \eta/2]$ and consider the map Φ on the interval J. Then, (15) for $\lambda' = \lambda$ and $x \in J$ gives that

$$0 < \frac{1}{2}|\Phi'(x_0)| \leq |\Phi'(x)|,$$

and therefore, by the Mean Value Theorem, for $z, w \in J$ we have that

$$\frac{1}{2}|\Phi'(x_0)| \cdot |z - w| \leq |\Phi(z) - \Phi(w)|. \quad (16)$$

We thus have that

$$|\Phi(x_0 + \eta/2) - x_0| = |\Phi(x_0 + \eta/2) - \Phi(x_0)| \geq \eta|\Phi'(x_0)|/4 = r,$$
$$|\Phi(x_0 - \eta/2) - x_0| = |\Phi(x_0 - \eta/2) - \Phi(x_0)| \geq \eta|\Phi'(x_0)|/4 = r.$$

Since Φ is monotonically increasing and continuous on the interval J, we therefore obtain that $I \subseteq \Phi(J)$. Therefore, for arbitrary $y \in I$ it holds that $\Phi^{-1}(y) \in J$ and hence from (16) applied to $z = \Phi^{-1}(y)$ and $w = \Phi^{-1}(x_0)$, we obtain that

$$|\Phi^{-1}(y) - x_0| = |\Phi^{-1}(y) - \Phi^{-1}(x_0)| \leq (2/|\Phi'(x_0)|)(y - x_0) \leq \eta/2.$$

$\Phi'(x_2) = -\gamma x_2^2$. Therefore $|\Phi'(x_1)| \neq |\Phi'(x_2)|$ and $1 = |\gamma x_1 x_2| = \sqrt{|\Phi'(x_1)||\Phi'(x_2)|}$. Therefore either $|\Phi'(x_1)| < 1$ or $|\Phi'(x_2)| < 1$.

Since $\lambda_1^*, \ldots, \lambda_t^*$ is a δ-covering of the interval $[\lambda - \eta/2, \lambda + \eta/2]$, it follows that there exists $j \in [t]$ such that

$$\left|\lambda + \Phi^{-1}(y) - x_0 - \lambda_j^*\right| \leq \delta = r/4.$$

Now, observe that $\Phi_j^{-1}(y) = \frac{1}{\gamma}\left(\frac{1}{y} - 1\right) - \lambda_j$ and $\Phi^{-1}(y) = \frac{1}{\gamma}\left(\frac{1}{y} - 1\right) - \lambda$, so we have that

$$\begin{aligned}\left|\Phi_j^{-1}(y) - x_0\right| &= \left|\frac{1}{\gamma}\left(\frac{1}{y} - 1\right) - \lambda_j - x_0\right| = \left|\lambda + \Phi^{-1}(y) - x_0 - \lambda_j\right| \\ &\leq \left|\lambda + \Phi^{-1}(y) - x_0 - \lambda_j^*\right| + \left|\lambda_j - \lambda_j^*\right| \leq r/4 + r/4 = r/2.\end{aligned}$$

It follows that $y \in \Phi_j(I)$ and therefore, since y was arbitrary, we have that $I \subseteq \Phi_1(I) \cup \cdots \cup \Phi_t(I)$. ◀

This completes the proof of Properties 1 and 2, and hence the proof of Lemma 30. ◀

Abstract

It is well-known that every planar graph has a *Tutte path*, i.e., a path P such that any component of $G-P$ has at most three attachment points on P. However, it was only recently shown that such Tutte paths can be found in polynomial time. In this paper, we give a new proof that 3-connected planar graphs have Tutte paths, which leads to a linear-time algorithm to find Tutte paths. Furthermore, our Tutte path has special properties: it visits all exterior vertices, all components of $G-P$ have exactly three attachment points, and we can assign distinct representatives to them that are interior vertices. Finally, our running time bound is slightly stronger; we can bound it in terms of the degrees of the faces that are incident to P. This allows us to find some applications of Tutte paths (such as binary spanning trees and 2-walks) in linear time as well.

1 Introduction

A *Tutte path* is a well-known generalization of Hamiltonian paths that allows to visit only a subset of the vertices of the graph, as long as all remaining vertices are in components with at most three attachment points. (Detailed definitions are below.) They have been studied extensively, especially for planar graphs, starting from Tutte's original result:

▶ **Theorem 1** (Tutte [19]). *Let G be a 2-connected planar graph with distinct vertices X, Y on the outer face. Let α be an edge on the outer face. Then G has a Tutte path from X to Y that uses edge α.*

We refer to the recent work by Schmid and Schmidt [15] for a detailed review of the history and applications of Tutte paths. It was long not known how to compute a Tutte path in less than exponential time. A breakthrough was achieved by Schmid and Schmidt in 2015 [13, 14], when they showed that one can find a Tutte path for 3-connected planar graphs in polynomial time. In 2018, the same authors then argued that Tutte paths can be found in polynomial time even for 2-connected planar graphs [15]. For both papers, the main insight is to prove the existence of a Tutte path by splitting the graph into non-overlapping subgraphs to recurse on; the split can be found in linear time and therefore the running time becomes quadratic.

In this paper, we show that Tutte paths can be computed in linear time. To do so, we give an entirely different proof of the existence of a Tutte path for 3-connected planar graph. This proof is very simple if the graph is triangulated, but requires more care when faces have larger degrees. Our path (and also the one by Schmid and Schmidt [13, 14]) comes with a system of distinct representatives, i.e., an injective assignment from the components of $G \setminus P$ to vertices of P that are attachment points. Such representatives are useful for various applications of Tutte paths.

Our proof for 3-connected planar graphs is based on a Hamiltonian-path proof by Asano, Kikuchi and Saito [1] that was designed to give a linear-time algorithm; with arguments much as in their paper we can therefore find the Tutte path and its representatives in linear time. Since 3-connected planar graphs are (as we argue) the bottleneck in finding Tutte paths, this shows that the path of Theorem 1 can be found in linear time.

1.1 Preliminaries

We assume familiarity with graphs, see, e.g., Diestel [7]. Throughout this paper, $G = (V, E)$ denotes a graph with n vertices and m edges. We assume that G is *planar*, i.e., can be drawn in 2D without edge crossings. A planar drawing of G splits $\mathbb{R}^2$ into connected regions called *faces*; the unbounded region is the *outer face* while all others are called *interior faces*. A vertex/edge is called *exterior* if it is incident to the outer face and *interior* otherwise. We assume throughout that G is *plane*, i.e., one particular abstract drawing of G has been fixed (by giving the clockwise order of edges around each vertex and the edges that are on the outer face). Any subgraph of G *inherits* this planar embedding, i.e., uses the induced order of edges and as outer face the face that contained the outer face of G. The following notion will be convenient: Two vertices v and w are *interior-face-adjacent* (in a plane graph G) if there exists an interior face that is incident to both v and w. We will simply write *face-adjacent* since we never consider adjacency via the outer face.

Nooses and connectivity. For a fixed planar drawing of G, let a *noose* be a simple closed curve $\mathcal{N}$ that goes through vertices and faces and crosses no edge except at endpoints. A noose can be described as a cyclic sequence $\langle x_0, f_1, x_1, \ldots, f_s, x_s{=}x_0\rangle$ of vertices and faces such that f_i contains x_{i-1} and x_i, and hence is independent of the chosen drawing. Frequently, the choice of faces will be clear from context or irrelevant; we then say that $\mathcal{N} = \langle x_0, \ldots, x_s{=}x_0\rangle$ *goes through* $\{x_1, \ldots, x_s\}$. The subgraph *inside/outside* $\mathcal{N}$ is the graph induced by the vertices that are on or inside/outside $\mathcal{N}$. The subgraph *strictly inside/outside* is obtained from this by deleting the vertices on $\mathcal{N}$.

A graph G is *connected* if for any two vertices v, w there is a path from v to w in G. A *cutting k-set* in G is a set $S = \{x_1, \ldots, x_k\}$ of vertices such that $G \setminus S$ has more connected components than G. We call it a *cutting pair* for $k = 2$ and a *cutting triplet* for $k = 3$. A graph G is called *k-connected* if it has no cutting $(k-1)$-set. Since we are only studying planar graphs, it will be convenient to use a characterization of connectivity via nooses. Consider a noose $\mathcal{N}$ that goes through $\{x_1, \ldots, x_k\}$ (and no other vertices), and there are vertices both strictly inside and strictly outside $\mathcal{N}$. Then clearly $S = \{x_1, \ldots, x_k\}$ is a cutting k-set. Vice versa, in a planar graph, any cutting k-set S for $k = 1, 2, 3$ gives rise to a noose $\mathcal{N}$ through S that has vertices both strictly inside and strictly outside. A *strict cut component* C of S is a subgraph strictly inside a noose $\mathcal{N}$ through some of the vertices of S such that C contains at least one vertex not in S and is inclusion-minimal among all such nooses. In particular, a strict cut component C contains no vertices or edges of S. A *cut component* C^+ is obtained from a strict cut component C by re-inserting those vertices of S that have neighbours of C, as well as the edges from them to C.

Hamiltonian paths and Tutte paths. A *Hamiltonian path* is a path that visits every vertex exactly once. To generalize it to Tutte paths, we need more definitions. Fix a path P in the graph. A *P-bridge* C is a cut component of P; its *attachment points* are its vertices on P.[1] A *Tutte path* is a path P such that any P-bridge C has at most three attachment points, and if C contains exterior edges, then it has at most two attachment points. Our Tutte paths for 3-connected graphs will be such that no P-bridges contain exterior edges, so the second restriction holds automatically.

A Tutte path with a *system of distinct representatives* (SDR), also called a *T_{SDR}-path* for short, is a Tutte path P together with an injective assignment σ from the P-bridges to vertices in P such that for every P-bridge C vertex $\sigma(C)$ is an attachment point of C.

Given a path P in a plane graph, we denote by $F(P)$ the set of all interior faces that contain at least one vertex of P.

1.2 From 3-connected to 2-connected

In this section, we show that, to find the path of Theorem 1 efficiently, it suffices to consider 3-connected planar graphs.

We re-prove Theorem 1, presuming it holds for 3-connected planar graphs, by induction on the number of vertices with an inner induction on the number of exterior vertices. Say we want to find a Tutte path from X to Y that uses exterior edge $\alpha = (U, W)$, where X, Y are exterior vertices. In the base case, G is 3-connected and we are done. So assume that G has cutting pairs. If edge (X, Y) does not exist, then add it in such a way that α stays exterior, and find a Tutte path P in the resulting graph recursively (it has fewer exterior vertices). Since $\{X, Y\} \neq \{U, W\}$ (because $(U, W) \in G$ while $(X, Y) \notin G$), path P visits at least one vertex other than X, Y, and so cannot use edge (X, Y). So it is also a Tutte path of G.

Now, assume that (X, Y) exists. Repeatedly split the graph at any cutting pair $\{u, v\}$ into cut components $C_1, \ldots, C_k$, and store the *3-connected components* $C_1^+, \ldots, C_k^+$ (induced by the cut components with an additional virtual edge between the cutting pairs) in a so-called *SPQR-tree* [6, 9], which additionally creates one leaf node for every edge of G. This can be done in linear time [10].

Root the SPQR-tree at the node of edge (X, Y). For each 3-connected component C^+ other than the root, set $\{X_C, Y_C\}$ to be the cutting pair that C^+ has in common with its parent component, and observe that these two vertices are necessarily exterior in C since X, Y are exterior in G; see Figure 1.

If C^+ has only these two vertices, then let P_C be the path (X_C, Y_C). Otherwise, define an edge $\alpha_C \neq (X_C, Y_C)$ of C^+ as follows: If the node of α is a descendant of C^+, then let α_C be the virtual edge of C^+ that it shares with the child that leads to this descendant. Note that α_C is a virtual edge, and it is necessarily on the outer face of C since α is on the outer face of G. Otherwise (α is not in a descendant of C^+) choose α_C to be an arbitrary exterior edge of C other than (X_C, Y_C). Let P_C be a Tutte path that begins at X_C, ends at Y_C, and uses edge α_C; we know that this exists since C^+ is either a triangle or a 3-connected graph.

Now obtain the Tutte path P of G by repeatedly substituting paths of 3-connected components. Specifically, initiate P as the virtual copy of edge (X, Y) that was added when we created the node for (X, Y). For as long as P contains a virtual edge (u, v), let C^+ be the child component at this virtual edge and observe that $\{X_C, Y_C\} = \{u, v\}$. *Substitute P_C in place of edge (u, v) of P*, i.e., set P to be $X \overset{P}{\rightsquigarrow} u/v \overset{P_C}{\rightsquigarrow} v/u \overset{P}{\rightsquigarrow} Y$. Note that, if C^+ is not

[1] Our definition of P-bridge considers only the *proper* P-bridges [19] that contain at least one vertex.

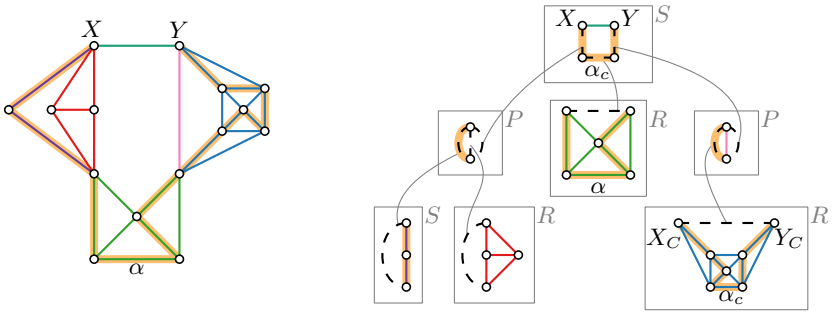

Figure 1 A 2-connected graph, its SPQR-tree (leaf nodes are omitted), and its Tutte path.

the singleton-edge (u, v), then P_C contains α_C, which is a virtual edge. This means that the process repeats until we have substituted the real edges from the leaves of the SPQR-trees. In particular (due to our choice of α_C), we will substitute the paths from all components between (X, Y) and α, which means that α is an edge of the final path P as required.

Observe that for some 3-connected components we do not substitute their paths; these become P-bridges with two attachment points. There may also be some P-bridges within each 3-connected components, but these have at most three attachment points since we used a Tutte path for each component. So the result is the desired Tutte path. Since we compute one Tutte path per 3-connected component, and this can be done in time proportional to the size of the component, the overall running time is linear.

2 Tutte paths in 3-connected planar graphs

For triangulated planar graphs, one can quite easily find a T_{SDR}-path by removing the interiors of all separating triangles, and finding for the resulting 4-connected planar graph a Hamiltonian path using the approach of Asano, Kikuchi, and Saito [1]. It is not hard to see that we can assign representatives to all separating triangles, possibly after expanding the path using the substitution trick described below. (We omit the details for space reasons.)

For 3-connected planar graphs that are not triangulated, we use the same approach, but must generalize many definitions from Asano, Kikuchi, and Saito [1] and add quite a few cases because now face-adjacent vertices are not necessarily adjacent. To keep the proof self-contained, we re-phrase everything from scratch.[2]

We need a few definitions. The *outer stellation* of a planar graph G is the graph obtained by adding a vertex in the outer face and connecting it to all exterior vertices. A planar graph G is called *internally 3-connected* if its outer stellation is 3-connected. Note that this implies that G is 2-connected, any cutting pair is *exterior* (i.e., has both vertices on the outer face) and has only two cut components. In the following, we endow G with k *corners*, which are k vertices $X_1, \ldots, X_k$ that appear in this order on the outer face. Usually, $k = 3$ or 4, but occasionally we allow larger k. A *side* of such a graph is the outer face path between two consecutive corners that does not contain any other corners. The *corner stellation* G^{s} is obtained by adding a vertex in the outer face and connecting it to the corners. We say

[2] Indeed, due to attempts to simplify the notations similar as done in [4], the reader familiar with [1] may barely see the correspondence between the proof and [1]. Roughly, their Condition (W) corresponds to $c3c(X, W, Y)$, their Case 1 is our Case 3a, and their Case 3 combines our Case 2 with our Case 4a (but resolves it in a symmetric fashion).

that G is *corner-3-connected with respect to corners* $X_1, \ldots, X_k$ (abbreviated to "G *satisfies* $c3c(X_1, \ldots, X_k)$") if G^s is 3-connected. Figure 2a illustrates this condition. It is easy to show that G satisfies $c3c(X_1, \ldots, X_k)$ if and only if $k \geq 3$, G is internally 3-connected, and no cutting pair $\{v, w\}$ of G has both v and w on one side of G.

For ease of proof, we make the induction hypothesis stronger than just having a T_{SDR}-path, by restricting which vertices *must* be visited and which vertices *must not* be representatives. A T_{int}*-path* is a T_{SDR}-path P that visits all exterior vertices, and where representative $\sigma(C)$ is interior, for all P-bridges C. The goal of the remainder of this section is to prove the following result (which immediately implies Theorem 1 for 3-connected graphs[3]):

▶ **Lemma 2.** *Let G be a plane graph with distinct vertices X, Y on the outer face. Let $(U, W) \neq (X, Y)$ be an edge on the outer face. If G satisfies $c3c(X, U, W, Y)$, then it has a T_{int}-path that begins at X, ends at Y, and contains (U, W).*

We need a second result for the induction. Let a T_{end}*-path* be a T_{SDR}-path P that visits all exterior vertices, and where representative $\sigma(C)$ is interior or the last vertex of P, for all P-bridges C.

▶ **Lemma 3.** *Let G be a plane graph with distinct vertices X, Y on the outer face. Let $(U, W) \neq (X, Y)$ be an edge on the outer face. If G satisfies $c3c(X, U, W, Y)$ and*

($\sqsupset$) *(W, Y) and (Y, X) are edges,*

then G has a T_{end}-path P that begins at X, ends at Y, and uses (U, W) and (W, Y).[4] *Further, if Y is the representative of a P-bridge C, then C has W and Y as attachment points.*

See Figure 5c for a graph that satisfies ($\sqsupset$).

We assume throughout that X, U, W, Y are enumerated in ccw order along the outer face, the other case can be resolved by reversing the planar embedding.

The following trick will help shorten the proof: If graph G satisfies ($\sqsupset$), then Lemma 3 implies Lemma 2. Namely, if Lemma 3 holds, then we have a T_{end}-path P from X to Y through (U, W) and (W, Y). If this is not a T_{int}-path, then some P-bridge C has Y as representative, and by assumption also has W as attachment point. It must have a third attachment point u, otherwise $\{W, Y\}$ would be a cutting pair within one side of G, contradicting corner-3-connectivity. It has no more attachment points since P is a Tutte path, so $\{W, Y, u\}$ is a cutting triplet. We apply the *substitution trick* described below (and useful in other situations as well), which replaces (W, Y) with a path through C that does not use u. Thus, C no longer needs a representative and we obtain a T_{int}-path.

The substitution trick. This trick can be applied whenever we have an edge $e = (w, y)$ used by some T_{SDR}-path P, and a P-bridge C that resides inside a noose through some cutting triplet $\{u, w, y\}$ for some vertex u. Define $C^+ = G[C] \cup \{(u, w), (w, y)\} \setminus \{(u, y)\}$, where edges are added only if they did not exist in $G[C]$.[5]

[3] Theorem 1 allows $(U, W) = (X, Y)$, but then holds trivially since using edge (X, Y) as path satisfies all conditions. We require $(U, W) \neq (X, Y)$ since we want not just a Tutte path but a T_{int}-path, and the single-edge path (X, Y) would allow only exterior vertices as representatives.

[4] This lemma is a special case of the "Three Edge Lemma" [17], which states that for any three edges on the outer face there exists a Tutte cycle containing them all. However, it cannot simply be obtained from it since we require restrictions on the location of representatives.

[5] We apply the substitution trick even when $V(C^+) = V(G)$ and G has a triangular outer face; not adding edge (w, y) will ensure that C^+ has fewer interior vertices and induction can be applied.

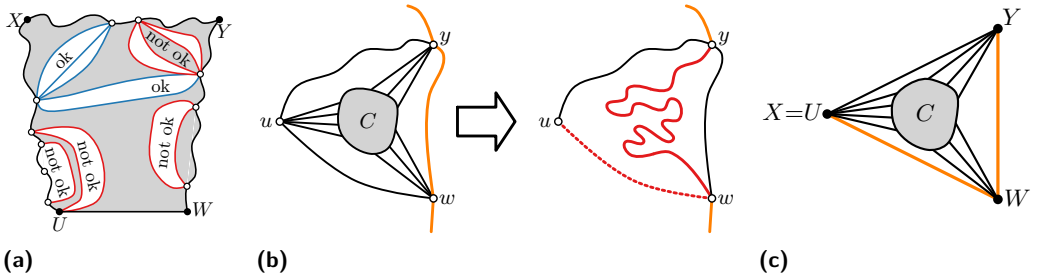

Figure 2 (a) Corner-3-connectivity $c3c(X, U, W, Y)$, (b) the substitution trick, and (c) Case 1.

C^+ satisfies $c3c(u, v, w)$, else there would have been a cutting pair in G that was interior or within one side. Hence, by induction, C^+ has a T_{int}-path P_{C^+} from u to y that uses edge (u, w). It does not use the edge (u, y) since P_{C^+} begins at u with edge (u, w). So $P_{C^+} \setminus (u, w)$ is a path in C from w to y that does not visit u. Substitute this in place of edge (w, y) of P; see Figure 2b. We claim that the resulting path P' is a T_{int}-path. We prove a more general statement in the full version [5], but roughly speaking, combining paths preserves T_{int}-paths because every P'-bridge can inherit its representative from P or P_{C^+}, and no vertex is used twice as representative since P_{C^+} does not use $\{u, v, w\}$ as representatives.

2.1 Proof of Lemma 2 and Lemma 3

We prove the two lemmas simultaneous by induction on the number of vertices of G, with an inner induction on the number of interior vertices. The base case is $n = 3$ where G is a triangle, but the same construction works whenever the outer face is a triangle (see below). For the induction step, we need the notation S_{xy}, which is the outer face path from x to y in ccw direction. In particular, the four sides are S_{XU}, S_{UW}, S_{WY}, and S_{YX}. We sometimes name sides as suggested by Figure 2a, so S_{XU}, S_{UW}, S_{WY}, and S_{YX} are the *left/bottom/right/top side*, respectively.

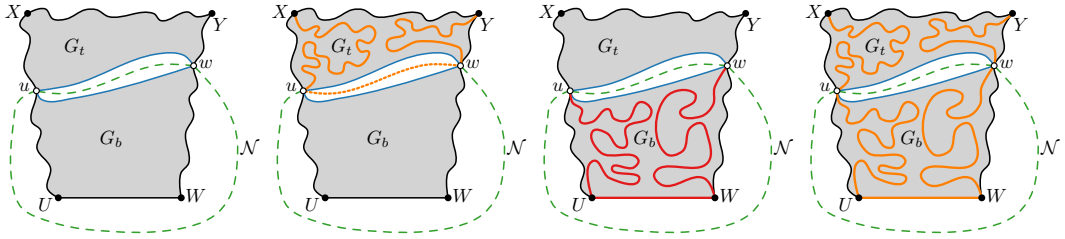
2.1.1 Case 1: The outer face is a triangle

Figure 2c illustrates this case. We know that $X \neq Y$ and $U \neq W$, so we must have $X = U$ or $W = Y$. For Lemma 3, we know that ($\sqsupset$) holds, which forces $W \neq Y$, hence $X = U$. For Lemma 2, we may assume $X = U$ by symmetry, for otherwise we reverse the planar embedding, find a path from Y to X that uses (W, U) (with this, we have $X' = U'$) and then reverse the result.

So $X = U$. Define P to be $\langle X{=}U, W, Y\rangle$ and observe that this is a T_{end}-path, because the unique P-bridge C (if any) has attachment points $\{U, W, Y\}$, and we can assign Y to be its representative. So Lemma 3 holds. Since condition ($\sqsupset$) is satisfied, this implies Lemma 2.

2.1.2 Case 2: G has a cutting pair $\{u, w\}$ with u and w on the left and right side

Figure 3 illustrates this case. Let $\mathcal{N}$ be a noose through u and w along a common interior face f^* and then going through the outer face. Let G_t and G_b be the subgraphs inside and outside $\mathcal{N}$, named such that G_b contains the bottom side. Let G_t^+/G_b^+ be the graphs obtained from G_t/G_b by adding (u, w) if not in the graph yet. We add (u, v) even if it did not exist in G (we will ensure that the final path does not use it).



(a) Case 2 **(b)** The path P_t **(c)** The path P_b **(d)** The path P

Figure 3 (a) Case 2, (b)–(d) proof of Lemma 2 for Case 2.

We first show Lemma 2. One can easily verify that G_t satisfies $c3c(X, u, w, Y)$ since its outer face is a simple cycle; see the full version [5]. Apply induction and find a T_{int}-path P_t of G_t^+ from X to Y that uses edge (u, w). Now apply a modified substitution trick to (u, w). Namely, by induction, there is a T_{int}-path P_b of G_b^+ from u to w that uses edge (U, W). Substitute P_b into P_t in place of (u, w) to get P. Path P uses (U, W) since P_b does. It does not use (u, w) since we removed this from P_t, and P_b starts at u, ends at w, and visits (U, W) in between. So after inheriting representatives from P_b and P_t we obtain a T_{int}-path P in G.

To prove Lemma 3, note that exactly one of G_t^+ and G_b^+ contains (W, Y); use a T_{end}-path for this subgraph and create P as above. Only one graph uses Y as representative, and one easily shows that P is a T_{end}-path.

2.1.3 Case 3: G has a cutting pair $\{y, w\}$ with y and w on the top and right side, respectively. Furthermore, there is an interior face f^* containing y and w that does not contain Y.

For later applications, we first want to point out that if G has a cutting pair $\{y, w\}$ on the top and right side for which (y, w) is an edge, then such a face f^* always exists, because there are two interior faces containing y and w, and not both can contain Y.

Figure 4 illustrates this case. We know that $w \neq Y \neq y$, else $\{y, w\}$ would be a cutting pair within one side. We may assume $y \neq X$; else we can use Case 2. Hence, the top side contains at least three vertices X, y, Y, so $(\sqsupset)$ does not hold and we have to prove only Lemma 2.

We choose $\{y, w\}$ such that w is as close to W as possible (along the right side). The face f^* containing y, w may have multiple edges on the top side; let y be the one that is as close to Y as possible. Define G_b, G_b^+, G_t, G_t^+ to be as in Case 2. Since the outer face of G_b^+ is a simple cycle, it satisfies $c3c(X, U, W, w, y)$. But since we chose w to be as close to W as possible, it also satisfies $c3c(X, U, W, y)$. Namely, assume for contradiction that some cutting pair $\{y', w'\}$ exists along the side $S_{Ww} \cup (w, y)$ of G_b^+; see Figure 4a. Since there is no cutting pair within S_{Ww}, it must have the form $\{y, w'\}$ for some $w' \neq w$ on S_{Ww}. As f^* does not contain Y, neither can any face containing $\{y, w'\}$, so $\{y, w'\}$ could have been used for Case 3, contradicting our choice of w.

By induction, we can find a T_{int}-path P_b of G_b^+ from X to y that includes the edge (U, W). The plan is to combine P_b with a path through G_t, but we must distinguish some cases.

Case 3a: P_b does not contain (y, w) or $(y, w) \in G$. Observe that G_t^+ satisfies $c3c(y, w, Y)$. By induction, find a T_{int}-path P_t in G_t^+ from Y to w that uses edge (y, w). Append the reverse of $P_t \setminus (y, w)$ to P_b to obtain a T_{int}-path; see Figure 4b.

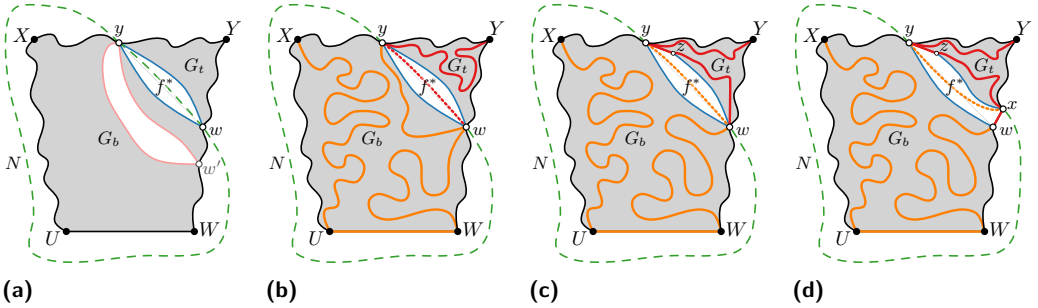


Figure 4 Case 3: (a) G_b^+ satisfies $c3c(X, U, W, y)$, (b) Case 3a, (c) Case 3b-1, (d) Case 3b-2.

Case 3b: P_b contains (y, w) and $(y, w) \notin G$. In this case, we must remove (y, w) from the path and hence use a subpath in G_t to reach vertex y. This requires further subcases. Let π_f be the path along f^* from y to w that becomes part of the the outer face of G_t. Let (y, z) be the edge incident to y on π_f.

Case 3b-1: π_f contains no vertex on the outer face of G other than y and w. See Figure 4c. The outer face of G_t is then a simple cycle and G_t satisfies $c3c(w, y, Y)$. By induction, we can find a T_{int}-path P_t in G_t that begins at Y, ends at w, and uses (y, z).

Case 3b-2: π_f contains a vertex $x \neq y, w$ on the outer face of G. See Figure 4d. Since x is on f^*, it cannot be on the top side by choice of y. So $x \in S_{wY} \setminus Y$. In fact, x must be the neighbor of w on both S_{wY} and π_f, else there would be a cutting pair within the right side. Set G'_t to be the graph inside a noose through y and x that has Y inside. Since π_f has no vertices other than y, x, w on the outer face of G, graph G'_t has a simple cycle as outer face, so it satisfies $c3c(Y, y, z, x)$. By induction, we can find a T_{int}-path P'_t of G_t that begins at Y, ends at x, and uses (y, z). We append (w, x) to obtain P_t.

In both cases, we obtain a path P_t that begins at Y, ends at w, and visits all of G_t. Appending the reverse of this to $P_b \setminus (y, w)$ gives the T_{int}-path.

2.1.4 Case 3′: G has a cutting pair $\{y, w\}$ with y and w on the top and left side, respectively. Furthermore, there is an interior face f^* containing y and w that does not contain X.

This is handled symmetrically to Case 3.

2.1.5 Case 4: None of the above

In this case, we split G into one big graph G_0 and (possibly many) smaller graphs $G_1, \ldots, G_s$, recurse in G_0, and then substitute T_{int}-paths of $G_1, \ldots, G_s$ or use them as P-bridges.

We need two subcases, but first give some steps that are common to both. Let Y_X be the neighbor of Y on the top side. Define a *B-necklace* (for $B \in \{U, W\}$) to be a noose $\mathcal{N}_0 : \langle Y_X{=}x_0, f_1, x_1, \ldots, x_{s-1}, f_s, x_s{=}B, f_o\rangle$, (where f_o is the outer face) for which x_i is face-adjacent to at least one vertex on $S_{WY} \setminus \{B\}$ for $1 \leq i \leq s-1$. See also Figure 5. We say that the necklace is *simple* if it contains no vertex twice, and *interior* if every x_i (for $0 < i < s$) is an interior vertex. One can argue that if none of the previous cases applies, then there always exists a simple interior B-necklace (see the full version [5]).

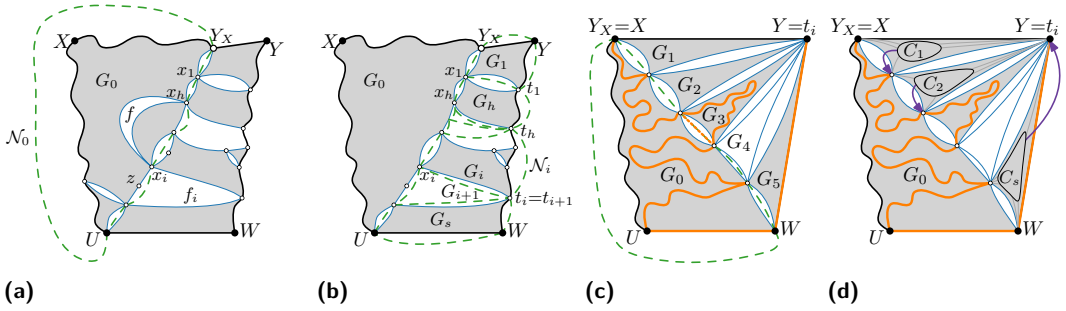

Figure 5 Case 4. (a) A simple interior U-necklace that is not leftmost due to face f (which yields a cutting pair $\{x_h, x_i\}$), and since it could include vertex z. (b) The graphs $G_1, \ldots, G_s$. (c–d) Case 4a. The path P^+ after using the substitution trick and (d) assignment of the representatives.

Route $\mathcal{N}_0$ through the outer face such that the left side is in its interior, and let G_0 (the "left graph") be the graph inside $\mathcal{N}_0$. We say that $\mathcal{N}_0$ is *leftmost* if (among all simple interior B-necklaces) its left graph G_0 is smallest, and (among all simple interior B-necklaces whose left graph is G_0) it contains the most vertices of G_0. Fix a leftmost B-necklace $\langle x_0, \ldots, x_s \rangle$.

▷ Claim 4. If (x_i, x_{i+1}) is not an edge for some $0 \le i < s$, then the face f_i of $\mathcal{N}_0$ contains no vertex of $S_{WY} \setminus \{B\}$.

Proof. If (x_i, x_{i+1}) is not an edge of G, then both paths from x_i to x_{i+1} on f_i contain at least one other vertex. One of them, say z, is inside $\mathcal{N}_0$. If f_i contains a vertex of $S_{WY} \setminus \{B\}$, then x_i and z are face-adjacent, z and x_{i+1} are face-adjacent, and z has a neighbor on $S_{WY} \setminus \{B\}$, so $x_0, \ldots, x_i, z, x_{i+1}, \ldots, x_s$ is a simple interior B-necklace with the same left graph but containing more vertices of G_0. Hence $\mathcal{N}_0$ is not leftmost, a contradiction. ◁

For $i = 0, \ldots, s-1$, let t_i be the vertex on $S_{WY} \setminus \{B\}$ that is face-adjacent to x_i and closest to Y (along the right side) among all such vertices. Set $t_s = W$ if $x_s = U$, and $t_s = Y$ otherwise. For $0 < i \le s$, define $\mathcal{N}_i$ to be the noose through $\langle x_{i-1}, x_i, t_i, t_{i-1} \rangle$ such that the left side is outside $\mathcal{N}_i$. For $0 < i \le s$ let G_i be the graph inside $\mathcal{N}_i$ (i.e., a cut component of $\{x_{i-1}, x_i, t_{i-1}, t_i\}$); see Figure 5b.

Let G^+ be the graph obtained from G by adding *virtual edges* (x_i, x_{i-1}) and (t_i, t_{i-1}) (for $i = 1, \ldots, s$) whenever these two vertices are distinct and the edge did not exist in G. Let G_0^+ be the graph obtained from G_0 by likewise adding virtual edges $(x_0, x_1), \ldots, (x_{s-1}, x_s)$. This makes the outer face of G_0 a simple cycle, so G_0^+ satisfies $c3c(X, U, B{=}x_s, \ldots, x_0{=}Y_X)$. We distinguish two cases.

Case 4a: ($\sqsupset$) holds, i.e., (X, Y) and (W, Y) are edges. We only have to prove Lemma 3 since this implies Lemma 2. Consider Figs. 5c and d. Let $\langle x_0{=}Y_X{=}X, x_1, \ldots, x_s{=}W \rangle$ be a leftmost W-necklace. By $S_{WY} = (W, Y)$, we have $t_i = Y$ for all i. Since $x_0 = Y_X = X$, we have that G_0^+ satisfies $c3c(X{=}x_0, x_1, \ldots, x_s{=}W, U)$. But observe that G_0^+ has no cutting pair $\{x_h, x_i\}$ with $0 \le h < i \le s$, for otherwise the face f containing x_h and x_i could be used as a shortcut and $\mathcal{N}_0$ was not leftmost (see Figure 5a). So G_0^+ actually satisfies $c3c(X, W, U)$. Use induction to obtain a T_{int}-path P_0 from X to W in G_0^+ that uses edge (U, W). Then $P^+ = P_0 \cup (W, Y)$ is a path in G^+ that contains (U, W), and (W, Y).

Fix some $i = 1, \ldots, s$. If P^+ used edge (x_{i-1}, x_i) and it was virtual, then by Claim 4 f_i contains no vertex of S_{WY}, which means that the interior of G_i is non-empty. Apply the substitution trick to remove (x_{i-1}, x_i) from P^+, replacing it with a path through G_i.

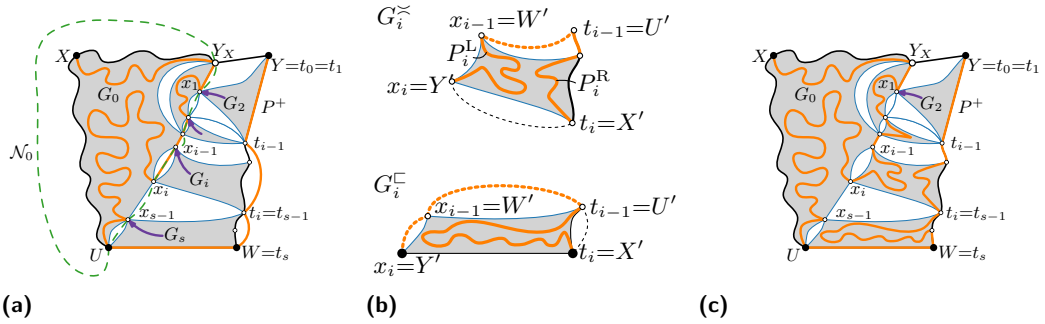

Figure 6 Case 4b. (a) Construction of P^+ with representatives; (b) $G_i^{\asymp}$ (Case 4b-2) and $G_i^{\sqsubset}$ (Case 4b-3) used to substitute virtual edges; (c) P^+ with representatives after all substitutions.

Otherwise, we keep G_i as a P^+-bridge. We let its representative be x_i if $1 \leq i < s$, and Y if $i = s$. Observe that this representative is interior or Y, and was not used by P_0 since P_0 was a T_{int}-path. So we obtain a T_{end}-path with the desired properties.

Case 4b: ($\sqsupset$) does not hold. We must prove only Lemma 2 and may therefore by symmetry assume that $X \neq U$. We claim that this implies that $\deg(Y_X) \geq 3$. For if $\deg(Y_X) = 2$, then its neighbors form a cutting pair, which by corner-3-connectivity means that Y_X is a corner, hence $Y_X = X$. Since $X \neq U$, the two neighbors of Y_X are then Y and a vertex on the left side, and we could have applied Case 2. So $\deg(Y_X) \geq 3$. Let (Y_X, x_1) be the edge at Y_X that comes after (Y_X, Y) in clockwise order (see Figure 6a). Note that x_1 is face-adjacent to Y. It must be an interior vertex, for otherwise by $\deg(Y_X) \geq 3$ edge (Y_X, x_1) is a cutting pair that we could have used for Case 3 or 3′.

Let $\mathcal{N}_0 = \langle x_0{=}Y_X, x_1, \ldots, x_s{=}U\rangle$ be a simple interior U-necklace; see Figure 6a. We use a U-necklace that is leftmost among all U-necklaces that contain x_1. Note that Claim 4 holds for $\mathcal{N}_0$ even with this restriction, since (x_0, x_1) is an edge. We know that G_0^+ satisfies $c3c(X, Y_X, x_1, \ldots, x_s{=}U)$. But observe that G_0^+ has no cutting pair $\{x_h, x_i\}$ for $1 \leq h < i \leq s$, for otherwise (as in Figure 5a) $\mathcal{N}_0$ would not be the leftmost necklace that uses x_1. So G_0^+ actually satisfies $c3c(X, Y_X, x_1, U)$.

Use induction to obtain a T_{int}-path P_0 in G_0 from U to X through edge (x_1, x_0). Append the path $\langle U, W, t_s, \ldots, t_0{=}Y\rangle$ to the reverse of P_0 to obtain path P^+. This path begins at X, ends at Y, and contains (U, W). Any P^+-bridge is either a P_0-bridge (and receives a representative there) or is G_i for some $1 \leq i \leq s$. For $i > 1$, assign x_{i-1} as representative to G_i. Graph G_1 has an empty interior by choice of x_1 and needs no representative.

There are two reasons why we cannot always use P^+ for the result. First, it may use virtual edges and hence not be a path in G. Second, some P^+-bridge G_i may have four attachment points. Both are resolved by expanding P^+ via paths through the G_i's. Fix one i with $1 \leq i \leq s$ and consider the following cases:

Case 4b-1: (x_{i-1}, x_i) is virtual and used by P^+, and $t_{i-1} = t_i$. By Claim 4, the interior of graph G_i is non-empty and inside the separating triplet $\{x_{i-1}, x_i, t_i\}$. Replace (x_{i-1}, x_i) by a path through G_i with the substitution trick; see graph G_3 in Figure 6.

Case 4b-2: (x_{i-1}, x_i) is virtual and used by P^+, and $t_{i-1} \neq t_i$. See Figure 6b(top). We want to replace both (x_{i-1}, x_i) and (t_{i-1}, t_i) (which is always used by P^+) with a path through G_i. Let $G_i^{\asymp}$ be the graph G_i with (t_i, x_i) and (t_{i-1}, x_{i-1}) added. The outer face of $G_i^{\asymp}$ is a simple cycle since f_i contains no vertex of the right side by Claim 4, so $G_i^{\asymp}$ satisfies $c3c(t_i, t_{i-1}, x_{i-1}, x_i)$. By induction, find a T_{int}-path P_i in $G_i^{\asymp}$ from t_i to x_i

that uses the edge (t_{i-1}, x_{i-1}). So removing (t_{i-1}, x_{i-1}) from P_i splits it into two paths: path P_i^{R} connects t_i to t_{i-1}, and path P_i^{L} connects x_{i-1} to x_i. (No other split is possible by planarity.) Neither path uses the added edge (t_i, x_i) since it connects the ends of P_i. Use P_i^{R} to replace (t_{i-1}, t_i) and P_i^{L} to replace (x_{i-1}, x_i) in P^+.

Case 4b-3: Subgraph G_i has a non-empty interior and $t_i \neq t_{i-1}$. See Figure 6b(bottom). In this case, G_i is a P^+-bridge with four attachment points, a violation of Tutte path properties. If Case 4b-2 applied to G_i, then G_i is no longer a bridge of the resulting path and we are done. Otherwise, we do a substitution that uses a different supergraph of G_i. Let $G_i^{\sqsubset}$ be G_i with edges from path $\langle t_{i-1}, x_{i-1}, x_i, t_i\rangle$ added if not already in G_i. This graph satisfies $c3c(t_i, t_{i-1}, x_{i-1}, x_i)$ and satisfies condition ($\sqsupset$) if we set $X' = t_i$, $U' = t_{i-1}, W' = x_{i-1}$, and $Y' = x_i$. So we can find a T_{end}-path P_i' of $G_i^{\sqsubset}$ from t_i to x_i that uses (t_{i-1}, x_{i-1}) and (x_{i-1}, x_i). Thus, P_i' ends with $\langle t_{i-1}, x_{i-1}, x_i\rangle$ and $P_i' \setminus \{(t_{i-1}, x_{i-1}), (x_{i-1}, x_i)\}$ is a path from t_{i-1} to t_i in G_i that does not visit x_{i-1} or x_i. Substitute this path in place of edge (t_{i-1}, t_i) in P^+. Note that one P_i'-bridge C may use x_i as its representative, but if so, then it also has x_{i-1} as attachment point. We set x_{i-1} (which was G_i's representative and is no longer needed as such) to be the representative of C.

Case 4b-4: $t_{i-1} \neq t_i$ and (t_{i-1}, t_i) is virtual. Since P^+ always uses edge (t_{i-1}, t_i), we must replace this edge with a path through G_i. This is done automatically because Case 4b-3 applies. Namely, if (t_{i-1}, t_i) is virtual, then there is at least one vertex between t_{i-1} and t_i on the right side. This vertex is exterior in G and hence neither x_i nor x_{i-1}. So it is strictly inside $\mathcal{N}_i$, hence G_i has a non-empty interior and (by $t_{i-1} \neq t_i$) Case 4b-3 applies.

After doing these substitutions, there are no virtual edges in the path, no bridges have four attachment points, every bridge has an interior vertex as representative, and no vertex was used twice as representative; see Figure 6c. This ends the proof of Lemma 2 and 3.

2.2 Linear time complexity

It should be clear that our proof is algorithmic. The main bottlenecks for its running time are to determine which case to apply (i.e., whether there is a cutting pair) and to find the B-necklace. Both can be done in linear time, by computing all cutting pairs [6, 9] and by finding a leftmost path in the subgraph induced by vertices that are face-adjacent to $S_{WY} \setminus B$. This would yield quadratic running time overall. For triangulated planar graphs, this is easily reduced to linear: cutting pairs correspond to interior edges where both ends are exterior, and the necklace can be found, as in [1], with a left-first search that only advances neighbors of $S_{WY} \setminus B$. But for graphs that are not triangulated we need a few extra data structures. We sketch only some ideas for this here; details are in the full version [5].

Globally, we keep track of the corners X, U, W, and Y. For each *interior vertex* w and every *side* S_{ab}, we keep a list $\mathcal{V}(w, S_{ab})$ of faces that contain w as well as a vertex on S_{ab}. In these lists, we can look up quickly whether an interior vertex is face-adjacent to a side. Also, each face knows for each side which vertices it has on it. Finally, for each *pair of sides* S_{ab} and S_{cd}, we store a list $\mathcal{P}(S_{ab}; S_{cd})$ of faces that are incident to a vertex on S_{ab} and a (different) vertex on S_{cd}, i.e., faces that connect cutting pairs.

This allows to test for Case 2 and Case 3 easily ("is $\mathcal{P}(S_{XU}, S_{WY})$ resp. $\mathcal{P}(S_{WY}, S_{YX})$ non-empty?"), and Case 1 and Case 4 are easily determined from the planar embedding. We keep $\mathcal{P}(S_{WY}, S_{YX})$ in an order such that its first entry is the appropriate cutting pair in Case 3. To find a necklace, we *scan* the faces incident to $x_1, \ldots, x_s$. More precisely, we

consider (for vertex x_i, presuming we know face f_i already) each face f in ccw order after f_i, and along face f each vertex w in ccw order after x_i, until we find vertex B (then we are done) or a vertex that is face-adjacent to a vertex in $S_{WY} \setminus B$ (then this is x_{i+1} and $f_{i+1} = f$ and we repeat). The running time for this is proportional to the degrees of vertices and faces that were scanned. We also need to update the data structures when recursing into a subgraph; here, we scan along all vertices (and their incident faces) that were in some necklace along which we cut the graph, or that became newly exterior.

A few crucial insights are needed to bound the running time. First, by corner-3-connectivity every face has at most two vertices on each side. In particular, the above data structures have linear size. Second, we need to scan vertices and faces only if they become incident to a side that they were not previously incident to. Finally, once a vertex or face is incident to a side, it remains incident to it forever (though the side may change role, e.g. from "left" to "top"). This means that every vertex and face is scanned only a constant number of times, because there are only four sides to have incidences with. In fact, we only scan vertices and faces that are incident to the outer face in some subgraph, which means that they will be incident to the path P that we compute, and we have the following:

▶ **Theorem 5.** *The Tutte path P for Theorem 1, Lemma 2 or Lemma 3 can be found in linear time. More specifically, the running time is $O(\sum_{f \in F(P)} \deg(f))$.*

3 Applications

A number of interesting properties of planar 3-connected graphs can be derived easily from the existence of T_{SDR}-paths. In particular, every planar 3-connected graph has a spanning tree of maximum degree 3 [2] (a concept known in the literature as a *3-tree*, but we prefer to use the term *binary spanning tree* to avoid confusion with maximal graphs of treewidth 3). Secondly, every planar 3-connected graph has a *2-walk*, i.e., a walk that visits every vertex at least once and at most twice [8]. In the full version [5], we show that, using Lemma 2, these can be found in linear time; this was known for binary spanning trees [16, 3], but for 2-walks the previous best running time was $O(n^3)$ [15].

▶ **Theorem 6.** *Let G be a 3-connected plane graph with exterior vertex X. Then G has a binary spanning tree T that can be found in linear time. Moreover, when rooting T at X, a vertex v has two children only if it is an interior vertex and part of a cutting triplet $\{v, w, x\}$ of G; one of the subtrees of v contains exactly the vertices interior to $\{v, w, x\}$.*

▶ **Theorem 7.** *Let G be a 3-connected plane graph with exterior vertex X. Then G has a 2-walk P that can be found in linear time. Moreover, P visits X exactly once, and it visits a vertex v twice only if v is part of a separating triplet.*

4 Outlook

In this paper, we improved on a very recent result that shows that Tutte paths in planar graphs can be found in quadratic time. We gave a different existence proof which leads to a linear-time algorithm. For 3-connected planar graphs, we obtain not only a Tutte path, but furthermore endow it with a system of distinct representatives, none of which is on the outer face. With this, we can also find 2-walks and binary spanning trees in 3-connected planar graphs in linear time.

The main remaining questions concern how to find Tutte path in other situations or with further restriction. For example, Thomassen [18] and later Sanders [12] improved Tutte's result and showed that we need not restrict the ends of the Tutte path to lie on the outer face. These paths can be found in quadratic time [15]. But our proof does not seem to carry over to the result by Sanders, because the ends of the path crucially must coincide with corners of the graph. Can we find such a path in linear time?

Furthermore, the existence of Tutte paths has been studied for other types of surfaces (see, e.g., Kawarabayashi and Ozeki [11] and the references therein). Can these Tutte paths be found in polynomial time, and preferably, linear time?

Abstract

A few years ago, Alon et al. [ISMB 2008] gave a *simple randomized* $\mathcal{O}((2e)^k m\epsilon^{-2})$-time exponential-space algorithm to approximately compute the number of paths on k vertices in a graph G up to a multiplicative error of $1 \pm \epsilon$. Shortly afterwards, Alon and Gutner [IWPEC 2009, TALG 2010] gave a *deterministic* exponential-space algorithm with running time $(2e)^{k+\mathcal{O}(\log^3 k)} m \log n$ whenever $\epsilon^{-1} = k^{\mathcal{O}(1)}$. Recently, Brand et al. [STOC 2018] provided a speed-up at the cost of reintroducing randomization. Specifically, they gave a *randomized* $\mathcal{O}(4^k m\epsilon^{-2})$-time exponential-space algorithm. In this article, we revisit the algorithm by Alon and Gutner. We modify the foundation of their work, and with a novel twist, obtain the following results.

- We present a *deterministic* $4^{k+\mathcal{O}(\sqrt{k}(\log^2 k+\log^2 \epsilon^{-1}))} m \log n$-time *polynomial-space* algorithm. This *matches* the running time of the best known deterministic polynomial-space algorithm for *deciding* whether a given graph G has a path on k vertices.
- Additionally, we present a *randomized* $4^{k+\mathcal{O}(\log k(\log k+\log \epsilon^{-1}))} m \log n$-time *polynomial-space* algorithm. While Brand et al. make non-trivial use of exterior algebra, our algorithm is very simple; we only make elementary use of the probabilistic method.

Thus, the algorithm by Brand et al. runs in time $4^{k+o(k)}m$ whenever $\epsilon^{-1} = 2^{o(k)}$, while our deterministic and randomized algorithms run in time $4^{k+o(k)} m \log n$ whenever $\epsilon^{-1} = 2^{o(k^{\frac{1}{4}})}$ and $\epsilon^{-1} = 2^{o(\frac{k}{\log k})}$, respectively. Prior to our work, no $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$-time *polynomial-space* algorithm was known. Additionally, our approach is embeddable in the classic framework of divide-and-color, hence it immediately extends to approximate counting of graphs of bounded *treewidth*; in comparison, Brand et al. note that their approach is limited to graphs of bounded *pathwidth*.

1 Introduction

The objective of the #k-Path problem is to compute the number of k-paths – that is, (simple) paths on k vertices – in a given graph G. Unfortunately, this problem is #W[1]-hard [19], which means that it is unlikely to be solvable in time $f(k)n^{\mathcal{O}(1)}$ for any computable function f of k. Nevertheless, this problem is long known to admit an FPT-approximation scheme (FPT-AS), that is, an $f(k, \epsilon^{-1})n^{\mathcal{O}(1)}$-time algorithm that approximately computes the number of k-paths in a given graph G up to a multiplicative error of $1 \pm \epsilon$. More than 15 years ago, Arvind and Raman [6] utilized the classic method of *color coding* [5] to design a *randomized* exponential-space FPT-AS for #k-Path with running time $k^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ whenever $\epsilon^{-1} \leq k^{\mathcal{O}(k)}$. A few years afterwards, the development and use of applications in computational biology to detect and analyze *network motifs* have already become common practice [34, 37, 36, 18, 24]. Roughly speaking, a network motif is a small pattern whose number of occurrences in a given network is substantially larger than its number of occurrences in a random network. Due to their tight relation to network motifs, #k-Path and other cases of the #Subgraph Isomorphism problem became highly relevant to the study of gene transcription networks, protein-protein interaction (PPI) networks, neural networks and social networks [31]. In light of these developments, Alon et al. [2] revisited the method of color coding to attain a running time whose dependency on k is *single-exponential* rather than *slightly super-exponential*. Specifically, they designed a *simple randomized* $\mathcal{O}((2e)^k m\epsilon^{-2})$-time exponential-space FPT-AS for #k-Path, which they employed to analyze PPI networks of unicellular organisms. In particular, their algorithm has running time $2^{\mathcal{O}(k)}m$ whenever $\epsilon^{-1} \leq 2^{\mathcal{O}(k)}$.

The first *deterministic* FPT-AS for #k-Path was found in 2007 by Alon and Gutner [4]; this algorithm has an exponential space complexity and running time $2^{\mathcal{O}(k \log\log k)}m \log n$ whenever $\epsilon^{-1} = 2^{o(\log k)}$. Shortly afterwards, Alon and Gutner [3] improved upon their previous work, and designed a deterministic exponential-space FPT-AS for #k-Path with running time $(2e)^{k+\mathcal{O}(\log^3 k)}m \log n$ whenever $\epsilon^{-1} = k^{\mathcal{O}(1)}$. For close to a decade, this algorithm has remained the state-of-the-art. In contrast, during this decade, the k-Path problem (the decision version of #k-Path) has seen several improvements that were considered to be breakthroughs at their time [14, 26, 8, 10, 21]. In 2016, Koutis and Williams [27] conjectured that #k-Path admits an FPT-AS with running time $2^k n^{\mathcal{O}(1)}$. Recently, at the cost of reintroducing randomization, Brand et al. [13] provided a speed-up towards the resolution of this conjecture. Specifically, they gave an algebraic *randomized* $\mathcal{O}(4^k m\epsilon^{-2})$-time exponential-space algorithm. In the context of Parameterized Complexity in general, and the k-Path problem in particular, the power of randomization is an issue of wide interest [1]. Specifically for the k-Path problem, an algebraic randomized $2^k n^{\mathcal{O}(1)}$-time algorithm has been found already a decade ago [38], and since then, the existence of a deterministic algorithm that exhibits the same time complexity has been repeatedly posed as a major open problem in the field. Both Koutis and Williams conjectured this question to have an affirmative answer in several venues [38, 28, 27]. Clearly, this question is simpler than the one of the design of a deterministic FPT-AS for #k-Path with running time $2^k n^{\mathcal{O}(1)}$.

In this article, we modify the foundation of the work of Alon and Gutner [4, 3], and with a novel twist, obtain the following results (see Theorem 21 and Corollary 10).

- First, we present a *randomized* $4^{k+\mathcal{O}(\log k(\log k+\log \epsilon^{-1}))}m \log n$-time *polynomial-space* algorithm. While Brand et al. [13] make non-trivial use of exterior algebra, *our randomized algorithm is very simple*: we only make elementary use of the probabilistic method.[1]

[1] Of course, simplicity is a subjective matter, which may depend on the background of the reader.

- Additionally, we present a *deterministic* $4^{k+\mathcal{O}(\sqrt{k}(\log^2 k+\log^2 \epsilon^{-1}))}m \log n$-time *polynomial-space* algorithm. In particular, *without compromising time complexity, we attain both the properties of having a polynomial space complexity and being deterministic simultaneously.* In fact, even though we deal with #k-Path, the running time of our algorithm *matches* the best known running time of a deterministic polynomial-space algorithm for k-Path (the decision version of #k-Path) [14].

Thus, the algorithm by Brand et al. [13] runs in time $4^{k+o(k)}m$ whenever $\epsilon^{-1} = 2^{o(k)}$, while our deterministic and randomized algorithms run in time $4^{k+o(k)}m \log n$ whenever $\epsilon^{-1} = 2^{o(k^{\frac{1}{4}})}$ and $\epsilon^{-1} = 2^{o(\frac{k}{\log k})}$, respectively.

Prior to our work, no $c^k n^{\mathcal{O}(1)}$-time *polynomial-space* (even randomized) algorithm for #k-Path was known *for any constant* c. The design of polynomial-space parameterized algorithms is an active research area in Parameterized Complexity. Even (sometimes) at a notable compromise of time complexity, the property of having polynomial space complexity is sought (see, e.g., [20, 30, 29, 7, 23]). Indeed, algorithms with high space complexity are in practice more constrained because the amount of memory is not easily scaled beyond hardware constraints whereas time complexity can be alleviated by allowing for more time for the algorithm to finish. Furthermore, algorithms with low space complexity are typically easier to parallelize and more cache-friendly.

Additionally, our approach is embeddable in the classic framework of divide-and-color, hence it immediately extends to approximate counting of graphs of bounded treewidth;in comparison, Brand et al. [13] note that their approach is limited to graphs of bounded pathwidth. Similarly, we can approximately count various other objects such as q-dimensional p-matchings, q-set p-packings, graph motifs, and more:

▶ **Theorem 1.** *The following problems admit deterministic* $4^{k+\mathcal{O}(\sqrt{k}(\log^2 k+\log^2 \frac{1}{\epsilon}))}n^{\mathcal{O}(1)}$*-time (resp. randomized* $4^{k+\mathcal{O}(\log^2 k)}(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}n^{\mathcal{O}(1)}$*-time) FPT-ASs with polynomial space complexity:* (i) #Subgraph Isomorphism *for* k*-vertex subgraphs of treewidth* $\mathcal{O}(1)$*;* (ii) #q-Dimensional p-Matching *with* $k = (q-1)p$*;* (iii) #q-Set p-Packing *with* $k = qp$*;* (iv) #Graph Motif *and* #Module Motif *with* $k = 2p$ *where* p *is the motif size;* (v) #p-Internal Out-Branching *with* $k = 2p$*;* (vi) #Partial Cover *for* k*-element solutions.*[2]

Towards the design of our algorithms, our first conceptual contribution is the introduction of the notion of an *approximate parsimonious splitter*. While a randomized construction of such an object is simple, we do not know how (or whether it is even possible) to compute it deterministically within the size and time bounds that we require. We believe that this gap in knowledge of derandomization is the main reason why, for close to a decade, no progress has been made upon the result by Alon and Gutner [4, 3]. Here, our second conceptual contribution comes into play. We show that for recursive procedures, a weaker object that can only split so called nice sets suffices, since the recursion itself can keep track on the "niceness" of sets. We believe that both the concept of approximate parsimonious splitters as well as our approach of how to weaken a randomized object (to efficiently compute it deterministically) at the cost of simple bookkeeping might find further applications in the future. Our ideas and methods are discussed in more detail in Section 3.

[2] For problems (i) and (iv), the basis 4 is replaced by the basis 4.001 (or, more precisely, $4+\delta$ for any fixed constant $\delta > 0$).

Related Work. The algorithms by Alon et al. [2] and Alon and Gutner [4, 3], just like our algorithms, extend to approximate counting of graphs of bounded treewidth. (This remark is also made by Alon and Gutner [4, 3].) In what follows, we briefly review works related to exact counting and decision from the viewpoint of Parameterized Complexity. Since these topics are not the focus of our work, the survey is illustrative rather than comprehensive.

The problem of counting the number of subgraphs of a graph G that are isomorphic to a graph H – that is, #Subgraph Isomorphism with Pattern H – admits a dichotomy: If the vertex cover number of H is bounded, then it is FPT [39], and otherwise it is #W[1]-hard [16]. The #W[1]-hardness of #k-Path, originally shown by Flum and Grohe [19], follows from this dichotomy. By using the "meet in the middle" approach, the #k-Path problem and, more generally, #Subgraph Isomorphism with Pattern H where H has bounded *pathwidth* and k vertices, was shown to admit an $n^{\frac{k}{2}+\mathcal{O}(1)}$-time algorithm [9]. Later, Björklund et al. [12] showed that $\frac{k}{2}$ is not a barrier (which was considered to be the case at that time) by designing an $n^{0.455k+\mathcal{O}(1)}$-time algorithm. Recently, a breakthrough that resulted in substantially faster running times took place: Curticapean et al. [15] showed that #Subgraph Isomorphism with Pattern H is solvable in time $\ell^{\mathcal{O}(\ell)}n^{0.174\ell}$ where ℓ is the number of edges in H; in particular, this algorithm solves #k-Path in time $k^{\mathcal{O}(k)}n^{0.174k}$.

The k-Path problem (on both directed and undirected graphs) is among the most extensively studied parameterized problems [17, 22]. After a long sequence of works in the past three decades, the current best known parameterized algorithms for k-Path have running times $1.657^k n^{\mathcal{O}(1)}$ (randomized, polynomial space, undirected only) [10, 8] (extended in [11]), $2^k n^{\mathcal{O}(1)}$ (randomized, polynomial space) [38], $2.597^k n^{\mathcal{O}(1)}$ (deterministic, exponential space) [40, 21, 35], and $4^{k+o(k)}n^{\mathcal{O}(1)}$ (deterministic, polynomial space) [14]. The $1.657^k n^{\mathcal{O}(1)}$-time algorithm of Björklund et al. [10, 8] crucially relies on the symmetric structure of undirected k-paths. However, all other algorithms above directly extend to the detection of subgraphs of bounded treewidth. In particular, if the running time of the algorithm is $c^k n^{\mathcal{O}(1)}$, then the running time of the extension is $c^k n^{t+\mathcal{O}(1)}$ where t is the treewidth of the sought graph. To ensure that the constant c remains the same when dealing with the two deterministic algorithms (of [40, 21, 35] and [14]), the "division into small trees" trick by Fomin et al. [21] can be used; for the randomized algorithm (of [38]), no trick is required.

2 Preliminaries

For the sake of readability, we ignore ceiling and floor signs. Given a graph G, we let $V(G)$ and $E(G)$ denote the vertex set and edge set of G, respectively. For a positive integer k, a *k-path* in G is a (simple) path on k vertices in G; in case G is directed, the path is directed as well. We let $n = |V(G)|$ and $m = |E(G)|$. For a subset $U \subseteq V(G)$, $G[U]$ denotes the subgraph of U induced by G, and $G - U = G[V(G) \setminus U]$.

For a function $f : A \to B$ and subsets $A' \subseteq A$ and $B' \subseteq B$, define $f(A') = \{f(a) : a \in A'\}$ and $f^{-1}(B') = \{a \in A : f(a) \in B'\}$. For two functions $f : A \to B$ and $g : B \to C$, the notation $g \circ f : A \to C$ refers to function composition. For two tuples $X = (x_1, x_2, \ldots, x_p)$ and $Y = (y_1, y_2, \ldots, y_q)$, denote their concatenation by $X \diamond Y = (x_1, x_2, \ldots, x_p, y_1, y_2, \ldots, y_q)$. By standard Chernoff bounds, we have the following bounds.

▶ **Proposition 2** ([32]). *Let $X_1, \ldots, X_n$ be independent random variables, each assigned a value in $\{0, 1\}$. Let $X = \sum_{i=1}^{n} X_i$, and let $\mu = E[X]$ denote the expected value of X. Then, for any $0 \leq \delta \leq 1$, it holds that* (i) $\Pr(X \leq (1-\delta)\mu) \leq e^{-\frac{\delta^2\mu}{2}}$ *and* (ii) $\Pr(X \geq (1+\delta)\mu) \leq e^{-\frac{\delta^2\mu}{3}}$.

Universal Families. For any $k \in \mathbb{N}$, a *k-set* is a set of size k. Given a universe U, denote $\binom{U}{k} = \{S \subseteq U : |S| = k\}$. Given a family $\mathcal{F}$ over U and two subsets $A, B \subseteq U$, denote $\mathcal{F}[A, B] = \{F \in \mathcal{F} : A \subseteq F, B \cap F = \emptyset\}$. Next, we present the definition of a universal family.

▶ **Definition 3** (Universal Family [33, 21]). *Let $n, p, q \in \mathbb{N}$. A family $\mathcal{F}$ of sets over a universe U of size n is an* (n, p, q)-universal family *if for each pair of disjoint sets $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$, there is a set $F \in \mathcal{F}$ that contains A and is disjoint from B, that is, $\mathcal{F}[A, B] \neq \emptyset$.*

In the classic setting by Naor et al. [33], $p = q$. However, as shown by Fomin et al. [21], cases where $p \neq q$ are also of interest. Specifically, the following well-known proposition asserts that small representative families can be computed efficiently.

▶ **Proposition 4** ([33, 21]). *Let $n, p, q \in \mathbb{N}$, and $k = p + q$. Let U be a universe of size n. Then, an (n, p, q)-universal family $\mathcal{F}$ of sets over U of size $\mathcal{O}(\binom{k}{p} \log n)$ can be computed with success probability $1 - 1/n$ in time $\mathcal{O}(\binom{k}{p} n \log n)$. Additionally, an (n, p, q)-universal family $\mathcal{F}$ of sets over U of size $\binom{k}{p} 2^{o(k)} \log n$ can be computed (deterministically) in time $\binom{k}{p} 2^{o(k)} n \log n$. Both computations can enumerate the sets in $\mathcal{F}$ with polynomial delay.*

Observe that the constructions above are essentially optimal since any (n, p, q)-universal family must be of size at least $\binom{k}{p}$. We later extend Definition 3 to be approximately parsimonious, and show how to compute approximate parsimonious universal families.

3 Overview of Our Ideas and Methods

In this section, we discuss our main ideas and methods. Additionally, we present a simplified version of one of our applications in detail.

3.1 Approx. Parsimonious Universal Family: Randomized Construction

For any pair of disjoint sets $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$, Definition 3 guarantees that $\mathcal{F}[A, B] \neq \emptyset$. However, the number of sets in $\mathcal{F}[A, B]$ can be arbitrary. In our applications, the number of sets in $\mathcal{F}[A, B]$ will be tightly linked to the number of solutions whose "first half" is in A and whose "second half" is in B; thus, to avoid over-counting some solutions, we need all families $\mathcal{F}[\cdot, \cdot]$ to be *roughly* of the same size. For this purpose, let us first extend Definition 3 to be approximately parsimonious.

▶ **Definition 5** (δ-Parsimonious Universal Family). *Let $n, p, q \in \mathbb{N}$ and $0 < \delta < 1$. Denote $k = p + q$. A family $\mathcal{F}$ of sets over a universe U of size n is a* δ-parsimonious (n, p, q)-universal family *if there exists $T = T(n, p, q, \delta) > 0$ such that for each pair of disjoint sets $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$, it holds that $(1-\delta) \cdot T \leq |\mathcal{F}[A, B]| \leq (1+\delta) \cdot T$.*

We call the value T above a *correction factor*, and suppose it to be given along with the family $\mathcal{F}$. Our randomized computation of a δ-parsimonious (n,p,q)-universal family is based on the probabilistic method, inspired by [33, 21]. Specifically, we prove the following.

▶ **Theorem 6.** *Let $n,p,q \in \mathbb{N}$ and $0 < \delta < 1$, and denote $k = p+q$. Let U be a universe of size n. A δ-parsimonious (n,p,q)-universal family $\mathcal{F}$ of sets over U of size $t = \mathcal{O}\left(\frac{k^k}{p^p q^q} \cdot k \log n \cdot \frac{1}{\delta^2}\right)$,[3] can be computed with success probability at least $1 - 1/n^{100k}$ in time $\mathcal{O}(t \cdot n)$. In particular, the sets in $\mathcal{F}$ can be enumerated with delay $\mathcal{O}(n)$.*

We note that the choice of 100 is arbitrary; it can be replaced by the choice of any fixed constant c. Crucially, we gain the extra property of being δ-parsimonious while essentially having the same time complexity and upper bound on the size of the output as in the non-parsimonious construction.

3.2 Warm Up Application: Simple Randomized FPT-AS for #k-Path

Before we delve into more technical and less intuitive definitions related to our deterministic construction, we find it important to understand the relation between Definition 5 and #k-Path. For this purpose, we present a simple randomized polynomial-space FPT-AS for #k-Path. The dependency of the time complexity on n is made almost linear in Section 3.3). While the improved algorithm is still short and simple, it is somewhat less intuitive and hence presented separately later. For the sake of illustration, suppose that G is undirected.

Algorithm. Let $\widehat{\epsilon} = \ln(1+\epsilon)$ and $\epsilon' = \widehat{\epsilon}/(k-1)$. Our algorithm is a recursive algorithm, denoted by $\mathcal{A}$. Each call to $\mathcal{A}$ is of the form $\mathcal{A}(G',k')$ where G' is an induced subgraph of G and $k' \in \{1,\ldots,k\}$. For all $u,v \in V(G')$, the call $\mathcal{A}(G',k')$ should output an integer $a_{u,v}$ that approximates the number of k'-paths with endpoints u and v in G'. The initial call to the algorithm is with $G' = G$ and $k' = k$, and the final output is $(\sum_{u,v \in V(G)} a_{u,v})/2$.

We turn to describe a call $\mathcal{A}(G',k')$. In the basis, where $k' = 1$, we return $a_{v,v} = 1$ for all $v \in V(G')$, and $a_{u,v} = 0$ for all $u,v \in V(G')$ (with $u \neq v$).

Now, suppose that $k' \geq 2$. By Theorem 6, for an ϵ'-parsimonious $(n, k'/2, k'/2)$-universal family $\mathcal{F}$ of sets over $V(G)$, we can enumerate the sets $F \in \mathcal{F}$ with delay $\mathcal{O}(n)$. For each set $F \in \mathcal{F}$, we proceed as follows. We first perform two recursive calls: *(i)* we call $\mathcal{A}$ with $(G'[F], k'/2)$; *(ii)* we call $\mathcal{A}$ with $(G' - F, k'/2)$. For any $u,v \in F \cap V(G')$, let $b^F_{u,v}$ denote the number returned by the first call. Similarly, for any $u,v \in V(G') \setminus F$, let $c^F_{u,v}$ denote the number returned by the second call. Then, for all $u \in F$ and $v \in V(G') \setminus F$, define $a^F_{u,v} = \sum_{\substack{\{p,q\} \in E(G') \\ \text{s.t. } p \in F, q \notin F}} b^F_{u,p} \cdot c^F_{q,v}$.

Let T be the correction factor of $\mathcal{F}$. After all sets $F \in \mathcal{F}$ were enumerated, for all $u,v \in V(G')$, we output $a_{u,v}$ calculated as follows: $a_{u,v} = \frac{1}{T} \cdot \sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } u \in F, v \notin F}} a^F_{u,v}$. Note that we do not store all the values $a^F_{u,v}$ simultaneously, but we merely store one such value at a time and delete it immediately after $a^F_{u,v}/T$ is added. This completes the description of $\mathcal{A}$.

[3] Note that as $p+q=k$, the value $\frac{k^k}{p^p q^q}$ is upper bounded by 2^k rather than being of the magnitude of k^k.

Analysis. The main part of the analysis is done in the proof of the following lemma.

▶ **Lemma 7.** *For some fixed constant $\eta > 0$, any call $\mathcal{A}(G', k')$ has polynomial space complexity and running time $\eta^{\log k'} 4^{k'} k'^{\log k'} (\log n)^{\log k'} mn^2 (\frac{1}{\epsilon'^2})^{\log k'}$. Additionally, if all constructions of approximate universal families were successful, then for all $u, v \in V(G')$, the number $a_{u,v}$ returned by $\mathcal{A}(G', k')$ satisfies $(1-\epsilon')^{k'-1} x_{u,v} \leq a_{u,v} \leq (1+\epsilon')^{k'-1} x_{u,v}$ where $x_{u,v}$ is the number of k'-paths with endpoints u and v in G'.*

Proof. Let $k' = k/2^d$. We choose $\eta = 10 \max\{\lambda, \tau\}$, where λ and τ are fixed constants defined later. The proof is by backwards induction of d. In the basis ($k' = 1$), the claim is trivial. Now, let $d \leq \log_2 k - 1$, and suppose that the claim holds for $d+1$. Clearly, $\mathcal{A}(G', k')$ has a polynomial space complexity. By Theorem 6, for a fixed constant $\lambda > 0$ (that is independent of η),

$$|\mathcal{F}| \leq \lambda \cdot \frac{k'^{k'}}{(k'/2)^{k'/2}(k'/2)^{k'/2}} \cdot k' \log n \cdot \frac{1}{\epsilon'^2} = \lambda \cdot 2^{k'} \cdot k' \log n \cdot \frac{1}{\epsilon'^2}.$$

Moreover, by the inductive hypothesis, for a fixed constant $\tau > 0$, the running time of $\mathcal{A}(G', k')$ is upper bounded by $|\mathcal{F}| \cdot \left(2 \cdot \eta^{\log \frac{k'}{2}} 4^{\frac{k'}{2}} (\frac{k'}{2})^{\log \frac{k'}{2}} (\log n)^{\log \frac{k'}{2}} mn^2 (\frac{1}{\epsilon'^2})^{\log \frac{k'}{2}} + \tau mn^2\right)$. Note that τ is independent of η. By choosing $\eta = 10 \max\{\lambda, \tau\}$, this means that the running time of $\mathcal{A}(G', k')$ is upper bounded by

$$\begin{aligned}
& |\mathcal{F}| \cdot \left(2 \cdot \eta^{\log \frac{k'}{2}} 4^{\frac{k'}{2}} (\frac{k'}{2})^{\log \frac{k'}{2}} (\log n)^{\log \frac{k'}{2}} mn^2 (\frac{1}{\epsilon'^2})^{\log \frac{k'}{2}} + \tau mn^2\right) \\
\leq\ & \frac{\eta}{10} 2^{k'} k' \log n \frac{1}{\epsilon'^2} \cdot \left(2 \cdot \eta^{\log k' - 1} 2^{k'} k'^{\log k' - 1} (\log n)^{\log k' - 1} mn^2 (\frac{1}{\epsilon'^2})^{\log k' - 1} + \frac{\eta}{10} mn^2\right) \\
\leq\ & \eta^{\log k'} 4^{k'} k'^{\log k'} (\log n)^{\log k'} mn^2 (\frac{1}{\epsilon'^2})^{\log k'}.
\end{aligned}$$

This completes the proof of the first item of the claim.

Towards the proof of the second item of the claim, suppose that all constructions of approximate universal families were successful, and consider some $u, v \in V(G')$. Let $x^{\widehat{G}}_{p,q}$ denote the number of $k'/2$-paths with endpoints p and q in $\widehat{G}$. By the inductive hypothesis, we have that

$$\begin{aligned}
a_{u,v} &= \frac{1}{T} \cdot \sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } u \in F, v \notin F}} a^F_{u,v} = \frac{1}{T} \cdot \sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } u \in F, v \notin F}} \left(\sum_{\substack{\{p,q\} \in E(G') \\ \text{s.t. } p \in F, q \notin F}} b^F_{u,p} \cdot c^F_{q,v} \right) \\
&\leq \frac{1}{T} \cdot \sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } u \in F, v \notin F}} \left(\sum_{\substack{\{p,q\} \in E(G') \\ \text{s.t. } p \in F, q \notin F}} (1+\epsilon')^{\frac{k'}{2}-1} x^{G'[F]}_{u,p} \cdot (1+\epsilon')^{\frac{k'}{2}-1} x^{G'-F}_{q,v} \right) \\
&= \frac{1}{T} \cdot (1+\epsilon')^{k'-2} \cdot \sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } u \in F, v \notin F}} \left(\sum_{\substack{\{p,q\} \in E(G') \\ \text{s.t. } p \in F, q \notin F}} x^{G'[F]}_{u,p} \cdot x^{G'-F}_{q,v} \right)
\end{aligned}$$

Let $\mathcal{P}_{u,v}$ denote the set of k'-paths in G' with endpoints u and v. In addition, for any subset $F \subseteq V(G')$, let $\mathcal{P}_{u,v}[F]$ denote the set of paths $P \in \mathcal{P}_{u,v}$ where the $k'/2$ vertices on P closest to u (including u) belong to F and the other $k'/2$ vertices on P do not belong to F. Thus,

$$a_{u,v} \leq (1+\epsilon')^{k'-2} \cdot \frac{\sum_{F \in \mathcal{F}} |\mathcal{P}_{u,v}[F]|}{T}.$$

Since $\mathcal{F}$ is an ϵ'-parsimonious $(n, k'/2, k'/2)$-universal family, for any path $P \in \mathcal{P}_{u,v}$ it holds that the number of sets $F \in \mathcal{F}$ such that $P \in \mathcal{P}_{u,v}[F]$ is upper bounded by $(1+\epsilon')T$. Thus,

$$a_{u,v} \leq (1+\epsilon')^{k'-2} \cdot \frac{(1+\epsilon')T|\mathcal{P}_{u,v}|}{T} = (1+\epsilon')^{k'-1} x_{u,v}.$$

Symmetrically, we derive that $(1-\epsilon')^{k'-1} x_{u,v} \leq a_{u,v}$. This completes the proof. ◀

We now conclude the following theorem.

▶ **Theorem 8.** *There is a randomized $(4^{k+o(k)}mn^2 + mn^{2+o(1)})(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}$-time polynomial-space algorithm that, given a graph G, a positive integer k and an accuracy value $0 < \epsilon < 1$, outputs a number y that (with high probability, say, at least $9/10$) satisfies $(1-\epsilon)x \leq y \leq (1+\epsilon)x$ where x is the number of k-paths in G. In particular, if $\frac{1}{\epsilon} = 2^{o(k/\log k)}$, then the running time is $4^{k+o(k)}mn^2 + mn^{2+o(1)}$.*

Proof. By Lemma 7 with $G' = G$ and $k' = k$, we know that the total running time of $\mathcal{A}(G,k)$ is bounded by $4^{k+\mathcal{O}(\log^2 k)}(\log n)^{\log k} mn^2 (\frac{1}{\epsilon'})^{\log k}$ and uses polynomial space. Additionally, if all constructions of approximate universal families were successful, then for all $u, v \in V(G)$, the number $a_{u,v}$ computed by $\mathcal{A}(G,k)$ satisfies $(1-\epsilon')^{k-1} x_{u,v} \leq a_{u,v} \leq (1+\epsilon')^{k-1} x_{u,v}$ where $x_{u,v}$ is the number of k-paths with endpoints u and v in G.

If $\log n \leq 2^{\sqrt{k}}$, then $(\log n)^{\log k} \leq 2^{o(k)}$. Otherwise, when $\log n > 2^{\sqrt{k}}$, it holds that $k < \log^2 \log n$. It follows that $4^{k+\mathcal{O}(\log^2 k)}(\log n)^{\log k} \leq 4^{\log^2 \log n + \mathcal{O}(\log\log\log n)}(\log n)^{2\log\log\log n} \leq n^{\mathcal{O}(\frac{\log^2 \log n}{\log n})} \leq n^{o(1)}$. In addition, by Taylor series $\ln(1+x) = \sum_{n=1}^{\infty}(-1)^{n+1}\frac{x^n}{n}$, it follows that $\epsilon/2 \leq \epsilon - \epsilon^2/2 \leq \ln(1+\epsilon) = \widehat{\epsilon} \leq \epsilon$, which means that $(\frac{1}{\epsilon'})^{\log k} = 2^{\mathcal{O}(\log^2 k)}(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}$. Thus, $4^{k+\mathcal{O}(\log^2 k)}(\log n)^{\log k} mn^2 (\frac{1}{\epsilon'})^{\log k} = (4^{k+o(k)}mn^2 + mn^{2+o(1)})(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}$.

We now claim that with high probability, all constructions of approximate universal families were successful. By Theorem 6, the probability that a single construction is successful is at least $1 - 1/n^{100k}$. Thus, the probability that all constructions are successful is at least $(1-1/n^{100k})^{\mu}$ where μ is the number of constructions. Clearly, the number of constructions is upper bounded by the running time of $\mathcal{A}$. In turn, we can assume w.l.o.g. that the upper bound proven on this running time is, in itself, upper bounded by n^k, since otherwise the problem can be solved exactly by brute force within it. Thus, $\mu \leq n^k$. From this, we know that the probability that all constructions are successful is at least $(1-1/n^{100k})^{n^k}$. As n grows larger, this value approaches 1. In particular, the success probability can be assumed to be at least $9/10$ (otherwise n is a fixed constant), which proves our claim.

Thus, we know that for all $u, v \in V(G)$, it holds that $(1-\epsilon')^{k-1} x_{u,v} \leq a_{u,v} \leq (1+\epsilon')^{k-1} x_{u,v}$. Substituting ϵ' by $\widehat{\epsilon}$, we have that for all $u, v \in V(G)$, it holds that $(1-\widehat{\epsilon})x_{uv} \leq (1-\frac{\widehat{\epsilon}}{k-1})^{k-1} x_{u,v} \leq a_{u,v} \leq (1+\frac{\widehat{\epsilon}}{k-1})^{k-1} x_{u,v} \leq e^{\widehat{\epsilon}} x_{u,v}$. Since $(1-\epsilon) \leq (1-\widehat{\epsilon})$ and $e^{\widehat{\epsilon}} = (1+\epsilon)$, we have that for all $u, v \in V(G)$, it holds that $(1-\epsilon)x_{u,v} \leq a_{u,v} \leq (1+\epsilon)x_{u,v}$. Thus,

$$\begin{aligned} y &= \left(\sum_{u,v \in V(G)} a_{u,v}\right)/2 \leq \left(\sum_{u,v \in V(G)} (1+\epsilon)x_{u,v}\right)/2 \\ &= (1+\epsilon)\left(\sum_{u,v \in V(G)} x_{u,v}\right)/2 = (1+\epsilon)x. \end{aligned}$$

Symmetrically, we obtain that $(1-\epsilon)x \leq y$. This completes the proof. ◀

3.3 Improved Randomized FPT-AS for #k-Path

As our improved randomized FPT-AS is less intuitive, we first discuss the intuition behind it. Here, in addition to G' and k', every call to the recursive algorithm $\mathcal{A}$ is given an assignment $\alpha' : V(G) \setminus V(G') \to \mathbb{N}_0$ of a non-negative integer to each vertex outside G'. Roughly speaking, for each vertex $v \in V(G) \setminus V(G')$, the value $\alpha'(v)$ is an approximation of the number of $\widehat{k}$-paths that end at v and are completely contained in $G - U$ for a certain integer $\widehat{k} \in \{1, 2, \ldots, k - k'\}$ and a subset $U \subseteq V(G)$ that contains $V(G')$. In particular, given that now the goal of each call is to output such an assignment for $G - (U \setminus V(G')$ (a precise definition of the goal of a call is given in the formal description of the algorithm), we do not need to consider every pair of vertices $u, v \in V(G')$ and compute a value $a_{u,v}$; instead, we only compute one value per vertex. Additionally, recall that in the previous algorithm in order to compute $a_{u,v}$, we considered every edge $\{p, q\} \in E(G')$ while computing $a^F_{u,v}$ and hence divided our task into the computation of $k'/2$-paths between u and p in one recursive call and $k'/2$-paths between q and u in the other. Here, we do not store the two endpoints of paths, but their "middle". More precisely, the flow of information differs: to compute the assignment we need to output in the current call, we perform one recursive call to which the assignment α' is given as input; this call will return an assignment that "handles" the first $\widehat{k} + k'/2$ vertices on the paths being counted, and be sent as input to the second recursive call to handle the next $k'/2$ vertices.

Algorithm. Let $\widehat{\epsilon} = \ln(1 + \epsilon)$ and $\epsilon' = \widehat{\epsilon}/(k - 1)$. We add a new vertex s to G and connect it to all vertices in G. Thus, rather than counting the number of k-paths in the former graph G, we can count the number of $(k + 1)$-paths with s as an endpoint in the new graph G. In what follows, we focus on this goal.

Our algorithm is a recursive algorithm, denoted by $\mathcal{A}$. Each call to $\mathcal{A}$ is of the form $\mathcal{A}(G', k', \alpha')$ where G' is an induced subgraph of G, $k' \in \{1, \ldots, k\}$, and $\alpha' : V(G) \setminus V(G') \to \mathbb{N}_0$. The call $\mathcal{A}(G', k', \alpha')$ should output an assignment $\alpha : V(G') \to \mathbb{N}_0$ with the following property: For each vertex $v \in V(G')$, it holds that $\alpha(v)$ approximates the following number:

$$\sum_{\substack{\{p,q\} \in E(G) \\ \text{s.t. } p \notin V(G'), q \in V(G')}} \alpha'(p) \cdot x_{q,v},$$

where $x_{q,v}$ is the number of k'-paths in G' between q and v.

The initial call to the algorithm is with $G' = G - \{s\}$, $k' = k$, and $\alpha'(s) = 1$. The final output is $\sum_{v \in V(G) \setminus \{s\}} \alpha(v)$.

We turn to describe a call $\mathcal{A}(G', k', \alpha')$. In the basis, where $k' = 1$, we return an assignment $\alpha : V(G') \to \mathbb{N}_0$ defined as follows: For each vertex $v \in V(G')$, define

$$\alpha(v) = \sum_{\substack{u \notin V(G') \\ \text{s.t. } \{u,v\} \in E(G)}} \alpha'(u).$$

Now, suppose that $k' \geq 2$. By Theorem 6, for an ϵ'-parsimonious $(n, k'/2, k'/2)$-universal family $\mathcal{F}$ of sets over $V(G)$, we can enumerate the sets $F \in \mathcal{F}$ with delay $\mathcal{O}(n)$. For each set $F \in \mathcal{F}$, we proceed as follows. We first recursively call $\mathcal{A}$ with $(G'[F], k'/2, \alpha')$ where α' is extended to assign 0 to every vertex in $V(G') \setminus F$. Let $\widehat{\alpha}_F$ be the output of this call, and extend it to assign 0 to every vertex in $V(G) \setminus V(G')$. Then, we recursively call $\mathcal{A}$ with $(G' - F, k'/2, \widehat{\alpha}_F)$. Let α_F be the output of this recursive call.

Let T be the correction factor of $\mathcal{F}$. After all sets $F \in \mathcal{F}$ were enumerated, the output $\alpha : V(G') \to \mathbb{N}_0$ is computed as follows. For all $v \in V(G')$, we calculate

$$\alpha(v) = \left(\sum_{\substack{F \in \mathcal{F} \\ \text{s.t. } v \notin F}} \alpha_F(v) \right) / T.$$

Note that we do not store all the assignments α_F simultaneously, but we merely store one such assignment at a time and delete it immediately after $\alpha_F(v)/T$, for every $v \in V(G')$, is added. This completes the description of $\mathcal{A}$.

Correctness. The proof of correctness of our algorithm roughly follows the same lines as the proof of correctness of Theorem 8. Due to space constraints, we omit the details, and conclude this section with the statement of our result.

▶ **Theorem 9.** *There is a randomized $(4^{k+o(k)}m + mn^{o(1)})(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}$-time polynomial-space algorithm that, given a graph G, a positive integer k and an accuracy value $0<\epsilon<1$, outputs a number y that (with high probability) satisfies $(1-\epsilon)x \leq y/2 \leq (1+\epsilon)x$ where x is the number of k-paths in G. In particular, if $\frac{1}{\epsilon} = 2^{o(k/\log k)}$, then the running time is $4^{k+o(k)}mn^{o(1)}$.*

Additionally, we can obtain the following corollary. (This corollary does not follow directly from Theorem 9, but requires a simple preliminary step to shrink the universe; due to space constraints, the details are omitted.)

▶ **Corollary 10.** *There is a randomized $4^{k+\mathcal{O}(\log^2 k)}m \log n(\frac{1}{\epsilon})^{\mathcal{O}(\log k)}$-time polynomial-space algorithm that, given a graph G, a positive integer k and an accuracy value $0<\epsilon<1$,'outputs a number y that (with high probability) satisfies $(1-\epsilon)x \leq y/2 \leq (1+\epsilon)x$ where x is the number of k-paths in G. In particular, if $\frac{1}{\epsilon} = 2^{o(k/\log k)}$, then the running time is $4^{k+o(k)}m \log n$.*

3.4 Approx. Parsimonious Universal Family: Deterministic Construction

We do not know how to deterministically construct small δ-parsimonious universal families. Indeed, the best construction that we are aware of is the one based on bipartite Paley graphs (see Theorem 11.9 in the book by Jukna [25] and the historical notes behind the result). This construction leads to families of size $4^{k+o(k)}$ for $p = q = \frac{k}{2}$, whereas we would like size $2^{k+o(k)}$. Instead, we provide an efficient deterministic computation of a small δ-parsimonious universal family that is suitable for handling so called "nice pairs". The crucial point is that with respect to our applications, this relaxed construction suffices. In this section, we present the definition of this relaxation, its construction and main property. Due to space constraints, the proofs of the two lemmas and the theorem stated in this section are omitted.

To simplify the following definitions, we introduce the following notation. To see the intuition behind this notation in the context of applications, throughout this section h can be thought of as a function that reduces the size of the universe from n to z, f can be thought of as a function that splits the reduced universe into t parts, and $\overline{\mathbf{p}}$ can be thought of as a function that tells us that each part has k/t "useful" elements (e.g., vertices of paths to be counted in a certain recursive call) among which either p_i or $(k/t) - p_i$ were "exhausted".

▶ **Definition 11.** *Let $n, p, q, t, z \in \mathbb{N}$, and $k = p+q$. Let U be a universe of size n. A function $\overline{\boldsymbol{p}} : \{1, 2, \ldots, t\} \to \{0, 1, \ldots, k/t\}$ such that $\sum_{i=1}^{t} p_i = p$, is called* (p, q, t)-compatible. *When $\overline{\boldsymbol{p}}$ is clear from context, for each $i \in \{1, 2, \ldots, t\}$, denote $p_i = \overline{\boldsymbol{p}}(i)$ and $q_i = (k/t) - p_i$.*

A triple $(h, f, \overline{\boldsymbol{p}})$ is called (n, p, q, t, z)-compatible *if $h : U \to \{1, 2, \ldots, z\}$, $f : \{1, 2, \ldots, z\} \to \{1, 2, \ldots, t\}$, and $\overline{\boldsymbol{p}}$ is (p, q, t)-compatible. (The universe U will be clear from context.)*

We begin by defining what is a nice pair.

▶ **Definition 12** (Nice Pair). *Let $n, p, q, t, z \in \mathbb{N}$. Let U be a universe of size n. Let $(h, f, \overline{\boldsymbol{p}})$ be (n, p, q, t, z)-compatible. A pair (A, B) is* nice *(with respect to $(h, f, \overline{\boldsymbol{p}})$) if $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$ are disjoint sets, and the following conditions hold.*

1. *The function h is injective when restricted to $A \cup B$.*
2. *For each $i \in \{1, 2, \ldots, t\}$, it holds that $|\{u \in A : f(h(u)) = i\}| = p_i$ and $|\{u \in B : f(h(u)) = i\}| = (k/t) - p_i$.*

Towards the definition of a δ-parsimonious universal family for nice pairs, we first present a weaker definition of this notion where we have a triple $(h, f, \overline{\mathbf{p}})$ at hand.

▶ **Definition 13** (Specific δ-Parsimonious Universal Family for Nice Pairs). *Let $n, p, q, t, z \in \mathbb{N}$. Let U be a universe of size n. Let $(h, f, \overline{\boldsymbol{p}})$ be (n, p, q, t, z)-compatible. Let $0 < \delta < 1$. A family $\mathcal{F}$ of sets over $\{1, \ldots, z\}$ is a* δ-parsimonious $(h, f, \overline{\mathbf{p}})$-universal family (for nice pairs) *if there exists $T = T(h, f, \overline{\boldsymbol{p}}, \delta) > 0$ such that for every nice pair (A, B), it holds that $(1 - \delta) \cdot T \leq |\mathcal{F}[h(A), h(B)]| \leq (1 + \delta) \cdot T$.*

Before we show how to extend Definition 13 to the notion useful for applications, we argue that small δ-parsimonious $(h, f, \overline{\mathbf{p}})$-universal families can be computed "efficiently".

▶ **Lemma 14.** *Let $p, q, t, z \in \mathbb{N}$, and denote $k = p + q$ and $s = k/t$. Let $(h, f, \overline{\boldsymbol{p}})$ be (n, p, q, t, z)-compatible. Let $0 < \delta < 1$. A δ-parsimonious $(h, f, \overline{\boldsymbol{p}})$-universal family $\mathcal{F}$ of sets over $\{1, \ldots, z\}$ of size $\ell = \mathcal{O}\left(\binom{k}{p} \cdot (k \cdot \log z \cdot \frac{\mathcal{O}(1)}{\delta})^{2t}\right)$ can be computed in time $\ell \cdot z^{s+1} s^{\mathcal{O}(1)} t$. In particular, the sets in $\mathcal{F}$ can be enumerated with delay $z^{s+1} s^{\mathcal{O}(1)} t$.*

Towards the definition of our general construction, we need to present the definitions of a balanced splitter and a balanced hash family. Constructions of such a splitter and a family were given by Alon and Gutner [4, 3].

▶ **Definition 15** (Definition 2.2 [4]). *Suppose that $1 \leq \ell \leq k \leq n$ and $0 < \epsilon < 1$, and let H be a family of functions from $\{1, \ldots, n\}$ to $\{1, \ldots, \ell\}$. For a set $S \in \binom{\{1,\ldots,n\}}{k}$, let $\mathtt{split}_H(S)$ denote the number of functions $h \in H$ that split H into equal size parts, that is, $|h^{-1}(i) \cap S| = k/\ell$. Then, H is an* ϵ-balanced (n, k, ℓ)-splitter *if there exists $T = T(n, k, \ell, \epsilon) > 0$ such that for every set $S \in \binom{\{1,\ldots,n\}}{k}$, we have $(1 - \epsilon)T \leq \mathtt{split}_H(S) \leq (1 - \epsilon)T$.*

▶ **Definition 16** (Definition 2.1 [4]). *Suppose that $1 \leq k \leq \ell \leq n$ and $0 < \epsilon < 1$. A family H of functions from $\{1, \ldots, n\}$ to $\{1, \ldots, \ell\}$ is an* (ϵ, k)-balanced family of hash functions *if there exists $T = T(n, k, \ell, \epsilon) > 0$ such that for every set $S \in \binom{\{1,\ldots,n\}}{k}$, the number of functions in H that are injective when restricted to S is between $(1 - \epsilon)T$ and $(1 + \epsilon)T$.*

We are now ready to define our general derandomization tool.

▶ **Definition 17** ((General) δ-Parsimonious Universal Family for Nice Pairs). *Let $n, p, q \in \mathbb{N}$ and $0 < \delta < 1$, and denote $k = p + q$, $z = \frac{2k^2}{\epsilon}$, $t = \sqrt{k}$, $s = k/t = \sqrt{k}$, and $\epsilon = \delta/3$. Let U be a universe of size n. A* δ-parsimonious (n, p, q)-universal tuple (for nice pairs) *is a tuple $(H, S, \{\mathcal{F}^{h,f,\overline{\boldsymbol{p}}}\}|_{h \in H, f \in S, \overline{\boldsymbol{p}}})$[4] that satisfies the following conditions.*

- *H is an (ϵ, k)-balanced family of hash functions from $\{1, \ldots, n\}$ to $\{1, \ldots, z\}$ (with correction factor T_H).*
- *S is an ϵ-balanced (z, k, t)-splitter (with correction factor T_S).*
- *For every hash function $h \in H$, splitter $f \in S$ and (p, q, t)-compatible function $\overline{\boldsymbol{p}}$, it holds that $\mathcal{F}^{h,f,\overline{\boldsymbol{p}}}$ is a δ-parsimonious $(h, f, \overline{\boldsymbol{p}})$-universal family (with correction factor $T_{\overline{\boldsymbol{p}}}$).*

[4] The enumeration is over every (p, q, t)-compatible $\overline{\mathbf{p}}$.

By *enumerating the quadruples of* $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$, we refer to the enumeration of every quadruple $(h, f, \overline{\mathbf{p}}, F)$ such that $h \in H$, $f \in S$ and $F \in \mathcal{F}^{h,f,\overline{\mathbf{p}}}$. We remark that below, for the sake of brevity, when we write $k, z, t, s, \epsilon, T_H, T_S$ and $T_{\overline{\mathbf{p}}}$, we refer to the notations given in Definition 17. Let us now state our construction.

▶ **Theorem 18.** *Let $n, p, q \in \mathbb{N}$ and $0 < \delta < 1$. Denote $k = p + q$. Let U be a universe of size n. A δ-parsimonious (n, p, q)-universal tuple $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ with ℓ quadruples can be computed in time $\frac{k^{\mathcal{O}(1)} n \log n}{\delta^{\mathcal{O}(1)}} + \ell \cdot \Delta$. In particular, after preprocessing time $\frac{k^{\mathcal{O}(1)} n \log n}{\delta^{\mathcal{O}(1)}}$, the quadruples of $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ can be enumerated with delay Δ. Here,*

$$\begin{aligned} \ell &= \binom{k}{p} \cdot 2^{\mathcal{O}(\sqrt{k}(\log^2 k + \log^2 \frac{1}{\delta}))} \cdot \log n, \text{ and} \\ \Delta &= 2^{\mathcal{O}(\sqrt{k}(\log k + \log \frac{1}{\delta}))}. \end{aligned}$$

In order to state the property of a δ-parsimonious (n, p, q)-universal tuple that makes it useful for applications, we need one last definition.

▶ **Definition 19.** *Let $n, p, q \in \mathbb{N}$ and $0 < \delta < 1$. Let U be a universe of size n. Furthermore, let $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ be a δ-parsimonious (n, p, q)-universal tuple. Finally, let $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$ be disjoint sets. We say that the pair (A, B)* fits *a quadruple $(h, f, \overline{\boldsymbol{p}}, F)$ of $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ if (A, B) is nice with respect to $(h, f, \overline{\boldsymbol{p}})$, and $h(A) \subseteq F$ and $f \cap h(B) = \emptyset$.*

Finally, we state the promised property.

▶ **Lemma 20.** *Let $n, p, q \in \mathbb{N}$ and $0 < \delta < 1$. Let U be a universe of size n. Furthermore, let $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ be a δ-parsimonious (n, p, q)-universal tuple. Then, there exist $T = T(n, p, q, \delta) > 0$ and for every $\overline{\boldsymbol{p}}$ that is (p, q, t)-compatible, $T_{\overline{\boldsymbol{p}}} = T_{\overline{\boldsymbol{p}}}(n, p, q, \delta) > 0$, such that for any $A \in \binom{U}{p}$ and $B \in \binom{U}{q}$ that are disjoint, the following conditions hold.*

1. *The number of triples $(h, f, \overline{\boldsymbol{p}})$ with respect to whom (A, B) is nice, where $h \in H$, $f \in S$ and $\overline{\boldsymbol{p}}$ is (p, q, t)-compatible, is between $(1 - \delta)T$ and $(1 + \delta)T$.*
2. *For any triple $(h, f, \overline{\boldsymbol{p}})$ with respect to whom (A, B) is nice, where $h \in H$, $f \in S$ and $\overline{\boldsymbol{p}}$ is (p, q, t)-compatible, the number of quadruples $(h, f, \overline{\boldsymbol{p}}, F)$ of $(H, S, \{\mathcal{F}^{h,f,\overline{p}}\}|_{h\in H, f\in S,\overline{p}})$ that fit (A, B) is between $(1 - \delta)T_{\overline{\boldsymbol{p}}}$ and $(1 + \delta)T_{\overline{\boldsymbol{p}}}$.*

3.5 Deterministic FPT-AS for #k-Path

Our deterministic FPT-AS builds upon the scheme of our second randomized FPT-AS, but it is more technical. Due to space constraints, the full details of the description of the algorithm and its proof of correctness is omitted. Here, we only discuss the main idea that underlies the design of this algorithm. Like our previous algorithm, this algorithm (denoted by $\mathcal{A}$) is recursive. However, in addition to G', k' and α', every call to $\mathcal{A}$ is also given two tuples $\mathcal{R}$ and $\mathcal{W}$. The number of elements in $\mathcal{R}$ and $\mathcal{W}$ equals the depth d of the current recursive call in the recursion tree.

Roughly speaking, every element in $\mathcal{R}$ is a quadruple $(h_i, f_i, \overline{\mathbf{p}}_i, \sigma_i)$ where *(i)* the triple $(h_i, f_i, \overline{\mathbf{p}}_i)$ corresponds to the interpretation preceding Definition 11, and *(ii)* $\sigma_i \in \{\texttt{left}, \texttt{right}\}$ indicates whether we should count paths that consist of $\overline{\mathbf{p}}_i(j)$ (in case $\sigma_i = \texttt{left}$) or $s_i - \overline{\mathbf{p}}_i(j)$ (in case $\sigma_i = \texttt{right}$) vertices of the j-th part of the reduced universe split by f_i. Thus, we "keep track" of all triples considered along the current recursion branch. The reason why we have to store this information is to ensure that, in the current recursive call, we only count paths P whose vertex set has the following property:

when we will return to the i-th recursive call, the partition (A, B) of $V(P)$ where A consists of the first $\widehat{k}$ vertices of P (for a certain $\widehat{k} \in \{1, 2, \ldots, k\}$ that depends on the location of this i-th call in the recursion tree) is nice with respect to $(h_i, f_i, \overline{\mathbf{p}}_i)$, see Definition 12. This simple (though perhaps slightly tedious) bookkeeping sidesteps the fact that Lemma 20 only suits nice pairs.

The tuple $\mathcal{W}$ is meant to keep track of how many vertices the paths that we currently count have used "so far" from the j-th part of the universe split by f_i for every choice of i and j. For this purpose, $\mathcal{W}$ is defined to have the form $(\overline{\mathbf{w}}_1, \overline{\mathbf{w}}_2, \ldots, \overline{\mathbf{w}}_d)$ such that for each $i \in \{1, 2, \ldots, d\}$, the following condition holds: For each $j \in \{1, 2, \ldots, t_i\}$, if $\sigma_i = \texttt{left}$ then $\overline{\mathbf{w}}_i(j) \leq \overline{\mathbf{p}}_i(j)$, and otherwise $\overline{\mathbf{w}}_i(j) \leq s_i - \overline{\mathbf{p}}_i(j)$. Here, $s_i = \sqrt{(k/2^i)}$ is the number of vertices the paths that we currently count should use (in total) from each part split by f_i.

Accordingly, the objective of a call $\mathcal{A}(G', k', \alpha', \mathcal{R}, \mathcal{W})$ is to output an assignment $\alpha : V(G') \to \mathbb{N}_0$ with the following property: For each vertex $v \in V(G')$, it holds that $\alpha(v)$ approximates $\sum_{\substack{\{p,q\} \in E(G) \\ \text{s.t. } p \notin V(G'), q \in V(G')}} \alpha'(p) \cdot |\mathcal{P}_{q,v}^{G',k',\mathcal{R},\mathcal{W}}|$. Roughly speaking, $\mathcal{P}_{q,v}^{G',k',\mathcal{R},\mathcal{W}}$ is the collection of all k'-paths in G' with endpoints q and v that "comply" with the constraints imposed by $\mathcal{R}$ and $\mathcal{W}$. (Due to space constraints, the formal definition is omitted.)

We conclude this section with the formal statement of our main result.

▶ **Theorem 21.** *There is a deterministic $4^{k+\mathcal{O}(\sqrt{k}(\log^2 k + \log^2 \frac{1}{\epsilon}))} m \log n$-time polynomial-space algorithm that, given a graph G, a positive integer k and an accuracy value $0 < \epsilon < 1$, outputs a number y that satisfies $(1-\epsilon)x \leq y/2 \leq (1+\epsilon)x$ where x is the number of k-paths in G. In particular, if $\frac{1}{\epsilon} = 2^{o(k^{\frac{1}{4}})}$, then the running time is $4^{k+o(k)} m \log n$.*

Due to space constraints, the discussion on extensions and other applications is omitted.

Abstract

We show that the permanent of an $n \times n$ matrix over any finite ring of $r \leq n$ elements can be computed with a deterministic $2^{n-\Omega(\frac{n}{r})}$ time algorithm. This improves on a Las Vegas algorithm running in expected $2^{n-\Omega(n/(r \log r))}$ time, implicit in [Björklund, Husfeldt, and Lyckberg, IPL 2017]. For the permanent over the integers of a 0/1-matrix with exactly d ones per row and column, we provide a deterministic $2^{n-\Omega(\frac{n}{d^{3/4}})}$ time algorithm. This improves on a $2^{n-\Omega(\frac{n}{d})}$ time algorithm in [Cygan and Pilipczuk ICALP 2013]. We also show that the number of Hamiltonian cycles in an n-vertex directed graph of average degree δ can be computed by a deterministic $2^{n-\Omega(\frac{n}{\delta})}$ time algorithm. This improves on a Las Vegas algorithm running in expected $2^{n-\Omega(\frac{n}{\mathrm{poly}(\delta)})}$ time in [Björklund, Kaski, and Koutis, ICALP 2017].

A key tool in our approach is a reduction from computing the permanent to listing pairs of *dissimilar* vectors from two sets of vectors, i.e., vectors over a finite set that differ in each coordinate, building on an observation of [Bax and Franklin, Algorithmica 2002]. We propose algorithms that can be used both to derandomise the construction of Bax and Franklin, and efficiently list dissimilar pairs using several algorithmic tools. We also give a simple randomised algorithm resulting in Monte Carlo algorithms within the same time bounds.

Our new fast algorithms for listing dissimilar vector pairs from two sets of vectors are inspired by recent algorithms for detecting and counting orthogonal vectors by [Abboud, Williams, and Yu, SODA 2015] and [Chan and Williams, SODA 2016].

1 Introduction

In recent years, the apparent impossibility of finding a pair of orthogonal vectors among two sets of N Boolean vectors in $N^{2-\varepsilon}$ time (the OV problem) has been used to derive conditional hardness results for many problems (e.g., [2] to name just one). However, when the dimensionality of the vectors is at most $d \log(N)$ for a constant d, N^c-time algorithms do exist for some $c < 2$, and these algorithms for OV have been used to derive faster algorithms for other problems; a prominent example is counting satisfying assignments to sparse CNF formulas [11]. In this paper we consider a natural generalisation of the OV problem, design algorithms for it, and apply those algorithms to derive faster deterministic algorithms for two other notoriously hard, well-known problems:

1. Computing matrix permanents over finite rings and regular 0/1 matrices over the integers.
2. Counting Hamiltonian cycles in sparse directed graphs.

The natural generalisation of OV is a problem we call **listing dissimilar vector pairs**: *Given N vectors over a finite set of size r, list all pairs of vectors that differ in every coordinate.* This problem can easily be reduced to listing orthogonal vector pairs (see Proposition 9). We also propose some tailored algorithms for listing dissimilar pairs for ease of understanding. (and in the hopes that our new algorithmic ideas will lead to interesting future work). As in the literature on orthogonal vector detection and counting [1, 11], we show how fast rectangular matrix multiplication can be used to list dissimilar vector pairs; we apply a fast algorithm for *counting* (not listing) orthogonal vectors ([11]) as a black box to derandomise our application algorithms.

A key difference in our work is that our applications to counting problems require us to list *all* dissimilar vector pairs, rather than merely finding one. The task of listing OV pairs also arises in the fastest known online algorithm for Boolean matrix-vector multiplication [15].

1.1 Faster Algorithm for Ring Permanents

The permanent of a square matrix $M = \{m_{i,j}\} \in K^{n\times n}$ over a ring K is defined as

$$\operatorname{per}(M) = \sum_{\sigma\in S_n} \prod_{i=1}^{n} m_{i,\sigma(i)}, \tag{1}$$

where S_n is the symmetric group on n elements. The problem of computing permanents is known to be #P-complete, even for sparse binary (i.e., 0/1) matrices over the integers [22], and hence we only expect exponential-time algorithms for the problem in general.

An inclusion–exclusion formula by Herbert Ryser from 1963 [18] states that

$$\operatorname{per}(M) = \sum_{X\subseteq[n]} (-1)^{n-|X|} \prod_{i=1}^{n} \left(\sum_{j\in X} m_{i,j} \right). \tag{2}$$

By enumerating the subsets X in a Gray code order (i.e., an enumeration that lists each subset exactly once by only adding or removing one element at a time) one can compute each term $\prod_{i=1}^{n} \left(\sum_{j\in X} m_{i,j}\right)$ in only $O(n)$ operations per subset, leading to an algorithm using $O(n2^n)$ additions and multiplications. To date, this is still the fastest method known for computing the permanent over general rings, and it is a major open question whether there is a $O((2-\epsilon)^n)$ time algorithm for some constant $\epsilon > 0$, even for the special case of binary matrices over the integers. For other special cases, like sparse matrices or finite rings, such algorithms *do* exist, and even for the computation of binary matrices over the integers, *somewhat* faster algorithms than Ryser's are known; see the Related Work section.

In this paper, we provide a faster algorithm for permanents over finite rings.

▶ **Theorem 1.** *There is a deterministic algorithm that computes the permanent of a matrix $M \in K^{n\times n}$ over any finite ring K on $r \le n$ elements in $2^{n-\Omega(n/r)}$ time.*

The previous best bound is a $2^{n-\Omega(n/(r\log r))}$ expected time algorithm implicit in [6].[1] Note that our result is much more than a "log-shaving" of the running time in the classical sense, as we are improving the *exponent* of the running time; moreover, our new algorithm is deterministic as opposed to the previous one.

[1] The randomised algorithms in that paper are stated for computations modulo a fixed prime and their first powers, but the algorithms can be adapted for finite rings on r elements.

We also provide a faster algorithm for d-regular 0/1 matrices with exactly d ones in each row and column.

▶ **Theorem 2.** *There is a deterministic algorithm that computes the permanent of a d-regular matrix $M \in \{0,1\}^{n\times n}$ over the integers in $2^{n-\Omega(n/d^{3/4})}$ time.*

This improves on the $2^{n-\Omega(n/d)}$ time bound of an algorithm for average d ones per row by Cygan and Pilipczuk [13].

1.2 Hamiltonian cycles

A Hamiltonian cycle in a directed graph is a simple cycle through all vertices. Counting Hamiltonian cycles is #P-complete, even in planar graphs of degree at most three [21, 16]. We provide a faster algorithm for sparse graphs.

▶ **Theorem 3.** *There is a deterministic algorithm that counts the number of Hamiltonian cycles in an n-vertex directed graph of average degree δ in $2^{n-\Omega(n/\delta)}$ time.*

The previously fastest counting algorithm (sensitive to the average degree) is a Las Vegas algorithm running in expected $2^{n-\Omega(n/\operatorname{poly}(\delta))}$ time outlined in [8]. The polynomial in the exponent is at least $\delta^4 \log \delta$.[2]

1.3 Related Work

The fastest known algorithms for the $n \times n$ matrix permanent over the integers, and counting Hamiltonian cycles in an n-vertex directed graph, are those of Björklund, Kaski, and Williams [9] which run in $2^{n-\Omega\left(\sqrt{n/\log\log n}\right)}$ time.

For permanents over the integers of binary matrices with d ones per row on average, Servedio and Wan [19] showed how to compute the permanent in $2^{n-\Omega(n/\exp(d))}$ time and polynomial space. Using exponential space, Izumi and Wadayama [14] derived a $2^{n-\Omega(n/(d\log d))}$ time algorithm. Cygan and Pilipczuk [13] gave a $2^{n-\Omega(n/d)}$ time algorithm that works over any ring, where d denotes the *average* number of non-zero entries per row. Björklund, Husfeldt, and Lyckberg [6] showed that the integer permanent can be computed modulo $p^{(1-\lambda)n/p}$ in $c_{p,\lambda}^n$ time, for $c_{p,\lambda} < 2$ depending only on the fixed prime p and $\lambda > 0$.

The fastest known algorithm for detecting the Hamiltonian cycles in an undirected graph is the $O(1.657^n)$ time Monte Carlo algorithm of Björklund [4]. For directed graphs, no detection algorithm running in $O((2-\epsilon)^n)$ time for any $\epsilon > 0$ is known, although for bipartite directed graphs, Hamiltonicity can be decided in $O(1.733^n)$ time [8]. Intriguingly, computing the *parity* of the number of Hamiltonian cycles can be done in $O(1.619^n)$ time [5], and they can be counted modulo certain integers with all prime factors at most p, in $2^{n-\Omega(n/p)}$ time [8].

There are also $6^{\operatorname{pw}(G)}\operatorname{poly}(n)$ time and $15^{\operatorname{tw}(G)}\operatorname{poly}(n)$ time algorithms parameterised by the pathwidth and treewidth of the underlying graph [10].

1.4 Our techniques and contributions

For binary 0/1 matrices over the integers, Bax and Franklin [3] gave a $2^{n-\Omega(n^{1/3}/\log n)}$ expected time Las Vegas algorithm for the $n \times n$ matrix permanent. Their algorithm is slower than the state-of-the-art algorithm of [9] (based on entirely different techniques), but still uses very interesting ingredients whose potential has probably not yet been fully utilised.

[2] See Theorem 8 in Appendix B of [7] for details.

Our algorithms in this paper stem from two ideas in Bax and Franklin's paper:

1. Perturb the input in a way that does not affect the answer, but "zeroes out" all but a tiny fraction of terms in an 2^n-sized formula for computing the answer (e.g., for permanents, we will zero-out most terms in Ryser's formula (2)). Hence to evaluate the sum, it is sufficient to list only the non-zero terms, offering an approach to a faster algorithm.
2. Divide the columns of the matrix in two halves of about $n/2$ columns each, construct vectors representing the terms restricted to the halves, and find ways to "combine" pairs of vectors corresponding to non-zero terms in the exponential sum.

By design, the vector pairs corresponding to non-zero terms will be those differing in each coordinate, which we call *dissimilar pairs*. Recently, Björklund, Kaski, and Koutis, translated this idea to the problem of counting Hamiltonian cycles [8]. In this paper, we present two new methods of listing dissimilar pairs that are more efficient than the simple tabulation-based schemes used in [3] and [8]. Our first listing algorithm is deterministic:

▶ **Theorem 4.** *Given two lists $\mathcal{X}$ and $\mathcal{Y}$ of N vectors in $[r]^d$ with $d < \log_3(N)/20$, and an integer $s > N$, the first s dissimilar pairs $(x, y) \in \mathcal{X} \times \mathcal{Y}$ can be listed in $\tilde{O}(N\sqrt{s})$ time.*[3]

The algorithm applies fast rectangular matrix multiplication. In particular, we use:

▶ **Theorem 5** (Coppersmith, 1984 [12])**.** *Over any finite field $\mathbb{F}$, the number of arithmetic operations needed to multiply an $N \times N^\alpha$ sized matrix with an $N^\alpha \times N$ sized matrix, for $\alpha < 0.17$, is $N^2 \cdot \operatorname{poly}\log(N)$.*

Our second listing algorithm is randomised, and based on hashing. It is arguably much more implementable, as it does not rely on fast matrix multiplication.

▶ **Theorem 6.** *Given two lists $\mathcal{X}$ and $\mathcal{Y}$ of N vectors in $[r]^d$, the set of dissimilar pairs $S \subseteq \mathcal{X} \times \mathcal{Y}$ can be listed in $\tilde{O}(|S| + 2^d \cdot N)$ time with probability of success $1 - o(1)$.*

We also prove a stronger upper bound on the number of non-zero terms needed to analyse in the special case of d-regular 0/1 matrices. The result can be seen as a sparsity parameterisation of Bax and Franklin's algorithm [3].

Outline. We describe our two dissimilarity listing algorithms in Sections 2 and 3. In Section 4 we review the (randomised) reductions from the permanent and Hamiltonian cycle counting to listing dissimilar vector pairs. Finally, in Section 5 we show how the randomised reductions can be derandomised by applying an algorithm for counting OV pairs, and using the method of conditional expectation.

2 Listing dissimilar vectors with fast matrix multiplication

We first describe a deterministic algorithm for listing dissimilar pairs based on fast rectangular matrix multiplication. Given two sets $\mathcal{X}, \mathcal{Y} \subseteq [r]^d$ with $|\mathcal{X}| = |\mathcal{Y}| = N$ and a positive integer s, we want to output a set of the (lexicographically) first s pairs $(x, y) \in \mathcal{X} \times \mathcal{Y}$ that are *dissimilar*, i.e., for all $i = 1, \ldots, d$, $x_i \neq y_i$.

▶ **Reminder of Theorem 4.** *Given lists $\mathcal{X}$ and $\mathcal{Y}$ of N vectors in $[r]^d$ with $d < \log_3(N)/20$, and $N < s \leq N^2$, the first s dissimilar pairs $(x, y) \in \mathcal{X} \times \mathcal{Y}$ can be listed in $\tilde{O}(N\sqrt{s})$ time.*

[3] Note that $s \leq N^2$ implies $s \leq N\sqrt{s}$, so the running time is at least s. Also note that for $s = 2^{n-\delta n}$ and $N = 2^{n/2}$ (our applications of interest), $N \cdot s^{1/2} \leq 2^{n-\delta n/2}$.

Proof. The idea of the algorithm is to partition both $\mathcal{X}$ and $\mathcal{Y}$ in $m = s^{1/4}\sqrt{N}$ pieces, each of size at most N/m, as $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2 \cup \cdots \cup \mathcal{X}_m$ and $\mathcal{Y} = \mathcal{Y}_1 \cup \mathcal{Y}_2 \cup \cdots \cup \mathcal{Y}_m$. First, the algorithm locates all pairs $(i, j) \in [m] \times [m]$ such that $\mathcal{X}_i \times \mathcal{Y}_j$ contains a dissimilar vector pair. This is achieved for all pairs simultaneously through several rectangular matrix products. Then the algorithm "brute-forces" all pairs in those $\mathcal{X}_i \times \mathcal{Y}_j$ containing dissimilar pairs.

Given a pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$, consider the following polynomial defined over $\mathbb{Z}$:

$$p(x, y) = \prod_{i=1}^{d} (x_i - y_i)^2. \tag{3}$$

Note that $p(x, y) > 0$ if (x, y) is a dissimilar vector pair, otherwise $p(x, y) = 0$.

We can write $p(x, y)$ as a sum of 3^d products:

$$p(x, y) = \sum_{z \in \{0,1,2\}^d} (-2)^{\text{ones}(z)} \left(\prod_{j=1}^{d} x_j^{z_j} \right) \left(\prod_{k=1}^{d} y_k^{2-z_k} \right), \tag{4}$$

where $\text{ones}(z)$ counts the number of coordinates i in z such that $z_i = 1$.

Let $c(i, j)$ be the sum of $p(x, y)$ over all pairs $(x, y) \in \mathcal{X}_i \times \mathcal{Y}_j$, and note $c(i, j) > 0$ if and only if some pair in $\mathcal{X}_i \times \mathcal{Y}_j$ is dissimilar. We wish to compute whether $c(i, j) > 0$ for all i, j. To this end, we construct an $m \times 3^d$ integer matrix $M_{\mathcal{X}}$ representing $\mathcal{X}$, with row i representing $\mathcal{X}_i$, and columns representing different terms in (4), labeled by the corresponding z-vector. Formally, the entry at row i and column $z \in \{0, 1, 2\}^d$ is

$$M_{\mathcal{X},i,z} = \sum_{x \in \mathcal{X}_i} (-2)^{\text{ones}(z)} \prod_{j=1}^{d} x_j^{z_j}. \tag{5}$$

Similarly, we construct an $m \times 3^d$ integer matrix $M_{\mathcal{Y}}$ representing $\mathcal{Y}$:

$$M_{\mathcal{Y},i,z} = \sum_{y \in \mathcal{Y}_i} \prod_{k=1}^{d} y_k^{2-z_k}. \tag{6}$$

We consider $P = M_{\mathcal{X}} \cdot M_{\mathcal{Y}}{}^{\mathrm{T}}$, and observe that $P_{i,j} = c(i, j)$ for all $i, j = 1, \ldots, m$. All entries in the result are $\text{poly}(\log N, \log r)$-bit non-negative integers. To see if $c(i, j) > 0$, we compute P modulo the first $\text{poly}(\log N, \log r)$ primes using Theorem 5. If any of the products has $P_{i,j} \neq 0$, we know that $c(i, j) > 0$ and mark (i, j) as containing dissimilar pairs.

Next, we loop over all marked entries (i, j) of the matrix, and test every $(x, y) \in \mathcal{X}_i \times \mathcal{Y}_j$ for dissimilarity by brute force in lexicographical order. As soon as s dissimilar pairs have been listed, the algorithm terminates.

Noting that the dimensions of the matrices obey the condition for Coppersmith's algorithm (Theorem 5), i.e., $3^d < m^{0.17}$, the running time is

$$(3^d N + m^2 + s(N/m)^2)\,\text{poly}(\log N, \log r) = N\sqrt{s}\,\text{poly}(\log N, \log r).$$

Here, the first two summands come from building the matrices and computing the product P, and the last summand arises from the worst case of the brute-force listing part, when every $\mathcal{X}_i \times \mathcal{Y}_j$ with $c(i, j) > 0$ contains only one dissimilar pair. This concludes the proof. ◀

3 Listing dissimilar vectors by hashing

In this section, we give an alternative listing method that avoids fast rectangular matrix multiplication. However, it is randomised, and only provides Monte Carlo algorithms running in the same time as the deterministic algorithms of Theorem 1, 2, and 3.

▶ **Reminder of Theorem 6.** *Given two lists $\mathcal{X}$ and $\mathcal{Y}$ of N vectors in $[r]^d$, the set of dissimilar pairs $S \subseteq \mathcal{X} \times \mathcal{Y}$ can be listed in $\tilde{O}(|S| + 2^d \cdot N)$ time with probability of success $1 - o(1)$.*

Proof. Let $\mathcal{H}$ be the family of hash functions $h : [r] \to \{0, 1\}$. Pick $t := 3 \cdot 2^d \log(N)$ vectors of d hash functions $h_j = (h_{j,1}, h_{j,2}, \ldots, h_{j,d}) \in \mathcal{H}^d$ for $j = 1, 2, \ldots, t$.

Consider a pair $(x, y) \in \mathcal{X} \times \mathcal{Y}$. We say (x, y) *passes the hash* j if

$$\forall i \in 1, \ldots, d,\ h_{j,i}(x_i) \neq h_{j,i}(y_i). \tag{7}$$

Note that a similar vector pair never passes any j. Let $\varphi_{j,(x,y)}$ be the indicator for the event that a dissimilar pair (x, y) passes j, then

$$\mathbb{E}[\varphi_{j,(x,y)}] = \Pr[(x, y) \text{ pass } j] = \frac{1}{2^d}. \tag{8}$$

Form the sum

$$X = \sum_{j=1}^{t} \sum_{x,y \in S} \varphi_{j,(x,y)}. \tag{9}$$

The quantity X is the number of the vector pairs in S that survive some j, counted with multiplicity when they pass several hashes. Applying linearity of expectation to (8) and (9),

$$\mathbb{E}[X] = \frac{t|S|}{2^d} = 3|S| \log(N). \tag{10}$$

Applying Markov's inequality to (10),

$$\Pr\left[X > 10\mathbb{E}[X]\right] \leq \frac{1}{10}. \tag{11}$$

Also, the probability that a particular $(x, y) \in S$ does not pass any j, is

$$\prod_{j=1}^{2^d 3 \log N} \Pr[(x, y) \text{ does not pass } j] = \left(1 - \frac{1}{2^d}\right)^{3 \cdot 2^d \log(N)} < \exp(-3 \log N). \tag{12}$$

By a union bound, the probability that some dissimilar pair does not pass any j is at most

$$N^2 \exp(-3 \log N) < \frac{1}{N}. \tag{13}$$

Suppose we list all pairs (x, y) that pass some j. From (11) and (13), we see that with probability at least $\frac{9}{10} - \frac{1}{N}$, we will list all dissimilar pairs (possibly with repetition), and we do not list more than $30 \log N$ times the number of dissimilar pairs.

Now we describe how to list these pairs. Iterate over $j \in [t]$. For each j, iterate over $y = (y_1, \ldots, y_d) \in \mathcal{Y}$, compute its hash vector $h_j(y) := (h_{j,1}(y_1), \ldots, h_{j,d}(y_d)) \in \{0, 1\}^d$, and build lists $\ell_j(v)$ for all relevant vectors $v \in \{0, 1\}^d$, where $\ell_j(v) := \{y \in \mathcal{Y} \mid h_j(y) = v\}$. Note that $\sum_{v \in \{0,1\}^d} |\ell_j(v)| = N$. Next, iterate over $x = (x_1, \ldots, x_d) \in \mathcal{X}$, and output the pair (x, y') for each $y' \in \ell_j(\overline{h_j(x)})$, where $\overline{h_j(x)} := (1 - h_{j,1}(x_1), \ldots, 1 - h_{j,d}(x_d))$.

Observe the running time is $\tilde{O}(tN + X) \leq \tilde{O}(N \cdot 2^d + |S|)$. ◀

4 Reductions to listing dissimilar vectors

Here we outline reductions from our two application problems to the problem of listing dissimilar vectors, roughly following Bax and Franklin [3] for the permanent, and Björklund et al. [8] for Hamiltonian cycles. We also provide bounds on the number of dissimilar pairs that are needed for the analysis of the resulting algorithms. In particular, in Section 4.2 we provide a novel stronger bound on the number of dissimilar pairs than was previously known, for the reduction from 0/1 matrix permanents with d ones in each row and column.

4.1 Reduction for the permanent

In the following, let K be a ring on r elements denoted by $e_1, \ldots, e_r$.

Bax and Franklin [3] observed the following simple but intriguing fact. For any $M \in K^{n\times n}$, let 0_n be the $1 \times n$ row vector of all zeros, and let $q \in K^{n\times 1}$ be any column vector. Form the $(n+1) \times (n+1)$ matrix

$$M_q = \begin{bmatrix} M & q \\ 0_n & 1 \end{bmatrix}. \tag{14}$$

Then we have

$$\mathrm{per}(M_q) = \mathrm{per}(M). \tag{15}$$

The equation (15) follows because every summand in the permanent (1) must include the 1 on the last row of M_q, and hence cannot include any elements of the vector q. The usefulness of this simple fact can be seen from inspecting Ryser's formula (2), partitioned in the form

$$\mathrm{per}(M_q) = \sum_{X\subseteq[n]} (-1)^{n-|X|} f(M_q, X),\ f(M_q, X) = \prod_{i=1}^{n} g_i(M_q, X),\ g_i(M_q, X) = q_i + \sum_{j\in X} M_{i,j}. \tag{16}$$

Note that $f(M_q, X) = 0$ if and only if $g_i(M_q, X) = 0$ for some i. So in order to compute $\mathrm{per}(M)$, it is enough to list those subsets $X \subseteq [n]$ such that $g_i(M_q, X) \neq 0$ for all i, and accumulate their contributions. We call such X's *contributing terms*. Furthermore, we say a subset $X \subseteq [n]$ is *k-weakly contributing* if $g_i(M_q, X)$ is non-zero for all $i \leq k$.

In particular, by choosing q uniformly at random, we can easily compute the expected number of k-weakly contributing terms, as the events $g_i(M_q, X) \neq 0$ for $i = 1, \ldots, k$ are mutually independent (they depend on different q_i). Let Y be the random variable equal to the number of k-weakly contributing terms under a random $q \in K^{n\times 1}$, i.e., $Y = \sum_X Y_X$ where Y_X is the indicator of whether X is k-weakly contributing. By linearity of expectation,

$$\mathbb{E}(Y) = \sum_{X\subseteq[n]} \mathbb{E}(Y_X) = 2^n \left(1 - \frac{1}{r}\right)^k < 2^n \exp(-k/r). \tag{17}$$

Thus, if we could efficiently list the k-weakly contributing terms for some $k \geq \Omega(n)$, we would have a Las Vegas algorithm running in expected $2^{n-\Omega(n/r)}$ time. In Theorem 1, we claim a *deterministic* algorithm, in which case we cannot choose q at random. We will address this issue later in Section 5. For now, we concentrate on finding the contributing terms for a fixed q. We describe next how k-weakly contributing terms can be viewed as *dissimilar vector pairs* from two sets of short vectors.

4.1.1 Contributing terms as dissimilar vectors

Here we show how to reduce the problem of listing contributing terms to the problem of listing dissimilar vectors, implying a randomised version of Theorem 1. Assume WLOG that our matrix M is $n \times n$ and n is even; recall its entries are elements from the ring $K = \{e_1, \ldots, e_r\}$. We begin by partitioning the columns in two halves $L = \{1, \ldots, n/2\}$ and $R = \{n/2+1, \ldots, n\}$. Let $\mathcal{L}$ be the power set of L, and $\mathcal{R}$ the power set of R. Define a map $\phi : K \to [r]$ by $\phi(e_i) := i$.

For every $A \in \mathcal{L}$, construct a vector $v^A \in [r]^k$ for $i \in \{1, \ldots, k\}$ as

$$v_i^A = \phi\left(\sum_{k \in A} M_{i,k}\right), \text{ for all } i = 1, \ldots, k. \tag{18}$$

Similarly, but asymmetrically, for every $B \in \mathcal{R}$ we construct the vector $v^B \in [r]^k$ as

$$v_i^B = \phi\left(-q_i - \sum_{k \in B} M_{i,k}\right), \text{ for all } i = 1, \ldots, k. \tag{19}$$

Recall two vectors u and v are dissimilar if they differ in each coordinate. One can easily verify for all $A \in \mathcal{L}$ and $B \in \mathcal{R}$, the two vectors v^A and v^B are dissimilar if and only if the subset $X = A \cup B$ is k-weakly contributing. Note that $\mathcal{L}$ and $\mathcal{R}$ describe $N = 2^{n/2}$ vectors each of dimension k. For $k \geq \Omega(n)$, the number of k-weakly contributing terms in (17) is (expected to be) at most $2^{n-cn/r}$ for a constant $c > 0$. In that case, the number of dissimilar vector pairs s in our instance of $O(2^{n/2})$ vectors is at most $2^{n-cn/r}$.

Given an algorithm that efficiently lists dissimilar vector pairs, we can then efficiently list all $2^{n-cn/r}$ of the k-weakly contributing terms in the modified Ryser's formula (16). Given the list of contributing terms, we can then compute the permanent via (16), in time $2^{n-cn/r} \cdot \text{poly}(n)$. Using the listing algorithm of Theorem 4 with $s = 2^{n-cn/r}$, we obtain an algorithm with running time $2^{n-\Omega(\frac{n}{r})}$ as claimed.

4.2 The permanent algorithm for regular matrices

We now turn to giving a Las Vegas version of Theorem 2, showing that for d-regular matrices the permanent can be computed in $2^{n-\Omega(n/d^{3/4})}$ time. Later in Section 5, we will outline how to derandomise the algorithm.

Let $M \in \{0,1\}^{n \times n}$ have exactly d ones in every row and column. As in the case of permanents over finite rings, we reduce to dissimilar pair listing and apply the algorithm of Theorem 4 to locate k-weakly contributing terms for the permanent of the perturbed matrix M_q of (14). However, here we will pick the vector q from a different distribution, and we may also permute the rows of M to select a suitable subset of rows to use in the reduction to dissimilar pair listing. Our choices drastically reduce the number of contributing terms.

Index the rows and columns of M by $[n]$. For $i = 1, \ldots, n$, the ith row of M naturally corresponds to a d-size subset R_i of $[n]$ indicating which columns have a 1 in the row.

We first consider the case $d \geq n^{4/5}$. Here our algorithm will work as in Bax and Franklin [3] (whose analysis works for $d \in \Omega(n)$, for which the slightly better bound $2^{n-\Omega(n^{1/3})}$ can be argued). The probability for a fixed row $i \in [n]$, that the sieved row sum $|X \cap R_i|$ is deviating significantly from its expectation, is small:

$$\Pr_X\left[\left||X \cap R_i| - \frac{d}{2}\right| > d^{3/4}\right] \leq \exp(-\Omega(\sqrt{d})), \tag{20}$$

as seen by a standard Chernoff bound. Note that $\frac{n}{d^{3/4}} \leq n^{2/5} \leq \sqrt{d}$ for $d \geq n^{4/5}$. By a union bound, the probability that some row has intersection with X outside of the $2d^{3/4}$-length interval in (20) is at most $n \cdot \exp(-\Omega(\sqrt{d})) \leq \exp(-\Omega(n/d^{3/4}))$. Hence there are at most $2^{n-\Omega(n/d^{3/4})}$ such deviating subsets $X \subseteq [n]$.

Therefore, if we run our previous permanent algorithm but with the vector q taking random values in the range $[\frac{d}{2} - d^{3/4}, \frac{d}{2} + d^{3/4}]$, we see that the probability that any X within the $2d^{3/4}$-span for every row, is k-weakly contributing, is at most

$$\Pr_q[X \text{ passes}] \leq \left(1 - \frac{1}{2d^{3/4}}\right)^k. \tag{21}$$

Hence for $k \geq \Omega(n)$, the expected number of non-zero terms is only $2^{n-\Omega(n/d^{3/4})}$, so we only need to list that many dissimilar vector pairs in our reduction.

Now consider the more interesting case of $d < n^{4/5}$. First, we preprocess the matrix via a process we call P, which puts the row sets representing M into a number of ordered lists.

> **Process P:** Start with an empty list L_1, and put the first row set R_1 in L_1. While there is another row set R_i, not yet assigned to a list, that has at most $d^{3/4}$ elements in common with the union of the row sets in L_1, insert R_i into L_1. This operation is repeated until there either are no more row sets that meet this criterion, or L_1 contains $n/(2d^{5/4})$ row sets. In the latter case we say that the list is *full*. We consider L_1 *finished*, put it aside, and start building a new, initially empty, list L_2. We insert row sets into L_2 in the same way, continue with a third list L_3 once L_2 is finished, and so on. The process P terminates when every row set has been assigned to some list.

After we have constructed the lists $L_1, L_2, \ldots$, we reorder the rows and columns of M according to the insertion order of the row sets during process P. This permutation does not change the value of the permanent. The following lemma ensures that the first $n/2$ rows of M, after the reordering step, can be partitioned into full lists.

▶ **Lemma 7.** *The first $d^{5/4}$ lists produced by process P are full, i.e., each list contains $n/(2d^{5/4})$ row sets.*

Proof. Assume there are at least $n/2 + n/(2d^{5/4})$ row sets left to place when we start populating the list L_j. After we have put t sets into a list L_j, their union covers no more than td elements. Each element of $[n]$ is covered d times in total, since M is d-regular. Thus there are at most $td^{2-3/4}$ row sets left that has an overlap of more than $d^{3/4}$ with the union.

Therefore, as long as $\frac{n}{2} + n/(2d^{5/4}) - t > td^{2-3/4}$, i.e., $t < \frac{n}{2(d^{2-3/4})}$, there is still a row set that can be put into L_j. Hence we can put at least $\frac{n}{2d^{5/4}}$ row sets into L_j, making it full. We can repeat this for $j = 1, 2, \ldots, d^{5/4}$, as there are still $n/2 + n/(2d^{5/4})$ row sets left when we start to populate $L_{d^{5/4}}$. ◀

Next we need a Chernoff-like concentration bound on the sum of variables with bounded dependence resulting from a list L_j.

▶ **Lemma 8.** *Let L be an ordered list of d-subsets $S_1, ..., S_m$ of $[n]$ such that for all i, $|S_i \cap (\cup_{j=1}^{i-1} S_j)| < d^{3/4}$. Pick $X \subseteq [n]$ uniformly at random. Let Z_i be the indicator variable for the event $\frac{d}{2} - 3d^{3/4} \leq |S_i \cap X| \leq \frac{d}{2} + 3d^{3/4}$. Then*

$$\Pr_X\left[\sum_{i=1}^{m} Z_i < \frac{m}{2}\right] \leq \exp(-\Omega(d^{1/2}m)). \tag{22}$$

Proof. Let $U = [\ell] = \cup_{i=1}^{m} S_i$ and $X_1, \ldots, X_\ell$ be indicator variables such that $X_i = 1 \Leftrightarrow i \in X$. Hence the X_i's are mutually independent with $E[X_i] = 1/2$. Construct the sets $T_i = S_i \setminus (\cup_{l=1}^{i-1} S_l)$ for $i = 1, \ldots, m$. Note that $|T_i| \geq d - d^{3/4}$ for all i, and that T_i and T_j are disjoint for $i \neq j$. Letting $Y_i = \sum_{j \in T_i} X_j$, we have

$$\Pr_X \left[\left| Y_i - \frac{d}{2} \right| > 2d^{3/4} \right] \leq \exp(-\Omega(d^{1/2})), \tag{23}$$

as seen by a standard Chernoff bound. Note that if $|Y_i - d/2| \leq 2d^{3/4}$, then also $Z_i = 1$, as there are only at most $d^{3/4}$ other elements of X that are in $S_i \setminus T_i$. Further note that the events $|Y_i - d/2| > 2d^{3/4}$ for different i are mutually independent as they depend on different mutually independent X_j's. Hence the probability that $\sum_i Z_i < m/2$ is at most $m/2 \cdot \exp(-\Omega(d^{1/2}))^{m/2} \binom{m}{m/2} \leq \exp(-\Omega(d^{1/2} m))$. ◀

We can now argue as in the dense case (where d is large). We first bound the number of X's such that for some list L_i, more than half of the row sets in the list have a deviating sieve row sum $\left| |R_j \cap X| - \frac{d}{2} \right| > 3d^{3/4}$. From Lemma 8, replacing $m = n/(2d^{5/4})$, and a union bound over all lists, we know that this happens for at most $2^{n - \Omega(n/d^{3/4})}$ X's. Thus we may restrict our analysis to the X's that are within the $6d^{3/4}$-length interval for at least half of the rows in the first $d^{5/4}$ lists (amounting to the first $n/2$ rows of the matrix, after the pre-processing reordering). Running our algorithm from before, but with the vector q taking random values in the range $[\frac{d}{2} - 3d^{3/4}, \frac{d}{2} + 3d^{3/4}]$, we see that each of these remaining well-behaved X's are k-weakly contributing with probability at most

$$\Pr_q[X \text{ passes}] \leq \left(1 - \frac{1}{6d^{3/4}}\right)^{k/2}. \tag{24}$$

Hence, for $k = \frac{n}{c}$ for some $c > 2$, we have in expectation $2^{n - \Omega(n/d^{3/4})}$ non-zero terms.

4.3 Reduction for counting Hamiltonian cycles

In the following let $G' = (V', A')$ be the directed input graph on $n = |V'|$ vertices in which we want to count Hamiltonian cycles. Let d_v for $v \in V'$ be the out-degree of the vertex v, and let $\delta = |A'|/n$ be the average out-degree of G'. It will be convenient to work on a slightly modified graph $G = (V, E)$ constructed from G' as follows: pick an arbitrary vertex $s' \in V'$, and obtain G from G' by replacing s' with two new vertices s and t (i.e., $V = V' \setminus \{s'\} \cup \{s, t\}$), where s retains all outgoing arcs from s', i.e. $(s', u) \in A' \Leftrightarrow (s, u) \in A$, and t retains all incoming arcs to s', i.e. $(u, s') \in A' \Leftrightarrow (u, t) \in A$. Note that the Hamiltonian paths from s to t in G are in one-to-one correspondence with the Hamiltonian cycles in G', and that the average degree of G is not larger than that of G'. In the following, we consider the problem of counting the s-t Hamiltonian paths on the modified $n + 1$ vertex graph G.

4.3.1 Random columns and contributing terms

Björklund, Kaski, and Koutis [8] observed that the number of Hamiltonian cycles in a directed graph can be evaluated as an inclusion–exclusion summation over a determinant of a polynomial matrix representing the graph. We will use their construction, and restate the main ideas here. The Laplacian of the graph G, is a $(n + 1) \times (n + 1)$ polynomial matrix

with rows and columns indexed by the vertices V, in the variables x_v for $v \in V$:

$$L(G)_{i,j} = \begin{cases} \sum_{(u,v)\in A} x_u & \text{if } i = j = v \\ -x_u & \text{if } i = u, j = v, (u,v) \in A \\ 0 & \text{otherwise.} \end{cases} \tag{25}$$

The Laplacian *punctured at the vertex* $s \in V$, is the matrix $L(G)_s$ obtained by omitting row and column s from $L(G)$. By Tutte's directed version of the Matrix-Tree theorem of Kirchhoff [20], we know that $\det(L(G)_s)$ is a polynomial where each term corresponds to a directed spanning out-branching rooted at s. Denote by $\mathrm{hp}(G)_{s,t}$ the number of Hamiltonian paths starting in s and ending in t. By the principle of inclusion–exclusion, we have[4]

$$\mathrm{hp}(G)_{s,t} = \sum_{\substack{x:(V\setminus\{t\})\to\{0,1\} \\ x_t=1}} (-1)^{n-1-|x|} \det\left(L(G)_s(x)\right). \tag{26}$$

The summation is over all 2^{n-1} assignments x with the restriction that $x_t = 1$. Next, we mimic the Bax and Franklin idea for computing permanents by perturbing the matrix (of (15)): we shall parametrise the Laplacian matrices so that in expectation, many summands in the above formula are zeroed-out. To this end we introduce fresh random variables $q_v \in \{0, 1, \ldots, d_v\}$ for $v \in V$, and define the *q-perturbed Laplacian* of G as

$$L_q(G)_{i,j} = \begin{cases} \sum_{(u,v)\in A} x_u - q_v & \text{if } i = j = v \\ -x_u & \text{if } i = u, j = v, (u,v) \in A \\ 0 & \text{otherwise.} \end{cases} \tag{27}$$

The extra q_v variables may be thought of as weighted arcs originating from t: these arcs cannot be used by any of the Hamiltonian paths from s to t. The point of our perturbation is that irrespective of q, we can still compute the number of Hamiltonian paths:

$$\mathrm{hp}(G')_{s',t'} = \sum_{\substack{x:(V\setminus\{t\})\to\{0,1\} \\ x_t=1}} (-1)^{n-1-|x|} \det\left(L_q(G)_s(x)\right). \tag{28}$$

However, in expectation, many assignments x may yield $\det\left(L_q(G)_s(x)\right) = 0$, particularly when a row in $L_q(G)_s(x)$ is all-zeroes. Observe that a row in $L_q(G)_s(x)$ is all-zero if and only if for some $v \in V \setminus \{s\}$ we have $x_v = 0$ and $\sum_{(u,v)\in A} x_u = q_v$. Let ε_v be a Boolean variable that is true if and only if $x_v = 0$ and $\sum_{(u,v)\in A} x_u = q_v$; i.e., $L_q(G)_s(x)$ is all-zero in the row indexed by v. In analogy with the case of the permanent, we say that an assignment x is *contributing* if ε_v is false for all vertices $v \in V \setminus \{s\}$, and x is *k-weakly contributing* if ε_v is false for the first k vertices. As in the case of the permanent, it is sufficient to list the k-weakly contributing terms for some k to compute the number of Hamiltonian paths in G (and hence the Hamiltonian cycles in G') through the formula of (28).

We can easily compute the expected number of contributing terms for a $q \in \{0, 1, \ldots, d_v\}^n$ picked uniformly at random, since the events ε_v are mutually independent (they depend on different q-values). The probability that $L_q(G)_s(x)$ is all-zero in the row v, with $x_v = 0$, is

$$\Pr_q[\varepsilon_v] = \frac{1}{(d_v + 1)}. \tag{29}$$

We will assign $k := cn$ for some $c < 1/2$, and assume WLOG that the vertices are sorted by increasing out-degree. This means by an averaging argument that for all $i \leq k$, $d_i < 2\delta$.

[4] See [8] for a proof of (26).

Let Z_x be the indicator variable that the assignment x is k-weakly contributing, under a randomly chosen q. Let Z be the random variable equal to the number of k-weakly contributing terms under a random q, i.e., $Z = \sum_x Z_x$. By linearity of expectation, and Jensen's inequality for concave functions,

$$\mathbb{E}(Z) = \sum_{X \subseteq V \setminus \{s\}} \prod_{v \in X \cap [k]} \left(1 - \frac{1}{d_v + 1}\right) \leq 2^n \left(1 - \frac{1}{2\delta + 1}\right)^k \leq 2^n \cdot \exp(-\Omega(k/\delta)). \quad (30)$$

Thus, the expected number of k-weak contributors behaves similarly as in previous cases.

4.3.2 Contributing terms as dissimilar vectors

We now turn to describing how the contributing terms can be encoded as dissimilar vectors. Assume WLOG that n is even, and identify $V \setminus \{s\}$ with the set $[n]$. Partition the vertices into $L = \{1, \ldots, n/2\}$ and $R = \{n/2 + 1, \ldots, n\}$, letting $\mathcal{L}$ and $\mathcal{R}$ be the power sets of L and R, respectively. For every $C \in \mathcal{L}$, we construct the vector $v^C \in [2\delta + 1]^k$ for $i = 1, \ldots, k$ as

$$v_i^C = \begin{cases} \sum_{(i,w) \in (A \cap C)} 1 & \text{if } i \notin C, \\ \star & \text{otherwise.} \end{cases} \quad (31)$$

where $\star$ is an extra symbol encoded as 2δ. Similarly, but asymmetrically, noting in particular that $i \notin R$ because $k < n/2$, for every $D \in \mathcal{R}$ we construct the k-length vector v^D as

$$v_i^D = q_i - \sum_{(i,w) \in (A \cap D)} 1, \text{ for all } i = 1, \ldots, k. \quad (32)$$

It is readily verified that for $C \in \mathcal{L}$ and $D \in \mathcal{R}$, the two vectors v^C and v^D are dissimilar if and only if the first k columns of $L_q(G)(x')$ are non-zero, where the Boolean vector x' is defined as $x'_v := 1 \iff v \in C \cup D$. Hence, the k-weakly contributing assignments x are precisely those corresponding to dissimilar pairs (v^C, v^D).

Note that $\mathcal{L}$ and $\mathcal{R}$ each contain $N = 2^{n/2}$ vectors of dimension k. Using a sufficiently fast algorithm for listing dissimilar vector pairs, we can enumerate all k-weakly contributing terms in (28) in $N^{2-\Omega(1/\delta)}$ time. Once we have a list of all the $2^n \cdot \exp(-\Omega(k/\delta))$ contributing terms, the number of Hamiltonian cycles can be computed with (28) in time $2^n \cdot \exp(-\Omega(k/\delta))$ as well. From (30), we know that the upper bound s on the number of dissimilar pairs can be set to $2^{n - cn/\delta}$, for some positive $c > 0$. Applying the dissimilar pair listing algorithm of Theorem 4, we arrive at the running time $2^{n - \Omega(\frac{n}{\delta})}$. This concludes the algorithm.

5 Derandomisation

Our deterministic algorithm for dissimilar pair listing from Section 2 can be used to list k-weakly contributing terms efficiently in all our desired applications (Theorems 1, 2, and 3), provided that the number of contributing terms is not much more than their expected number would be on a random vector q.

To make all of our application algorithms fully deterministic, we must provide a deterministic procedure for setting the vector q so that the number of resulting terms is bounded by the expectation. This can be done by using other known algorithmic tools, along with the well-known method of conditional expectation (see e.g., [17]).

It turns out that a fast deterministic algorithm for counting dissimilar pairs will suffice. This can be obtained by reducing our problem to counting orthogonal pairs:

▶ **Proposition 9.** *Counting the dissimilar pairs on two sets of N vectors in $[r]^d$ can be reduced in $O(Nrd)$ time to counting orthogonal pairs on two sets of N vectors in $\{0,1\}^{rd}$.*

Proof. Let $e_1, \ldots, e_r \in \{0,1\}^r$ be the standard basis vectors, where e_i is 1 in the ith component and is 0 everywhere else. Map every vector $x \in [r]^d$ to the Boolean vector

$$\rho(x) = [e_{x_1}\ e_{x_2}\ \cdots\ e_{x_d}].$$

That is, $x' \in \{0,1\}^{rd}$ is obtained by *concatenating* the d standard basis vectors corresponding to the entries of x. Note $x, y \in [r]^d$ are dissimilar $\iff$ $\rho(x)$ and $\rho(y)$ are orthogonal. ◀

Applying the proposition, we can count dissimilar pairs by counting OV pairs:

▶ **Theorem 10** (Chan and Williams [11])**.** *For every $c \leq 2^{o(\sqrt{\log N})}$, there is a deterministic algorithm that for two sets of N vectors from $\{0,1\}^{c \log N}$, counts the orthogonal vector pairs in $N^{2-1/O(\log c)}$ time.*

An immediate corollary is that, for $d \leq \log(N)$, we can deterministically count all dissimilar pairs over N vectors in $[r]^d$ in only $N^{2-1/O(\log r)}$ time. We can use this counting algorithm to *deterministically* search for a vector q that has at most as many k-weakly contributing terms as the expected number for a random q. We describe the procedure generically, as it is essentially the same for all three applications in the paper:

> Iterate over $j = 1, \ldots, k$. Suppose we have determined the first $j-1$ components of our vector q, and we wish to determine the jth component, q_j. Let us inductively suppose that there are at most $2^n \cdot \prod_{i=1}^{j-1}(1 - 1/C_i)$ contributing terms remaining (where the C_i depend on the application), and let there be C_j possible values for q_j. Construct and compute C_j distinct instances of dissimilar pair counting with j-dimensional vectors, corresponding to the C_j different values for q_j. Finally, set q_j to be the value which minimises the number of dissimilar pairs obtained.

Since we always choose q_j to minimise the number of dissimilar pairs, and we know a random setting of q_j reduces the number by a $(1 - 1/C_j)$ fraction in expectation (by our analyses in previous sections), our k-dimensional vector q produces a number of k-weakly contributing terms which is at most the expectation. Finally, note that this initial procedure for selecting the vector q is much faster than the overall running time in our applications.

This concludes our derandomisation, and the proofs of Theorems 1, 2, and 3.

Abstract

We consider the problem of finding solutions to systems of polynomial equations over a finite field. Lokshtanov et al. [SODA'17] recently obtained the first worst-case algorithms that beat exhaustive search for this problem. In particular for degree-d equations modulo two in n variables, they gave an $O^*\big(2^{(1-1/(5d))n}\big)$ time algorithm, and for the special case $d = 2$ they gave an $O^*\big(2^{0.876n}\big)$ time algorithm.

We modify their approach in a way that improves these running times to $O^*\big(2^{(1-1/(2.7d))n}\big)$ and $O^*\big(2^{0.804n}\big)$, respectively. In particular, our latter bound – that holds for all systems of quadratic equations modulo 2 – comes close to the $O^*\big(2^{0.792n}\big)$ expected time bound of an algorithm empirically found to hold for *random* equation systems in Bardet et al. [*J. Complexity*, 2013]. Our improvement involves three observations:

1. The Valiant-Vazirani lemma can be used to reduce the solution-finding problem to that of counting solutions modulo 2.
2. The monomials in the probabilistic polynomials used in this solution-counting modulo 2 have a special form that we exploit to obtain better bounds on their number than in Lokshtanov et al. [SODA'17].
3. The problem of solution-counting modulo 2 can be "embedded" in a smaller instance of the original problem, which enables us to apply the algorithm as a subroutine to itself.

1 Introduction

We study the problem of finding a simultaneous root to a system of m polynomials

$$P_1(x) = 0\,, \quad P_2(x) = 0\,, \quad \ldots\,, \quad P_m(x) = 0 \tag{1}$$

over n variables $x = (x_1, x_2, \ldots, x_n)$. The computational tractability of this problem is known to dramatically depend on the domain of the variables and polynomial coefficients. Over the integers, the problem is undecidable, by Matiyasevich's celebrated solution of

Hilbert's tenth problem on the algorithmic decidability of Diophantine equations [10]. Over an algebraically closed field, the problem reduces via Hilbert's Nullstellensatz to deciding whether 1 belongs to the ideal generated by the polynomials, which for polynomials with rational coefficients can be decided in exponential space by computing a reduced Gröbner basis for the ideal [3, 4, 11]. Over the integers *modulo two* – our object of study in this paper – the problem is NP-complete even when the polynomials are severely constrained. Indeed, systems of polynomial equations modulo two enable the compact modeling of a versatile range of tasks. For example, one can easily represent k-CNFSAT formulas on n Boolean variables by expressing each clause in the formula as a degree-k polynomial [5]. A similar reduction from NAE3SAT proves that the problem remains NP-hard even in the case of quadratic equations modulo two. As the fastest known worst-case algorithms for k-CNF satisfiability (for example, see Moser and Scheder [13]) run in time $2^{n-\Omega(n/k)}$, it is a difficult challenge to design faster-than-$2^{n-\Omega(n/k)}$-time algorithms for solving systems of degree-k polynomial equations. Still it is interesting to ask precisely how much savings over the brute-force $O^*\big(2^n\big)$-time solution one can obtain, particularly in the case of quadratic equations, since the postulated hardness of solving quadratic systems modulo two forms the basis of several proposed cryptographic primitives, such as HFE proposed by Patarin [15] and UOV proposed by Kipnis, Patarin, and Goubin [8].

An $O^*\big(2^{0.792n}\big)$ expected-time algorithm for a system of $m = n$ quadratic polynomials over n variables modulo two was proposed by Bardet, Faugère, Salvy, and Spaenlehauer [1]. However, their algorithm only works for systems satisfying certain algebraic assumptions, and these assumptions were only experimentally verified to hold for the vast majority of such systems. Still, further refinements of the method makes it practical even for small systems [6], and the algorithmic ideas underlies the to date fastest known implementation we are aware of [14].

Such a result highlights the potential vulnerability of cryptographic primitives whose security is based on the postulated hardness of solving random systems. However, from a theoretical viewpoint it is preferable to have rigorous proofs and algorithms that work efficiently on all inputs. The algorithm of Bardet et al. [1] is based on finding proofs of non-solvability, a so-called effective Nullstellensatz of finding low-degree polynomials H_i such that

$$\sum_i H_i(x')P_i(x', r) = 1,$$

for each specialisation r of the polynomials, i.e. after replacing a fixed subset of the variables to a restriction r. The algorithm then continues to look for solutions only in those specialisations r for which no proof was found. The search for proofs is formulated as a linear equation system whose dimensions depend on the bound of the degree in the proofs. The argument made in their paper is that for most equation systems with sufficiently more equations than variables, "small-degree" polynomials can be used in the proofs. Getting rigorous bounds on the degree appears to be a difficult problem, and in the worst case some systems will likely require large-degree proofs.

Lokshtanov, Paturi, Tamaki, Williams, and Yu [9] took a radically different approach and presented an $O^*\big(2^{0.876n}\big)$-time algorithm for quadratic equation systems modulo two that uses no algebraic assumptions at all and works for all quadratic systems. They also gave a general $O^*\big(2^{n-n/(5d)}\big)$ time algorithm for systems of equations of degree bounded by d.

Their approach uses the so-called "polynomial method": the entire system of equations is randomly replaced by a single "probabilistic" polynomial that has a "small" exponential number of terms, and is consistent with the system on exponentially many assignments. This polynomial is then evaluated quickly on many assignments using an FFT or fast matrix multiplication, gaining an advantage over exhaustive search.

We present a new algorithm that largely follows the approach of Lokshtanov et al. [9] but offers a few simplifications to their scheme. Most prominently, we will consider the problem of computing the parity of the number of solutions, rather than the decision problem directly. Whereas Lokshtanov et al. [9] apply a random parity sieve on monomials of a subset of the variables to implement a decision-to-parity reduction within the algorithm, our main observation is that this can be done on the system itself. That is, rather than explicitly being tailored into the algorithm, we can reduce decision to the parity problem by adding random affine equations to the system. This is based on the well-known theorem of Valiant and Vazirani [18] in complexity theory to isolate solutions to Boolean satisfiability by adding random equations. Our analysis in Section 2.5 is borrowed from theirs and is included here solely for the sake of completeness.

One immediate effect of our alternative parity-counting approach is that it reduces the need for random bits from exponential in n to merely polynomial in n. A more interesting gain is that our approach leads to faster algorithms, via two further observations. Our algorithm for quadratic systems runs in $O^*\big(2^{0.804n}\big)$ time, and for degree-d systems we provide a $O^*\big(2^{n-n/(2.7d)}\big)$ time algorithm. Our running time for quadratic equation systems in particular comes much closer to the $O^*\big(2^{0.792n}\big)$ running time of Bardet et al. [1]. To get a quantitive feeling of our incremental result, note:

1. We can solve quadratic systems modulo two with 9% more variables in about the same time as the algorithm of [9].
2. Our algorithm for degree-3 systems is faster than the one for degree-2 systems in [9].

Our first observation is that the seemingly more difficult problem of computing the parity of solutions apparently makes it easier to identify the structure of monomials in the probabilistic polynomials used in the polynomial method. Making use of this structure leads to better bounds on their number and (indirectly) on the total running time, and is the source of most of our improvement. Our second observation is that the parity-summation part in the method is identical to the original problem, leading to a self-reduction: we can use our algorithm as a subroutine to itself, again leading to a faster algorithm.

We present our algorithm for computing the parity of the number of solutions to a polynomial equation system in Section 3. We shall highlight the differences to the original decision algorithm by Lokshtanov et al. [9] as we go along. We begin by some preliminaries in the subsequent section.

2 Preliminaries

Here we review some notation and well-known facts. Let $\mathbb{F}_2$ denote the field of two elements; that is, integer arithmetic modulo two. For a non-negative integer n, we write $[n]$ for the set $\{1, 2, \ldots, n\}$. For a finite set D, we write 2^D for the power set of D, $\binom{D}{k}$ for the set of all k-element subsets of D, and $\binom{D}{\downarrow k} = \bigcup_{j=0}^{k} \binom{D}{j}$ for the set of all at-most-k-element subsets of D. Accordingly, we write $\binom{n}{\downarrow k} = \sum_{j=0}^{k} \binom{n}{j}$. For a function $f(n)$, the notation $O^*\big(f(n)\big)$ suppresses factors polynomial in n.

2.1 Yates's algorithm

Let us write I_ℓ for an $\ell \times \ell$ identity matrix. For an $s \times t$ matrix A and a non-negative integer n, the n^{th} Kronecker power of A factors into the sequence of matrices

$$A^{\otimes n} = \prod_{j=1}^{n} \left(I_s^{\otimes j-1} \otimes A \otimes I_t^{\otimes n-j} \right). \tag{2}$$

Each matrix $I_s^{\otimes j-1} \otimes A \otimes I_t^{\otimes n-j}$ is sparse with at most $s^{j-1} \cdot st \cdot t^{n-j} = s^j t^{n-j+1}$ nonzero entries. Thus, using sparse matrix–vector multiplication along the sequence (2), we may multiply the matrix $A^{\otimes n}$ with a given vector in at most

$$2\sum_{j=1}^{n} s^j t^{n-j+1} = \begin{cases} 2ns^{n+1} & \text{if } s = t, \\ \frac{2st(s^n - t^n)}{s-t} & \text{if } s \neq t \end{cases} \tag{3}$$

operations on scalars. This algorithm is known as Yates's algorithm [19].

2.2 The fast zeta transform for the subset lattice

The matrix $\zeta = \left[\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right]$ is invertible over any ring, with inverse $\zeta^{-1} = \left[\begin{smallmatrix} 1 & 0 \\ -1 & 1 \end{smallmatrix}\right]$. In particular, in the field $\mathbb{F}_2$ of two elements, we have $\zeta = \zeta^{-1}$. Let x and y be vectors whose components are indexed by the subsets in $2^{[n]}$. Then, the matrix–vector multiplication $y = \zeta^{\otimes n} x$ implements the linear map $x \mapsto y$ defined for all $B \subseteq [n]$ by $y_B = \sum_{A \subseteq B} x_A$. This map is the *zeta transform* for the lattice $(2^{[n]}, \subseteq)$. By (3) in Section 2.1, Yates's algorithm can be used to implement the zeta transform in $O(2^n n)$ operations. This algorithm is known as the *fast zeta transform*. The inverse transform is called the Möbius transform. In characteristic 2, these transforms coincide. The zeta transform remains invertible when the relevant vectors and matrices are restricted from $2^{[n]}$ to $\binom{[n]}{\downarrow d}$. The corresponding restriction of Yates's algorithm runs in $O\left(\binom{n}{\downarrow d} n\right)$ operations. See [2, 7] and the references therein for more on fast zeta transforms.

2.3 Polynomials modulo two: the monomial basis and the evaluation basis

Observe $x^2 = x$ holds for all $x \in \mathbb{F}_2$. Thus, WLOG, an n-variate polynomial $f = f(x_1, x_2, \ldots, x_n)$ in the polynomial ring $\mathbb{F}_2[x_1, x_2, \ldots, x_n]$ consists of only *multilinear* monomials indicated by a function $M_f : 2^{[n]} \to \mathbb{F}_2$ with

$$f = \sum_{Y \subseteq [n]} M_f(Y) \prod_{j \in Y} x_j \,.$$

Intuitively, $M_f(S)$ gives the coefficient of $\prod_{i \in S} x_i$ in the (unique) multilinear polynomial representing f. In particular, $\mathbb{F}_2[x_1, x_2, \ldots, x_n]$ is a 2^n-dimensional vector space over $\mathbb{F}_2$, and the function M_f, viewed as a vector with entries indexed by $2^{[n]}$, represents f in the *monomial basis*. We say that f has *degree* at most d if M_f vanishes outside $\binom{[n]}{\downarrow d}$. The monomial basis is the algebraic normal form of the Boolean function.

Associate each vector $x \in \mathbb{F}_2^n$ with the subset $X = \{i \in [n] : x_i = 1\} \subseteq [n]$. Define the *evaluation map* $E_f : 2^{[n]} \to \mathbb{F}_2$ for all $X \subseteq [n]$ by the rule $E_f(X) = f(x)$, where x is the vector corresponding to X. In what follows we often find it convenient to abuse notation slightly and write simply $f(X)$ in place of $E_f(X)$. Viewing the function E_f as a vector with entries indexed by $2^{[n]}$, we say that E_f represents f in the *evaluation basis*.

The monomial basis and the evaluation basis are related by the zeta transform. That is, for all $f \in \mathbb{F}_2[x]$, we have

$$E_f = \zeta^{\otimes n} M_f \,. \tag{4}$$

Indeed, for all $Z \subseteq [n]$ we have

$$E_f(Z) = f(Z) = \sum_{Y \subseteq Z} M_f(Y) \,.$$

By properties of the zeta transform, the basis-change identity (4) holds also when restricted from $2^{[n]}$ to $\binom{[n]}{\downarrow d}$; that is, when restricted from arbitrary polynomials to polynomials of degree at most d. Fast zeta transforms enable fast basis changes between the monomial basis and the evaluation basis as needed.

2.4 From finding to decision, from decision to parity-counting

The task of finding a solution to a given system of polynomial equations reduces to the task of deciding whether a given system has at least one solution. Indeed, assuming the system has a solution, we may try both values 0 and 1 to a selected variable, and focus on one assignment that indicates that the system after the substitution of the value has a solution. Thus, finding a solution takes at most $2n$ queries to a decision algorithm.

The task of deciding whether a given system of polynomial equations has a solution reduces to computing the parity of the number of such solutions by randomized isolation techniques. One elegant isolation technique is Valiant–Vazirani [18] affine hashing, which inserts $O(n)$ random linear equations into the system, without increasing the number of variables. For completeness, we recall affine hashing in Section 2.5. Thus, from here on, we consider the problem of counting the parity of solutions to a system of polynomial equations.

2.5 Valiant–Vazirani affine hashing

For completeness, this section recalls Valiant–Vazirani [18] affine hashing for isolating a unique solution (if any) by introducing a collection of random linear equations into to the system of polynomial equations. In particular, affine hashing does not increase the number of variables or the degree of the system, only the number of equations increases.

Let $\mathcal{S} \subseteq \{0,1\}^n$ be the set of solutions the system of polynomial equations. If $\mathcal{S}$ is empty there is nothing to isolate, so let us assume that $\mathcal{S}$ is nonempty in what follows. Let $k = 0, 1, \ldots, n$ be the unique integer such that $2^k \leq |\mathcal{S}| < 2^{k+1}$.

Draw independent uniform random values $\alpha_{ij} \in \{0,1\}$ for $i = 1, 2, \ldots, k+2$ and $j = 1, 2, \ldots, n$. For each $i = 1, 2 \ldots, k+2$, draw an independent uniform random value $\beta_i \in \{0,1\}$ and introduce the linear equation

$$\sum_{j=1}^{n} \alpha_{ij} x_j = \beta_i \tag{5}$$

into the system of polynomial equations.

Let us say that a solution $x \in \mathcal{S}$ *survives* if it satisfies every introduced equation (5). Let us write S_x for the event that x survives, and U_x for the event that x is the unique solution in $\mathcal{S}$ that survives. We want to control the probability

$$\Pr(U_x) = \Pr\bigl(S_x \cap \textstyle\bigcap_{y \in \mathcal{S} \setminus \{x\}} \bar{S}_y\bigr) \,.$$

By the union bound, we have

$$\Pr\big(S_x \cap \bigcap_{y\in\mathcal{S}\setminus\{x\}} \bar{S_y}\big) \geq \Pr(S_x) - \sum_{y\in\mathcal{S}\setminus\{x\}} \Pr\big(S_x \cap S_y\big)\,.$$

By independence of the events S_x and S_y for all $x, y \in \mathcal{S}$ with $x \neq y$, we have

$$\Pr(S_x) - \sum_{y\in\mathcal{S}\setminus\{x\}} \Pr\big(S_x \cap S_y\big) = \Pr(S_x)\left(1 - \sum_{y\in\mathcal{S}\setminus\{x\}} \Pr(S_y)\right).$$

By mutual independence of the $k+2$ equations, we have

$$\Pr(S_x) = \frac{1}{2^{k+2}}\,.$$

Hence,

$$\Pr(U_x) \geq \frac{1}{2^{k+2}}\left(1 - \frac{2^{k+1}}{2^{k+2}}\right) = \frac{1}{2^{k+3}}\,.$$

By mutual exclusiveness of the events U_x, we have

$$\Pr\big(\bigcup_{x\in\mathcal{S}} U_x\big) = \sum_{x\in\mathcal{S}} \Pr(U_x) \geq 2^k \frac{1}{2^{k+3}} = \frac{1}{8}\,.$$

From $(1-\frac{1}{8})^r \leq \exp(-\frac{r}{8}) \leq \epsilon$ we observe that $r = \lceil \ln \epsilon^{-1} \rceil$ independent repetitions will isolate a unique solution in $\mathcal{S}$ with probability at least $1-\epsilon$. Furthermore, we do not know the value of k, but we can exhaustively try out all the values $k = 0, 1, \ldots, n$ with $\epsilon = \frac{1}{n}$ so that a solution, if one exists, will be isolated and hence witnessed as odd parity in the solution space with high probability in total $O(n \log n)$ repetitions of the parity-counting algorithm.

3 A randomized reduction from parity-counting to itself

This section presents our technical contribution. All arithmetic in this section is over $\mathbb{F}_2$. Our task is to determine the parity of the number of solutions $x \in \{0,1\}^n$ to a given system of degree-d polynomial equations

$$P_1(x) = 0, \quad P_2(x) = 0, \quad \ldots, \quad P_m(x) = 0\,. \tag{6}$$

We present a randomized self-reduction that reduces (6) to multiple similar systems of degree at most d but over $\ell = \lambda n$ variables for a constant $0 < \lambda < 1$. Optimizing λ and applying the reduction recursively yields our main result.

3.1 Parity-counting as summation over the domain

We start with the elementary observation that determining the parity of the number of solutions to (6) amounts to computing the sum

$$I_F = \sum_{x\in\{0,1\}^n} F(x) \tag{7}$$

of the polynomial function

$$F(x) = (1 + P_1(x))(1 + P_2(x)) \cdots (1 + P_m(x))\,. \tag{8}$$

Indeed, for $x \in \{0,1\}^n$ we have $F(x) = 1$ if and only if x is a solution to (6), and otherwise $F(x) = 0$. For comparison, Lokshtanov et al. [9] used

$$J_F = \bigvee_{x \in \{0,1\}^{n-n'}} \left(\sum_{y \in \{0,1\}^{n'}} s_y \cdot F(x,y) \right) \tag{9}$$

with s_y independently and uniformly sampled scalars from $\{0,1\}$, with the observation that J_F is one with probability at least $1/2$ if the original system has a solution, and is always zero if the original system has no solutions. In the following, we show how to obtain a faster algorithm by dealing with I_F instead.

We do not know how to quickly evaluate I_F directly, but we will take an indirect and randomized approach to perform the summation.

3.2 Approximate the summand F by a low-degree probabilistic polynomial

The main difficulty in directly working with the polynomial F of (8) is its degree, which could be dm in general. As in Lokshtanov et al. [9], we construct a *probabilistic* polynomial $\tilde{F}$ with the property that for $0 < \epsilon \leq 1$ and for all $x \in \{0,1\}^n$ we have

$$\Pr_{f \in \tilde{F}} (F(x) = f(x)) \geq 1 - \epsilon \,. \tag{10}$$

We use the following construction generally credited to Razborov [16] and Smolensky [17]. For $i = 1, 2, \ldots, \lceil \log_2 \epsilon^{-1} \rceil$ and $j = 1, 2, \ldots, m$, draw an independent uniform random value $\rho_{ij} \in \{0,1\}$, and construct the polynomials

$$R_i(x) = \sum_{j=1}^{m} \rho_{ij} \cdot P_j(x) \,. \tag{11}$$

Let us now study the polynomial

$$f(x) = (1 + R_1(x))(1 + R_2(x)) \cdots (1 + R_{\lceil \log_2 \epsilon^{-1} \rceil}(x)) \,. \tag{12}$$

We easily observe that (10) holds. Furthermore, since each of the polynomials R_i has degree at most d, the degree of f is at most $d\lceil \log_2 \epsilon^{-1} \rceil$, rather than the degree $\Omega(dm)$ of F.

3.3 Sum the parts of multiple independent approximations

Suppose we replace the summands $F(x)$ in the computation of $I_F = \sum_x F(x)$ with $f(x)$'s from (12). By doing so we have reduced the degrees of the summands, but we also introduced a difficulty in the process: the summands $f(x)$ may introduce errors in the computation of I_F. We resolve this issue by drawing a sample of $s = O(n)$ independent Razborov–Smolensky approximations $f_1, f_2, \ldots, f_s \in \tilde{F}$, and then sum each of these, *in parts*.

Let us define precisely what we mean. Suppose our summand is g. Let us view g as the set function $g : 2^{[n]} \to \{0,1\}$ defined over the set of subsets of $[n]$. Let $A, B \subseteq [n]$ be disjoint with $A \cup B = [n]$. Think of A and B as a partition of n variables (indexed by $[n]$) into two parts; a subset $X \subseteq A$ will be construed as a 0-1 assignment to the variables in A, and a subset $Z \subseteq B$ will be construed as a 0-1 assignment to the variables in B. We will compute (7) as

$$I_F = \sum_{Z \in 2^B} \sum_{X \in 2^A} F(X \cup Z).$$

This is similar to Lokshtanov et al. [9] with $A = [n']$ in (9), except we take the actual sum modulo 2 over 2^B assignments, instead of a disjunction over the assignments.

For every $Z \subseteq B$ (construed as a 0-1 assignment to the variables in B), define the function

$$g|_A^{Z\to B} : 2^A \to \{0,1\}$$

for all $X \subseteq A$ by

$$g|_A^{Z\to B}(X) = g(X \cup Z)\,.$$

That is, $g|_A^{Z\to B}$ is the *part of* g obtained from fixing the variables in B to the 0-1 assignment g by Z. Each part of g is a polynomial over the variables in A.

Summing g in parts now amounts to computing the sums of all parts

$$I_{g|_A^{Z\to B}} = \sum_{X\subseteq A} g(X \cup Z) \quad \text{for each} \quad Z \subseteq B\,.$$

Once we have the sums of all parts, we can easily compute the overall sum:

$$I_g = \sum_{X\subseteq[n]} g(X) = \sum_{Z\subseteq B} I_{g|_A^{Z\to B}}\,.$$

However, we will *not* sum up the parts' sums directly. Indeed, we are summing potentially erroneous approximations of the true summands, and obtaining the (full) sum of a potentially erroneous approximation is not what we want. What we want, with high probability, is the sum of the true summands.

3.4 Correct the sum of each part by "scoreboarding"

Recall that we proposed to work with a sample of $s \le O(n)$ independent polynomials $f_1, f_2, \ldots, f_s \in \tilde{F}$ that approximate the true summand F. Suppose we have summed each approximation, in parts, to obtain the summand of each part of each approximation. That is, for each $Z \subseteq B$ we have the *scoreboard* of s sums

$$I_{f_1|_A^{Z\to B}} = \sum_{X\subseteq A} f_1(X\cup Z), \quad I_{f_2|_A^{Z\to B}} = \sum_{X\subseteq A} f_2(X\cup Z), \quad \ldots, \quad I_{f_s|_A^{Z\to B}} = \sum_{X\subseteq A} f_s(X\cup Z).$$

Each of these s sums is $\{0,1\}$-valued. Assuming s is odd, we take the unique majority value across the scoreboard and set, for every $Z \subseteq B$,

$$\tilde{I}_Z = \text{Majority}\big(I_{f_1|_A^{Z\to B}}, I_{f_2|_A^{Z\to B}}, \ldots, I_{f_s|_A^{Z\to B}}\big) = \begin{cases} 1 & \text{if } \sum_{j=1}^s I_{f_j|_A^{Z\to B}} > \frac{s}{2}\,, \\ 0 & \text{if } \sum_{j=1}^s I_{f_j|_A^{Z\to B}} < \frac{s}{2}\,. \end{cases} \tag{13}$$

Consider now the true summand F and a sum of its part $I_{F|_A^{Z\to B}}$. We can control the probability of error $\Pr[\tilde{I}_Z \neq I_{F|_A^{Z\to B}}]$ as follows. First, set $\epsilon = 2^{-(|A|+2)}$ and use the union bound with (10) to conclude that, for all $Z \subseteq B$ and $j = 1, 2, \ldots, s$, we have

$$\Pr\big[I_{F|_A^{Z\to B}} = I_{f_j|_A^{Z\to B}}\big] \ge 1 - 2^{|A|}\cdot\epsilon \ge \frac{3}{4}\,. \tag{14}$$

Consequently, the approximate summands f_j are bounded in degree by at most

$$\Delta = \lceil \log_2 \epsilon^{-1} \rceil d = (|A| + 2)d\,. \tag{15}$$

Second, recalling that $f_1, f_2, \ldots, f_s$ are independent, we can use a standard Chernoff bound to control the error from scoreboarding. When T is a sum of independent identically distributed random variables, for all $0 \leq \delta \leq 1$ it holds that [12]

$$\Pr\big[T \leq (1-\delta)\mathbb{E}[T]\big] \leq \exp\big(-\tfrac{\delta^2 \mathbb{E}[T]}{2}\big)\,. \tag{16}$$

Take $T_Z = \sum_{j=1}^{s} I_{f_j|_A^{Z\to B}}$. From (14) we have

$$\begin{aligned} \mathbb{E}[T_Z \,|\, I_{F|_A^{Z\to B}} = 1] &\geq \tfrac{3}{4}s\,, \\ \mathbb{E}[s - T_Z \,|\, I_{F|_A^{Z\to B}} = 0] &\geq \tfrac{3}{4}s\,, \end{aligned} \tag{17}$$

Recalling that we assume s to be odd, from (16) and (17) with $\delta = 1/3$ we thus have

$$\begin{aligned} \Pr\big[T_Z > \tfrac{s}{2} \,\big|\, I_{F|_A^{Z\to B}} = 1\big] &\geq 1 - \exp\big(-\tfrac{s}{24}\big)\,, \\ \Pr\big[s - T_Z > \tfrac{s}{2} \,\big|\, I_{F|_A^{Z\to B}} = 0\big] &\geq 1 - \exp\big(-\tfrac{s}{24}\big)\,. \end{aligned} \tag{18}$$

Set $s = 48n + 1$ and use (18) in (13) to conclude that

$$\Pr\big[\tilde{I}_Z = I_{F|_A^{Z\to B}}\big] \geq 1 - 2^{-2n}\,.$$

Taking a union bound over all $Z \subseteq B$, we have

$$\Pr\big[I_F = \textstyle\sum_{Z\subseteq B} \tilde{I}_Z\big] \geq 1 - 2^{-n}\,.$$

That is, error-correction by scoreboarding enables us to recover the sum $I_F = \sum_x F(x)$ with only exponentially small error probability. All that now remains is to sum in parts.

3.5 Summing the parts of a low-degree polynomial

As before, we view the summand as a set function $f : 2^{[n]} \to \{0,1\}$ and assume that the underlying polynomial representing f has degree at most Δ. For each $Z \subseteq B$, we want to produce the sum $I_{f|_A^{Z\to B}} = \sum_{X\subseteq A} f(X \cup Z)$.

Our strategy for summation will rely on the fact that these sums are linearly dependent, and fast basis changes via fast zeta transforms will enable fast summation of parts.

To witness the linear dependence, let us put to use the fact that f is low-degree. Let $M_f : 2^{[n]} \to \{0,1\}$ be the representation of f in the monomial basis (M_f maps monomials to coefficients). For all $W \subseteq [n]$, we thus have

$$f(W) = \sum_{U\subseteq W} M_f(U)\,.$$

Now recall that f has degree at most Δ if and only if M_f vanishes on subsets of size greater than Δ. That is, the representation in the monomial basis is sparse; we seek to express our sums in this basis.

Toward this end, let us study summing a part from the perspective of the coefficients M_f rather than f. For each $Z \subseteq B$, we have

$$I_{f|_A^{Z\to B}} = \sum_{X\subseteq A} f(X \cup Z) = \sum_{X\subseteq A} \sum_{U\subseteq X\cup Z} M_f(U) = \sum_{Y\subseteq Z} M_f(A \cup Y)\,. \tag{19}$$

The last equality in (19) follows because *every monomial (viewed as a subset) not containing A will cancel modulo two*, because it contributes to the sum an even number of times. This

property of contributing monomials being known to contain A is the key difference from the approach of Lokshtanov et al. [9]; the property is lost if we take a disjunction (as in (9)) instead of a sum modulo 2 (as in (7)). It will yield a smaller upper bound on the number of monomials.

Let us now get some corollaries of (19). First, since only monomials that contain A contribute to the sums $I_{f|_A^{Z\to B}}$, knowledge of only these monomials is sufficient information to compute the sum $I_{f|_A^{Z\to B}}$ for each $Z \subseteq B$. Second, we know that M_f vanishes on all subsets of size greater than Δ. Since each monomial must contain A, we only have to consider subsets from B of size at most $\delta = \Delta - |A|$, compared to $\delta = \Delta$ used in Lokshtanov et al. [9].

These two corollaries yield the following three-step strategy for summing the parts:

(i) Compute $I_{f|_A^{B\to Z}} = \sum_{X\subseteq A} f(X \cup Z)$ for each set $Z \in \binom{B}{\downarrow\delta}$.
By (19), we thus have $\binom{|B|}{\downarrow\delta}$ equations for the $\binom{|B|}{\downarrow\delta}$ unknowns $M_f(A \cup Y)$, for $Y \in \binom{B}{\downarrow\delta}$.

(ii) Solve the equations for the values $M_f(A \cup Y)$ for $Y \in \binom{B}{\downarrow\delta}$ (the coefficients of f as a polynomial).

(iii) Use the solved values to produce the sum $I_{f|_A^{B\to Z}}$ for each $Z \subseteq B$.

Observe that the only actual summations are made in (i). The step (iii) produces the sums in batch from the values obtained in (ii). To solve the equations in (ii), we use the fast zeta transform over the sets in $\binom{B}{\downarrow\delta}$. For the step (iii), use the fast zeta transform over 2^B with the knowledge that $M_f(A \cup Y)$ vanishes in 2^B outside $Y \in \binom{B}{\downarrow\delta}$.

3.6 Summing a part reduces back to parity-counting

Let us now define in detail what it means to sum a part in step (i). First, let us parameterise the partition A, B of $[n]$. For $1 \le \ell \le n$, set

$$|A| = \ell \qquad \text{and} \qquad |B| = n - |A| = n - \ell\,.$$

By (15), we have

$$\lceil \log_2 \epsilon^{-1} \rceil = |A| + 2 = \ell + 2.$$

Thus our polynomials have degree $\Delta \le (\ell + 2)d$, and

$$\delta = \Delta - |A| = (|A| + 2)d - |A| = (d - 1)\ell + 2d\,.$$

Recall that the given input consists of the polynomials $P_1, P_2, \ldots, P_m$ in (6). Using the polynomials $P_1, P_2, \ldots, P_m$, the algorithm draws s samples, where each sample is an independent collection of Razborov–Smolensky polynomials $R_1, R_2, \ldots, R_{\ell+2}$ constructed using (11). (Recall the R_i's are simply random linear combinations of the P_j's.) Each collection forms one of the approximate summands $f_j = \prod_i (1 + R_i)$ of (12). However, in our algorithm these approximate summands f_j are never constructed in explicit form: in Lokshtanov et al. [9] they are constructed explicitly, which leads to a worse running time.

Rather, we observe that we can access a part $f_j|_A^{Z\to B}$ for $Z \in \binom{B}{\downarrow\delta}$ by making the substitution $Z \to B$ directly into the Razborov–Smolensky polynomials $R_1, R_2, \ldots, R_{\ell+2}$ that define f_j, without constructing f_j itself. In particular, after the substitution, the polynomials have variables $x_A = (x_j : j \in A)$. In notation, we construct by the substitution $Z \to B$ the polynomials

$$Q_1(x_A) = R_1|_A^{Z\to B}(x_A)\,, \quad Q_2(x_A) = R_2|_A^{Z\to B}(x_A)\,, \quad \ldots, \quad Q_{\ell+2}(x_A) = R_{\ell+2}|_A^{Z\to B}(x_A)\,.$$

Since the R_i's are just linear combinations of polynomials of degree at most d, these polynomials also have degree at most d, and are over $\ell = |A|$ variables. Thus, computing the sum $I_{f|_A^{Z\to B}}$ of the part $f|_A^{Z\to B}$ is exactly the task of summing over $x_A \in \{0,1\}^{|A|}$ the polynomial

$$f|_A^{Z\to B}(x_A) = (1 + Q_1(x_A))(1 + Q_2(x_A)) \cdots (1 + Q_{\ell+2}(x_A)) \,.$$

Recalling (8), this is exactly the task of determining the parity of the number of solutions $x_A \in \{0,1\}^{|A|}$ to the system of polynomial equations

$$Q_1(x_A) = 0 \,, \quad Q_2(x_A) = 0 \,, \quad \ldots, \quad Q_{\ell+2}(x_A) = 0 \,.$$

This completes our randomized reduction from parity-counting to itself: we have reduced parity counting for a system of degree-d polynomials in n variables to $\binom{|B|}{\downarrow\delta} = \binom{n-\ell}{\downarrow(d-1)\ell+2d}$ calls to parity counting a system of degree-d polynomials in ℓ variables.

To compare, in Lokshtanov et al. [9], such a self-reduction seems not to be possible when one uses (9) instead of (7). A full $O^*(2^{|A|})$ time summation was used in their paper.

3.7 Running time analysis

Let us now analyze the running time as a function of the number of variables n and the reduction parameter ℓ with $1 \le \ell \le n$. Let us write $T(n,m)$ for an upper bound for the worst-case running time when the input consists of at most m polynomials of degree at most d in at most n variables. Similarly, let us write $S(n,m)$ for an upper bound for the worst-case space complexity.

Let us now recall the structure of the self-reduction, then analyze its recursive application. The reduction first builds the $s = 48n + 1$ approximate summands (via the constituent polynomials $R_1, R_2, \ldots, R_{\ell+2}$) and then works to complete $2^{|B|} = 2^{n-\ell}$ scoreboards, each recording the sum (over the integers to enable majority-voting) of summation of s parts. The summation of parts proceeds across the scoreboards, one entire approximate summand at a time using steps (i), (ii), and (iii). In step (i), we recursively perform summations for $\binom{|B|}{\downarrow\delta} = \binom{n-\ell}{\downarrow(d-1)\ell+2d}$ parts, each via the constituent polynomials $Q_1, Q_2, \ldots, Q_{\ell+2}$ of degree at most d over ℓ variables. In step (ii), we run the fast zeta transform over $\binom{B}{\downarrow\delta}$ to recover the monomials of the summand for all $A \cup Y$ with $Y \in \binom{B}{\downarrow\delta}$. In step (iii), we run the fast zeta transform over 2^B to recover all sums of parts for one approximate summand. This procedure is repeated for each of the approximate summands, updating the scoreboard as we go. Once the scoreboards are complete, the algorithm takes the majority vote in each scoreboard, and returns the parity of the majority votes.

The space complexity of the reduction can be upper-bounded via the recursive scoreboards and the representation of the polynomials in the monomial basis, with

$$S(n,m) \le S(\ell, \ell+2) + O\big(2^{n-\ell} \log s + m\tbinom{n}{\downarrow d}\big) \,. \tag{20}$$

Indeed, the zeta transforms at each level of recursion require only space $O(2^{n-\ell})$.

The time complexity of the reduction can be upper-bounded via the brute-force base case $T(n,m) \le O(2^n nm\binom{n}{\downarrow d})$ and the recurrence

$$T(n,m) \le s\tbinom{n-\ell}{\downarrow(d-1)\ell+2d} T(\ell,\ell+2) + O\big(s\big(\tbinom{n-\ell}{\downarrow(d-1)\ell+2d}\big)\big(n+(\ell+2)m\tbinom{n}{\downarrow d}\big)+2^{n-\ell}(n-\ell)\big)\big) \,. \tag{21}$$

The first term accounts for the parity self-reduction; the second term accounts for the fast zeta transforms.

Let us now assume that $d = 2, 3, \ldots$ is a fixed constant. We will run the reduction (21) recursively for $D = D(d)$ levels, and then switch to the brute-force base case. The parameter ℓ at each level is set by means of a constant $\lambda = \lambda(d)$ with $0 < \lambda < \frac{1}{2d-1}$ so that $\ell = \lfloor \lambda n \rfloor$ where n is the number of variables in the input to the level. Let

$$H(\rho) = -\rho \log_2 \rho - (1-\rho)\log_2(1-\rho)$$

be the binary entropy function and recall that we have $\binom{k}{\lfloor u \rfloor} \leq 2^{kH(u/k)}$ for all $1 \leq u \leq \frac{k}{2}$.

Since $\ell \leq \frac{n}{2d-1}$, the sums of binomial coefficients in (21) can be upper-bounded as follows:

$$\tbinom{n-\ell}{\downarrow(d-1)\ell+2d} \leq n^{2d+1}\tbinom{n-\ell}{(d-1)\ell} \leq n^{2d+2}2^{n(1-\lambda)H\left(\frac{(d-1)\lambda}{1-\lambda}\right)}.$$

Assuming that we run the recursion for $D = D(d)$ levels and then use brute force, we observe that there exists a constant $C = C(d) > 0$ such that we have

$$T(n,m) = O(mn^C(1 + 2^{\tau(1)n}))\,,$$

where $\tau(\lambda^k)$ is a parameter defined for $k = 0, 1, \ldots, D-1$ by

$$\tau(\lambda^k) = \lambda^k \max\bigl((1-\lambda)H\bigl(\tfrac{(d-1)\lambda}{1-\lambda}\bigr) + \tau(\lambda^{k+1}),\, 1-\lambda\bigr) \tag{22}$$

and

$$\tau(\lambda^D) = \lambda^D\,. \tag{23}$$

Recalling that $1 + \lambda + \lambda^2 + \ldots = \frac{1}{1-\lambda}$, and choosing a large enough D, we have that

$$\tau(1) \leq 1-\lambda \quad \text{whenever} \quad H\bigl(\tfrac{(d-1)\lambda}{1-\lambda}\bigr) < 1-\lambda\,.$$

Thus, for any $d \geq 2$ we can select $\lambda = 1/(2.7d)$ to obtain the running time $O^*\bigl(2^{(1-1/(2.7d))n}\bigr)$. For $d = 2$, we can select $\lambda = 0.196774680497$ to obtain the running time $O^*\bigl(2^{0.803225n}\bigr)$.

Abstract

We give two new quantum algorithms for solving semidefinite programs (SDPs) providing quantum speed-ups. We consider SDP instances with m constraint matrices, each of dimension n, rank at most r, and sparsity s. The first algorithm assumes an input model where one is given access to an oracle to the entries of the matrices at unit cost. We show that it has run time $\tilde{O}(s^2(\sqrt{m}\epsilon^{-10} + \sqrt{n}\epsilon^{-12}))$, with ϵ the error of the solution. This gives an optimal dependence in terms of m, n and quadratic improvement over previous quantum algorithms (when $m \approx n$). The second algorithm assumes a fully quantum input model in which the input matrices are given as quantum states. We show that its run time is $\tilde{O}(\sqrt{m} + \mathrm{poly}(r)) \cdot \mathrm{poly}(\log m, \log n, B, \epsilon^{-1})$, with B an upper bound on the trace-norm of all input matrices. In particular the complexity depends only polylogarithmically in n and polynomially in r.

We apply the second SDP solver to learn a good description of a quantum state with respect to a set of measurements: Given m measurements and a supply of copies of an unknown state ρ with rank at most r, we show we can find in time $\sqrt{m} \cdot \mathrm{poly}(\log m, \log n, r, \epsilon^{-1})$ a description of the state as a quantum circuit preparing a density matrix which has the same expectation values as ρ on the m measurements, up to error ϵ. The density matrix obtained is an approximation to the maximum entropy state consistent with the measurement data considered in Jaynes' principle from statistical mechanics.

As in previous work, we obtain our algorithm by "quantizing" classical SDP solvers based on the matrix multiplicative weight update method. One of our main technical contributions is a quantum Gibbs state sampler for low-rank Hamiltonians, given quantum states encoding these Hamiltonians, with a poly-logarithmic dependence on its dimension, which is based on ideas developed in quantum principal component analysis. We also develop a "fast" quantum OR lemma with a quadratic improvement in gate complexity over the construction of Harrow et al. [14]. We believe both techniques might be of independent interest.

1 Introduction

Motivation. Semidefinite programming has been a central topic in the study of mathematical optimization, theoretical computer science, and operations research in the last decades. It has become an important tool for designing efficient optimization and approximation algorithms. The power of semidefinite programs (SDPs) lies in their generality (that extends the better-known linear programs (LPs)) and the fact that they admit polynomial-time solvers.

It is natural to ask whether quantum computers can have advantage in solving this important optimization problem. In Ref. [9], Brandão and Svore provided an affirmative answer, giving a quantum algorithm with worst-case running time $\tilde{O}(\sqrt{mn}s^2(R\tilde{R}/\varepsilon)^{32})$ [1], where n and s are the dimension and row sparsity of the input matrices, respectively, m the number of constraints, ϵ the accuracy of the solution, and $R, \tilde{R}$ upper bounds on the norm of the optimal primal and dual solutions. This is a *polynomial* speed-up in m and n comparing to the two state-of-the-art classical SDP-solvers [20, 7] (with complexity $\tilde{O}(m(m^2 + n^\omega + mns)\operatorname{poly}\log(R/\epsilon))$ [20], where ω is the exponent of matrix multiplication, and $\tilde{O}(mns(R\tilde{R}/\varepsilon)^4 + ns\left(R\tilde{R}/\varepsilon\right)^7)$ [7]), and beating the classical lower bound of $\Omega(m+n)$ [9]. The follow-up work by van Apeldoorn et al. [5] improved the running time giving a quantum SDP solver with complexity $\tilde{O}(\sqrt{mn}s^2(R\tilde{R}/\epsilon)^8)$. In terms of limitations, Ref. [9] proved a quantum lower bound $\Omega(\sqrt{m}+\sqrt{n})$ when $R, \tilde{R}, s, \epsilon$ are constants; stronger lower bounds can be proven if R and/or $\tilde{R}$ scale with m and n [5]. We note all these results are shown in an input model in which there is an oracle for the entry of each of the input matrices (see Oracle 1.1 below for a formal definition).

In this paper, we investigate quantum algorithms for SDPs (i.e., quantum SDP solvers) further in the following two perspectives: (1) the best dependence of parameters, especially the dimension n and the number of constraints m; (2) whether there is any reasonable alternative input model for quantum SDP solvers and what is its associated complexity. To that end, let us first formulate the precise SDP instance in our discussion.

The SDP approximate feasibility problem. We will work with the SDP approximate feasibility problem formulated as follows: Given an $\epsilon > 0$, m real numbers $a_1, \ldots, a_m \in \mathbb{R}$, and Hermitian $n \times n$ matrices $A_1, \ldots, A_m$ where $-I \preceq A_i \preceq I, \forall\, j \in [m]$, define the convex

[1] $\tilde{O}$ hides factors that are polynomial in $\log m$ and $\log n$.

region $\mathcal{S}_\epsilon$ as all X such that

$$\begin{aligned} \mathrm{Tr}(A_i X) &\leq a_i + \epsilon \quad \forall\, i \in [m]; \\ X &\succeq 0;\ \mathrm{Tr}[X] = 1. \end{aligned} \tag{1.1}$$

For approximate feasibility testing, it is required that either (1) If $\mathcal{S}_0 = \emptyset$, output fail; or (2) If $\mathcal{S}_\epsilon \neq \emptyset$, output an $X \in \mathcal{S}_\epsilon$. Throughout the paper, we denote by n the the dimension of the matrices, m the number of constraints, and ϵ the (additive) error of the solution. For Hermitian matrices A and B, we denote $A \preceq B$ if $B - A$ is positive semidefinite, and $A \succeq B$ if $A - B$ is positive semidefinite. We denote I_n to be the $n \times n$ identity matrix.

There are a few reasons that guarantee our choice of approximate SDP feasibility problem do not lose generality: (1) first, it is a routine[2] to reduce general optimization SDP problems to the feasibility problem; (2) second, for general feasible solution $X \succeq 0$ with width bound $\mathrm{Tr}(X) \leq R$, there is a procedure[3] to derive an equivalent SDP feasibility instance with variable $\hat{X}$ s.t. $\mathrm{Tr}(\hat{X}) = 1$. Note, however, the change of ϵ to ϵ/R in this conversion. Also note one can use an approximate feasibility solver to find a strictly feasible solution, by changing ϵ to $\epsilon/R\tilde{R}$ (see Lemma 18 of Ref. [9]). The benefit of our choice of (1.1) is its simplicity in presentation, which provides a better intuition behind our techniques and an easy adoption of our SDP solver in learning quantum states. In contrast to Ref. [5], we do not need to formulate the dual program of Eq. (1.1) since our techniques do not rely on it. We will elaborate more on these points in Section 1.4.

1.1 Quantum SDP solvers with optimal dependence on m and n

Existing quantum SDP solvers [9, 5] have close-to-optimal dependence on some key parameters but poor dependence on others. Seeking optimal parameter dependence has been an important problem in the development of classical SDP solvers and has inspired many new techniques. It is thus well motivated to investigate the optimal parameter dependence in the quantum setting. Our first contribution is the construction of a quantum SDP solver with the optimal dependence on m and n in the (plain) input model as used by [9, 5], given as follows:

▶ **Oracle 1.1** (Plain model for A_j)**.** *A quantum oracle, denoted $\mathcal{P}_A$, such that given the indices $j \in [m]$, $k \in [n]$ and $l \in [s]$, computes a bit string representation of the l-th non-zero element of the k-th row of A_j, i.e. the oracle performs the following map:*

$$|j, k, l, z\rangle \to |j, k, l, z \oplus (A_j)_{k f_{jk}(l)}\rangle, \tag{1.2}$$

with $f_{jk} : [r] \to [N]$ a function (parametrized by the matrix index j and the row index k) which given $l \in [s]$ computes the column index of the l-th nonzero entry.

Before we move on to our main result, we will define two primitives which will appear in our quantum SDP solvers. Our main result will also be written in terms of the cost for each primitive.

---

[2] To see why this is the case, for any general SDP problem, one can guess a candidate value (e.g., c_0) for the objective function (e.g., $\mathrm{Tr}(CX)$ and assume one wants to maximize $\mathrm{Tr}(CX)$) and convert it into a constraint (e.g., $\mathrm{Tr}(CX) \geq c_0$). Hence one ends up with a feasibility problem and the candidate value c_0 can then be found via binary search with $O(\log(1/\epsilon))$ overhead when $\mathrm{Tr}(CX) \in [-1, 1]$.

[3] The procedure goes as follows: (a) scale down every constraint by a factor R and let $X' = X/R$ (thus $\mathrm{Tr}(X') \leq 1$) (b) let $\hat{X} = \mathrm{diag}\{X, w\}$ be a block-diagonal matrix with X in the upper-left corner and a scaler w in the bottom-right corner. It is easy to see that $\mathrm{Tr}(\hat{X}) = 1 \iff \mathrm{Tr}(X) \leq 1$.

▶ **Definition 1** (trace estimation). *Assume that we have an s-sparse $n \times n$ Hermitian matrix H with $\|H\| \leq \Gamma$ and a density matrix ρ. Then we define $\mathcal{S}_{\mathrm{Tr}}(s, \Gamma, \epsilon)$ and $\mathcal{T}_{\mathrm{Tr}}(s, \Gamma, \epsilon)$ as the number of copies of ρ and the time complexity (in terms of oracle call and number of gates) of using the plain model (Oracle 1.1) for H, respectively, such that one can compute $\mathrm{Tr}[H\rho]$ with additive error ϵ with success probability at least $2/3$.*

▶ **Definition 2** (Gibbs sampling). *Assume that we have an s-sparse $n \times n$ Hermitian matrix H with $\|H\| \leq \Gamma$. Then we define $\mathcal{T}_{Gibbs}(s, \Gamma, \epsilon)$ as the complexity of preparing the Gibbs state $\frac{e^{-H}}{\mathrm{Tr}[e^{-H}]}$ with additive error ϵ using the plain model (Oracle 1.1) for H.*

Our main result is as follows.

▶ **Theorem 3.** *In the plain input model (Oracle 1.1), for any $0 < \epsilon < 1$, there is a quantum SDP solver for the feasibility problem (1.1) using $\frac{s}{\epsilon^4}\tilde{O}\big(\mathcal{S}_{\mathrm{Tr}}\big(\frac{s}{\epsilon^2}, \frac{1}{\epsilon}, \epsilon\big)\mathcal{T}_{Gibbs}\big(\frac{s}{\epsilon^2}, \frac{1}{\epsilon}, \epsilon\big) + \sqrt{m}\mathcal{T}_{\mathrm{Tr}}\big(\frac{s}{\epsilon^2}, \frac{1}{\epsilon}, \epsilon\big)\big)$ quantum gates and queries to Oracle 1.1, where s is the sparsity of $A_j, j \in [m]$.*

When combined with specific instantiation of these primitives (i.e., in our case, we directly make use of results on $\mathcal{S}_{\mathrm{Tr}}(s, \Gamma, \epsilon)$ and $\mathcal{T}_{\mathrm{Tr}}(s, \Gamma, \epsilon)$ from Ref. [9], and results on $\mathcal{T}_{\mathrm{Gibbs}}(s, \Gamma, \epsilon)$ from Ref. [24]), we end up with the following concrete parameters:

▶ **Corollary 4.** *In the plain input model (Oracle 1.1), for any $0 < \epsilon < 1$, there is a quantum SDP solver for the feasibility problem (1.1) using $\tilde{O}(s^2(\frac{\sqrt{m}}{\epsilon^{10}} + \frac{\sqrt{n}}{\epsilon^{12}}))$ quantum gates and queries to Oracle 1.1, where s is the sparsity of $A_j, j \in [m]$.*

Comparing to prior art, our main contribution is to decouple the dependence on m and n, which used to be $O(\sqrt{mn})$ and now becomes $O(\sqrt{m} + \sqrt{n})$. Note that the $(\sqrt{m} + \sqrt{n})$ dependence is optimal due to the quantum lower bound proven in Ref. [9].

▶ Remark 1.5. Even though our result achieves the optimal dependence on m and n, it is nontrivial to obtain quantum speed-ups by directly applying our quantum SDP solvers to SDP instances from classical combinatorial problems. The major obstacle is the poly-dependence on $1/\epsilon$, whereas, for interesting SDP instances such as Max-Cut, $1/\epsilon$ is linear in n. In fact, the general framework of the classical Arora-Kale SDP solver also suffers from the poly-dependence on $1/\epsilon$ and cannot be applied directly either. Instead, one needs to specialize the design of SDP solvers for each instance to achieve better time complexity.

Extending this idea to quantum seems challenging. One difficulty is that known classical approaches require explicit information of intermediate states, which requires $\Omega(n)$ time and space even to store. It is not clear how one can directly adapt classical approaches on intermediate states when stored as amplitudes in quantum states, which is the case for our current SDP solvers. It seems to us that a resolution of the problem might require an independent tool beyond the scope of this paper. We view this as an important direction for future work.

However, our quantum SDP solvers are sufficient for instances with mild $1/\epsilon$, which are natural in the context of quantum information, such as learnability of the quantum state problem (elaborated in Section 1.5) as well as examples in [4]. For those cases, we do establish a quantum speed-up as any classical algorithm needs at least linear time in n and/or m.

1.2 Quantum SDP solvers with quantum inputs

Given the optimality of the algorithm presented before (in terms of m and n), a natural question is to ask about the existence of alternative input models, *which can be justified for specific applications, and at the same time allows more efficient quantum SDP solvers.* This

is certainly a challenging question, but we can get inspiration from the application of SDPs in quantum complexity theory (e.g., Refs. [16, 12]) and quantum information (e.g., Refs. [1, 2]). In these settings, input matrices of SDP instances, with dimension 2^ℓ, are typically quantum states and/or measurements generated by poly(ℓ)-size circuits on ℓ qubits. For the sake of these applications, it might be reasonable to equip quantum SDP solvers with the ability to leverage these circuit information, rather than merely allowing access to the entries of the input matrices.

In this paper, we propose a *truly* quantum input model in which we can construct quantum SDP solvers with running time only *poly-logarithmic* in the dimension. We note that such proposal was mentioned in an earlier version of Ref. [9], whose precise mathematical form and construction of quantum SDP solvers were unfortunately incorrect, and later removed. Note that since we consider a non-standard input model in this section, our results are incomparable to those in the plain input model. We argue for the relevance of our quantum input model, by considering an applications of the framework to the problem of learning quantum states in Section 1.5.

Quantum input model. Consider a specific setting in which we are given decompositions of each A_j: $A_j = A_j^+ - A_j^-$, where $A_j^+, A_j^- \succeq 0$. (For instance, a natural choice is to let A_j^+ (resp. A_j^-) be the positive (resp. negative) part of A.)

▶ **Oracle 1.2** (Oracle for traces of A_j)**.** *A quantum oracle (unitary), denoted O_{Tr} (and its inverse $O_{\mathrm{Tr}}^\dagger$), such that for any $j \in [m]$,*

$$O_{\mathrm{Tr}}|j\rangle|0\rangle|0\rangle = |j\rangle|\operatorname{Tr}[A_j^+]\rangle|\operatorname{Tr}[A_j^-]\rangle, \tag{1.3}$$

where the real values $\operatorname{Tr}[A_j^+]$ and $\operatorname{Tr}[A_j^-]$ are encoded into their binary representations.

▶ **Oracle 1.3** (Oracle for preparing A_j)**.** *A quantum oracle (unitary), denoted O (and its inverse $O^\dagger$), which acts on $\mathbb{C}^m \otimes (\mathbb{C}^n \otimes \mathbb{C}^n) \otimes (\mathbb{C}^n \otimes \mathbb{C}^n)$ such that for any $j \in [m]$,*

$$O|j\rangle|0\rangle|0\rangle = |j\rangle|\psi_j^+\rangle|\psi_j^-\rangle, \tag{1.4}$$

where $|\psi_j^+\rangle, |\psi_j^-\rangle \in \mathbb{C}^n \otimes \mathbb{C}^n$ are any purifications of $\frac{A_j^+}{\operatorname{Tr}[A_j^+]}, \frac{A_j^-}{\operatorname{Tr}[A_j^-]}$, respectively.

▶ **Oracle 1.4** (Oracle for a_j)**.** *A quantum oracle (unitary), denoted O_a (and its inverse $O_a^\dagger$), such that for any $j \in [m]$,*

$$O_a|j\rangle|0\rangle = |j\rangle|a_j\rangle, \tag{1.5}$$

where the real value a_j is encoded into its binary representation.

Throughout the paper, let us assume that A_j has rank at most r for all $j \in [m]$ and $\operatorname{Tr}[A_j^+] + \operatorname{Tr}[A_j^-] \leq B$. The parameter B is therefore an upper bound to the trace-norm of all input matrices which we assume is given as an input of the problem. Similar to the plain input model, we will define the same two primitives and their associated costs in the quantum input model.

▶ **Definition 6** (trace estimation)**.** *We define $\mathcal{S}_{\mathrm{Tr}}(B, \epsilon)$ and $\mathcal{T}_{\mathrm{Tr}}(B, \epsilon)$ as the sample complexity of a state $\rho \in \mathbb{C}^{n\times n}$ and the gate complexity of using the quantum input oracles (Oracle 1.2, Oracle 1.3, Oracle 1.4), respectively, for the fastest quantum algorithm that distinguishes with success probability at least $1 - O(1/m)$ whether for a fixed $j \in [m]$, $\operatorname{Tr}(A_j\rho) > a_j + \epsilon$ or $\operatorname{Tr}(A_j\rho) \leq a_j$.*

▶ **Definition 7** (Gibbs sampling). *Assume that $K = K^+ - K^-$, where $K^\pm = \sum_{j\in S} c_j A_j^\pm$, $c_j > 0$, $S \subseteq [m]$ and $|S| \leq \Phi$, and that K^+, K^- have rank at most r_K. Moreover, assume that $\mathrm{Tr}(K^+) + \mathrm{Tr}(K^-) \leq B_K$ for some B_K. Then we define $\mathcal{T}_{Gibbs}(r_K, \Phi, B_K, \epsilon)$ as the gate complexity of preparing the Gibbs state $\rho_G = \exp(-K)/\mathrm{Tr}(\exp(-K))$ to ϵ precision in trace distance using Oracle 1.2, Oracle 1.3, and Oracle 1.4.*

Our main result in the quantum input model is as follows.

▶ **Theorem 8.** *For any $\epsilon > 0$, there is a quantum algorithm for the approximate feasibility of the SDP using at most $\frac{1}{\epsilon^2}\tilde{O}\big(\mathcal{S}_{\mathrm{Tr}}(B,\epsilon)\mathcal{T}_{Gibbs}\big(\frac{r}{\epsilon^2}, \frac{1}{\epsilon^2}, \frac{B}{\epsilon}, \epsilon\big) + \sqrt{m}\mathcal{T}_{\mathrm{Tr}}(B,\epsilon)\big)$ quantum gates and queries to Oracle 1.2, Oracle 1.3, and Oracle 1.4.*

In contrast to the plain model setting, the quantum input model is a completely new setting so that we have to construct these two primitive by ourselves. In particular, we give a construction of trace estimation with $\mathcal{S}_{\mathrm{Tr}}(B,\epsilon) = \mathcal{T}_{\mathrm{Tr}}(B,\epsilon) = O(B^2 \log m/\epsilon^2)$ and a construction of Gibbs sampling $\mathcal{T}_{\mathrm{Gibbs}}(r_K, \Phi, B_K, \epsilon) = O(\Phi \cdot \mathrm{poly}(\log n, r_K, B_K, \epsilon^{-1}))$[4]. As a result,

▶ **Corollary 9.** *For any $\epsilon > 0$, there is a quantum algorithm for the feasibility of the SDP using at most $(\sqrt{m} + \mathrm{poly}(r)) \cdot \mathrm{poly}(\log m, \log n, B, \epsilon^{-1})$ quantum gates and queries to Oracle 1.2, Oracle 1.3, and Oracle 1.4.*

We also show the square-root dependence on m is also optimal by establishing the following result:

▶ **Theorem 10** (lower bound on Corollary 9). *There exists an SDP feasibility testing problem such that $B, r, \epsilon = \Theta(1)$, and solving the problem requires $\Omega(\sqrt{m})$ calls to Oracle 1.2, Oracle 1.3, and Oracle 1.4.*

Comparison between the plain model and the quantum input model. In the quantum input model (Oracle 1.2, Oracle 1.3, and Oracle 1.4), our quantum SDP solver has a *poly-logarithmic* dependence on n (but polynomial in r) and a *square-root* dependence on m, while in the plain input model (Oracle 1.1), the dependence on n needs to be $\Omega(\sqrt{n})$ [9]. It is also worth mentioning that our quantum SDP solver in Corollary 9 does *not* assume the *sparsity* of A_i's, which are crucial for the quantum SDP solvers with the plain model (such as Corollary 4 and Refs. [9, 5]). This is because the quantum input models provide an alternative way to address the technical difficulty that was resolved by the sparsity condition (namely efficient algorithms for Hamiltonian evolution associated with the input matrices of the SDP).

Comparison between quantum and classical input models. The poly-logarithmic dependence on n in Corollary 9 is intriguing and suggests that quantum computers might offer exponential speed-ups for some SDP instances. However one has to be cautious as the input model we consider is inherently quantum, so it is incomparable to classical SDP solvers. As suggested to us by Aram Harrow (personal communication), we could consider a classical setting in which we get as input all inner products between all eigenvectors of the input matrices. Then in that case one could solve the problem classically in time $\mathrm{poly}(r, m, 1/\epsilon)$ (essentially using Jaynes' principle which will be discussed in Section 1.5 to reduce the problem

[4] The construction details are given in Lemma 10 and 12 in the full version of our paper [8].

to a SDP of dimension poly(r)). We have not formalized this approach, and there seems to be some technical problems doing so when the input matrices have close-by eigenvalues. However Harrow's observation shows the importance of justifying the input model in terms of natural applications to argue for the relevance of the run time obtained. We present one application of it in Section 1.5; more applications are given in Ref. [4].

Furthermore, several quantum-inspired classical algorithms were recently proposed originated from Tang [25]. Such classical algorithms assume the following sampling access:

▶ **Definition 11** (Sampling access). *Let $A \in \mathbb{C}^{n\times n}$ be a matrix. We say that we have the* sampling access *to A if we can*

1. *sample a row index $i \in [n]$ of A where the probability of row i being chosen is $\frac{\|A_{i\cdot}\|^2}{\|A\|_F^2}$, and*[5]
2. *for all $i \in [n]$, sample an index $j \in [n]$ where the probability of j being chosen is $\frac{|A_{ij}|^2}{\|A_{i\cdot}\|^2}$*

with time and query complexity $O(\mathrm{poly}(\log n))$ for each sampling.

In particular, we notice that Ref. [10] recently gave a classical SDP solver for (1.1) with complexity $O(m\cdot\mathrm{poly}(\log n, r, \epsilon^{-1}))$, given the above sampling access to $A_1, \ldots, A_m$. We point out that this result is incomparable to Corollary 9 because the sampling access (Definition 11) and our quantum state model (Oracle 1.2, Oracle 1.3, and Oracle 1.4) are incomparable. Nevertheless, it reminds us that under various input models, the speedup of quantum SDP solvers (compared to their classical counterparts) can also vary.

1.3 Related works on quantum SDP solvers

Previous quantum SDP solvers [9, 5] focus on the plain input model. A major contribution of ours is to improve the dependence $O(\sqrt{mn})$ to $O(\sqrt{m}+\sqrt{n})$ (ignoring dependence on other parameters) which is optimal given the lower bound $\Omega(\sqrt{m}+\sqrt{n})$ in [9]. To that end, we have also made a few technical contributions, including bringing in a new SDP solving framework and a fast version of quantum OR lemma, which will be elaborated in Section 1.4.

The quantum input model was briefly mentioned in an earlier version of [9]. The construction of quantum SDP solvers under the quantum input model therein was unfortunately incorrect. We provide the first rigorous mathematical formulation of the quantum input model and its justification in the context of learning quantum states (see Section 1.5). We also provide a construction of quantum SDP solvers in this model with a rigorous analysis. Moreover, we construct the first Gibbs state sampler with quantum inputs.

Subsequent to a previous version of this paper, an independent interesting result by van Apeldoorn and Gilyén [4] has improved the complexity of trace-estimation and Gibbs sampling. After a personal communication [26] introducing our fast version of the quantum OR lemma, the authors of Ref. [4] observed independently that the application of the quantum OR lemma [14] can be applied to decouple the dependence of m and n. As a result, Ref. [4] improved the complexity of Corollary 4 to $\tilde{O}(s(\frac{\sqrt{m}}{\epsilon^4}+\frac{\sqrt{n}}{\epsilon^5}))$ in the quantum operator model, a stronger input model than the plain one proposed by Ref. [4]. Using novel techniques, it also has improved the complexity of Corollary 9 to $\tilde{O}(\frac{B\sqrt{m}}{\epsilon^4}+\frac{B^{3.5}}{\epsilon^{7.5}})$ in the quantum input model. Note there is no explicit dependence on the rank r, which is an important advance (though it can be argued that rank r is implicitly included in the parameter B).

[5] Here $\|A\|_F$ is the Frobenius norm of A and $\|A_{i\cdot}\|$ is the ℓ_2 norm of the i^{th} row of A.

1.4 Techniques

At a high level, and in similarity to Refs. [9, 5], our quantum SDP solver can be seen as a "quantized" version of classical SDP solvers based on the matrix multiplicative weight update (MMWU) method [6]. In particular, we will leverage quantum Gibbs samplers as the main source of quantum speed-ups. In Refs. [9, 5], quantum Gibbs samplers with quadratic speed-ups (e.g., [24, 11]) have been exploited to replace the classical Gibbs state calculation step in [6]. Because the number of iterations in MMWU is poly-logarithmic in terms of the input size, the use of quantum Gibbs samplers, together with a few other tricks, leads to the overall quadratic quantum speed-up.

However, there are a few key differences (our major technical contributions) which are essential for our improvements.

Zero-sum game approach for MMW. Our quantum SDP solvers do not follow the primal-dual approach in Arora-Kale's SDP solver [7] which is the classical counterpart of previous quantum SDP solvers [9, 5]. Instead, we follow a zero-sum game framework to solve SDP feasibility problems, which is also based on the MMWU method. This framework has appeared in the classical literature (e.g., [15]) and has already been used to in semidefinite programs of relevance in quantum complexity theory (e.g., [27, 12, 19]). Let us briefly describe how the zero-sum game framework works when solving the SDP feasibility problem (1.1).

Assume there are two players. Player 1 wants to provide a feasible $X \in \mathcal{S}_\epsilon$. Player 2, on the other side, wants to find any violation of any proposed X, which can be formulated as follows.

▶ **Oracle 1.5** (Search for violation). *Inputs a density matrix X, outputs an $i \in [m]$ such that $\mathrm{Tr}(A_i X) > a_i + \epsilon$. If no such i exists, output "FEASIBLE".*

If the original problem is feasible, there exists a feasible point X_0 (provided by Player 1) such that there is no violation of X_0 that can be found by Player 2 (i.e., Oracle 1.5). This actually refers to an *equilibrium* point of the zero-sum game, which can also be approximated by the matrix multiplicative weight update method [6].

We argue that there are a few advantages of adopting this framework. One prominent example is its simplicity, which perhaps provides more intuition than the primal-dual approach. Together with our choice of the approximate feasibility problem, our presentation is simple both conceptually and technically (indeed, the simplicity of this framework has led to the development of the fast quantum OR lemma, another main technical contribution of ours.) Another example is that the zero-sum game approach does not make use of the dual program of SDPs and thus there is no dependence on the size of any dual solution. The game approach also admits an intuitive application of our SDP solvers to learning quantum states Section 1.5, which coincides with the approach adopted by [19] in a similar context.

One might wonder whether the simplicity of this framework will restrict the efficiency of SDP solvers. As indicated by the independent work of van Apeldoorn and Gilyén [4] which has achieved the same complexity of quantum SDP solvers following both the primal-dual approach and the zero-sum approach, we conclude that it is not the case at least up to our current knowledge.

Fast quantum OR lemma. We now outlines what is the main idea to find a solution to Oracle 1.5 efficiently. Roughly speaking, the idea behind previous quantum SDP solvers [9, 5] when applied to this context was to generate a new copy of a quantum state X for each time one would query the expectation value of one of the input matrices on it. The cost of

generating X (i.e., Gibbs sampling) is $O(\sqrt{n})$ (ignoring the dependence on other parameters) and one can use a Grover-search-like approach to test for m constraints with $O(\sqrt{m})$ iterations. The resultant cost is then $O(\sqrt{mn})$. Our key observation is to leverage the quantum OR lemma [14] to detect a single violation with only a single copy of X.

At a high level, given a single copy of any state ρ and m projections $\Lambda_1, \ldots, \Lambda_m$, the quantum OR lemma describes a procedure to distinguish between the case that $\exists\, i \in [m]$ s.t. $\mathrm{Tr}[\rho\Lambda_i]$ is very large, or $\frac{1}{m}\sum_{i=1}^{m} \mathrm{Tr}[\rho\Lambda_i]$ is very small. It is not hard to see that with some gap-amplification step and a search-to-decision reduction, the above procedure will output a violation i^* if any. By using quantum OR lemma, one can already decouple the cost of generating X and the number of iterations in violation-detection.

Unfortunately, Ref. [14] has only been focusing on the use of a single copy of ρ, while its gate complexity is $O(m)$ for m projections. To optimize the gate complexity, we develop the following fast implementation of the quantum OR lemma with gate complexity $O(\sqrt{m})$, using ideas from the fast amplification technique in [22]. Overall, this leads to a complexity of $O(\sqrt{m} + \sqrt{n})$.

▶ **Lemma 12.** *Let $\Lambda_1, \ldots, \Lambda_m$ be projections, and fix parameters $0 < \varepsilon \leq 1/2$ and $\varphi, \xi > 0$. Let ρ be a state such that either $\exists\, j \in [m]$ $\mathrm{Tr}[\rho\Lambda_j] \geq 1 - \varepsilon$, or $\frac{1}{m}\sum_{j=1}^{m} \mathrm{Tr}[\rho\Lambda_j] \leq \varphi$. There is a test using one copy of ρ and $O(\xi^{-1}\sqrt{m}(p + \mathrm{poly}(\log m)))$ operations such that: in the former case, accepts with probability at least $(1-\varepsilon)^2/4 - \xi$; in the latter case, accepts with probability at most $3\varphi m + \xi$.*

The dependence on m is also tight, as one can easily embed Grover search into this problem.

Gibbs sampler with quantum inputs. To work with the quantum input model, as our main technical contribution, we construct the first quantum Gibbs sampler of low-rank Hamiltonians when given Oracles 1.2 and 1.3:

▶ **Theorem 13.** *Assume the $n \times n$ matrix $K = K^+ - K^-$ and K^+, K^- are PSD matrices with rank at most r_K and $\mathrm{Tr}[K^+] + \mathrm{Tr}[K^-] \leq B$. Given quantum oracles that prepare copies of $\rho^+ = K^+/\mathrm{Tr}(K^+)$, $\rho^- = K^-/\mathrm{Tr}(K^-)$ and estimates of $\mathrm{Tr}(K^+)$, $\mathrm{Tr}(K^-)$, there is a quantum Gibbs sampler that prepares the Gibbs state $\rho_G = \exp(-K)/\mathrm{Tr}(\exp(-K))$ to precision ϵ in trace distance, using $\mathrm{poly}(\log n, r_K, B, \epsilon^{-1})$ quantum gates.*

Our quantum Gibbs sampler has a poly-logarithmic dependence on n and polynomial dependence on the maximum rank of the input matrices, while in the plain input model the dependence of n is $\Theta(\sqrt{n})$ [24, 11]. Our construction deviates significantly from [24, 11]. Because of the existence of copies of ρ^+ and ρ^-, we rely on efficient Hamiltonian simulation techniques developed in quantum principle component analysis (PCA) [21] and its follow-up work in [18]. As a result, we can also get rid of the sparsity assumption which is crucial for evoking results about efficient Hamiltonian simulation into the Gibbs sampling used in [24, 11].

1.5 Application: Efficient learnability of quantum states

Problem description. Given many realizations of an experiment producing a quantum state with density matrix ρ, learning an approximate description of ρ is a fundamental task in quantum information and experimental physics. It refers to *quantum state tomography*, which has been widely used to identify quantum systems. However, to tomograph an ℓ-qubit state ρ (with dimension $n = 2^\ell$) , the optimal procedure [23, 13] requires n^2 number of copies of ρ, which is impractical already for relatively small ℓ.

An interesting alternative is to find a description of the unknown quantum state ρ which approximates $\mathrm{Tr}[\rho E_i]$ up to error ϵ for a specific collection of POVM elements $E_1, \ldots, E_m$, where $I \succeq E_i \succeq 0$ and $E_i \in \mathbb{C}^{n\times n}, \forall i \in [m]$. This is an old problem, dating back at least to the work of Jaynes on statistical mechanics in the 50ies. Jaynes' principle [17] (also known as the principle of maximum entropy) gives a general form for the solution of the problem above. It shows that there is always a state of the form

$$\frac{\exp\left(\sum_i \lambda_i E_i\right)}{\mathrm{Tr}\left(\exp\left(\sum_i \lambda_i E_i\right)\right)}, \tag{1.6}$$

which has the same expectation values on the E_i's as the original state ρ, where the λ_i's are real numbers. In words, there is always a Gibbs state with Hamiltonian given by a linear combination of the E_i's which gives the same expectation values as the state described by ρ. Therefore one can solve the learning problem by finding the right λ_i's (or finding a quantum circuit creating the state in Eq. (1.6)).

Applying quantum SDP solvers. By formulating the learning problem in terms of the SDP feasibility problem (with each A_i replaced by E_i) where one looks for a trace unit PSD σ matching the measurement statistics, i.e., $\mathrm{Tr}(\sigma E_i) \approx \mathrm{Tr}(\rho E_i), \forall i \in [m]$, we observe that our quantum SDP solvers actually provides a solution to the learning problem with associated speed-ups on m and n.

In fact, our algorithm also outputs each of the λ_i's (one can show that $\mathrm{poly}(\log(mn))/\varepsilon^2$ non-zero of them suffices for a solution with error ε), as well as a circuit description of the Gibbs state in Eq. (1.6) achieving the same expectation values as ρ up to error ε. (This is mainly because the similarity between the matrix multiplicative update method and Jaynes' principle.) In this sense our result can be seen as an *algorithmically* version of Jaynes' principle. We note that a similar idea was adopted by [19] in learning quantum states, although for a totally different purpose (namely proving lower bounds on the size of SDP approximations to constraint satisfaction problems).

It is worthwhile noting that our quantum SDP solvers when applied in this context will output a description of the state ρ in the form of Eq. (1.6) which has the same expectation values as ρ on measurements $E_1, \ldots, E_m$ up to error ϵ. This is slightly different from directly outputting estimates of $\mathrm{Tr}(E_i\rho)$ for each $i \in [m]$, which by itself will take $\Omega(m)$ time.

Relevance of quantum input model. More importantly, we argue that our quantum input model is *relevant* in this setting for low-rank measurements E_i's. Since all $E_i \succeq 0$ by definition, we can consider the following (slightly simplified version of) oracles:

Oracle 1.2 for traces of E_i: A unitary O_{Tr} such that for any $i \in [m]$, $O_{\mathrm{Tr}}|i\rangle|0\rangle = |i\rangle|\,\mathrm{Tr}[E_i]\rangle$.

Oracle 1.3 for preparing E_i: A unitary O such that for any $i \in [m]$, $O|i\rangle\langle i| \otimes |0\rangle\langle 0|O^\dagger = |i\rangle\langle i| \otimes |\psi_i\rangle\langle\psi_i|$, where $|\psi_i\rangle\langle\psi_i|$ is any purification of $E_i/\,\mathrm{Tr}[E_i]$.

We now show how one can implement this oracle in the case where each E_i is a low rank projector and we have an efficient (with $\mathrm{poly}\log(n)$ many gates) implementation of the measurement. Let the rank of E_i's bounded by r and suppose the measurement operators E_i's are of the form

$$E_i = V_i P_i V_i^\dagger \tag{1.7}$$

for polynomial (in $\log(n)$) time circuits V_i, and projectors P_i of the form

$$P_i := \sum_{i=1}^{r_i} |i\rangle\langle i| \tag{1.8}$$

with $|i\rangle$ the computational basis and $r_i \leq r$. Then for Oracle 1.2 we just need to output the r_i's. Oracle 1.3 can be implemented efficiently (in time $r \operatorname{poly}\log(n)$) by first creating a maximally entangled state between the subspace spanned by P_i and a purification and applying V_i to one half of it. In more detail, consider the following purification of $E_i/\operatorname{Tr}(E_i)$:

$$|\psi_i\rangle := \frac{1}{\sqrt{r_i}} \sum_{i=1}^{r_i} (V_i \otimes I)|i,i\rangle \tag{1.9}$$

This can be constructed first by preparing the state $\frac{1}{\sqrt{r_i}} \sum_{i=1}^{r_i} |i,i\rangle$ in time r_i and then applying $V_i \otimes I$ to it (which can be done in time $\operatorname{poly}\log(n)$).

Efficient learning for low rank measurements. By applying our SDP solver in the quantum input model, we obtain that

▶ **Theorem 14.** *For any $\epsilon > 0$, there is a quantum procedure that outputs a description of the state ρ in the form of Eq. (1.6) (namely the λ_i's parameters) using at most $\operatorname{poly}(\log m, \log n, r, \epsilon^{-1})$ copies of ρ and at most $\sqrt{m} \cdot \operatorname{poly}(\log m, \log n, r, \epsilon^{-1})$ quantum gates and queries to Oracle 1.2 and Oracle 1.3.*

Let us briefly sketch how our SDP solver applies to this setting. Note first that we do not aim to estimate $\operatorname{Tr}(E_i\rho)$ for each $i \in [m]$, which helps us circumvent the $\Omega(m)$ lower bound. What we really want is to generate a state $\tilde{\rho}$ such that $\operatorname{Tr}(E_i\tilde{\rho}) \approx \operatorname{Tr}(E_i\rho)$ for each i. Our SDP solver will maintain and update a description of $\tilde{\rho}$ per iteration. In each iteration, given copies of $\tilde{\rho}$ and the actual unknown state ρ, we want to know whether $\operatorname{Tr}(E_i\tilde{\rho}) \approx \operatorname{Tr}(E_i\rho)$ $\forall i \in [m]$ or there is at least a violation i^*. To that end, we design for each i a projection for the following procedure: (1) perform multiple independent SWAP tests between $E_i/\operatorname{Tr}[E_i]$ (from Oracle 1.3) and ρ, $\tilde{\rho}$ respectively; (2) accept when the statistics of both SWAP tests (one with ρ, the other with $\tilde{\rho}$) are close. Hence, one can apply our fast quantum OR lemma on these projections to find such i^* if it exists.

Note that both the sample complexity and the gate complexity of the above procedure have a poly-log dependence on n (i.e., the dimension of the quantum state to learn).

Shadow tomography problem. In a sequence of works [1, 2], Aaronson asked whether one can predict information about a dimension-n quantum state with poly-log(n) many copies. In Ref. [1], he showed that a linear number of copies is sufficient to predict the outcomes of "most" measurements according to some (arbitrary) distribution over a class of measurements. Very recently, in Ref. [2], he referred the following problem as the "shadow tomography" problem: for any n-dimensional state ρ and two-outcome measurements $E_1, \ldots, E_m$, estimate $\operatorname{Tr}[\rho E_i]$ up to error ϵ, $\forall i \in [m]$. He has further designed a quantum procedure for the shadow tomography problem with $\tilde{O}(\ell \cdot \log^4 m/\epsilon^5)$ [6] copies of ρ.

[6] Here $\tilde{O}$ hides factors that are polynomial in $\log\log m$, $\log\log n$, and $\log 1/\epsilon$.

Noting that the shadow tomography problem is essentially the same problem considered by Jaynes [17], one can apply Jaynes' principle and its algorithmic version we discussed before. Although this can be used to give a version of the result of Ref. [2], Aaronson obtained his result [2] through a different route, based on a post-selection argument. A drawback of this approach is that its gate complexity is high, scaling linearly in m and as $n^{O(\log\log n)}$ (for fixed error).

Our Theorem 14 can be applied here to improve the time complexity. It gives a quantum procedure with a *square-root* dependence on m and $n^{O(1)}$ dependence on n for arbitrary E_i's.

When we assume r is small, say $r = O(\mathrm{poly}\log n)$, the gate complexity of the entire procedure becomes $\tilde{O}(\sqrt{m}\,\mathrm{poly}\log(n))$. This gives a class of measurement (namely any set of low-rank measurements which can be efficiently implemented) for which the learning problem is efficient both in the number of samples and the computational complexity. This solves an open problem proposed in Ref. [1]

Although we have not worked out an explicit bound of the sample complexity of our procedure, the authors of [4] followed our approach with more sophisticated techniques and obtained a sample complexity of $\tilde{O}(\ell \cdot \log^4 m/\epsilon^4)$, improving on the bound from [2]. We also note that very recently, Aaronson et al. claimed the same sample complexity (i.e., $\tilde{O}(\ell \cdot \log^4 m/\epsilon^4)$) in [3].

1.6 Overview of detailed results and proofs

In the full version of our paper [8], we formulate the SDP feasibility problem and prove the correctness of the basic framework in Appendix A. Our implementation of the fast quantum OR lemma is given in Appendix B. We describe our main results the constructions of quantum SDP solvers in the plain input model and the quantum input model in Appendix C and Appendix D, respectively. The application to learning quantum states is illustrated in Appendix E. In Appendix F (with full details in Appendix G) we demonstrate how to sample from the Gibbs state of low-rank Hamiltonians.

1.7 Open questions

This work leaves several natural open questions for future work. For example:

- Are there more examples of interesting SDPs where our form of input is meaningful? We have shown the example of learning quantum states. Intuitively, we are looking for SDP instances where the constraints are much "simpler" than the solution space. Is there any such example in the context of big data and/or machine learning?
- Our work has identified one setting where Gibbs sampling has a poly-log dependence on the dimension? Is there any other setting for the same purpose?
- For any reasonable quantum input setting, what is the effect of potential noises on quantum inputs in practice?
- Can we improve further on other parameters (e.g., the dependence on m and $1/\epsilon$)? In particular, is it possible to improve the error dependence to $\mathrm{poly}\log(1/\epsilon)$? This probably implies that we have to consider a quantum version of the interior point method.
- Are there other classes of measurements for which the quantum learning problem can solved in a computationally efficient way beyond the low-rank measurements we consider in this work? We note that most measurements of interest are not low rank (e.g. local measurements) and therefore the practical applicability of the present result is limited.

A Simple Protocol for Verifiable Delegation of Quantum Computation in One Round

Alex B. Grilo

QuSoft, Amsterdam, The Netherlands
abgrilo@gmail.com

Abstract

The importance of being able to verify quantum computation delegated to remote servers increases with recent development of quantum technologies. In some of the proposed protocols for this task, a client delegates her quantum computation to non-communicating servers in multiple rounds of communication. In this work, we propose the first protocol where the client delegates her quantum computation to two servers in one-round of communication. Another advantage of our protocol is that it is conceptually simpler than previous protocols. The parameters of our protocol also make it possible to prove security even if the servers are allowed to communicate, but respecting the plausible assumption that information cannot be propagated faster than speed of light, making it the first relativistic protocol for quantum computation.

1 Introduction

With the recent progress in the development of quantum technologies, large-scale quantum computers may be available in a not-so-distant future. Their costs and infrastructure requirements make it impractical for them to be ubiquitous, however clients could send their quantum computation to be performed remotely by a quantum server in the cloud [9], broadening the use of quantum advantage to solve computational problems (see Ref. [24] for such examples). For the clients, it is a major concern whether the quantum servers are performing the correct computation and quantum speedup is really being experienced.

In order to solve this problem, we aim a protocol for verifiable delegation of quantum computation where the client exchanges messages with the server, and, at the end of the protocol, either the client holds the output of her computation, or she detects that the server is defective. Ideally, the client is a classical computer and an honest server only needs polynomial-time quantum computation to answer correctly. Also, one would aim for *blind* protocols, in which the server does not learn the circuit delegated by the client. We

notice that verification protocols could also be used for validating devices that claim to have quantum computational power, but in this work we focus on the point of view of delegation of computation.

There are efficient protocols that can perform this task if the model is relaxed, for instance giving limited quantum power and quantum communication to the client [14, 3, 8, 25, 26]. There are also protocols where the security of the protocol only holds against bounded malicious servers [20].In this work, we focus on a third line of protocols, where a classical client delegates her computation to non-communicating quantum servers. Although the servers are supposed to share and maintain entangled states, which is feasible in principle but technologically challenging, these protocols are "plug-and-play" in the sense that the client only needs classical communication with the quantum servers.

Following standard notation in these protocols, we start calling the client and servers by verifier and provers, respectively. The security of such protocols relies on the so called self-testing of non-local games. We consider games where a verifier interacts with non-communicating provers by exchanging one round of classical communication and, based on the correlation of the provers' answers, the verifier decides to accept or reject. The goal of the provers is to maximize the acceptance probability in the game and they can share a common strategy before the game starts. A game is non-local [6] whenever there exists a quantum strategy for the provers that achieves acceptance probability strictly higher than any classical strategy, allowing the verifier to certify that the provers share some entanglement, if the classical bound is surpassed. Self-testing [21] goes one step further, proving that if the correlation of the provers' answers is close to the optimal quantum value, their strategy is close to the honest one.

Reichardt, Unger and Vazirani [32] used the ideas of self-testing to propose a verifiable delegation scheme where the verifier interleaves questions of non-local games and instructions for the computation, and from the point of view of the provers, these two types of questions are indistinguishable. In this case, the correctness of the quantum computation is inherited by the guarantees achieved in self-testing. Follow-up works [22, 15, 17, 13, 27, 10] have used the same approach in order to propose more efficient protocols (see Table 1 for summary of the properties of the different protocols).

In this work, we present the first one-round protocol for verifiable delegation of quantum computation. We notice that our protocol is conceptually simple, in contrast with previous protocols that have a rather complicated structure. We expect that its main ideas can be generalized to other contexts as MIP* protocols for iterated non-deterministic exponential time and even in new protocols for delegation of quantum computation. We also remark that the parameters of the protocol allow us to replace the unjustified assumption that the provers do not communicate to a more plausible assumption that the communication cannot be faster than speed of light.

Technically, we achieve our protocol by showing a non-local game for Local Hamiltonian problem, where the verifier plays against two provers in one round of classical communication. In this game, honest provers perform polynomial time quantum computation on copies of the groundstate of the Hamiltonian. This non-local game is of independent interest since it was an open question if a one-round game for Local Hamiltonian problem could be achieved with only two efficient provers. This non-local game can be used as a delegation protocol through the circuit-to-Hamiltonian construction.

1.1 Our contributions

New Non-local game for Local Hamiltonians. The main technical result of this work is presenting one-round two-prover game for the Local Hamiltonian problem, where honest provers only need quantum polynomial time computation, copies of the groundstate of the Hamiltonian and shared EPR pairs. More concretely, we show how to construct a game $G(H)$ based on a XZ Local Hamiltonian[1] H acting on n qubits and the upper and lower bounds on the maximum acceptance probability in $G(H)$ are tightly related to the groundstate energy of H. Then, based on $G(H)$, we devise a game $\tilde{G}(H)$ such that if the groundstate energy of H is low, then the maximum acceptance probability in $\tilde{G}(H)$ is at least $\frac{1}{2} + \Delta$, while if the groundstate energy is high, the acceptance probability in the game is at most $\frac{1}{2} - \Delta$. We describe now the main ideas of $G(H)$.

The game is composed by two tests: the Pauli Braiding Test (PBT) [27], where the verifier checks if the provers share the expected state and perform the indicated Pauli measurements, and the Energy Test (ET), where the verifier estimates the groundstate energy of H.

The same structure was used in a different way in the non-local game for LH proposed by Natarajan and Vidick [27] (and implicitly in Ji [18]). In their game, 7 provers are expected to share the encoding of the groundstate of H under a quantum error correcting code. In ET, the provers estimate the groundstate energy by jointly performing the measurements on the state, while PBT checks if the provers share a correct encoding of some state and if they perform the indicated measurements. The provers receive questions consisting in a Pauli tensor product observable and they answer with the one-bit outcome of the measurement on their share of the state. The need of 7 provers comes from the fact that the verifier must test if the provers are committed to an encoded state and use it in all of their measurements. It is an open problem if the number of provers can be decreased in this setup.

In this work, we are able to reduce the number of provers to 2 by making them asymmetric. In ET, one of the provers holds the groundstate of H and teleports it to the second prover, who is responsible for measuring it. In our case, PBT checks if the provers share EPR pairs

[1] An XZ Local Hamiltonian is a Hamiltonian that can be decomposed in sum of polynomially many terms that are tensor products of Paulis σ_X, σ_Z and σ_I

and if the second prover's measurements are correct. We remark that no test is needed for the state, since the chosen measurement is not known by the first prover. We notice that the size of the answers in our protocol is polynomial in n, since the verifier needs the teleportation results for every qubit (in order to hide the measurement). We leave as an open problem if the size of the answers can be reduced, hopefully achieving constant-size answers as in [27].

We state now the key ideas to upper bound the maximum acceptance probability of $G(H)$. The behavior of the second prover in ET can be verified thanks to PBT, since the two tests are indistinguishable to him. On the other hand, the first prover can perfectly distinguish PBT and ET, but he has no information about the measurement being performed. We show that his optimal strategy is to teleport the groundstate of H, but in this case the acceptance probability is high iff the groundstate energy is low.

Protocol for verifiable delegation of quantum computation. The task of verifiable delegation of quantum computation can be easily reduced to estimating the groundenergy of local Hamiltonians through the circuit-to-Hamiltonian construction [13, 27], which has been called *post-hoc verification of quantum computation*. In this construction, a quantum circuit Q is reduced to an instance H_Q of LH, such that H_Q has low groundstate energy iff Q accepts with high probability. Our non-local game for H_Q can be seen as a delegation protocol, where the verifier interacts with two non-communicating entangled provers in one-round of classical communication.

When compared to previous protocols, our result has some very nice properties. First, differently to previous results, our protocol is very simple to state, which could make it easier to be extended to other settings. Secondly, using standard techniques in relativistic cryptography, we can replace the unjustified assumption that the two servers do not communicate by the No Superluminal Signaling (NSS) principle: the security of the protocol would only rely that the two servers cannot communicate faster than the speed of light.

The circuit-to-Hamiltonian construction also causes an overhead on the resources needed by honest provers. Namely, in our protocol the provers need $\tilde{O}(ng^2)$ EPR pairs for delegating the computation of a quantum circuit acting on n qubits and composed by g gates, while other protocols need only $\tilde{O}(g)$ EPR pairs [10]. We leave as an open problem finding more efficient two-provers one-round protocol for delegating quantum computation.

We also leave as an open question if it is possible to create a one-round and blind verifiable delegation scheme for quantum computation, or proving that this is improbable, in the lines of Ref. [1].

Non-local games for QMA. In Complexity Theory, the connection between the PCP theorem [5, 4, 12] and multi-prover games [7] has had a lot of fruitful consequences, such as tighter inapproximability results [31]. Our protocol directly implies a one-round two-prover game for QMA but with polynomial-size questions and answers. We wonder if it could be used to prove the game version of the quantum PCP theorem with two prover [28].

Organization

In Section 2, we give the necessary preliminaries, including the definition of the Pauli Braiding Test. Then, in Section 3 we present our non-local game for local Hamiltonian problem.

2 Preliminaries

We assume basic knowledge on Quantum Computation topics and we refer the readers that are not familiar with them to Ref. [29].

2.1 Notation

We denote $[n]$ as the set $\{1, ..., n\}$. For a finite set S, we denote $x \in_R S$ as x being an uniformly random element from S. We assume that all Hilbert spaces are finite-dimensional. For a Hilbert space $\mathcal{H}$ and a linear operator M on $\mathcal{H}$, we denote $\lambda_0(M)$ as its smallest eigenvalue and $\|M\|$ as its maximum singular value. An n-qubit binary observable O is a Hermitian matrix with eigenvalues ± 1. We denote $\mathrm{Obs}(\mathcal{H})$ as the set of binary observables on the Hilbert space $\mathcal{H}$.

We will use the letters X, Z and I to denote questions in multi-prover games, the letters in the sans-serif font X, Z and I to denote unitaries and σ_X, σ_Z and σ_I to denote observables such that

$$\mathsf{I} = \sigma_I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \mathsf{X} = \sigma_X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \text{ and } \qquad \mathsf{Z} = \sigma_Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

2.2 Non-local games, Self-testing and the Pauli Braiding Test

We consider games where a verifier plays against two provers in the following way. The verifier sends questions to the provers according to a publicly known distribution and the provers answer back to the verifier. Based on the correlation of the answers, the verifier decides to accept or reject according to an acceptance rule that is also publicly known. The provers share a common strategy before the game starts in order to maximize the acceptance probability in the game, but they do not communicate afterwards.

For a game G, its classical value $\omega(G)$ is the maximum acceptance probability in the game if the provers share classical randomness, while the quantum value $\omega^*(G)$ is the maximum acceptance probability if they are allowed to follow a quantum strategy, i.e. share a quantum state and apply measurements on it. Non-local games (or Bell tests) [6] are such games where $\omega^*(G) > \omega(G)$ and they have played a major role in Quantum Information Theory, since they allow the verifier to certify that there exists some quantumness in the strategy of the provers, if the classical bound is surpassed.

Self-testing (also known as device-independent certification or rigidity theorems) of a non-local game G allows us to achieve stronger conclusions by showing that if the acceptance probability on G is close to $\omega^*(G)$, then the strategy of the provers is close to the ideal one, up to local isometries.

2.2.1 Magic Square game

The Magic Square or Mermin-Peres game [23, 30], is a two-prover non-local game where one of the provers is asked a row $r \in \{1, 2, 3\}$ and the second prover is asked with a column $c \in \{1, 2, 3\}$. The first and second prover answer with $a_1, a_2 \in \{\pm 1\}$ and $b_1, b_2 \in \{\pm 1\}$, respectively. By setting $a_3 = a_1 \oplus a_2$ and $b_3 = b_1 \oplus b_2$, the provers win the game if $a_c = b_r$.

If the provers follow a classical strategy, their maximum winning probability in this game is $\frac{8}{9}$, while we describe now a quantum strategy that makes them win with probability 1. The provers share two EPR pairs and, on question r (resp. c), the prover performs the measurements indicated in the first two columns (resp. rows) of row r (resp. column c) of the following table

IZ	ZI	ZZ
XI	IX	XX
XZ	ZX	YY

and answer with the outcomes of the measurements. The values a_3 and b_3 should correspond to the measurement of the EPR pairs according to the third column and row, respectively.

The self-testing theorem proved by Wu, Bancal and Scarani [33] states that if the provers win the Magic Square game with probability close to 1, they share two EPR pairs and the measurements performed are close to the honest Pauli measurements, up to local isometries.

▶ **Lemma 1.** *Suppose a strategy for the provers, using state $|\psi\rangle$ and observables W, succeeds with probability at least $1-\varepsilon$ in the Magic Square game. Then there exist isometries $V_D : \mathcal{H}_D \to (\mathbb{C}^2 \otimes \mathbb{C}^2)_{D'} \otimes \mathcal{H}_{\hat{D}}$, for $D \in \{A, B\}$ and a state $|\mathrm{AUX}\rangle_{\hat{A}\hat{B}} \in \mathcal{H}_{\hat{A}} \otimes \mathcal{H}_{\hat{B}}$ such that*

$$\left\|(V_A \otimes V_B)|\psi\rangle_{AB} - |\Phi_{00}\rangle^{\otimes 2}_{A'B'}|\mathrm{AUX}\rangle_{\hat{A}\hat{B}}\right\|^2 = O(\sqrt{\varepsilon}),$$

and for $W \in \{I, X, Z\}^2$,

$$\left\|\left(W - V_A^\dagger \sigma_W V_A\right) \otimes I_B|\psi\rangle\right\|^2 = O(\sqrt{\varepsilon}).$$

2.2.2 Pauli Braiding Test

The starting point of our work is the Pauli Braiding Test(PBT) [27], a non-local game that allows the verifier to certify that two provers share t EPR pairs and perform the indicated measurements, which consist of tensors of Pauli observables.

We define PBT in details later in this section and here we state the main properties that will be used in our Hamiltonian game. In PBT, each prover receives questions in the form $W \in \{X, Z, I\}^t$, and each one is answered with some $b \in \{-1, +1\}^t$. For $W \in \{X, Z\}^t$ and $a \in \{0, 1\}^t$, we have $W(a) \in \{X, Z, I\}^t$ where $W(a)_i = W_i$ if $a_i = 1$ and $W(a)_i = I$ otherwise.

In the honest strategy, the provers share t EPR pairs and measure them with respect to the observable $\sigma_W \stackrel{\text{def}}{=} \bigotimes_{i\in[t]} \sigma_{W_i}$ on question W. However, the provers could deviate and perform an arbitrary strategy, sharing an entangled state $|\psi\rangle_{AB} \in \mathcal{H}_\mathsf{A} \otimes \mathcal{H}_\mathsf{B}$ and performing projective measurements τ^A_W and τ^B_W for each possible question W. It was shown that if the provers pass PBT with probability $1-\varepsilon$, their strategy is, up to local isometries, $O(\sqrt{\varepsilon})$-close to sharing t EPR pairs and measuring σ_W on question W [27].

We describe now PBT. The test is divided in three different tests, which are performed with equal probability. The first one, the Consistency Test, checks if the measurement performed by both provers on question W are equivalent, i.e. $\tau^A_W \otimes I_B|\psi\rangle_{AB}$ is close to $I_A \otimes \tau^B_W|\psi\rangle_{AB}$. In the Linearity Test, the verifier checks if the measurement performed by the provers are linear, i.e. $\tau^A_{W(a)}\tau^A_{W(a')} \otimes I_B|\psi\rangle_{AB}$ is close to $\tau^A_{W(a+a')} \otimes I_B|\psi\rangle_{AB}$. Finally, in the Anti-commutation Test, the verifier checks if the provers' measurements follow commutation/anti-commutation rules consistent with the honest measurements, namely $\tau^A_{W(a)}\tau^A_{W'(a')} \otimes I_B|\psi\rangle_{AB}$ is close to $(-1)^{|\{W_i \neq W'_i \text{ and } a_i = a'_i = 1\}|}\tau^A_{W'(a')}\tau^A_{W(a)} \otimes I_B|\psi\rangle_{AB}$.

The Consistency Test and Linearity Test are very simple and are described in Figure 1. For the Anti-commutation Test, we can use non-local games that allow the verifier to check that the provers share a constant number of EPR pairs and perform Pauli measurements on them. In this work we use the Magic Square game since there is a perfect quantum strategy for it.

The verifier performs the following steps, with probability $\frac{1}{3}$ each:

(A) Consistency test
- **a.** The verifier picks $W \in_R \{X, Z\}^n$ and $a \in \{0,1\}^n$.
- **b.** The verifier sends $W(a)$ to both provers.
- **c.** The verifier accepts iff the provers' answers are equal.

(B) Linearity test
- **a.** The verifier picks $W \in_R \{X, Z\}^t$ and $a, a' \in_R \{0,1\}^t$.
- **b.** The verifier sends $(W(a), W(a'))$ to P_1 and $W' \in_R \{W(a), W(a')\}$ to P_2.
- **c.** The verifier receives $b, b' \in \{\pm 1\}^t$ from P_1 and $c \in \{\pm 1\}^t$ from P_2.
- **d.** The verifier accepts iff $b = c$ when $W' = W(a)$ or $b' = c$ when $W' = W(a')$.

(C) Anti-commutation test
- **a.** The verifier makes the provers play Magic Square games in parallel with the t EPR pairs (see Section 2.2.1).

Figure 1 Pauli Braiding Test.

▶ **Theorem 2** (Theorem 14 of [27]). *Suppose $|\psi\rangle \in \mathcal{H}_A \otimes \mathcal{H}_B$ and $W(a) \in \mathrm{Obs}(\mathcal{H}_A)$, for $W \in \{X, Z\}^t$ and $a \in \{0,1\}^t$, specify a strategy for the players that has success probability at least $1-\varepsilon$ in the Pauli Braiding Test. Then there exist isometries $V_D : \mathcal{H}_D \to ((\mathbb{C}^2)^{\otimes t})_{D'} \otimes \hat{\mathcal{H}}_{\hat{D}}$, for $D \in \{A, B\}$, such that*

$$\left\| (V_A \otimes V_B)|\psi\rangle_{AB} - |\Phi_{00}\rangle^{\otimes t}_{A'B'} |\mathrm{AUX}\rangle_{\hat{A}\hat{B}} \right\|^2 = O(\sqrt{\varepsilon}),$$

and on expectation over $W \in \{X, Z\}^t$,

$$\mathop{\mathrm{E}}_{a \in \{0,1\}^t} \left\| \left(W(a) - V_A^\dagger (\sigma_W(a) \otimes I) V_A\right) \otimes I_B |\psi\rangle \right\|^2 = O(\sqrt{\varepsilon}).$$

Moreover, if the provers share $|\Phi_{00}\rangle^{\otimes t}_{A'B'}$ and measure with the observables $\bigotimes \sigma_{W_i}$ on question W, they pass the test with probability 1.

2.3 Local Hamiltonian problem

The Local Hamiltonian problem can be seen as the quantum analog of MAX-SAT problem. An instance for this problem consists in m Hermitian matrices $H_1, \ldots, H_m$, where each H_i acts non-trivially on at most most k qubits. For some parameters $\alpha, \beta \in \mathbb{R}$, $\alpha < \beta$, the Local Hamiltonian problem asks if there is a global state such that its energy in respect of $H = \frac{1}{m} \sum_{i \in [m]} H_i$ is at most α or all states have energy at least β. This problem was first proved to be QMA-complete for $k = 5$ and $\beta - \alpha \geq \frac{1}{\mathrm{poly}(n)}$ [19]. In this work, we are particularly interested in the version of LH where all the terms are tensor products of σ_X, σ_Z and σ_I.

▶ **Definition 3** (XZ Local Hamiltonian). *The XZ k-Local Hamiltonian problem, for $k \in \mathbb{Z}^+$ and parameters $\alpha, \beta \in [0,1]$ with $\alpha < \beta$, is the following promise problem. Let n be the number of qubits of a quantum system. The input is a sequence of $m(n)$ values $\gamma_1, ..., \gamma_{m(n)} \in [-1, 1]$ and $m(n)$ Hamiltonians $H_1, \ldots, H_{m(n)}$ where m is a polynomial in n, and for each $i \in [m(n)]$, H_i is of the form $\bigotimes_{j \in n} \sigma_{W_j} \in \{\sigma_X, \sigma_Z, \sigma_I\}^{\otimes n}$ with $|\{j | j \in [n] \text{ and } \sigma_{W_j} \neq \sigma_I\}| \leq k$. For $H \stackrel{\mathrm{def}}{=} \frac{1}{m(n)} \sum_{j=1}^{m(n)} \gamma_j H_j$, one of the following two conditions hold.*

Yes. *There exists a state $|\psi\rangle \in \mathbb{C}^{2^n}$ such that $\langle\psi|H|\psi\rangle \leq \alpha(n)$*

No. *For all states $|\psi\rangle \in \mathbb{C}^{2^n}$ it holds that $\langle\psi|H|\psi\rangle \geq \beta(n)$.*

Whenever the value of n is clear from the context, we call $\alpha(n)$, $\beta(n)$ and $m(n)$ by α, β and m. The XZ k-LH problem has been also proved QMA-complete [11, 18].

▶ **Lemma 4** (Lemma 22 of [18], Lemma 22 of [11]). *There exist $\alpha, \beta \in [0,1]$ satisfying $\beta - \alpha \geq \frac{1}{poly(n)}$ such that XZ k-Local Hamiltonian is QMA-complete, for some constant k.*

It is an open question if k-LH is QMA-complete for $\beta - \alpha = O(1)$ while maintaining k constant [2]. However, it is possible to achieve this gap at the cost of increasing the locality of the Hamiltonian [27].

▶ **Lemma 5** (Lemma 26 of [27]). *Let H be an n-qubit Hamiltonian with minimum energy $\lambda_0(H) \geq 0$ and such that $\|H\| \leq 1$. Let $\alpha, \beta \geq \frac{1}{poly(n)}$ and $\alpha < \beta$ for all n. Let H' be the following Hamiltonian on $(\beta - \alpha)^{-1} n$ qubits*

$$H' = \sigma_I^{\otimes na} - (\sigma_I^{\otimes n} - (H - a^{-1}\sigma_I^{\otimes n}))^{\otimes a}, \text{ where } a = (\beta - \alpha)^{-1}.$$

It follows that if $\lambda_0(H) \leq \alpha$ then $\lambda_0(H') \leq \frac{1}{2}$, while if $\lambda_0(H) \geq \beta$ then $\lambda_0(H') \geq 1$. Moreover if H is a XZ Hamiltonian, so is H'.

Finally, we define now non-local games for Local Hamiltonian problems.

▶ **Definition 6** (Non-local games for Hamiltonians). *A non-local game for the Local Hamiltonian problem consists in a reduction from a Hamiltonian H acting on n qubits to a non-local game $G(H)$ where a verifier plays against r provers, and for some parameters $\alpha, \beta, c, s \in [0,1]$, for $\alpha < \beta$ and $c > s$, the following holds.*
Completeness. *If $\lambda_0(H) \leq \alpha$, then $\omega^*(G(H)) \geq c$*
Soundness. *If $\lambda_0(H) \geq \beta$, then $\omega^*(G(H)) \leq s$.*

3 One-round two-prover game for Local Hamiltonian

In this section, we define our non-local game for Local Hamiltonian problem, proving Theorem 9. We start with a XZ Hamiltonian $H = \frac{1}{m}\sum_{l \in m} \gamma_l H_l$ acting on n qubits and $\alpha, \beta \in [0,1]$ with $\alpha < \beta$. We propose then the Hamiltonian Test $G(H)$, a non-local game based on H, whose maximum acceptance probability upper and lower bounds are tightly related to $\lambda_0(H)$. Based on $G(H)$, we show how to construct another non-local game $\tilde{G}(H)$ for which there exists some universal constant $\Delta > 0$ such that if $\lambda_0(H) \leq \alpha$, then $\omega^*(\tilde{G}(H)) \geq \frac{1}{2} + \Delta$, whereas if $\lambda_0(H) \geq \beta$, then $\omega^*(\tilde{G}(H)) \leq \frac{1}{2} - \Delta$. The techniques used to devise $G(H)$ and $\tilde{G}(H)$ are based on Ref. [18, 27].

We describe now the Hamiltonian Test $G(H)$, which is composed by the Pauli Braiding Test (PBT) (see Section 2.2) and the Energy Test (ET), which allows the verifier to estimate $\lambda_0(H)$. The provers are expected to share t EPR pairs and the first prover holds a copy of the groundstate of H. In ET, the verifier picks $l \in_R [m]$, $W \in_R \{X, Z\}^t$ and $e \in_R \{0,1\}^t$, and chooses $\mathcal{T}_1, ..., \mathcal{T}_n \in [t]$ such that $W(e)_{\mathcal{T}_i}$ matches the i-th Pauli observable of H_l. By setting $t = O(n \log n)$, it is possible to choose such positions for a random $W(e)$ with overwhelming probability. The verifier sends $\mathcal{T}_1, ..., \mathcal{T}_n$ to the first prover, who is supposed to teleport the groundstate of H through the EPR pairs in these positions. As in PBT, the verifier sends $W(e)$ to the second prover, who is supposed to measure his EPR halves with the corresponding observables. The values of $\mathcal{T}_1, ..., \mathcal{T}_n$ were chosen in a way that the first prover teleports the groundstate of H in the exact positions of the measurement according to H_l.

The verifier performs each of the following steps with probability $1-p$ and p, respectively:
(A) Pauli Braiding Test
(B) Energy Test
- **a.** The verifier picks $W \in_R \{X,Z\}^t$, $e \in_R \{0,1\}^t$ and $l \in_R [m]$
- **b.** The verifier picks positions $\mathcal{T}_1$, ...$\mathcal{T}_n$ such that $H_l = \bigotimes \sigma_{W(e)_{\mathcal{T}_i}}$.
- **c.** The verifier sends $\mathcal{T}_1, ..., \mathcal{T}_n$ to the first prover and $W(e)$ to the second prover.
- **d.** The first prover answers with $a, b \in \{0,1\}^n$ and the second prover with $c \in \{+1,-1\}^t$.
- **e.** Let $d \in \{-1,+1\}^n$ such that $d_i = (-1)^{a_i} c_{\mathcal{T}_i}$ if $W_{\mathcal{T}_i} = X$ and $d_i = (-1)^{b_i} c_{\mathcal{T}_i}$ if $W_{\mathcal{T}_i} = Z$.
- **f.** If $\prod_{i\in[n]} d_i \neq sign(\gamma_l)$, the verifier accepts.
- **g.** Otherwise, the verifier rejects with probability $|\gamma_l|$.

Figure 2 Hamiltonian Test $G(H)$ for a XZ Hamiltonian H.

With the outcomes of the teleportation measurements, the verifier can correct the output of the measurement of the second prover and estimate $\lambda_0(H)$. The full description of the game is presented in Figure 2.

We state now two auxiliary lemmas with lower and upper bounds on the maximum acceptance probability on $G(H)$.

▶ **Lemma 7.** *Let $H = \sum_{l\in[m]} \gamma_l H_l$ be a XZ Hamiltonian, let $G(H)$ be the Hamiltonian-self test for H, described in Figure 2, and*

$$\omega_h(H) \stackrel{\text{def}}{=} 1 - p\left(\frac{1}{2m}\sum_{l\in[m]} |\gamma_l| - \frac{1}{2}\lambda_0(H)\right).$$

If the provers use the honest strategy in PBT*, the maximum acceptance probability in $G(H)$ is $\omega_h(H)$. Moreover, this probability is achieved if the first prover behaves honestly in* ET*.*

▶ **Lemma 8.** *Let H, $G(H)$ and $\omega_h(H)$ be defined as Lemma 7. For every $\eta > 0$, there is some value of $p = O(\sqrt{\eta})$ such that $\omega^*(G(H)) \leq \omega_h(H) + \eta$.*

We defer the proof of these lemmas to Section 3.1 and we concentrate now in proving our main theorem.

▶ **Theorem 9.** *There exists a universal constant Δ such that the following holds. Let $H = \sum_{l\in m} \gamma_l H_l$ be XZ k-Local Hamiltonian acting on n qubits with parameters $\alpha, \beta \in (0,1)$, for $\beta > \alpha$. There exists one-round two-prover non-local game such that*
- *if $\lambda_0(H) \leq \alpha$, then the verifier accepts with probability at least $\frac{1}{2} + \Delta$; and*
- *if $\lambda_0(H) \geq \beta$, then the verifier accepts with probability at most $\frac{1}{2} - \Delta$.*

Moreover, each message is $\tilde{O}(n(\beta-\alpha)^{-1})$-bit long.

Proof. Lemma 5 states that from H we can construct a Hamiltonian H' such that

$$\lambda_0(H) \leq \alpha \Rightarrow \lambda_0(H') \leq \frac{1}{2} \text{ and } \lambda_0(H) \geq \beta \Rightarrow \lambda_0(H') \geq 1,$$

and $H' = \sum_{l\in m'} \gamma'_l H'_l$ is an instance of XZ Local Hamiltonian problem.

We now bound the maximum acceptance probability of the Hamiltonian Test on H', relating it to the groundstate energy of H. From Lemma 7 it follows that

$$\lambda_0(H) \leq \alpha \Rightarrow \omega^*(G(H')) \geq 1 - p\left(\frac{1}{2m}\sum_{l\in[m]} |\gamma'_l| - \frac{1}{4}\right) \stackrel{\text{def}}{=} c,$$

while from Lemma 8, for any $\eta > 0$ and some $p \leq C\sqrt{\eta}$, we have that

$$\lambda_0(H) \geq \beta \Rightarrow \omega^*(G(H')) \leq 1 - p\left(\frac{1}{2m}\sum_{l\in[m]}|\gamma_l'| - \frac{1}{2}\right) + \eta = c - \frac{C\sqrt{\eta}}{4} + \eta.$$

By choosing η to be a constant such that $\eta' \stackrel{\text{def}}{=} \frac{C\sqrt{\eta}}{4} - \eta > 0$, it follows that

$$\lambda_0(H) \leq \alpha \Rightarrow \omega^*(G(H')) \geq c \text{ and } \lambda_0(H) \geq \beta \Rightarrow \omega^*(G(H')) \leq c - \eta'.$$

We describe now the game $\tilde{G}(H)$ that achieves the completeness and soundness properties stated in the theorem. In this game, the verifier accepts with probability $\frac{1}{2} - \frac{2c-\eta'}{4}$, rejects with probability $\frac{2c-\eta'}{4}$ or play $G(H')$ with probability $\frac{1}{2}$. Within this new game, if $\lambda_0(H) \leq \alpha$ then $\omega^*(\tilde{G}(H')) \geq \frac{1}{2} + \frac{\eta'}{4}$, whereas when $\lambda_0(H) \geq \beta$, we have that $\omega^*(\tilde{G}(H')) \leq \frac{1}{2} - \frac{\eta'}{4}$. ◀

▶ **Corollary 10.** *There exists a protocol for verifiable delegation of quantum computation where a classical client communicates with two entangled servers in one round of classical communication.*

Proof. The corollary holds from composing the circuit-to-Hamiltonian construction (see the full version [16] of the paper for more details) with our non-local game. ◀

▶ Remark 11. The parameters of our delegation protocol allow us to use standard arguments in relativistic cryptography to replace the assumption that the provers do not communicate by the assumption that they can only communicate at most as fast as the speed of light. See the full version [16] of this paper for more details on this matter.

3.1 Proof of Lemmas 7 and 8

We start by proving Lemma 7, showing an upper bound on the acceptance probability if the provers are honest in PBT.

Proof of Lemma 7. Since PBT and ET are indistinguishable to the second prover, he also follows the honest strategy in ET and the acceptance probability in $G(H)$ depends uniquely in the strategy of the first prover in ET.

Let $a, b \in \{0,1\}^n$ be the answers of the first prover in ET and τ be the reduced state held by the second prover on the positions $\mathcal{T}_1, ..., \mathcal{T}_n$ of his EPR halves, after the teleportation.

For a fixed H_l, the verifier rejects with probability

$$\frac{|\gamma_l| + \gamma_l \mathbb{E}\left[\prod_{i\in n} d_i\right]}{2}. \tag{1}$$

We notice that measuring a qubit $|\phi\rangle$ in the Z-basis with outcome $f \in \{\pm 1\}$ is equivalent of considering the outcome $(-1)^g f$ when measuring $X^g Z^h |\phi\rangle$ in the same basis. An analog argument follows also for the X-basis. Therefore, by fixing the answers of the first prover, instead of considering that the second prover measured τ in respect of H_l with outcome c, we consider that he measured $\rho = \mathsf{Z}^b\mathsf{X}^a\tau\mathsf{X}^a\mathsf{Z}^b$ with respect to H_l with outcome d. In this case, by taking $\prod_{i\in n} d_i$ as the outcome of the measurement of H_l on ρ, and averaging over all $l \in [m]$, it follows from Equation (1) that the verifier rejects in ET with probability

$$\frac{1}{m}\sum_{l\in[m]}\frac{|\gamma_l| + \gamma_l \mathrm{Tr}(\rho H_l)}{2} = \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| + \frac{1}{2}\mathrm{Tr}(\rho H),$$

and this value is minimized when ρ is the groundstate of H. In this case the overall acceptance probability in $G(H)$ is at most

$$1 - p\left(\frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{1}{2}\lambda_0(H)\right) = \omega_h(H).$$

Finally, this acceptance probability is achieved if the first prover teleports the groundstate $|\psi\rangle$ of H and report the honest outcomes from the teleportation, since $\tau = \mathsf{X}^a\mathsf{Z}^b|\psi\rangle\langle\psi|\mathsf{Z}^b\mathsf{X}^a$ and $\rho = |\psi\rangle\langle\psi|$. ◀

We use now the self-testing of PBT to certify the measurements of the second prover in ET. In this way, we can bound the acceptance probability in $G(H)$ with Lemma 7 and prove Lemma 8.

Proof of Lemma 8. Let S be the strategy of the provers, which results in acceptance probabilities $1-\varepsilon$ in PBT and $1 - \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{1}{2}\lambda_0(H) + \delta$ in ET, for some ε and δ.

By Lemma 2, their strategy in PBT is $O(\sqrt{\varepsilon})$-close to the honest strategy, up to the local isometries V_A and V_B. Let S_h be the strategy where the provers follow the honest strategy in PBT and, for ET, the first prover performs the same operations of S, but considering the isometry V_A from Theorem 2. Since the measurements performed by the provers in S and S_h are $O(\sqrt{\varepsilon})$-close to each other, considering the isometries, the distributions of the corresponding transcripts have statistical distance at most $O(\sqrt{\varepsilon})$. Therefore, the provers following strategy S_h are accepted in ET with probability at least

$$1 - \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{1}{2}\lambda_0(H) + \delta - O(\sqrt{\varepsilon}).$$

Since in S_h the provers perform the honest strategy in PBT, it follows from Lemma 7 that

$$1 - \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{1}{2}\lambda_0(H) + \delta - O(\sqrt{\varepsilon}) \leq 1 - \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{1}{2}\lambda_0(H),$$

which implies that $\delta \leq C\sqrt{\varepsilon}$, for some constant C.

The original strategy S leads to acceptance probability at most

$$(1-p)(1-\varepsilon) + p\left(1 - \frac{1}{2m}\sum_{l\in[m]}|\gamma_l| - \frac{\lambda_0(H)}{2} + C\sqrt{\varepsilon}\right) = \omega_h(H) - (1-p)\varepsilon + pC\sqrt{\varepsilon}.$$

For any η, we can pick $p = \min\left\{\frac{\sqrt{\eta}}{D}, 1\right\}$, for $D \geq 2C$, and it follows that

$$pC\sqrt{\varepsilon} - (1-p)\varepsilon \leq \frac{2C\sqrt{\eta}\sqrt{\varepsilon}}{D} - \varepsilon \leq \sqrt{\eta}\sqrt{\varepsilon} - \varepsilon \leq \eta$$

and therefore the maximum acceptance probability is at most $\omega_h(H) + \eta$. ◀

Abstract

The Constraint Satisfaction Problem (CSP) and its counting counterpart appears under different guises in many areas of mathematics, computer science, statistical physics, and elsewhere. Its structural and algorithmic properties have demonstrated to play a crucial role in many of those applications. For instance, topological properties of the solution set such as connectedness is related to the hardness of CSPs over random structures. In approximate counting and statistical physics, where CSPs emerge in the form of spin systems, mixing properties and the uniqueness of Gibbs measures have been heavily exploited for approximating partition functions or the free energy of spin systems. Additionally, in the decision CSPs, structural properties of the relational structures involved – like, for example, dismantlability – and their logical characterizations have been instrumental for determining the complexity and other properties of the problem.

In spite of the great diversity of those features, there are some eerie similarities between them. These were observed and made more precise in the case of graph homomorphisms by Brightwell and Winkler, who showed that the structural property of dismantlability of the target graph, the connectedness of the set of homomorphisms, good mixing properties of the corresponding spin system, and the uniqueness of Gibbs measure are all equivalent. In this paper we go a step further and demonstrate similar connections for arbitrary CSPs. This requires much deeper understanding of dismantling and the structure of the solution space in the case of relational structures, and new refined concepts of mixing introduced by Briceño. In addition, we develop properties related to the study of valid extensions of a given partially defined homomorphism, an approach that turns out to be novel even in the graph case. We also add to the mix the combinatorial property of finite duality and its logic counterpart, FO-definability, studied by Larose, Loten, and Tardif.

1 Introduction

The Constraint Satisfaction Problem (CSP) provides a powerful framework in a wide range of areas of mathematics, computer science, statistical physics, and elsewhere. The goal in a CSP is to find an assignment to variables from a given set that satisfies a number of given constraints. The counting version of the problem asks about the number of such assignments. The CSP however appears in different forms: as the standard one outlined above in AI and computer science [19], as the homomorphism problem in graph and model theory [22, 27], as conjunctive query evaluation in logic and database theory [30], as computing the partition function of a spin system in statistical physics [39] and related areas, like symbolic dynamics and coding [35, 37].

The CSP allows for many approaches of diverse nature, and every application field exploits some of its many facets: structural properties of constraints for complexity and algorithms, probabilistic properties and the topology of the solution space in Random CSP and random structures, mixing properties in statistical physics and dynamical systems, decay of correlations and the uniqueness of probabilistic measures in approximate counting, and homomorphic duality and logical characterizations in model theory. In [12], Brightwell and Winkler observed that some of these properties are actually closely related, at least in the simple case of graph homomorphisms. In this paper we take this research direction a step further by extending Brightwell and Winkler's results to the general CSP, and by refining and widening the range of the properties involved.

We start off with a brief introduction of the features of the CSP considered in this paper. Afterwards, we provide a detailed account of the necessary background and a description of our results.

Every CSP involves a set of variables and a domain, a set of possible values for the variables. Assumptions about these two sets differ in different areas. The most studied case in combinatorics and complexity theory is when both sets are finite. However, many interesting problems such as scheduling and temporal and spatial reasoning involve infinite domains; see also extensive literature on infinite CSPs (see, for example, [4] and the references therein). In other cases such as in statistical physics, it is natural to choose the set of variables to be infinite (a lattice, for example). Then, it is also natural to study probability distributions over such assignments – where *Gibbs measures* and the problem of their *(non-)uniqueness* appear naturally [25] – and also study quantities such as *entropy* and *free energy* [3, 7].

Following [22], CSPs can be formulated as the problem of deciding the existence of a homomorphism from a finite relational structure $\mathbb{G}$ to a target relational structure $\mathbb{H}$, where $\mathbb{G}$ and $\mathbb{H}$ encode the variables and the values of the CSP. The complexity of this problem, especially the case when $\mathbb{H}$ is a fixed finite relational structure, has received a lot of attention, culminating with the proof of the Feder-Vardi conjecture [14, 44]. In the present paper we focus as well on the case when $\mathbb{H}$ is finite, although our main focus is not algorithmic but rather structural. In particular, we are interested in studying the space $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ of homomorphism from $\mathbb{G}$ to $\mathbb{H}$. Furthermore, following [12] we consider homomorphisms from both finite and infinite relational structures $\mathbb{G}$ (although [12] only considers graphs), a flexibility that turns out to be useful to see different aspects of homomorphism spaces $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that otherwise would be meaningless.

There is a vast literature concerning graph homomorphisms and their properties through the lenses of statistical physics [5, 20, 11, 39]. In this context, it is very common to encode a *spin system* as a pair of relational structures $\mathbb{G}$ and $\mathbb{H}$, where $\mathbb{G}$ contains a set of variables/particles and $\mathbb{H}$ contains the set of values/spins that each particle could take, imposing *hard constraints* on them, i.e., disregarding configurations of values that do not satisfy all the given constraints. In practical terms, all this reduces to study – individually and as a set – the maps from $\mathbb{G}$ to $\mathbb{H}$ that are homomorphisms. In particular, many important parameters of a spin system such as free energy and entropy can be learned from studying such a set of homomorphisms.

In [12], Brightwell and Winkler observed that many of the properties of graph homorphisms used in the above areas are equivalent to a single structural property of graphs, namely, dismantlability. In this paper we follow a similar approach and study properties of CSPs over general relational structures that we put into basically three categories: (1) dismantlability, (2) connectedness, and (3) mixing. Furthermore, as a consequence of our results, we established a connection with a fourth notion not initially contemplated in [12]: (4) finite duality.

Dismantlability

A graph is said to be dismantlable if it can be reduced to a single vertex removing vertices whose neighborhood is contained in the neighborhood of some other vertex. Such transformations are called *folds*, and they can be viewed as *retractions* of a very particular kind. Dismantlable graphs were introduced in [41], based on ideas already present in [29] in the context of lattices, and have been intensively studied in combinatorics. Distamantlability can be generalized in a natural way to relational structures. Indeed, some variants of this notion have been used in the study of CSPs. In particular, dismantlability has been applied in [15] to the problem of enumerating all solutions of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ with polynomial delay. Also, it has played a major role in the study of CSPs definable in first-order logic [18, 34].

Connectedness

When $\mathbb{G}$ is finite, it is often useful to convert $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ into a graph and explore the connectivity properties of this graph. The set of edges of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ can be defined in a variety of ways, usually the most suitable to the problem at hand. For example, it is common to say that two elements from $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ are close (and therefore adjacent in the graph) if the Hamming distance between them is smaller than a certain threshold. The particular case when this threshold is 1 has been intensively studied, motivated initially by the fact that the connectedness of the solution space for SAT problems over random instances is linked to the performance of standard satisfiability algorithms, such as WalkSAT or DPLL [1, 32]. This has given rise to a general framework called *reconfiguration* [28] (see also [40] for a recent survey) that goes way beyond homomorphisms. Work in this area encompasses both structural questions (under which conditions is $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ connected?) and algorithmic ones (what is the complexity of, deciding, given $\mathbb{G}$ and $\mathbb{H}$ as input, whether $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is connected? Its diameter? The shortest path between two given members of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$? Etc.). In the context of spin systems, the connectedness of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is related to processes that consists on periodically updating the spin of a single or a small set of particles (e.g., irreducibility of *Glauber dynamics*).

We also consider an alternative way to define adjacency in $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ via *links* as in [34]. This notion of adjacency is linked to the so-called *finite duality property*, which is another of the main themes of our work.

Mixing

Mixing properties have been intensively studied in statistical physics and related areas (see [2, 6, 8, 10, 17, 42]), and are usually applied when the set of particles in $\mathbb{G}$ is very large or infinite. In this case, it can be very useful to be able to "glue" together partial homomorphisms, provided their domains are far from each other. There are several properties that formalize this phenomenon and it is common to establish hierarchies among them. More concretely, given a metric in $\mathbb{G}$, it is natural to ask whether there exists some uniform gap such that for any two subsets A and B of particles sufficiently far apart (in terms of the gap), and for any pair of homomorphisms $\phi, \psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$, we can find a third one, γ, such that restriction of γ to A and B coincides with the restrictions of ϕ and ψ on A and B, respectively. On the contrary, whenever the information content of a given set (at least partially) determines the information content of another set (i.e., the possible values that the variables on it can take), no matter how far it is, such a phenomenon has been called *long range action* in previous work (e.g., see [13]).

Similar phenomena are used in the related area of approximate computing of partition functions, where many algorithms are based on decay of correlations between values of remote elements of $\mathbb{G}$, which allows for approximation of partition functions based only on local neighborhoods of variables.

Finite duality and logic characterizations

Homomorphism duality often helps to design a solution algorithm for a CSP or establish its useful properties. A graph (or relational structure) $\mathbb{H}$ is said to have *homomorphism duality* if there is a set $\mathcal{O}$ of graphs, called obstructions, such that a graph $\mathbb{G}$ has a homomorphism to $\mathbb{H}$ if and only if no graph from $\mathcal{O}$ is homomorphic to $\mathbb{G}$. Sometimes the set of obstructions is very simple, say, any bipartite graph has homomorphic duality, where $\mathcal{O}$ is the set of all odd cycles. If $\mathcal{O}$ can be chosen finite, we say that $\mathbb{H}$ has *finite duality*.

Homomorphism duality is closely related to another property of CSPs. Let $\mathcal{L}$ be a logic language such as first order, second order, etc. The problem of deciding homomorphisms to a relational structure $\mathbb{H}$ is said to be *expressible in* $\mathcal{L}$ if there is a formula Φ in the language $\mathcal{L}$ such that $\mathbb{G}$ has a homomorphism to $\mathbb{H}$ if and only if Φ is true on $\mathbb{G}$. It is known, for instance, that $\mathbb{H}$ has a set of obstructions consisting of relational structures of bounded treewidth if and only if the corresponding homomorphism problem is expressible in Datalog [22], or that $\mathbb{H}$ has finite duality if and only if the corresponding problem is expressible in first order logic [34] (see, for example, [16] for a survey on dualities for CSP).

Our results

The main result of this paper is Theorem 10, that shows, for a relational structure $\mathbb{H}$, the equivalence of the following three conditions: (A) $\mathbb{H}^2$ dismantles to a substructure of its diagonal, that is, the substructure of $\mathbb{H}^2$ induced by the set $\{(a, a) \mid a \in \mathbb{H}\}$; (B) for any $\mathbb{G}$, the homomorphism graph $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is connected; and (C) for any relational structure $\mathbb{G}$, the graph $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ satisfies certain mixing properties. These results generalize the results from [12] to the case of general relational structures. Observe that the case of graphs considered in [12] does not fully reflect the richness of the theory behind our result.

As a byproduct of our results, we obtain two applications. On the one hand, we establish a link with *strong spatial mixing* (e.g., see [21]) and *topological strong spatial mixing* (introduced in [7]). These two last properties have played an important role in the development of deterministic approximate counting algorithms. In this paper we address the

following question: What fixed targets $\mathbb{H}$ are suitable for both of these properties to hold for any $\mathbb{G}$? On the other hand, we establish a connection with finite duality, which allows us to reprove the main theorem in [34]. We hope that our work opens the possibility of developing new counting techniques based on this approach in a very general setting. We stress that many of these results are new even in the graph case.

Due to space restrictions proofs are ommitted. They can be found at the full version [9].

2 Preliminaries

Let H be a countable (finite or denumerable) set and k a positive integer. The set of k-tuples over H is denoted by H^k. A (k-ary) **relation** R over H is a subset $R \subseteq H^k$. The elements of a relation R will be denoted in boldface, e.g., $\mathbf{a}$, $\mathbf{b}$, etc., and $\mathbf{a}[i]$ will denote the ith entry of $\mathbf{a}$ for $1 \leq i \leq k$.

Given another countable set G and a map $\phi : G \to H$, for a k-tuple $\mathbf{a}$ over G we shall use $\phi(\mathbf{a})$ to denote the k-tuple over H obtained after applying ϕ to $\mathbf{a}$ componentwise. If $V \subseteq G$, we will denote by $\phi|_V$ the restriction of ϕ to V. Furthermore, if ψ is another map with domain H, we shall use $\psi \circ \phi$ to denote the composition of ψ with ϕ, i.e., the map $x \mapsto \psi(\phi(x))$.

A **signature** τ is a finite collection of relation symbols R, each of them with an associated arity. For a given signature τ, a **relational structure** (with signature τ) – or simply, a **τ-structure** – $\mathbb{H}$ consists of a countable set H called the **universe** of $\mathbb{H}$ and a relation $R(\mathbb{H})$ for each $R \in \tau$, such that the arity of $R(\mathbb{H})$ equals that of R. We shall use the same capital letter to denote the universe of a τ-structure, e.g., H is the universe of $\mathbb{H}$. We will usually consider τ to be a fixed signature, and $\mathbb{G}$ and $\mathbb{H}$ to be τ-structures with universes G and H, respectively.

A relational structure is said to be **finite** if its universe is finite and **locally finite** if every element in its universe occurs only in a finite number of its tuples.

▶ Remark 1. A digraph $\mathbb{G}$ (with self-loops allowed) is a very particular case of a relational structure, where the signature τ consists of a unique relation symbol E of arity 2. Moreover, graphs correspond to the digraph case where $E(\mathbb{G})$ is a symmetric relation.

A map $\phi : G \to H$ is said to be a **homomorphism** from $\mathbb{G}$ to $\mathbb{H}$ if, for every relation symbol $R \in \tau$,

$$\mathbf{a} \in R(\mathbb{G}) \;\Rightarrow\; \phi(\mathbf{a}) \in R(\mathbb{H}).$$

We will denote by $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ the set of all homomorphisms from $\mathbb{G}$ to $\mathbb{H}$.

▶ **Example 2.** A particular example of CSPs that cannot be represented in the setting of Brightwell and Winkler (that is, as homomorphisms of graphs) is the case of **d-dimensional nearest-neighbor (n.n.) shifts of finite type (SFTs)**, a fundamental object in dynamical systems and probability (see [35, 36, 37]). Given a positive integer d, consider the signature $\tau = \{R_1, \ldots, R_d\}$, where R_i is a 2-ary relation for all $1 \leq i \leq d$. We consider two τ-structures $\mathbb{G}$ and $\mathbb{H}$. Here, $\mathbb{G}$ will be an infinite relational structure with universe $G = \mathbb{Z}^d$ and relations $R_i(\mathbb{G})$, $1 \leq i \leq d$, representing the usual d-dimensional hypercubic lattice and the adjacency of pairs of elements in it. On the other hand, $\mathbb{H}$ will be a finite relational structure with universe H and $R_i(\mathbb{H})$ representing pairs of "colors" from H that are allowed to be adjacent in the canonical ith direction of the lattice, $1 \leq i \leq d$. Then, $X = \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is known as a d-dimensional n.n. SFT, a set of colorings of $\mathbb{Z}^d$ with not necessarily *isotropic* adjacency rules (i.e., we do not need to have the same restrictions in every direction), and any such object can be represented in this way.

A relational structure $\mathbb{J}$ is a **substructure** of $\mathbb{H}$ if $J \subseteq H$ and, for every relation symbol $R \in \tau$, we have that $R(\mathbb{J}) \subseteq R(\mathbb{H})$. Furthermore, if for every k-ary $R \in \tau$, we have that $R(\mathbb{J}) = R(\mathbb{H}) \cap J^k$, then we say that $\mathbb{J}$ is the substructure of $\mathbb{H}$ **induced by** J. If $J \subseteq H$ and $\phi : H \to J$ is a homomorphism acting as the identity on J, then ϕ is said to be a **retraction**.

The **product** of $\mathbb{H}_1$ and $\mathbb{H}_2$, denoted $\mathbb{H}_1 \times \mathbb{H}_2$, is the τ-structure with universe $H_1 \times H_2$ where, for every k-ary relation symbol $R \in \tau$, we have that $R(\mathbb{H}_1 \times \mathbb{H}_2)$ consists of all tuples $((a_1, b_1), \ldots, (a_k, b_k))$ with $(a_1, \ldots, a_k) \in R(\mathbb{H}_1)$ and $(b_1, \ldots, b_k) \in R(\mathbb{H}_2)$. We shall denote by $\mathbb{H}^2$ the product $\mathbb{H} \times \mathbb{H}$. The **projections** $\pi_1, \pi_2 : H^2 \to H$ are the maps $(a, b) \mapsto a$ and $(a, b) \mapsto b$, respectively, for $(a, b) \in H^2$. An element (a, b) of H^2 is *diagonal* if $a = b$. The **diagonal set** of H^2, denoted $\Delta(H^2)$, is the set of its diagonal elements. Similarly, the **diagonal structure** of $\mathbb{H}^2$, denoted $\Delta(\mathbb{H}^2)$, is the substructure of $\mathbb{H}^2$ induced by $\Delta(H^2)$. A substructure $\mathbb{K}$ of $\mathbb{H}^2$ is **symmetric** whenever $(a, b) \in K$ if and only if $(b, a) \in K$. Notice that $\mathbb{H}^2$ is always symmetric.

In this paper, we will study properties of $\mathbb{H}$ and how they relate to other properties of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ for arbitrary $\mathbb{G}$. We mainly consider three families of properties, namely, *dismantling* of $\mathbb{H}$, connectedness of some particular *graphs with vertex set* $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$, and *mixing properties* of $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$.

2.1 Dismantling

Let $\mathbb{H}$ be a τ-structure and let a, b be elements in its universe H. We say that b **dominates** a (in $\mathbb{H}$) if for every k-ary $R \in \tau$, any $i \in \{1, \ldots, k\}$, and any $(a_1, \ldots, a_k) \in R(\mathbb{H})$ with $a_i = a$, we also have that $(a_1, \ldots, a_{i-1}, b, a_{i+1}, \ldots, a_k) \in R(\mathbb{H})$. Additionally, if $a \neq b$, then we say that a is **dominated** (in $\mathbb{H}$).

A sequence of τ-structures $\mathbb{J}_0, \ldots, \mathbb{J}_\ell$ is a **dismantling sequence** if for every $0 \leq j < \ell$ there exist $a_j, b_j \in J_j$ such that b_j dominates a_j in $\mathbb{J}_j$, and $\mathbb{J}_{j+1}$ is the substructure of $\mathbb{J}_j$ induced by $J_j \setminus \{a_j\}$. In this case, we say that $\mathbb{J}_0$ **dismantles to** $\mathbb{J}_\ell$. We can alternatively denote a dismantling sequence by giving the initial relational structure $\mathbb{J}_0$ and the sequence of elements $a_0, \ldots, a_{\ell-1}$. We say that $\mathbb{H}$ is **dismantlable** if it dismantles to a τ-structure such that its universe is a singleton.

Note that for every $0 \leq j < \ell$ there is a natural retraction r_j from $\mathbb{J}_j$ to $\mathbb{J}_{j+1}$, where r_j maps a_j to b_j and acts as the identity elsewhere. We call such retractions a **fold**. By successive composition, one can define a retraction (namely, $r_{j'-1} \circ \cdots \circ r_j$) from $\mathbb{J}_j$ to $\mathbb{J}_{j'}$ for every $j \leq j'$.

It is well known that if $\mathbb{H}$ dismantles to some substructure $\mathbb{K}$, then this dismantling can be found in a greedy manner. Formally,

▶ **Lemma 3** ([34, Lemma 5.1]). *If $\mathbb{H}$ dismantles to $\mathbb{K}$ and $a \in H \setminus K$ is dominated in $\mathbb{H}$, then the substructure of $\mathbb{H}$ induced by $H \setminus \{a\}$ dismantles to $\mathbb{K}$.*

Let $J \subseteq H$. We say that $\mathbb{H}$ is **J-non-foldable** if every dominated element in $\mathbb{H}$ belongs to J.

2.2 Walks in relational structures

We define a **walk** w in a τ-structure $\mathbb{H}$ to be a sequence

$$a_0, i_1, (R_1, \mathbf{a}_1), j_1, a_1, \ldots, a_{n-1}, i_n, (R_n, \mathbf{a}_n), j_n, a_n$$

for some $n \geq 0$, such that, for all $1 \leq \ell \leq n$,

- $R_\ell \in \tau$, $\mathbf{a}_\ell \in R_\ell(\mathbb{H})$, $i_\ell \neq j_\ell$, and
- $a_{\ell-1} = \mathbf{a}_\ell[i_\ell]$ and $a_\ell = \mathbf{a}_\ell[j_\ell]$.

In this case, we will say that w **joins** a_0 (the **starting point**) and a_n (the **ending point**), and that the **length** of the walk w is n. Notice that if a walk w joins a_0 and a_n, then there is another walk w' that joins a_n and a_0 obtained by just reversing the order of indices. The **distance** $\mathrm{dist}(a,b)$ between two elements $a,b \in H$ is defined to be the smallest length among all the walks w that join a and b. The distance $\mathrm{dist}(V,W)$ between sets $V,W \subseteq H$ is defined to be the minimum distance between an element from V and an element from W.

Note that the definition of walk above coincides with the standard definition of walk when $\mathbb{H}$ is a graph. However, in the case of graphs it will be convenient to describe the walk merely as the list $a_0,\dots,a_n$ of its nodes, as usual.

A τ-structure $\mathbb{H}$ is **connected** if there is a walk joining any pair of elements of its universe H and a **connected component** is any induced substructure that is connected and maximal in the sense of inclusion. A walk w is a **circuit** if $n>0$, the starting and ending points of w coincide, and for all $1 \le \ell < \ell' \le n$, we have that $(R_\ell, \mathbf{a}_\ell) \neq (R_{\ell'}, \mathbf{a}_{\ell'})$. A τ-structure $\mathbb{T}$ is a **τ-forest** if it has no circuits. If, additionally, it is connected then it is a **τ-tree**. Usually, τ-trees are defined using the notion of incidence multigraph (see for example [34]). It is easy to verify that the definition given here is equivalent.

2.3 Forest of walks

Given a τ-structure $\mathbb{H}$, we proceed to define a new τ-structure $\mathbb{T}_\mathbb{H}$. The universe $T_\mathbb{H}$ of $\mathbb{T}_\mathbb{H}$ consists of all the walks w in $\mathbb{H}$. For a k-ary $R \in \tau$, we define $R(\mathbb{T}_\mathbb{H})$ as follows: for all $\mathbf{a}=(a_1,\dots,a_k) \in R(\mathbb{H})$, for all $1 \le i \le k$, and for all walks w ending in a_i, we include in $R(\mathbb{T}_\mathbb{H})$ the tuple $(w_1,\dots,w_{i-1},w,w_{i+1},\dots,w_k)$, where w_j, $j \neq i$, is the walk obtained from w by extending it with $i,(R,\mathbf{a}),j,a_j$.

We note that $\mathbb{T}_\mathbb{H}$ does not have circuits and has exactly $|H|$ connected components, i.e., $|H|$ τ-trees. It is easy to check that for every substructure $\mathbb{I}$ of $\mathbb{H}$, the τ-structure $\mathbb{T}_\mathbb{I}$ is a substructure of $\mathbb{T}_\mathbb{H}$.

▶ Remark 4. If $\mathbb{H}$ is connected and we consider a slight modification of this previous definition, where the walks are asked to be non-backtracking (i.e., for every $1 \le \ell < n$, we have that either $i_\ell \neq j_{\ell+1}$, or $j_\ell \neq i_{\ell+1}$, or $(R_\ell,\mathbf{x}_\ell) \neq (R_{\ell+1},\mathbf{x}_{\ell+1})$), then we obtain that each connected component of the resulting τ-structure corresponds to the *universal covering tree* of $\mathbb{H}$ [31, 33] (in particular, they are all the same up to isomorphism).

Note that, by construction, the map $\rho_\mathbb{H} : T_\mathbb{H} \to H$ that sends every walk w in $T_\mathbb{H}$ to its ending point, that from now on we refer as the **label map**, defines a homomorphism from $\mathbb{T}_\mathbb{H}$ to $\mathbb{H}$. Furthermore,

▶ **Lemma 5.** *Assume that $\mathbb{H}$ is J-non-foldable for some $J \subseteq H$ and let U be a cofinite subset of $T_\mathbb{H}$ containing $\rho_\mathbb{H}^{-1}(J)$. Then, every homomorphism in $\mathrm{Hom}(\mathbb{T}_\mathbb{H},\mathbb{H})$ that agrees with $\rho_\mathbb{H}$ in U is identical to $\rho_\mathbb{H}$.*

Proof. Given $n \ge 0$, let W_n be the set of walks of length at least n in $\mathbb{H}$ (notice that $W_n \subseteq W_{n-1}$ and $W_0 = T_\mathbb{H}$). We shall show that any $\rho' \in \mathrm{Hom}(\mathbb{T}_\mathbb{H},\mathbb{H})$ that agrees with $\rho_\mathbb{H}$ in $W_n \cup \rho_\mathbb{H}^{-1}(J)$ for arbitrary n also agrees with $\rho_\mathbb{H}$ in W_{n-1} . Let w be any walk of length $n-1$ and let a be its ending point. We first show that $\rho'(w)$ dominates a in $\mathbb{H}$. Indeed, let $R \in \tau$ and let $\mathbf{a}=(a_1,\dots,a_k) \in R(\mathbb{H})$, where a appears, say, in the ith coordinate. By construction, $R(\mathbb{T}_\mathbb{H})$ contains the tuple $\mathbf{w}=(w_1,\dots,w_{i-1},w,w_{i+1},\dots,w_k)$, where for every $j \neq i$, w_j is obtained by concatenating $i,(R,\mathbf{x}),j,a_j$ at the end of w. Since w_j has length n for every $j \neq i$, it follows by assumption that $\rho'(w_j)=a_j$. That is, $\rho'(\mathbf{w})$ (which must be a tuple in $R(\mathbb{H})$) is obtained by replacing, in $\mathbf{a}$, a_i by $\rho'(w)$.

Hence, we have shown that $\rho'(w)$ dominates a in $\mathbb{H}$. Since $\mathbb{H}$ is J-non-foldable it follows that either $\rho'(w) = a$ (and, hence, $\rho'(w) = \rho_{\mathbb{H}}(w)$) or $a \in J$ (and, hence, $\rho'(w) = \rho_{\mathbb{H}}(w)$ since $w \in \rho_{\mathbb{H}}^{-1}(J)$). To conclude the proof it is only necessary to observe that, since U is a cofinite set containing $\rho_{\mathbb{H}}^{-1}(J)$, it follows that any homomorphism that agrees with $\rho_{\mathbb{H}}$ in U, agrees as well in $W_n \cup \rho_{\mathbb{H}}^{-1}(J)$ for sufficiently large n. ◀

2.4 Graphs of homomorphisms

Let $\mathbb{G}$ and $\mathbb{H}$ be τ-structures and suppose that $\mathbb{H}$ is finite. We define two different kinds of graphs with vertex set $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$. The first notion has been heavily studied, from an algorithmic perspective, in the context of the so-called CSP reconfiguration problem (see [26] and the references therein) and, in the special cases when $\mathbb{G}$ and $\mathbb{H}$ are graphs also from an structural point of view [12]. We define $C(\mathbb{G}, \mathbb{H})$ as the (reflexive) graph with vertex set $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ such that for every $\phi, \psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$, ϕ and ψ are adjacent if and only if ϕ and ψ differ in at most one value, i.e., there exists at most one $x \in G$ such that $\phi(x) \neq \psi(x)$. More generally, for any $n \geq 1$ we can define $C_n(\mathbb{G}, \mathbb{H})$ on $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ by declaring ϕ and ψ adjacent if they differ in at most n values (in particular, $C(\mathbb{G}, \mathbb{H}) = C_1(\mathbb{G}, \mathbb{H})$).

A second notion of graph of homomorphisms appears in [34] and uses the notion of *links*. The **1-link** $\mathbb{L}$ (with signature τ) is the τ-structure with universe $\{0, 1\}$, where $R(\mathbb{L}) = \{0, 1\}^k$ for every k-ary $R \in \tau$. Define a (di)graph $L(\mathbb{G}, \mathbb{H})$ with vertex set $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ as follows: set $\phi \to \psi$ – i.e., a directed edge starting from ϕ and ending in ψ – if for any k-ary $R \in \tau$ and any $(x_1, \ldots, x_k) \in R(\mathbb{G})$, we have that $(\gamma_1(x_1), \ldots, \gamma_k(x_k)) \in R(\mathbb{H})$ whenever $\gamma_1, \ldots, \gamma_k \in \{\phi, \psi\}$. Alternatively, one can say that there ϕ and ψ are joined by a directed edge if there exists a homomorphism from $\mathbb{L}$ to $\mathbb{H}^{\mathbb{G}}$, the *$\mathbb{H}$th power of* $\mathbb{G}$ (see [34, Section 5.2]), mapping 0 to ϕ and 1 to ψ. Notice that the symmetry in the definition of 1-link implies that $L(\mathbb{G}, \mathbb{H})$ is, in fact, an undirected graph.

Clearly, $C_n(\mathbb{G}, \mathbb{H})$ is a subgraph of $C_{n+1}(\mathbb{G}, \mathbb{H})$. In contrast, $C_n(\mathbb{G}, \mathbb{H})$ and $L(\mathbb{G}, \mathbb{H})$ are not included in one another in general.

Note that there is a one-to-one correspondence between the elements in $\mathrm{Hom}(\mathbb{L} \times \mathbb{G}, \mathbb{H})$ and the edges of $L(\mathbb{G}, \mathbb{H})$. More generally, for $\ell \geq 1$ we define the **ℓ-link** $\mathbb{L}_\ell$ (with signature τ) as the τ-structure with universe $\{0, 1, \ldots, \ell\}$, where $R(\mathbb{L}_\ell) = \cup_{i=0}^{\ell-1} \{i, i+1\}^k$, for every k-ary $R \in \tau$. In other words, the ℓ-link is a sequence of 1-links with their endpoints identified. Then the following result is immediate:

▶ **Lemma 6.** *For every map $\phi : \{0, 1, \ldots, \ell\} \times G \to H$ and every $1 \leq i \leq \ell$, let $\phi(i) : G \to H$ be the map defined by $\phi(i)(x) \mapsto \phi(i, x)$ for $x \in G$. Then, $\phi \in \mathrm{Hom}(\mathbb{L}_\ell \times \mathbb{G}, \mathbb{H})$ if and only if $\phi(0), \ldots, \phi(\ell)$ is a walk in $L(\mathbb{G}, \mathbb{H})$.*

2.5 Mixing properties

Given τ-structure $\mathbb{G}$ and $\mathbb{H}$, it is useful to study properties in $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that allow us to *glue together* partially defined homomorphisms. This kind of properties are usually referred in the literature as *mixing properties* (e.g., see [8, 10]).

A natural mixing property is *irreducibility*. We say that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is **(V, W)-irreducible** for $V, W \subseteq G$, if for every $\phi, \psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$, there exists a map $\gamma \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that agrees with ϕ on V and agrees with ψ on W.

Given $g \geq 0$, we say that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is **strongly irreducible with gap g** if for every V, W such that $\mathrm{dist}(V, W) \geq g$ and for all $\phi, \psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$, there exists $\gamma \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that agrees with ϕ on V and agrees with ψ on W. We say that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is **strongly irreducible** if it is strongly irreducible with gap g for some g.

A strengthening of strong irreducibility is the following property, introduced in [7]. Given $g \geq 0$, we say that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is **topologically strong spatial mixing (TSSM) with gap** g if for every $V, W, S \subseteq G$ such that $\mathrm{dist}(V, W) \geq g$ and for all $\phi, \psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that agree on S, there exists $\gamma \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ that agrees with ϕ on $V \cup S$ and agrees with ψ on $S \cup W$. We say that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is **topologically strong spatial mixing** if it is TSSM with gap g for some g.

Clearly, $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is TSSM only if $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is strongly irreducible but not viceversa (see [7, 8] for some counterexamples).

An antithesis of having good mixing properties is the existence of configurations which are *frozen*. We say that $\phi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is a **frozen configuration** if for any cofinite set $U \subseteq G$, the only homomorphism $\psi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H})$ such that $\psi|_U = \phi|_U$ is $\psi = \phi$ itself.

3 Dismantlability, Connectivity, and Irreducibility

In this section we present our main theorem, which characterizes in several ways a special class of relational structures. This theorem generalizes some of the equivalences characterizing *dismantlable graphs* that appear in [12, Theorem 4.1] – which were developed only for the case of graphs – to arbitrary relational structures.

3.1 The case of graphs

The following theorem is a rephrasing of the equivalences that appear in [12, Theorem 4.1] which are relevant to us. We will use this as a prototypical example of the kind of results that we are aiming for, where we split the properties in 3 main categories (A) dismantlability, (B) connectedness, and (C) mixing.

▶ **Theorem 7** ([12, Theorem 4.1]). *Let $\mathbb{H}$ be a graph. The following are equivalent:*

(A) *$\mathbb{H}$ is dismantlable;*

(B) *$C(\mathbb{G}, \mathbb{H})$ is connected for every locally finite graph $\mathbb{G}$;*

(C) *there exists $g \geq 0$ such that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is strongly irreducible with gap g for every graph $\mathbb{G}$.*

▶ **Lemma 8.** *A graph $\mathbb{H}$ is dismantlable if and only if $\mathbb{H}^2$ dismantles to a substructure of its diagonal.*

Proof. This follows from our own results. In Theorem 10, we prove that, for a finite τ-structure $\mathbb{H}$, we have that $\mathbb{H}^2$ dismantles to a substructure of its diagonal if and only if there exists $g \geq 0$ such that $\mathrm{Hom}(\mathbb{G}, \mathbb{H})$ is strongly irreducible with gap g for all τ-structures $\mathbb{G}$. In particular, this applies if $\tau = \{E\}$, the usual binary relation of adjacency in graphs. Therefore, by Theorem 7, these two properties are also equivalent to $\mathbb{H}$ being dismantlable, and we conclude. ◀

In other words, thanks to Lemma 8, at least in the realm of graphs, we can freely replace "dismantlable" by "the square dismantles to a substructure of its diagonal", which will be the relevant class of general relational structures in this work.

▶ Remark 9. It is important to notice that the equivalence between "dismantlable" and "the square dismantles to a substructure of its diagonal" is not true for general relational structures. For example, given $\tau = \{R\}$ for R a binary relation symbol, we can take $\mathbb{H}$ such that $H = \{0, 1\}$ and $R(\mathbb{H}) = \{(0, 1)\}$. Then, $\mathbb{H}$ is not dismantlable, but $\mathbb{H}^2$ dismantles to its diagonal.

3.2 Main Theorem

The following theorem shows that different dismantling, connectedness, and mixing notions are equivalent. It can be seen as a generalization of Theorem 7 to relational structures.

▶ **Theorem 10.** *Let $\mathbb{H}$ be a finite τ-structure with universe H. Then the following are equivalent:*

(A1s) *$\mathbb{H}$ dismantles to a structure $\mathbb{I}$ such that $\mathbb{I}^2$ dismantles to its diagonal;*

(A2s) *$\mathbb{H}^2$ dismantles to a substructure of its diagonal;*

(B1s) *$C(\mathbb{G},\mathbb{H})$ is connected for every locally finite τ-structure $\mathbb{G}$;*

(B2s) *there exists some $n \geq 1$ such that $C_n(\mathbb{G},\mathbb{H})$ is connected for every finite τ-structure $\mathbb{G}$;*

(B3s) *$C(\mathbb{L}\times\mathbb{H}^2,\mathbb{H})$ is connected;*

(B4s) *$L(\mathbb{G},\mathbb{H})$ is connected for every finite τ-structure $\mathbb{G}$;*

(B5s) *the projections π_1 and π_2 are connected in $L(\mathbb{H}^2,\mathbb{H})$;*

(C1s) *there exists $g \geq 0$, such that $\mathrm{Hom}(\mathbb{G},\mathbb{H})$ is strongly irreducible with parameter g for every τ-structure $\mathbb{G}$; and*

(C2s) *there exists $g \geq 0$, such that $\mathrm{Hom}(\mathbb{T}_{\mathbb{H}^2},\mathbb{H})$ is $(\{x\},W)$-mixing with parameter g, for all $x \in T_{\mathbb{H}^2}$ and $W \subseteq T_{\mathbb{H}^2}$.*

The proof of Theorem 10 can be found in the full version. Indeed, we prove a more general version of it which will allow us to derive the applications contained in the rest of the paper. Although due to space restrictions we cannot state the theorem in its more general form we believe is interesting in its own. In particular, it is motivated by the fact that, sometimes, it is natural – particularly in the context of statistical physics – to work by forcing a certain subset of particles to take each of them a particular spin and work with the remaining ones. For example, this is a common scenario when the particles in the boundary of a given set in a lattice are fixed to take particular spins and we want to study the distribution of spins in the interior of the set, conditioned on such boundary configuration. These ideas inspired the most general version, which can be regarded as the study of *boundary long range actions*, i.e., long range action phenomena where some boundary configuration is fixed, very similar to the concept of *boundary phase transition* in relation to phase transitions (e.g., see [38]).

4 First application: Gibbs measures and mixing conditions

4.1 Basic definitions

Given a finite τ-structure $\mathbb{H}$ with universe H, a **weight function** for $\mathbb{H}$ is a map $\lambda : H \to \mathbb{R}^+$.

Let $\mathbb{G}$ be a locally finite τ-structure. If $V \subseteq G$ is a finite set and $\phi \in \mathrm{Hom}(\mathbb{G},\mathbb{H})$, we define $\mathbb{P}_{V,\phi}$ to be the probability measure on $\mathrm{Hom}(\mathbb{G},\mathbb{H})$ given by

$$\mathbb{P}_{V,\phi}(\{\psi\}) := \begin{cases} Z_{V,\phi}(\lambda)^{-1}\prod_{x\in V}\lambda(\psi(x)) & \text{if } \psi|_V\, \phi|_{G\setminus V} \in \mathrm{Hom}(\mathbb{G},\mathbb{H}), \\ 0 & \text{otherwise,} \end{cases}$$

for $\psi \in \mathrm{Hom}(\mathbb{G},\mathbb{H})$, where $\psi|_V\, \phi|_{G\setminus V}$ is the map that coincides with ψ in V and with ϕ in $G \setminus V$, and $Z_{V,\phi}(\lambda)$ is a normalization constant – the *partition function* – defined as

$$Z_{V,\phi}(\lambda) := \sum_{\substack{\psi\in\mathrm{Hom}(\mathbb{G},\mathbb{H}) \\ \psi|_V\,\phi|_{G\setminus V}\in\mathrm{Hom}(\mathbb{G},\mathbb{H})}} \prod_{x\in V}\lambda(\psi(x)).$$

We will call the collection of probability measures $\{\mathbb{P}_{V,\phi}\}$, the **Gibbs** $(\mathbb{G},\mathbb{H},\lambda)$**-specification**. The **boundary** of a set $V \subseteq G$, denoted by ∂V, is defined as the set of elements in G at distance exactly 1 from V. Notice that $\mathbb{P}_{V,\phi}$ depends exclusively on $\phi|_{\partial V}$. Now, consider events of the form

$$A(\phi, V) = \{\psi \in \mathrm{Hom}(\mathbb{G},\mathbb{H}) : \psi|_V = \phi|_V\}.$$

Next, consider the σ-algebra $\mathcal{F}$ generated by all events of the form $A(\phi, V)$ for V finite, and define $\mathcal{M}(\mathbb{G},\mathbb{H})$ to be the set of probability measures on $(\mathrm{Hom}(\mathbb{G},\mathbb{H}),\mathcal{F})$.

A measure $\mu \in \mathcal{M}(\mathbb{G},\mathbb{H})$ is a **Gibbs measure** for the Gibbs $(\mathbb{G},\mathbb{H},\lambda)$-specification if for any finite $V \subseteq G$ and for all $\phi_1 \in \mathrm{Hom}(\mathbb{G},\mathbb{H})$,

$$\mu\left(A(\phi_1, V) | A(\phi_2, G \setminus V)\right) = \mathbb{P}_{V,\phi_2}\left(\{\phi_1\}\right) \text{ for } \mu\text{-a.e. } \phi_2 \in \mathrm{Hom}(\mathbb{G},\mathbb{H}).$$

In other words, the probability distribution of a random ϕ_1 inside a finite V conditioned on its values outside V to coincide with those of ϕ_2, depends only on the values of $\phi_1|_V$ and on the boundary, $\phi_2|_{\partial V}$. Furthermore, the conditional distribution is the same as for $\mathbb{P}_{V,\phi_2}$ (see also [12, Definition 2.1]).

If $\mathrm{Hom}(\mathbb{G},\mathbb{H}) \neq \emptyset$, then there always exists at least one Gibbs measure [25, Chapter 4]. A fundamental question in statistical physics is whether there exists a unique Gibbs measure or multiple for a given Gibbs $(\mathbb{G},\mathbb{H},\lambda)$-specification.

4.2 Non-uniqueness and spatial mixing properties

In [12], it is shown that if $\mathbb{H}$ is a graph and it is dismantlable (or equivalently, by Lemma 8, its square dismantles to a subgraph of its diagonal), then, for any locally finite graph $\mathbb{G}$, there exists some λ such that there is a unique Gibbs measure [12, Theorem 7.2]. Conversely, in [12] it is also proven that if $\mathbb{H}$ is a non-dismantlable graph, then there exists $\mathbb{G}$ such that for any λ there exists multiple Gibbs measures [12, Theorem 8.2].

Here, following a similar path, we show that when extending this question to arbitrary relational structures, the first implication does not remain true in general, but the second still holds. More exactly,

▶ **Proposition 11.** *There exists a finite τ-structure $\mathbb{H}$ such that $\mathbb{H}^2$ dismantles to a substructure of its diagonal and a locally finite τ-structure $\mathbb{G}$ such that for any λ there exists multiple Gibbs measures for the Gibbs $(\mathbb{G},\mathbb{H},\lambda)$-specification. Moreover, $\mathbb{H}$ can be chosen so that $\mathbb{H}^2$ dismantles to its full diagonal $\Delta(\mathbb{H}^2)$.*

▶ **Proposition 12.** *Let $\mathbb{H}$ be a finite τ-structure. If $\mathbb{H}^2$ does not dismantle to a substructure of $\Delta(\mathbb{H}^2)$, then there exists a locally finite τ-structure $\mathbb{G}$ such that for any λ there exists multiple Gibbs measures for the Gibbs $(\mathbb{G},\mathbb{H},\lambda)$-specification.*

In what follows we introduce some *spatial mixing* properties related to our results.

▶ **Definition 13.** *Given $J \subseteq H$, we say that a Gibbs $(\mathbb{G},\mathbb{H},\lambda)$-specification satisfies* ***spatial J-mixing (J-SM)*** *if there exists constants $C, \alpha > 0$ such that for all $\phi_1, \phi_2 \in \mathrm{Hom}(\mathbb{G},\mathbb{H})$, for all finite $V \subseteq G$, and for all $x \in V$ and $a \in H$,*

$$|\mathbb{P}_{V,\phi_1}(\{\psi(x) = a\}) - \mathbb{P}_{V,\phi_2}(\{\psi(x) = a\})| \leq C \cdot \exp(-\alpha \cdot \mathrm{dist}(x, D_V^J(\phi_1,\phi_2))), \tag{1}$$

where

$$D_V^J(\phi_1,\phi_2) = \{x \in \partial V : (\phi_1(x),\phi_2(x)) \in H^2 \setminus \Delta(J^2)\}$$

and $\{\psi(x) = a\}$ refers to the event that a random ψ takes the value a at x.

The definition of J-SM unifies and interpolates two well-known properties. If $J = \emptyset$, then $D_V^{\emptyset}(\phi_1, \phi_2) = \partial V$ and Eq. (1) corresponds to the definition of **weak spatial mixing (WSM)**, i.e., $\emptyset$-SM. On the other hand, if $J = H$, then $D_V^{H}(\phi_1, \phi_2) = \{x \in \partial V : \phi_1(x) \neq \phi_2(x)\}$ and Eq. (1) corresponds to the definition of **strong spatial mixing (SSM)**, i.e., H-SM.

In general, spatial mixing properties are forms of *correlation decay* that have been of interest because of their many applications. On the one hand, WSM is related with uniqueness of Gibbs measures and the absence of phase transitions [21]. On the other hand, SSM is a strengthening of WSM and it is related to the absence of *boundary phase transitions* [38], and has connections with the existence of FPTAS for #P-hard counting problems [3, 43], mixing time of Glauber dynamics [21], and efficient approximation algorithms for thermodynamic quantities [24, 7].

In [8], there were explored sufficient and necessary conditions for a graph $\mathbb{H}$ to have, for any locally finite graph $\mathbb{G}$, the existence of a weight function λ such that the Gibbs $(\mathbb{G}, \mathbb{H}, \lambda)$-specification satisfies WSM and SSM. In particular, it was proven that dismantlability was equivalent to the existence of Gibbs $(\mathbb{G}, \mathbb{H}, \lambda)$-specifications satisfying WSM for all locally finite graph $\mathbb{G}$, and therefore uniqueness, since WSM implies it. In addition, it was observed that a direct consequence is that a necessary condition for SSM to hold is that $\mathbb{H}$ is dismantlable, because SSM implies WSM. However, it was also shown that it is not a sufficient condition. Here, we strengthen this necessary condition and extend it to the realm of relational structures.

▶ **Proposition 14.** *If $\mathbb{H}^2$ does not dismantle to a substructure of $\Delta(\mathbb{H}^2)$ whose universe contains $\Delta(J^2)$, then there exists a locally finite τ-structure $\mathbb{G}$ such that the Gibbs $(\mathbb{G}, \mathbb{H}, \lambda)$-specification does not satisfy J-SM for any λ.*

Two direct corollaries of this fact are the following.

▶ **Corollary 15.** *If $\mathbb{H}^2$ does not dismantle to some substructure of the diagonal $\Delta(\mathbb{H}^2)$, then there exists a locally finite τ-structure $\mathbb{G}$ such that the Gibbs $(\mathbb{G}, \mathbb{H}, \lambda)$-specification does not satisfy WSM for any λ.*

▶ **Corollary 16.** *If $\mathbb{H}^2$ does not dismantle to the full diagonal $\Delta(\mathbb{H}^2)$, then there exists a locally finite τ-structure $\mathbb{G}$ such that the Gibbs $(\mathbb{G}, \mathbb{H}, \lambda)$-specification does not satisfy SSM for any λ.*

5 Second application: finite duality revisited

Throughout this section all relational structures are assumed to be finite. We say a τ-structure $\mathbb{H}$ is a **core** if every homomorphism from $\mathbb{H}$ to $\mathbb{H}$ is one-to-one. An **obstruction** to $\mathbb{H}$ is a τ-structure $\mathbb{G}$ that admits no homomorphism to $\mathbb{H}$; the obstruction $\mathbb{G}$ is **critical** if every *proper* substructure (i.e., any substructure different from $\mathbb{G}$ itself) admits a homomorphism to $\mathbb{H}$. A relational structure $\mathbb{H}$ is said to have **finite duality** if it has only finitely many critical obstructions.

We say that a τ-structure $\mathbb{H}$ **contains all constants** if for every $a \in H$ there exists $R_a \in \tau$ such that $R_a(\mathbb{H}) = \{a\}$. Note that every such τ-structure is a core. It is well know that relational structures with constants allow us to specify the desired image of a given element. More formally, let $\mathbb{G}$ be any τ-structure, $x \in G$, and $a \in H$. It is immediate that the τ-structure $\mathbb{G}_a$ obtained from $\mathbb{G}$ by adding a to $R_a(\mathbb{G})$, satisfies the following property: For every $\phi : G \to H$,

$$\phi \in \mathrm{Hom}(\mathbb{G}_a, \mathbb{H}) \Leftrightarrow \phi \in \mathrm{Hom}(\mathbb{G}, \mathbb{H}) \text{ and } \phi(x) = a.$$

We shall say that $\mathbb{G}_a$ is obtained by *coloring x to a* in $\mathbb{G}$.

The main result in [34] states that a core relational structure $\mathbb{H}$ has finite duality if and only if $\mathbb{H}^2$ dismantles to its diagonal. It is not difficult ot see that this result follows from our work. In addition, in can be shown that, when $\mathbb{H}$ contains all constants, having finite duality is equivalent to having finitely many critical τ-tree obstructions, which was not previously known.

▶ **Theorem 17.** *Let $\mathbb{H}$ be a finite τ-structure which is a core. Then, the following are equivalent:*
(A1c) *$\mathbb{H}^2$ dismantles to its diagonal;*
(D1c) *$\mathbb{H}$ has finitely many critical obstructions.*

Furthermore, if $\mathbb{H}$ contains all the constants then the following condition is also equivalent:
(D2c) *$\mathbb{H}$ has finitely many critical τ-tree obstructions.*

It has been shown in [23] that if a τ-structure $\mathbb{H}$ has finite duality then there exists some finite set $\mathcal{F}$ of τ-trees such that for every τ-structure $\mathbb{I}$ not homomorphic to $\mathbb{H}$, there exists a τ-tree in $\mathcal{F}$ that is homomorphic to $\mathbb{I}$ but not homomorphic to $\mathbb{H}$. We want to note that the equivalence between conditions $(D2c)$ and $(D1c)$ does not follow from this fact. Indeed, direction $(D2c) \Rightarrow (D1c)$ does not even hold when we do not require that the τ-structure $\mathbb{H}$ is equipped with constants as witnessed by the case when $\mathbb{H}$ is the oriented 3-cycle. Note that, in this case, $\mathbb{H}$ satisfies $(D2c)$ since every τ-tree is homomorphic to $\mathbb{H}$ and, hence, $\mathbb{H}$ has no critical τ-tree obstructions at all. However, since any oriented cycle whose length is not a multiple of 3 is a critical obstruction of $\mathbb{H}$, it follows that $\mathbb{H}$ does not satisfy $(D1c)$.

Abstract

The communication class $\mathbf{UPP}^{\mathrm{cc}}$ is a communication analog of the Turing Machine complexity class $\mathbf{PP}$. It is characterized by a matrix-analytic complexity measure called sign-rank (also called dimension complexity), and is essentially the most powerful communication class against which we know how to prove lower bounds.

For a communication problem f, let $f \wedge f$ denote the function that evaluates f on two disjoint inputs and outputs the AND of the results. We exhibit a communication problem f with $\mathbf{UPP}^{\mathrm{cc}}(f) = O(\log n)$, and $\mathbf{UPP}^{\mathrm{cc}}(f \wedge f) = \Theta(\log^2 n)$. This is the first result showing that $\mathbf{UPP}$ communication complexity can increase by more than a constant factor under intersection. We view this as a first step toward showing that $\mathbf{UPP}^{\mathrm{cc}}$, the class of problems with polylogarithmic-cost $\mathbf{UPP}$ communication protocols, is not closed under intersection.

Our result shows that the function class consisting of intersections of two majorities on n bits has dimension complexity $n^{\Omega(\log n)}$. This matches an upper bound of (Klivans, O'Donnell, and Servedio, FOCS 2002), who used it to give a quasipolynomial time algorithm for PAC learning intersections of polylogarithmically many majorities. Hence, fundamentally new techniques will be needed to learn this class of functions in polynomial time.

1 Introduction

The unbounded-error communication complexity model $\mathbf{UPP}^{\mathrm{cc}}$ was introduced by Paturi and Simon [21] as a natural communication analog of the Turing Machine complexity class $\mathbf{PP}$. In a $\mathbf{UPP}^{\mathrm{cc}}$ communication protocol for a Boolean function $f(x, y)$, there are two parties, one with input x and one with input y. The two parties engage in a private-coin randomized communication protocol, at the end of which they are required to output $f(x, y)$ with probability strictly greater than $1/2$. The cost of the protocol is the number of bits exchanged by the two parties. As is standard, we use the notation $\mathbf{UPP}^{\mathrm{cc}}$ not only to denote the communication model, but also the class of functions solvable in the model by protocols of cost polylogarithmic in the size of the input.

Observe that success probability $1/2$ can be achieved with no communication by random guessing, so the $\mathbf{UPP}^{\mathrm{cc}}$ model merely requires a strict improvement over this trivial solution.

Owing to this liberal acceptance criterion, $\mathbf{UPP}^{\mathrm{cc}}$ is a very powerful communication model, essentially the most powerful one against which we know how to prove lower bounds. In particular, $\mathbf{UPP}^{\mathrm{cc}}$ is powerful enough to simulate many other models of computing, and this makes $\mathbf{UPP}^{\mathrm{cc}}$ *lower bounds* highly useful. As one example, any function $f(x, y)$ computable by a Threshold-of-Majority circuit of size s has $\mathbf{UPP}^{\mathrm{cc}}$ complexity at most $O(\log s)$, and this connection has been used to translate $\mathbf{UPP}^{\mathrm{cc}}$ lower bounds into state of the art lower bounds against threshold circuits (see, for example, [10, 22, 8, 28, 6]).

$\mathbf{UPP}^{\mathrm{cc}}$ also happens to be characterized by a natural matrix-analytic complexity measure called *sign-rank* [21]. Here, the sign-rank of a matrix $M \in \{-1, 1\}^{N \times N}$ is the minimum rank of a real matrix whose entries agree in sign with M. Equivalently, $\mathrm{sr}(M) := \min_A \mathrm{rk}(A)$, where the minimum is over all matrices A such that $A_{i,j} \cdot M_{i,j} > 0$ for all $i, j \in [N]$. Paturi and Simon [21] showed the following tight connection between $\mathbf{UPP}^{\mathrm{cc}}$ and sign-rank: if we associate a function $f(x, y)$ with the matrix $M = [f(x, y)]_{x,y}$, then the $\mathbf{UPP}^{\mathrm{cc}}$ communication complexity of f equals $\log(\mathrm{sr}(M)) \pm \Theta(1)$.

While lower bounds on $\mathbf{UPP}^{\mathrm{cc}}$ complexity (equivalently, sign-rank) are useful in complexity theory, *upper bounds* on these quantities imply state of the art learning algorithms, including the fastest known algorithms for PAC learning DNFs and read-once formulas [17, 1]. More specifically, suppose we want to learn a concept class $\mathcal{C}$ of functions mapping $\{-1, 1\}^n$ to $\{-1, 1\}$. $\mathcal{C}$ is naturally associated with a $|\mathcal{C}| \times 2^n$ matrix M, whose ith row equals the truth table of the ith function in $\mathcal{C}$. Then $\mathcal{C}$ can be distribution-independently PAC learned in time polynomial in the sign-rank of M. (The sign-rank of M is often referred to in the learning theory literature as the *dimension complexity* of $\mathcal{C}$.) Moreover, the resulting learning algorithm is robust to random classification noise, a property not satisfied by the handful of known PAC learning algorithms that are *not* based on dimension complexity.

For the purpose of our work, one particularly important application of the dimension-complexity approach to PAC learning was derived by Klivans et al. [16], who showed that the concept class consisting of intersections of 2 majority functions has dimension complexity at most $\binom{n}{O(\log n)} \leq n^{O(\log n)}$. They thereby obtained a quasipolynomial time algorithm for PAC learning intersections of two majority functions.[1] Prior to our work, it was consistent with current knowledge that the dimension complexity of this concept class is in fact $\mathrm{poly}(n)$, which would yield a polynomial time PAC learning algorithm for intersections of constantly many majority functions.

1.1 Our Results

Despite considerable effort, progress on understanding sign-rank (equivalently, $\mathbf{UPP}^{\mathrm{cc}}$) has been slow. Our lack of knowledge is highlighted via the following well-known open question (cf. Göös et al. [13]). Throughout, for any function $f\colon \{-1, 1\}^n \to \{-1, 1\}$, $f \wedge f$ denotes the function on twice as many inputs obtained by evaluating f on two disjoint inputs and outputting -1 only if both copies of f evaluate to -1, i.e., $(f \wedge f)(x_1, x_2) := f(x_1) \wedge f(x_2)$.

▶ **Question 1.** *Is the class* $\mathbf{UPP}^{cc}$ *closed under intersection? In other words, suppose the function* $f(x, y)\colon \{-1, 1\}^n \times \{-1, 1\}^n \to \{-1, 1\}$ *satisfies* $\mathbf{UPP}^{cc}(f) = O((\log n)^c)$ *for some constant* c*. Is there always some constant* c_1 *(which may depend on* c*) such that* $\mathbf{UPP}(f \wedge f) \leq O\left((\log n)^{c_1}\right)$*? More generally and informally, if* $\mathbf{UPP}^{cc}(f)$ *is "small", does this imply any non-trivial upper bound on* $\mathbf{UPP}^{cc}(f \wedge f)$*?*

[1] In fact, their algorithm runs in quasipolynomial time for intersections of polylogarithmic many majorities.

Prior to our work, essentially nothing was known about Question 1. In particular, we are not aware of prior work ruling out the possibility that $\mathbf{UPP}^{\mathrm{cc}}(f \wedge f) \leq O(\mathbf{UPP}^{\mathrm{cc}}(f))$. On the other hand, for reasons that will become apparent in Section 1.2, there is good reason to suspect that there exists a function f with $\mathbf{UPP}^{\mathrm{cc}}(f) = O(\log n)$, yet $\mathbf{UPP}^{\mathrm{cc}}(f \wedge f) \geq \Omega(n)$. While we do not obtain a full resolution of Question 1, we do show for the first time that $\mathbf{UPP}^{\mathrm{cc}}$ complexity can increase significantly under intersection.

Babai, Frankl and Simon [2] observed that there are two natural communication complexity analogs of the Turing machine class $\mathbf{PP}$, namely $\mathbf{PP}^{\mathrm{cc}}$ and $\mathbf{UPP}^{\mathrm{cc}}$. It is well known [3] that $\mathbf{PP}^{\mathrm{cc}}$ *is* closed under intersection. Our work can be viewed as a first step towards showing that, in contrast, $\mathbf{UPP}^{\mathrm{cc}}$ is *not* closed under intersection.

▶ **Theorem 1.** *There is a function* $f(x, y)\colon \{-1,1\}^n \times \{-1,1\}^n \to \{-1,1\}$ *such that* $\mathbf{UPP}^{cc}(f) = O(\log n)$*, yet* $\mathbf{UPP}^{cc}(f \wedge f) = \Theta(\log^2 n)$*.*

In fact, for each fixed $x \in \{-1,1\}^n$, the function $f(x, y)$ from Theorem 1 simply outputs the majority of some subset of the bits of y. This yields the following corollary.

▶ **Corollary 2.** *Let* $\mathcal{C}$ *be the concept class in which each concept is the intersection of two majorities on* n *bits. Then* $\mathcal{C}$ *has dimension complexity* $n^{\Theta(\log n)}$*.*

Corollary 2 shows that the dimension complexity upper bound of Klivans et al. [16] is tight for intersections of two majorities, and new approaches will be needed to PAC learn this concept class in polynomial time. For context, we remark that learning intersections of majorities is a special case of the more general problem of learning intersections of many *halfspaces*.[2] The latter is a central and well-studied challenge in learning theory, as intersections of halfspaces are powerful enough to represent any convex set, and they contain many basic problems (like learning DNFs) as special cases. In contrast to the well-understood problem of learning a single halfspace, for which many efficient algorithms are known, no $2^{o(n)}$-time algorithm is known for PAC learning even the intersection of two halfspaces. There have been considerable efforts devoted to showing that learning intersections of halfspaces is a hard problem [18, 9, 15, 4], but these results apply only to intersections of many halfspaces, or make assumptions about the form of the output hypothesis of the learner. Our work can be seen as a new form of evidence that learning intersections of even two majorities is hard.

1.2 Our Techniques

$\mathbf{UPP}^{\mathrm{cc}}$ has a *query complexity* analog, denoted $\mathbf{UPP}^{\mathrm{dt}}$ and defined as follows. A $\mathbf{UPP}^{\mathrm{dt}}$ algorithm is a randomized algorithm which on input x, queries bits of x, and must output $f(x)$ with probability strictly greater than $1/2$; the cost of the protocol is the number of bits of x queried. How $\mathbf{UPP}^{\mathrm{dt}}$ behaves under intersection is now well understood. More specifically, it is known [25] that there is a function $f\colon \{-1,1\}^n \to \{-1,1\}$ (in fact, a halfspace) such that $\mathbf{UPP}^{\mathrm{dt}}(f) = O(1)$, yet $\mathbf{UPP}^{\mathrm{dt}}(f \wedge f) = \Theta(n)$. Define the Majority function, which we denote by MAJ, to be -1 if at least half of its input bits are -1. It is also known [26, 20] that MAJ satisfies $\mathbf{UPP}^{\mathrm{dt}}(\mathrm{MAJ}) = O(1)$, yet $\mathbf{UPP}^{\mathrm{dt}}(\mathrm{MAJ} \wedge \mathrm{MAJ}) = \Theta(\log n)$. Our goal in this paper is, to the extent possible, to show that the $\mathbf{UPP}^{\mathrm{cc}}$ communication model behaves similarly to its query complexity analog.

[2] A halfspace is any function of the form $\mathrm{sgn}\left(\sum_{i=1}^n w_i \cdot x_i + w_0\right)$ for some real numbers $w_0, \ldots, w_n$.

Over the course of the last decade, there has been considerable progress in proving *lifting theorems* [23, 12, 11]. These theorems seek to show that if a function f has large complexity in some query model $\mathbf{C}$, then for some "sufficiently complicated" function g on a "small" number of inputs, the composition $f \circ g$ has large complexity in the associated communication model (ideally, $\mathbf{C}^{\mathrm{cc}}(f \circ g) \gtrsim \mathbf{C}^{dt}(f)$).

Unfortunately, a "generic" lifting theorem for $\mathbf{UPP}$ complexity is not known. That is, it is not know how to take an arbitrary function f with high $\mathbf{UPP}^{\mathrm{dt}}$ complexity, and by composing it with a function g on a small number of inputs, yield a function with high $\mathbf{UPP}^{\mathrm{cc}}$ complexity.

However, as we now explain, some significant partial results have been shown in this direction. It is well-known that $\mathbf{UPP}^{\mathrm{dt}}(f)$ is equivalent to an approximation-theoretic notion called *threshold degree*, denoted $\deg_{\pm}(f)$ (which we do not define here). The threshold degree of f can in turn be expressed as the value of a certain (exponentially large) linear program. Linear programming duality then implies that one can prove lower bounds on $\deg_{\pm}(f)$ by exhibiting good solutions to the dual linear program. We refer to such dual solutions as *dual witnesses* for threshold degree. Sherstov [24] and Razborov and Sherstov [22] showed that if $\deg_{\pm}(f)$ is large, and moreover this can be exhibited by a dual witness satisfying a certain *smoothness* condition, then there is a function g defined on a constant number of inputs such that $f \circ g$ *does* have large $\mathbf{UPP}^{\mathrm{cc}}$ complexity. Several recent works [6, 5, 7, 28] have managed to prove new $\mathbf{UPP}^{\mathrm{cc}}$ lower bounds by constructing, for various functions f, smooth dual witnesses exhibiting the fact that $\deg_{\pm}(f)$ is large.

Our key technical contribution is to bring this approach to bear on the function $F(x, y) = \mathrm{MAJ}(x) \wedge \mathrm{MAJ}(y)$. Specifically, we show that the (known) threshold degree lower bound $\deg_{\pm}(F) \geq \Omega(\log n)$ can be exhibited by a smooth dual witness.

We do this as follows. Sherstov [26] showed that for any function $f\colon \{-1,1\}^n \to \{-1,1\}$, the threshold degree of the function $F = f \wedge f$ is characterized by the *rational* approximate degree of f, i.e., the least total degree of real polynomials p and q such that $|f(x) - p(x)/q(x)| \leq 1/3$ for all $x \in \{-1,1\}^n$. He then showed that the rational approximate degree of MAJ is $\Omega(\log n)$, thereby concluding that $F(x, y)$ has threshold degree $\Omega(\log n)$.

From Sherstov's arguments, one can derive a dual witness ψ for the fact that the rational approximate degree of MAJ is $\Omega(\log n)$, and then transform ψ into a dual witness ϕ for the fact that $F(x, y)$ has threshold degree $\Omega(\log n)$. Unfortunately, neither ψ nor ϕ satisfies the type of smoothness condition required by Razborov and Sherstov's machinery to yield $\mathbf{UPP}^{\mathrm{cc}}$ lower bounds.

The smoothness condition required for the Razborov-Sherstov machinery to work essentially states that the the mass of the dual witness ψ has to be "relatively large" (a reasonably large fraction of what mass the uniform distribution would have placed) on a "large" set of inputs (the fraction of inputs which do not have large mass has to be small).

To construct a *smooth* dual witness ψ' for F, our primary technical contribution is to construct a *smooth* dual witness ϕ' for the fact that the rational approximate degree of MAJ is $\Omega(\log n)$. We then apply a different transformation, due to Sherstov [27], of ϕ' into a dual witness for the fact that the threshold degree of F is $\Omega(\log n)$, and we show that this transformation *preserves the smoothness* of ψ'.

In a nutshell, our smooth dual witness for MAJ is obtained in two steps: first we define for all inputs x whose Hamming weight lies in $[n/2 - \lfloor n^{2/3} \rfloor, n/2 + \lfloor n^{2/3} \rfloor]$, a dual witness ϕ'_x that places a large mass on x and not too much mass on other points. Next, we define the final dual witness $\phi'(x)$ to be a certain weighted average over x of all the dual witnesses thus obtained. The resulting mass on $\phi'(x)$ for each x of Hamming weight

in $[n/2 - \lfloor n^{2/3} \rfloor, n/2 + \lfloor n^{2/3} \rfloor]$ is large enough, and the fraction of inputs whose Hamming weight is not in $[n/2 - \lfloor n^{2/3} \rfloor, n/2 + \lfloor n^{2/3} \rfloor]$ is small enough, to allow us to use the Razborov-Sherstov framework (Theorem 5) to prove the desired sign-rank lower bound on the pattern matrix of F.

2 Preliminaries

All logarithms in this paper are taken base 2. We use the notation $\exp(x)$ to denote e^x, where e is Euler's number. Given any finite set X and any functions $f, g : X \to \mathbb{R}$, define $\|f\|_1 := \sum_{x \in X} |f(x)|$ and $\langle f, g \rangle := \sum_{x \in X} f(x)g(x)$. We refer to $\|f\|_1$ as the ℓ_1-norm of f. For any $x \in \{-1,1\}^n$, we use the notation $|x|$ to denote the *Hamming weight* of x, which is the number of -1's in the string x.

Paturi and Simon [21] showed the following equivalence between the sign-rank of a matrix and the $\mathbf{UPP}^{\mathrm{cc}}$ cost of its corresponding communication game.

▶ **Theorem 3.** *For any $F : \{-1,1\}^{2n} \times \{-1,1\}^n \to \{-1,1\}$, let M_F denote its* communication matrix*, defined by $M_F(x,y) = F(x,y)$. Then, $\mathbf{UPP}^{cc}(F) = \log \mathrm{sr}(M_F) \pm O(1)$.*

Let n, N be positive integers such that n divides N. Partition the set $[N] := \{1, \ldots, N\}$ into n disjoint blocks $\{1, 2, \ldots, N/n\}, \{N/n + 1, \ldots, 2N/n\}, \ldots, \{(n-1)N/n + 1, \ldots, N\}$. Define the set $\mathcal{P}(N,n)$ to be the collection of subsets of $[N]$ which contain exactly one element from each block. For $x \in \{-1,1\}^n$ and $S \in \mathcal{P}(N,n)$, let $x|_S = (x_{s_1}, \ldots, x_{s_n})$, where $s_1 < s_2 < \cdots < s_n$ are the elements of S.

▶ **Definition 4** (Pattern matrix)**.** *For any function $\phi : \{-1,1\}^n \to \mathbb{R}$, the (N, n, ϕ)-pattern matrix M is defined as follows.*

$$M = [\phi(x|_S) \oplus w]_{x \in \{-1,1\}^N, (S,w) \in \mathcal{P}(N,n) \times \{-1,1\}^n}.$$

Note that M is a $2^N \times (N/n)^n 2^n$ matrix.

In a breakthrough result, Forster [10] proved that an upper bound on the spectral norm of a sign matrix implies a lower bound on its sign-rank. Razborov and Sherstov [22] established a generalization of Forster's theorem [10] that can be used to prove sign-rank lower bounds for pattern matrices. Specifically, we require the following result, implicit in their work [22, Theorem 1.1].

▶ **Theorem 5** (Implicit in [22])**.** *Let $f : \{-1,1\}^n \to \{-1,1\}$ be any Boolean function and $\alpha > 1$ be a real number. Suppose there exists a function $\phi : \{-1,1\}^n \to \mathbb{R}$ satisfying the following conditions.*

- $\sum_{x \in \{-1,1\}^n} |\phi(x)| = 1$.
- *For all polynomials p of degree at most d, $\sum_{x \in \{-1,1\}^n} \phi(x)p(x) = 0$.*
- $f(x) \cdot \phi(x) \geq 0 \ \forall x \in \{-1,1\}^n$.
- $|\phi(x)| \geq \gamma$ *for all but a Δ fraction of inputs $x \in \{-1,1\}^n$.*

Then, the sign-rank of the (N, n, f)-pattern matrix M can be bounded below as

$$\mathrm{sr}(M) \geq \frac{\gamma}{\frac{1}{2^n}\left(\frac{n}{N}\right)^{d/2} + \gamma\Delta}.$$

We require the following well-known combinatorial identity.

▷ Claim 6. For every polynomial p of degree less than $2n$, we have $\sum_{t=-n}^{n} (-1)^t \binom{2n}{n+t} p(t) = 0$.

Recall from Section 1.2 that the rational ϵ-approximate degree of f is the least degree of two polynomials p and q such that $|f(x) - p(x)/q(x)| \leq \epsilon$ for all x in the domain of f. Sherstov [27, Theorem 6.9] showed that a dual witness to the rational approximate degree of any function f can be converted to a threshold degree dual witness for $\mathrm{OR}_n \circ f$. Implicit in his theorem is the fact that a *smooth* dual witness to the rational approximate degree of f can be converted to a *smooth* dual witness for the threshold degree of $\mathrm{OR}_n \circ f$. More precisely, the following result is established by the proof of [27, Theorem 6.9].

▶ **Theorem 7** (Sherstov [27]). *Let $f : \{-1,1\}^n \to \{-1,1\}$ be any function. Let F denote $\mathrm{OR}_t \circ f : \{-1,1\}^{nt} \to \{-1,1\}$, and $\delta > \varepsilon > 0$ be any real numbers.*

Suppose there exist functions $\psi_0, \psi_1 \colon \{-1,1\}^n \to \mathbb{R}$ that are not identically 0 and satisfy the following properties:

$$f(x) = 1 \implies \psi_0(x) \geq \delta|\psi_1(x)|, \tag{1}$$

$$f(x) = -1 \implies \psi_1(x) \geq \delta|\psi_0(x)|, \tag{2}$$

$$\deg(p) < d \implies \langle \psi_0, p\rangle = 0 \text{ and } \langle \psi_1, p\rangle = 0. \tag{3}$$

Then there exist functions $A, B : \{-1,1\}^{nt} \to \mathbb{R}$ such that $\Psi = \frac{1}{\delta}A - \frac{1}{\varepsilon}B$ satisfies the following properties.

$$\deg(p) \leq \min\left\{\lfloor \varepsilon^2 t \rfloor d, d\right\} \implies \langle \Psi, p\rangle = 0. \tag{4}$$

$$F(x) \cdot \Psi(x_1, \ldots, x_t) \geq (\delta - \varepsilon)^{2t} \prod_{i=1}^{t} |\psi_0(x_i)| \text{ for all } x \in \{-1,1\}^{nt}. \tag{5}$$

$$|A(x_1, \ldots, x_t)| \leq \prod_{i=1}^{t} |\psi_0(x_i)| \text{ for all } x = (x_1, \ldots, x_t) \in \{-1,1\}^{nt}. \tag{6}$$

$$|B(x_1, \ldots, x_t)| \leq \prod_{i : f(x_i) = 0} |\psi_0(x_i)| \cdot \prod_{i : f(x_i) = 1} \delta\psi_1(x_i) + \prod_{i=1}^{t} (|\psi_0(x_i)| - \delta\psi_1(x_i))$$
$$\text{for all } x = (x_1, \ldots, x_t) \in \{-1,1\}^{nt}. \tag{7}$$

3 A Smooth Dual Witness for Majority

Our main technical contribution in this paper is captured in Theorem 8 below. This theorem constructs a *smooth* dual witness R for the hardness of rationally approximating the sign function on $\{0, \pm 1, \ldots, \pm n\}$. We defer the proof until Section 4.

▶ **Theorem 8.** *Let $1 \leq d \leq \frac{1}{3}\log n$ and let n be odd. There exists a function $R : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ such that*

- $$\sum_{t=-n}^{n} |R(t)| = 1. \tag{8}$$
- *For $\delta = \exp(-18/(n^{1/(6d)}))$ and every $t = 1, 2, \ldots, n$,*

  $$R(t) \geq \delta|R(-t)|. \tag{9}$$

- *If $p : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ is any polynomial of degree less than $d - 2$, then*

  $$\langle R, p\rangle = 0. \tag{10}$$

- *For every* $t \in \{0, \pm 1, \pm 2, \ldots, \pm\lfloor n^{2/3} \rfloor\}$ *we have*

$$|R(t)| \geq \Omega\left(\frac{1}{n^{20}}\right). \tag{11}$$

The following theorem shows how to convert the (univariate) function R from Theorem 8 into a dual witness for the (multivariate) MAJ function.

▶ **Theorem 9.** *Let* $1 \leq d \leq \frac{1}{3}\log n$ *and let* n *be odd. Let* $R : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ *be any function obtained in Theorem 8. Then, the multivariate polynomial* $R' : \{-1,1\}^{2n} \to \mathbb{R}$ *defined by* $R'(x) = R(n - |x|)/\binom{2n}{|x|}$ *satisfies the following properties.*

- $\|R'\|_1 = 1.$ (12)
- *For* $\delta = \exp(-18/(n^{1/(6d)}))$ *and every* $t = 1, 2, \ldots, n,$

$$R'(x) \geq \delta |R'(y)| \tag{13}$$

for any $x, y \in \{-1,1\}^{2n}$ *such that* $|x| = n - t, |y| = n + t.$
- *For any polynomial* p *of degree at most* $d - 2,$

$$\langle R', p \rangle = 0. \tag{14}$$

- *For all* $x \in \{-1,1\}^{2n}$ *such that* $n - \lfloor n^{2/3} \rfloor \leq |x| \leq n + \lfloor n^{2/3} \rfloor,$

$$|R'(x)| \geq \Omega\left(\frac{1}{n^{20} \cdot 2^{2n}}\right). \tag{15}$$

Proof. To establish Equation (12), observe:

$$\begin{aligned}\|R'\|_1 &= \sum_{x \in \{-1,1\}^{2n}} |R'(x)| = \sum_{t=0}^{2n} \left(\sum_{x \in \{-1,1\}^{2n} : |x| = t} |R'(x)| \right) \\ &= \sum_{t=0}^{2n} \binom{2n}{t} |R(n-t)| / \binom{2n}{t} = \sum_{t=-n}^{n} |R(t)| = 1,\end{aligned}$$

where the last equality follows from Equation (8). Equation (13) follows directly from Equation (9) and the definition of R'.

To establish Equation (14), consider any polynomial $p : \{-1,1\}^{2n} \to \mathbb{R}$ of degree at most $d - 2$. For any permutation $\sigma \in S_{2n}$, define the polynomial p_σ by $p_\sigma(x_1, \ldots, x_{2n}) = p(x_{\sigma(1)}, \ldots, x_{\sigma(2n)})$. Note that, since R' is symmetric, $\langle R', p_\sigma \rangle = \langle R', p \rangle$ for all $\sigma \in S_{2n}$. Define $q = \mathbb{E}_{\sigma \in S_{2n}}[p_\sigma]$. Note that q is symmetric and $\langle R', p \rangle = \langle R', q \rangle$. It is a well-known fact (cf. [19]) that q can be written as a polynomial q' of degree at most $d - 2$ in the variable $\sum_{i=1}^{2n} x_i$, and so can R'. Hence, $\langle R', p \rangle = \langle R', q \rangle = \sum_{t=0}^{2n} \binom{2n}{t} \frac{R(n-t)}{\binom{2n}{t}} \cdot q'(t) = 0$, where the final equality holds by Equation (10).

To establish Equation (15), observe that by Equation (11) and the definition of R', we have that for all $x \in \{-1,1\}^{2n}$ such that $|x| \in \left[n - \lfloor n^{2/3} \rfloor, n + \lfloor n^{2/3} \rfloor\right]$, $|R'(x)| \geq \Omega\left(\frac{1}{n^{20} \cdot \binom{2n}{|x|}}\right) \geq \Omega\left(\frac{1}{n^{20} \cdot 2^{2n}}\right).$ ◀

We are ready to derive a lower bound on the sign-rank of the $(4n^2, 4n, \mathrm{OR}_2 \circ \mathrm{MAJ}_{2n})$-pattern matrix.

▶ **Theorem 10.** *The* $(4n^2, 4n, \mathrm{OR}_2 \circ MAJ_{2n})$*-pattern matrix* M *satisfies* $\mathrm{sr}(M) \geq n^{\Omega(\log n)}.$

Proof. Let F denote the function $\mathrm{OR}_2 \circ \mathrm{MAJ}_{2n}$ in this proof. Set $d = \log n/100$ and consider the function $R : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ obtained via Theorem 8. Define the function $R' : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ by $R'(t) = R(-t)$. Define the functions $\psi_0, \psi_1 : \{-1,1\}^{2n} \to \mathbb{R}$ by $\psi_1(x) = R(n - |x|)/\binom{2n}{|x|}$, and $\psi_0(x) = R'(n - |x|)/\binom{2n}{|x|}$. We now verify that ψ_0, ψ_1 satisfy the conditions in Theorem 7 for $\delta = \exp(-18/(n^{1/(6d)})) = \exp(-18/n^{100/6 \log n}) = \exp(-18/2^{100/6}) > 0.99$. Set $\varepsilon = \delta \cdot c$, where $c > 0$ is a constant such that $0.98 > \delta \cdot c > 1/\sqrt{2}$.

- By the definitions of ψ_0, ψ_1 and Equation (13), Properties (1) and (2) in the statement of Theorem 7 are satisfied.
- Equation (14) implies that $\langle \psi_0, p \rangle = \langle \psi_1, p \rangle = 0$ for any polynomial p of degree at most $d - 2$, and hence Property (3) is satisfied.

Moreover, Equation (15) implies that $|\psi_0(x)|, |\psi_1(x)| \geq \Omega\left(\frac{1}{n^{20} \cdot 2^{2n}}\right)$ for all $x \in \{-1,1\}^{2n}$ such that $n - \lfloor n^{2/3} \rfloor \leq |x| \leq n + \lfloor n^{2/3} \rfloor$, and Equation (12) implies $\|\psi_0\|_1 = \|\psi_1\|_1 = 1$. Theorem 7 now implies the existence of a function Ψ satisfying the following properties.

- By Equation (4), $\deg(p) < \min\left\{\lfloor 2\varepsilon^2 \rfloor \cdot ((\log n)/100 - 2), (\log n)/100 - 2\right\} \implies \langle \Psi, p \rangle = 0$. Since $\varepsilon > 1/\sqrt{2}$, this implies that

$$\deg(p) < (\log n)/100 - 2 \implies \langle \Psi, p \rangle = 0.$$

- By Equation (5), $\Psi(x) \cdot F(x) \geq 0$ for all $x \in \{-1,1\}^{2n} \times \{-1,1\}^{2n}$.
- We now note that the functions A and B obtained in Theorem 7 have ℓ_1-norm at most a constant. Since $\|\psi_0\|_1 = \|\psi\|_1 = 1$, we use Equation (6) to conclude that

$$\sum_{x_1, x_2 \in \{-1,1\}^{2n} \times \{-1,1\}^{2n}} |A(x_1, x_2)| \leq \sum_{x_1 \in \{-1,1\}^{2n}} |\psi_0(x_1)| \cdot \sum_{x_2 \in \{-1,1\}^{2n}} |\psi_0(x_2)| = 1.$$

  By Equation (7), we have

$$\sum_{x_1, x_2 \in \{-1,1\}^{2n}} |B(x_1, x_2)| \leq \max\left\{\|\psi_0\|_1, \delta\|\psi_1\|_1\right\}^2 + \|\psi_0\|_1^2 + \delta\|\psi_0\|_1\|\psi_1\|_1 + \delta^2\|\psi_1\|_1^2,$$

  which is at most a constant, since $\delta = O(1)$.
  Combined with the fact that ε is a constant, we conclude $\|\Psi\|_1 \leq \frac{1}{\delta}\|A\|_1 + \frac{1}{\varepsilon}\|B\|_1 \leq O(1)$.
- By Equation (5), $F(x) \cdot \Psi(x_1, x_2) \geq (\delta - \varepsilon)^4 |\psi_0(x_1)| \cdot |\psi_0(x_2)| \ \forall x \in \{-1,1\}^{4n}$. This implies that for $|x_1|, |x_2| \in [n - \lfloor n^{2/3} \rfloor, n + \lfloor n^{2/3} \rfloor]$,

$$|\Psi(x_1, x_2)| \geq \Omega\left(\frac{1}{n^{40} \cdot 2^{4n}}\right),$$

  since $\delta - \varepsilon = \Omega(1)$.
- By a standard Chernoff bound, the number of inputs in $\{-1,1\}^{2n} \times \{-1,1\}^{2n}$ such that $|x_1|, |x_2| \in [n - \lfloor n^{2/3} \rfloor, n + \lfloor n^{2/3} \rfloor]$ is at least $(1 - 2\exp(-n^{1/3}/3)) \cdot 2^{4n}$.

Plugging $f = \mathrm{OR}_2 \circ \mathrm{MAJ}_{2n}$ and $\phi = \frac{\Psi}{\|\Psi\|_1}$ into Theorem 5, we conclude that the sign-rank of the $(4n^2, 4n, \mathrm{OR}_2 \circ \mathrm{MAJ}_{2n})$ pattern matrix M is bounded below as

$$\mathrm{sr}(M) \geq \Omega\left(\frac{\frac{1}{n^{40}} \cdot \frac{1}{2^{4n}}}{\left(\frac{1}{n^{(\log n/200)-1}} \cdot \frac{1}{2^{4n}}\right) + \left(\frac{1}{n^{40}} \cdot \frac{1}{2^{4n}} \cdot 2\exp(-n^{1/3}/3)\right)}\right) \geq n^{\Omega(\log n)}. \qquad \blacktriangleleft$$

We are now ready to prove Theorem 1.

Proof of Theorem 1. Note that the function $\mathrm{AND} \circ \mathrm{MAJ}(x) = \overline{\mathrm{OR} \circ \mathrm{MAJ}(\overline{x})}$. Consider the dual witness $\phi = \frac{\Psi}{\|\Psi\|_1}$ obtained for the threshold degree of $\mathrm{OR}_2 \circ \mathrm{MAJ}_{2n}$ in the previous proof. Note that the function ϕ' defined by $\phi'(x) = -\phi(\overline{x})$ acts as a dual witness for the threshold degree of $\mathrm{AND}_2 \circ \mathrm{MAJ}_{2n}$, and satisfies all the conditions in Theorem 5 with the same parameters as in the proof of Theorem 10. Proceeding in exactly the same way as in the previous proof, we conclude that sign-rank of the $(4n^2, 4n, \mathrm{AND}_2 \circ \mathrm{MAJ}_{2n})$ pattern matrix M' is bounded below as

$$\mathrm{sr}(M') \geq n^{\Omega(\log n)}. \tag{16}$$

Denote by f the communication game corresponding to the $(2n^2, 2n, \mathrm{MAJ}_{2n})$ pattern matrix. For completeness, we now sketch a standard $\mathbf{UPP}^{\mathrm{cc}}$ protocol of cost $O(\log n)$ for f. Note that Alice holds $2n^2$ input bits, and Bob holds a $(2n \cdot \log n)$-bit string indicating the "relevant bits" in each block of Alice's input and a $2n$-bit string w. Bob sends Alice the index of a uniformly random relevant bit using $\log(2n^2)$ bits of communication. Alice responds with her value b of that input bit, and Bob outputs $b \oplus w_i$. It is easy to check that this is a valid $\mathbf{UPP}^{\mathrm{cc}}$ protocol, and it has cost $O(\log n)$.

One can verify by the definition of pattern matrices (Definition 4) that the communication game corresponding to the $(4n^2, 4n, \mathrm{AND}_2 \circ \mathrm{MAJ}_{2n})$ pattern matrix M' equals $f \wedge f$. By Theorem 3 and Equation (16), we obtain that

$$\mathbf{UPP}(f \wedge f) = \Theta(\log \mathrm{sr}(M')) = \Omega(\log^2 n).$$

As mentioned in Section 1, the result of Klivans et al. [16] implies that $\mathrm{sr}(M') = n^{O(\log n)}$. Thus, the function f satisfies $\mathbf{UPP}^{\mathrm{cc}}(f) = O(\log n)$, but $\mathbf{UPP}^{\mathrm{cc}}(f \wedge f) = \Theta(\log^2 n)$. ◀

Corollary 2 follows immediately from the previous proof and the definition of pattern matrices.

4 Proof of Theorem 8

The rest of this paper is dedicated towards proving Theorem 8. Before proving the theorem, we describe the main auxiliary construction and prove some preliminary facts about it.

Let $\Delta = \lfloor n^{1/(3d)} \rfloor \geq 2$. Fix any $u \in \{1, \ldots, \lfloor n^{2/3} \rfloor - 1, \lfloor n^{2/3} \rfloor\}$. Define the set

$$S_u = \{\pm u, \pm u\Delta, \pm u\Delta^2, \ldots, \pm u\Delta^{d-1}\}.$$

Define the polynomial $r_u : \{0, \pm 1, \ldots, \pm n\} \to \mathbb{R}$ by

$$r_u(t) = \frac{1}{(2n)!} \prod_{i=0}^{d-1} \left(t - \left(u\Delta^i \sqrt{\Delta}\right)\right) \prod_{s \notin S_u} (t - s).$$

Since n is odd, notice that $\mathrm{sgn}(r_u(t)) = (-1)^t$, for $t \in \{u, u\Delta, u\Delta^2, \ldots, u\Delta^{d-1}\}$, and $r_u(t) = 0$ for $t \notin S_u$.

Define

$$p_u(t) = \binom{2n}{n+t} r_u(t) = \begin{cases} (-1)^{n-t} \cdot \dfrac{\prod_{i=0}^{d-1} \left(t - \left(u\Delta^i \sqrt{\Delta}\right)\right)}{\prod_{\substack{s \in S_u \\ s \neq t}} (t - s)} & \text{if } t \in S_u \\ 0 & \text{otherwise.} \end{cases}$$

The following claim tells us that for any $u \in \{1, \ldots, \lfloor n^{2/3} \rfloor\}$, the function p_u places a reasonably large mass on input $-u$.

▷ Claim 11.

$$|p_u(-u)| \geq \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{-(d-1)^2/2}.$$

Proof. We calculate

$$\begin{aligned}
|p_u(-u)| &= \frac{u(\sqrt{\Delta}+1)}{2u} \cdot \prod_{i=1}^{d-1} \frac{u(\Delta^i\sqrt{\Delta}+1)}{u^2(\Delta^i+1)(\Delta^i-1)} \\
&\qquad \text{(pairing terms corresponding to } u\Delta^i \text{ and } -u\Delta^i\text{)} \\
&= \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \prod_{i=1}^{d-1} \frac{\Delta^{i+\frac{1}{2}}+1}{\Delta^{2i}-1} \geq \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{(d-1)/2} \cdot \prod_{i=1}^{d-1} \frac{\Delta^i}{\Delta^{2i}} \\
&= \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{-(d-1)^2/2}.
\end{aligned}$$

◁

The next claim tells us that the mass placed by p_u on other points in its support is small.

▷ Claim 12. For every $j = 1, 2, \ldots, d-1$,

$$|p_u(-u\Delta^j)| \leq e^4 \cdot \Delta^{-(j^2-3j-2)/2} \cdot \left(\frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{-(d-1)^2/2} \right).$$

Proof. We calculate

$$\begin{aligned}
|p_u(-u\Delta^j)| &= \frac{u(\Delta^j\sqrt{\Delta}+\Delta^j)}{2u\Delta^j} \cdot \prod_{i=0}^{j-1} \frac{u(\Delta^i\sqrt{\Delta}+\Delta^j)}{u^2(\Delta^i+\Delta^j)(\Delta^j-\Delta^i)} \cdot \prod_{i=j+1}^{d-1} \frac{u(\Delta^i\sqrt{\Delta}+\Delta^j)}{u^2(\Delta^i+\Delta^j)(\Delta^i-\Delta^j)} \\
&\qquad \text{(pairing terms corresponding to } u\Delta^i \text{ and } -u\Delta^i\text{)} \\
&\leq \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \prod_{i=0}^{j-1} \frac{\sqrt{\Delta}}{\Delta^j-\Delta^i} \cdot \prod_{i=j+1}^{d-1} \frac{\sqrt{\Delta}}{\Delta^i-\Delta^j} \\
&\leq \frac{\sqrt{\Delta}+1}{2} \cdot (\sqrt{\Delta} \cdot u^{-1})^{d-1} \cdot \prod_{i=0}^{j-1} \frac{\Delta^{j-i} \cdot \Delta^{-j}}{\Delta^{j-i}-1} \cdot \prod_{i=j+1}^{d-1} \frac{\Delta^{-i} \cdot \Delta^{i-j}}{\Delta^{i-j}-1} \\
&\leq \frac{\sqrt{\Delta}+1}{2} \cdot (\sqrt{\Delta} \cdot u^{-1})^{d-1} \cdot \prod_{i=0}^{j-1} \Delta^{-j} \cdot \prod_{i=j+1}^{d-1} \Delta^{-i} \cdot \left(\prod_{k=1}^{\infty} \frac{\Delta^k}{\Delta^k-1} \right)^2 \\
&\leq \frac{\sqrt{\Delta}+1}{2} \cdot (\sqrt{\Delta} \cdot u^{-1})^{d-1} \cdot \Delta^{-j^2-(d(d-1)-(j+2)(j+1))/2} \cdot \exp\left(2\sum_{k=1}^{\infty} \frac{1}{\Delta^k-1} \right) \\
&\qquad \text{(since } 1+x \leq e^x \text{ for all } x \in \mathbb{R}\text{)} \\
&\leq \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{-(j^2-3j-2)/2} \cdot \Delta^{-(d-1)^2/2} \cdot \exp\left(4\sum_{k=1}^{\infty} \frac{1}{\Delta^k} \right) \quad \text{(since } \Delta \geq 2\text{)} \\
&\leq e^4 \cdot \frac{\sqrt{\Delta}+1}{2} \cdot u^{-(d-1)} \cdot \Delta^{-(j^2-3j-2)/2} \cdot \Delta^{-(d-1)^2/2}. \qquad \text{(again using } \Delta \geq 2\text{)}
\end{aligned}$$

◁

The following claim tells us that for each u and j, the masses placed by r_u (and hence p_u) on $u\Delta^j$ and $-u\Delta^j$ are comparable.

▷ Claim 13. For every $j = 0, 1, \ldots, d-1$, we have

$$|r_u(-u\Delta^j)| \geq |r_u(u\Delta^j)| \geq \exp(-18/\sqrt{\Delta})|r_u(-u\Delta^j)|$$
$$\text{and } |p_u(-u\Delta^j)| \geq |p_u(u\Delta^j)| \geq \exp(-18/\sqrt{\Delta})|p_u(-u\Delta^j)|.$$

Proof. We may write the ratio

$$\frac{|p_u(u\Delta^j)|}{|p_u(-u\Delta^j)|} = \frac{|r_u(u\Delta^j)|}{|r_u(-u\Delta^j)|} = \prod_{i=0}^{j-1} \frac{u(\Delta^j - \Delta^i\sqrt{\Delta})}{u(\Delta^j + \Delta^i\sqrt{\Delta})} \cdot \prod_{i=j}^{d-1} \frac{u(\Delta^i\sqrt{\Delta} - \Delta^j)}{u(\Delta^j + \Delta^i\sqrt{\Delta})}.$$

This is a product of terms smaller than 1, yielding the first inequality. For the second, we follow Sherstov's argument [26, Theorem 5.3] and note that this product is at least

$$\left(\prod_{i=1}^{\infty} \frac{\Delta^{i/2}-1}{\Delta^{i/2}+1}\right)^2 \geq \exp\left(-5\sum_{i=1}^{\infty} \frac{1}{\Delta^{i/2}}\right)$$
since $(a-1)/(a+1) > \exp(-2.5/a)$ for $a \geq \sqrt{2}$
$$= \exp\left(\frac{-5}{\sqrt{\Delta}}\sum_{i=0}^{\infty} \frac{1}{\Delta^{i/2}}\right) \geq \exp\left(\frac{-5}{\sqrt{\Delta}} \cdot \frac{1}{1-1/\sqrt{2}}\right) \quad \text{since } \Delta \geq 2$$
$$\geq \exp\left(-\frac{18}{\sqrt{\Delta}}\right). \qquad \triangleleft$$

Putting the three claims together, we obtain the following conclusion, which states that the mass placed by p_u on $-u$ and u is a relatively large fraction of its ℓ_1-norm.

▶ **Lemma 14.** *$|p_u(-u)| \geq \|p_u\|_1/(8\Delta^2 e^4)$ and $|p_u(-u)| \geq |p_u(u)| \geq \frac{\exp(-18/\sqrt{\Delta}-4)}{8\Delta^2} \cdot \|p_u\|_1$.*

Proof. We bound the ratio

$$\frac{\|p_u\|_1}{|p_u(-u)|} \leq 2\sum_{j=0}^{d-1} \frac{|p_u(-u\Delta^j)|}{|p_u(-u)|} \quad \text{by the first inequality in Claim 13}$$
$$\leq 2\left(1 + \sum_{j=0}^{d-1} e^4 \Delta^{-(j^2-3j-2)/2}\right) \quad \text{by Claims 11 and 12}$$
$$\leq 2 + 2e^4\left(\sum_{j=0}^{3} \Delta^{-(j^2-3j-2)/2} + \sum_{j=4}^{\infty} \Delta^{-(j^2-3j-2)/2}\right)$$
$$\leq 8\Delta^2 \cdot e^4 \cdot \sum_{k=1}^{\infty} \Delta^{-k} \leq 8 \cdot \Delta^2 \cdot e^4. \quad \text{since } \Delta \geq 2$$

By the above and the second inequality in Claim 13,

$$|p_u(u)| \geq \exp(-18/\sqrt{\Delta})|p_u(-u)| \geq \frac{\exp(-18/\sqrt{\Delta}-4)}{8\Delta^2} \cdot \|p_u\|_1. \qquad \blacktriangleleft$$

We are now ready to prove Theorem 8.

Proof of Theorem 8. Define the function $P(t) = \sum_{u=1}^{\lfloor n^{2/3} \rfloor} u^{20} \cdot \frac{p_u(t)}{\|p_u\|_1}$. We claim that the function $R : \{0, \pm 1, \ldots, \pm n\} \to \{-1, 1\}$ defined by $R(t) = \frac{(-1)^t P(t)}{\|P\|_1}$ satisfies the conditions in Theorem 8.

- Clearly, $\sum_{t=-n}^{n} |R(t)| = 1$, i.e., R satisfies Equation (8).

- By Claim 13, for every $u = 1, \ldots, \lfloor n^{2/3} \rfloor$ and every $t = 1, \ldots, n$, $(-1)^t p_u(t) \geq \delta |p_u(-t)|$ for $\delta = \exp(-18/\sqrt{\Delta}) = \exp(-18/n^{(1/6d)})$. Therefore, for all such t we also have $(-1)^t P(t) \geq \delta |P(t)|$, which implies $R(t) \geq \delta |R(-t)|$ for every $t = 1, 2, \ldots, n$.
- We have

$$R(t) = \frac{(-1)^t P(t)}{\|P\|_1} = \frac{(-1)^t}{\|P\|} \sum_{u=1}^{\lfloor n^{2/3} \rfloor} u^{20} \cdot \frac{p_u(t)}{\|p_u\|_1} = \frac{(-1)^t}{\|P\|_1} \binom{2n}{n+t} \sum_{u=1}^{\lfloor n^{2/3} \rfloor} u^{20} \cdot \frac{r_u(t)}{\|p_u\|_1}.$$

  Since each r_u is a polynomial of degree at most $(2n+1) - d$, Claim 6 implies that for any polynomial p of degree at most $d-2$, $\langle R, p \rangle = 0$.
- It now remains to verify the smoothness condition. Fix a point $v \in \{1, \ldots, \lfloor n^{2/3} \rfloor\}$. Since $\operatorname{sgn}(p_u(v)) = (-1)^v$ for all u and for all $v > 0$, we have that

$$\begin{aligned} \frac{|P(v)|}{\|P\|_1} &\geq v^{20} \cdot \frac{|p_v(v)| \cdot \|p_v\|_1^{-1}}{\sum_{u=1}^{\lfloor n^{2/3} \rfloor} u^{20}} \geq \frac{\exp(-18/\sqrt{\Delta} - 4)/8\Delta^2}{\lfloor n^{2/3} \rfloor \cdot (\lfloor n^{2/3} \rfloor)^{20}} && \text{by Lemma 14} \\ &\geq \frac{\exp(-18/\sqrt{2} - 4)}{8n^{15}} \geq \frac{e^{-15}}{8n^{15}}. && \text{since } n^{1/3} \geq \Delta = \lfloor n^{1/3d} \rfloor \geq 2 \end{aligned}$$

  If $v < 0$, the argument needs some more care because we do not have the guarantee that $\operatorname{sgn}(p_u(v)) = (-1)^v$. The large mass placed by p_{-v} on the point v plays a crucial role.

$$\begin{aligned} |P(v)| &\geq \frac{(-v)^{20} \cdot |p_{-v}(v)|}{\|p_{-v}\|_1} - \sum_{\substack{u=1 \\ u \neq v}}^{\lfloor n^{2/3} \rfloor} u^{20} \cdot \frac{p_u(-v)}{\|p_u\|_1} \\ &\geq \frac{(-v)^{20}}{8\Delta^2 e^4} - \sum_{j=1}^{\lfloor \log_\Delta(-v) \rfloor} (-v\Delta^{-j})^{20} \cdot \frac{p_{-v\Delta^{-j}}(v)}{\|p_{-v\Delta^{-j}}\|_1} \\ &&& \text{by Lemma 14, the definition of } p_u \text{ and its support} \\ &\geq (-v)^{20} \left[\frac{1}{8\Delta^2 e^4} - e^4 \sum_{j=1}^{\infty} \Delta^{-20j} \cdot \Delta^{(-j^2+3j+2)/2} \right] && \text{by Claims 11 and 12} \\ &= (-v)^{20} \left[\frac{1}{8\Delta^2 e^4} - e^4 \sum_{j=1}^{\infty} \Delta^{(-j^2-37j+2)/2} \right] \geq (-v)^{20} \left[\frac{1}{8\Delta^2 e^4} - e^4 \sum_{j=1}^{\infty} \Delta^{-18j} \right] \\ &\geq (-v)^{20} \left[\frac{1}{8\Delta^2 e^4} - \frac{e^4}{\Delta^{17}} \right] = (-v)^{20} \left[\frac{\Delta^{15} - 8e^8}{8\Delta^{17} e^4} \right] \geq \frac{20}{\Delta^{17}} \geq \frac{20}{n^6} \\ &&& \text{since } n^{1/3} \geq \Delta \geq 2 \text{ and } (-v) \geq 1 \end{aligned}$$

  Thus, we have that for $v < 0$,

$$\frac{|P(v)|}{\|P\|_1} \geq \frac{20}{n^6 \sum_{u=1}^{\lfloor n^{2/3} \rfloor} u^{20}} \geq \frac{20}{n^6 \lfloor n^{2/3} \rfloor \cdot (\lfloor n^{2/3} \rfloor)^{20}} \geq \frac{20}{n^{20}}.$$

◀

5 Conclusion

We have exhibited a communication problem f with $\mathbf{UPP}^{\mathrm{cc}}(f) = O(\log n)$, and $\mathbf{UPP}^{\mathrm{cc}}(f \wedge f) = \Theta(\log^2 n)$. This is the first result showing that **UPP** communication complexity can increase by more than a constant factor under intersection. As a consequence, we have concluded that the dimension-complexity-based quasipolynomial time PAC learning algorithm of [16] for learning intersections of polylogarithmically many majorities is optimal. That is, new learning algorithms not based on dimension complexity will be required to learn this class in polynomial time.

A glaring open question left by our work is whether the class of problems with polylogarithmic $\mathbf{UPP}^{cc}$ complexity is closed under intersection. Our results represent an important first step in this direction. It would also be very interesting to extend our result that dimension-complexity-based algorithms cannot PAC learn intersections of two majorities in polynomial time, to rule out an even larger class of learning algorithms. Specifically, it would be very interesting to show that no algorithm working in the important *statistical query* model [14] can learn this concept class in polynomial time.

Abstract

Traditionally, computation within self-assembly models is hard to conceal because the self-assembly process generates a crystalline assembly whose computational history is inherently part of the structure itself. With no way to remove information from the computation, this computational model offers a unique problem: how can computational input and computation be hidden while still computing and reporting the final output? Designing such systems is inherently motivated by privacy concerns in biomedical computing and applications in cryptography.

In this paper we propose the problem of performing "covert computation" within tile self-assembly that seeks to design self-assembly systems that "conceal" both the input and computational history of performed computations. We achieve these results within the growth-only restricted abstract tile assembly model (aTAM) with positive and negative interactions. We show that general-case covert computation is possible by implementing a set of basic covert logic gates capable of simulating any circuit (functionally complete). To further motivate the study of covert computation, we apply our new framework to resolve an outstanding complexity question; we use our covert circuitry to show that the unique assembly verification problem within the growth-only aTAM with negative interactions is coNP-complete.

1 Introduction

Since the discovery of DNA over half a century ago, humans have been continually working to understand and harness the vast amount of information it contains. The Human Genome Project [16], which began in 1990 and took a decade, was the first major attempt to fully sequence the human genome. In the years since, sequencing has become extremely cheap and easy, and our ability to manipulate DNA has emerged as a central tool for many applications related to nanotechnology and biomedical engineering.

Although this progress has many benefits, as we learn more about the information, we also must be careful with the shared data. There are databases of anonymous DNA sequences, which can sometimes be deanonymized with only small amounts of information such as a surname [13], or by reconstructing physical features from the DNA [6]. In order to address these issues, there has been work on cryptographic schemes aimed at obscuring results related to DNA or the input/output [7, 11, 14, 26].

In this work we take the first steps in addressing some of these issues within self-assembling systems by proposing a new style of computation termed *covert computation* with important motivations for private biomedical computing and cryptography. Self-assembly is the process by which systems of simple objects autonomously organize themselves through local interactions into larger, more complex objects. Understanding how to design and efficiently program molecular self-assembly systems is fundamental for the future of nanotechnology. The Abstract Tile Self-Assembly Model (aTAM) [8, 18], motivated by a DNA implementaiton [12], has become the premiere model for the study of the computational power of self-assembling systems. In the aTAM, system monomers are modeled by four-sided Wang tiles which randomly combine and attach if the respective bonding domains on tile edges are sufficiently strong. The aTAM is known to be computationally universal [25] and intrinsically universal [10].

Covert Computation. As a computational model, tile self-assembly differs from traditional models of computation in that computational steps are defined by permanently placing particular tile types at specific locations in geometric space. A history of each computational step is thereby recorded in the final assembled structure. This presents a unique problem to this type of computation: is it possible to conceal the input and history of a computation within the final assembly while still computing and reporting the output of the computation? Concealing the computational histories of the self-assembly process in this way requires designing a computational system which encodes computational steps in the *order* of tile placement, rather than the type and location of tile placements. We use the term *covert*[1] to describe this concealment of inputs and computational histories. This method of computing is different than previous tile self-assembly computing methods and requires novel techniques.

Also, while the reader may notice many parallels between our work and traditional secure multiparty computation [5], it should be made clear that our main result is the secure computation of a function with only a single party. The challenges presented above make this an interesting problem for tile self-assembly.

Motivation. The concept of covert computation within self-assembly has many potential applications. We briefly outline a few biomedical computing applications. Consider a set of diagnostic tiles sent to a patient as a droplet of DNA to which the patient adds some biological input such as a blood sample. From this the diagnostic system could compute some desired function that outputs specific diagnostic statistics. The patient sends the combined product to a medical facility for interpretation. With covert computation, only the results can be read by the lab and the user's biological input is obscured ensuring privacy.

Another potential use involves implementing a cryptography system within a molecular computing framework. The ability to covertly compute allows users to provide a personal key input that may be combined with a publicly available covert system where the combination

[1] It is important to note that the term *covert* has specific meaning in cryptography which does not apply here.

Table 1 The complexity of Unique Assembly Verification in the aTAM in relation to negative glues. $|A|$ refers to the size of an assembly and $|T|$ is the number of tile types.

Model	Negative Glues	Detachment	Complexity	Theorem
aTAM	No	No	$O(\|A\|^2 + \|A\|\|T\|)$	Thm. 3.2 in [1]
aTAM	Yes	No	coNP-complete	Thm. 3
aTAM	Yes	Yes	Undecidable	[9]

verifies some computable property of the input key without revealing any additional details of the key. This style of cryptographic scheme fits well when the input keys are biological based inputs.

A final potential biological application might be engineering a system for unlocking key biological properties within bio-engineered crops. For example, by releasing a hidden "key" input, covert computation might allow a field of crops to become fertile. A company owning the patent on this type of activation might desire the security of ensuring that the release key cannot be deciphered from the activated crop based on a covert molecular computation.

The final motivation of covert computation is within algorithmic self-assembly. We believe the concept of covert computation is fundamental and hope that our novel design techniques will be applicable to a number of future problems in the area. As evidence towards this, we apply our techniques to resolve the complexity of the fundamental question of verifying whether a tile system uniquely assembles a given assembly within the growth-only negative-glue aTAM.

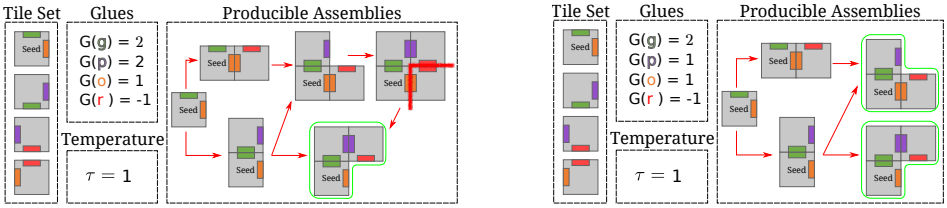
Contributions. After formally defining the concept of covert computation in tile self-assembly, we implement several covert logic gates within the negative-glue growth-only abstract Tile Assembly Model (this growth-only restriction to negative glues has been seen in the 2HAM [4], and negative glues in tile assembly have received extensive study [3, 9, 17, 20, 19, 21, 22]), and show these gates may be combined to create general circuits, thereby showing that general covert computation is possible. Finally, we apply our techniques and framework to address the fundamental problem of deciding if a negative-glue aTAM system uniquely produces a given assembly. We show this problem is coNP-complete. Table 1 outlines how our result compares to what was previously known.

2 Definitions

We begin with an overview of the Abstract Tile-Assembly Model (aTAM) and then give the new definitions introducing covert computation. Due to space constraints, we only give a high-level overview of the aTAM.

2.1 Abstract Tile Assembly Model

Figure 1 gives a high-level overview of the models with a couple of example systems. Essentially, we have non-rotating square *tiles* that have a *glue* label on each edge. The tile with its labels is a *tile type*. The *tile set* is all the tile types. A glue function determines the strength of matching glue labels. An *assembly* is a single tile or a finite set of tiles that have combined via the glues. If the combined strength of the glue labels of a single attaching tile to an assembly is greater than or equal to the *temperature* τ, the tile may attach. A *producible* assembly is any assembly that might be achieved by beginning with the *seed* (the



(a) Negative aTAM. **(b)** Growth aTAM.

Figure 1 High-level overview of the aTAM with repulsive forces. Both systems have tiles that can attach to the seed tile given they can attach with τ strength. The arrows show the possible assembly paths from the seed tile with the terminal assembly being outlined. (a) A negative aTAM system that has a possible assembly path causing disassembly. One path is growth-only, but the other path can attach the tile with the purple/red glues, which causes the orange/red tile to become unstable and detach. (b) A growth only aTAM system where negative glues are used to block, but never cause disassembly. The only difference is that the purple glue attaches with strength 1, $G(p) = 1$. This yields two possible terminal assemblies, neither of which include disassembly.

specified starting assembly) and attaching tiles. A producible assembly is further said to be *terminal* if no further tile attachment is possible. A tile system is said to *uniquely produce* a (terminal) assembly A if all producible assemblies will eventually grow into A. A tile system is formally represented as an ordered triplet $\gamma = (T, s, \tau)$ representing the tile set, seed assembly, and temperature parameter of the system respectively.

In a standard aTAM system, all glues are positive integral values, but here we look at the negative aTAM where the glues may be negative/repulsive. Such repulsive forces may be used to block the attachment of tiles despite the presence of strong attractive glues. Moreover, the inclusion of repulsive forces may yield unstable producible assemblies where a subassembly could detach because it no longer has enough binding strength. While this type of detachment has been studied in the literature [9, 22], we avoid this feature in this work as it's inclusion drastically changes the complexity of the model by making most types of verification problem undecidable, and may require more sophisticated techniques for experimental implementation. Thus, we consider a system to be a *valid growth-only* system if all producible assemblies are τ-stable. In this paper we restrict our consideration to valid growth-only systems.

2.2 Covert Computation

Here, we provide formal definitions for computing a function with a tile system, and the further requirement for covert computation of a function. Our formulation of computing functions is based on that of [15] but modified to allow for each bit to be represented by a sub-assembly potentially larger than a single tile.

Informally, a Tile Assembly Computer (TAC) for a function f consists of a set of tiles, along with a format for both input and output. The input format is a specification for how to build an input seed to the system that encodes the desired input bit-string for function f. We require that each bit of the input be mapped to one of two assemblies for the respective bit position: a sub-assembly representing "0", or a sub-assembly representing "1". The input seed for the entire string is the union of all these sub-assemblies. This seed, along with the tile set of the TAC, forms a tile system. The output of the computation is the final terminal assembly this system builds. To interpret what bit-string is represented by the output, a second *output* format specifies a pair of sub-assemblies for each bit. The bitstring represented by the union of these subassemblies within the constructed assembly is the output of the system.

For a TAC to *covertly* compute f, the TAC must compute f and produce a unique assembly for each possible output of f. We note that our formulation for providing input and interpreting output is quite rigid and may prohibit more exotic forms of computation. We acknowledge this, but caution that any formulation must take care to prevent "cheating" that could allow the output of a function to be partially or completely encoded within the input, for example. To prevent this, some type of *uniformity* constraint, similar to what is considered in circuit complexity [24], should be enforced. We now provide the formal definitions of function computing and covert computation.

Input/Output Templates. An n-bit input/output template over tile set T is a sequence of ordered pairs of assemblies over T: $A = (A_{0,0}, A_{0,1}), \ldots, (A_{n-1,0}, A_{n-1,1})$. For a given n-bit string $b = b_0, \ldots, b_{n-1}$ and n-bit input/output template A, the *representation* of b with respect to A is the assembly $A(b) = \bigcup_i A_{i,b_i}$. A template is valid for a temperature τ if this union never contains overlaps for any choice of b, and is always τ-stable. An assembly $B \supseteq A(b)$, which contains $A(b)$ as a subassembly, is said to represent b as long as $A(d) \nsubseteq B$ for any $d \neq b$.

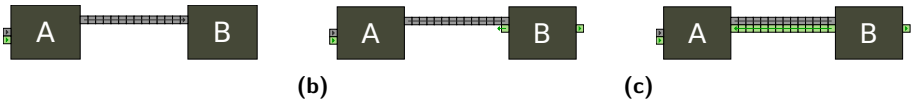
Function Computing Problem. A *tile assembly computer* (TAC) is an ordered quadruple $\Im = (T, I, O, \tau)$ where T is a tile set, I is an n-bit input template, and O is a k-bit output template. A TAC is said to compute function $f : \mathbb{Z}_2^n \to \mathbb{Z}_2^k$ if for any $b \in \mathbb{Z}_2^n$ and $c \in \mathbb{Z}_2^k$ such that $f(b) = c$, then the tile system $\Gamma_{\Im,b} = (T, I(b), \tau)$ uniquely assembles a set of assemblies which all represent c with respect to template O.

Covert Computation. A TAC *covertly* computes a function $f(b) = c$ if 1) it computes f, and 2) for each c, there exists a unique assembly A_c such that for all b, where $f(b) = c$, the system $\Gamma_{\Im,b} = (T, I(b), \tau)$ uniquely produces A_c. In other words, A_c is determined by c, and every b where $f(b) = c$ has the exact same final assemby.

3 Covert Circuits

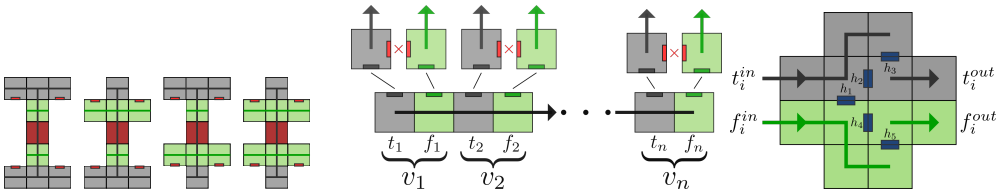
Here we cover the machinery for making covert gadgets and the covert gadgets needed for functional completeness in circuits based on a dual-rail logic implementation: variables, wires, fanouts, and NANDs. We cover a NOT gate as a primitive used in the NAND construction. Traditionally, a crossover is also given, and we discuss why this is unnecessary in Section 4. For simplicity, we give some other common gates in Section 5.

Some Conventions. All solid lines through two neighboring tiles indicate strength-2 glues between them. The arrows indicate the build order (which may branch). Blue single glues are strength 1, and red are strength -1. Following the variable gadget (Figure 3b), all variables have a true and false path adjacent to each other (dual-rail logic), but only one may be traversed at a time until the next gadget. The true value is always to the left or on top of the false value, and for most gadgets, the true input is colored grey while the false input is colored green. Once a variable wire, true or false, reaches the next gadget, the unused variable wire is *backfilled* so that both wires are present. This is a key concept used in all constructions and is further explained in Figure 2.



(a) (b) (c)

Figure 2 Backfilling in covert computation. Given two gadgets A and B. (a) If true is output from Gadget A, that wire assembles to the next gadget. (b) Gadget B builds, and based on its function, outputs the true or false wire (false in this case). Once it received the input, it backfills the false wire towards A. (c) The false wire finishes assembling and both Gadget A and B have true and false paths filled. The true output wire of Gadget B will be backfilled from the next gadget. In this way, the input to B/output from A is "hidden".



(a) Possible Input Seeds. **(b)** Variable. **(c)** Logic Diode.

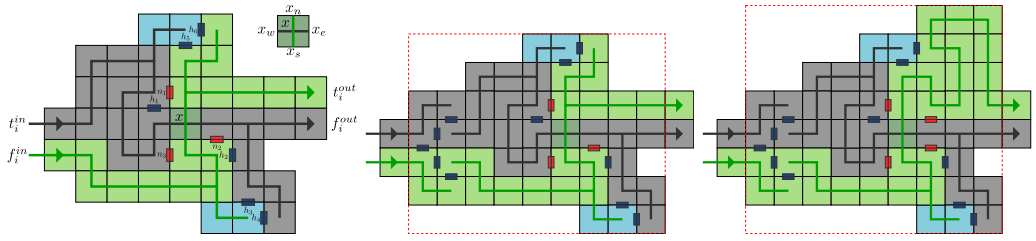
Figure 3 (a) Example of the 4 possible input seeds for a half-adder from Section 5.1. (a) Variables are represented by a true and a false line where only one may exist. The variables build off the seed, but only the t_i or the f_i tile may attach due to the negative glue between the two tiles. (b) A gadget referred to as a logic diode. This ensures input from one direction and stops tiles from assembling in the wrong direction.

3.1 Variables and Wires

A variable in our system is represented by two lines of connected tiles where only one exists at a time when the wire is in use (dual rail). Figure 3a shows an example of the possible input seeds on 2-bits used in a half-adder. Figure 3b demonstrates how the variables might be set nondeterministically, although generally the specific bits desired would already be attached as part of the input seed (as in Figure 3a). Each variable v_i has a sequence of tiles t_i representing a true setting and f_i a false setting. The first tiles have a negative glue of strength -1 meaning only the t_i or the f_i tile can attach. The other shown glues are strength 2. Once the variable is set, the setting travels to the gadget as a *wire*.

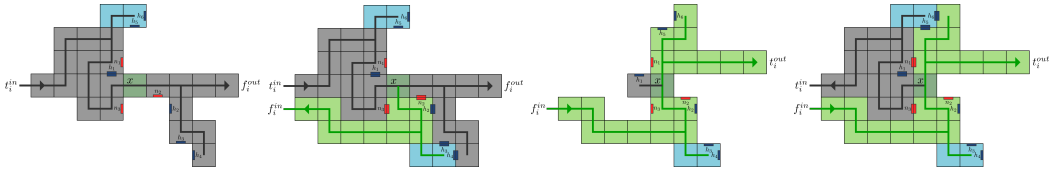
The variable setup in Figure 3b is used in one of two ways: In the case of providing an input to a covert computation, this variable setup defines the *input template* for the computation, with the seed for a given binary input being the seed assembly with either a true or false tile (but not both) placed at each bit position. An example system (a half-adder) with a big seed input is shown in Section 5. Alternatively, the seed begins as a single seed tile that nondeterministically creates a valid input over all possible n-bit inputs. This approach is used in Section 4 to show coNP-completeness for unique assembly verification.

Figure 3c shows what we refer to as a *logic diode*, and prevents timing issues. These appear in every gadget and serves two purposes: if backfilling, this stops the filling at the gadget level so it does not backfill a wire that has not been set, and second it ensures that a gadget must have input from the wire. All shown glues are strength 1 and the lines are strength 2. This gadget is important for later constructions.



(a) Basic NOT. **(b)** NOT. **(c)** H-NOT.

Figure 4 (a) Basic NOT gate (b) NOT gate with the logic diode on the input (c) A covert NOT gate with an additional negative horizontal glue on the output to prevent incorrect backfilling. This modification is needed when using this gate for the construction of the NAND gate.



(a) True Input 1. **(b)** True Input 2. **(c)** False Input 1. **(d)** False Input 2.

Figure 5 (a) A NOT gadget with true input t_i^{in} and output f_i^{out}. The true output can not place from tile x due to the negative glues n_1 and n_3 of strength -1. (b) Once the NOT gadget passes the false output, glues h_3, h_4 cooperatively allow the false portion and wire to backfill. Glue h_2 is needed to fill in the tile with n_2. (c) A NOT gadget with false input f_i^{in} and output t_i^{out}. The false output can not attach due to the negative glue n_2. The tile to the west of x may attach, but due to glue n_3, no other tile can attach. (d) Once the NOT gadget passes the true output, glues h_5, h_6 allow the true portion and wire to backfill. Glue h_1 is needed to counteract the n_1 glue when backfilling that tile.

3.2 Covert NOT Gadget

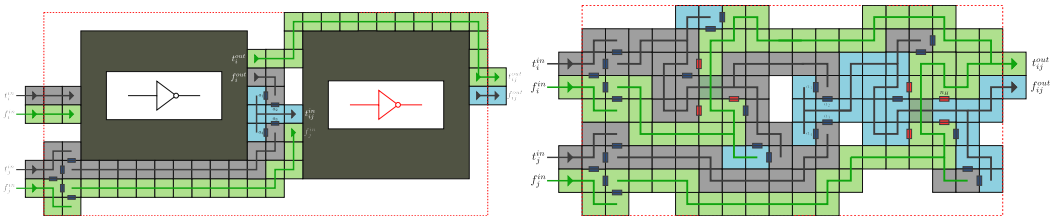
The first covert gadget we introduce is a NOT gadget. This gadget displays some of the key insights needed for covert computation, such as how blocking with negative glue adds power to the system. The NOT gadget is also used as a submodule within our NAND gadget. The NOT gadget in Figure 4a is the basic gadget with 4b only adding the logic diode on the input to ensure no backfill happens past the gadget and that the gadget had input.

Given the variables and wires work as shown, the difficulty in a dual-rail NOT is that there must be at least one crossing tile that both the true and false paths place. This tile can be thought of as where the signals cross or switch. Figure 4a shows the basic NOT gadgets, and the tile shared by both paths is labelled x. The negative glues allow blocking around this tile so that only one path is possible once x is placed.

The properies of the not gadget guarantee that it works correctly and that the gadget is covert (the gadget looks indistinguishable before the output regardless of the input), and that the backfill works correctly. Figure 5 discusses these elements and walks through how the true/false inputs block and crossover correctly. The Figure does not show the logic diode though.

3.3 Covert NAND Gadget

The basic idea for the NAND gadget is to flip one of the inputs using a covert NOT, and then we can compare the two true input lines to see if both inputs were true. Since a NAND is false only when both inputs are true, this is the only path that should result in a false



(a) NAND Block Diagram. **(b)** NAND.

Figure 6 (a) Diagram of the covert NAND gate with NOTs shown as blocks. The boxes for the NOT blocks are shown outlined in Figures 4b and 4c. The left box is the standard NOT gadget and the right box is the H-NOT gadget. (b) The full NAND gate with the two NOT gadgets filled in and compacted.

output. The basic idea for the gadget is shown in Figure 6a with a representative block for the NOT gadget already discussed. The second NOT block is the modified NOT gadget (H-NOT) from Figure 4c. Both false inputs are routed to the true output. One must go through another NOT in order to flip to the top output position, while the other false line skips this NOT and ties directly to the true output.

Once we flip the top input, we can use cooperative binding to compare the two true inputs, and only if both are true do we send it as true into the second NOT block (so the gadget outputs false). All other input combinations output true.

We will show why NOT and H-NOT are both necessary. Looking at Figure 6b, the negative glue n_H is necessary in H-NOT to ensure that t_i^{out}, which skips the second NOT gadget, does not set the output t_{ij}^{out}, and then also set f_{ij}^{out} based on the assembly order. Essentially, this protects from incorrect backfilling and setting both outputs. However, the n_H glue should not exist in the standard NOT gadget, or it may backfill and could cause a tile to break off depending on build order. Given we want a purely growth model, this would not be allowed. It is possible to create a single NOT that incorporates these properties, but we prefer to avoid the added complexity.

Finally, the logic diodes on the inputs (Figure 3c) ensure that if we only have one input, the gadget does not backfill down the other input wire. Even if the gadget has already been set, that input will wait until either the true or false wire comes before backfilling the wire.

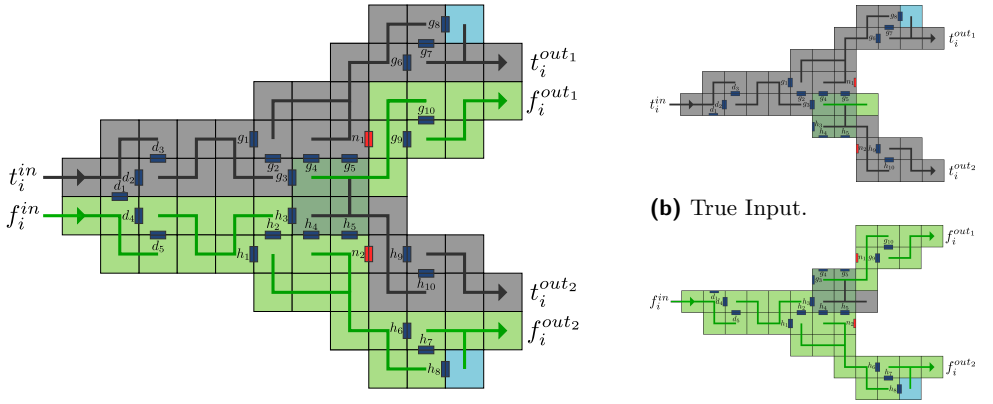
3.4 Covert FANOUT Gadget

The FANOUT gadget needs to duplicate the geometric wire, and also needs to only backfill once both outgoing wires have backfilled. Figure 7a shows the FANOUT gadget. Similar to the NOT, there is a shared set of tiles placed by both the true and the false path. Figures 7b and 7c show the true and false paths without any backfilling, respectively.

4 Covert Computation and Unique Assembly Verification

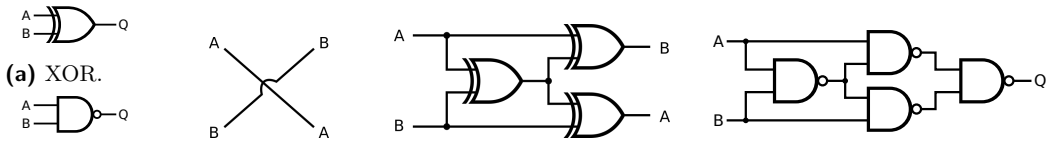
In this section we establish our main results related to covert computation in self-assembly systems. We first utilize our covert circuitry to show that any function is covertly computable (Thm. 1). We then apply covert circuitry to show that the open problem of Unique Assembly Verification within the growth-only negative glue aTAM is coNP-complete (Thm. 3).

▶ **Theorem 1.** *For any function f computed by a boolean circuit, there exists a tile assembly computer (TAC) that covertly computes f.*



(a) FANOUT. **(b)** True Input. **(c)** False Input.

Figure 7 (a) FANOUT gadget. (b) True input wire for the FANOUT gadget t_i^{in} results in output wires $t_i^{out_1}$ and $t_i^{out_2}$. (c) False input wire for the FANOUT gadget f_i^{in} results in output wires $f_i^{out_1}$ and $f_i^{out_2}$.



(a) XOR. **(b)** NAND. **(c)** Crossover. **(d)** XOR Crossover. **(e)** XOR with NANDs.

Figure 8 Constructing planar crossover gadgets with NAND gates. (a) XOR symbol. (b) NAND symbol. (c) Two wires in a circuit that cross making it non-planar. (d) A planar circuit using XOR gates that act as a crossover. (e) A planar circuit using only NAND gates that implement an XOR gate.

Proof. The proof of this theorem consists of a direct simulation of boolean circuits by way of a series of covert gadget implementations for various logic gates and how to connect them. The proof follows from the gadgets and machinery given in Section 3. ◀

We now prove that Unique Assembly Verification (UAV) in a growth-only negative glue aTAM system is coNP-complete by utilizing our covert gadgets. Without the growth-only constraint, UAV in the atam with negative glues is undecidable as a Turing machine simulation could use negative interactions to break down produced assemblies into a final unique terminal assembly exactly when the Turing machine halts [9]. With no negative glues however, the problem is in P [1]. We prove that with the ability to temporarily block, the problem becomes coNP-complete. This result is achieved with a reduction from Circuit SAT. Unique Assembly Verification in our model is formally defined as follows:

▶ **Problem** (Unique Assembly Verification (growth only)). *Given a tile-system* $\Gamma = (T, S, \tau)$ *with the promise that it is a growth-only system, and an assembly* A*. Does* Γ *uniquely assemble* A*?*

A reduction from Circuit SAT generally requires a functionally universal set of gates and variable, wire, fanout, and crossover gadgets. Both NAND and NOR are functionally complete gates, so given either, all gates can be made. A crossover gadget is redundant since it can be made with XOR gates and XOR gates can be made with NAND gates [23]. Figure 8 shows this derivation. Finally, Circuit SAT requires a DAG, and thus there are no cycles,

and so the gadgets can be topologically sorted so that there are no crossovers that cause a loop (the output of a gadget can not crossover one of its input lines). Thus, a reduction from Planar Circuit SAT is equivalent to a reduction from Circuit SAT.

▶ **Definition 2** (Planar Circuit SAT). *Instance: A planar directed acyclic graph (DAG) $G = (V, E)$ with n boolean inputs, one output, and all gates are NAND gates (or NOR gates). Every $v \in V$ is either a NAND gate ($deg^-(v) = 2$, $deg^+(v) = 1$) or a fanout ($deg^-(v) = 1$, $deg^+(v) = 2$). The source vertices, $v_i \in V$ s.t. $deg^-(v_i) = 0$ and $1 \leq i \leq n$, are the variables. The sink vertex, $s \in V$ s.t. $deg^+(v_i) = 0$ is the "output" of the boolean circuit.*
Question: Does there exist a setting of the inputs such that the output to the circuit is 1?

▶ **Theorem 3.** *Unique Assembly Verification in the aTAM with repulsive forces in a growth only system is coNP-complete.*

Proof. We first observe that Unique Assembly Verification with repulsive forces is in coNP as any failure to uniquely assemble a target assembly A comes in the form of a polynomially sized assembly that is inconsistent with A. The producibility of this assembly can be verified in polynomial time, and thus serves as a certificate for "no" instances to the UAV problem.

We now show coNP-hardness by a reduction from Planar Circuit SAT. Given an instance of planar Circuit SAT C with inputs $i_1, \ldots, i_n$ where $i \in \{0, 1\}$, i.e., a boolean circuit. By our definition we assume there are only NAND gates, fanouts, input variables and an ouput variable in the planar DAG.

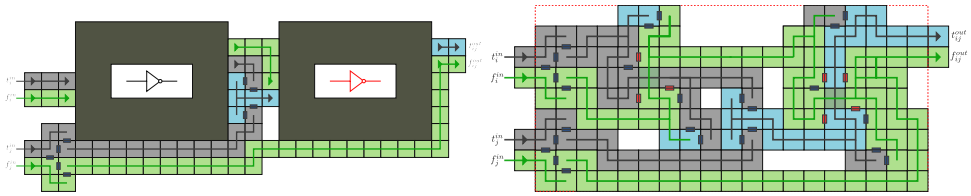
For our reduction, we build a tileset T by adding tiles corresponding to the covert gadgets and connections described in Section 3. Replace each NAND gate with a unique set of tiles implementing a NAND gadget, and each FANOUT gate with a unique set of tiles implementing a FANOUT gadget. For each edge, a unique sequence of tiles is added to T that connects the two gadgets representing the two gates the edge connected.

This yields a tile assembly computer (TAC), $\Im = (T, I, O, \tau)$, for covertly computing the circuit C. The key modification to show coNP-hardness is the utilization of a seed that non-deterministically grows any one of the possible n-bit input seeds for this TAC, and then evaluates the circuit. If the circuit is not-satisfiable, then the final computation will be false regardless of the guessed input, and therefore will yield the unique "no" assembly of the TAC based on the fact that the circuit is computed covertly. On the other hand, if there exists some satisfying n-bit input, there will be at least one final assembly that differs from the "no" assembly. Thus, the "no" assembly is uniquely produced if and only if the circuit C is not satisfiable, thereby showing coNP-hardness.

Non-deterministic input selection. To non-deterministically form the possible input bits, we include the tile types and seed tile described in Figure 3b. The seed grows a length $O(n)$ line with each bit being encoded by a pair of adjacent locations which expose a glue on the north edge. For each pair of positions, the presence of the left tile denotes a "1" for the respective bit, and the placement of the right tile denotes a "0". The "1" and "0" tiles share a negative strength 1 glue, making their mutual placement impossible until the covert gadgets have passed on the computed signal and backfilled. ◀

Given that UAV is coNP-complete with negative glues by way of covert circuitry, yet UAV is in P without negative glues [1], it is reasonable to conjecture that the use of negative interactions is needed to perform covert computation.

▶ **Conjecture.** *For some function f computed by a boolean circuit, there does not exist a tile assembly computer (TAC) that covertly computes f in the aTAM without negative glues.*



(a) AND Block Diagram. **(b)** AND.

Figure 9 (a) Diagram of the covert AND gate with NOTs shown as blocks. The left box is the standard NOT gadget and the right box is the V-NOT gadget (has an additional vertical glue). (b) The full AND gate with the two NOT gadgets filled in and some simplification for space.

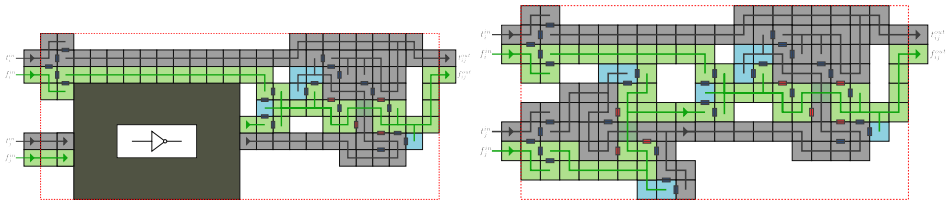
5 Further Motivation

Here, we give a few more motivating examples and some simplified gadgets. There is a lot of future work in this vein of research that is extremely relevant to modern society. We first cover the covert AND and OR gadgets.

Simplified Gadgets. Even though NAND gates alone are functionally complete, for some gates the circuit is larger than desired. Here, we give compact direct versions of some other useful gadgets and gates. This does not affect the complexity, but does help build a more efficient covert computation toolkit.

Covert AND Gadget. The covert AND gadget is nearly identical to the NAND gadget. The only real difference is which two inputs the second NOT takes in. Also, similar to the H-NOT needed for the NAND, we create a V-NOT, which is a NOT with one additional vertically aligned negative glue. Figure 9a shows the AND gadget with the blocks in place of NOTs for clarity, and Figure 9b shows the full gadget.

Covert OR Gadget. The covert OR gadget still uses a NOT to flip one of the inputs, but does several checks on the second flip to the point of drastically differing from a NOT. Figure 10a shows the AND gadget with the blocks in place of NOTs for clarity, and Figure 10b shows the full gadget.

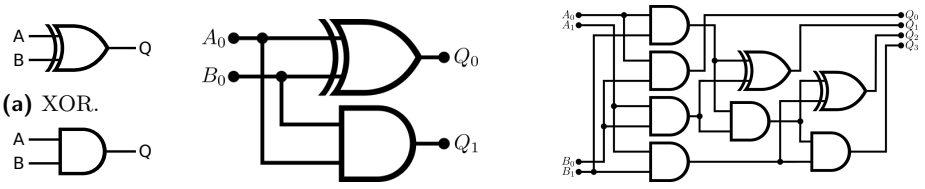


(a) Block OR. **(b)** OR.

Figure 10 (a) Block diagram for the OR gadget. (b) The covert OR gadget with the NOT gadget filled in.

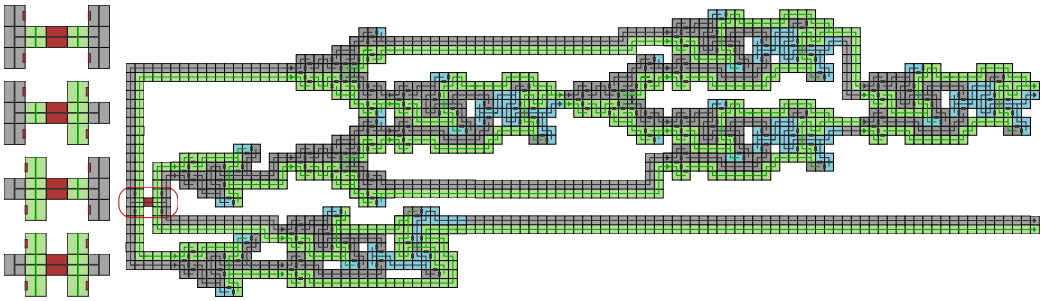
5.1 Encryption and Cryptography

Several encryption methods are based off problems that we believe to be "hard" computationally. One of the most common is factoring the product of large prime numbers, which is the basis for several encryption schemes. Although factoring may be difficult, the function



(a) XOR. **(b)** AND. **(c)** Half-Adder. **(d)** 2-Bit Multiplier.

Figure 11 Constructing covert circuits for arithmetic building up to cryptography examples. (a) XOR symbol. (b) AND symbol. (c) A half-adder, which has two 1-bit numbers as input and a 2-bit number as output. (d) A 2-bit multiplier which has two 2-bit numbers as input and outputs a 4-bit number that is their product. This can be expanded to use two large primes resulting in a large number that would be hard to factor.



(a) Seed. **(b)** Covert Half-Adder.

Figure 12 Covert Half-Adder made with 4 NANDs, 3 FANOUTs, 2 NOTs, and 1 AND. The seed input is highlighted and all 4 possible seeds are shown in (a). Regardless of the seed, the final assembly will look identical except the final T/F representing the bits of the numbers added. This implements the schematic shown in Figure 11c and the XOR is implemented with NANDs as shown in Figure 8e.

to generate the number is simple multiplication, which can be accomplished with simple circuits. Figure 11d shows a simple 6-gate circuit implementing a 2-bit number multiplier resulting in a 4-bit output number. An n-bit multiplier scales linearly (in the number of bits) with additional AND gates and full and half adders.

Implementing the multiplier with covert gates is not difficult, but the resulting assembly is large due to the inefficient crossover gadget used. Instead, we demonstrate a simple half-adder. The schematic for a half-adder is in Figure 11c. A covert half-adder as a TAC is shown in Figure 12b. The XOR has been replaced by the 4 NAND gates as shown in Figure 8e. Further, 3 FANOUTs were needed, an AND gadget as shown above in Section 5, and 2 NOT gadgets were used to flip the input for the gadgets. Figure 12a shows the four possible input seeds to build the assembly. A half-adder is simple enough to know which seed was used if 00 or 10 are output, but if 01 is output there is no way to know.

6 Conclusions and Future Work

We have introduced the concept of covert computation in self-assembly and provided a general scheme to implement any boolean circuit under this restriction. Beyond potential applications to biomedical privacy, cryptography, and intellectual property, our techniques and framework promise to impact self-assembly theory itself. As a first example we have

applied our techniques to the fundamental problem of Unique Assembly Verification in the negative glue aTAM, and shown it to be coNP-complete with growth-only systems, essentially as a corollary of our covert computation theory.

A number of future directions stem from our work. Having established the general computation power of covert computation, a natural next step is the consideration of efficiency for computing classes of functions. The *time* complexity of self-assembly computation has been studied [2, 15] and shown to allow for a substantial amount of parallelism. Can similar results be achieved under the covert constraint? What general connections exists between the time complexity for unrestricted self-assembly computation versus that of covert computation? Other natural metrics include minimizing the number of distinct tile types, along with the space taken up by the final assembly of the computation.

Randomness and Intractability in Kolmogorov Complexity

Igor Carboni Oliveira
Department of Computer Science, University of Oxford, UK
igor.carboni.oliveira@cs.ox.ac.uk

Abstract

We introduce *randomized* time-bounded Kolmogorov complexity (rKt), a natural extension of Levin's notion [24] of Kolmogorov complexity. A string w of low rKt complexity can be decompressed from a short representation via a time-bounded algorithm that outputs w with high probability.

This complexity measure gives rise to a decision problem over strings: MrKtP (The Minimum rKt Problem). We explore ideas from pseudorandomness to prove that MrKtP and its variants cannot be solved in randomized quasi-polynomial time. This exhibits a natural string compression problem that is provably intractable, even for randomized computations. Our techniques also imply that there is no $n^{1-\varepsilon}$-approximate algorithm for MrKtP running in randomized quasi-polynomial time.

Complementing this lower bound, we observe connections between rKt, the power of randomness in computing, and circuit complexity. In particular, we present the first hardness magnification theorem for a natural problem that is unconditionally hard against a strong model of computation.

1 Introduction

The Kolmogorov complexity of a string w is the length of the shortest program that prints w. This concept has found connections to a variety of topics in mathematics and computer science. Notably, Kolmogorov complexity can be used to derive Gödel's incompleteness theorems (see e.g. [12, 20, 22] and references therein), and the associated *incompressibility method* has numerous applications in areas such as graph theory, combinatorics, probability, and number theory (see [25] for a comprehensive treatment of the subject).

It is well known that computing the Kolmogorov complexity of a string is undecidable. Indeed, it is easy to see that if it were computable, then it would be possible to inspect all strings of length n and print the first string z that has complexity at least n. The resulting program provides a shorter description of z, which is contradictory.

Despite its many applications, the uncomputability of Kolmogorov complexity can render it useless in situations where an upper bound on the running time of algorithms is desirable. A time-bounded variant of Kolmogorov complexity introduced by Levin [24] has been very influential in algorithms and complexity theory (see e.g. [1, 2, 13]). In Levin's definition, the complexity of a string w takes into account not only the description length of a program generating w, but also its running time. A bit more formally, we use $\mathsf{Kt}(w)$ to denote the

minimum over $|M| + \log t$, where M is a machine that prints w when it computes for t steps. The choice of $\log t$ in this definition can be justified by its applications in theory of computation, such as Levin's optimal universal search (see [1]).

Kolmogorov complexity and Levin complexity are important measures of the "randomness", or "information", of a string. But while the computability aspects of Kolmogorov complexity are well understood, the complexity-theoretic aspects of time-bounded Kolmogorov complexity remain mysterious. It is easy to see that $\mathsf{Kt}(w)$ can be computed in exponential time $2^{O(|w|)}$. Note however that the argument presented above for the uncomputability of Kolmogorov complexity simply does not work when one takes into account running time.

Let MKtP (The Minimum Kt Problem) denote the problem of deciding the Kt complexity of an input string. The question of whether $\mathsf{MKtP} \in \mathsf{P}$ was explicitly posed in [4]. There is evidence that the problem is hard, since under standard cryptographic assumptions it follows that $\mathsf{MKtP} \notin \mathsf{P}$. The best known upper bound on the complexity of MKtP is its inclusion in $\mathsf{E} = \mathsf{DTIME}[2^{O(n)}]$. Since it is known that $\mathsf{E} \nsubseteq \mathsf{P}$ by the deterministic time hierarchy theorem, unconditionally proving that $\mathsf{MKtP} \notin \mathsf{P}$ might be within reach of existing techniques.

In this work, we investigate time-bounded Kolmogorov complexity in the presence of *randomness*. More precisely, we consider a natural extension of Kt complexity obtained when one allows the algorithm generating the string to be randomized. The only requirement is that it generates the desired string (in some fixed time bound t) with high probability. Thus we let $\mathsf{rKt}(w)$ denote the minimum over $|M| + \log t$, where M is a *probabilistic* machine that prints w with probability at least $2/3$ when it computes for t steps.

This extension of Kt complexity is motivated from several perspectives. First, it is in line with the ubiquitous role of probabilistic algorithms in modern theoretical computer science. Second, it allows many results on time-bounded Kolmogorov complexity to be extended to the randomized setting. (For instance, it is not hard to see that if $\mathsf{SAT} \in \mathsf{BPTIME}[t]$, then every satisfiable formula ϕ admits a satisfying assignment of (conditional) rKt complexity at most $O(\log t + \log |\phi|)$.[1] This allows one to define an optimal *randomized* universal search, in the spirit of Levin's result [23].) Moreover, rKt complexity can be interpreted as an extension of Kt complexity to the *pseudodeterministic* setting (see [15] and papers citing this reference), an active research direction in algorithms and complexity. Finally, by interpreting time-bounded Kolmogorov complexity as a measure of data compression, it becomes rather natural to admit representations that can be decoded via randomized algorithms. This might allow better compression rates and faster decompression procedures.[2]

Several basic questions pose themselves: What is the computational complexity of deciding $\mathsf{rKt}(w)$? Does randomization provide better compression, in the sense that $\mathsf{rKt}(w)$ might be substantially smaller than $\mathsf{Kt}(w)$ for some strings w? How does rKt and its associated decision problem relate to the complexity of deciding MKtP?

In addition to putting forward the concept of randomized time-bounded Kolmogorov complexity, our work contains the following contributions.

---

[1] It is possible to use the assumption to find the lexicographic first satisfying assignment of ϕ given the description of ϕ in probabilistic time $\mathsf{poly}(t, |\phi|)$.

[2] While the definition of rKt appears to be rather natural in hindsight, to our knowledge it has not been previously considered in the literature, despite the many variants of time-bounded Kolmogorov complexity investigated in other works (see e.g. [4, 5]). Intuitively, allowing randomness in the computation is somewhat counter-intuitive, given that Kolmogorov complexity tries to capture how far from random the output string is. This may explain in part why this concept had not been identified before this work. It is worth noting that our definition is influenced by the emerging area of pseudodeterministic algorithms. Indeed, rKt is a candidate definition for the "pseudodeterministic complexity" of a string. This might explain why defining rKt is more evident at this point compared to previous works.

Our Results. In order to state our results in a general form, we let rKt_λ denote the minimum over $|M| + \log t$, where M is a probabilistic machine that prints w with probability at least λ when it computes for t steps.[3] We let $\mathsf{MrKtP}[\beta, \alpha, s]$ denote the promise problem of distinguishing whether $\mathsf{rKt}_\beta(w) \leq s(|w|)$ or $\mathsf{rKt}_\alpha(w) > s(|w|)$, where $1/2 < \alpha \leq \beta < 1$ and $s \colon \mathbb{N} \to \mathbb{N}$. The problem is easier the larger the gap between α and β, but our lower bound applies to all settings of the two parameters.

It is not hard to prove that MrKtP can be solved in randomized exponential time if $\alpha < \beta$. Our main technical result is the following *unconditional* lower bound.

▶ **Theorem 1.** *Let* $1/2 < \alpha \leq \beta < 1$ *and* $s(n) = n^\gamma$*, where* $0 < \gamma < 1$*. Then* $\mathsf{MrKtP}[\beta, \alpha, s] \notin \mathsf{Promise\text{-}BPTIME}[n^{\mathsf{poly}(\log n)}]$.

Note that MrKtP is a total function if $\alpha = \beta$, and that the lower bound also holds in this regime. Theorem 1 presents a natural string compression problem that is provably intractable, even with randomness. While it is known that $\mathsf{BPEXP} \not\subseteq \mathsf{BPQP}$, existing proofs of this separation and its extensions only produce artificial computational problems (see e.g. [19, 7, 14, 9] for more background). The proof of Theorem 1 employs different techniques, and the argument is robust enough to establish the hardness of several variants of the problem. We will discuss one of these extensions later in this section.

The main technique used in the proof of Theorem 1 is indirect diagonalization. The argument makes use of results from the theory of pseudorandomnenss, and relies on recent insights from the investigation of pseudodeterministic algorithms [30] and connections between learning algorithms and lower bounds [29]. While pseudorandomness has been explored in the context of Kolmogorov complexity at least since the work of [4], these new perspectives were crucial in the discovery of this unconditional lower bound.

Theorem 1 can be extended to running times that are larger than quasi-polynomial, but it is unclear how to adapt the proof to show a lower bound against randomized algorithms running in time 2^{n^ε} for a small $\varepsilon > 0$. (Similarly, it is not known if $\mathsf{BPTIME}[2^n] \subseteq \mathsf{BPTIME}[2^{n^\varepsilon}]$.) A sub-exponential lower bound is open even with respect to *deterministic* algorithms. Nevertheless, we can prove a weaker lower bound in this direction that relates the deterministic complexities of MKtP and $\mathsf{MrKtP}[\beta, \alpha, s]$. For convenience, we let MrKtP denote the problem with parameters $\beta = 3/4$, $\alpha = 2/3$, and $s(n) = n/2$.

▶ **Theorem 2.** *Either* $\mathsf{MKtP} \notin \mathsf{P}$ *or* $\mathsf{MrKtP} \notin \mathsf{Promise\text{-}EXP}$.

Since MrKtP can be computed in $\mathsf{Promise\text{-}BPE}$, this result shows a weakness of deterministic algorithms solving these problems. The proof of Theorem 2 combines previous results on MKtP that also rely on pseudorandomness with some observations about rKt and MrKtP.

Theorems 1 and 2 indicate that these problems are good candidates for non-uniform circuit lower bounds. In order to discuss our next result, it is convenient to introduce a variant of MrKtP. For a string $w \in \{0,1\}^n$, let $\mathsf{rKt}(w) \stackrel{\text{def}}{=} \mathsf{rKt}_\lambda(w)$ for $\lambda = 2/3$. For functions $s_1, s_2 \colon \mathbb{N} \to \mathbb{N}$, we let $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ be the (promise) problem of distinguishing between $\mathsf{rKt}(w) \leq s_1(n)$ versus $\mathsf{rKt}(w) > s_2(n)$. Again, it is not hard to solve this problem in randomized exponential time if there is a certain (small) gap between $s_1(n)$ and $s_2(n)$.

We obtain the following complexity results for $\mathsf{Gap\text{-}MrKtP}$.

[3] We assume for definiteness that M is a "clocked" machine that runs in time at most t on all computation paths. This is not essential, and does not significantly affect the asymptotics of rKt.

▶ **Theorem 3.** *Let $C \geq 1$ be a sufficiently large constant. The following results hold.*

(i) *For every constructive $s\colon \mathbb{N} \to \mathbb{N}$,* $\mathsf{Gap\text{-}MrKtP}[s(n), s(n) + C\log n] \in \mathsf{Promise\text{-}BPTIME}[2^{O(n)}]$.

(ii) *For every $0 < \gamma < 1$,* $\mathsf{Gap\text{-}MrKtP}[n^{\gamma}, n/2] \notin \mathsf{Promise\text{-}BPTIME}[n^{\mathsf{poly}(\log n)}]$.

(iii) *If there is $\varepsilon > 0$ such that for every $0 < \gamma < 1$,* $\mathsf{Gap\text{-}MrKtP}[n^{\gamma}, n^{\gamma} + C\log n] \notin \mathsf{SIZE}[n^{1+\varepsilon}]$, *then* $\mathsf{Promise\text{-}BPEXP} \not\subseteq \mathsf{SIZE}[\mathsf{poly}]$.

Theorem 3 (*ii*) implies a strong *inapproximability* result for computing rKt (see [16] for a recent work where inapproximability of "complexity" plays a role). On the other hand, Theorem 3 (*iii*) proves that weak non-uniform lower bounds for $\mathsf{Gap\text{-}MrKtP}$ can be "magnified" (cf. [31]) to super-polynomial lower bounds for a problem in $\mathsf{Promise\text{-}BPEXP}$. (Such lower bounds are only known for languages in MAEXP [10], which combines *randomness* and *nondeterminism* in the exponential-time regime.)

In contrast to previous work (cf. [28] and references therein), Theorem 3 provides the first hardness magnification theorem for a natural problem that is *provably hard* against a strong model of computation (randomized polynomial-time algorithms).[4] The proof of Theorem 3 (*ii*) is similar to the proof of Theorem 1, while part (*iii*) follows by an adaptation of a version of the result established for $\mathsf{Gap\text{-}MKtP}$ in [28]. Note that Theorem 3 exhibits an interesting contrast between proving uniform and non-uniform lower bounds.

Finally, we consider the relation between Kt and rKt. In other words, can we have shorter descriptions if we allow randomized decoding?[5] As a concrete example, the results in [30] imply that infinitely many prime numbers (represented as binary strings) have sub-polynomial rKt complexity. This is not known to hold with respect to Kt complexity.

We employ standard techniques to establish two results that relate rKt and Kt. The first result links the deterministic complexity of MKtP to the gap between Kt and rKt.

▶ **Theorem 4.** *If $\mathsf{MKtP} \in \mathsf{P}$ then there is a sequence $\{w_n\}_{n\geq 1}$ with $w_n \in \{0,1\}^n$ such that $\mathsf{rKt}(w_n) = O(\log n)$ and $\mathsf{Kt}(w_n) = \Omega(n)$.*

On the other hand, the next theorem (roughly) shows that Kt and rKt are linearly related for every string if and only if randomized exponential time computations can be derandomized. (We refer to [2] for similar results involving other notions of time-bounded Kolmogorov complexity.)

▶ **Theorem 5.** *The following implications hold.*

(i) *If $\mathsf{Promise\text{-}BPE} \subseteq \mathsf{Promise\text{-}E}$, then $\mathsf{Kt}(w) = O(\mathsf{rKt}(w))$ for every string w.*

(ii) *If $\mathsf{Kt}(w) = O(\mathsf{rKt}(w))$ for every string w, then $\mathsf{BPE} \subseteq \mathsf{E}/O(n)$.*

In particular, rKt and Kt are linearly related if E requires exponential size boolean circuits.

This result implies that, under the standard derandomization assumption that $\mathsf{Promise\text{-}BPE}$ is contained in $\mathsf{Promise\text{-}E}$, the problems MrKtP and MKtP essentially coincide. Therefore, our unconditional results for MrKtP and its variants provide strong evidence that MKtP is intractable.

---

[4] Discussions on the feasibility of previous magnification results as an approach toward new non-uniform lower bounds relied either on conjectured separations between complexity classes or on cryptographic assumptions.

[5] Note that it is possible to recover with high probability a string w from its description in time at most $2^{O(\mathsf{rKt}(w))}$. Additionally, one can *exactly* recover w (i.e. with probability 1) by cycling through all choices of the randomness and taking a majority vote.

Related Work. Pseudodeterministic algorithms and hardness magnification are active research areas. We refer to the references in [15, 28] and to papers citing these works for more details. Quantum versions of Kolmogorov complexity have been proposed in [32, 26, 35, 8]. Before this work, unconditional lower bounds were shown for a non-deterministic formulation of Kt, where it was proved that the corresponding decision problem is in P^{NE} but not in $\mathsf{NP} \cap \mathsf{coNP}$. We refer to [5] for more information. Finally, there is a huge literature on time-bounded Kolmogorov complexity and its applications in theory of computation. A recent reference such as [3] contains pointers to many other works in the area.

Concluding Remarks. We view the unconditional lower bounds in Theorem 1 and Theorem 3 (*ii*) as a step toward understanding the hardness of computing the "complexity" of strings. Such problems are important in computer science. In particular, the conjectured security of modern cryptography implies that distinguishing "structured" strings from "random" strings (according to different measures) is hard. In this work, the complexity of a string is explored from the perspective of rKt, which is likely to be essentially equivalent to Kt complexity (as suggested by Theorem 5). Previous unconditional lower bounds on the associated decision problems applied only to strong measures, such as the non-deterministic version of Kolmogorov complexity studied in [5]. Our work is the first to show an unconditional lower bound for a notion of complexity that appears to be equivalent to Levin's seminal Kt complexity. Our techniques are also robust, and lead to a hardness of approximation result. We mention that an average-case lower bound in the sense of [17] can be proved as well.

We leave open the problem of showing an exponential lower bound on the complexity of deciding rKt complexity. Theorem 3 (*iii*) and its extensions to different circuit classes also suggest that investigating non-uniform lower bounds for this problem might be a fruitful direction.

Organization. The next section formalizes some definitions and observations mentioned above, and discusses a couple of basic facts and examples related to randomized time-bounded Kolmogorov complexity. The proofs of Theorems 1 and 2 appear in Section 3. This is followed by a sketch of the proof of Theorem 3 in Section 4. Section 5 discusses Theorems 4 and 5.

2 Preliminaries

For background in (time-bounded) Kolmogorov complexity and related topics, we refer to [25]. We fix a reasonable representation of Turing machines, and let $|M|$ denote the length of the binary encoding of a machine M. Our results are not sensitive to particular encoding choices. We assume that machines have an extra tape with random bits. We let $\boldsymbol{M}_{\leq t}$ denote the random variable that represents the content of the output tape of M when it computes for (at most) t steps over the empty string.

▶ **Definition 6** (Kt_λ Complexity). *For $\lambda \in [0,1]$ and $w \in \{0,1\}^*$, we let*

$$\mathsf{Kt}_\lambda(w) = \min_{M,t}\{|M| + \lceil \log t \rceil \mid \Pr[\boldsymbol{M}_{\leq t} = w] \geq \lambda\}.$$

The randomized time-bounded Kolmogorov complexity of w is given by $\mathsf{rKt}(w) \stackrel{\text{def}}{=} \mathsf{Kt}_{2/3}(w)$.

As a concrete example, the main result of [30] implies that for every $\varepsilon > 0$, there is a sequence $\{p_m\}_{m \geq 1}$ of increasing prime numbers such that $\mathsf{rKt}(p_m) \leq |p_m|^\varepsilon$ for every m, where $|p_m|$ denotes the length of the binary representation of p_m. For the reader familiar

with the ideas from [15] and subsequent work, the randomized time-bounded Kolmogorov complexity of a string can be seen as a measure of its "pseudodeterministic" complexity.

It is easy to see that the definition of $\mathsf{rKt}(w)$ does not change substantially if we use another threshold parameter $1/2 < \lambda < 1$.[6] The (deterministic) time-bounded Kolmogorov complexity of a string w corresponds to $\mathsf{Kt}_\lambda(w)$ for $\lambda = 1$. Note that if $\alpha \leq \beta$ then $\mathsf{Kt}_\alpha(w) \leq \mathsf{Kt}_\beta(w)$.

▶ **Definition 7** ($\mathsf{MrKtP}[\beta, \alpha, s]$)**.** *For $0 < \alpha \leq \beta \leq 1$ and $s\colon \mathbb{N} \to \mathbb{N}$, we let $\mathsf{MrKtP}[\beta, \alpha, s]$ be the promise problem $(\mathcal{YES}_n, \mathcal{NO}_n)_{n\in\mathbb{N}}$, where*

$$\begin{aligned} \mathcal{YES}_n &= \{w \in \{0,1\}^n \mid \mathsf{Kt}_\beta(w) \leq s(n)\}, \\ \mathcal{NO}_n &= \{w \in \{0,1\}^n \mid \mathsf{Kt}_\alpha(w) > s(n)\}. \end{aligned}$$

For concreteness, we let MrKtP denote $\mathsf{MrKtP}[\beta, \alpha, s]$ for $\beta = 3/4$, $\alpha = 2/3$, and $s = n/2$.

We will tacitly assume that s is constructive in all results.

▶ **Lemma 8.** *For rationals $0 < \alpha < \beta \leq 1$ and a function $s\colon \mathbb{N} \to \mathbb{N}$, $\mathsf{MrKtP}[\beta, \alpha, s] \in \mathsf{Promise\text{-}BPE}$.*

Proof Sketch. Let $\alpha < \eta < \beta$, for a fixed rational η. For all appropriate machines M and running times t, estimate with confidence at least $1 - 2^{-\omega(n)}$ the probability that M generates w when it computes for t steps. Consider M and its time bound t to be "good" if this probability estimate is at least η. Accept w if and only if a good pair has combined complexity at most s.

The correctness of the algorithm follows by a concentration bound and a standard union bound. The upper bound on its running time uses that $\mathsf{Kt}_\lambda(w)$ is at most $O(|w|)$ for every string w and $\lambda \in [0,1]$. ◀

Note that if $\beta = \alpha$ then $\mathsf{MrKtP}[\beta, \alpha, s]$ is a total problem. However, it is unclear if the problem is in BPE for this choice of parameters.

It is also convenient to consider a close variant of MrKtP. Recall that $\mathsf{rKt}(w) = \mathsf{Kt}_{2/3}(w)$.

▶ **Definition 9** ($\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$)**.** *Let $s_1, s_2\colon \mathbb{N} \to \mathbb{N}$, where $s_1(n) \leq s_2(n)$ for every $n \in \mathbb{N}$. We let $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ be the promise problem $(\mathcal{YES}_n, \mathcal{NO}_n)_{n\in\mathbb{N}}$, where*

$$\begin{aligned} \mathcal{YES}_n &= \{w \in \{0,1\}^n \mid \mathsf{rKt}(w) \leq s_1(n)\}, \\ \mathcal{NO}_n &= \{w \in \{0,1\}^n \mid \mathsf{rKt}(w) > s_2(n)\}. \end{aligned}$$

▶ **Lemma 10.** *Suppose that $s_1(n) + c \log n \leq s_2(n)$, where $c \geq 1$ is a large enough constant. Then $\mathsf{Gap\text{-}MrKtP}[s_1, s_2] \in \mathsf{Promise\text{-}BPE}$.*

Proof. Given Lemma 8, it is enough to reduce $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ to $\mathsf{MrKtP}[2/3, 3/5, s_1]$. Clearly, the set of positive instances of both problems coincide. On the other hand, it is easy to see that $\mathsf{Kt}_{2/3}(w) \leq \mathsf{Kt}_{3/5}(w) + c \log n$ if c is a sufficiently large universal constant, by amplification of the underlying randomized algorithm. As a consequence,

$$\{w \in \{0,1\}^n \mid \mathsf{rKt}(w) > s_2(n)\} \subseteq \{w \in \{0,1\}^n \mid \mathsf{Kt}_{3/5}(w) > s_1(n)\},$$

since if $\mathsf{rKt}(w) > s_2(n)$ then $\mathsf{Kt}_{3/5}(w) > s_2(n) - c \log n$, and by assumption $s_2(n) - c \log n \geq s_1(n)$. In other words, the set of negative instances of $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ is contained in the set of negative instances of $\mathsf{MrKtP}[2/3, 3/5, s_1]$. ◀

[6] It is not hard either to prove this claim for a constant $0 < \lambda \leq 1/2$, and we leave it as an exercise. (Hint: Use a short advice string to distinguish w from any other string that is output with probability $\geq \lambda/2$.)

▶ Remark. For simplicity of the exposition, we might abuse notation in some statements and compare a promise problem with a standard complexity class. However, in all proofs the distinction between the two cases is carefully considered.

3 The computational hardness of MrKtP

3.1 MrKtP is not in BPP

The main result established in this section is the following lower bound.

▶ **Theorem 11.** *Let $1/2 < \alpha \leq \beta < 1$ and $n^\gamma \leq s(n) \leq n/2$ for every large enough $n \in \mathbb{N}$, where $\gamma > 0$ is fixed but arbitrary. Then $\mathsf{MrKtP}[\beta, \alpha, s] \notin \mathsf{BPTIME}[n^{\mathsf{poly}(\log n)}]$. In other words, no randomized algorithm running in quasi-polynomial time accepts with probability $\geq 2/3$ the positive instances of $\mathsf{MrKtP}[\beta, \alpha, s]$ and rejects with probability $\geq 2/3$ the negative instances of $\mathsf{MrKtP}[\beta, \alpha, s]$.*

The proof given here requires the following results, which assume parameters α, β, and s as in Theorem 11. (We refer to [4] for applications of similar techniques.)

▶ **Lemma 12.** $\mathsf{BPE} \leq_{\mathsf{tt}}^{\mathsf{P/poly}} \mathsf{MrKtP}[\beta, \alpha, s]$. *In particular, given any sequence $\{g_n\}_{n\geq 1}$ of total boolean functions $g_n \colon \{0,1\}^n \to \{0,1\}$ that compute $\mathsf{MrKtP}[\beta, \alpha, s]$, every language in BPE can be computed by (deterministic) polynomial size oracle circuits with access to $\{g_n\}_{n\geq 1}$.*

▶ **Lemma 13.** $\mathsf{PSPACE} \subseteq \mathsf{BPP}^{\mathsf{MrKtP}[\beta,\alpha,s]}$. *More precisely, given any fixed oracle $\mathcal{O} \subseteq \{0,1\}^*$ that agrees with $\mathsf{MrKtP}[\beta, \alpha, s]$ over the relevant input strings, $\mathsf{PSPACE} \subseteq \mathsf{BPP}^{\mathcal{O}}$. Furthermore, if $\mathcal{O}$ is randomized and satisfies the promise of bounded acceptance probabilities over the inputs of $\mathsf{MrKtP}[\beta, \alpha, s]$, then the corresponding algorithm in $\mathsf{BPP}^{\mathcal{O}}$ satisfies this promise over all input strings.*

We postpone the proof of these lemmas. The next lemma is well known, and can be proved by a diagonalization argument (see e.g. [29, Corollary 2]).

▶ **Lemma 14.** *Let $s_1, s_2 \colon \mathbb{N} \to \mathbb{N}$ be space-constructible functions such that $s_2(n)^2 = o(s_1(n))$, $s_2(n) = \Omega(n)$, and $s_1(n) = 2^{o(n)}$. Then there is a language in $\mathsf{DSPACE}[s_1(n)]$ that cannot be computable by circuits of size $s_2(n)$.*

We are ready to prove Theorem 11, assuming these results.

Proof of Theorem 11. Suppose toward a contradiction that $\mathsf{MrKtP}[\beta, \alpha, s]$ can be computed in $\mathsf{BPTIME}[n^{(\log n)^a}]$, for some $a > 0$. Then, by standard non-uniform derandomization, $\mathsf{MrKtP}[\beta, \alpha, s]$ can be computed by circuits of size $O(n^{(\log n)^b})$, for some $b > 0$. It follows from Lemma 12 that every language $L \in \mathsf{BPE}$ can be computed by circuits of size $O(n^{(\log n)^{c_L}})$, for some $c_L > 0$.

Let L^* be a language given by Lemma 14 for appropriate parameters $s_1(n) = 2^{n^{o(1)}}$ and $s_2(n) = n^{(\log n)^{\omega(1)}}$. In other words, $L^* \in \mathsf{DSPACE}[s_1] \setminus \mathsf{SIZE}[s_2]$. Lemma 13 and our initial assumption imply that $\mathsf{PSPACE} \subseteq \mathsf{BPTIME}[n^{\mathsf{poly}(\log n)}]$. By a standard padding argument, we get that $L^* \in \mathsf{BPE}$. But then the upper and lower bounds on the circuit complexity of L^* are in contradiction. This completes the proof of Theorem 11. ◀

We proceed with the proofs of Lemmas 12 and 13. Given a function $f \colon \{0,1\}^* \to \{0,1\}$, we consider an associated "pseudorandom" generator G_f. (Formally, the argument employs a uniform sequence of generators, one for each $n \geq 1$.) More precisely, the generator $G_f^{\mathsf{BFNW}} \colon \{0,1\}^{n^\varepsilon} \to \{0,1\}^n$ can be computed in deterministic time $\exp(O(n^\varepsilon))$ given oracle access to f on inputs of length at most n^ε, and satisfies the following crucial property.

▶ **Theorem 15** (see [6, 21]). *Let $f\colon \{0,1\}^* \to \{0,1\}$ be a function, $\varepsilon > 0$ be arbitrary, and G_f^{BFNW} be the associated sequence of functions mentioned above. Moreover, let $T \subseteq \{0,1\}^*$ be an arbitrary test. If*

$$\left| \Pr_{\boldsymbol{r} \in U_n} [\boldsymbol{r} \in T] - \Pr_{\boldsymbol{x} \in U_{n^\varepsilon}} [G_f^{\mathsf{BFNW}}(\boldsymbol{x}) \in T] \right| \geq 1/n$$

for every large enough n, then there is a sequence $\{C_n\}_{n \geq 1}$ of polynomial size oracle circuits with access to T that compute f on each input length n and query T nonadaptively.

Proof of Lemma 12. Let $L \in \mathsf{BPE}$, and $\{f_n\}_{n \geq 1}$ be the corresponding sequence of boolean functions that compute L. Recall the constants $1/2 < \alpha \leq \beta < 1$ and $\gamma > 0$ from the statements of Theorem 11 and Lemma 12. Take $\varepsilon \stackrel{\text{def}}{=} \gamma/2$, and consider the generator G_f^{BFNW} obtained from f and ε. Moreover, let $\{g_n\}_{n \geq 1}$ be a sequence of boolean functions $g_n\colon \{0,1\}^n \to \{0,1\}$ that agree with $\mathsf{MrKtP}[\beta, \alpha, s]$ over input strings in $\mathcal{YES}_n \cup \mathcal{NO}_n$. Finally, set $T \stackrel{\text{def}}{=} \bigcup_{n \geq 1} g_n^{-1}(0)$.

We claim that T distinguishes the output of G_f^{BFNW} from a random n-bit string. First, for each seed $w \in \{0,1\}^{n^\varepsilon}$, $G_f^{\mathsf{BFNW}}(w)$ can be computed in time at most $\exp(O(n^\varepsilon))$ given w and oracle access to $f_1, \ldots, f_{n^\varepsilon}$. Since each function f_i for $i \leq n^\varepsilon$ can be computed in randomized time $\exp(O(n^\varepsilon))$ and with error probability at most $\exp(-n)$ by a uniform algorithm, it follows that $\mathsf{Kt}_\beta(G_f^{\mathsf{BFNW}}(w)) \leq \mathsf{Kt}_{1-o(1)}(G_f^{\mathsf{BFNW}}(w)) \leq O(n^\varepsilon) < n^\gamma \leq s(n)$, for n sufficiently large. Therefore, $G_f^{\mathsf{BFNW}}(w) \notin T$ for every $w \in \{0,1\}^{n^\varepsilon}$. On the other hand, a typical random n-bit string $\boldsymbol{r} \in U_n$ has (standard) Kolmogorov complexity $K(\boldsymbol{r}) \geq (1 - o(1))n$. It is easy to see that if $\lambda > 1/2$, then $K(x) \leq \mathsf{Kt}_\lambda(x)$ for a string x. As a consequence, with high probability $\mathsf{Kt}_\alpha(\boldsymbol{r}) > n/2 \geq s(n)$, in which case we have $\boldsymbol{r} \in T$.

Since T distinguishes the generator from random, it follows from Theorem 15 that L can be computed by polynomial size oracle circuits that make non-adaptive queries to T, i.e., to the functions $\{g_n\}_{n \geq 1}$. ◀

In order to prove Lemma 13, we need a *uniform* version of Theorem 15. A result of this form was established in [18], and we discuss it in more detail now. For $\varepsilon > 0$ and a function $f\colon \{0,1\}^* \to \{0,1\}$, the generator $G_f^{\mathsf{IW}}\colon \{0,1\}^{n^\varepsilon} \to \{0,1\}^n$ is also computable in deterministic time $\exp(O(n^\varepsilon))$ with oracle access to f on inputs of size at most n^ε. In addition, it satisfies the following property.

▶ **Theorem 16** (see [18]). *Let $f\colon \{0,1\}^* \to \{0,1\}$ be a function that is both random self-reducible and downward self-reducible, $\varepsilon > 0$ be arbitrary, and G_f^{IW} be the associated sequence of functions mentioned above. Moreover, let $T \subseteq \{0,1\}^*$ be an arbitrary test. If*

$$\left| \Pr_{\boldsymbol{r} \in U_n} [\boldsymbol{r} \in T] - \Pr_{\boldsymbol{x} \in U_{n^\varepsilon}} [G_f^{\mathsf{IW}}(\boldsymbol{x}) \in T] \right| \geq 1/n$$

for every large enough n, then there is a randomized polynomial-time Turing machine with oracle access to T that on every input x outputs $f(x)$ with high probability.

▶ **Theorem 17** (see [33]). *There is a language $L_{\mathsf{TV}} \in \mathsf{DSPACE}[O(n)]$ that is PSPACE-hard, random self-reducible, and downward self-reducible.*

We are ready to prove Lemma 13, which completes the proof of Theorem 11.

Proof of Lemma 13 (Sketch). Let L_{TV} be the language from Theorem 17. Since this language is PSPACE-hard under polynomial-time reductions, it suffices to show that $L_{\mathsf{TV}} \in \mathsf{BPP}^{\mathsf{MrKtP}[\beta,\alpha,s]}$.

We argue as in the proof of Lemma 12. More precisely, we let $\varepsilon \stackrel{\text{def}}{=} \gamma/2$, and we instantiate the generator G_f^{IW} using the function f that computes the characteristic function of L_{TV}. If $\mathcal{O}$ is a deterministic test that agrees with $\mathsf{MrKtP}[\beta, \alpha, s]$, then a similar argument shows that every output string of the generator has randomized Kt complexity at most $s(n)$, while a random string has almost maximum complexity. The only modification here is that $f_1, \ldots, f_{n^\varepsilon}$ can all be computed in *deterministic* time $\exp(O(n^\varepsilon))$, which follows from the fact that L_{TV} is computable in linear space. Theorem 16 immediately implies that $L_{\mathsf{TV}} \in \mathsf{BPP}^{\mathcal{O}}$, as desired.

Suppose that $\mathcal{O}$ is a *randomized* procedure that accepts the positive instances of $\mathsf{MrKtP}[\beta, \alpha, s]$ with high probability, and rejects the negative instances of $\mathsf{MrKtP}[\beta, \alpha, s]$ with high probability. We make no assumptions on the acceptance probabilities of $\mathcal{O}$ over the remaining input strings. In order to establish the furthermore part in Lemma 13, it is necessary to inspect the proof of Theorem 16. The crucial observation is that the oracle $\mathcal{O}$ is only used as a distinguisher during the computation of L_{TV}, and that any procedure that distinguishes with noticeable advantage the output of the generator from a random string can be used in place of $\mathcal{O}$. (The argument sketched in the paragraph above can be used to show that the output of $\mathcal{O}$ on strings that violate the promise condition affects in a negligible way its advantage as a distinguisher.)

We also note that it is possible to reduce the analysis of the case of a randomized algorithm A as oracle to the deterministic case. By running polynomially many independent copies of A and taking a majority vote, one gets a randomized algorithm A' that is correct with probability at least $1 - 2^{-m^2}$ on every fixed string of length at most m satisfying the promise condition (think of m as n^ℓ for a large enough constant ℓ, where n is the input length of L_{TV}). By a union bound, randomly fixing the string in the random tape of A' provides w.h.p a deterministic oracle $\mathcal{O}$ that is correct on all strings of length at most m satisfying the promise condition. The analysis now reduces to the deterministic case.

This completes the proof of Lemma 13. ◀

Sketch of an alternate presentation via learning algorithms. Suppose that $\mathsf{MrKtP} \in \mathsf{BPP}$, i.e., there is a polynomial time randomized algorithm that is correct with high probability over inputs satisfying the promise condition. Then, by adapting ideas from [11], it is possible to prove that for every reasonable function $t\colon \mathbb{N} \to \mathbb{N}$, $\mathsf{SIZE}[t]$ can be learned in $\mathsf{BPTIME}[\mathsf{poly}(t)]$ in the model of learning with membership queries under the uniform distribution. The connection between learning algorithms and lower bounds (see [29]) now implies that, for any choice of $s(n) \leq n^{\mathsf{poly}(\log n)}$, $\mathsf{BPEXP} \not\subseteq \mathsf{SIZE}[s(n)]$. But this is in contradiction to Lemma 12 and the assumption that $\mathsf{MrKtP} \in \mathsf{BPP}$, which imply $\mathsf{BPEXP} \subseteq \mathsf{SIZE}[\mathsf{poly}(n)]$.

We remark that common to both approaches are elements from the theory of pseudorandomness, such as the use of pseudorandom generators based on [27], and ideas that go back to the work of [18] on connections between algorithms and lower bounds via random self-reducibility and downward self-reducibility. The use of [6] in the proof of Lemma 12 appears to be crucial in the arguments presented above.

3.2 Weakness of deterministic algorithms for MKtP and MrKtP

It is natural to conjecture that $\mathsf{BPEXP} \not\subseteq \mathsf{BPTIME}[2^{o(n)}]$ (a strong hierarchy theorem for randomized time) and $\mathsf{MrKtP} \notin \mathsf{BPTIME}[2^{o(n)}]$ (a nearly-optimal lower bound for MrKtP). However, it is unclear even how to show that $\mathsf{MrKtP} \notin \mathsf{DTIME}[2^{n^{o(1)}}]$. It is also open whether $\mathsf{MKtP} \in \mathsf{P}$. In this section, we place limits on the efficiency of deterministic algorithms solving these problems. We start with the following observation.

▶ **Proposition 18.** *Either* $\mathsf{EXP} \not\subseteq \mathsf{BPTIME}[2^{o(n)}]$ *or* $\mathsf{MrKtP} \notin \mathsf{EXP}$.

Proof. Suppose $\mathsf{MrKtP} = \mathsf{MrKtP}[\beta, \alpha, s]$ is in $\mathsf{DTIME}[2^{n^d}]$ for some constant d, where $\beta = 3/4$, $\alpha = 2/3$, and $s = n/2$. Let M_{MrKtP} be a Turing machine that witnesses this inclusion. Consider the following language:

$$L \stackrel{\text{def}}{=} \{\langle M, 1^n, w\rangle \mid M \text{ is a TM that accepts in time } \leq 2^{n^d} \text{ some } n\text{-bit string } y \text{ whose prefix is } w\}.$$

Note that $L \in \mathsf{EXP}$, i.e., L can be computed in deterministic time $2^{m^{O(1)}}$ on inputs of length m. Assume that $\mathsf{EXP} \subseteq \mathsf{BPTIME}[2^{o(n)}]$, and let M_L be a randomized Turing machine for L that witnesses this inclusion. It is easy to see that M_L can be used to find w.h.p. and in time $2^{o(n)}$ the lexicographic first string $z \in \{0,1\}^n$ accepted by $\overline{M_{\mathsf{MrKtP}}}$, the complement of machine M_{MrKtP} (observe that such string must exist). It follows that the triple $(M_L, M_{\mathsf{MrKtP}}, 1^n)$ can be used to give a shorter description of z. More precisely, $\mathsf{rKt}_{1-o(1)}(z) = o(n)$. On the other hand, since $\overline{M_{\mathsf{MrKtP}}}(z) = 1$ and M_{MrKtP} computes MrKtP, we must have $\mathsf{rKt}_\beta(z) > s$. These inequalities imply that $n/2 = s < \mathsf{rKt}_\beta(z) \leq \mathsf{rKt}_{1-o(1)}(z) \leq o(n)$, a contradiction. This completes the proof of Proposition 18. ◀

Additionally, we will use the following reductions.

▶ **Lemma 19** (see [4])**.** $\mathsf{EXP} \subseteq \mathsf{NP}^{\mathsf{MKtP}}$.

▶ **Lemma 20** (see [4])**.** *If* $\mathsf{MKtP} \in \mathsf{P}$ *then* $\mathsf{PSPACE} \subseteq \mathsf{ZPP}$.

As alluded to above, the next result shows hardness of deciding deterministic/randomized time-bounded Kolmogorov complexity using deterministic algorithms. (It should be contrasted with the inclusion $\mathsf{MrKtP} \in \mathsf{Promise\text{-}BPE}$ from Lemma 8.)

▶ **Theorem 21.** *Either* $\mathsf{MKtP} \notin \mathsf{P}$ *or* $\mathsf{MrKtP} \notin \mathsf{EXP}$.

Proof. Suppose $\mathsf{MKtP} \in \mathsf{P}$. Then $\mathsf{PSPACE} \subseteq \mathsf{ZPP}$ follows by Lemma 20. Moreover, Lemma 19 gives $\mathsf{EXP} \subseteq \mathsf{NP}$. Combining these two class inclusions, we get that $\mathsf{EXP} \subseteq \mathsf{BPP}$. But this implies that $\mathsf{MrKtP} \notin \mathsf{EXP}$ via Proposition 18, which is the desired result. ◀

4 Non-uniform versus randomized lower bounds for MrKtP

It is not hard to see that the proof of Theorem 11 carries over with $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ in place of $\mathsf{MrKtP}[\beta, \alpha, s]$. We state the result here for completeness.

▶ **Theorem 22.** *Let* $\gamma > 0$ *be an arbitrarily small constant, and consider functions* $s_1, s_2 \colon \mathbb{N} \to \mathbb{N}$. *Suppose that* $n^\gamma \leq s_1(n) \leq s_2(n) \leq n/2$. *Then* $\mathsf{Gap\text{-}MrKtP}[s_1, s_2] \notin \mathsf{BPTIME}[n^{\mathsf{poly}(\log n)}]$.

Proof Sketch. The algorithm for $\mathsf{MrKtP}[\beta, \alpha, s]$ is only used as a distinguisher in the proof of Theorem 11. It is possible to check that an algorithm for $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ works equally well as a distinguisher in the proofs of Lemmas 12 and 13. ◀

By a straightforward extension of results from [31, 28], one can show that weak *non-uniform* lower bounds for $\mathsf{Gap\text{-}MrKtP}[s_1, s_2]$ can be "magnified" to super-polynomial circuit lower bounds for some explicit problem. We state a version of the result for general boolean circuits, but the proof can be adapted to other boolean devices (similarly to [28]).

▶ **Theorem 23.** *There is a universal constant $d \geq 1$ for which the following holds. If there exists $\varepsilon > 0$ such that for every small enough $\beta > 0$ we have* $\mathsf{Gap\text{-}MrKtP}[n^\beta, n^\beta + d \log n] \notin \mathsf{SIZE}[n^{1+\varepsilon}]$*, then* $\mathsf{Promise\text{-}BPEXP} \not\subseteq \mathsf{SIZE}[\mathrm{poly}]$.

Proof Sketch. We verify that the relevant steps in the proof of [28, Theorem 1 Part 1, Section 3] carry over to $\mathsf{Gap\text{-}MrKtP}[n^\beta, n^\beta + d \log n]$, under minor modifications. (Note that N denotes the input length in [28], while here input length is denoted by n.) First, we observe that Claims 11 and 12 also work for rKt, since the error-correcting code routines are deterministic. Using a similar notation (i.e., $z = \mathsf{ECC}(w) \in \{0,1\}^m$, where $m = m(n) = O(n)$ and $n = |w|$), it follows that if $\mathsf{rKt}(w) \leq n^\beta$ then $\mathsf{rKt}(z) \leq n^\beta + c_0 \log n$, and that if $\mathsf{rKt}(w) > n^\beta + d \log n$ then $\mathsf{rKt}(z') > n^\beta + c_1 \log n$ for any $z' \in \{0,1\}^m$ that disagrees with z on at most a δ-fraction of coordinates, where $1 \leq c_0 < c_1 < d$ are constants, and we assume that d is large enough so that c_0 and c_1 are sufficiently far apart.

The crucial part of the argument is to replace the language $L \in \mathsf{EXP}$ from their Claim 13 by an appropriate problem $\Pi \in \mathsf{Promise\text{-}BPEXP}$. The input to Π is a string y encoding a tuple of the form $(m, 1^t, (i_1, b_1), \ldots, (i_r, b_r))$, where m is a positive integer represented in binary, t is a positive integer, $i_1, \ldots, i_r \in \{0,1\}^{\log m}$, $b_1, \ldots, b_r \in \{0,1\}$, and $r \in \mathbb{N}$. For $t = n^\beta$ and $r = n^{2\beta}$, we let

$$\Pi_n^{\mathsf{yes}} \stackrel{\text{def}}{=} \{y \mid \exists z \in \{0,1\}^m \text{ such that } \mathsf{rKt}(z) \leq t + c_0 \log n \text{ and } z_{i_1} = b_1, \ldots, z_{i_r} = b_r\}, \text{ and}$$
$$\Pi_n^{\mathsf{no}} \stackrel{\text{def}}{=} \{y \mid \nexists z \in \{0,1\}^m \text{ such that } \mathsf{rKt}(z) \leq t + c_1 \log n \text{ and } z_{i_1} = b_1, \ldots, z_{i_r} = b_r\}.$$

Note that these sets are disjoint, and that $\Pi \in \mathsf{Promise\text{-}BPEXP}$ by an argument analogous to the proof of Lemma 10, using that the gap between constants c_0 and c_1 is sufficiently large.

It remains to check that their Claim 14 still holds in our context. For part (a), note that if $\mathsf{rKt}(w) \leq n^\beta$ then by the discussion above $\mathsf{rKt}(z) \leq n^\beta + c_0 \log n$. Consequently, the corresponding input y generated by the randomized reduction is in Π_n^{yes} with probability 1. Similarly, for part (b) we rely on the claim that if $\mathsf{rKt}(w) > n^\beta + d \log n$ then $\mathsf{rKt}(z') > n^\beta + c_1 \log n$ for any $z' \in \{0,1\}^m$ that disagrees with z on at most a δ-fraction of coordinates. The same union bound over exponentially small probabilities shows that $y \in \Pi_n^{\mathsf{no}}$ with probability at least $\geq 1/2$.

The rest of the construction remains unaffected. ◀

5 On the relation between rKt and Kt

First, we observe that the worst-case gap between rKt and Kt over strings of length n is closely related to the derandomization of exponential time computations.[7]

▶ **Theorem 24.** *The following implications hold.*

(i) *If* $\mathsf{Promise\text{-}BPE} \subseteq \mathsf{Promise\text{-}E}$*, then* $\mathsf{Kt}(w) = O(\mathsf{rKt}(w))$ *for every string w.*

(ii) *If* $\mathsf{Kt}(w) = O(\mathsf{rKt}(w))$ *for every string w, then* $\mathsf{BPE} \subseteq \mathsf{E}/O(n)$.

In particular, rKt *and* Kt *are linearly related if* E *requires exponential size boolean circuits.*

[7] Recall that if $\mathsf{BPP} \subseteq \mathsf{P}$ then $\mathsf{BPEXP} \subseteq \mathsf{EXP}$ by translation. Consequently, derandomizing exponential time computations is not harder than derandomizing polynomial time computations. Indeed, it is not hard to prove that the derandomization of exponential time is equivalent to the derandomization of sparse languages in BPP.

Proof. We start with a proof of (i). Let $w \in \{0,1\}^n$, and suppose M and t are such that $\Pr[\boldsymbol{M}_{\leq t} = w] \geq 2/3$ and $|M| + \log t = \mathsf{rKt}(w)$. We would like to use M and the assumption that $\mathsf{Promise\text{-}BPE} \subseteq \mathsf{Promise\text{-}E}$ to upper bound the Kt complexity of w. A potential difficulty here is that the latter inclusion offers an asymptotic upper bound, while M and w are fixed objects of finite size. In order to handle this issue, we adopt a more general perspective.

Let U be a randomized universal Turing machine that simulates computations with a polynomial overhead. In other words, given the description of a randomized machine M', a time bound t' specified as a binary string, and an input string x', $U(M', t', x')$ uses its internal randomness to simulate $M'(x')$ for at most t' steps, and outputs whatever M' outputs on x'. We assume that the computation of $U(M', t', x')$ takes time at most $c(|M'| + t' + |x'|)^c$, where $c = c(U) \geq 1$ is a universal constant.

We consider a promise problem Π, defined as follows. The $\mathcal{YES}$ instances consist of tuples $(M', t', 1^{c \cdot \log t'}, i)$, where M' is the description of a randomized Turing machine, t' and i are positive integers represented in binary, and $\Pr[\text{The } i\text{-th bit of } \boldsymbol{M}'_{\leq t'} \text{ is } 1] \geq 2/3$. On the other hand, the set $\mathcal{NO}$ of negative instances of Π is defined by the condition $\Pr[\text{The } i\text{-th bit of } \boldsymbol{M}'_{\leq t'} \text{ is } 0] \geq 2/3$. Clearly, $\mathcal{YES} \cap \mathcal{NO} = \emptyset$. We claim that $\Pi \in \mathsf{Promise\text{-}BPE}$. In order to see this, given a valid input $(M', t', 1^{c \cdot \log t'}, i)$ of Π, run the randomized universal machine U on (M', t', ϵ) for t' steps, where ϵ is the empty string, and output 1 if and only if the i-th bit in the output of M' is 1. This defines a randomized machine that runs in time $O((|M'| + t')^c + i)$, which is at most exponential in its total input length. Since the randomness of U is used to simulate the randomness of M', every string in $\mathcal{YES}$ is accepted with probability at least $2/3$, while every string in $\mathcal{NO}$ is rejected with probability at least $2/3$. This shows that $\Pi \in \mathsf{Promise\text{-}BPE}$.

Under the hypothesis of (i), we obtain that Π is computed by a deterministic machine A_Π that runs in time at most 2^{Cm} on inputs of length m, where C is fixed. Now given the pair (M, t) witnessing the rKt complexity of w (a string of length n), we can use A_Π, M, t, and n to upper bound its Kt complexity. Indeed, w can be generated by the deterministic machine that runs A_Π on $(M, t, 1^{c \cdot \log t}, i)$ for each $i \in [n]$. Note that each input to A_Π satisfies the promise condition of Π, and that A_Π runs in time at most $2^{C(|M| + \log t + c \log t + \log i)}$. Therefore, $\mathsf{rKt}(w) \leq O(|M| + |A_\Pi| + \log t + \log n) + \log(O(n \cdot 2^{C(|M| + \log t + c \log t + \log n)})) = O(|M| + \log t + \log n) = O(\mathsf{rKt}(w) + \log |w|) = O(\mathsf{rKt}(w))$, where the last inequality uses that $\mathsf{rKt}(w) \geq \log |w|$ since any machine that prints w runs in time at least $|w|$.

To prove (ii), let $L \in \mathsf{BPE}$, and let M be a machine for L that runs in randomized exponential time. Define a sequence $\{w_n\}_{n \geq 1}$ of strings $w_n \in \{0,1\}^{2^{n+1}}$, where w_n encodes the output of L on all strings of length at most n. Given n as an input, by amplifying the success probability of M, we can print w_n with high probability in time $2^{O(n)}$. Consequently, $\mathsf{rKt}(w_n) = O(n)$, which is logarithmic in $|w_n|$. Under the assumption that $\mathsf{Kt}(w) = O(\mathsf{rKt}(w))$ for every string w, it follows that for every n, $\mathsf{Kt}(w_n) = O(n)$. In particular, some deterministic machine M_n with $|M_n| = O(n)$ decides L on inputs of length at most n in time $2^{O(n)}$. Now using the sequence $\{M_n\}_{n \geq 1}$ as advice and computing in the obvious way, it follows that $L \in \mathsf{E}/O(n)$. This completes the proof of (ii).

Finally, under the assumption that there is a language in E that requires circuits of size $2^{\Omega(n)}$ on every large input length, there are quick pseudorandom generators of logarithmic seed length (cf. [34]). Such generators can be used to derandomize not only $\mathsf{BPTIME}[t]$ but also $\mathsf{Promise\text{-}BPTIME}[t]$, hence it follows from (i) that rKt and Kt are linearly related. ◀

We now relate the deterministic complexity of MKtP to the gap between rKt and Kt.

▶ **Theorem 25.** *If* $\mathsf{MKtP} \in \mathsf{P}$ *then there is a sequence* $\{w_n\}_{n\geq 1}$ *with* $w_n \in \{0,1\}^n$ *such that* $\mathsf{rKt}(w_n) = O(\log n)$ *and* $\mathsf{Kt}(w_n) = \Omega(n)$.

Proof. The proof is inspired by a related idea of Schuichi Hirahara (private communication). Let $\{D_n\}_{n\geq 1}$ be a P-uniform sequence of polynomial size circuits computing MKtP_t, for a Kt complexity threshold parameter $t(n) = n/2$. The existence of such circuits follows from the hypothesis of the theorem. Now Lemma 20 implies that there is a randomized algorithm running in time polynomial in n that solves the circuit satisfiability problem for circuits of size $\mathsf{poly}(n)$ over n input variables. We can use this algorithm and self-reduction to find with high probability the lexicographic first string w_n accepted by the complement of D_n. Then, by construction, we get that $\mathsf{rKt}(w_n) = O(\log n)$ and $\mathsf{Kt}(w_n) = \Omega(n)$. ◀

Abstract

We apply the framework of block-encodings, introduced by Low and Chuang (under the name standard-form), to the study of quantum machine learning algorithms and derive general results that are applicable to a variety of input models, including sparse matrix oracles and matrices stored in a data structure. We develop several tools within the block-encoding framework, such as singular value estimation of a block-encoded matrix, and quantum linear system solvers using block-encodings. The presented results give new techniques for Hamiltonian simulation of non-sparse matrices, which could be relevant for certain quantum chemistry applications, and which in turn imply an exponential improvement in the dependence on precision in quantum linear systems solvers for non-sparse matrices.

In addition, we develop a technique of variable-time amplitude *estimation*, based on Ambainis' variable-time amplitude amplification technique, which we are also able to apply within the framework.

As applications, we design the following algorithms: (1) a quantum algorithm for the quantum weighted least squares problem, exhibiting a 6-th power improvement in the dependence on the condition number and an exponential improvement in the dependence on the precision over the previous best algorithm of Kerenidis and Prakash; (2) the first quantum algorithm for the quantum generalized least squares problem; and (3) quantum algorithms for estimating electrical-network quantities, including effective resistance and dissipated power, improving upon previous work.

1 Introduction

A rapidly growing and important class of quantum algorithms are those that use Hamiltonian simulation subroutines to solve linear algebraic problems, many with potential applications to machine learning. This subfield began with the HHL algorithm, due to Harrow, Hassidim and Lloyd [18], which solves the *quantum linear system problem* (QLS problem). In this problem, the input consists of a matrix $A \in \mathbb{R}^{N\times N}$ and a vector $\vec{b} \in \mathbb{R}^N$, in some specified format, and the algorithm should output a quantum state proportional to $\sum_{i=1}^{N} x_i|i\rangle$, where $\vec{x} = A^{-1}\vec{b}$.

The format in which the input is presented is of crucial importance. For a sparse A, given an efficient algorithm to query the i-th non-zero entry of the j-th row of A, the HHL algorithm and its subsequent improvements [2, 14] can solve the QLS problem in complexity that depends poly-logarithmically on N. Here, if A were given naively as a list of all its entries, it would generally take time proportionally to N^2 just to read the input. We will refer to the model of accessing A, in which we can query the i-th non-zero entry of the j-th row, as the *sparse-access input model*.[1]

In [19] and [20], Kerenidis and Prakash consider several linear algebraic problems in a different input model. They assume that data has been collected and stored in some carefully chosen data structure in advance. If the data is described by an arbitrary $N \times N$ matrix, then of course, this collection will take time at least N^2 (or, if the matrix is sparse, at least the number of non-zero entries). However, processing the data, given such a data structure, is significantly cheaper, depending only poly-logarithmically on N. Kerenidis and Prakash describe a data structure that, when stored in quantum-random-access read-only memory (QROM)[2], allows for the preparation of a superposition over N data points in complexity poly-logarithmic in N. We call this the *quantum data structure input model* and discuss it more in Section 2.2. Although in some applications it might be too much to ask for the data to be presented in such a structure, one advantage of this input model is that it is not restricted to sparse matrices. This result can potentially also be useful for some quantum chemistry applications, since a recent proposal of Babbush et al. [4] uses a database of all Hamiltonian terms in order to simulate the electronic structure.

The HHL algorithm and its variants and several other applications are based on techniques from Hamiltonian simulation. Given a Hermitian matrix H and an input state $|\psi\rangle$, the Hamiltonian simulation problem is to simulate the unitary e^{iH} on $|\psi\rangle$ for some time t. Most work in this area has considered the sparse-access input model [22, 1, 6, 7, 5, 8, 12, 13, 15, 26, 31, 9, 25, 10], but recent work of Low and Chuang [24] has considered a different model, which we call *the block-encoding framework*[3].

The block-encoding framework. A block-encoding of a matrix $A \in \mathbb{C}^{N\times N}$ is a unitary U such that the top left block of U is equal to A/α for some normalizing constant $\alpha \geq \|A\|$:

$$U = \begin{pmatrix} A/\alpha & \cdot \\ \cdot & \cdot \end{pmatrix},$$

i.e. $(\langle 0|^{\otimes a} \otimes I)U(|0\rangle^{\otimes a} \otimes = A/\alpha$. In other words, for some a, for any state $|\psi\rangle$ of appropriate dimension, $\alpha(\langle 0|^{\otimes a} \otimes I)U(|0\rangle^{\otimes a} \otimes |\psi\rangle) = A|\psi\rangle$.

[1] If the matrix is not symmetric (or Hermitian) we also assume access to its transpose in a similar fashion.
[2] This refers to memory that is only required to store classical (non-superposition) data, but can be addressed in superposition.
[3] Low and Chuang call this input model *standard form*.

Such an encoding is useful if U can be implemented efficiently. In that case, U, combined with amplitude amplification, can be used to generate the state $A|\psi\rangle/\||A|\psi\rangle\|$ given a circuit for generating $|\psi\rangle$. The main motivation for using block-encodings is that Low and Chuang showed [24] how to perform optimal Hamiltonian simulation given a block-encoded Hamiltonian A.

In Ref. [19], Kerenidis and Prakash implicitly prove that if an $N \times N$ matrix A is given as a quantum data structure, then there is an ε-approximate block-encoding of A that can be implemented in complexity $\text{polylog}(N/\varepsilon)$. This implies that all results about block-encodings – including Low and Chuang's Hamiltonian simulation when the input is given as a block-encoding [24], and other techniques we develop in this paper – also apply to input presented in the quantum data structure model. This observation is the essential idea behind our applications. Implicit in work by Childs [13] is the fact that, given A in the sparse-access input model, there is an ε-approximate block-encoding of A that can be implemented in complexity $\text{polylog}(N/\varepsilon)$, so our results also apply to the sparse-access input model. In fact, the block-encoding framework unifies a number of possible input models, and also enables one to work with hybrid input models, where some matrices may come from purifications of density operators, whereas other input matrices may be accessed through sparse oracles or a quantum data structure. For a very recent overview of these general techniques see e.g. [16].

We demonstrate the elegance of the block-encoding framework by showing how to combine and modify block-encodings to build up new block-encodings, similar to building new algorithms from existing subroutines. For example, given block-encodings of A and B, their product yields a block-encoding of AB. Given a block-encoding of a Hermitian A, it is possible to construct a block-encoding of e^{iA}, using which one can implement a block-encoding of A^{-1}. We present these techniques in Section 3.

To illustrate the elegance of the block-encoding framework, consider one of our applications: generalized least squares. This problem, defined in Section 4, requires that given inputs $X \in \mathbb{R}^{M\times N}$, $\Omega \in \mathbb{R}^{M\times M}$ and $\vec{y} \in \mathbb{R}^M$, we output a quantum state proportional to

$$\vec{\beta} = (X^T\Omega^{-1}X)^{-1}X^T\Omega^{-1}\vec{y}.$$

Given block-encodings of X and Ω, it is simple to combine them to get a block-encoding of $(X^T\Omega^{-1}X)^{-1}X^T\Omega^{-1}$, which can then be applied to a quantum state proportional to $\vec{y}$.

Variable-time amplitude estimation. A variable-stopping-time quantum algorithm is a quantum algorithm $\mathcal{A}$ consisting of m stages $\mathcal{A} = \mathcal{A}_m \dots \mathcal{A}_1$, where $\mathcal{A}_j\mathcal{A}_{j-1}\dots\mathcal{A}_1$ has complexity t_j, for $t_m > \dots > t_1 > 0$. At each stage, a certain flag register, which we can think of as being initialized to a neutral symbol, may be marked as "good" in some branches of the superposition, or "bad" in some branches of the superposition, or left neutral. Each subsequent stage only acts non-trivially on those branches of the superposition in which the flag is not yet set to "good" or "bad".

At the end of the algorithm, we would like to project onto that part of the final state in which the flag register is set to "good". This is straightforward using amplitude amplification, however this approach may be vastly sub-optimal. If the algorithm terminates with amplitude $\sqrt{p_{succ}}$ on the "good" part of the state, then standard amplitude amplification requires that we run $1/\sqrt{p_{succ}}$ rounds, each of which requires us to run the full algorithm $\mathcal{A}$ to generate its final state, costing $t_m/\sqrt{p_{succ}}$.

To see why this might be sub-optimal, suppose that after $\mathcal{A}_1$, the amplitude on the part of the state in which the flag register is set to "bad" is already very high. Using amplitude amplification at this stage is very cheap, because we only have to incur the cost

t_1 of $\mathcal{A}_1$ at each round, rather than running all of $\mathcal{A}$. In [2], Ambainis showed that given a variable-stopping-time quantum algorithm, there exists an algorithm that approximates the "good" part of the algorithm's final state in cost $\widetilde{\mathcal{O}}\left(t_m + \sqrt{\sum_{j=1}^{m} \frac{p_j}{p_{succ}} t_j^2}\right)$[4], where p_j is the amplitude on the part of the state that is moved from neutral to "good" or "bad" during application of $\mathcal{A}_j$ (intuitively, the probability that the algorithm stops at stage j).

While amplitude amplification can easily be modified to not only project a state onto its "good" part, but also return an estimate of p_{succ} (i.e. the probability of measuring "good" given the output of $\mathcal{A}$), this is not immediate in variable-time amplitude amplification. The main difficulty is that a variable-time amplification algorithm applies a lot of subsequent amplification phases, where in each amplification phase the precise amount of amplification is a priori unknown. We overcome this difficulty by separately estimating the amount of amplification in each phase with some additional precision and finally combining the separate estimates in order to get a multiplicative estimate of p_{succ}.

We prove rigorously in the full version of this paper [11], how to estimate the success probability of a variable-stopping-time quantum algorithm to within a multiplicative error of ε in complexity

$$\widetilde{\mathcal{O}}\left(\frac{1}{\varepsilon}\left(t_m + \sqrt{\sum_{j=1}^{m} \frac{p_j}{p_{succ}} t_j^2}\right)\right).$$

Meanwhile we also derive some logarithmic improvements to the complexity of variable-time amplitude amplification.

Applications. We give several applications of the block-encoding framework and variable-time amplitude estimation.

We first present a quantum weighted least squares solver (WLS solver), which outputs a quantum state proportional to the optimal solution to a weighted least squares problem, when the input is given either in the quantum data structure model of Kerenidis and Prakash, or the sparse-access input model. We remark that the sparse-access input model is perhaps less appropriate to the setting of data analysis, where we cannot usually assume any special structure on the input data, however, since our algorithm is designed in the block-encoding framework, it works for either input model. Our quantum WLS solver improves the dependence on the condition number from κ^6 in [20][5] to κ, and the dependence on ε from $1/\varepsilon$ to $\mathrm{polylog}(1/\varepsilon)$.

We next present the first quantum generalized least squares solver (GLS solver), which outputs a quantum state proportional to the optimal solution to a generalized least squares problem. We again assume that the input is given in either the quantum data structure model or the sparse-access model. The complexity is again polynomial in $\log(1/\varepsilon)$ and in the condition numbers of the input matrices. We describe our WLS and GLS solvers in Section 4.

We build on the algorithms of Wang [29] to estimate effective resistance between two nodes of an electrical network and the power dissipated across a network when the input is given as a quantum data structure or in the sparse-access model. We estimate the norm of the output state of a certain linear system by applying the variable-time amplitude estimation algorithm. In the sparse-access model, we find that our algorithm outperforms Wang's linear-system-based algorithm. In the quantum data structure model, our algorithms offer

[4] We use the notation $\widetilde{\mathcal{O}}(f(x))$ to indicate $\mathcal{O}(f(x)\mathrm{polylog}(f(x)))$.
[5] In the paper of Kerenidis and Prakash their κ corresponds to our κ^2.

a speedup whenever the maximum degree of an electrical network of n nodes is $\Omega(n^{1/3})$. Our algorithms also have a speedup over the quantum walk based algorithm by Wang in certain regimes.

Throughout the article, the theorems, lemmas, and corollaries that are provided without a reference, are all rigorously proven in the full version of this paper [11].

Related Work. Independently of this work, recently, Wang and Wossnig [28] have also considered Hamiltonian simulation of a Hamiltonian given in the quantum data structure model, using quantum-walk based techniques from earlier work on Hamiltonian simulation [9]. Their algorithm's complexity scales as $\|A\|_1$ (which they upper bound by $\sqrt{N}$); whereas our Hamiltonian simulation results (Theorem 8), which follow from Low and Chuang's block-Hamiltonian simulation result, have a complexity that depends poly-logarithmically on the dimension, N. Instead, our complexity depends on the parameter μ, described below, which is also at most $\sqrt{N}$.

2 Preliminaries

For $A \in \mathbb{C}^{M\times N}$, define $\overline{A} \in \mathbb{C}^{(M+N)\times(M+N)}$ by

$$\overline{A} = \begin{bmatrix} 0 & A \\ A^\dagger & 0 \end{bmatrix}. \tag{1}$$

For many applications where we want to simulate A, or a function of A, it suffices to simulate $\overline{A}$.

For $A \in \mathbb{C}^{N\times N}$, we will let $\|A\|$ denote the spectral norm and $\|A\|_F$ the Frobenius norm. For $A \in \mathbb{C}^{M\times N}$, let $A_{i,\cdot}$ denote the i-th row of A, and define the following:

- For $q \in [0,1]$, $s_q(A) = \max_{i\in M} \|A_{i,\cdot}\|_q^q$
- For $p \in [0,1]$, $\mu_p(A) = \sqrt{s_{2p}(A)s_{2(1-p)}(A^T)}$
- $\sigma_{\min}(A) = \min\{\||A|u\rangle\| : |u\rangle \in \mathrm{row}(A), \||u\rangle\| = 1\}$ (the smallest non-zero singular value)
- $\sigma_{\max}(A) = \max\{\||A|u\rangle\| : \||u\rangle\| = 1\}$ (the largest singular value)
- $\|A\| = \left\|\overline{A}\right\| = \sigma_{\max}(A)$

For $A \in \mathbb{C}^{M\times N}$ with singular value decomposition $A = \sum_i \sigma_i |u_i\rangle\langle v_i|$, we define the Moore-Penrose pseudoinverse of A by $A^+ = \sum_i \sigma_i^{-1}|v_i\rangle\langle u_i|$. For a matrix A, we let $A^{(p)}$ be defined $A^{(p)}_{i,j} = (A_{i,j})^p$.

2.1 Block-encodings

Following [16] we use the following definition:

▶ **Definition 1** (Block-encoding). *Suppose that A is an s-qubit operator, $\alpha, \varepsilon \in \mathbb{R}_+$ and $a \in \mathbb{N}$. Then we say that the $(s+a)$-qubit unitary U is an (α, a, ε)-block-encoding[6] of A, if*

$$\left\|A - \alpha(\langle 0|^{\otimes a} \otimes I)U(|0\rangle^{\otimes a} \otimes I)\right\| \leq \varepsilon.$$

Block-encodings are really intuitive to work with. For example, one can easily take the product of two block-encoded matrices by keeping their ancilla qubits separately. The following lemma shows that the errors during such a multiplication simply add up as one would expect, and the block-encoding does not introduce any additional errors.

[6] Note that since $\|U\| = 1$ we necessarily have $\|A\| \leq \alpha + \varepsilon$.

▶ **Lemma 2.** *If U is an (α, a, δ)-block-encoding of an s-qubit operator A, and V is a (β, b, ε)-block-encoding of an s-qubit operator B then*[7] *$(I_b \otimes U)(I_a \otimes V)$ is an $(\alpha\beta, a+b, \alpha\varepsilon + \beta\delta)$-block-encoding of AB.*

Proof.

$$\begin{aligned}
&\left\|AB - \alpha\beta(\langle 0|^{\otimes a+b} \otimes I)(I_b \otimes U)(I_a \otimes V)(|0\rangle^{\otimes a+b} \otimes I)\right\| \\
=&\left\|AB - \underbrace{\alpha(\langle 0|^{\otimes a} \otimes I)U(|0\rangle^{\otimes a} \otimes I)}_{\tilde{A}}\underbrace{\beta(\langle 0|^{\otimes b} \otimes I)V(|0\rangle^{\otimes b} \otimes I)}_{\tilde{B}}\right\| \\
=&\left\|AB - \tilde{A}B + \tilde{A}B - \tilde{A}\tilde{B}\right\| = \left\|(A-\tilde{A})B + \tilde{A}(B-\tilde{B})\right\| = \left\|A-\tilde{A}\right\|\beta + \alpha\left\|B-\tilde{B}\right\| \\
\leq&\alpha\varepsilon + \beta\delta.
\end{aligned}$$

◀

The above lemma can be made more efficient in some cases when both A and B are significantly subnormalized.

The following theorem about block-Hamiltonian simulation is a corollary of the results of [24, Theorem 1], which also includes bounds on the propagation of errors.

▶ **Theorem 3.** *Suppose that U is an $(\alpha, a, \varepsilon/|2t|)$-block-encoding of the Hamiltonian H. Then we can implement an ε-precise Hamiltonian simulation unitary V which is an $(1, a+2, \varepsilon)$-block-encoding of e^{itH}, with $\mathcal{O}(|\alpha t| + \log(1/\varepsilon))$ uses of controlled-U or its inverse and with $\mathcal{O}(a|\alpha t| + a\log(1/\varepsilon))$ two-qubit gates.*

2.2 Data structures and sparse access

We will consider the following data structure, studied in [19]. We will refer to this data structure as a *quantum-accessible* data structure, because it is a classical data structure, which, if stored in QROM, is addressable in superposition, but needn't be able to store a quantum state, facilitates the implementation of certain useful quantum operations. In our complexity analysis, we consider the cost of accessing a QROM of size N to be polylog(N). Although this operation requires order N gates [17, 3], but the gates can be arranged in parallel such that the depth of the circuit indeed remains polylog(N).

The following is proven in [19].

▶ **Theorem 4** (Implementing quantum operators using an efficient data structure [19])**.** *Let $A \in \mathbb{R}^{M\times N}$ be a matrix with $A_{ij} \in \mathbb{R}$ being the entry of the i-th row and the j-th column. If w is the number of non-zero entries of A, then there exists a data structure of size*[8] *$\mathcal{O}\left(w\log^2(MN)\right)$ that, given the entries (i, j, A_{ij}) in an arbitrary order, stores them such that time*[8] *taken to store each entry of A is $\mathcal{O}(\log(MN))$. Once this data structure has been initiated with all non-zero entries of A, there exists a quantum algorithm that can perform the following maps with ε-precision in $\mathcal{O}(polylog(MN/\varepsilon))$ time:*

$$\widetilde{U} : |i\rangle|0\rangle \mapsto |i\rangle \frac{1}{\|A_{i,\cdot}\|}\sum_{j=1}^{N} A_{i,j}|j\rangle = |i, A_i\rangle,$$

[7] In the expression $(I_b \otimes U)(I_a \otimes V)$, the identity operator I_b should be seen as acting on the ancilla qubits of V, and I_a on those of U.

[8] Here, for simplicity we assume that we can store a real number in 1 data register, however more realistically we should actually count the number of bits, incurring logarithmic overheads. Also in this theorem we assign unit cost for classical arithmetic operations.

$$\widetilde{V} : |0\rangle|j\rangle \mapsto \frac{1}{\|A\|_F} \sum_{i=1}^{M} \|A_{i,\cdot}\| \, |i\rangle|j\rangle = |\widetilde{A}, j\rangle,$$

where $|A_{i,\cdot}\rangle$ *is the normalized quantum state corresponding to the* i*-th row of* A *and* $|\widetilde{A}\rangle$ *is a normalized quantum state such that* $\langle i|\widetilde{A}\rangle = \|A_{i,\cdot}\|$*, i.e. the norm of the* i*-th row of* A*.*

In particular, given a vector $\vec{v} \in \mathbb{R}^{M\times 1}$ *stored in this data structure, we can generate an* ε*-approximation of the superposition* $\sum_{i=1}^{M} v_i|i\rangle / \|\vec{v}\|$ *in complexity* $\mathrm{polylog}(M/\varepsilon)$*.*

As a corollary, we have the following, which allows us to generate alternative quantum state representations of the rows of A, as long as we have stored A appropriately beforehand:

▶ **Corollary 5.** *If* $A^{(p)}$ *is stored in a quantum data structure, then there exists a quantum algorithm that can perform the following map with* ε*-precision in* $\mathrm{polylog}(MN/\varepsilon)$ *time:*

$$|i\rangle|0\rangle \mapsto |i\rangle \frac{1}{s_{2p}(A)} \sum_{j=1}^{N} A_{i,j}^{p} |j\rangle.$$

The following was proven in [20], although not in the language of block-encodings.

▶ **Lemma 6** (Implementing block-encodings from quantum data structures)**.** *Let* $A \in \mathbb{C}^{M\times N}$*.*

1. *Fix* $p \in [0,1]$*. If* $A \in \mathbb{C}^{M\times N}$*, and* $A^{(p)}$ *and* $(A^{(1-p)})^\dagger$ *are both stored in quantum-accessible data structures*[9]*, then there exist unitaries* U_R *and* U_L *that can be implemented in time* $\mathcal{O}\left(\mathrm{polylog}(MN/\varepsilon)\right)$ *such that* $U_R^\dagger U_L$ *is a* $(\mu_p(A), \lceil \log(N+M+1)\rceil, \varepsilon)$*-block-encoding of* $\overline{A}$*.*
2. *On the other hand, if* A *is stored in a quantum-accessible data structure*[9]*, then there exist unitaries* U_R *and* U_L *that can be implemented in time* $\mathcal{O}\left(\mathrm{polylog}(MN)/\varepsilon\right)$ *such that* $U_R^\dagger U_L$ *is a* $(\|A\|_F, \lceil \log(M+N)\rceil, \varepsilon)$*-block-encoding of* $\overline{A}$*.*

This allows us to apply our block-encoding results in the quantum data structure setting, including Hamiltonian simulation (Section 3.1), quantum linear system solvers (Section 3.3) and implementing negative powers of a Hamiltonian (Section 3.3).

In contrast, in the *sparse-access model* we assume that the input matrix $A \in \mathbb{C}^{M\times N}$ has s_r-sparse rows and s_c-sparse columns, such that the matrix elements can be queried via an oracle

$$\mathrm{O}_A : |i\rangle|j\rangle|0\rangle^{\otimes b} \mapsto |i\rangle|j\rangle|a_{ij}\rangle \qquad \forall i \in [M], j \in [N].$$

Moreover, the indices of non-zero elements of each row can be queried via an oracle

$$\mathrm{O}_r : |i\rangle|k\rangle \mapsto |i\rangle|r_{ik}\rangle \qquad \forall i \in [N], k \in [s_r], \text{ where}$$

r_{ij} is the index for the j-th non-zero entry of the i-th row of A, or if there are less than i non-zero entries, then it is $j+N$. If A is not symmetric (or Hermitian) then we also assume the analogous oracle for columns. It is not difficult to prove [13] that a block-encoding of A can be efficiently implemented in the sparse-access input model, see [16, Lemma 48] for a direct proof.

▶ **Lemma 7** (Constructing block-encodings for sparse-access matrices [16, Lemma 48])**.** *Let* $A \in \mathbb{C}^{M\times N}$ *be an* s^r, s^c *row and column-sparse matrix given in the sparse-access input model. Then for any* $\varepsilon \in (0,1)$*, we can implement a* $(\sqrt{s^r s^c}, \mathrm{polylog}(MN/\varepsilon), \varepsilon)$*-block-encoding of* A *with* $\mathcal{O}(1)$ *queries and* $\mathrm{polylog}(MN/\varepsilon)$ *elementary gates.*

Thus, our block-encoding results also apply to the sparse access model.

[9] Here we assume that the data structure stores the matrices with sufficient precision.

3 Techniques for block-encodings

We develop several tools within the block-encoding framework that are crucial to our applications, but also likely of independent interest. Since an input given either in the sparse-access model or as a quantum data structure can be made into a block-encoding, our block-encoding results imply analogous results in each of the sparse-access and quantum data structure models.

Throughout this section, let $\mu(A)$, and "μ-encoding of A" be one of:

(1) $\mu(A) = \|A\|_F$, the Frobenius norm of A, in which case μ-encoding refers to a quantum data structure encoding A;

(2) for some $p \in [0,1]$, $\mu(A) = \sqrt{s_{2p}(A)s_{2(1-p)}(A)}$, where $s_p(A) = \max_j \|A_{j,\cdot}\|_p^p$, in which case μ-encoding refers to quantum data structures encoding both $A^{(p)}$ and $(A^{(1-p)})^T$, defined by $A^{(q)}_{i,j} := (A_{i,j})^q$; or

(3) $\mu(A) = \sqrt{s^r s^c}$, where s^r and s^c are the row and column sparsities of A, in which case, μ-encoding refers to having sparse access to A.

3.1 Hamiltonian simulation from quantum data structure

We first have the following important building block for our other results:

▶ **Theorem 8.** *For any $t \in \mathbb{R}$ and $\varepsilon \in (0, 1/2)$, let $H \in \mathbb{C}^{N\times N}$ be a Hermitian matrix that is μ-encoded, with $\|H\| \leq 1$. Then we can implement a unitary $\widetilde{U}$ that is a $(1, n+3, \varepsilon)$-block-encoding of e^{itH} in time $\widetilde{\mathcal{O}}\left(t\mu(A)\mathrm{polylog}(N/\varepsilon)\right)$.*

This follows from the quantum Hamiltonian simulation algorithm of Low and Chuang that expects the input as a block-encoding, and Lemmas 6 and 7. Independently, Wang and Wossnig have proven a similar result, with $\|A\|_1 \leq \sqrt{N}$ in place of $\mu(A)$ [28].

3.2 Quantum singular value estimation

Given access to a matrix $A \in \mathbb{R}^{M\times N}$ with singular value decomposition $A = \sum_j \sigma_j |u_j\rangle\langle v_j|$, and given some input state, the quantum singular value estimation (QSVE) problem requires estimating the singular values of A up to some precision with a high probability. We present a quantum algorithm for singular value estimation of a matrix A given as a block-encoding. In particular, using our algorithm it is possible to obtain an estimate of σ_j, $\tilde{\sigma}_j$ such that with probability $1-\varepsilon$, $|\sigma_j - \tilde{\sigma}_j| \leq \Delta$. We give a precise description of quantum singular value estimation, and prove the following theorem:

▶ **Theorem 9.** *Let $\varepsilon, \Delta \in (0,1)$, and $\varepsilon' = \frac{\varepsilon\Delta}{4\log^2(1/\Delta)}$. Let U be an $(\alpha, a, \varepsilon')$-block-encoding of a matrix A that can be implemented in cost T_U. Then we can implement a quantum algorithm that solves QSVE of A in complexity*

$$\mathcal{O}\left(\frac{\alpha}{\Delta}(a+T_U)\mathrm{polylog}(1/\varepsilon)\right).$$

In the special case when the block-encoding is implemented by a quantum data structure, we recover the complexity of the quantum algorithm for singular value estimation by Kerenidis and Prakash [19].

3.3 Quantum linear system solver

The quantum linear system problem (QLS problem) is the following. Given access to an $N \times N$ matrix A, and a procedure for computing a quantum state $|b\rangle$ in the image of A, prepare a state that is within ε of $A^+|b\rangle / \|A^+|b\rangle\|$. Given a block-encoding of A, we can use Theorem 3 to get a block-encoding of e^{itA}, from which we can implement a $(2\kappa, a, \varepsilon)$-block-encoding of A^{-1} (for some a and ε), where κ is an upper bound on[10] $\left\|A^{-1}\right\|$. Such a block-encoding can be applied to a state $|b\rangle$ to get $\frac{1}{2\kappa}|0\rangle^{\otimes a}(A^{-1}|b\rangle) + |0^\perp\rangle$ for some unnormalized state $|0^\perp\rangle$ orthogonal to every state with $|0\rangle$ in the first a registers. Performing amplitude amplification on this procedure, we can approximate the state $A^{-1}|b\rangle / \left\|A^{-1}|b\rangle\right\|$. However, this gives quadratic dependence on κ, whereas only linear dependence is needed for quantum linear systems solvers in the sparse-access input model, thanks to the technique of variable-time amplitude amplification. Using this technique, we are able to show the following:

▶ **Theorem 10.** *Let $\kappa \geq 2$, and A be an $N \times N$ Hermitian matrix[11] such that the non-zero eigenvalues of H lie in the range $[-1, -1/\kappa] \bigcup [1/\kappa, 1]$. Suppose that for $\delta = o\left(\varepsilon/(\kappa^2 \log^3 \frac{\kappa}{\varepsilon})\right)$ we have a unitary U that is a (α, a, δ)-block-encoding of A that can be implemented using T_U elementary gates. Also suppose that we can prepare an input state $|\psi\rangle$ which spans the eigenvectors of A in time T_ψ. Then there exists a variable time amplitude amplification based quantum algorithm that outputs a state that is ε-close to $A^{-1}|\psi\rangle / \left\|A^{-1}|\psi\rangle\right\|$ at a cost*

$$\mathcal{O}\left(\kappa\left(\alpha\big(T_U + a\big)\log^2\left(\frac{\kappa}{\varepsilon}\right) + T_\psi\right)\log(\kappa)\right).$$

From this we get the following theorem:

▶ **Theorem 11.** *Let $\varepsilon \in (0, 1/2)$, suppose that $A \in \mathbb{C}^{M \times N}$ such that $\|A\| \leq 1$, $\left\|A^{-1}\right\| \leq \kappa$, and A is μ-encoded. Also assume that there is a unitary U which acts on $\mathrm{polylog}(MN/\varepsilon)$ qubits and prepares the state $|b\rangle$ with complexity T_b. Then*

- **(i)** *The QLS problem can be solved in time $\widetilde{\mathcal{O}}\left(\kappa\left(\mu(A) + T_b\right)\mathrm{polylog}(MN/\varepsilon)\right)$.*
- **(ii)** *If $\varepsilon \in (0, 1)$, then an ε-multiplicative approximation of $\|A^+|b\rangle\|$ can be obtained in time $\widetilde{\mathcal{O}}\left(\frac{\kappa}{\varepsilon}\left(\mu(A) + T_b\right)\mathrm{polylog}(MN)\right)$*

For (ii), we use our new technique of variable time amplitude estimation.

Finally, we generalize our QLS solver to apply A^{-c} for any $c \in (0, \infty)$. Using variable-time amplification techniques we show the following:

▶ **Theorem 12.** *Let $\kappa \geq 2$, $c \in (0, \infty)$, $q = \max(1, c)$, and A be an $N \times N$ Hermitian matrix such that the eigenvalues of A lie in the range $[-1, -1/\kappa] \bigcup [1/\kappa, 1]$. Suppose that for $\delta = o\left(\varepsilon/\left(\kappa^q q \log^3 \frac{\kappa^q}{\varepsilon}\right)\right)$ we have a unitary U that is a (α, a, δ)-block-encoding of A which can be implemented using T_U elementary gates. Also suppose that we can prepare an input state $|\psi\rangle$ that is spanned by the eigenvectors of A in time T_ψ. Then there exists a variable time amplitude amplification based quantum algorithm that outputs a state that is ε-close to $A^{-c}|\psi\rangle / \|A^{-c}|\psi\rangle\|$ with a cost of*

$$\mathcal{O}\left(\left(\alpha\kappa^q\big(T_U + a\big)q\log^2\left(\frac{\kappa^q}{\varepsilon}\right) + \kappa^c T_\psi\right)\log\left(\kappa\right)\right).$$

[10] In the special case when $\|A\| = 1$, κ is an upper bound on the condition number of A, justifying the notation.

[11] Since for any matrix $C \in \mathbb{C}^{M' \times N'}$ we have that $\overline{C} \in \mathbb{C}^{(M'+N') \times (M'+N')}$ is Hermitian, and the eigenvalues of $\overline{C}$ are ± 1 times the singular values of C, this statement and its corollaries also apply to non-symmetric matrices.

Also, there exists a variable time amplitude amplification based quantum algorithm that outputs a number Γ *such that*

$$1-\varepsilon \leq \frac{\Gamma}{\|A^{-c}|\psi\rangle\|} \leq 1+\varepsilon,$$

with success probability at least $1-\delta$*, at a cost*

$$\mathcal{O}\left(\frac{1}{\varepsilon}\left(\alpha\kappa^q\left(T_U+a\right)q\log^2\left(\frac{\kappa^q}{\varepsilon}\right)+\kappa^c T_\psi\right)\log^3(\kappa)\log\left(\frac{\log(\kappa)}{\delta}\right)\right).$$

4 Application to least squares

The problem of *ordinary least squares (OLS)* is the following. Given data points $\{(\vec{x}^{(i)}, y^{(i)})\}_{i=1}^M$ for $\vec{x}^{(1)},\ldots,\vec{x}^{(M)} \in \mathbb{R}^N$ and $y^{(1)},\ldots,y^{(M)} \in \mathbb{R}$, find $\vec{\beta} \in \mathbb{R}^N$ that minimizes:

$$\sum_{i=1}^{M}(y^{(i)} - \vec{\beta}^T\vec{x}^{(i)})^2. \tag{2}$$

The motivation for this task is the assumption that the samples are obtained from some process such that at every sample i, $y^{(i)}$ depends linearly on $\vec{x}^{(i)}$, up to some random noise, so $y^{(i)}$ is drawn from a random variable $\vec{\beta}^T\vec{x}^{(i)} + E_i$, where E_i is a random variable with mean 0, for example, a Gaussian. The vector $\vec{\beta}$ that minimizes (2) represents a good estimate of the underlying linear function. We assume $M \geq N$ so that it is feasible to recover this linear function.

We can generalize this task to settings in which certain samples are thought to be of higher quality than others, for example, because the random variables E_i are not identical. We express this belief by assigning a positive weight w_i to each sample, and minimizing

$$\sum_{i=1}^{M} w_i(y^{(i)} - \vec{\beta}^T\vec{x}^{(i)})^2. \tag{3}$$

Let $X \in \mathbb{R}^{M\times N}$ be the matrix such that its i^{th} row is $\vec{x}^{(i)T}$. Finding $\vec{\beta}$ given X, $\vec{w}$ and $\vec{y}$ is the problem of *weighted least squares (WLS)*.

We can further generalize to settings in which the random variables E_i for sample i are correlated. In the problem of *generalized least squares (GLS)*, the presumed correlations in error between pairs of samples are given in a symmetric non-singular covariance matrix Ω. We then want to find the vector $\vec{\beta}$ that minimizes

$$\sum_{i,j=1}^{M} \Omega^{-1}_{i,j}(y^{(i)} - \vec{\beta}^T\vec{x}^{(i)})(y^{(j)} - \vec{\beta}^T\vec{x}^{(j)}). \tag{4}$$

We will consider solving *quantum* versions of these problems. Specifically, a *quantum WLS solver* (resp. *quantum GLS solver*) is given access to $\vec{y} \in \mathbb{R}^M$, $X \in \mathbb{R}^{M\times N}$, and positive weights $w_1,\ldots,w_M$ (resp. Ω), in some specified manner, and outputs an ε-approximation of a quantum state $\sum_i \beta_i|i\rangle / \left\|\vec{\beta}\right\|$, where $\vec{\beta}$ minimizes the expression in (3) (resp. (4)).

Quantum algorithms for least squares fitting were first considered in [32]. They considered query access to X, and a procedure for outputting $|y\rangle = \sum_i y_i|i\rangle / \|\vec{y}\|$, which we refer to as the sparse-access input model. They present a *quantum* OLS solver, outputting a state

proportional to a solution $\vec{\beta}$, that runs in time $\widetilde{\mathcal{O}}\left(\min\{\log(M)s^3\kappa^6/\varepsilon, \log(M)s\kappa^6/\varepsilon^2\}\right)$, where s is the sparsity of X, and κ the condition number. To compute a state proportional to $\vec{\beta}$, they first apply X^T to $|y\rangle$ to get a state proportional to $X^T\vec{y}$, using techniques similar to [18]. They then apply $(X^TX)^{-1}$ using the quantum linear system solving algorithm of [18], giving a final state proportional to $(X^TX)^{-1}X^T\vec{y} = X^+\vec{y}$.

The approach of [32] was later improved upon by [21], who also give a quantum OLS solver in the sparse-access input model. Unlike [32], they apply X^+ directly, by using Hamiltonian simulation of X and phase estimation to estimate the singular values of X, and then apply a rotation depending on the inverse singular value if it's larger than 0, and using amplitude amplification to de-amplify the singular-value-zero parts of the state. This results in an algorithm with complexity $\widetilde{\mathcal{O}}\left(s\kappa^3\log(M+N)/\varepsilon^2\right)$.

Several works have also considered quantum algorithms for least squares problems with a classical output. The first, due to Wang [30], outputs the vector $\vec{\beta}$ in a classical form. The input model should be compared with the sparse-access model – although $\vec{y}$ is given in classical random access memory, an assumption about the regularity of $\vec{y}$ means the quantum state $|y\rangle$ can be efficiently prepared. The algorithm also requires a regularity condition on the matrix X. The algorithm's complexity is $\mathrm{poly}(\log M, N, \kappa, \frac{1}{\varepsilon})$. Like [21], Wang's algorithm uses techniques from quantum linear system solving to apply X^+ directly to $|y\rangle$. To do this, Hamiltonian simulation of X is accomplished via what we would call a block-encoding of X. This outputs a state proportional to $X^+\vec{y}$, whose amplitudes can be estimated one-by-one to recover $\vec{\beta}$.

A second algorithm to consider least squares with a classical output is [27], which does not output $\vec{\beta}$, but rather, given an input $\vec{x}$, outputs $\vec{x}^T\vec{\beta}$, thus predicting a new data point. This algorithm requires that $\vec{x}$, $\vec{y}$, and even X be given as quantum states, and assumes that X has low approximate rank. The algorithm uses techniques from quantum principal component analysis [23], and runs in time $\mathcal{O}\left(\log(N)\kappa^2/\varepsilon^3\right)$.

Recently, Kerenidis and Prakash introduced the quantum data structure input model [19]. This input model fits data analysis tasks, because unlike in more abstract problems such as Hamiltonian simulation, where the input matrix may be assumed to be sparse and well-structured so that we can hope to have implemented efficient subroutines to find the non-zero entries of the rows and columns, the input to least squares is generally noisy data for which we may not assume any such structure. In Ref. [20], utilizing this data structure, they solve the quantum version of the *weighted* least squares problem. Their algorithm assumes access to quantum data structures storing X, or some closely related matrix (see Section 2.2), $W = \mathrm{diag}(\vec{w})$, and $\vec{y}$, and have running time $\widetilde{\mathcal{O}}\left(\frac{\kappa^6\mu}{\varepsilon}\mathrm{polylog}(MN)\right)$, where κ is the condition number of $X^T\sqrt{W}$, and μ is some prior choice of $\left\|X^T\sqrt{W}\right\|_F$ or $\sqrt{s_{2p}(X^T\sqrt{W})s_{2(1-p)}(X^T\sqrt{W})}$ for some $p \in [0,1]$[12]. Note that the choice of μ impacts the way X must be encoded, leading to a family of algorithms requiring slightly different encodings of the input.

[12] We stress that our algorithms do not achieve the minimum possible μ, but rather, we need to store the input in QROM with a particular μ in mind. We might more accurately describe the quantum data structure input model as a *family* of input models, parametrized by μ.

4.1 Our results

We give quantum WLS and GLS solvers in the model where the input is given as a block-encoding. As a special case, we get quantum WLS and GLS solvers in the quantum data structure input model of Kerenidis and Prakash. First, we give the following WLS solver:

▶ **Theorem 13.** *Let $A = \sqrt{W}X$ such that $\|A^+\| \leq \kappa_A$. Suppose $\sqrt{W}\vec{y}$ is stored in a quantum-accessible data structure, and A is μ-encoded. Suppose the data points have residual error $\overline{SS}^W_{\text{res}}$ satisfying $\overline{SS}^W_{\text{res}} \leq \eta$. Then we can implement a quantum WLS solver with error ε in complexity:*

$$\widetilde{\mathcal{O}}\left(\frac{\kappa_A \mu(A)}{\sqrt{1-\eta}}\text{polylog}\left(MN/\varepsilon\right)\right).$$

The *residual error* is a measure of how well the data can be linearly approximated. It is reasonable to assume that it's close to 0, as otherwise, linear regression is inappropriate. Indeed, previous work seems to implicitly assume it's bounded by a constant below 1.

Theorem 13 is a 6-th power improvement in the dependence on κ, and an exponential improvement in the dependent on $1/\varepsilon$ as compared with the quantum WLS solver of [20]. As a special case we get a quantum OLS solver, which compares favourably to previous quantum OLS solvers in the sparse-access model [32, 21] in having a linear dependence on κ, and a polylog$(1/\varepsilon)$ dependence on the precision. However, these previous results rely on QLS solver subroutines which have since been improved, so their complexity can also likely be improved.

In addition, we give the first quantum GLS solver. We first show how to implement a GLS solver when the inputs are given as block-encodings. We prove the following general Theorem:

▶ **Theorem 14.** *Suppose that we have a unitary U_y preparing a quantum state proportional to $\vec{y}$ in complexity T_y. Suppose $X \in \mathbb{R}^{M\times N}$, $\Omega \in \mathbb{R}^{M\times M}$ are such that $\|X\| \leq 1$, $\|\Omega\| \leq 1$ and $\Omega \succ 0$ is positive definite. Suppose that we have access to U_X that is an $(\alpha_X, a_X, 0)$-block-encoding of X which has complexity $T_X \geq a_X$, and similarly we have access U_Ω that is an $(\alpha_\Omega, a_\Omega, 0)$-block-encoding of $\Omega^{-\frac{1}{2}}$ which has complexity $T_\Omega \geq a_\Omega$. Let $A := \Omega^{-\frac{1}{2}}X$, and suppose we have the following upper bounds: $\|A^+\| \leq \kappa_A$, $\left\|\Omega^{-1}\right\| \leq \kappa_\Omega$, and $\overline{SS}^\Omega_{\text{res}} \leq \eta$. Then we can implement a quantum GLS-solver with error ε in complexity*

$$\mathcal{O}\left(\frac{\kappa_A \log\left(\kappa_A\right)}{\sqrt{1-\eta}}\left(\left(\sqrt{\kappa_\Omega}\alpha_X T_X + \alpha_\Omega T_\Omega\right)\log^3\left(\frac{\kappa_A}{\varepsilon}\right) + \sqrt{\kappa_\Omega}T_y\right)\right).$$

As a special case, we get the following:

▶ **Corollary 15.** *Suppose $\vec{y}$ is stored in a quantum-accessible data structure, and X, Ω are such that $\|X\| \leq 1$, $\|\Omega\| \leq 1$ and Ω is positive definite. Further assume they are μ-encoded and $\|X^+\| \leq \kappa_X$, $\|\Omega^+\| \leq \kappa_\Omega$. Then we can implement a quantum GLS-solver with error ε in complexity*

$$\widetilde{\mathcal{O}}\left(\frac{\kappa_X\sqrt{\kappa_\Omega}}{\sqrt{1-\eta}}\left(\mu(X) + \mu(\Omega)\kappa_\Omega\right)\text{polylog}\left(MN/\varepsilon\right)\right).$$

Note that for Theorem 14 and Corollary 15, the parameter κ_X is not exactly the condition number of X. In fact, what we require is that the product of the upper bounds on $\|X\|$ and $\|X^+\|$ respectively, be upper bounded by κ_X. Thus without loss of generality it suffices to consider that $\|X\| \leq 1$ and $\|X^+\| \leq \kappa_X$ (same holds for Ω).

Abstract

We examine connections between combinatorial notions that arise in machine learning and topological notions in cubical/simplicial geometry. These connections enable to export results from geometry to machine learning. Our first main result is based on a geometric construction by H. Tracy Hall (2004) of a partial shelling of the cross-polytope which can not be extended. We use it to derive a maximum class of VC dimension 3 that has no corners. This refutes several previous works in machine learning from the past 11 years. In particular, it implies that the previous constructions of optimal unlabeled compression schemes for maximum classes are erroneous.

On the positive side we present a new construction of an optimal unlabeled compression scheme for maximum classes. We leave as open whether our unlabeled compression scheme extends to ample (a.k.a. lopsided or extremal) classes, which represent a natural and far-reaching generalization of maximum classes. Towards resolving this question, we provide a geometric characterization in terms of unique sink orientations of the 1-skeletons of associated cubical complexes.

1 Introduction

The Sauer-Shelah-Perles Lemma [28, 30, 32] is arguably the most basic fact in VC theory; it asserts that any class $C \subseteq \{0,1\}^n$ satisfies $|C| \leq \binom{n}{\leq d}$, where $d = \text{VC-dim}(C)$. A beautiful generalization of Sauer-Shelah-Perles's inequality asserts that $|C| \leq |\overline{X}(C)|$, where $\overline{X}(C)$ is the family of subsets that are shattered by C.[1] The latter inequality is a part of the Sandwich Lemma [1, 4, 7, 23], which also provides a lower bound for $|C|$ (and thus "sandwiches" $|C|$) in terms of the number of its *strongly shattered subsets* (see Section 2). A class C is called *maximum/ample* if the Sauer-Shelah-Perles/Sandwich upper bounds are tight (respectively). Every maximum class is ample, but not vice versa.

Maximum classes were studied mostly in discrete geometry and machine learning, e.g. [34, 11, 9, 10, 14]. The history of ample classes is more interesting as they were discovered independently by several works in disparate contexts [1, 15, 4, 19, 3, 7, 35]. Consequently, they received different names such as lopsided classes [15], extremal classes [4, 19], and ample classes [3, 7]. Lawrence [15] was the first to define them for the investigation of the possible sign patterns realized by points of a convex set of $\mathbb{R}^d$. Interestingly, Lawrence's definition of these classes does not use the notion of shattering nor the Sandwich Lemma. In this context, these classes were discovered by Bollobás and Radcliffe [4] and Bandelt et al. [3], and the equivalence between the two definitions appears in [3]. Ample classes admit a multitude of combinatorial and geometric characterizations [3, 4, 15] and comprise many natural examples arising from discrete geometry, combinatorics, graph theory, and geometry of groups [3, 15].

Main Results

Corner Peelings. A *corner* in an ample class C is any concept $c \in C$ that belongs to a unique maximal cube of C (equivalently, c is a corner if $C \setminus \{c\}$ is also ample, see Claim 6). A sequence of corner removals leading to a single concept is called a *corner peeling*. Wiedemann [35] and independently Chepoi (unpublished, 1996) asked whether every ample class has a corner. The machine learning community studied this question independently in the context of *sample compression schemes* for maximum classes: Rubinstein and Rubinstein [25] showed that corner peelings lead to optimal *unlabeled sample compression schemes (USCS)*.

In Theorem 9 we refute this conjecture. The crux of the proof is an equivalence between corner peelings and partial shellings of the cross-polytope. This equivalence translates the question whether corners always exist to the question whether partial shellings can always be extended. The latter was an open question in Ziegler's book on polytopes [38], and was resolved in H. Tracy Hall's PhD thesis where she presented an interesting counterexample [13]. The ample class resulting from Hall's construction yields a maximum class without corners.

Sample Compression. Sample compression is a powerful technique to derive generalization bounds in statistical learning. Littlestone and Warmuth [16] introduced it and asked if every class of VC-dimension $d < \infty$ has a sample compression scheme of a finite size. This question was later precised by Floyd and Warmuth [10, 33] to *whether a sample compression scheme of size $O(d)$ exists*. The first question was recently resolved by [21] who exhibited an $\exp(d)$ sample compression. The second question however remains one of the oldest open problems in machine learning (for more background we refer the reader to [20] and the books [29, 36]).

[1] Note that this inequality indeed implies the Sauer-Shelah-Perles Lemma, since $|\overline{X}(C)| \leq \binom{n}{\leq d}$.

Rubinstein and Rubinstein [25, Theorem 16] showed that the existence of a corner peeling for a maximum class C implies a *representation map* for C (see Section 3 for a definition), which is known to yield an optimal unlabeled sample compression scheme of size VC-dim(C) [14].[2] They claim, using an interesting topological approach, that maximum classes admit corner peelings. Unfortunately, our Theorem 9 shows that this does not hold.

While our Theorem 9 rules out the program of deriving representation maps from corner peelings, in Theorem 10 we provide an alternative derivation of representation maps for maximum classes and therefore also of an unlabeled sample compression scheme for them.

Sample Compression and Unique Sink Orientations. We next turn to construction of representation maps for ample classes. In Theorem 15 we present geometric characterizations of such maps via *unique sink orientations*: an orientation of the edges of a cube B is a *unique sink orientation (USO)* if any subcube $B' \subseteq B$ has a unique sink. Szabó and Welzl [31] showed that any USO of B leads to a representation map for B. We extend this bijection to ample classes C by proving that representation maps are equivalent to orientations o of C such that (i) o is a USO on each subcube $B \subseteq C$, and (ii) for each $c \in C$ the edges outgoing from c belong to a subcube $B \subseteq C$. We further show that any ample class admits orientations satisfying each one of those conditions. However, *the question whether all ample classes admit representation maps remains open.*

Implications on Previous Works. Our Theorem 9 establishes the existence of maximum classes without any corners, thus countering several previous results in machine learning:

- Rubinstein and Rubinstein [25, Theorem 32] showed that any maximum class can be represented by a simple arrangement of piecewise-linear hyperplanes. In [25, Theorem 39], they claim that sweeping such an arrangement leads to a corner peeling of the corresponding maximum class. This is unfortunately false, as witnessed by Theorem 9.
- Kuzmin and Warmuth [14] constructed unlabeled sample compression schemes for maximum classes based on the presumed uniqueness of a certain matching (their Theorem 10). This theorem is wrong as it implies the existence of corners. However their conclusion is correct: in our Theorem 10 we show that such unlabeled compression schemes exist.
- Theorem 3 by Samei, Yang, and Zilles [27] is built on a generalization of Theorem 10 from [14] to the multiclass case which is also incorrect.
- Theorem 26 by Doliwa et al. [6] uses the result by [25] to show that the Recursive Teaching Dimension (RTD) of maximum classes equals to their VC dimension. However the VC dimension 3 maximum class from Theorem 9 has RTD at least 4. It remains open whether the RTD of every maximum class C is bounded by $O(\text{VC-dim}(C))$.

Organization. Section 2 presents the main definitions and notations. Section 3 reviews characterizations of ample/maximum classes and presents characteristic examples. Section 4 demonstrates the existence of the maximum class C_H without corners. Section 5 establishes the existence of representation maps for maximum classes. Section 6 establishes a bijection between representation maps and unique sink orientations for ample classes. Due to space limitations, some proofs are omitted and can be found in the full version of this paper [5].

[2] Pálvölgyi and Tardos [24] recently exhibited a (non-ample) class C with no USCS of size VC-dim(C).

2 Preliminaries

A *concept class* C is a set of subsets (concepts) of a finite ground set U which is called the *domain* of C and denoted $\mathrm{dom}(C)$. We sometimes treat the concepts as characteristic functions rather than subsets. The *support* (or *dimension set*) $\mathrm{supp}(C)$ of C is the set $\{x \in U : x \in c' \setminus c'' \text{ for some } c', c'' \in C\}$. $C^* := 2^U \setminus C$ is the *complement* of C. The *restriction* of C on $Y \subseteq U$ is the class $C|Y = \{c \cap Y : c \in C\}$ whose domain is Y. We use C_Y as shorthand for $C|(U \setminus Y)$; in particular, we write C_x for $C_{\{x\}}$, and c_x for $c|(U \setminus \{x\})$ for $c \in C$ (note that $c_x \in C_x$). A class $B \subseteq 2^U$ is a *cube* if there exists $Y \subseteq U$ such that $B|Y = 2^Y$ and B_Y contains a single concept (denoted by $\mathrm{tag}(B)$). Note that $\mathrm{supp}(B) = Y$ and therefore we say that B is a *Y-cube*; $|Y|$ is called the *dimension* $\dim(B)$ of B. Two cubes B, B' with the same support are called *parallel cubes*. A cube B is *maximal* if there is no cube B' such that $B \subsetneq B'$.

Let Q_n denote the n-dimensional cube where $n = |U|$; $c, c' \in Q_n$ are called adjacent if the symmetric difference $c \Delta c'$ is of size 1. The *1-inclusion graph* of C is the subgraph $G(C)$ of Q_n induced by the vertex-set C when the concepts of C are identified with the corresponding vertices of Q_n. Any cube $B \subseteq C$ is called *a cube of* C. The *cube complex* of C is the set $Q(C) = \{B : B \text{ is a cube of } C\}$. The *dimension* of $Q(C)$ is $\dim(Q(C)) := \max_{B \in Q(C)} \dim(B)$. A concept $c \in C$ is called a *corner* of C if c belongs to a unique maximal cube of C. The *reduction* C^Y of C to $Y \subseteq U$ is the class $C^Y := \{\mathrm{tag}(B) : B \in Q(C) \text{ and } \mathrm{supp}(B) = Y\}$ whose domain is $U \setminus Y$. When $x \in U$ we denote $C^{\{x\}}$ by C^x and call it *the x-hyperplane of* C. Note that a concept c belongs to C^x if and only if c and $c \cup \{x\}$ both belong to C. The union of all cubes of C having x in their support is called the *carrier* of C^x and is denoted by $N_x(C)$. If $c \in N_x(C)$, we also denote $c|U \setminus \{x\}$ by c^x (note that $c^x \in C^x$).

A class C is *connected* if the graph $G(C)$ is connected. Let $d_{G(C)}(c, c')$ denote the distance between c and c' in $G(C)$. Note that $d_{Q_n}(c, c') =: d(c, c')$ coincides with the Hamming distance $|c \Delta c'|$. Let $B(c, c') = \{t \subseteq U : d(c, t) + d(t, c') = d(c, c')\}$ be the *interval* between c and c' in Q_n. A class C is called *isometric* if $d(c, c') = d_{G(C)}(c, c')$ for any $c, c' \in C$ and *weakly isometric* if $d(c, c') = d_{G(C)}(c, c')$ if $d(c, c') \leq 2$. Any path connecting two concepts $\mathrm{tag}(B)$ and $\mathrm{tag}(B')$ of C^Y inside C^Y can be lifted to a path of Y-cubes connecting B and B' in C; such a path of cubes is called a *gallery*.

A class C *shatters* $Y \subseteq U$ if $C|Y = 2^Y$. C *strongly shatters* Y if C contains a Y-cube. Let $\overline{X}(C)$, $\underline{X}(C)$ denote the simplicial complexes $\overline{X}(C) = \{Y : C \text{ shatters } Y\}$, $\underline{X}(C) = \{Y : C \text{ strongly shatters } Y\}$. Note that $\underline{X}(C) \subseteq \overline{X}(C)$. The *VC-dimension* $\text{VC-dim}(C)$ of C is the size of a largest set C shatters. The *Sandwich Lemma* asserts that $|\underline{X}(C)| \leq |C| \leq |\overline{X}(C)|$.

A *labeled sample* is a set $s = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, where $x_i \in U$ and $y_i \in \{0, 1\}$. An *unlabeled sample* is a set $\{x_1, \ldots, x_m\}$, where $x_i \in U$. Given a labeled sample $s = \{(x_1, y_1), \ldots, (x_m, y_m)\}$, the unlabeled sample $\{x_1, \ldots, x_m\}$ is the domain of s and is denoted by $\mathrm{dom}(s)$. A sample s is *realizable* by a concept $c : U \to \{0, 1\}$ if $c(x_i) = y_i$ for every i, and s is realizable by a concept class C if it is realizable by some $c \in C$.

A *sample compression scheme* for a concept class C is best viewed as a protocol between a *compressor* and a *reconstructor*. The compressor gets a realizable sample s from which it picks a small subsample s'. The compressor sends s' to the reconstructor. Based on s', the reconstructor outputs a concept c that needs to be consistent with the entire input sample s. A sample compression scheme has size k if for every realizable input sample s the size of the compressed subsample s' is at most k. An *unlabeled (sample) compression scheme* (USCS) is a sample compression scheme in which the compressed subsample s' is unlabeled. So, the compressor removes the labels before sending the subsample to the reconstructor.

3 Ample and Maximum Classes

We briefly review the main characterizations and basic geometric examples of ample and maximum classes. The next theorem summarizes the main characterizations of ample classes:

▶ **Theorem 1** ([3, 4, 15]). *The following are equivalent for a class C: (1) C is ample; (2) C^* is ample; (3) $\underline{X}(C) = \overline{X}(C)$; (4) $|\underline{X}(C)| = |C|$; (5) $|\overline{X}(C)| = |C|$; (6) $C \cap B$ is ample for any cube B; (7) $(C^Y)_Z = (C_Z)^Y$ for all partitions $U = Y \cup Z$; (8) for all partitions $U = Y \cup Z$, either $Y \in \underline{X}(C)$ or $Z \in \underline{X}(C^*)$.*

Condition (3) leads to a simple definition of ampleness: C is ample if whenever $Y \subseteq U$ is shattered by C, then there is a Y-subcube of C. Thus, if C is ample we will write $X(C)$ instead of $\underline{X}(C) = \overline{X}(C)$. A *representation map* for an ample class C is a bijection $r : C \to X(C)$ satisfying the *non-clashing condition*: $c|(r(c) \cup r(c')) \neq c'|(r(c) \cup r(c'))$, for all $c, c' \in C, c \neq c'$. We continue with metric and recursive characterizations of ample classes:

▶ **Theorem 2** ([3]). *The following are equivalent for a class C: (1) C is ample; (2) C^Y is connected for all $Y \subseteq U$; (3) C^Y is isometric for all $Y \subseteq U$; (4) C is isometric, and both C_x and C^x are ample for all $x \in U$; (5) C is connected and all hyperplanes C^x are ample.*

▶ **Corollary 3.** *Two maximal cubes of an ample class C have different supports.*

Indeed, if B and B' are two d-cubes with the same support, by Theorem 2(2) B and B' can be connected in C by a gallery, and thus B is contained in a $d+1$-cube. Therefore, B and B' cannot be maximal.

The Sandwich Lemma and Theorem 1(5) imply that maximum classes are ample. Basic examples of maximum classes are concept classes derived from hyperplane arrangements in $\mathbb{R}^n$, ball arrangements in $\mathbb{R}^n$, and unions of n intervals in $\mathbb{R}$. The following theorem summarizes some characterizations of maximum classes provided in [11, 9, 10, 34]:

▶ **Theorem 4.** *The following are equivalent for a class C: (1) C is maximum; (2) C_Y is maximum for all $Y \subseteq U$; (3) C_x and C^x are maximum for all $x \in U$; (4) C^* is maximum.*

We continue with some important geometric examples of ample classes.

1. Simplicial Complexes. Every simplicial complex S (viewed as a set system closed under taking subsets) is ample since $\overline{X}(S) = \underline{X}(S)$.

2. Realizable Ample Classes. Let $K \subseteq \mathbb{R}^n$ be a convex set. Let $C(K) := \{\text{sign}(v) : v \in K, v_i \neq 0 \, \forall i \leq n\}$, where $\text{sign}(v) \in \{\pm 1\}^n$ is the sign pattern of v. Lawrence [15] showed that $C(K)$ is ample, and called ample classes representable in this manner *realizable*.

3. Median Classes. A class C is called *median* if for every three concepts c_1, c_2, c_3 of C their *median* $m(c_1, c_2, c_3) := (c_1 \cap c_2) \cup (c_1 \cap c_3) \cup (c_2 \cap c_3)$ also belongs to C. Median classes are ample by [3, Proposition 2]. Due to their relationships with other discrete structures, median classes are one of the most important examples of ample classes. Median classes are equivalent to finite median graphs (a well-studied class in metric graph theory, see [2]), to CAT(0) cube complexes, i.e., cube complexes of global nonpositive curvature (central objects in geometric group theory, see [12, 26]), and to the domains of event structures (a basic model in concurrency theory [22, 37]).

4. Convex Geometries and Conditional Antimatroids. Let C be a class such that (i) $\varnothing \in C$ and (ii) $c, c' \in C$ implies that $c \cap c' \in C$. Call $x \in c \in C$ *extremal* if $c \setminus \{x\} \in C$. We say that $c \in C$ is *generated* by $s \subseteq c$ if c is the smallest member of C containing s. A class C satisfying (i) and (ii) with the additional property that every member c of C is generated by its extremal points is called a *conditional antimatroid* [3, Section 3]. If $U \in C$, then we obtain the well-known structure of a *convex geometry* (called also an *antimatroid*) [8]. By [3, Proposition 1], conditional antimatroids C are ample since $\underline{X}(C)$ coincides with the sets of extremal points and $\overline{X}(C)$ coincides with the set of all minimal generating sets of sets from C. Convex geometries comprise many examples from geometry, ordered sets, and graphs; see the foundational paper [8]. For example, a *realizable convex geometry* is a convex geometry $C \subseteq U$ such that U can be realized as a set of $\mathbb{R}^n$ and $c \in C$ if and only if c is the intersection of a convex set of $\mathbb{R}^n$ with U.

4 Corner Peelings and Partial Shellings

In this section, we prove that corner peelings of ample classes are equivalent to isometric orderings of C as well as to partial shellings of the cross-polytope. This equivalence, combined with a result by Hall [13] yields a maximum class with VC dimension 3 without corners (Theorem 9 below). Let $C_< := (c_1, \ldots, c_m)$ be an ordering of the concepts in C. For any $1 \leq i \leq m$, let $C_i := \{c_1, \ldots, c_i\}$ denote the *i'th level set*. The ordering $C_<$ is called:

- an *ample* ordering if every level set C_i is ample;
- a *corner peeling* if every c_i is a *corner* of C_i;
- an *isometric* ordering if every level set C_i is isometric;
- a *weakly isometric* ordering if every level set C_i is weakly isometric.

▶ **Proposition 5.** *The following are equivalent for an ordering $C_<$ of an isometric class C: (1) $C_<$ is ample; (2) $C_<$ is a corner peeling; (3) $C_<$ is isometric; (4) $C_<$ is weakly isometric.*

Proof. Clearly, (3)⇒(4). Conversely, suppose $C_<$ is weakly isometric but one of its levels is not isometric. Hence, there exists $i < j$ such that any shortest (c_i, c_j)-path in C contains some c_k with $k > j$. Additionally, assume that c_i, c_j minimizes the distance $d(c_i, c_j)$ among all such pairs. Since C_j is weakly isometric, necessarily $d(c_i, c_j) \geq 3$. Let c_r be the first concept among $\{c_{j+1}, \ldots, c_m\}$ lying in $B(c_i, c_j) \cap C$. If $d(c_i, c_r) \geq 3$ or $d(c_r, c_j) \geq 3$ (say the first), then one can replace c_i, c_j by c_i, c_r, which contradicts the choice of c_i, c_j. Thus, $d(c_i, c_r), d(c_r, c_j) \leq 2$, and at least one of them equals 2 (say $d(c_i, c_r) = 2$). Now, weak isometricity implies that c_i and c_r have a common neighbor c_ℓ with $\ell < \max\{i, r\} = r$. If $\ell < j$ then c_ℓ, c_j contradicts the minimality of c_i, c_j, and if $j < \ell < r$ then c_ℓ contradicts the minimality of c_r. This shows (4)⇒(3).

If c_i is a corner of C_i, then any two neighbors of c_i in C_i have a second common neighbor in C_i, and therefore $d_{G(C_{i-1})}$ is the restriction of $d_{G(C_i)}$ on C_{i-1}. Since $C_m = C$ is isometric, this proves (2)⇒(3). We now prove (3)⇒(1)⇒(2) using the next lemma. For $t \notin C$, let $F[t]$ be the smallest cube of Q_n containing t and all neighbors of t in $G(C)$. Note that the dimension of $F[t]$ is the number of neighbors of t in $G(C)$.

▷ Claim 6. Let C be ample. Then: *(i)* If $t \notin C$ then $F[t] \subseteq C \cup \{t\}$. *(ii)* If c is a corner of C then $C \setminus \{c\}$ is ample. *(iii)* If $t \notin C$ and $C' := C \cup \{t\}$ is isometric then C' is ample and t is a corner of C'.

Proof. Item (i): Suppose $F[t] \setminus C \neq \{t\}$. Pick $s \neq t$ that is closest to t in $F[t] \setminus C$ (with respect to the Hamming distance of Q_n). Then t and s are not adjacent (by the definition of $F[t]$). By the choice of s, $B(s,t) \setminus \{s,t\} \subseteq C$, i.e., $B(s,t) \cap C^* = \{t,s\}$, contrary to the ampleness of C^*.

Item (ii): If $c \in C$ is a corner then there is a unique maximal cube $F \subseteq C$ containing it. Combined with Corollary 3, this implies that $\underline{X}(C \setminus \{c\}) = \underline{X}(C) \setminus \{\mathrm{supp}(F)\}$. Next, since $|C| = |\underline{X}(C)|$, we get that $|C \setminus \{c\}| = |\underline{X}(C \setminus \{c\})|$, and by Theorem 1 $C \setminus \{c\}$ is ample.

Item (iii): To prove that C' is ample, we use Theorem 2(2). First note that by item (i), $F[t] \subseteq C'$. Let $F' \neq F''$ be parallel cubes of C'. If $t \notin F' \cup F''$, then a gallery connecting F' and F'' in C is a gallery in C'. So, assume $t \in F'$. If F' is a proper face of $F[t]$, then F' is parallel to a face F of $F[t]$ not containing t. Since F' and F are connected in $F[t]$ by a gallery and F and F'' are connected in C by a gallery, we obtain a gallery between F' and F'' in C'. Finally, let $F' = F[t]$. In this case, we assert that F'' does not exist. Otherwise, let π be the parallelism map between F' and F'' (π maps each concept in F' to its unique closest concept in F''). Note that for any $r \in F'$: $d(t,\pi(t)) = d(r,\pi(r)) = d(F',F'')$. Since C' is isometric, t and $\pi(t)$ can be connected in C' by a path P of length $d(t,\pi(t))$. Let s be the neighbor of t in P. Since $s \in C$ it follows that $s \in F[t] = F'$. So, s is a concept in F' that is closer to $\pi(t)$ than t; this contradicts that $d(t,t'') = d(F',F'')$. ◁

To show (1)⇒(2), let $C_<$ be an ample order of C. We assert that each c_i is a corner of C_i. Indeed, since C_{i-1} is ample and $c_i \notin C_{i-1}$, by Item (i) in Claim 6 the cube $F[c_i]$, defined with respect to C_{i-1}, is included in C_i. Thus, c_i belongs to a unique maximal cube $F[c_i]$ of C_i, i.e., c_i is a corner of C_i. To prove (3)⇒(1), let $C_<$ be isometric. The ampleness of each C_i follows by induction from Item (iii) of Claim 6. ◀

A concept class C is *dismantlable* if it admits an ordering satisfying any of the equivalent conditions (1)-(4) in Proposition 5. Isometric orderings of Q_n are closely related to shellings of its dual, the *cross-polytope* O_n (which we define next). Define $\pm U := \{\pm x_1, \ldots, \pm x_n\}$; so, $|\pm U| = 2n$, and we call $-x_i, +x_i$ *antipodal*. The n-dimensional *cross-polytope* is the pure simplicial complex of dimension n whose facets are all $\sigma \subseteq \pm U$ that contain exactly one element in each antipodal pair. Thus, O_n has 2^n facets and each facet σ of O_n corresponds to a vertex c of Q_n ($+x_i \in \sigma$ if and only if $x_i \in c$). Observe that $x_i \in c' \Delta c''$ if and only if $\{+x_i, -x_i\} \subseteq \sigma' \Delta \sigma''$ where σ' correspond to c' and σ'' corresponds to c''.

Let X be a pure simplicial complex (PSC) of dimension d, i.e., a simplicial complex in which all facets have size d. Two facets σ, σ' are adjacent if $|\sigma \Delta \sigma'| = 2$. A *shelling* of X is an ordering $\sigma_1, \ldots, \sigma_p$ of all of its facets such that $2^{\sigma_j} \bigcap (\bigcup_{i<j} 2^{\sigma_i})$ is a PSC of dimension $d-1$ for every $j \leq p$ [38, Lecture 8]. A *partial shelling* is an ordering of some facets that satisfies the above condition. Note that $\sigma_1, \ldots, \sigma_m$ is a partial shelling if and only if for every $i < j$ there exists $k < j$ such that $\sigma_i \cap \sigma_j \subseteq \sigma_k \cap \sigma_j$, and $\sigma_k \cap \sigma_j$ is a facet of both σ_j and σ_k. X is *extendably shellable* if every partial shelling can be extended to a shelling. We next establish a relationship between partial shellings and isometric orderings.

▶ **Proposition 7.** *Every partial shelling of the cross-polytope O_n defines an isometric ordering of the corresponding vertices of the cube Q_n. Conversely, if C is an isometric class of Q_n, then any isometric ordering of C defines a partial shelling of O_n.*

Proof. Let $\sigma_1, \ldots, \sigma_m$ be a partial shelling of O_n and $c_1, \ldots, c_m$ be the ordering of the corresponding vertices of Q_n. We need to prove that each level set $C_j = \{c_1, \ldots, c_j\}$ is isometric. It suffices to show that for every $i < j$ there is $k < j$ such that $d(c_k, c_j) = 1$ and $c_k \in B(c_i, c_j)$. Equivalently, that $|\sigma_k \Delta \sigma_j| = 2$ and $\sigma_i \cap \sigma_j \subseteq \sigma_k \subseteq \sigma_i \cup \sigma_j$: since

$\sigma_1, \ldots, \sigma_m$ is a partial shelling, there is a facet σ_k with $k < j$ such that $|\sigma_k \cap \sigma_j| = n-1$ and $\sigma_i \cap \sigma_j \subseteq \sigma_k \cap \sigma_j$. We claim that σ_k is the desired facet. It remains to show that (i) $|\sigma_j \Delta \sigma_k| = 2$ and (ii) $\sigma_k \subseteq \sigma_i \cup \sigma_j$. Item (i) follows since $|\sigma_j| = |\sigma_k| = n$, and $|\sigma_k \cap \sigma_j| = n-1$. For Item (ii), let $\sigma_j \setminus \sigma_k = \{+x\}$ and $\sigma_k \setminus \sigma_j = \{-x\}$. We need to show that $-x \in \sigma_i$, or equivalently that $+x \notin \sigma_i$. The latter follows since $+x \in \sigma_j \setminus \sigma_k$ and $\sigma_j \cap \sigma_i \subseteq \sigma_k$.

Conversely, let $c_1, \ldots, c_m$ be an isometric ordering and $\sigma_1, \ldots, \sigma_m$ be the ordering of the corresponding facets of O_n. We assert that this is a partial shelling. Let $i < j$. It suffices to exhibit $k < j$ such that $|\sigma_k \cap \sigma_j| = n-1$ and $\sigma_i \cap \sigma_j \subseteq \sigma_k \cap \sigma_j$. Since C_j is isometric, c_j has a neighbor $c_k \in B(c_i, c_j) \cap C_j$. Since $d(c_j, c_k) = 1$ it follows that $|\sigma_k \cap \sigma_j| = n-1$. Since $c_k \in B(c_i, c_j)$ it follows that $\sigma_i \cap \sigma_j \subset \sigma_k \subset \sigma_i \cup \sigma_j$ and hence that $\sigma_i \cap \sigma_j \subseteq \sigma_k \cap \sigma_j$. ◀

▶ **Corollary 8.** *If all ample classes are dismantlable, then O_n is extendably shellable.*

Proof. Let $\sigma_1, \ldots, \sigma_m$ be a partial shelling of O_n and let $C = \{c_1, \ldots, c_m\}$ be the corresponding vertices of Q_n. By Proposition 7, the level sets are isometric, thus C is ample by Proposition 5. The complement C^* is also ample, thus dismantlable. Thus C^* contains a concept t such that $C^* \setminus \{t\}$ is ample. Consequently, $C' := C \cup \{t\}$ is ample. Let τ be the facet of O_n corresponding to t. Since $c_1, \ldots, c_m, t$ is an isometric ordering of C', by Proposition 7, $\sigma_1, \ldots, \sigma_m, \tau$ is a partial shelling of O_n. ◀

It was asked in [38] if any cross-polytope O_n is extendably shellable. In the PhD thesis of H. Tracy Hall from 2004, a nice counterexample to this question is given [13]. Hall's counterexample arises from the 299 regions of an arrangement of 12 pseudo-hyperplanes. These regions are encoded as facets of the cross-polytope O_{12} and it is shown in [13] that the subcomplex of O_{12} consisting of all other facets admits a shelling which cannot be extended. By the proof of Corollary 8, the ample concept class C_H defined by those 299 simplices does not have any corner.[3] A counting shows that C_H is a maximum class of VC-dimension 3. This completes the proof of our first main result:

▶ **Theorem 9.** *There exists a maximum class C_H of VC-dimension 3 without any corner.*

However, conditional antimatroids and 2-dimensional ample classes are dismantlable. The 2-dimensional case was proved in [25, Theorem 34] for maximum classes and in [18] for ample classes. The proof for conditional antimatroids appears in the full version of this paper [5], as well as a different proof for the 2-dimensional case that is based on a local characterization of convex sets of ample classes.

5 Representation Maps for Maximum Classes

In this section, we prove that maximum classes admit representation maps and therefore by [14, Lemma 1], they admit optimal unlabeled compression schemes.

▶ **Theorem 10.** *Any maximum class $C \subseteq 2^U$ of VC-dimension d admits a representation map, and consequently, an unlabeled compression scheme of size d.*

The crux of the proof of Theorem 10 is the following proposition. Let C be a d-dimensional maximum class and let $D \subseteq C$ be a $(d-1)$-dimensional maximum subclass. A *missed simplex* for the pair (C, D) is a simplex $\sigma \in X(C) \setminus X(D)$. Note that any missed simplex has size d.

[3] For the interested reader, a file containing the 299 concepts of C_H represented as elements of $\{0,1\}^{12}$ is available at `https://arxiv.org/src/1812.02099/anc/CH.txt`.

An *incomplete cube* Q for (C, D) is a cube of C such that $\mathrm{supp}(Q)$ is a missed simplex. For any incomplete cube Q with $\sigma = \mathrm{supp}(Q)$, $C|\sigma$ and $D|\sigma$ are maximum classes of dimensions d and $d-1$, respectively. Since $|\sigma| = d$, we have $|C|\sigma| = \binom{d}{\leq d} = \binom{d}{\leq d-1} + 1 = |D|\sigma| + 1$. Since $Q|\sigma = C|\sigma$, there exists a unique concept $c \in Q$ such that $c|\sigma \notin D|\sigma$. We denote c by $s(Q)$, and call c the *source* of Q. In fact, the source map is a bijection between missed simplices for (C, D) and concepts of $C \setminus D$:

▶ **Proposition 11.** *Each $c \in C \setminus D$ is the source of a unique incomplete cube. Moreover, if $r' : D \to X(D)$ is a representation map for D and $r : C \to X(C)$ extends r' by setting $r(c) = \mathrm{supp}(s^{-1}(c))$ for each $c \in C \setminus D$, then r is a representation map for C.*

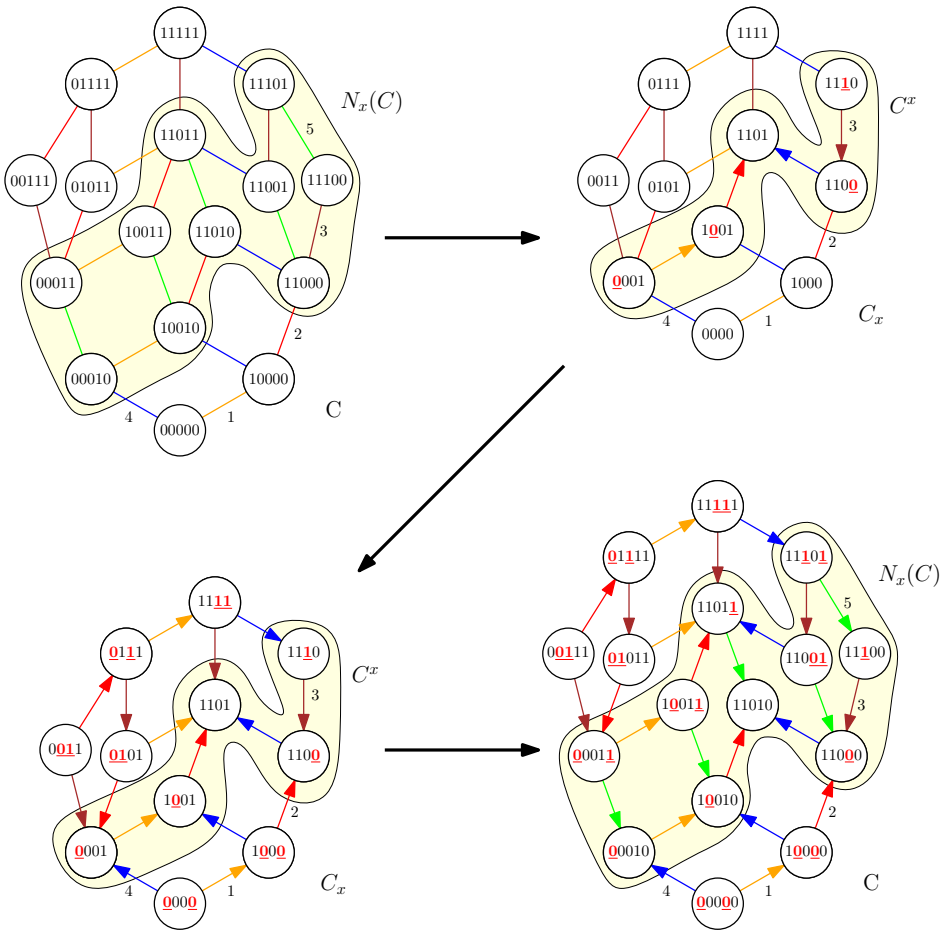

Figure 1 Illustrating the proof of Theorem 10 (when $x = 5$): to construct a representation map for C, we inductively construct a representation map r^x for C^x, extend it to a representation map r_x for C_x using Proposition 11 with $D = C^x$, and finally extend it to a representation map r for C. The representation maps r^x, r_x, and r are defined by the orientation as in Theorem 15 and by the coordinates of the underlined bits.

Proof of Theorem 10. Following the general idea of [14], we derive a representation map for C by induction on $|U|$. For the induction step (see Fig. 1), pick $x \in U$ and consider the maximum classes C_x and $C^x \subset C_x$ with domain $U \setminus \{x\}$. By induction, C^x has a representation map r^x. Use Proposition 11 to extend r^x to a representation map r_x of C_x. Define a map r on C as follows:

- $r(c) = r_x(c_x)$ if $c_x \notin C^x$ or $x \notin c$,
- $r(c) = r_x(c_x) \cup \{x\}$ if $c_x \in C^x$ and $x \in c$.

It is easy to verify that r is non-clashing: indeed, if $c' \neq c'' \in C$ satisfy $c'_x \neq c''_x$ then $c'_x | r_x(c'_x) \cup r_x(c''_x) \neq c''_x | r_x(c'_x) \cup r_x(c''_x)$. Since $r_x(c'_x) \subseteq r(c'), r_x(c''_x) \subseteq r(c'')$, it follows that also c', c'' disagree on $r(c') \cup r(c'')$. Else, $c'_x = c''_x \in C^x$ and $c'(x) \neq c''(x)$. In this case, $x \in r(c') \cup r(c'')$ and therefore c', c'' disagree on $r(c') \cup r(c'')$.

It remains to show that r is a bijection between C and $X(C) = \binom{U}{\leq d}$. It is easy to verify that r is injective. So, it remains to show that $|r(c)| \leq d$, for every $c \in C$. This is clear when $c_x \notin C^x$ or $x \notin c$. If $c_x \in C^x$ and $x \in c$, then $r(c) = r^x(c_x) \cup \{x\}$ and $|r^x(c_x)| \leq d-1$ (since C^x is $(d-1)$-dimensional). Hence, $|r(c)| \leq d$ as required, concluding the proof. ◀

Proof of Proposition 11. Call a maximal cube of C a *chamber* and a facet of a chamber a *panel* (a σ'-*panel* if its support is σ'). Any σ'-panel in C satisfies $|\sigma'| = d-1$ and $\sigma' \in X(D)$. Recall that a gallery between two parallel cubes Q', Q'' (say, two σ'-cubes) is any simple path of σ'-cubes $(Q_0 := Q', Q_1, \ldots, Q_k := Q'')$, where $Q_i \cup Q_{i+1}$ is a d-cube. By Theorem 2(3), any two parallel cubes of C are connected by a gallery in C. Since D is a maximum class, any panel of C is parallel to a panel that is a maximal cube of D. Also for any maximal simplex $\sigma' \in X(D)$, the class $C^{\sigma'}$ is a maximum class of dimension 1 and $D^{\sigma'}$ is a maximum class of dimension 0 (single concept). Thus $C^{\sigma'}$ is a tree (e.g. [11, Lemma 7]) which contains the unique concept $c \in D^{\sigma'}$. We call c *the root* of $C^{\sigma'}$ and denote the σ'-panel P such that $P^{\sigma'} = c$ by $P(\sigma')$.

▷ Claim 12. Let Q be an incomplete cube for (C, D) with source s and support σ, and let $x, y \in U$ such that $x \notin \sigma$ and $y \in \sigma$. Then, the following holds:

(i) Q_x is an incomplete cube for (C_x, D_x) whose source is s_x.

(ii) Q^y is an incomplete cube for (C^y, D^y) whose source is s^y.

Proof. Item (i): C_x and D_x are maximum classes on $U \setminus \{x\}$ of VC-dimensions d and $d-1$, and $\mathrm{supp}(Q_x) = \sigma$. Therefore, Q_x is an incomplete cube for (C^x, D^x). By definition, s is the unique concept $c \in Q$ such that $c|\sigma \notin D|\sigma$. Since $x \notin \sigma$, $D|\sigma = D_x|\sigma$ and s_x is the unique concept c of Q_x so that $c|\sigma \notin D_x|\sigma$, i.e., s_x is the source of Q_x.

Item (ii): C^y and D^y are maximum classes on $U \setminus \{y\}$ of VC-dimensions $d-1$ and $d-2$. Since $y \in \mathrm{supp}(Q)$, $\dim(Q^y) = d-1$ and Q^y is an incomplete cube for (C^y, D^y). Let $\sigma' = \sigma \setminus \{y\}$. It remains to show that $s^y|\sigma' \notin D^y|\sigma'$. Indeed, otherwise both extensions of s^y in σ, namely $s, s\Delta\{y\}$, are in $D|\sigma$ which contradicts that $s = s(Q)$. ◁

Next we prove that each concept of $C \setminus D$ is the source of a unique incomplete cube. Assume the contrary and let (C, D) be a counterexample minimizing the size of U. First, if a concept $c \in C \setminus D$ is the source of two incomplete cubes Q_1, Q_2, then $\mathrm{dom}(C) = \mathrm{supp}(Q_1) \cup \mathrm{supp}(Q_2)$. Indeed, let $\sigma_1 = \mathrm{supp}(Q_1)$ and $\sigma_2 = \mathrm{supp}(Q_2)$. By Claim 12(i) and minimality of (C, D), $\mathrm{dom}(C) = \sigma_1 \cup \sigma_2$. By Claim 12(ii) and minimality of (C, D), $\sigma_1 \cap \sigma_2 = \varnothing$. Indeed, if there exists x in $\sigma_1 \cap \sigma_2$, c^x is the source of the incomplete cubes Q_1^x and Q_2^x for (C^x, D^x), contrary to minimality of (C, D).

Next we assert that any $c \in C \setminus D$ is the source of at most 2 incomplete cubes. Indeed, let c be the source of incomplete cubes Q_1, Q_2, Q_3. Then $\mathrm{dom}(C) = \mathrm{supp}(Q_1) \uplus \mathrm{supp}(Q_2)$, i.e., $\mathrm{supp}(Q_2) = \mathrm{dom}(C) \setminus \mathrm{supp}(Q_1)$. For similar reasons, $\mathrm{supp}(Q_3) = \mathrm{dom}(C) \setminus \mathrm{supp}(Q_1) = \mathrm{supp}(Q_2)$. Thus, by Corollary 3, $Q_2 = Q_3$.

▷ Claim 13. Let $c', c'' \in C \setminus D$ be neighbors and let $c'\Delta c'' = \{x\}$. Then, c' is the source of 2 incomplete cubes if and only if c'' is the source of 0 incomplete cubes. Consequently, every connected component in $G(C \setminus D)$ either contains only concepts c with $|s^{-1}(c)| \in \{0, 2\}$, or only concepts c with $|s^{-1}(c)| = 1$.

Proof. By minimality of (C, D), $(c')^x = (c'')^x$ is the source of a unique incomplete cube for (C^x, D^x) and $c'_x = c''_x$ is the source of a unique incomplete cube for (C_x, D_x). Let Q_1 be the incomplete cube for (C, D) such that $(c')^x$ is the source of Q_1^x. Let Q_2 be the incomplete cube for (C, D) such that c'_x is the source of $(Q_2)_x$. By Claim 12, items (i) and (ii), both $s(Q_1), s(Q_2)$ are in $\{c', c''\}$. Consequently, c' is the source of 2 incomplete cubes (Q_1 and Q_2) if and only if c'' is the source of 0 incomplete cubes. ◁

Pick $c \in C \setminus D$ that is the source of two incomplete cubes for (C, D) and an incomplete cube Q such that $c = s(Q)$. Let $\sigma = \mathrm{supp}(Q)$, $x \in \sigma$, and $\sigma' = \sigma \setminus \{x\}$. The concept c belongs to a unique σ'-panel P. Let $L = (P_0 = P(\sigma'), P_1, \ldots, P_{m-1}, P_m = P)$ be the unique gallery between the root $P(\sigma')$ of the tree C^σ and P. For $i = 1, \ldots, m$, denote the chamber $P_{i-1} \cup P_i$ by Q_i. Since $P_i \cap D$ and $Q_i \cap D$ are ample for $i \geq 0$, and P_i is not contained in D for $i > 0$, it follows that the complements $P_i \setminus D$ and $Q_i \setminus D$ are nonempty ample classes. Hence $P_i \setminus D$ and $Q_i \setminus D$ induce nonempty connected subgraphs of $G(C \setminus D)$. Therefore, it follows that c and each concept $c' \in Q_i \setminus D$ are connected in $G(C \setminus D)$ by a path for $i > 0$, and by Claim 13 it follows that

For every $i > 0$, each $c' \in Q_i \setminus D$ is the source of either 0 or 2 incomplete cubes. (5.1)

Consider the chamber $Q_1 = P_0 \cup P_1$ and its source $s = s(Q_1)$. By the definition of the source, necessarily $s \in P_1$ and $s \notin D$. Therefore, Equation (5.1) implies that there must exist another cube Q' such that $s = s(Q')$. Let s' be the neighbor of s in $P_0 = P(\sigma')$; note that $s' \in D$. Since $\mathrm{supp}(Q_1) \cap \mathrm{supp}(Q') = \varnothing$, it follows that $s|\mathrm{supp}(Q') = s'|\mathrm{supp}(Q') \in D|\mathrm{supp}(Q')$, contradicting that $s = s(Q')$. This establishes the first assertion of Proposition 11.

We prove now that the map r defined in Proposition 11 is a representation map for C. It is easy to verify that it is a bijection between C and $X(C)$, so it remain to establish the non-clashing property: $c|(r(c) \cup r(c')) \neq c'|(r(c) \cup r(c'))$ for all distinct pairs $c, c' \in C$. This holds when $c, c' \in D$ because r' is a representation map. Next, if $c \in C \setminus D$ and $c' \in D$, this holds because $c|r(c) \notin D|r(c)$ by the properties of s. Thus, it remains to show that every distinct $c, c' \in C \setminus D$ satisfy $c|(\mathrm{supp}(Q) \cup \mathrm{supp}(Q')) \neq c'|(\mathrm{supp}(Q) \cup \mathrm{supp}(Q'))$, where $Q = s^{-1}(c), Q' = s^{-1}(c')$. Assume towards contradiction that this does not hold and consider a counterexample with minimal domain size $|U|$. By minimality, $\mathrm{supp}(Q') \cup \mathrm{supp}(Q) = U$ (or else (C_x, D_x), for some $x \notin \mathrm{supp}(Q') \cup \mathrm{supp}(Q)$ would be a smaller counterexample). Therefore, since c, c' are distinct, there must be $x \in U = \mathrm{supp}(Q') \cup \mathrm{supp}(Q)$ such that $c(x) \neq c'(x)$, which is a contradiction. This ends the proof of Proposition 11. ◀

6 Representation Maps for Ample Classes

In this section, we provide combinatorial and geometric characterizations of representation maps of ample classes (which lead to optimal unlabeled compression schemes).

▶ **Theorem 14.** *For an ample class C and a map $r : C \to X(C)$,* (i)-(iii) *are equivalent:*

- **(i)** *r is a representation map;*
- **(ii)** *$c'|r(c')\Delta r(c'') \neq c''|r(c')\Delta r(c'')$ for all $c', c'' \in C, c' \neq c''$;*
- **(iii)** *r is a bijection and for every realizable sample s of C, there is a unique $c \in C$ that is consistent with s and $r(c) \subseteq \mathrm{dom}(s)$.*

This theorem implies that for any representation map $r : C \to X(C)$ and any x-edge cc', $r(c)\Delta r(c') = \{x\}$. Hence, r defines an orientation o_r of $G(C)$: an x-edge cc' is oriented from c to c' iff $x \in r(c) \setminus r(c')$. Moreover, as a corollary of Theorem 14, we can show that:

- **(C1)** for any $c \in C$, all outgoing neighbors of c belong to a cube of C;
- **(C2)** o_r is a USO on each cube of C.

An orientation o of the edges of $G(C)$ is a *unique sink orientation (USO)* if o satisfies (C1) and (C2). The *out-map* r_o of an orientation o associates to each $c \in C$ the coordinate set of the edges outgoing from c. We continue with a characterization of representation maps of ample classes as out-maps of USOs, extending a similar result of Szabó and Welzl [31] for cubes. This characterization is "local-to-global", since (C1) and (C2) are conditions on the *stars* $\mathrm{St}(c)$ of all concepts $c \in C$ ($\mathrm{St}(c)$ is the set of all faces of the cubes containing c).

▶ **Theorem 15.** *For an ample class C and a map $r : C \to 2^U$,* (i)-(iii) *are equivalent:*
- **(i)** *r is a representation map;*
- **(ii)** *r is the out-map of a USO;*
- **(iii)** *$r(c) \in X(C)$ for any $c \in C$ and o_r satisfies (C2).*

Proof. The implication (i)⇒(ii) is a consequence of Theorem 14. Now, we prove (ii)⇒(i). Clearly, property (C1) implies that $r(c) \in X(C)$ for any $c \in C$, whence r is a map from C to $X(C)$. Let C be an ample class of smallest size admitting a non-representation map $r : C \to X(C)$ satisfying (C1) and (C2). Hence there exist $u_0, v_0 \in C$ such that $u_0|(r(u_0)\Delta r(v_0)) = v_0|(r(u_0)\Delta r(v_0))$, i.e., $(u_0\Delta v_0) \cap (r(u_0)\Delta r(v_0)) = \varnothing$; (u_0, v_0) is called a *clashing pair*.

▷ Claim 16. If (u_0, v_0) is a clashing pair, then $C = C \cap B(u_0, v_0)$ and $r(u_0) = r(v_0) = \varnothing$.

Proof. Since $C \cap B(u_0, v_0)$ is ample and $(u_0\Delta v_0) \cap (r(u_0)\Delta r(v_0)) = \varnothing$, (u_0, v_0) is a clashing pair for $C \cap B(u_0, v_0)$ and the restriction r_B of r to $\mathrm{supp}(B(u_0, v_0))$. Since r_B and $C \cap B(u_0, v_0)$ satisfy (C1) and (C2), by minimality of C, $C = C \cap B(u_0, v_0)$. Moreover, if $r(u_0) \neq r(v_0)$, then there is $x \in r(u_0)\Delta r(v_0)$ and $x \in u_0\Delta v_0$, contradicting that (u_0, v_0) is a clashing pair.

Suppose $r(u_0) \neq \varnothing$ and pick $x \in r(u_0) = r(v_0)$. Consider the carrier $N_x(C)$ of C^x. Note that $r(u_0) \subseteq \mathrm{supp}(N_x(C))$. Indeed, let $y \in r(u_0)$. By (C1), u_0 belongs to an $\{x, y\}$-square of C, whence $y \in \mathrm{supp}(N_x(C))$. Analogously, $r(v_0) \subseteq \mathrm{supp}(N_x(C))$, thus (u_0, v_0) is a clashing pair for $N_x(C)$ and the restriction of r to $N_x(C)$. $N_x(C)$ is ample as the product of C^x by an x-edge. By minimality of C, $C = N_x(C)$. Define $r^x : C^x \mapsto X(C^x)$ by
- $r^x(c) = r(c) \setminus \{x\}$ if $x \in r(c)$,
- $r^x(c) = r(cx) \setminus \{x\}$ otherwise.

Consequently, for an x-edge of C between c and cx, $r^x(c)$ is the label of the origin of this edge minus x; we call r^x the *x-out-map* of r. We assert that r^x satisfies (C1) and (C2). Condition (C1) is trivial because it holds for cubes of C. To establish condition (C2), suppose that there exists a cube B' of C^x and $u', v' \in B'$ such that $r^x(u') \cap \mathrm{supp}(B') = r^x(v') \cap \mathrm{supp}(B')$. The cube $B := B' \times \{x\}$ is included in C since B' is a cube of C^x. Then among the four pairs $(u', v'), (u', v'x), (u'x, v'), (u'x, v'x)$ of B one can select a pair (u, v) such that $r(u) = r^x(u') \cup \{x\} = r^x(v') \cup \{x\} = r(v)$, a contradiction with condition (C2) for C and r. This shows that r^x satisfies (C1) and (C2). Recall that $x \in r(u_0) = r(v_0)$, suppose wlog that $x \in v_0 \setminus u_0$, and let $u_0' = u_0$ and $v_0' = v_0 \setminus \{x\}$. Then $r^x(u_0') = r(u_0) \setminus \{x\} = r(v_0) \setminus \{x\} = r^x(v_0')$, and consequently (u_0', v_0') is a clashing pair for the restriction of r on $C^x \cap B(u_0', v_0')$. Since $C^x \cap B(u_0', v_0')$ is ample and smaller than C, this contradicts the minimality of C. ◁

▷ Claim 17. C is a cube minus a vertex.

Proof. By (C2), C is not a cube. If C is not a cube minus a vertex, since the complement $C^* = 2^U \setminus C$ is also ample (thus $G(C^*)$ is connected), $G(C^*)$ contains an x-edge ww' with $x \notin w$ and $x \in w'$. Consider C_x and define the map $r_x : C_x \mapsto X(C_x)$ by
- $r_x(c) = r(c)$ if $c \in C$ and $x \notin r(c)$,
- $r_x(c) = r(cx)$ otherwise.

Hence $r_x(c \setminus \{x\}) = r(c)$ for each $c \in C$ with $x \notin r(c)$. We call r_x the *x-in-map* of r; r_x satisfies (C1), because r satisfies (C1). Suppose that r_x violates (C2). Then there exists a cube B' of C_x and $u', v' \in B'$ such that $(u'\Delta v') \cap (r_x(u')\Delta r_x(v')) = \varnothing$. Let $u \in \{u', u'x\}$ such that $r(u) = r(u')$ and let $v \in \{v', v'x\}$ such that $r(v) = r(v')$. The restriction C'_x of the ample class $C' := C \cap B(u, v)$ is the cube B'. Since $w, w' \notin C$ and ww' is an x-edge, $w \notin C'_x$. Thus there exists $y \in \mathrm{supp}(C)$ such that C' and the edge ww' of C^* belong to different y-half-spaces $C^- = \{c \in C : y \notin c\}$ and $C^+ = \{c \in C : y \in c\}$ of the cube 2^U. Since $y \in \mathrm{supp}(C)$, the half-space containing ww' also contains a concept of C. Hence, C' is a proper ample subset of C. Since $u \subseteq u' \cup \{x\}$, $v \subseteq v' \cup \{x\}$, $x \notin r(u) = r_x(u')$, $x \notin r(v) = r_x(v')$, we deduce that $u \cap (r(u)\Delta r(v)) = u' \cap (r_x(u')\Delta r_x(v'))$ and $v' \cap (r_x(u')\Delta r_x(v')) = v \cap (r(u)\Delta r(v))$. Since $(u'\Delta v') \cap (r_x(u')\Delta r_x(v')) = \varnothing$, (u, v) is a clashing pair for the restriction of r on C', contrary to the minimality of C. Hence by minimality of C, r_x is a representation map for C_x.

Consider a clashing pair (u_0, v_0) for C and r, and let $u'_0 = u_0 \setminus \{x\}$ and $v'_0 = v_0 \setminus \{x\}$. Observe that $r_x(u'_0) = r(u_0) = r(v_0) = r_x(v'_0) = \varnothing$. Since r_x is a representation map for C_x, necessarily $u'_0 = v'_0$. Consequently, $u_0\Delta v_0 = \{x\}$, i.e., u_0v_0 is an x-edge of $G(C)$. This is impossible since C satisfies (C2). Therefore, C is necessarily a cube minus a vertex. ◁

Now, we complete the proof of the implication (ii)⇒(i). By Claim 16, $r(u_0) = r(v_0) = \varnothing$. By condition (C1), $r(c) \neq U$ for any $c \in C$. Thus there exists a set $s \in X(C) = 2^U \setminus \{U, \varnothing\}$ such that $s \neq r(c)$ for any $c \in C$. Every s-cube B of C contains a source $p(B)$ for o_{r_B} (i.e., $s \subseteq r(p(B))$). For each s-cube B of C, let $t(B) = r(p(B)) \setminus s$. Notice that $\varnothing \subsetneq t(B) \subsetneq U \setminus s$ since $s \subsetneq r(p(B)) \subsetneq U$. Consequently, there are $2^{|U|-|s|} - 2$ choices for $t(B)$ and since C is a cube minus one vertex by Claim 17, there are $2^{|U|-|s|} - 1$ s-cubes in C. Consequently, there exist two s-cubes B, B' such that $t(B) = t(B')$. Thus $\varnothing \subsetneq s \subsetneq r(p(B)) = r(p(B'))$ and $(p(B), p(B'))$ is a clashing pair for C and r, contradicting Claim 16.

The implication (ii)⇒(iii) is trivial. To prove (iii)⇒(ii), we show by induction on $|U|$ that a map $r : C \to X(C)$ satisfying (C2) also satisfies (C1). For any $x \in U$, let r^x denote the x-out-map defined in Claim 16. Recall that if cc' is an x-edge directed from c to c', then $x \in r(c)$ and r^x maps $c^x = (c')^x \in C^x$ to $r(c) \setminus \{x\} \in X(C^x)$. Thus r^x maps C^x to $X(C^x)$. Moreover, each cube B^x of C^x is contained in a unique cube B of C such that $\mathrm{supp}(B) = \mathrm{supp}(B^x) \cup \{x\}$. If there exist $c^x_1, c^x_2 \in B^x$ such that $r^x(c^x_1) = r(c^x_2)$, then there exist $c_1, c_2 \in B$ such that $r(c_1) = r^x(c^x_1) \cup \{x\} = r^x(c^x_2) \cup \{x\} = r(c_2)$, contradicting (C2). Consequently, o_{r_x} satisfies (C2). By induction hypothesis, o_{r_x} satisfies (C1) for any $x \in U$.

For any concept $c \in C$, pick $x \in r(c)$. Since r^x satisfies (C1), c^x belongs to a σ'-cube in C^x with $\sigma' = r^x(c^x) = r(c) \setminus \{x\}$. This implies that c belongs to a σ-cube in C with $\sigma = \sigma' \cup \{x\} = r(c)$. Thus o_r satisfies (C1), concluding the proof of Theorem 15. ◀

We conclude with some remarks regarding Theorems 14 and 15. First, corner peelings correspond *exactly* to acyclic USOs. Second, given a representation map for C one can derive representations maps for intersections of C with cubes, reductions C^Y, and restrictions C_Y. Third, there exist a bijection $r' : C \to X(C)$ satisfying (C1) and an injection $r'' : C \to 2^U$ satisfying (C2). Nevertheless, we were not able to find a map satisfying (C1) and (C2). It is surprising that, while each d-cube has at least $d^{\Omega(2^d)}$ USOs [17], it is so difficult to find a single USO for ample classes. One can try to find such maps by extending the approach for maximum classes: given ample classes C and D with $D \subset C$, a representation map r for C is called *D-entering* if all edges cd with $c \in C \setminus D$ and $d \in D$ are directed by o_r from c to d. The representation map defined in Proposition 11 is D-entering. Given $x \in \mathrm{dom}(C)$, suppose that r_x is a C^x-entering representation map for C_x. We can extend the orientation o_{r_x} to an orientation o of $G(C)$ as follows. Each x-edge cc' of $G(C)$ is directed arbitrarily, while each

other edge cc' is directed as the edge $c_x c'_x$ is directed by o_{r_x}. Since o_{r_x} satisfies (C1), (C2) and r_x is C^x-entering, o also satisfies (C1), (C2), thus the map r_o is a representation map for C. So, ample classes would admit representation maps, if *for any ample classes $D \subseteq C$, any representation map r' of D extends to a D-entering representation map r of C.*

Abstract

We prove a new query-to-communication lifting for randomized protocols, with inner product as gadget. This allows us to use a much smaller gadget, leading to a more efficient lifting. Prior to this work, such a theorem was known only for deterministic protocols, due to Chattopadhyay et al. [4] and Wu et al. [22]. The only query-to-communication lifting result for randomized protocols, due to Göös, Pitassi and Watson [13], used the much larger indexing gadget.

Our proof also provides a unified treatment of randomized and deterministic lifting. Most existing proofs of deterministic lifting theorems use a measure of information known as *thickness*. In contrast, Göös, Pitassi and Watson [13] used blockwise min-entropy as a measure of information. Our proof uses the blockwise min-entropy framework to prove lifting theorems in both settings in a unified way.

1 Introduction

In this work, we prove new lifting theorems that use the inner-product function as a gadget. Let $f\colon \{0,1\}^n \to \{0,1\}^m$ and $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ be functions (where g is referred to as a *gadget*). The block-composed function $f \circ g^n$ is the function that takes n instances $(x_1, y_1), \ldots, (x_n, y_n)$ of inputs for g and computes $f \circ g^n$ as,

$$f \circ g^n((x_1, y_1), \ldots, (x_n, y_n)) = f(g(x_1, y_1), g(x_2, y_2), \ldots, g(x_n, y_n)).$$

Lifting theorems are theorems that relate the communication complexity of $f \circ g^n$ to the query complexity of f and the communication complexity of g.

More specifically, consider the following communication problem: Alice gets $x_1, \ldots, x_n$, Bob gets $y_1, \ldots, y_n$, and they wish to compute the output of $f \circ g^n$ on their inputs. The natural protocol for doing so is the following: Alice and Bob jointly *simulate* a decision tree of optimal height for solving f. Any time the tree queries the i-th bit, they compute g on the i-th instance by invoking the best possible communication protocol for g. A *lifting theorem* is a theorem that says that this natural protocol is optimal.

Lifting theorems are interesting because they create a connection between query complexity and communication complexity. This connection, besides being interesting in its own right, allows us to transfer lower bounds and separations from the from query complexity (which is a relatively simple model) to a communication complexity (which is a significantly richer model).

In particular, the first result of this form, due to Raz and McKenzie [19], proved a lifting theorem from *deterministic* query complexity to *deterministic* communication complexity when g is the index function. They then used it to prove new lower bounds on communication complexity by lifting query-complexity lower-bounds. More recently, Göös, Pitassi and Watson [12] applied that theorem to separate the logarithm of the partition number and the deterministic communication complexity of a function, resolving a long-standing open problem. This too was done by proving such a separation in the setting of query complexity and lifting it to the setting of communication complexity. This result stimulated a flurry of work on lifting theorems of various kinds, such as: round-preserving lifting theorems with applications to time-space trade-offs for proof complexity [6], deterministic lifting theorems with other gadgets [4, 22], lifting theorems from randomized query complexity to randomized communication complexity [13], lifting theorems for DAG-like protocols [8] with applications to monotone circuit lower bounds, lifting theorems for asymmetric communication problems [5] with applications to data-structures, and a lifting theorem [18] for the EQUALITY gadget. There are also lifting theorems which lifts more analytic properties of the function like approximate degree due to Sherstov [20] and independently due to Shi and Zhu [21], that enabled several important later developments. Although such lifting theorems lift analytical properties of functions, several later works [11] showed how analytical arguments can be made to work for lifting relations.

Viewed from another angle, lifting theorems are natural generalizations of classic theorems such as direct-sum theorems and XOR lemmas [23, 15, 7, 16, 1, 2]: in particular, if we set f to be the identity function or the parity function, we get a direct sum theorem or an XOR lemma for g, respectively. This point of view motivates the work of Hatami et al. [14] that made progress towards proving a lifting theorem with a constant-size gadget.

In almost all known lifting theorems, the function f can be arbitrary (and may also be a general search problem) while g is usually a specific function (e.g., the index function). This raises the following natural question: for which choices of g can we prove lifting theorems?

This question is interesting both because many applications depend on the choice of g, and because if we view lifting theorems as generalizations of direct-sum theorems, we would like them to work for as many choices of g as possible.

In particular, applications of lifting theorems often depend on the size of the gadget, which is the length of the input to g. Both the deterministic lifting theorem of Raz and McKenzie [19] and the randomized lifting theorem of Göös et al. [13] use the indexing function INDEX, which has very large size (polynomial in n). Reducing the gadget size to a constant would have many interesting applications like reproducing tight randomized lower bounds for important functions such as set-disjointness etc. We would like point out that, although we reduce the gadget size to logarithmic in n in this work, it is not enough to obtain the interesting applications a constant sized gadget would have yielded.

In the deterministic setting, the gadget size was recently improved to logarithmic by the independent works of [4] and [22], who chose the gadget g to be the inner product function. Moreover, [4, 17] showed the lifting to work for a large class of gadgets. However, the randomized lifting theorem of Göös et al. [13], until our work, seemed to work only with INDEX as gadget.

In this work, we prove a randomized lifting theorem using an inner product gadget of logarithmic size. This has the immediate application that any lower bound on the outer function f can now be lifted to a much stronger lower bound on the composed function $f \circ g^n$, since hardness is measured as a function of the input length. This allows us, for example, to simplify the lower bounds of Göös, and Jayram [9] on AND-OR trees and MAJORITY trees, since we can now obtain them directly from the randomized query complexity lower bounds rather than going through conical juntas.

We now turn to state our main result more formally. Let $n \in \mathbb{N}$ be such that $n \geq 2$ and let $b \stackrel{\text{def}}{=} 40,000 \cdot \log n$. Let $\Lambda \stackrel{\text{def}}{=} \{0,1\}^b$, and let $g \colon \Lambda \times \Lambda \to \{0,1\}$ denote the inner product (mod 2) gadget. We prove lifting theorems for various lifted versions of $G \stackrel{\text{def}}{=} g^n$. That is, $G \colon \Lambda^n \times \Lambda^n \to \{0,1\}^n$ is the function that takes n independent instances of g and computes g on all of them. Here is our main result:

▶ **Theorem 1** (Randomized lifting). *Let $S \colon \{0,1\}^n \to \Sigma$ be any search problem and let Π be a bounded-error randomized communication protocol that solves $S \circ G$ with complexity c and error probability ε. Then, there exists a randomized decision tree T that solves S with complexity $O(\frac{c}{b})$ and bounded error probability.*

Using essentially the same proof method, we also prove a similar result in the deterministic setting:

▶ **Theorem 2** (Deterministic lifting). *Let S be any search problem that takes inputs from $\{0,1\}^n$, and let Π be a deterministic communication protocol that solves $S \circ G$ with complexity c. Then, there exists a deterministic decision tree T that solves S with complexity $O(\frac{c}{b})$.*

Most existing proofs of deterministic lifting theorems employ an information measure known as *thickness*, borrowed from earlier work on the KRW conjecture. The one deviation from this is the recent beautiful work of Garg et al. [8] who prove a deterministic lifting theorem in the dag-like setting. Curiously, their result does not use the thickness measure of information, but rather uses the blockwise min-entropy measure of information that was used by Göös, Pitassi and Watson [13] in order to prove a randomized lifting theorem. A natural direction of further research is to investigate if these disparate techniques can be unified. Indeed, a related question was asked in the first work to employ the measures of min-entropy for lifting by Göös et al. [10]: they asked if min-entropy and density based techniques could be used to prove (or simplify the existing proof of) Raz–McKenzie style deterministic lifting theorems.

Our unified proof answers this question by showing that the same information measure (blockwise min entropy) can in fact be used in both the deterministic and randomized settings. The main difference between the two proofs is the way in which we decide the next bit of the communication protocol: in the deterministic setting, we make a greedy choice, and in the randomized setting, we make a (non-uniform) random choice. Whereas in the randomized setting, our information measure guarantees that we are able to estimate the distribution of the next bit of the protocol, in the deterministic setting it guarantees *richness*, that is, when the protocol ends, there is some input consistent with answers of all queries made by the decision tree.

Organization of the paper. In Section 2 we set up the machinery that is used in both the deterministic and the randomized lifting theorems. We prove the deterministic lifting theorem in Section 3, and the randomized lifting theorem in Section 4. Both proofs use a Fourier-theoretic lemma, proved in Section 5.

2 Common Machinery

In this paper we consider lifting theorems for the most general case of search problems. A search problem $\mathcal{S}$ is defined by a relation $\mathcal{I} \times \mathcal{O}$ where $\mathcal{I}$ is a finite set of inputs and $\mathcal{O}$ is a finite set of outputs. The goal of the search problem, given an input $x \in \mathcal{I}$ is to find at least one output $o \in \mathcal{O}$ such that $(x, o) \in \mathcal{S}$. Like in the statement of the main theorem, let S be any search problem that takes inputs from $\{0,1\}^n$, and let Π be a bounded-error randomized communication protocol that solves $S \circ G$ with complexity c and error probability ε. We prove the randomized and deterministic lifting theorems, by building deterministic and randomized decision trees of cost $O(c/b)$ based on respective protocols of cost c. Intuitively, in both theorems, on input $z \in \{0,1\}^n$, the tree T will simulate the action of the protocol Π on inputs $(x, y) \in G^{-1}(z)$. More specifically, the tree will simulate the protocol bit by bit, and maintain a rectangle $\mathcal{X} \times \mathcal{Y}$ that is consistent with the protocol so far such that all the strings in $G(\mathcal{X} \times \mathcal{Y})$ are consistent with the queries made so far. To this end, we consider random variables X and Y that are distributed uniformly over $\mathcal{X}$ and $\mathcal{Y}$ respectively. We now state a few useful definitions and results about such random variables

The first such definition ensures that the random variables we consider have enough blockwise min-entropy.

▶ **Definition 3.** *Let X be a random variable taking values in Λ^n. We say that X is* δ-dense *if for every $I \subseteq [n]$ it holds that $H_\infty(X_I) \geq \delta \cdot b \cdot |I|$.*

We would like these random variables to be consistent with the query answers obtained by the decision tree thus far in the simulation. To this end, we also define the following notion of restrictions.

▶ **Definition 4.** *Given a restriction $\rho \in \{0,1,*\}^n$, we denote by* $\mathrm{fix}(\rho)$ *and* $\mathrm{free}(\rho)$ *the set of fixed and free coordinates of ρ respectively.*

Intuitively, $\mathrm{fix}(\rho)$ represents the query answers obtained thus far, and $\mathrm{free}(\rho)$ represents the yet unqueried coordinates. With these definitions, we define the property that we would like to maintain for X and Y during the simulation.

▶ **Definition 5** (following [13])**.** *Let X, Y be random variables taking values in Λ^n, and let $\rho \in \{0,1,*\}^n$ be a restriction. We say that X and Y are ρ-structured if $X_{\mathrm{free}(\rho)}$ and $Y_{\mathrm{free}(\rho)}$ are 0.9-dense, and $g^{\mathrm{fix}(\rho)}\left(X_{\mathrm{fix}(\rho)}, Y_{\mathrm{fix}(\rho)}\right) = \rho_{\mathrm{fix}(\rho)}$.*

In both lifting theorems, the decision tree T starts by setting X and Y to be uniform over Λ^n, and maintains throughout the simulation the invariant that, if ρ is the restriction that represents the current "state of knowledge" regarding the input z, then X and Y are ρ-structured. In order to maintain this invariant, we use the following Fourier-analytic result, which is proved in Section 5.

▶ **Definition 6.** *Let $\alpha \in \Lambda^n$ and let Y be a random variable taking values in Λ^n. We say that α is η-*bad *for Y if there exists a set $I \subset [n]$ and a string $\sigma \in \{0,1\}^I$ such that the random variable*

$$Y_{[n]-I} \left| g^I(\alpha_I, Y_I) = \sigma_I \right.$$

is not η-dense or

$$\Pr\left[g^I(\alpha_I, Y_I) = \sigma_I\right] < 2^{-|I|-1}.$$

▶ **Theorem 7** (Main Technical Tool)**.** *Let $n \in \mathbb{N}$ and let $b \in \mathbb{N}$ such that $b \geq 40000 \cdot \log(n)$. Let X and Y be random variables taking values in Λ^n that are δ_X-dense and δ_Y-dense respectively. Suppose that $\delta_X + \delta_Y \geq 1.3$ and $\delta_Y \geq 0.1$. Then, the probability that X takes a value that is $\frac{\delta_Y}{2.01}$-bad for Y is at most $2^{-0.01 \cdot b}$.*

We also use the following analogue of the "uniform marginals lemma" of [13] for the inner product gadget.

▶ **Lemma 8** (Uniform marginals lemma)**.** *Let X, Y be random variables uniformly distributed over sets $\mathcal{X}, \mathcal{Y} \subseteq \Lambda^n$, and suppose they are ρ-structured. Then, for any $z \in \{0,1\}^n$ that is consistent with ρ, the uniform distribution over $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$ has its marginal distributions $\frac{1}{n^3}$-close to X and Y respectively.*

In order to prove Lemma 8, we use the following definition and lemma from Göös et al. [10].

▶ **Definition 9.** *Let $\varepsilon > 0$ and let V be a random variable taking values from a set $\mathcal{V}$. We say that V is* ε-pointwise close to uniform *if for every $v \in \mathcal{V}$ it holds that $\Pr[V = v] \in (1 \pm \varepsilon) \cdot \frac{1}{|\mathcal{V}|}$.*

▶ **Lemma 10.** *Let A, B be 0.6-dense random variables taking values from Λ^m. Then $g^m(A, B)$ is $2^{-\frac{b}{20}}$-uniform.*

The proof of this lemma, which is similar to the proof of the uniform marginals lemma in [13], appears in the full version [3] of the paper.

We use the following simple folklore fact about density.

▶ **Proposition 11.** *Let X be a random variable over Λ^J, and let $I \subseteq J$ be maximal subset of coordinates such that $H_\infty(X_I) < \delta \cdot b \cdot |I|$. Let $\alpha \in \Lambda^I$ be a value such that*

$$\Pr[X_I = \alpha] > 2^{-\delta \cdot b \cdot |I|}.$$

Then, the random variable $X_{J-I} | X_I = \alpha$ is δ-dense.

We also use the following decomposition result from Göös et al. [13], which extends the last proposition.

▶ **Lemma 12** (Density-restoring partition)**.** *Let X be a random variable over $\mathcal{X} \subseteq \Lambda^J$. Then, there exists a partition*

$$\mathcal{X} \stackrel{\text{def}}{=} \mathcal{X}^1 \cup \cdots \cup \mathcal{X}^r$$

such that every $\mathcal{X}^i$ is associated with a set $I_i \subseteq J$, a value $\alpha_i \in \Lambda^{I_i}$, and a probability $p_{\geq i} \stackrel{\text{def}}{=} \Pr\left[X \in \mathcal{X}^i \cup \ldots \cup \mathcal{X}^r\right]$ that satisfy the following properties: Denote by X^i the random variable X conditioned on $X \in \mathcal{X}^i$.

- $X^i_{I_i}$ *is fixed to* α_i.
- $X^i_{J-I_i}$ *is* 0.9*-dense.*
- $H_\infty(X^i) \geq H_\infty(X) - 0.9 \cdot b \cdot |I_i| - \log \frac{1}{p_{\geq i}}$.

3 The deterministic lifting theorem

In this section, we prove the deterministic lifting theorem, restated from the Introduction.

▶ **Theorem 13** (Restatement of Theorem 2)**.** *Let S be any search problem that takes inputs from $\{0,1\}^n$, and let Π be a deterministic communication protocol that solves $S \circ G$ with complexity c. Then, there exists a decision tree T that solves S with complexity $O(\frac{c}{b})$.*

As noted earlier, the decision tree T we construct would simulate the protocol Π. Throughout the simulation, the tree keeps track of random variables X, Y, which represent the inputs to the protocol, and maintains the invariant that they are ρ-structured. When the protocol Π ends, the decision tree T ends as well and outputs the output of Π. In order to complete the proof of Theorem 2, we need to show three things:

- How to simulate a single bit of the protocol while maintaining the above invariant.
- After the decision tree ends, its output is a correct output of S on z.
- The total number of queries made by the decision tree T during the lifting is $O(\frac{c}{b})$.

Due to space constraints, we will only briefly describe the simulation, relegating its analysis to the full version [3] of the paper.

Consider a given step in the simulation where the tree is at a particular node of the protocol Π. Let $\mathcal{X}, \mathcal{Y}$ be the current set of inputs that are being maintained which are consistent with this node, and let X, Y be random variables uniformly distributed over $\mathcal{X}, \mathcal{Y}$. Let $\rho \in \{0,1,*\}^n$ denote the restriction that represents the queries that have been made so far and their answers, i.e., coordinates that were queried are fixed to the answers that were received, and coordinates that were not queried are free. By the invariant we maintain, the variables X, Y are ρ-structured.

We would like to simulate the next bit of the protocol. Suppose without loss of generality that it is Alice's turn to speak. The tree T chooses the next bit to be the bit that has the highest probability of being sent by Alice, if the inputs are chosen according to X. The tree then updates the set $\mathcal{X}$ to be consistent with the new bit, and updates the random variable X accordingly. Now, if the ρ-structure property of X, Y has been violated, then it must be because $X_{\text{free}(\rho)}$ is no longer 0.9-dense, since the new bit did not affect Y. The tree now modifies the sets $\mathcal{X}, \mathcal{Y}$ and the restriction ρ to restore the structuredness of X, Y. In order to do so, the tree T repeats the following steps iteratively until X and Y are ρ-structured:

1. Condition $X_{\text{free}(\rho)}$ on not taking a value that is 0.4-bad for $Y_{\text{free}(\rho)}$, and update $\mathcal{X}$ accordingly.
2. If $X_{\text{free}(\rho)}$ is now 0.9-dense, then we are done – the structuredness has been restored. Otherwise continue.
3. Let $I \subseteq \text{free}(\rho)$ be a maximal set that violates the density of $X_{\text{free}(\rho)}$ (i.e., $H_\infty(X_I) < 0.9 \cdot b \cdot |I|$), and let $\alpha_I \in \Lambda^I$ be a "heavy" value that satisfies $\Pr[X_I = \alpha_I] > 2^{-0.9 \cdot b \cdot |I|}$.
4. Condition X on $X_I = \alpha_I$, and update $\mathcal{X}$ accordingly. Proposition 11 implies that $X_{\text{free}(\rho)-I}$ is now 0.9-dense.
5. Query the coordinates in I, and update ρ accordingly.
6. Condition Y on $g^I(\alpha_I, Y_I) = \rho_I$, and update $\mathcal{Y}$ accordingly.
7. If $Y_{\text{free}(\rho)}$ is now 0.9-dense then we are done – the structuredness has been restored. Otherwise go back to Step 1 but replace the roles of X and Y.

In order for the steps of the above process to always be well-defined, we need to show that we never condition on events with probability 0. If this is always satisfied, it follows that the algorithm terminates and at termination the random variables X, Y are ρ-structured. To see this, note that the process only stops if $X_{\text{free}(\rho)}$ and $Y_{\text{free}(\rho)}$ are 0.9-dense, and the process clearly maintains the invariant that

$$g^{\text{fix}(\rho)}\left(X_{\text{fix}(\rho)}, Y_{\text{fix}(\rho)}\right) = \rho_{\text{fix}(\rho)}.$$

Moreover, the process always stops, since in every iteration the size of the set $\text{free}(\rho)$ decreases, and it cannot decrease below 0.

We turn to show that we never condition on a zero probability event. To this end, we will show that the process preserves the following property: At the beginning of every iteration, one of the variables $X_{\text{free}(\rho)}$ and $Y_{\text{free}(\rho)}$ is 0.9-dense, and the other is at least 0.4-dense. Observe that this property indeed holds at the beginning of the first iteration: at this point, Y is 0.9-dense, and X must be at least 0.4-dense – since we chose the next bit of Alice to be the one with the highest probability, and therefore the min-entropy of any set of coordinates could have dropped by at most 1.

Suppose that the property holds at the beginning of a given iteration. The first conditioning takes place at Step 1. When Step 1 is performed, we know by Theorem 7 that the event that $X_{\text{free}(\rho)}$ does not take values that are 0.4-bad for $Y_{\text{free}(\rho)}$ has non-zero probability: to see it, note that by assumption $\delta_X \geq 0.4$ and $\delta_Y \geq 0.9$, so it holds that $\delta_X + \delta_Y \geq 1.3$ and $\frac{\delta_Y}{2.01} \geq 0.4$, so the requirements of the theorem are satisfied.

The next conditioning takes place at Step 4, but here the event has non-zero probability by definition. The last conditioning takes place at Step 6, and here the event has non-zero probability due to the assumption that $X_{\text{free}(\rho)}$ does not take values that are bad for $Y_{\text{free}(\rho)}$ – and in particular

$$\Pr\left[g^I(\alpha_I, Y_I) = \rho_I\right] \geq 2^{-|I|-1}.$$

Finally, we need to show that the above property is maintained for the next iteration. As stated in Step 4, at this point X is 0.9-dense. Moreover, since we know that $X_{\text{free}(\rho)}$ does not take values that are 0.4-bad for $Y_{\text{free}(\rho)}$, it follows in particular that

$$Y_{\text{free}(\rho)} \left| g^I(\alpha_I, Y_I) = \rho_I \right.$$

is 0.4-dense. This concludes the proof. The rest of the analysis can be found in the full version [3] of the paper.

3.1 Concluding the simulation

In this section, we prove that when the simulation ends, the protocol Π outputs an answer in $S(z)$. To this end, all we need to prove is that when the simulation ends, we can find $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ such that $G(x, y) = z$: To see why, observe that the output of the protocol at this point must be its output on (x, y), since the rectangle $\mathcal{X} \times \mathcal{Y}$ is contained in the rectangle of the leaf to which the protocol arrived. Now, since we assumed that Π computes $S \circ G$, it follows that its output must be $(S \circ G)(x, y) = S(z)$.

We thus turn to show that there exist $x, y \in \mathcal{X} \times \mathcal{Y}$ such that $G(x, y) = z$. Recall that when the protocol ends, it holds that X, Y are ρ-structured (by the invariant that we maintained). This means that $g^{\text{fix}(\rho)}(X_{\text{fix}(\rho)}, Y_{\text{fix}(\rho)}) = z_{\text{fix}(\rho)}$, and that $X_{\text{free}(\rho)}, Y_{\text{free}(\rho)}$ are 0.9-dense. By Theorem 7, it follows that $X_{\text{free}(\rho)}$ takes a value that is not 0.4-bad for $Y_{\text{free}(\rho)}$ with non-zero probability. This means that there exists some $x \in \mathcal{X}$ such that $x_{\text{free}(\rho)}$ is not 0.4-bad for $Y_{\text{free}(\rho)}$. By the definition of badness, it follows that

$$\Pr\left[g^{\text{free}(\rho)}(x_{\text{free}(\rho)}, Y_{\text{free}(\rho)}) = z_{\text{free}(\rho)}\right] \geq 2^{-|\text{free}(\rho)|-1} > 0$$

and therefore there exists some $y \in \mathcal{Y}$ such that $g^{\text{free}(\rho)}(x_{\text{free}(\rho)}, y_{\text{free}(\rho)}) = z_{\text{free}(\rho)}$. It follows that x and y satisfy

$$\begin{aligned} g^{\text{fix}(\rho)}(x_{\text{fix}(\rho)}, y_{\text{fix}(\rho)}) &= z_{\text{fix}(\rho)} \\ g^{\text{free}(\rho)}(x_{\text{free}(\rho)}, y_{\text{free}(\rho)}) &= z_{\text{free}(\rho)} \end{aligned}$$

and therefore $G(x, y) = z$, as required.

3.2 The query complexity

We conclude by showing that the total number of queries the tree T makes is $O(\frac{c}{b})$. To this end, we define the deficiency of X, Y to be

$$\Delta \stackrel{\text{def}}{=} 2 \cdot b \cdot |\text{free}(\rho)| - H_\infty(X_{\text{free}(\rho)}) - H_\infty(Y_{\text{free}(\rho)}).$$

We prove that whenever the protocol Π transmits a bit in the simulation, the deficiency increases by $O(1)$, and that whenever the tree T makes a query, the deficiency is decreased by $\Omega(b)$. Since the deficiency is always non-negative, and the protocol transmits at most c bits, it follows that the tree must make at most $O(\frac{c}{b})$ bits.

We start by showing that when the protocol Π transmits a bit in the simulation, the deficiency increases by $O(1)$. When a bit is transmitted, either X or Y is conditioned on an event of probability at least $\frac{1}{2}$, depending on which player spoke, and the other variable remains unchanged. This means that the sum $H_\infty(X_{\text{free}(\rho)}) + H_\infty(Y_{\text{free}(\rho)})$ decreases by at most 1, and therefore the deficiency increases by at most 1. Next, the simulation might perform Step 1 in the process above, i.e., condition X or Y on taking a value that is not bad. This event has probability $1 - 2^{-0.01 \cdot b} \geq \frac{1}{2}$, so conditioning on it increases the deficiency by at most 1. All in all, we increased the deficiency by at most 2. All the other steps that might be taken are only taken if a query is being made, so we account their deficiency increases to the following "query part" of the analysis.

We turn to show that when a query is being made, the deficiency decreases by $\Omega(b)$. Suppose that the decision tree queried a set $I \subseteq \text{free}(\rho)$. This applies the following changes to the deficiency:

- The variable X is conditioned on the event $X_I = \alpha_I$, which has probability greater than $2^{-0.9 \cdot b \cdot |I|}$ by the definition of α_I. Hence, this conditioning increases the deficiency by at most $0.9 \cdot b \cdot |I|$.
- The variable Y is conditioned on the event $g^I(\alpha_I, Y_I) = \rho_I$, which has probability at least $2^{-|I|-1}$ by the assumption that X does not take bad values. This increases the deficiency by at most $|I| + 1$.
- The set I is removed from the set $\text{free}(\rho)$. Looking at the definition of deficiency, this decreases the first term, $2 \cdot b \cdot |\text{free}(\rho)|$, by at most $2 \cdot b \cdot |I|$, decreases $H_\infty(Y_{\text{free}(\rho)})$ by at most $b \cdot |I|$, and does not change $H_\infty(X_{\text{free}(\rho)})$ (since at this point X_I is fixed to α_I). All in all, the deficiency is decreased by $b \cdot |I|$.
- Finally, the queries may make the process repeat for another iteration, so Step 1 may be performed again, increasing the deficiency by another 2 bits.

Summing all those effects together, we get that the deficiency was decreased by at least

$$b \cdot |I| - 0.9 \cdot b \cdot |I| - (|I| + 1) - 2 \geq 0.05 \cdot b \cdot |I|$$

in each iteration, as required. This concludes the proof.

4 The randomized lifting theorem

In this section, we prove the randomized lifting theorem, restated next.

▶ **Theorem 14** (Restatement of Theorem 1). *Let S be any search problem that takes inputs from $\{0,1\}^n$, and let Π be a randomized communication protocol that solves $S \circ G$ with complexity c and error probability ε. Then, there exists a decision tree T that solves S with complexity $O(\frac{c}{b})$ and error probability $\varepsilon + \frac{1}{10}$.*

As noted earlier, the decision tree T we construct simulates the protocol Π. The simulation is similar to the deterministic one, with two main differences:

- Instead of choosing the next bit of the protocol to be the most likely bit, we choose it randomly according to the distribution of the next bit (except that we abort the simulation on bits of very small probability).
- Instead of choosing I and α_I arbitrarily, we choose them from the density-restoring partition of Lemma 12, according to the distribution induced by this partition (except that we truncate parts of the partition that have very small probability).

In the following sections, we describe the simulation, analyze its error probability, and analyze its query complexity, respectively. For simplicity, we describe a simulation that has a better error probability of $\varepsilon + o(1)$ but query complexity that is efficient *only in expectation*. This simulation can be transformed into one with error probability $\varepsilon + \frac{1}{10}$, and efficient query complexity in the worst case, using standard arguments.

4.1 The simulation

As before, the decision tree T simulates the protocol Π while maintaining a rectangle $\mathcal{X} \times \mathcal{Y}$ that is contained in the rectangle of the current node of Π. When the simulation ends, T outputs the output of Π. Throughout the simulation, the decision tree T considers random variables X, Y that are uniformly distributed over $\mathcal{X} \times \mathcal{Y}$ and maintains the invariant that they are ρ-structured (for a restriction ρ that records the queries made so far). For the purpose of the simulation, we may assume without loss of generality that Π is deterministic (since T can use its randomness to choose the randomness of Π, and then pretend that Π is deterministic for the rest of the simulation).

We turn to explain how to simulate a single bit of the protocol. Suppose that at a given point it is Alice's turn to speak. The protocol partitions $\mathcal{X}$ into $\mathcal{X}_0 \cup \mathcal{X}_1$. The tree now chooses the next bit to be 0 with probability $\frac{|\mathcal{X}_0|}{|\mathcal{X}|}$ and to be 1 otherwise. If the bit that was chosen had probability less than $\frac{1}{n^2}$, the tree halts and declares error. Otherwise, the tree updates $\mathcal{X}$ to the corresponding set among $\mathcal{X}_0, \mathcal{X}_1$ and updates the random variable X accordingly.

Now, if the ρ-structure property of X, Y has been violated, then it must be because $X_{\mathrm{free}(\rho)}$ is no longer 0.9-dense, since the new bit did not affect Y. The tree now modifies the sets $\mathcal{X}, \mathcal{Y}$ and the restriction ρ to restore the structuredness of X, Y. In order to do so, the tree T repeats the following steps iteratively until X, Y are ρ-structured:

1. Condition $X_{\mathrm{free}(\rho)}$ on not taking a value that is 0.4-bad for $Y_{\mathrm{free}(\rho)}$, and update $\mathcal{X}$ accordingly.
2. If X is now 0.9-dense, then we are done – the structuredness has been restored. Otherwise continue.
3. Let $\mathcal{X}_{\mathrm{free}(\rho)} = \mathcal{X}^1 \cup \ldots \cup \mathcal{X}^r$ be the density-restoring partition of Lemma 12 with respect to $X_{\mathrm{free}(\rho)}$. Choose a random class in the partition, where the class $\mathcal{X}^i$ is chosen with probability $\Pr\left[X_{\mathrm{free}(\rho)} \in \mathcal{X}^i\right]$.

4. Recall that we defined the probability

$$p_{\geq i} \stackrel{\text{def}}{=} \Pr\left[X_{\text{free}(\rho)} \in \mathcal{X}^i \cup \ldots \cup \mathcal{X}^r\right].$$

   If $p_{\geq i} < \frac{1}{n^3}$, the tree T halts and declares error.
5. Let I_i and α_i be the set and the value associated with the class $\mathcal{X}^i$. The tree conditions X on the event $X_{\text{free}(\rho)} \in \mathcal{X}^i$ and updates $\mathcal{X}$ accordingly. The variable $X_{\text{free}(\rho)-I_i}$ is now 0.9-dense by the properties of the density-restoring partition.
6. Query the coordinates in I_i, and update ρ based on the query answers.
7. Condition Y on $g^I(\alpha_i, Y_{I_i}) = \rho_{I_i}$, and update $\mathcal{Y}$ accordingly.
8. If $Y_{\text{free}(\rho)}$ is now 0.9-dense then we are done – the structuredness has been restored. Otherwise go back to Step 1 but replace the roles of X and Y.

The proof that the process is well-defined and always halts, and that the ρ-structuredness invariant is maintained, is the same as in the deterministic simulation. The only difference here is that choosing the next bit of the protocol decreases the min-entropy of the blocks by at most $2\log n$ bits rather than by at most 1 bit. Nevertheless, since the random variable X started as 0.9-dense and $b > 20\log n$, the variable X is still 0.4-dense after choosing the next bit.

4.2 Correctness

We prove that the decision tree errs with probability at most $\varepsilon + o(1)$ (recall that ε is the error probability of the protocol Π). Fix an input $z \in \{0,1\}^n$. Let π be the (random) transcript generated by the simulation of T on z (if we the simulation declares error, we set $\pi = \perp$). Let π' denote the (random) transcript of Π on random inputs (X', Y') that are distributed uniformly over $G^{-1}(z)$ (again, we assume that Π' is deterministic and that the only randomness comes from the choice of (X', Y')). We will prove that the distributions of π and π' are $o(1)$-close. Since π' outputs the correct answer on z with probability at least $1-\varepsilon$, it will follow that π outputs the correct answer on z with probability at least $1 - \varepsilon - o(1)$.

To prove that π and π' are $o(1)$-close, we describe a coupling of π with π' that satisfies that $\pi = \pi'$ with probability at least $1 - o(1)$. To this end, we show that there exists a coupling of the random choices of the simulation with X', Y' such that, up to some bad event $\mathcal{E}$ of small probability, it holds that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$. Since $\mathcal{X} \times \mathcal{Y}$ determines the transcript π of the simulation (as $\mathcal{X} \times \mathcal{Y}$ is contained the rectangle of the current node in the protocol), whenever $(X', Y') \in (\mathcal{X}, \mathcal{Y})$ it holds that $\pi = \pi'$.

More specifically, we prove that there exists a coupling and an event $\mathcal{E}$ with probability at most $\frac{6 \cdot b}{n} = o(1)$ such that, when the simulation ends, conditioned on $\neg\mathcal{E}$ it holds that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$. To this end, we define a sequence of events $\mathcal{E}_1, \mathcal{E}_2, \ldots$ such that $\Pr[\mathcal{E}_t] \leq \frac{6}{n^2} \cdot (t-1)$ and at the begining of the t-th iteration, conditioned on $\neg\mathcal{E}_t$ it holds that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$. We then set $\mathcal{E}$ to be the event at the end of the last iteration. Since the number of iterations is at most $c \leq n \cdot b$ (as each iteration transmits 1-bit), it follows that the probability of $\mathcal{E}$ is at most $\frac{6}{n^2} \cdot c \leq \frac{6b}{n}$. In order to construct the coupling and the events $\mathcal{E}_1, \mathcal{E}_2, \ldots$, we prove the following auxiliary result.

▶ **Lemma 15.** *Suppose that we constructed the coupling until the beginning of the t-th iteration, and there is an event $\mathcal{E}_t$ such that conditioned on $\neg\mathcal{E}_t$ it holds that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$. Then, there exists a way to extend the coupling until the end of the t-th iteration, and there exists an event $\mathcal{E}_{t+1}$, such that $\Pr[\mathcal{E}_{t+1}] \leq \Pr[\mathcal{E}_t] + \frac{6}{n^2}$ and at the end of the t-th iteration, conditioned on $\neg\mathcal{E}_{t+1}$ it holds that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$.*

Given Lemma 15, we design the coupling and the events $\mathcal{E}_1, \mathcal{E}_2, \ldots$ by setting $\mathcal{E}_1$ to be the empty event and then applying Lemma 15 repeatedly until we reach the last iteration.

Proof. Suppose that the simulation ran until the beginning of the t-th iteration according to our coupling. If the event $\mathcal{E}_t$ happened, then the coupling behaves arbitrarily until the end of the simulation, and we assume that the simulation failed. Let us now condition on the event $\mathcal{E}_t$ not having happened, so we may assume that at the beginning of the t-th iteration, the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$. We start by setting $\mathcal{E}_{t+1}$ to be the event $\mathcal{E}_t$, and we will add more events to it as the simulation progresses.

The simulation starts by choosing the next bit of the protocol, and suppose that it is Alice's turn to speak. The simulation has probability $\frac{|\mathcal{X}_0|}{|\mathcal{X}|}$ to choose 0, and by the uniform marginals lemma (Lemma 8), the random variable X' has probability $\frac{|\mathcal{X}_0|}{|\mathcal{X}|} \pm \frac{1}{n^3}$ to be in $\mathcal{X}_0$. In other words, the distribution of the class that the simulation chooses among $\mathcal{X}_0, \mathcal{X}_1$, and the distribution of the class that X' chooses, are $\frac{1}{n^3}$-close, and therefore there exists a coupling of those choices such that the same class is chosen in both with probability at least $1 - \frac{1}{n^3}$, so we use it to extend our coupling. We add to $\mathcal{E}_{t+1}$ the event in which the simulation and X' choose a different class among $\mathcal{X}_0, \mathcal{X}_1$, and for the rest of the proof we assume that it did not happen. We also add to $\mathcal{E}_{t+1}$ the event in which the simulation declared failure since it chose a bit with probability less than $\frac{1}{n^2}$ (clearly, this event has probability less than $\frac{1}{n^2}$), and for the rest of the proof we assume that it did not happen. We may thus assume that after this step, the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$.

Next, the simulation removes from $\mathcal{X}$ the values that are 0.4-bad for Y. The probability that X takes such a value is at most $2^{-0.01 \cdot b} \leq \frac{1}{n^3}$, and therefore the probability that X' takes such a value is at most $\frac{2}{n^3}$ by the uniform marginals lemma. We add the event that X' takes a bad value to $\mathcal{E}_{t+1}$ and assume for the rest of the proof that it did not happen. Hence, we may again assume that after this step, X' belongs to $\mathcal{X}$, and that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$.

In the following step, a class $\mathcal{X}^i$ is chosen according to the distribution induced by $X_{\mathrm{free}(\rho)}$. Let us now choose the class $\mathcal{X}^{i'}$ to which $X'_{\mathrm{free}(\rho)}$ belongs. By the uniform marginals lemma, the distributions of $\mathcal{X}^i$ and $\mathcal{X}^{i'}$ are $\frac{1}{n^3}$-close, and therefore there is a coupling of those classes such that they are equal with probability at least $1 - \frac{1}{n^3}$, so we use it to extend our coupling. We add to $\mathcal{E}_{t+1}$ the event in $\mathcal{X}^i \neq \mathcal{X}^{i'}$, and for the rest of the proof we assume that it did not happen. We also add to $\mathcal{E}_{t+1}$ the event in which the simulation declared error since $p_{\leq i} < \frac{1}{n^3}$ (clearly, this event has probability less than $\frac{1}{n^3}$), and for the rest of the proof we assume that it did not happen. We therefore assume again that after this step, X' belongs to $\mathcal{X}$, and that the pair (X', Y') is uniformly distributed in $G^{-1}(z) \cap (\mathcal{X} \times \mathcal{Y})$.

Finally, the simulation conditions Y on $g^I(\alpha_i, Y_{I_i}) = \rho_{I_i}$. This conditioning trivially holds for Y' (since by assumption $(X', Y') \in G^{-1}(z)$ and by this point we chose $X'_{I_i} = \alpha_{I_i}$), and no further coupling needs to be done.

We conclude the proof by upper bounding the probability of the event $\mathcal{E}_{t+1}$. At the beginning, we set $\mathcal{E}_{t+1}$ to be $\mathcal{E}_t$, and therefore at this point its probability is $\Pr[\mathcal{E}_t]$. The step of choosing the next bit of the protocol contribute to $\mathcal{E}_{t+1}$ events whose total probability is at most $\frac{1}{n^3} + \frac{1}{n^2}$. Steps 1 to 7 above add to $\mathcal{E}_{t+1}$ events of total probability at most $\frac{4}{n^3}$. Those latter steps are now repeated until (X, Y) are ρ-structured. However, they may be repeated at most n times, since each time they are repeated, the tree makes at least one query, and it cannot make more than n queries. Hence, in all of those repetitions together, those steps in the simulation contribute to $\mathcal{E}_{t+1}$ events whose total probability is at most $\frac{4}{n^2}$.

It follows that

$$\Pr[\mathcal{E}_{t+1}] \leq \Pr[\mathcal{E}_t] + \frac{1}{n^3} + \frac{1}{n^2} + \frac{4}{n^2} \leq \Pr[\mathcal{E}_t] + \frac{6}{n^2},$$

as required. ◀

4.3 The query complexity

We show that the *expected* query complexity of this simulation is $O(\frac{c}{b})$. Again, we define the deficiency of X, Y to be

$$\Delta \stackrel{\text{def}}{=} 2 \cdot b \cdot |\text{free}(\rho)| - H_\infty(X_{\text{free}(\rho)}) - H_\infty(Y_{\text{free}(\rho)}).$$

We will show that whenever the simulation sends one bit in the protocol, the deficiency is increased by $O(1)$ *in expectation*. On the other hand, we will show that whenever a query is made, the deficiency is always decreased by at least $\Omega(b)$. Thus, the expected deficiency at any point is at most

$$O(\#\text{bits communicated}) - \Omega(b \cdot \#\text{queries}).$$

Since the deficiency is always at least 0 and the number of bits communicated is at most c, it follows that the expected number of queries is upper bounded by $O(\frac{c}{b})$.

Whenever we choose the next bit for Alice, the deficiency increases by $\log \frac{|\mathcal{X}|}{|\mathcal{X}_0|}$ (if the next bit is 0) or by $\log \frac{|\mathcal{X}|}{|\mathcal{X}_1|}$ (if the next bit is 1). Thus, the expected increase in deficiency is

$$\frac{|\mathcal{X}_0|}{|\mathcal{X}|} \cdot \log \frac{|\mathcal{X}|}{|\mathcal{X}_0|} + \frac{|\mathcal{X}_1|}{|\mathcal{X}|} \cdot \log \frac{|\mathcal{X}|}{|\mathcal{X}_1|}.$$

This is the value of the binary entropy function on $\frac{|\mathcal{X}_0|}{|\mathcal{X}|}$, and hence it is upper bounded by 1. Conditioning on X not taking a value that is 0.4-bad for Y increases the deficiency by at most 1 bit since its probability is at least $\frac{1}{2}$. All in all, the expected increase in the deficiency is at most 2.

We turn to show that when a query is being made, the deficiency decreases by $\Omega(b)$. Suppose that the decision tree queried a set $I_i \subseteq \text{free}(\rho)$. This brings about the following changes to the deficiency:

- The variable X was conditioned on the event $X_{\text{free}(\rho)} \in \mathcal{X}^i$. By Lemma 12, this decreases the min-entropy of X by at most $0.9 \cdot b \cdot |I_i| + \log \frac{1}{p_{\geq i}}$. Now, Step 4 guarantees that $p_i \geq \frac{1}{n^3}$, and therefore $\log \frac{1}{p_i} \leq 3 \log n < 0.01 \cdot b$. All in all, this step increases the deficiency by at most $0.91 \cdot |I_i|$
- The variable Y is conditioned on the event $g^{I_i}(\alpha_{I_i}, Y_{I_i}) = \rho_{I_i}$, which has probability at least $2^{-|I_i|-1}$ by the assumption that X does not take bad values. This increases the deficiency by at most $|I_i| + 1$.
- The set I_i is removed from the set $\text{free}(\rho)$. By definition of deficiency, this dereases the term of $2 \cdot b \cdot |\text{free}(\rho)|$ by $2 \cdot b \cdot |I_i|$, decreases $H_\infty(Y_{\text{free}(\rho)})$ by at most $b \cdot |I_i|$, and does not change $H_\infty(X_{\text{free}(\rho)})$ (since at this point X_{I_i} is fixed to α_{I_i}). All in all, the deficiency is decreased by at least $b \cdot |I_i|$.
- Finally, the queries may make the process repeat for another iteration, so Step 1 may be performed again, increasing the deficiency by another 2 bits.

Summing all those effects together, we get that the deficiency was decreased by at least

$$b \cdot |I_i| - 0.91 \cdot b \cdot |I_i| - (|I_i| + 1) - 2 \geq 0.05 \cdot b \cdot |I_i|,$$

as required. This concludes the proof.

5 Fourier-theoretic result

We recall our notation, some definitions and the result. Let $n \in \mathbb{N}$ and let $b \in \mathbb{N}$ be such that $b \geq 40,000 \cdot \log n$. We denote the domain of the inner product gadget by $\Lambda = \{0,1\}^b$ (so the inner product is over $\Lambda \times \Lambda$), and denote $q = |\Lambda| = 2^b$. Given a string $\gamma \in \Lambda$, we denote the corresponding Fourier character by $\chi_\gamma(x) \stackrel{\text{def}}{=} (-1)^{\langle \gamma, x \rangle}$. When considering a set $I \subseteq [n]$ and the space of functions $f \colon \Lambda^I \to \mathbb{R}$, we index the corresponding Fourier characters by tuples from Λ^I, such that for every $\gamma \in \Lambda^I$ it holds that $\chi_\gamma = \prod_{i \in I} \chi_{\gamma_i}$.

▶ **Definition 16.** *Let $\alpha \in \Lambda^n$ and let Y be a random variable taking values in Λ^n. We say that α is* η-bad *for Y if there exists a set $I \subset [n]$ and a string $\sigma \in \{0,1\}^I$ such that the random variable*

$$Y_{[n]-I} \,|\forall_{i \in I} \langle \alpha_i, Y_i \rangle = \sigma_i$$

is not η-dense or

$$\Pr\left[\forall_{i \in I} \langle \alpha_i, Y_i \rangle = \sigma_i\right] < 2^{-|I|-1}.$$

In this section we prove the following result.

▶ **Theorem 17** (Restatement of Theorem 7)**.** *Let X and Y be random variables taking values in Λ^n that are δ_X-dense and δ_Y-dense respectively. Suppose that $\delta_X + \delta_Y \geq 1.3$ and $\delta_Y \geq 0.1$. Then, the probability that X takes a value that is $\frac{\delta_Y}{2.01}$-bad for Y is at most $q^{-0.01}$.*

For the rest of this section, fix the random variables X and Y, and suppose that they are δ_X-dense and δ_Y-dense respectively where $\delta_X + \delta_Y \geq 1.3$ and $\delta_Y \geq 0.1$. We use the following definition, which essentially isolates "badness" to a particular set of coordinates.

▶ **Definition 18.** *Let $\varepsilon > 0$. We say that $\alpha \in \Lambda^n$ is* ε-bad *for Y on $J \subseteq [n]$ if there exist a string $\beta_J \in \Lambda^J$, a non-empty set $I \subset [n] - J$ and a string $\sigma \in \{0,1\}^I$ such that*

$$\Pr\left[Y_J = \beta_J \text{ and } \forall_{i \in I} \langle \alpha_i, Y_i \rangle = \sigma_i\right] \notin 2^{-|I|} \cdot \left(\Pr\left[Y_J = \beta_J\right] \pm \varepsilon\right).$$

In particular, if $J = \emptyset$, we view Y_J, β_J as the empty string and the event $Y_J = \beta_J$ as an event that occurs with probability 1 vacuously.

Morally, a value is not bad if it is not bad on any J. Theorem 17 will follow as a corollary from the following result (see that last part of the full version [3] of the paper).

▶ **Lemma 19.** *For every $J \subseteq [n]$, the probability that X takes a value that is ε-bad for Y on J is at most $q^{-\delta_Y \cdot |J| - 0.05}/\varepsilon^2$.*

In order to analyze the probability of bad values, it is more convenient to consider "unbiased" values, i.e., values α for which the event $Y_J = \beta_J$ is not correlated with inner products of the form $\forall_{i \in I} \langle \alpha_i, Y_i \rangle = \sigma_i$. This bias is naturally measured using Fourier coefficients. We denote by $D \colon \Lambda^n \to [0,1]$ the distribution of Y, i.e., the function that for every $\beta \in \Lambda^n$ outputs $\Pr[Y = \beta]$. For a set of indices $K \subseteq [n]$, we denote by D_K the function corresponding to the marginal distribution over K. Moreover, given disjoint sets $J, K \subseteq [n]$ and a string $\beta_J \in \Lambda^J$ we denote by $D_{K,\beta_J} \colon \Lambda^K \to [0,1]$ the function that maps each $\beta_K \in \Lambda^K$ to $\Pr[Y_K = \beta_K \text{ and } Y_J = \beta_J]$.

▶ **Definition 20.** *We say that a value $\alpha \in \Lambda^n$ is* ε-biased *for Y with respect to $J \subseteq [n]$ if for every non-empty $I \subseteq [n] - J$ and for every $\beta_J \in \Lambda^J$ it holds that $\left|\hat{D}_{I,\beta_J}(\alpha_I)\right| \leq \varepsilon \cdot q^{-1.1 \cdot |I|}$.*

Lemma 19 follows immediately from the next two propositions. The first proposition is a "Vazirani lemma" type of result that shows that small bias implies small distortion of probabilities.

▶ **Proposition 21.** *If a value $\alpha \in \Lambda^n$ is ε-biased for Y with respect to $J \subseteq [n]$, then it is not ε-bad with respect to J.*

The second proposition upper bounds the probability of X taking a value with large bias using the fact that X and Y are δ_X-dense and δ_Y-dense respectively.

▶ **Proposition 22.** *For every $J \subseteq [n]$, the probability that X takes a value that is not ε-biased for Y with respect to J is at most $q^{-\delta_Y \cdot |J| - 0.05}/\varepsilon^2$.*

The rest of the proof can be found in the full version [3] of the paper.

Estimating the Frequency of a Clustered Signal

Abstract

We consider the problem of locating a signal whose frequencies are "off grid" and clustered in a narrow band. Given noisy sample access to a function $g(t)$ with Fourier spectrum in a narrow range $[f_0 - \Delta, f_0 + \Delta]$, how accurately is it possible to identify f_0? We present generic conditions on g that allow for efficient, accurate estimates of the frequency. We then show bounds on these conditions for k-Fourier-sparse signals that imply recovery of f_0 to within $\Delta + \widetilde{O}(k^3)$ from samples on $[-1, 1]$. This improves upon the best previous bound of $O\big(\Delta + \widetilde{O}(k^5)\big)^{1.5}$. We also show that no algorithm can do better than $\Delta + \widetilde{O}(k^2)$.

In the process we provide a new $\widetilde{O}(k^3)$ bound on the ratio between the maximum and average value of continuous k-Fourier-sparse signals, which has independent application.

1 Introduction

A natural question, dating at least to the work of Prony in 1795, is to estimate a signal from samples, assuming the signal has a k-sparse Fourier representation, i.e., that the signal is a sum of k complex exponentials: $g(t) = \sum_{j=1}^{k} v_j e^{2\pi \mathbf{i} f_j t}$ for some set of frequencies f_j and coefficients v_j.

If the frequencies are located on a discrete grid (giving a sparse discrete Fourier transform), then a long line of work has studied efficient algorithms for recovering the signal (e.g., [11, 7, 1, 8, 9, 10]). If the frequencies are not on a grid, then Prony's method from 1795 [14] or matrix pencil [3] can still identify them in the absence of noise. With noise, however, one cannot robustly recover frequencies that are too close together: if one listens to a signal for the interval $[-T, T]$ then any two frequencies θ and $\theta + \varepsilon/T$ will be $O(\varepsilon)$-close to each other, and so cannot be distinguished with noise. As shown in [12], this nonrobustness grows exponentially in k. On the other hand, [12] also showed that recovery with polynomially

small noise is possible if all the frequencies have separation $1/2T$, and [13] showed that a constant fraction of noise is tolerable with separation $\log^{O(1)}(FT)/T$, where F is the bandlimit of the signal.

So what *is* possible for arbitrary Fourier-sparse signals, without any assumption of frequency separation? One cannot hope to identify the frequencies exactly, but one can still estimate the *signal itself*. If two frequencies are similar enough to be indistinguishable over the sampled interval, we do not need to distinguish them. In [4], this led to an algorithm for an arbitrary k-Fourier-sparse signal that used $\mathrm{poly}(k, \log(FT))$ samples to estimate it with only a constant factor increase in the noise. However, this polynomial is fairly poor.

Since prior work could handle the case of well-separated frequencies, a key challenge in [4] is the setting with all the frequencies in a narrow cluster. Formally, consider the following subproblem: if all the frequencies f_i of the signal lie in a narrow band $[f_0 - \Delta, f_0 + \Delta]$, how accurately can we estimate f_0? Note that while we would like an efficient algorithm that takes a small number of samples, the key question is *information theoretic*. And we can ask this question more generally: if the signal is not k-sparse, but still has all its frequencies in a narrow band, can we locate that band?

▶ **Question 1.** *Let $g(t)$ be a signal with Fourier transform supported on $[f_0 - \Delta, f_0 + \Delta]$, for some $f_0 \in [-F, F]$. Suppose that we can sample from $y(t) = g(t) + \eta(t)$ at points in $[-T, T]$, where $\eta(t)$ could be any ℓ_2 bounded noise on $[-T, T]$ with*

$$\mathop{\mathbb{E}}_{t\in[-T,T]}\left[|\eta(t)|^2\right] \le \varepsilon \mathop{\mathbb{E}}_{t\in[-T,T]}\left[|g(t)|^2\right]$$

for a small constant ε. Under what conditions on g can we estimate f_0, and how accurately?

One might expect to be able to estimate f_0 to $\pm(\Delta + O(\frac{1}{T}))$ for all functions g; after all, g is just a combination of individual frequencies, each of which points to some frequency in the right range, and each individual frequency in isolation can be estimated to within $\pm O(\frac{1}{T})$ in the presence of noise. Unfortunately, this intuition is false.

To see this, consider the family of k-sparse Fourier functions with $f_j = \varepsilon j$, i.e.,

$$\mathrm{span}(e^{2\pi \mathbf{i}(j\varepsilon)t} \mid j \in [k]).$$

By sending $\varepsilon \to 0$ and taking a Taylor expansion, this family can get arbitrarily close to any degree $k-1$ polynomial, on any interval $[-T', T']$. Thus, to solve the question, one would also need to solve it when $g(t)$ is a polynomial even for arbitrarily small Δ.

There are two ways in which $g(t)$ being a degree d polynomial can lead to trouble. The first is that $g(t)$ could itself be a Taylor expansion of $e^{\pi \mathbf{i} f t}$. If $d \gtrsim fT$, this Taylor approximation will be quite accurate on $[-T, T]$; with the noise η, the observed signal can *equal* $e^{\pi \mathbf{i} f t}$. Thus the algorithm has to output f, which can be $\Theta(d/T)$ far from the "true" answer $f_0 = 0$.

The second way in which $g(t)$ can lead to trouble is by removing most of the signal energy. If $g(t)$ is the (slightly shifted) Chebyshev polynomial $g(t) = T_d\big(t/T + O(\frac{\log^2 d}{d^2})\big)$, then $|g(t)| \le 1$ for $t \le \big(1 - O(\frac{\log^2 d}{d^2})\big)T$, while $g(t) \ge d$ for $t \ge \big(1 - O(\frac{\log^2 d}{d^2})\big)T$. That is to say, the majority of the ℓ_2 energy of g can lie in the final $O(\frac{\log^2 d}{d^2})$ fraction of the interval. In such a case, a small constant noise level η can make samples outside that $T \cdot \widetilde{O}(1/d^2)$ size region equal to zero, and hence completely uninformative; and samples in that region still have to tolerate noise. This leads to an "effective" interval size of $T' = T \cdot \widetilde{O}(\frac{1}{d^2})$, leading to accuracy $O(1/T') = \widetilde{O}(d^2)/T$.

Our main result is that, in a sense, these two types of difficulties are the only ones that arise. We can measure the second type of difficulty by looking at how much larger the maximum value of g is than its average:

$$R := \frac{\sup_{t\in[-T,T]} |g(t)|^2}{\mathbb{E}_{t\in[-T,T]} |g(t)|^2}.$$

We can measure the former by observing that while a polynomial may approximate a complex exponential on a bounded region, as $t \to \infty$ the polynomial will blow up. In particular, we take the S such that

$$|g(t)|^2 \le \mathsf{poly}(R) \cdot \mathop{\mathbb{E}}_{t\in[-T,T]} \left[|g(t)|^2\right] \cdot |\frac{t}{T}|^S$$

for all $|t| \ge T$. We show that if R and S are bounded, one can estimate f_0 to within $\Delta + \widetilde{O}(R+S)/T$, which is almost tight from the above discussion of polynomials. Moreover, the time and number of samples required are fairly efficient:

▶ **Theorem 2.** *Given any $T > 0, F > 0, \Delta > 0, R$, and $S > 0$, let $g(t)$ be a signal with the following properties:*

1. $\mathsf{supp}(\widehat{g}) \subseteq [f_0 - \Delta, f_0 + \Delta]$ *where* $f_0 \in [-F, F]$.
2. $\sup_{t\in[-T,T]} \left[|g(t)|^2\right] \le R \cdot \mathop{\mathbb{E}}_{t\in[-T,T]} \left[|g(t)|^2\right]$.
3. $|g(t)|^2$ *grows as at most* $\mathsf{poly}(R) \cdot \mathop{\mathbb{E}}_{t\in[-T,T]} \left[|g(t)|^2\right] \cdot |\frac{t}{T}|^S$ *for* $t \notin [-T,T]$.

Let $y(t) = g(t) + \eta(t)$ be the observable signal on $[-T,T]$, where $\mathop{\mathbb{E}}_{t\in[-T,T]} \left[|\eta(t)|^2\right] \le \epsilon \cdot \mathop{\mathbb{E}}_{t\in[-T,T]} \left[|g(t)|^2\right]$ for a sufficiently small constant ϵ. For $\Delta' = \Delta + \frac{\widetilde{O}(R+S)}{T}$ and any $\delta > 0$, there exists an efficient algorithm that takes $O(R \log \frac{F}{\Delta'\cdot\delta})$ samples from $y(t)$ and outputs $\widetilde{f}$ satisfying $|f_0 - \widetilde{f}| \le O(\Delta')$ with probability at least $1 - \delta$.

Application to sparse Fourier transforms. Specializing to k-Fourier-sparse signals, we give bounds on R and S for this family. Since (as described above) this family can approximate degree-$(k-1)$ polynomials, we know that $R \gtrsim k^2$ and $S \gtrsim k$; we show that $R \lesssim k^3 \log^2 k$ and $S \lesssim k^2 \log k$. Thus, whenever R is between k^2 and $\widetilde{O}(k^3)$, we can identify k-Fourier-sparse signals to within $\Delta + \widetilde{O}(R)/T$. This is an improvement over the results in [4] in several ways.

Formally, for a given sparsity level k, we consider signals in

$$\mathcal{F} := \left\{ g(t) = \sum_{j=1}^{k} v_j e^{2\pi \boldsymbol{i} f_j t} \middle| f_j \in [-F, F] \right\}.$$

▶ **Theorem 3.** *For any k and T,*

$$R := \sup_{g\in\mathcal{F}} \frac{\sup_{x\in[-T,T]} |g(x)|^2}{\mathop{\mathbb{E}}_{x\in[-T,T]} [|g(x)|^2]} = O(k^3 \log^2 k). \tag{1}$$

It was previously known that $R \lesssim k^4 \log^3 k$ [4], and this fact was used in [2]. (Thus, our improved bound on R immediately implies an improvement in Theorem 8 of [2], from $s_{\mu,\varepsilon}^5 \log^3 s_{\mu,\varepsilon}$ to $s_{\mu,\varepsilon}^4 \log^2 s_{\mu,\varepsilon}$.)

Next we bound the growth $S = \widetilde{O}(k^2)$ for any $|t| \ge T$.

▶ **Theorem 4.** *There exists $S = O(k^2 \log k)$ such that for any $|t| > T$ and $g(t) = \sum_{j=1}^{k} v_j \cdot e^{2\pi \boldsymbol{i} f_j t}$, $|g(t)|^2 \le \mathsf{poly}(k) \cdot \mathop{\mathbb{E}}_{x\in[-T,T]}[|g(x)|^2] \cdot |\frac{t}{T}|^S$.*

This is analogous to Theorem 5.5 of [4], which proves a bound of $(kt)^k$ rather than $t^{\widetilde{O}(k^2)}$. These bounds are incomparable, but the $t^{\widetilde{O}(k^2)}$ bound is actually more useful for this problem: what really matters is showing that $g(t)$ is not too large just outside the interval. Theorem 4 gives the "correct" polynomial dependence at $t = (1 + 1/k^2)T$.

We can now apply Theorem 2 to get an efficient algorithm to recover the center of a cluster of k frequencies within accuracy $\tilde{O}(R)$.

▶ **Theorem 5.** *Given F, T, and k, let R be the ratio between the maximum and average value of continuous k-Fourier-sparse signals defined in (1). Given Δ, let $g(t)$ be a k-Fourier-sparse signal centered around f_0: $g(t) = \sum_{i\in[k]} v_i \cdot e^{2\pi \mathbf{i} f_i t}$ where each $f_i \in [f_0 - \Delta, f_0 + \Delta]$ and $y(t) = g(t) + \eta(t)$ be the observable signal on $[-T, T]$, where $\mathop{\mathbb{E}}_{t\in[-T,T]}\left[|\eta(t)|^2\right] \le \epsilon \cdot \mathop{\mathbb{E}}_{t\in[-T,T]}\left[|g(t)|^2\right]$ for a sufficiently small constant ϵ.*

For any $\delta > 0$, there exist $\Delta' = \Delta + \frac{\tilde{O}(R)}{T}$ and an efficient algorithm that takes $O(k \log^2 k \log \frac{F}{\Delta' \cdot \delta})$ samples from $y(t)$ and outputs $\widetilde{f}$ satisfying $|f_0 - \widetilde{f}| \le O(\Delta')$ with probability at least $1 - \delta$.

Note that the sample complexity here is $\widetilde{O}(k)$ not $\widetilde{O}(R)$. This is because, based on the structure of the problem, we can use a nonuniform sampling procedure that performs better. Otherwise this theorem is just Theorem 2 applied to the R and S from Theorems 3 and 4.

Theorem 5 is a direct improvement on Theorem 7.5 of [4], which for $T = 1$ could estimate to within $O\left(\Delta + \widetilde{O}(k^5)\right)^{1.5}$ accuracy and used $\mathrm{poly}(k)$ samples. In particular, in addition to improving the additive $\mathrm{poly}(k)$ term, our result avoids a multiplicative increase in the bandwidth Δ of g.

The main technical lemma in proving Theorems 2 and 5 is a filter function H with a compact supported Fourier transform $\widehat{H}$ that simulates a box function on $[-T, T]$ for any g satisfying the conditions in Theorem 2.

▶ **Lemma 6.** *Given any T, S, and R, there exists a filter function H with $\left|\mathsf{supp}(\widehat{H})\right| \le \frac{\tilde{O}(R+S)}{T}$ such that for any $g(t)$ satisfying the second and third conditions in Theorem 2,*

1. *H is close to a box function on $[-T, T]$: $\int_{-T}^{T} |g(t) \cdot H(t)|^2 \mathrm{d}t \ge 0.9 \int_{-T}^{T} |g(t)|^2 \mathrm{d}t$.*
2. *The tail of $H(t) \cdot g(t)$ is small: $\int_{-T}^{T} |g(t) \cdot H(t)|^2 \mathrm{d}t \ge 0.95 \int_{-\infty}^{\infty} |g(t) \cdot H(t)|^2 \mathrm{d}t$.*

Organization. We introduce some notation and tools in Section 2. Then we provide a technical overview in Section 3. We show our filter function and prove Lemma 6 in Section 4. Next we present the algorithm about frequency estimation of Theorem 2 in Section 5. Finally we prove the results about sparse Fourier transform – Theorem 3 and Theorem 4 in Section 6.

2 Preliminaries

In the rest of this work, we fix the observation interval to be $[-1, 1]$ and define

$$\|g\|_2 = \left(\mathop{\mathbb{E}}_{x\sim[-1,1]} |g(x)|^2\right)^{1/2}, \tag{2}$$

because we could rescale $[-T, T]$ to $[-1, 1]$ and $[-F, F]$ to $[-FT, FT]$.

We first review several facts about the Fourier transform. The Fourier transform $\widehat{g}(f)$ of an integrable function $g : \mathbb{R} \to \mathbb{C}$ is

$$\widehat{g}(f) = \int_{-\infty}^{+\infty} g(t)e^{-2\pi \boldsymbol{i} ft}\mathrm{d}t \text{ for any real } f.$$

We use $g \cdot h$ to denote the pointwise dot product $g(t) \cdot h(t)$ and g^k to denote $\underbrace{g(t) \cdots g(t)}_{k}$. Similarly, we use $g*h$ to denote the convolution of g and h: $\int_{-\infty}^{+\infty} g(x) \cdot h(t-x)\mathrm{d}x$. In this work, we always set g^{*k} as the convolution $\underbrace{g(t) * \cdots * g(t)}_{k}$. Notice that $\mathsf{supp}(g \cdot h) = \mathsf{supp}(g) \cap \mathsf{supp}(h)$ and $\mathsf{supp}(g * h) = \mathsf{supp}(g) + \mathsf{supp}(h)$.

We define the box function and its Fourier transform sinc function as follows. Given a width $s > 0$, the box function $\mathrm{rect}_s(t) = 1/s$ iff $|t| \leq s/2$; and its Fourier transform is $\mathrm{sinc}(sf) = \frac{\sin(\pi fs)}{\pi fs}$ for any f.

We state the Chernoff bound for random sampling [6].

▶ **Lemma 7.** *Let $X_1, X_2, \cdots, X_n$ be independent random variables in $[0, R]$ with expectation 1. For any $\varepsilon < 1/2$ and $n \gtrsim \frac{R}{\epsilon^2}$, $X = \frac{\sum_{i=1}^{n} X_i}{n}$ with expectation 1 satisfies*

$$\Pr[|X - 1| \geq \varepsilon] \leq 2\exp(-\frac{\varepsilon^2}{3} \cdot \frac{n}{R}).$$

3 Proof Overview

We first outline the proofs of Lemma 6 and Theorem 2. Then we show the proof sketch of $R = \tilde{O}(k^3)$ and $S = \tilde{O}(k^2)$ of k-Fourier-sparse signals.

The filter functions $(H, \widehat{H})$ in Lemma 6. Ideally, to satisfy the two claims in Lemma 6, we could set $H(t)$ to be the box function $2\,\mathrm{rect}_2(t)$ on $[-1, 1]$. However, by the uncertainty principle, it is impossible to make its Fourier transform $\widehat{H}$ compact using such an $H(t)$. Hence our construction of $(H, \widehat{H})$ is in the inverse direction: we build $\widehat{H}(f)$ by box functions and $H(t)$ by the Fourier transform of box functions – the sinc function. In the rest of this discussion, we focus on using the sinc function to prove Lemma 6 given the properties of g in Theorem 2.

We first notice that any H with the following two properties is effective in Lemma 6 for g satisfying $|g(t)|^2 \leq R \cdot \|g\|_2^2$ for any $|t| \leq 1$ and $|g(t)|^2 \leq \mathsf{poly}(R)\|g\|_2^2 \cdot |t|^S$ for $|t| > 1$:

1. $H(t) = 1 \pm 0.01$ for any $t \in [-1 + \frac{1}{C \cdot R}, 1 - \frac{1}{C \cdot R}]$ of a large constant C. This shows

$$\int_{-1}^{1} |H(t) \cdot g(t)|^2\mathrm{d}t \geq 0.99^2 \int_{-1+\frac{1}{C \cdot R}}^{1-\frac{1}{C \cdot R}} |g(t)|^2\mathrm{d}t.$$

   Because $|g(t)|^2 \leq R \cdot \|g\|_2^2$ for any $t \in [-1, 1] \setminus [-1 + \frac{1}{C \cdot R}, 1 - \frac{1}{C \cdot R}]$, the constant on the R.H.S. is at least $0.99^2 \cdot (1 - \frac{1}{C}) \geq 0.9$, which implies the first claim of Lemma 6.
2. $H(t)$ declines to $\frac{1}{\mathsf{poly}(R) \cdot t^{2S}}$ for any $|t| > 1$. This shows

$$\int_{1}^{\infty} |H(t) \cdot g(t)|^2\mathrm{d}t \leq 0.01 \int_{-1}^{1} |g(t)|^2\mathrm{d}t,$$

   which implies the second claim.

For ease of exposition, we start with $S = 0$. We plan to design a filter $H_0(t)$ with compact $\widehat{H_0}$ dropping from 0.99 at $t = 1 - \frac{1}{C \cdot R}$ to $\frac{1}{\mathsf{poly}(R)}$ at $t = 1$ in a small range $\frac{1}{CR}$ using the sinc function. To apply the sinc function, we notice that

$$\mathrm{sinc}(CR \cdot t)^{O(\log R)} = \left(\frac{\sin(\pi CR \cdot t)}{\pi CR \cdot t}\right)^{O(\log R)}$$

decays from 1 at $t = 0$ to $1/\mathsf{poly}(R)$ at $t = \frac{1}{C \cdot R}$, which matches the dropping of $H_0(t)$ from $t = 1 - \frac{1}{C \cdot R}$ to $t = 1$.

Then, to make $H(t) \approx 1$ for any $|t| \le 1 - \frac{1}{C \cdot R}$, let us consider a convolution of $\mathrm{rect}_1(t)$ and $\mathrm{sinc}(CR \cdot t)^{O(\log R)}$. Because most of the mass of the latter is in $[-\frac{1}{CR}, \frac{1}{CR}]$, this convolution keeps almost the same value in $[-\frac{1}{2} + \frac{1}{CR}, \frac{1}{2} - \frac{1}{CR}]$ and drops down to $1/\mathsf{poly}(R)$ at $t = \frac{1}{2} + \frac{1}{CR}$. At the same time, it will keep the compactness of $\widehat{H_0}$ since it corresponds to the dot product on the Fourier domain. By normalizing and scaling, this gives the desired $(H_0, \widehat{H_0})$ for $S = 0$.

Next we describe the construction of $S > 0$. The high level idea is to consider the decays of $H(t)$ in $\log_2 S + O(1)$ segments rather than one segment of $S = 0$:

$$(1 - \frac{1}{CR}, 1], (1, 1 + \frac{1}{S}], (1 + \frac{1}{S}, 1 + \frac{2}{S}], \ldots, (1 + \frac{2^j}{S}, 1 + \frac{2^{j+1}}{S}], \ldots, (1 + \frac{S/2}{S}, 2], (2, +\infty).$$

For each segment, we provide a power of sinc functions matching its decay in $H(t)$ like the construction of H_0 on $(1 - \frac{1}{CR}, 1]$. The final construction is the convolution of the dot product of all sinc powers and a box function, which appears in Section 4.

The Algorithm of Theorem 2. Now we show how to estimate f_0 given the observable signal $y = g + \eta$ where $\mathsf{supp}(\widehat{g}) \subseteq [f_0 - \Delta, f_0 + \Delta]$ and $\|\eta\|_2^2 \le \varepsilon \|g\|_2^2$ (with ℓ_2 norm taken over $[-T, T]$ defined in (2)). We instead consider $y_H(t) = y(t) \cdot H(t)$ with the filter function $(H, \widehat{H})$ from Lemma 6 and the corresponding dot products $g_H = g \cdot H$ and $\eta_H = \eta \cdot H$. The starting point is that for a sufficiently small β, we expect

$$y_H(t + \beta) \approx e^{2\pi \boldsymbol{i} f_0 \beta} \cdot y_H(t)$$

because y_H has Fourier spectrum concentrated around f_0. This does not hold for *all* t, but it does hold on average:

$$\int_{-1}^{1} |y_H(t + \beta) - e^{2\pi \boldsymbol{i} f_0 \beta} \cdot y_H(t)|^2 \mathrm{d}t \lesssim \varepsilon \cdot \int_{-1}^{1} |y_H(t)|^2 \mathrm{d}t. \tag{3}$$

This is because we can use Parseval's identity to replace these integrals by an integral over Fourier domain – Parseval's identity would apply if the integrals were from $-\infty$ to ∞, but because of the filter function H, relatively little mass in y_H lies outside $[-1, 1]$. Then, the Fourier transform of the term inside the left square is $e^{2\pi \boldsymbol{i} f \beta} \cdot \widehat{y_H}(f) - e^{2\pi \boldsymbol{i} f_0 \beta} \cdot \widehat{y_H}(f)$. Note that $\widehat{y_H} = \widehat{g_H} + \widehat{\eta_H}$ has most of its ℓ_2 mass in $\mathsf{supp}(g_H) \subseteq [f_0 - \Delta', f_0 + \Delta']$ for $\Delta' = \Delta + |\mathsf{supp}(\widehat{H})|$, and every such frequency shrinks in the left by a factor $|e^{2\pi \boldsymbol{i} f \beta} - e^{2\pi \boldsymbol{i} f_0 \beta}| = O(\beta \Delta')$. Thus, for $\beta \ll 1/\Delta'$, (3) holds.

To learn f_0 through $e^{2\pi \boldsymbol{i} f_0 \beta}$, we design a sampling procedure to output α satisfying

$$|y_H(\alpha + \beta) - e^{2\pi \boldsymbol{i} f_0 \beta} y_H(\alpha)| \le 0.3 \cdot y_H(\alpha) \text{ with probability } \textit{more than half}.$$

Even though the above discussion shows the left hand side is smaller than the R.H.S. on average, a uniformly random $\alpha \sim [-1, 1]$ may not satisfy it with good probability: $|y_H(\alpha)| \ge \|y_H\|_2$ may be only true for $1/R$ fraction of $\alpha \in [-1, 1]$, while the corruption by

adversarial noise η has $\|\eta\|_2^2 \gtrsim \varepsilon\|y_H\|_2^2$ for a constant $\varepsilon \gg 1/R$. At the same time, even for many points $\alpha_1, \ldots, \alpha_m$ where some of them satisfy the above inequality, it is infeasible to verify such an α_i given f_0 is unknown. We provide a solution by adopting the importance sampling: for $m = O(R)$ random samples $\alpha_1, \ldots, \alpha_m \in [-1, 1]$, we output α with probability proportional to the weight $|y_H(\alpha_i)|^2$.

We prove the correctness of this sampling procedure in Lemma 11 in Section 5.

Finally, learning $e^{2\pi \mathbf{i} f_0 \beta}$ is not enough to learn f_0: because of the noise, we only learn $e^{2\pi \mathbf{i} f_0 \beta}$ to within a constant ε, which gives f_0 to within $\pm O(\varepsilon/\beta)$; and because of the different branches of the complex logarithm, this is only up to integer multiples of $1/\beta$. Therefore to fully learn f_0, we repeat the sampling procedure at logarithmically many different scales of β, from $\beta = 1/2F$ to $\beta = \frac{\Theta(1)}{\Delta'}$.

***k*-Fourier-sparse signals.** Finally, we show $R = \widetilde{O}(k^3)$ and $S = \widetilde{O}(k^2)$ such that for any $g(t) = \sum_{j=1}^k v_j \cdot e^{2\pi \mathbf{i} f_j t}$ – not necessarily one with the f_j clustered together –

$$\frac{\sup_{t \in [-1,1]} |g(t)|^2}{\|g\|_2^2} \le R \text{ and } |g(t)|^2 \le \mathsf{poly}(R) \cdot \|g\|_2^2 \cdot |t|^S.$$

We first review the previous argument of $R = \widetilde{O}(k^4)$ [4]. The key point is to show for some $d = \widetilde{O}(k^2)$ that $g(1)$ is a linear combination of $g(1-\theta), \ldots, g(1-d\cdot\theta)$ using bounded integer coefficients $c_1, \ldots, c_d = O(1)$ for any $\theta \le \frac{2}{d}$. Then

$$g(1) = \sum_{j \in [d]} c_j \cdot g(1 - j\cdot\theta) \text{ implies } |g(1)|^2 \le (\sum_{j\in[d]} |c_j|^2) \cdot (\sum_{j\in[d]} |g(1-j\cdot\theta)|^2). \tag{4}$$

If we think of $g(1)$ as the supremum and $g(1-j\cdot\theta)$ as the average $\|g\|_2$ – which we can formally do up to logarithmic factors by averaging over θ – this shows $|g(1)|^2 \le \widetilde{O}(d^2)\|g\|_2^2$. One natural idea to improve it is to use a smaller value d and a shorter linear combination [5]. However, $d = \tilde{\Omega}(k^2)$ for such a combination when g is approximately the degree $k-1$ Chebyshev polynomial. In this work, we use a geometric sequence to control c_j such that $\sum_j |c_j|^2 = O(d/k)$ instead of $O(d)$, which provides an improvement of a factor $\widetilde{O}(k)$ on R.

Then we bound $S = \widetilde{O}(k^2)$ for $g(t)$ at $|t| > 1$. The intuition is that given (4) holds for any $g(t)$ in terms of $g(t-\theta), \ldots, g(t-d\cdot\theta)$ with $\theta = \frac{2}{d}$, it implies $|g(t)|^2 \le \mathsf{poly}(k)\cdot\|g\|_2^2 \cdot e^{(t-1)\cdot O(d)}$ for $t > 1$. Combining this with an alternate bound $|g(t)|^2 \le \mathsf{poly}(k) \cdot \|g\|_2^2 \cdot (k\cdot t)^{O(k)}$ for $t > 1 + 1/k$, it completes the proof of Theorem 4 about S.

Finally we notice that we could improve the sample complexity in Theorem 5 to $\widetilde{O}(k) \log \frac{F}{\Delta'}$ using a biased distribution [5] to generate α. These results about k-Fourier-sparse signals appear in Section 6.

4 Our Filter Function

The main result is an explicit filter function H with compact support $\widehat{H}$ that is close to the box function on $[-1, 1]$ for any g satisfying the conditions in Theorem 2.

We show our filter function as follows.

▶ **Definition 8.** *Given R, the growth rate S and an even constant C, we define the filter function*

$$H(t) = s_0 \cdot \left(\mathrm{sinc}(CR\cdot t)^{C\log R} \cdot \mathrm{sinc}\left(C\cdot S\cdot t\right)^C \cdot \mathrm{sinc}\left(\frac{C\cdot S}{2}\cdot t\right)^{2C} \cdots \mathrm{sinc}\left(C\cdot t\right)^{C\cdot S}\right) * \mathrm{rect}_2(t)$$

where $s_0 \in \mathbb{R}^+$ *is a parameter to normalize* $H(0) = 1$. *On the other hand, its Fourier transform is*

$$\widehat{H}(f) = s_0 \cdot \left(\mathrm{rect}_{CR}(f)^{*C\log R} * \mathrm{rect}_{C\cdot S}(f)^{*C} * \mathrm{rect}_{\frac{C\cdot S}{2}}(f)^{*2C} * \cdots * \mathrm{rect}_{C}(f)^{*CS}\right) \cdot \mathrm{sinc}(2t),$$

whose support size is $O(CR \cdot C\log R + CS \cdot C + \cdots + C \cdot C \cdot S) = O(R\log R + S\log S)$.

We prove Lemma 6 using $H(\alpha x)$ with a large constant C and a scale parameter $\alpha = \frac{1}{2} + \frac{1.2}{\pi CR}$. For convenience, we state the full version of Lemma 6 for $T = 1$ as follows.

▶ **Theorem 9.** *Let* $R, S > 0$, *let* C *be a large even constant, and define* $\alpha = (\frac{1}{2} + \frac{1.2}{\pi CR})$. *Consider any function* g *satisfying the following two conditions:*

1. $\sup_{t\in[-1,1]} |g(t)|^2 \le R \cdot \|g\|_2^2$
2. *And* $|g(t)|^2 \le \mathsf{poly}(R) \cdot \|g\|_2^2 \cdot |t|^S$ *for* $t \notin [-1,1]$,

Then the filter function $H\big(\alpha x\big)$ *is such that* $H\big(\alpha x\big) \cdot g(x)$ *satisfies*

1. $\int_{-1}^{1} |g(x) \cdot H\big(\alpha x\big)|^2 \mathrm{d}x \ge 0.9 \int_{-1}^{1} |g(x)|^2 \mathrm{d}x$.
2. $\int_{-1}^{1} |g(x) \cdot H\big(\alpha x\big)|^2 \mathrm{d}x \ge 0.95 \int_{-\infty}^{\infty} |g(x) \cdot H\big(\alpha x\big)|^2 \mathrm{d}x$.
3. $|H(x)| \le 1.01$ *for any* x.

Due to the space constraint, we defer the proof of Theorem 9 to the full version.

5 Frequency Estimation

We show the algorithm for frequency estimation and prove Theorem 2 in this section. We fix $T = 1$ and use the definition $\|h\|_2^2 = \mathop{\mathbb{E}}_{x\sim[-1,1]}[|h(x)|^2]$ to restate the theorem.

▶ **Theorem 10.** *Given any* $F > 0, \Delta > 0, R$, *and* $S > 0$, *let* $g(t)$ *be a signal with the following properties:*

1. $\mathsf{supp}(\widehat{g}) \subseteq [f_0 - \Delta, f_0 + \Delta]$ *where* $f_0 \in [-F, F]$.
2. $\sup_{t\in[-1,1]} \big[|g(t)|^2\big] \le R \cdot \|g\|_2^2$.
3. $|g(t)|^2$ *grows as at most* $\mathsf{poly}(R) \cdot \|g\|_2^2 \cdot |t|^S$ *for* $t \notin [-1,1]$.

Let $y(t) = g(t) + \eta(t)$ *be the observable signal on* $[-1,1]$, *where* $\|\eta\|_2^2 \le \epsilon \cdot \|g\|_2^2$ *for a sufficiently small constant* ϵ. *For* $\Delta' = \Delta + \widetilde{O}(R+S)$ *and any* δ, *there exists an efficient algorithm that takes* $O(R\log\frac{F}{\Delta'\cdot\delta})$ *samples from* $y(t)$ *and outputs* $\widetilde{f}$ *satisfying* $|f_0 - \widetilde{f}| \le O(\Delta')$ *with probability at least* $1 - \delta$.

For convenience, we set $h_H(t) = h(t) \cdot H(\alpha t)$ for any signal $h(t)$ with the filter function H defined in Theorem 9 such that $y_H(t) = y(t) \cdot H(\alpha t)$.

Given the observation $y(t)$ with most Fourier mass concentrated around f_0, the main technical result in this section is an estimation of $e^{2\pi \mathbf{i}\beta f_0}$ through $y_H(\alpha)e^{2\pi i f_0 \beta} \approx y_H(\alpha+\beta)$.

▶ **Lemma 11.** *Given parameters* F, R, S, *and* Δ, *let* g *be a signal satisfying the three conditions in Theorem 2 for some* $f_0 \in [-F, F]$ *and* $\Delta' = \Delta + O(R\log R + S\log S)$.

Let $y(t) = g(t) + \eta(t)$ *be the observable signal on* $[-1,1]$ *where the noise* $\|\eta\|_2^2 \le \epsilon\|g\|_2^2$ *for a sufficiently small constant* ϵ. *There exist a constant* γ *and an algorithm such that for any* $\beta \le \frac{\gamma}{\Delta'}$, *it takes* $O(R)$ *samples to output* α *satisfying* $|y_H(\alpha)e^{2\pi i f_0\beta} - y_H(\alpha+\beta)| \le 0.3|y_H(\alpha)|$ *with probability at least 0.6.*

We show our algorithm in Algorithm 1. We finish the proof of Theorem 5 here and defer the proof of Lemma 11 to Section 5.1.

Algorithm 1 Obtain one good α.

procedure ObtainOneGoodSample($R, y(t)$)
  Let $m = C \cdot R$ for a large constant C.
  Take m random samples $x_1, \cdots, x_m$ uniform in $[-1, 1]$.
  Query $y(x_i)$ and compute $y_H(x_i) = y(x_i) \cdot H(x_i)$ for each i.
  Set a distribution D_m proportional to $|y_H(x_i)|^2$, i.e., $D_m(x_i) = \frac{|y_H(x_i)|^2}{\sum_{j=1}^m |y_H(x_j)|^2}$.
  Output $\alpha \sim D_m$.
end procedure

Proof of Theorem 10. From Lemma 11, $\frac{y_H(\alpha+\beta)}{y_H(\alpha)}$ gives a good estimation of $e^{2\pi i f_0 \beta}$ with probability 0.6 for any $\beta \le \frac{\gamma}{\Delta'}$. We use the frequency search algorithm of Lemma 7.3 in [4] with the sampling procedure in Lemma 11. Because the algorithm in [4] uses the sampling procedure $O(\log \frac{F}{\Delta' \cdot \delta})$ times to return a frequency $\widetilde{f}$ satisfying $|\widetilde{f} - f_0| \le \Delta'$ with prob. at least $1 - \delta$, the sample complexity is $O(R \cdot \log \frac{F}{\Delta' \cdot \delta})$. ◀

5.1 Proof of Lemma 11

For $y_H(x) = g_H(x) + \eta_H(x)$, we have the following concentration lemma for estimation $g_H(x)$.

▷ Claim 12. Given any g satisfying the three conditions in Theorem 2 and any ε and δ, there exists $m = O(R \log \frac{1}{\delta}/\varepsilon^2)$ such that for m random samples $x_1, \ldots, x_m \sim [-1, 1]$, with probability $1 - \delta$,

$$\frac{\sum_{i=1}^m |g_H(x_i)|^2}{m} \in [1 - \varepsilon, 1 + \varepsilon] \cdot \mathop{\mathbb{E}}_{x \sim [-1,1]} [|g_H(x)|^2].$$

Proof. Notice that $\frac{\sup_{x \sim [-1,1]} [|g_H(x)|^2]}{\mathop{\mathbb{E}}_{x \sim [-1,1]} [|g_H(x)|^2]} \le 2R$. From the Chernoff bound in Lemma 7, $m = O(R \log \frac{1}{\delta}/\varepsilon^2)$ suffices to estimate $\|g_H\|_2^2$. ◁

Next we consider the effect of noise $\eta_H(x_i)$ and $y_H(x_i)$.

▷ Claim 13. With probability 0.9 over m random samples in $[-1, 1]$, $\sum_{i=1}^m |y_H(x_i)|^2/m \ge 0.8\|g\|_2^2$.

Proof. From Theorem 9, $\|g_H\|_2^2 \ge 0.95\|g\|_2^2$. Thus Claim 12 implies $\sum_{i=1}^m |g_H(x_i)|^2/m \ge 0.98 \cdot 0.95\|g\|_2^2$ for $m = O(R)$ with probability 0.99.

At the same time, because $\mathbb{E}[\sum_{i=1}^m |\eta_H(x_i)|^2/m] = \|\eta_H\|_2^2$, $\sum_{i=1}^m |\eta_H(x_i)|^2/m \le 14\|\eta_H\|_2^2$ with probability at least $1 - \frac{1}{14}$ from the Markov inequality. This is also less than $14 \cdot 1.02^2\|\eta\|_2^2 \le 15\epsilon\|g\|_2^2$ from the upper bound on $H(t)$.

We have

$$\frac{1}{m}\sum_{i=1}^m |y_H(x_i)|^2 \ge \frac{1}{m}\sum_{i=1}^m \Big(|g_H(x_i)|^2 - 2|g_H(x_i)| \cdot |\eta_H(x_i)| + |\eta_H(x_i)|^2\Big).$$

By the Cauchy-Schwartz inequality, the cross term $\sum_{i=1}^m |g_H(x_i)| \cdot |\eta_H(x_i)| \le (\sum_{i=1}^m |g_H(x_i)|^2)^{1/2} \cdot (\sum_{i=1}^m |\eta_H(x_i)|^2)^{1/2}$. From all discussion above,

$$\frac{1}{m}\sum_{i=1}^m |y_H(x_i)|^2 \ge \big(0.93 - 2\sqrt{0.93 \cdot 15\epsilon}\big)\|g\|_2^2.$$

When ε is a small constant, it is at least $0.8 \cdot \|g\|_2^2$. ◁

We set $z(t) = y_H(t) \cdot e^{2\pi \boldsymbol{i} f_0 \beta} - y_H(t+\beta)$ for convenience and bound it as follows.

▷ Claim 14. Given any small constant γ, $\Delta' = \Delta + \mathsf{supp}(H)$, and $z(t) = y_H(t) \cdot e^{2\pi \boldsymbol{i} f_0 \beta} - y_H(t+\beta)$ for $\beta \le \frac{\gamma}{\Delta'}$, $\|z\|_2^2 \lesssim (\gamma^2 + \epsilon)\|g\|_2^2$.

Proof. Notice that $y_H = g_H + \eta_H$ where $\mathsf{supp}(\widehat{g_H}) \in [f_0 - \Delta, f_0 + \Delta]$ such that

$$\int_{f \notin [f_0-\Delta', f_0+\Delta']} |\widehat{y}(f)|^2 \mathrm{d}f \le \int_{-\infty}^{\infty} |\widehat{\eta_H}(f)|^2 \mathrm{d}f = \int_{-\infty}^{\infty} |\eta_H(t)|^2 \mathrm{d}t \le 1.02^2 \epsilon \int_{-1}^{1} |g(t)|^2 \mathrm{d}t.$$

We bound $\|z\|_2^2$ through

$$\begin{aligned}\int_{-1}^{1} |z(t)|^2 \mathrm{d}t \le \int_{-\infty}^{\infty} |z(t)|^2 \mathrm{d}t &= \int_{-\infty}^{\infty} |\widehat{z}(f)|^2 \mathrm{d}f \\ &= \int_{f_0-\Delta'}^{f_0+\Delta'} |\widehat{z}(f)|^2 \mathrm{d}f + \int_{f \notin [f_0-\Delta', f_0+\Delta']} |\widehat{z}(f)|^2 \mathrm{d}f.\end{aligned}$$

Therefore we write

$$\begin{aligned}\int_{f_0-\Delta'}^{f_0+\Delta'} |\widehat{z}(f)|^2 \mathrm{d}f &= \int_{f_0-\Delta'}^{f_0+\Delta'} |\widehat{y_H}(f) \cdot e^{2\pi \boldsymbol{i} f_0 \beta} - \widehat{y_H}(f) \cdot e^{2\pi \boldsymbol{i} f \beta}|^2 \mathrm{d}f \\ &\le \int_{f_0-\Delta'}^{f_0+\Delta'} |\widehat{y_H}(f)|^2 \cdot |e^{2\pi \boldsymbol{i} f_0 \beta} - e^{2\pi \boldsymbol{i} f \beta}|^2 \mathrm{d}f.\end{aligned}$$

Because $f \in [f_0 - \Delta', f_0 + \Delta']$ and $\beta \le \frac{\gamma}{\Delta'}$, $|e^{2\pi \boldsymbol{i} f_0 \beta} - e^{2\pi \boldsymbol{i} f \beta}| \le 4\pi\gamma$. So

$$\int_{f_0-\Delta'}^{f_0+\Delta'} |\widehat{z}(f)|^2 \mathrm{d}f \lesssim \gamma^2 \int_{-\infty}^{+\infty} |\widehat{y_H}(f)|^2 \mathrm{d}f = \gamma^2 \int_{-\infty}^{+\infty} |y_H(t)|^2 \mathrm{d}t \lesssim \gamma^2 (1 + 2\epsilon) \int_{-1}^{1} |g(t)|^2 \mathrm{d}t.$$

On the other hand,

$$\begin{aligned}\int_{f \notin [f_0-\Delta', f_0+\Delta']} |\widehat{z}(f)|^2 \mathrm{d}f &= \int_{f \notin [f_0-\Delta', f_0+\Delta']} |\widehat{y_H}(f) \cdot e^{2\pi \boldsymbol{i} f_0 \beta} - \widehat{y_H}(f) \cdot e^{2\pi \boldsymbol{i} f \beta}|^2 \mathrm{d}f \\ &\le 4 \int_{f \notin [f_0-\Delta', f_0+\Delta']} |\widehat{y_H}(f)|^2 \mathrm{d}f \\ &\le 4 \int_{-\infty}^{+\infty} |\widehat{\eta_H}(f)|^2 \mathrm{d}f = 4 \int_{-\infty}^{+\infty} |\widehat{\eta_H}(t)|^2 \mathrm{d}t\end{aligned}$$

which is less than $5\epsilon \int_{-1}^{1} |g(t)|^2 \mathrm{d}t$.

From all discussion above, $\int_{-1}^{1} |z(t)|^2 \mathrm{d}t \lesssim (\gamma^2 + \epsilon) \int_{-1}^{1} |g(t)|^2 \mathrm{d}t$. ◁

For sufficiently small γ and ε, by Markov inequality, we have the following corollary.

▶ **Corollary 15.** *For sufficiently small constants γ and ϵ, with probability 0.9 over m random samples in $[-1, 1]$, $\sum_{i=1}^{m} |z(x_i)|^2 \le 0.01\|g\|_2^2$.*

Finally we finish the proof of Lemma 11.

Proof of Lemma 11. We assume Claim 13 and Corollary 15 hold in this proof, i.e.,

$$\sum_{i=1}^{m} |y_H(x_i)|^2/m \ge 0.8\|g\|_2^2 \text{ and } \sum_{i=1}^{m} |z(x_i)|^2/m \le 0.01\|g\|_2^2.$$

For a random sample $\alpha \sim D_m$, we bound

$$\mathop{\mathbb{E}}_{\alpha\sim D_m}\left[\frac{|y_H(\alpha)e^{2\pi i f_0\beta} - y_H(\alpha+\beta)|^2}{|y_H(\alpha)|^2}\right] = \mathop{\mathbb{E}}_{\alpha\sim D_m}\left[\frac{|z(\alpha)|^2}{|y_H(\alpha)|^2}\right] = \sum_{i=1}^{m}\frac{|z(x_i)|^2}{|y_H(x_i)|^2}\cdot\frac{|y_H(x_i)|^2}{\sum_{j=1}^m|y_H(x_j)|^2}.$$

This is $\frac{\sum_{i=1}^m|z(x_i)|^2}{\sum_{j=1}^m|y_H(x_j)|^2} \le \frac{0.01}{0.8}$. Thus with probability 0.8, $\frac{|y_H(\alpha)e^{2\pi i f_0\beta}-y_H(\alpha+\beta)|^2}{|y_H(\alpha)|^2}$ is less than $0.05/0.8 \le 0.09$. From all discussion above, $\frac{|y_H(\alpha)e^{2\pi i f_0\beta}-y_H(\alpha+\beta)|}{|y_H(\alpha)|} \le 0.3$ with probability 0.6. ◀

6 Bounds on Fourier-sparse Signals

We consider $g(t) = \sum_{j=1}^k v_j e^{2\pi \boldsymbol{i} f_j t}$ where each $f_j \in [f_0-\Delta, f_0+\Delta]$ in this section. The main result is to prove $R = \tilde{O}(k^3)$ and $S = \tilde{O}(k^2)$ for k arbitrary real frequencies. We restate Theorem 5 after fixing $T = 1$.

▶ **Theorem 16.** *Given F, Δ, and k, let $g(t)$ be a k-Fourier-sparse signal centered around $f_0 \in [-F, F]$: $g(t) = \sum_{i\in[k]} v_i \cdot e^{2\pi \mathbf{i} f_i t}$ where $f_i \in [f_0-\Delta, f_0+\Delta]$ and $y(t) = g(t) + \eta(t)$ be the observable signal on $[-1, 1]$, where $\|\eta\|_2^2 \le \epsilon \cdot \|g\|_2^2$ for a sufficiently small constant ϵ.*

For any $\delta > 0$, there exist $\Delta' = \Delta + \tilde{O}(R)$ and an efficient algorithm that takes $O(k\log^2 k \log\frac{F}{\Delta'\cdot\delta})$ samples from $y(t)$ and outputs $\widetilde{f}$ satisfying $|f_0 - \widetilde{f}| \le O(\Delta')$ with probability at least $1-\delta$.

The main improvement is a biased distribution that saves the sample complexity from $O(R)\cdot\log\frac{F}{\Delta'\cdot\delta}$ to $\widetilde{O}(k)\cdot\log\frac{F}{\Delta'\cdot\delta}$.

We provide the main technical lemma here and defer the proofs of Theorem 3, 4, and 16 to the full version.

▶ **Theorem 17.** *Given $z_1, \ldots, z_k$ with $|z_1| = |z_2| = \cdots = |z_k| = 1$, there exists a degree $d = O(k^2\log k)$ polynomial $P(z) = \sum_{j=0}^d c(j)\cdot z^j$ satisfying*

1. *$P(z_i) = 0$ for each $i \in [k]$.*
2. *Coefficients $c(0) = \Omega(1)$, $c(j) = O(1)$ and $\sum_{j=1}^d |c(j)|^2 = O(k)\cdot|c(0)|^2$.*

▶ **Corollary 18.** *Given any $g(t) = \sum_{j=1}^k v_j e^{2\pi \boldsymbol{i} f_j t}$ and $\theta > 0$, there exist $d = O(k^2\log k)$ and a sequence of coefficients $(\alpha_1, \ldots, \alpha_d)$ such that*

1. *$\alpha_j = O(1)$ for any $j = 1, \ldots, d$.*
2. *For any x (not necessarily in $[-1, 1]$), $g(x) = \sum_{j=1}^d \alpha_j \cdot g(x - j\theta)$.*

Proof. Given θ, we set $z_i = e^{-2\pi \boldsymbol{i} f_j\theta}$ and apply Theorem 17 to obtain coefficients $c(0), \ldots, c(d)$. Then we set $\alpha_j = -c(j)/c(0)$. It is straightforward to verify the second property because of

$$e^{2\pi \boldsymbol{i} f_j x} - \sum_j \alpha_j \cdot e^{2\pi \boldsymbol{i} f_j(x-j\theta)} = 0.$$ ◀

The proof of Theorem 17 requires the following bound on the coefficients of residual polynomials, which is stated as Lemma 5.3 in [4].

▶ **Lemma 19.** *Given $z_1, \ldots, z_k$, for any integer n, let $r_{n,k}(z) = \sum_{i=0}^{k-1} r_{n,k}^{(i)}\cdot z^i$ denote the residual polynomial of $r_{n,k} \equiv z^n \mod \prod_{j=1}^k(z-z_j)$. Then each coefficient in $r_{n,k}$ is bounded: $|r_{n,k}^{(i)}| \le \binom{k-1}{i}\cdot\binom{n}{k-1}$ for $n \ge k$ and $|r_{n,k}^{(i)}| \le \binom{k-1}{i}\cdot\binom{|n|+k-1}{k-1}$ for $n < 0$.*

We finish the proof of Theorem 17 here.

Proof. Let C_0 be a large constant and $d = 5 \cdot k^2 \log k$. We use $\mathcal{P}$ to denote the following subset of polynomials with bounded coefficients:

$$\left\{ \sum_{j=0}^{d} \alpha_j \cdot 2^{-j/k} \cdot z^j \middle| \alpha_0, \ldots, \alpha_d \in [-C_0, C_0] \cap \mathbb{Z} \right\}.$$

For each polynomial $P(z) \in \mathcal{P}$, we rewrite $P(z) \mod \prod_{j=1}^{k}(z - z_j)$ as

$$\sum_{j=0}^{d} \alpha_j \cdot 2^{-j/k} \cdot \left(z^j \mod \prod_{j=1}^{k}(z - z_j) \right) = \sum_{i=0}^{k-1} \left(\sum_{j=0}^{d} \alpha_j \cdot 2^{-j/k} \cdot r_{n,k}^{(i)} \right) z^i.$$

The coefficient $\sum_{j=0}^{d} \alpha_j \cdot 2^{-j/k} \cdot r_{n,k}^{(i)}$ is bounded by

$$\sum_{j=0}^{d} C_0 \cdot 2^{-j/k} \cdot 2^k j^{k-1} \leq d \cdot C_0 \cdot 2^k \cdot d^k \leq d^{2k}.$$

Then we apply the pigeonhole principle on the $(2C_0 + 1)^d$ polynomials in $\mathcal{P}$ after module $\prod_{j=1}^{d}(z - z_j)$: there exist $m > (2C_0 + 1)^{0.9d}$ polynomials $P_1, \ldots, P_m$ such that each coefficient of $(P_i - P_j) \mod \prod_{j=1}^{k}(z - z_j)$ is d^{-2k} small from the counting

$$\frac{(2C_0 + 1)^d}{(d^{2k}/4d^{-2k})^k} > (2C_0 + 1)^{0.9d}.$$

Because $m > (2C_0 + 1)^{0.9d}$, there exists $j_1 \in [m]$ and $j_2 \in [m] \setminus \{j_1\}$ such that the lowest monomial z^l with different coefficients in P_{j_1} and P_{j_2} satisfies $l \leq 0.1d$. Eventually we set

$$P(z) = z^{-l} \cdot \big(P_{j_1}(z) - P_{j_2}(z)\big) - \left(z^{-l} \mod \prod_{j=1}^{k}(z - z_j) \right) \cdot \left(P_{j_1}(z) - P_{j_2}(z) \mod \prod_{j=1}^{k}(z - z_j) \right)$$

to satisfy the first property $P(z_1) = P(z_2) = \cdots = P(z_k) = 0$. We prove the second property in the rest of this proof.

We bound every coefficient in $\big(z^{-l} \mod \prod_{j=1}^{k}(z - z_j)\big) \cdot \big(P_{j_1}(z) - P_{j_2}(z) \mod \prod_{j=1}^{k}(z - z_j)\big)$ by

$$k \cdot \text{max-coefficient}\left(z^{-l} \mod \prod_{j=1}^{k}(z - z_j) \right) \cdot \text{max-coefficient}\left(P_{j_1}(z) - P_{j_2}(z) \mod \prod_{j=1}^{k}(z - z_j) \right),$$

which is less than $k \cdot 2^k (l + k)^{k-1} \cdot d^{-2k} \leq d \cdot 2^k d^{k-1} \cdot d^{-2k} \leq d^{-0.5k}$ from Lemma 19 and the above discussion.

On the other hand, the constant coefficient in $z^{-l} \cdot \big(P_{j_1}(z) - P_{j_2}(z)\big)$ is at least $2^{-l/k} \geq 2^{-0.1d/k} = k^{-0.5k}$ because z^l is the smallest monomial with different coefficients in P_{j_1} and P_{j_2} from $\mathcal{P}$. Thus the constant coefficient $|C(0)|^2$ of $P(z)$ is at least $0.5 \cdot 2^{-2l/k}$.

Next we upper bound the sum of the rest of the coefficients $\sum_{j=1}^{d} |C(j)|^2$ by

$$\sum_{j=1}^{d} (2C_0 \cdot 2^{-(l+j)/k} + d^{-0.5k})^2 \leq 2 \cdot 4C_0^2 \sum_{j=1}^{d} 2^{-2(l+j)/k} + 2 \cdot \sum_{j=1}^{d} d^{-0.5k \cdot 2} \lesssim k \cdot 2^{-2l/k},$$

which demonstrates the second property after normalizing $C(0)$ to 1. ◀

Abstract

Document exchange and error correcting codes are two fundamental problems regarding communications. In the first problem, Alice and Bob each holds a string, and the goal is for Alice to send a short sketch to Bob, so that Bob can recover Alice's string. In the second problem, Alice sends a message with some redundant information to Bob through a channel that can add adversarial errors, and the goal is for Bob to correctly recover the message despite the errors. In both problems, an upper bound is placed on the number of errors between the two strings or that the channel can add, and a major goal is to minimize the size of the sketch or the redundant information. In this paper we focus on deterministic document exchange protocols and binary error correcting codes.

Both problems have been studied extensively. In the case of Hamming errors (i.e., bit substitutions) and bit erasures, we have explicit constructions with asymptotically optimal parameters. However, other error types are still rather poorly understood. In a recent work [7], the authors constructed explicit deterministic document exchange protocols and binary error correcting codes for edit errors with almost optimal parameters. Unfortunately, the constructions in [7] do not work for other common errors such as block transpositions.

In this paper, we generalize the constructions in [7] to handle a much larger class of errors. These include bursts of insertions and deletions, as well as block transpositions. Specifically, we consider document exchange and error correcting codes where the total number of block insertions, block deletions, and block transpositions is at most $k \leq \alpha n/\log n$ for some constant $0 < \alpha < 1$. In addition, the total number of bits inserted and deleted by the first two kinds of operations is at most $t \leq \beta n$ for some constant $0 < \beta < 1$, where n is the length of Alice's string or message. We construct explicit, deterministic document exchange protocols with sketch size $O((k\log n + t)\log^2 \frac{n}{k\log n + t})$ and explicit binary error correcting code with $O(k \log n \log\log\log n + t)$ redundant bits. As a comparison, the information-theoretic optimum for both problems is $\Theta(k\log n + t)$. As far as we know, previously there are no known explicit deterministic document exchange protocols in this case, and the best known binary code needs $\Omega(n)$ redundant bits even to correct just *one* block transposition [23].[1]

2012 ACM Subject Classification Mathematics of computing → Coding theory

[1] We note that by combining the techniques in [14] and [15], one can get an explicit binary code that corrects k block transpositions with $\widetilde{O}(\sqrt{kn})$ redundant bits. However to our knowledge this result has not appeared anywhere in the literature, and moreover it requires at least $\widetilde{\Omega}(\sqrt{n})$ redundant bits even to correct one block transposition.

1 Introduction

In communications and more generally distributed computing environments, there often arise questions regarding the synchronization of files or messages. For example, a message sent from one party to another party through a channel may get modified by channel noise or adversarial errors, and files stored on distributed servers may become out of sync due to different edit operations by different users. In many situations, these questions can be formalized in the framework of the following two fundamental problems.

- *Document exchange.* In this problem, two parties Alice and Bob each holds a string x and y, and the two strings are within distance k in some metric space. The goal is for Alice to send a short sketch to Bob, so that Bob can recover x based on his string y and the sketch.
- *Error correcting codes.* In this problem, two parties Alice and Bob are linked by a channel, which can change any string sent into another string within distance k in some metric space. Alice's goal is to send a message to Bob. She does this by sending an encoding of the message through the channel, which contains some redundant information, so that Bob can recover the correct message despite any changes to the codeword.

These two problems are closely related. For example, in many cases a solution to the document exchange problem can also be used to construct an error correcting code, but the reverse direction is not necessarily true. In both problems, a major goal is to is to minimize the size of the sketch or the redundant information. For applications in computer science, we also require the computations of both parties to be efficient, i.e., in polynomial time of the input length. In this case we say that the solutions to these problems are *explicit*. Here we focus on deterministic document exchange protocols and error correcting codes with a binary alphabet, arguably the most important setting in computer science.

Both problems have been studied extensively, but the known solutions and our knowledge vary significantly depending on the distance metric in these problems. In the case of Hamming distance (or Hamming errors), we have a near complete understanding and explicit constructions with asymptotically optimal parameters. However, for other distance metrics/error types, our understanding is still rather limited.

An important generalization of Hamming errors is edit errors, which consist of bit insertions and deletions. These are strictly more general than Hamming errors since a bit substitution can be replaced by a deletion followed by an insertion. Edit errors can happen in many practical situations, such as reading magnetic and optical media, mutations in gene sequences, and routing packets in Internet protocols. However, these errors are considerably harder to handle, due to the fact that a single edit error can change the positions of all the bits in a string.

Non-explicitly, by using a greedy graph coloring algorithm or a sphere packing argument, one can show that the optimal size of the sketch in document exchange, or the redundant information in error correcting codes is roughly the same for both Hamming errors and edit errors. Specifically, suppose that Alice's string or message has length n and the distance bound k is relatively small (e.g., $k \leq n/4$), then for both Hamming errors and edit errors, the optimal size in both problems is $\Theta(k \log(\frac{n}{k}))$ [19]. For Hamming errors, this can be achieved by using sophisticated linear Algebraic Geometric codes [16], but for edit errors the situation is quite different. We now describe some of the previous works regarding both document exchange and error correcting codes for edit errors.

Document exchange

Orlitsky [21] first studied the document exchange problem for generally correlated strings x, y. Using the greedy graph coloring algorithm mentioned before, he obtained a deterministic protocol with sketch size $O(k \log n)$ for edit errors, but the running time is exponential in k. Subsequent improvements appeared in [9], [17], and [18], achieving sketch size $O(k \log(\frac{n}{k}) \log n)$ [17] and $O(k \log^2 n \log^* n)$ [18] with running time $\tilde{O}(n)$. A recent work by Chakraborty et al. [5] further obtained sketch size $O(k^2 \log n)$ and running time $\tilde{O}(n)$, by using a clever randomized embedding from the edit distance metric to the Hamming distance metric. Based on this work, Belazzougui and Zhang [2] gave an improved protocol with sketch size $O(k(\log^2 k + \log n))$, which is asymptotically optimal for $k = 2^{O(\sqrt{\log n})}$. The running time in [2] is $\tilde{O}(n + \mathsf{poly}(k))$.

Unfortunately, all of the above protocols, except the one in [21] which runs in exponential time, are randomized. Although randomized protocols are still useful in practice, having deterministic ones would certainly bring much more benefits. Furthermore, randomized protocols are also not suitable for the applications in constructing error correcting codes. However, designing an efficient deterministic protocol appears quite tricky, and it was not until 2015 when Belazzougui [1] gave the first deterministic protocol even for $k > 1$. The protocol in [1] has sketch size $O(k^2 + k \log^2 n)$ and running time $\tilde{O}(n)$.

Error correcting codes

As fundamental objects in both theory and practice, error correcting codes have been studied extensively from the pioneering work of Shannon and Hamming. While great success has been achieved in constructing codes for Hamming errors, the progress on codes for edit errors has been quite slow despite much research. A work by Levenshtein [19] in 1966 showed that the Varshamov-Tenengolts code [22] corrects one deletion with an optimal redundancy of roughly $\log n$ bits, but even correcting two deletions requires $\Omega(n)$ redundant bits. In 1999, Schulman and Zuckerman [23] gave an explicit asymptotically good code, that can correct up to $\Omega(n)$ edit errors with $O(n)$ redundant bits. However the same amount of redundancy is needed even for smaller number of errors. For more earlier works on this subject, we refer the reader to the survey by Mercier et al. [20].

In recent years there have been several works trying to improve the situation. Specifically, a line of work by Guruswami et. al [11], [10], [4] constructed explicit codes that can correct $1 - \varepsilon$ fraction of edit errors with rate $\Omega(\varepsilon^5)$ and alphabet size $\mathsf{poly}(1/\varepsilon)$; and codes that can correct $1 - \frac{2}{t+1} - \varepsilon$ fraction of errors with rate $(\varepsilon/t)^{\mathsf{poly}(1/\varepsilon)}$ for a fixed alphabet size $t \geq 2$. Another line of work by Haeupler et al. [13], [14], [6] introduced and constructed a combinatorial object called *synchronization string*, which can be used to transform standard error correcting codes into codes for edit errors by increasing the alphabet size. Via this

transformation, [13] achieved explicit codes that can correct δ fraction of edit errors with rate $1-\delta-\varepsilon$ and alphabet size exponential in $\frac{1}{\varepsilon}$, which approaches the singleton bound. All of these works however require a relatively large alphabet size.

In the case of binary alphabets, for any fixed constant k, a recent work by Brakensiek et. al [3] constructed an explicit code that can correct k edit errors with $O(k^2 \log k \log n)$ redundant bits. This is asymptotically optimal when k is a fixed constant, but the construction in [3] only works for constant k, and breaks down for larger k (e.g., $k = \log n$). Based on his deterministic document exchange protocol, Belazzougui [1] also gave an explicit code that can correct up to k edit errors with $O(k^2 + k \log^2 n)$ redundant bits. Finally, the work by Haeupler et. al [15] constructed explicit codes that can correct δ fraction of edit errors with rate $1 - \Theta(\sqrt{\delta \log(1/\delta)})$, whereas the (non-explicit) optimal rate is $1 - \Theta(\delta \log(1/\delta))$.

In a very recent work by the authors [7], we significantly improved the situation. Specifically, we constructed an explicit document exchange protocol with sketch size $O(k \log^2 \frac{n}{k})$, which is optimal except for an additional $\log \frac{n}{k}$ factor. This also implies an explicit binary code that can correct δ fraction of edit errors with rate $1 - \Theta(\delta \log^2(1/\delta))$, which is optimal up to an additional $\log(1/\delta)$ factor. These two results are also independently obtained by Haeupler [12]. We also constructed explicit codes for k edit errors with $O(k \log n)$ redundant bits, which is optimal for $k \leq n^{1-\alpha}$, any constant $0 < \alpha < 1$. These results bring our understanding of document exchange and error correcting codes for edit errors much closer to that of standard Hamming errors.

However, the constructions in [7] and [12] do not work for other common types of errors, such as *block transpositions*. Given any string x, a block transposition takes an arbitrary substring z of x, cuts it to make x become $\tilde{x}$, and then finds a different position in $\tilde{x}$ and insert z as a block into $\tilde{x}$. These errors happen frequently in distributed file systems and Internet protocols. For example, it is quite common that a user, when editing a file, moves a whole paragraph in the file to somewhere else; and in Internet routing protocols, packets can often get rearranged during the process. Block transpositions also arise naturally in biological processes, where a subsequence of genes can be moved in one step during mutation. In the setting of document exchange or error correcting codes, it is easy to see that even a single transposition of a block with length t can result in $2t$ edit errors, thus a naive application of document exchange protocols or codes for edit errors will result in very bad parameters.

Model of the adversary: block insertions, deletions, and transpositions

We consider edit errors that happen in *bursts*. This kind of errors is also pretty common, as most errors that happen in practice, such as in wireless or mobile communications and magnetic disk readings, tend to be concentrated. We model such errors as *block* insertions and deletions, where in one operation the adversary can insert or delete a whole block of bits. It is again easy to see that this is indeed a generalization of standard edit errors.

For some parameters k and t and an alphabet Σ, a (k, t) block edit adversary is allowed to perform three kinds of operations: block insertion, block deletion and block transposition. The adversary is allowed to perform at most k such operations, while the total number of symbols inserted/deleted by the first two operations is at most t. We also use (k, t) block edit errors to denote errors introduced by such an adversary. All our results focus on the case of binary alphabet, but in our protocols and analysis we will be using larger alphabets.

We note that by the result of Schulman and Zuckerman [23], to correct $\Omega(n/\log n)$ block transpositions one needs at least $\Omega(n)$ redundant bits. Thus we only consider $k \leq \alpha n/\log n$ for some constant $0 < \alpha < 1$. Similarly, we only consider $t \leq \beta n$ for some constant $0 < \beta < 1$ since otherwise the adversary can simply delete the whole string. We also note the following

subtle difference between the three block edit operations. While we need a bound t on the total number of bits that the adversary can insert or delete, for block transposition an adversary can choose to move an *arbitrarily long* substring. Therefore, we need to consider the three operations separately, and cannot simply replace a block transposition by a block deletion followed by a block insertion.

Edit errors with block transpositions have been studied before in several different contexts. For example, Shapira and Storer [24] showed that finding the distance between two given strings under this metric is NP-hard, and they gave an efficient algorithm that achieves $O(\log n)$ approximation. Interestingly, a work by Cormode and Muthukrishnan [8] showed that this metric can be embedded into the L_1 metric with distortion $O(\log n \log^* n)$; and they used it to give a near linear time algorithm that achieves $O(\log n \log^* n)$ approximation for this distance, something currently unknown for the standard edit distance. Coming back to document exchange and error correcting codes, in our model, we show in the appendix that non-explicitly, the information optimum for both the sketch size of document exchange, and the redundancy of error correcting codes, is $\Theta(k \log n + t)$.

Related previous work on block transpositions

When it comes to more general errors such as block transpositions, as far as we know, there are no known explicit deterministic document exchange protocols. The only known randomized protocols which can handle edit errors as well as block transpositions are the protocol of [17], which has sketch size $O(k \log(\frac{n}{k}) \log n)$; and the protocol of [18], which has sketch size $\tilde{O}(k \log^2 n)$. The protocol of [17] uses a recursive tree structure and random hash functions, while the protocol of [18] is based on the embedding of Cormode and Muthukrishnan [8]. We stress that both of these protocols are randomized, and there are very good reasons why it is not easy to modify them into deterministic ones. Specifically, unlike in our previous work [7] and the work of Haeupler [12], a direct derandomization of the hash functions used in [17] (for example by using almost k-wise independent sample space) does *not* give a deterministic protocol, because block transpositions will make the computation of a matching problematic. We shall discuss this in more details when we give an overview of our techniques. On the other hand, the embedding of Cormode and Muthukrishnan [8] results in an exponentially large dimension, thus directly sending a sketch deterministically will result in a prohibitively large size. This is why the protocol of [18] has to perform a dimension reduction first, which is necessarily randomized.

Similarly, the only previous explicit codes that can handle edit errors as well as block transpositions are the work of Schulman and Zuckerman [23], and the work of Haeupler et al. [14]. Both can recover from $\Omega(n/\log n)$ block transpositions with $\Omega(n)$ redundant bits ([14] can also recover from block replications), but [23] has a binary alphabet while [14] has a constant size alphabet. However the work of Schulman and Zuckerman [23] also needs $\Omega(n)$ redundant bits even to correct one block transposition. We further note that by combining the techniques in [14] and [15], one can get an explicit binary code that corrects k block transpositions with $\widetilde{O}(\sqrt{kn})$ redundant bits. However to our knowledge this result has not appeared anywhere in the literature, and moreover it requires at least $\widetilde{\Omega}(\sqrt{n})$ redundant bits even to correct one block transposition. We note that however none of the previous works mentioned studied edit errors that can allow block insertions/deletions.

1.1 Our results

In this paper we construct explicit deterministic document exchange protocols, and error correcting codes for adversaries discussed above. We have the following theorems.

▶ **Theorem 1.** *There exist constants $\alpha, \beta \in (0,1)$ such that for every $n, k, t \in \mathbb{N}$ with $k \leq \alpha n/\log n, t \leq \beta n$, there exists an explicit binary document exchange protocol with sketch size $O((k\log n + t)\log^2 \frac{n}{k\log n+t})$, against a (k,t) block edit adversary.*

This is the first explicit, deterministic document exchange protocol for block edit errors. The sketch size matches the randomized protocols of [17] and [18] up to an additional $\log \frac{n}{k\log n+t}$ factor, and is optimal up to an additional $\log^2 \frac{n}{k\log n+t}$ factor. Using this protocol, we can construct the following error correcting code.

▶ **Theorem 2.** *There exist constants $\alpha, \beta \in (0,1)$ such that for every $n, k, t \in \mathbb{N}$ with $k \leq \alpha n/\log n, t \leq \beta n$, there exists an explicit binary error correcting code with message length n and codeword length $n + O((k\log n + t)\log^2 \frac{n}{k\log n+t})$, against a (k,t) block edit adversary.*

For small k, t we can actually achieve the following result, which gives better parameters.

▶ **Theorem 3.** *There exist constants $\alpha, \beta \in (0,1)$ such that for every $n, k, t \in \mathbb{N}$ with $k \leq \alpha n/\log n, t \leq \beta n$, there exists an explicit binary code with message length n and codeword length $n + O(k\log n \log\log\log n + t)$, against a (k,t) block edit adversary.*

In the case of small k, t, these results significantly improve the result of Schulman and Zuckerman [23], which needs $\Omega(n)$ redundant bits even to correct one block transposition, and the result obtained by combining the techniques in [14] and [15], which needs $\widetilde{\Omega}(\sqrt{n})$ redundant bits even to correct one block transposition. The redundancy here is also optimal up to an extra $\log\log\log n$ factor or $\log^2 \frac{n}{k\log n+t}$ factor.

As a special case, we obtain the following corollaries for standard edit errors with block transpositions.

▶ **Corollary 4.** *There exist a constant $\alpha \in (0,1)$ such that for every $n, k \in \mathbb{N}$ with $k \leq \alpha n/\log n$, there exists an explicit binary document exchange protocol with sketch size $O(k\log n \log^2 \frac{n}{k\log n})$, against an adversary who can perform k edit operations or block transpositions.*

▶ **Corollary 5.** *There exist a constant $\alpha \in (0,1)$ such that for every $n, k \in \mathbb{N}$ with $k \leq \alpha n/\log n$, there exists an explicit binary error correcting code with message length n and codeword length $\min\{n + O(k\log n \log^2 \frac{n}{k\log n}), n + O(k\log n \log\log\log n)\}$, against an adversary who can perform k edit operations or block transpositions.*

▶ Remark 6. As illustrated by our theorems and corollaries, the sketch size in our document exchange protocol or the number of redundant bits in our error correcting codes do *not* depend on the size of a block in block transpositions, they only depend on the number of such operations performed. In contrast, the sketch size or the number of redundant bits do depend on the size of a block in block insertions or deletions. This again shows that we cannot simply treat a block transposition as a block deletion followed by a block insertion, because that will lead to a sketch size dependent on the block size.

2 Document Exchange

This section describes the construction of our document exchange protocol and its proof in sketch. Details are deferred to the appendix.

▶ **Definition 7** (Collision free hash functions). *Given $n, p, q \in \mathbb{N}, p \leq n$ and a string $x \in \{0,1\}^n$, we say a hash function $h : \{0,1\}^p \to \{0,1\}^q$ is collision free (for x), if for every $i, j \in [n-p+1]$, $h(x[i, i+p)) = h(x[j, j+p))$ if and only if $x[i, i+p) = x[j, j+p)$.*

▶ **Theorem 8.** *There exists an algorithm which, on input $n, p, q \in \mathbb{N}, p \leq n, q = c_0 \log n$ for large enough constant c_0, $x \in \{0,1\}^n$, outputs a description of a hash function $h : \{0,1\}^p \to \{0,1\}^q$ that is collision free for x, in time $\mathsf{poly}(n)$, where the description length is $O(\log n)$.*

Also there is an algorithm which, given the description of h and any $u \in \{0,1\}^p$, can output $h(u)$ in time $\mathsf{poly}(n)$.

Proof Sketch. The construction uses almost κ-wise independence generator to get the hash functions, assuring no pair of blocks of x collides. The number of pairs is $O(n^2)$. The seed length is $O(\log n)$. So we can do an exhaustive search to find such sequence of collision free hash functions. For details, see the full version. ◀

▶ **Definition 9** (Matching). *Given $n, n', p, q \in \mathbb{N}, p \leq n, p \leq n'$, a function $h : \{0,1\}^p \to \{0,1\}^q$ and two strings $x \in \{0,1\}^n, y \in \{0,1\}^{n'}$, a matching (may not be monotone) between x and y under h is a sequence of matches (pairs of indices) $w = ((i_1, j_1), \ldots (i_{|w|}, j_{|w|}))$ s.t.*

- *for every $k \in [|w|]$,*
  - *$i_k = 1 + pl_k \in [n]$ for some l_k,*
  - *$j_k \in [n']$,*
  - *$h(x[i_k, i_k + p)) = h(y[j_k, j_k + p))$,*
- *$i_1, \ldots, i_{|w|}$ are distinct.*

A non-overlapping matching is a matching with one more restriction.

- *Intervals $[j_k, j_k + p), k \in [|w|]$, are disjoint.*

When considering overlaps, the matching has overlapping degree d, if each bit of y appears in at most d matched pairs for some small number d.

For a match (i, j), it matches two intervals, one from x, the other from y. When we say the y's interval (of the match (i, j)), we mean $[j, j + p)$, and similarly the x's interval is $[i, i + p)$. A match (i, j) in a matching is called a wrong match (or wrong pair) if $x[i, i+p) \neq y[j, j+p)$. Otherwise it is called a correct match (or correct pair). A pair of indices (i, j) is called a potential match between x and y if $h(x[i, i + p)) = h(y[j, j + p))$. It may be wrong because $x[i, i + p)$ may not be $y[j, j + p)$. When x, y are clear from the context we simply say (i, j) is a potential match.

To compute a monotone non-overlapping matching we can use the dynamic programming method in [7]. But our matching is not necessarily monotone. So this raises the question of how hard this problem is.

It seems difficult to find a polynomial algorithm which can exactly compute it. So instead we use constant approximation techniques. There're two difficulties at the first thought. One is that if we compute the non-overlapping matching over the entire strings, then a constant approximation is too bad since there will be $O(n)$ unmatched blocks. So for each level, we restrict our attention to blocks that are uncovered and wrongly recovered (but discovered by us). The other problem is that we need the approximation rate to be a large enough constant. To achieve this goal, we actually computing matchings with constant degree.

We start from a 1/3-approximation algorithm, which is greedy.

▶ **Construction 10.** *Given $n, n', p, q \in \mathbb{N}, p \leq n, p \leq n'$, a polynomial time computable function $h : \{0,1\}^p \to \{0,1\}^q$ and two strings $x \in \{0,1\}^n, y \in \{0,1\}^{n'}$, we have the following 1/3-approximation algorithm for computing the non-overlapping matching.*

1. *Let the sequence of matches w be empty;*
2. *Find $i = 1 + pl \in [n]$ and $j \in [n']$, where $l \in \mathbb{N}$, s.t.*
   - *$h(x[i, i+p)) = h([j, j+p))$,*
   - *i is not in any match (as the first entry) of the current w,*
   - *$[j, j+p)$ does not overlap with any $[j', j'+p)$ for any j' as the second entry in any matches of the current w;*
3. *If there is such a pair of indices i, j, then add the match (i, j) to w and go to step 2; Otherwise, output w and stop.*

▶ **Lemma 11.** *Construction 10 gives a 1/3-approximation algorithm for computing the non-overlapping matching.*

Proof deferred to the full version.

Next we give an explicit algorithm which computes a even larger matching (better approximation), but it allows overlaps.

▶ **Construction 12.** *Given $n, n', p, q \in \mathbb{N}, p \leq n, p \leq n'$, a (polynomial time computable) function $h : \{0,1\}^p \to \{0,1\}^q$ and two strings $x \in \{0,1\}^n, y \in \{0,1\}^{n'}$, we have the following algorithm.*

1. *Let the matching w be empty, set $S = \{i = 1 + pl \mid l \in \mathbb{N}, i \in [n]\}$, integer $c = 0$;*
2. *Conduct Construction 10 to compute a matching w' between x_S and y under h. Here x_S is the projection of x on intervals in set S;*
3. *Let $w = w \cup w'$;*
4. *Let $S = S \setminus \{u \mid \exists (u, v) \in w\}$;*
5. *$c = c + 1$;*
6. *If $c \geq 3$, output w; Otherwise go to step 2.*

Note that Construction 12 is in polynomial time since it simply conducts Construction 10 for 3 times and after each conduction it removes matched blocks of x and only considers the remaining blocks in the next iteration. So we only need to show its correctness.

▶ **Lemma 13.** *Construction 12 computes a degree 3 overlapping matching w between x and y under h, such that $|w| \geq 2/3|w^*|$, where w^* is the maximum non-overlapping matching between x and y under h.*

Proof. Let $w_i, i = 1, 2, 3$ be the matching the algorithm computes after round i. Also let $S_i, i = 1, 2, 3$ be the set S after the ith round.

By Lemma 11, $|w_1| \geq 1/3|w^*|$. The number of unmatched blocks is $\bar{n} - |w_1| \leq \bar{n} - 1/3|w^*|$, where $\bar{n} = \lfloor n/p \rfloor$ is the total number of blocks of x.

The maximum matching between x_{S_1} and y is at least $|w^*| - |w_1|$. This is because that, each of the matched blocks of x by w_1, should be among the x's blocks in the matches of w^*. There are at most $|w_1|$ of them. So there are still $|w^*| - |w_1|$ remaining matches in w^* which corresponds to blocks in x_{S_1}.

Again by Lemma 11, for $i \geq 2$, at least $1/3(|w^*| - |w_{i-1}|)$ blocks of $x_{S_{i-1}}$ will be matched in the ith round.

Thus

$$\begin{aligned}
|w_i| &\geq |w_{i-1}| + 1/3(|w^*| - |w_{i-1}|) && (1)\\
&= 1/3|w^*| + 2/3|w_{i-1}| && (2)\\
&\geq (1-(2/3)^{i-1})|w^*| + (2/3)^{i-1}|w_1| && (3)\\
&\geq (1-(2/3)^{i-1})|w^*| + (1/3)(2/3)^{i-1}|w^*| && (4)\\
&= (1-(2/3)^{i})|w^*|. && (5)
\end{aligned}$$

Inequality 1 is due to Lemma 11 as explained above. Equality 2 is due to a direct computation. 3 is by recursively applying 1 and 2 from $i-1$ to 2. 4 is because $|w_1| \geq 1/3|w^*|$.

As a result, $|w_3| \geq 19/27|w^*| \geq 2/3|w^*|$.

Note that we apply Construction 10 for 3 times, where in each time, it gives a non-overlapping matching. So each entry of y is in at most one of the matches in that round. So finally we get a degree 3 overlapping matching. ◀

We now give the following document exchange protocol.

▶ **Construction 14.** *The protocol works for every input length $n \in \mathbb{N}$, every (k_1, t) block-insertions/deletions k_2 block-transpositions, $k_1, k_2 \leq \alpha n/\log n, t \leq \beta n$, for some constant α, β. (If k_1 or $k_2 > \alpha n/\log n$, or $t > \beta n$, we simply let Alice send her input string.) Let $k = k_1 + k_2$.*

Both Alice's and Bob's algorithms have $L = O(\log \frac{n}{k\log n + t})$ levels.

For every $i \in [L]$, in the i-th level,

- *Let the block size be $b_i = \frac{n}{18\cdot 2^i(k+\frac{t}{\log n})}$, i.e., in each level, divide every block of x in the previous level evenly into two blocks. We choose L properly s.t. $b_L = O(\log n)$;*
- *The number of blocks $l_i = n/b_i$;*

Alice: On input $x \in \{0,1\}^n$,

▶ **Lemma 15.** *For every* i*, the maximum non-overlapping matching between* x_S *and* y *under* h_i *has size at least* $|S| - (2k_1 + 3k_2 + t/\log n)$*.*

▶ **Lemma 16.** *For every* i*,* $|w_i| \geq 2/3(|S| - (2k_1 + 3k_2 + t/\log n))$*.*

▶ **Lemma 17.** *For every* i*, if* $v[1], \ldots, v[i]$ *are correctly recovered, then in the* i*-th level the number of wrongly recovered blocks of* x *is at most* $3i(2k_1 + 3k_2 + \frac{t}{\log n})$*.*

Proof. Consider the matching w^* corresponding to the current recovering of x after i levels, i.e., this matching is generated at level 1 and adjusted level by level. In level j, we first use hash values to test every block to see if it is correctly recovered. For wrongly recovered blocks we delete their corresponding matches. Then for remaining wrongly recovered blocks and unrecovered blocks, we compute a matching w_j for them, and add all matches in w_j to w^*.

For $w_j, j \leq i$, after level i, the number of wrongly recovered blocks in level i caused by (the remaining part of) w_j is at most $3(2k_1 + 3k_2 + \frac{t}{\log n})$.

This is because in w_j is constructed by Construction 12, which is a union of 3 matchings. Each matching of them is non-overlapping. We only need to show that w_j, after eliminating detected wrong pairs in these i levels, contains at most $2k_1 + 3k_2 + \frac{t}{\log n}$ wrong matches between x's and y's blocks in the i-th level. To see this, first note that these matches' y intervals are only from blocks which are modified from x's blocks or newly inserted. For each block-insertion of t_j bits, it can contribute at most $\lceil t_j/b_i \rceil + 1$ wrong matches. Each block-deletion can contribute at most 2 wrong matches. So totally block insertions/deletions can cause $\sum_{j=1}^{k_1}(\lceil t_j/b_i \rceil + 1) \leq 2k_1 + t/b_i$ wrong matches. On the other hand, k_2 block-transpositions can contribute at most $3k_2$ wrong matches, because 1 block-transposition can only cause 1 wrong match when deleting the block and inserting the block to its destination may contribute 2 wrong matches. Hence the total number wrong matches is at most $2k_1 + 3k_2 + t/b_i$.

Since there are i matchings $w_1, \ldots, w_i$, each containing 3 non-overlapping matchings, the number of wrongly recovered blocks remaining in w^* is at most $3i(2k_1 + 3k_2 + \frac{t}{\log n})$. ◀

▶ **Lemma 18.** *For every* i*, if* $v[1], \ldots, v[i]$ *are correctly recovered, then in level* i*, the number of unrecovered blocks is at most* $36i(k + \frac{t}{\log n})$*.*

Proof is in the full version.

▶ **Lemma 19.** *Bob can recover* x *correctly.*

Proof. We use induction to show that for every $i \in [L]$, $v[i]$ can be computed correctly by Bob.

For the first level, $v[1]$ is directly received from Alice.

Assume $v[1], \ldots, v[i-1]$ can be computed correctly. By Lemma 18, the number of unrecovered blocks after level $i-1$ is at most $36(i-1)(k + t/\log n)$. By Lemma 17, the number of wrongly recovered blocks is at most $9(i-1)(k + t/\log n)$. So the total number of wrongly recovered and unrecovered blocks is at most

$$2 \times (36(i-1)(k + t/\log n) + 9(i-1)(k + t/\log n)) \leq 90(i-1)(k + t/\log n) < 90i(k + t/\log n).$$

Note that with the redundancy $z[i]$, its corresponding code has distance at least $180(k+t/b_i)i$. So Bob can recover $v[i]$ correctly by the property of the algebraic geometry code.

As a result, at level L. By Lemma 17, the number of wrongly recovered blocks is at most $3L(2k_1 + 3k_2 + \frac{t}{b_L})$. By Lemma 18 the number of unrecovered blocks, is at most $36L(k + t/\log n)$. So the total number of wrongly recovered and unrecovered blocks is at most $45L(k + t/\log n)$. Note that the code distance corresponding to the redundancy z_{final} is at least $90(k + t/b_L)L$. So all blocks of x can be recovered correctly by using the decoding of the algebraic geometry code. ◀

Communication Complexity and running time computation are in the full version.

To this end, we showed Theorem 1.

3 Error Correcting Codes

We now briefly describe how to construct an error correcting code from a document exchange protocol for block edit errors. Similar to the construction in [7], our starting point is to first encode the sketch of the document exchange protocol using the code by Schulman and Zuckerman [23], which can resist edit errors and block transpositions. Then we concatenate the message with the encoding of the sketch. When decoding, we first decode the sketch, then apply the document exchange protocol on Bob's side to recover the message.

However, here we have an additional issue with this approach: a block transposition may move some parts of the encoding of the sketch to somewhere in the middle of the message, or vice versa. In this case, we won't be able to tell which part of the received string is the encoding of the sketch, and which part is the original message.

To solve this issue, we use a fixed string $\mathsf{buf} = 0^{\ell_{\mathsf{buf}}} \circ 1$ as a buffer to mark the encoding of the sketch, for some $\ell_{\mathsf{buf}} = O(\log n)$. More specifically, we evenly divide the encoding of the sketch into small blocks of length ℓ_{buf}, and insert buf before every block. Note that this only increases the length of the encoding of the sketch by a constant factor. The reason we use such a small block length is that, even if the adversary can forge or destroy some buffers, the total number of bits inserted or deleted caused by this is still small. In fact, we can bound this by $O(k)$ block insertions/deletions with at most $O(k \log n)$ bits inserted/deleted, for which both the sketch and the encoding of the sketch can handle. When decoding, we first recognize all the buf's. Then we take the ℓ_{buf} bits after each buf to form the decoding of the sketch, and take the remaining bits as the message.

Unfortunately, this approach introduces two additional problems here. The first problem is that the original message may contain buf as a substring. If this happens then in the decoding procedure again we will be taking part of the message to be in the encoding of the sketch. The second problem is that the small blocks of the encoding of the sketch may also contain buf. In this case we will be deleting information from the encoding of the sketch, which causes too many edit errors.

To address the first problem, we turn the original message into a *pseudorandom* string by computing the XOR of the message with the output of an appropriate pseudorandom generator that has seed length $O(\log n)$. We show that with high probability buf does not appear as a substring in the XOR. We can then exhaustively search for a seed that satisfies this requirement, and append the seed to the sketch of the document exchange protocol.

To address the second problem, we choose the length of the buffer to be longer than the length of each block in the encoding of the sketch, so that buf doesn't appear as a substring in any block. This is exactly why we choose the length of the buffer to be $\ell_{\mathsf{buf}} + 1$ while we choose the length of each block to be ℓ_{buf}.

If we directly apply our document exchange protocol to the construction above, we obtain an error correcting code with $O((k \log n + t) \log^2 \frac{n}{k \log n + t})$ redundant bits. Next we discuss how to achieve better redundancy for small k and t.

We first briefly describe the construction of the explicit binary code for k edit errors with redundancy $O(k \log n)$ in [7]. The construction in [7] starts by transforming the message into a string with the *B-distinct* property: any two substrings of length some $B = O(\log n)$ are distinct. This is obtained by computing the XOR of the message with the output of an appropriately designed pseudorandom generator. The construction then designs a document exchange protocol for such a string, and encodes the sketch of the document exchange protocol to give an error correcting code.

The document exchange protocol for a B-distinct string in [7] actually consists of two stages: in stage I, Alice uses a fixed pattern p to divide her string into blocks of size $\mathsf{poly}(\log n)$. Next, Alice sends a sketch of size $O(k \log n)$ to help Bob recover the partition of her string. To achieve this, Bob also divides his string into blocks in the same way that Alice does. Alice creates a vector V where each entry of V is indexed by a binary string of length B. Specifically, Alice looks at each block in her partition, and stores the B-prefix (the prefix of length B) of its next block and the length of the current block in the entry of V indexed by the B-prefix of the current block. This ensures each entry of the vector V has only $O(\log n)$ bits. Bob creates a vector V' in the same way. [7] shows that V and V' differ in at most $O(k)$ entries, thus Alice can send a sketch of size $O(k \log n)$ using the Reed-Solomon Code to help Bob recover V from V'. Once this is done, Bob can use V to obtain a guess of Alice's string.

Stage II consists of several levels. In each level, both parties divide each of their blocks evenly into $O(\log^{0.4} n)$ smaller blocks, and Alice generates a sequence of special hash functions called *ϵ-synchronization hash functions*. The nice properties of these hash functions guarantee that in each level Alice can send $O(k \log n)$ bits to Bob, so that Bob can recover all but $O(k)$ blocks of Alice's string. This stage ends in $O(\log_{\log^{0.4} n}(\mathsf{poly}(\log n))) = O(1)$ levels, where in the last level Alice can simply send a sketch of size $O(k \log n)$ for Bob to recover her string x.

Checking these two stages, it turns out that stage I can be modified to work for block edit errors as well. Intuitively, this is because it is still true that such errors won't cause too many different blocks between V and V'. On the other hand, stage II becomes problematic, since the use of ϵ-synchronization hash functions crucially relies on the monotone property of standard edit errors. Allowing block transpositions ruins this property, and it is not clear how to give suitable ϵ-synchronization hash functions to work in this case.

To solve the issue, in stage II, we can apply the deterministic document exchange protocol we developed earlier. This implies an error correcting code of redundancy $O(k \log n \log\log n + t)$. However, we show that we can further reduce the redundancy to $O(k \log n \log\log\log n + t)$ by using the string parsing idea in [8] to improve the partition in Stage I.

Given an input string, string parsing builds a tree where each leaf corresponds to a symbol of the input string, and each non-leaf node corresponds to a substring of the input string. Each node of the tree is associated with a label, which is the hash value of its corresponding substring under some hash function. The structure of the tree only depends locally on the input string, e.g., an edit error on the input string only affects $O(\log n \log^* n)$ nodes.

More specifically, string parsing builds the tree bottom-up from one level to another. The labels in the bottom level are obtained by directly applying the hash function to the symbols. Then, the algorithm builds one level of the tree as follows. The labels of the nodes in the previous level form a string of alphabet size $\mathsf{poly}(n)$. The algorithm first finds all repetitive substrings in this string (we say a substring is repetitive, if it's of the form a^l, for some $l \geq 2$). The remaining substrings satisfy the property that any two adjacent symbols are different, and we say such substrings are *non-repetitive*. [8] then applies an alphabet reduction algorithm to the non-repetitive substrings, and obtains a new non-repetitive string

for each substring over the alphabet $\{0,1,2\}$. The alphabet reduction works in $\log^* n$ steps, where in each step the alphabet size is reduced from the current size a to $\log a$. Thus in $\log^* n$ steps the alphabet size becomes a constant. Now for all the new strings obtained, the algorithm finds local maximums and local minimums that are not adjacent to any local maximum as *landmarks*, and partition the strings into small blocks of length 2 or 3 by using the landmarks. Finally, for each block, the algorithm builds a new node in this level, whose children are the nodes in the block and whose label is the hash value of the subtree.

Here, in our construction of error correcting codes, we use the idea of string parsing in stage I to partition Alice's string x into small blocks. Our goal is to partition the string into blocks of length roughly $\Theta(\log n \cdot \mathsf{poly}(\log\log n))$, while an edit error on the string can only affect a small number of contiguous blocks. In this way, stage II only takes $O(\log\log\log n)$ levels and the sketch size in stage II is $O(k\log n\log\log\log n + t)$. Note that each node in the parsing tree depends only locally on the input string. We use this property to bound the number of errors among the small blocks obtained in stage I.

To achieve our goal, instead of building a full parsing tree, we only build a partial parsing tree. That is, in each level of the parsing tree, we check the number of leaves under each node. If a node has more than T leaves for some threshold T, we mark the node as "finish". We also mark a node as "frozen", if all its adjacent nodes are marked as "finish". For each "finish" node, we build a new node in the next level, with the only child being this "finish" node. We then use these "finish" nodes to divide the string into several substrings, and apply alphabet reduction to the substrings, choose the landmarks, and partition each substring into small blocks according to the landmarks. Then for each small block, we build a new node in the next level, and set the children of the new node to be all nodes in the same block. We keep doing this until each node is either marked as "finish" or "frozen". Finally, we merge each "frozen" node to the "finish" node on its left or right. At the end of this process, we obtain several trees, and we partition the string x into small blocks, where each block consists of all the leaves in a tree. To remove the $O(\log^* n)$ factor, we only do two levels of alphabet reduction in each level of the tree. However, this will result in an alphabet size of $O(\log\log n)$, which means the tree may have $O(\log\log n)$ children. Hence, the block size may be as large as $O(T\log\log n)$. Note that each block depends on $O(\log T)$ blocks on its left and right, since in each level of the partial parsing tree, each node depends locally on a constant number of adjacent nodes. We prove that, if y is obtained from x by (k,t) block edit errors, then the partition of y can be obtained from the partition of x by $(k, O(t/T + k\log T))$ block edit errors over a larger alphabet. If we set $T = \log n$, then in stage I Alice still needs to send a sketch of $O(k\log n\log\log n + t)$ bits. To further reduce the redundancy, we apply the partial parsing tree method again with another threshold $T' = \Theta(\log\log n)$. Now the errors are reduced to $(k, O(\frac{t}{TT'} + k\log T'))$ block edit errors over a larger alphabet, and the block size increases by a $O(T'\log\log n\log\log\log n)$ factor, and becomes $O(\log n(\log\log n)^2)$.

We show that now in stage I, Alice can send a sketch with $O(\frac{t}{TT'} + k\log T')\cdot O(\log n) = O(k\log n\log\log\log n + t)$ bits; and in stage II, Alice can send a sketch with $O(k\log n\log\log\log n + t)$ bits. So the total sketch size is still $O(k\log n\log\log\log n + t)$. By using the encoding of Schulman and Zuckerman [23] and the buffer buf, the final redundancy of the error correcting code is also $O(k\log n\log\log\log n + t)$.

Abstract

Asadpour, Feige, and Saberi proved that the integrality gap of the configuration LP for the restricted max-min allocation problem is at most 4. However, their proof does not give a polynomial-time approximation algorithm. A lot of efforts have been devoted to designing an efficient algorithm whose approximation ratio can match this upper bound for the integrality gap. In ICALP 2018, we present a $(6+\delta)$-approximation algorithm where δ can be any positive constant, and there is still a gap of roughly 2. In this paper, we narrow the gap significantly by proposing a $(4+\delta)$-approximation algorithm where δ can be any positive constant. The approximation ratio is with respect to the optimal value of the configuration LP, and the running time is $poly(m,n) \cdot n^{poly(\frac{1}{\delta})}$ where n is the number of players and m is the number of resources. We also improve the upper bound for the integrality gap of the configuration LP to $3+\frac{21}{26} \approx 3.808$.

1 Introduction

Background

In the max-min fair allocation problem, we are given a set P of n players, a set R of m indivisible resources, and a set of non-negative values $\{v_{pr}\}_{p\in P, r\in R}$. For each $r \in R$ and each $p \in P$, resource r is worth a value of v_{pr} to player p. An allocation is a partition of R into disjoint subsets $\{D_p\}_{p\in P}$ so that each player p is assigned the resources in D_p. The goal is to find an allocation that maximizes the welfare of the least lucky player, that is, we want to maximize $\min_{p\in P} \sum_{r\in D_p} v_{pr}$. Unfortunately, unless P = NP, no polynomial-time algorithm can achieve an approximation ratio smaller than 2 [6].

Bezáková and Dani [6] tried to solve the problem using the assignment LP – a technique for the classic scheduling problem of makespan minimization [16]. However, they showed that the integrality gap of the assignment LP is unbounded, so rounding the assignment LP gives no guarantee on the approximation ratio. Later, Bansal and Sviridenko [4] proposed a stronger LP relaxation, the configuration LP, for the max-min allocation problem. Asadpour and Saberi [3] developed a polynomial-time rounding scheme for the configuration LP that gives an approximation ratio of $O(\sqrt{n}\log^3 n)$. Saha and Srinivasan [18] improved it to $O(\sqrt{n\log n})$. These approximation ratios almost match the lower bound of $\Omega(\sqrt{n})$ for the integrality gap of the configuration LP proved by Bansal and Svirodenko [4]. Bateni et al. [5]

and Chakrabarty et al. [7] established a trade-off between the approximation ratio and the running time. For any $\delta > 0$, they can achieve an approximation ratio of $O(n^{\delta})$ with $O(n^{1/\delta})$ running time.

In this paper, we study the restricted max-min allocation problem. In the restricted case, we have $v_{pr} \in \{v_r, 0\}$. That is, each resource r has an intrinsic value v_r, and it is worth value v_r to those players who desire it and value 0 to those who do not. Assuming P $\neq$ NP, the restricted case has a lower bound of 2 for the approximation ratio. The integrality gap of configuration LP for the restricted case also has a lower bound of 2. Bansal and Sviridenko [4] proposed an $O\big(\frac{\log\log n}{\log\log\log n}\big)$-approximation algorithm by rounding the configuration LP. Feige [11] proved that the integrality gap of the configuration LP is bounded by a constant, albeit large and unspecified. His proof was later made constructive by Haeupler et al. [12], and hence a constant approximation can be found in polynomial time. Asadpour et al. [2] viewed the restricted max-min allocation problem as a bipartite hyper-graph matching problem. Let T^* be the optimal value of the configuration LP. By adapting Haxell's [13] alternating tree technique for bipartite hyper-graph matchings, they proposed a local search algorithm that returns an allocation where every player receives at least $T^*/4$ worth of resources, and hence proved that the integrality gap of the configuration LP is at most 4. However, their algorithm is not known to run in polynomial time. A lot of efforts have been devoted to making their algorithm run in polynomial time. Polacek and Svensson [17] showed that the local search can be done in quasi-polynomial time by building the alternating tree in a more careful way. Annamalai, Kalaitzis and Svensson [1] carried out the local search in a more structured way. Together with two new *greedy* and *lazy update* strategies, they can find in polynomial time an allocation in which every player receives a value of at least $T^*/(6 + 2\sqrt{10} + \delta)$. Recently, we proposed a more flexible, aggressive greedy strategy that improves the approximation ratio to $6 + \delta$ [9]. Davies et al. [10] claimed a $(6 + \delta)$-approximation algorithm for the restricted max-min allocation problem by reducing it to the fractional matroid max-min allocation problem.

Our Contribution

We adapt the framework in [1] by introducing two new strategies: *layer-level node-disjoint paths* and *limited blocking*. The performance of our framework is determined by three parameters, and a trade-off between the running time and the quality of solution can be achieved by tuning these parameters. On one extreme, our framework acts exactly the same as the original local search in [2], which achieves a ratio of 4 but not necessarily run in polynomial time. On the other extreme, it becomes something like the algorithm in [1], which achieves a polynomial running time but a much worse ratio. We show that, in order to achieve a polynomial running time, one doesn't have to go from one extreme to the other – a marginal movement is sufficient. As a result, a ratio slightly worse than 4 can be achieved in polynomial time.

▶ **Theorem 1.** *For any constant $\delta > 0$, there is a $(4 + \delta)$-approximation algorithm for the restricted max-min allocation problem that runs in poly$(m, n) \cdot n^{poly(\frac{1}{\delta})}$ time.*

Although the algorithm we present takes the optimal value of the configuration LP as its input, one can avoid solving the configuration LP by combining our algorithm with binary search to zoom into the optimal value of configuration LP. The binary search technique is similar to that in [1, 9].

We also show that the integrality gap of the configuration LP is at most $3 + \frac{21}{26} \approx 3.808$ by giving a better analysis of the AFS algorithm. This improves the bound of $3 + \frac{5}{6} \approx 3.833$ recently obtained in [8, 15].

Primal

$$\sum_{C \in \mathcal{C}_p(T)} x_{p,C} \geqslant 1 \forall p \in P$$

$$\sum_{p \in P} \sum_{C \in \mathcal{C}_p(T): r \in C} x_{p,C} \leqslant 1 \forall r \in R$$

$$x_{p,C} \geqslant 0$$

Dual

$$\max \quad \sum_{p \in P} y_p - \sum_{r \in R} z_r$$

$$s.t. \quad y_p \leqslant \sum_{r \in C} z_r \qquad \forall p \in P, \forall C \in \mathcal{C}_p(T)$$

$$y_p \geqslant 0 \qquad \forall p \in P$$

$$z_r \geqslant 0 \qquad \forall r \in R$$

Figure 1 The configuration LP and its dual.

▶ **Theorem 2.** *The integrality gap of the configuration LP for the restricted max-min allocation problem is at most* $3 + \frac{21}{26} \approx 3.808$.

We focus on only the proof of Theorem 1 in the main text. The proof of Theorem 2 can be found in the full version of the paper. Other omitted proofs can also be found in the full version of the paper.

2 Preliminaries

2.1 The Configuration LP

Suppose that we hope to find an allocation where every player receives at least T worth of resources. A *configuration* for a player p is a subset D of the resources desired by p such that $\sum_{r \in D} v_r \geqslant T$. Let $\mathcal{C}_p(T)$ denote the set of all configurations for p.

The configuration LP is given on the left of Figure 1. Given a target T, the configuration LP, denoted as $CLP(T)$, associates a variable $x_{p,C}$ with each player p and each configuration C in $\mathcal{C}_p(T)$. Its first constraint ensures that each player receives at least 1 unit of configurations, and the second constraint guarantees that every resource r is used in at most 1 unit of configurations. The optimal value of the configuration LP is the largest T for which $CLP(T)$ is feasible. We denote this optimal value by T^*. Without loss of generality, we assume that $T^* = 1$ for the rest of the paper. Although the configuration LP may have an exponential number of variables, it can be solved within any constant relative error in polynomial time [4]. Viewing the objective function of the configuration LP as a minimization of a constant, one can get the dual LP on the right of the Figure 1.

2.2 Fat and thin edges

Our goal is to find an allocation in which every player receives at least λ worth of resources for some $\lambda \in (0, 1)$. In particular, our approximation algorithm sets $\lambda = \frac{1}{4+\delta}$ where δ is a positive constant. For each resource $r \in R$, we call r *fat* if $v_r \geqslant \lambda$, and *thin* otherwise. To find the target allocation, it suffices to assign each player p either a fat resource desired by p or a subset D of the thin resources desired by p with $\sum_{r \in D} v_r \geqslant \lambda$.

For every $p \in P$ and every fat resource r desired by p, we call $\{p, r\}$ a *fat edge*. For every $p \in P$ and every subset D of the thin resources desired by p, we call (p, D) a *thin edge* if $\sum_{r \in D} v_r \geqslant \lambda$. Two edges are *compatible* if they share no common resource. We say that a fat edge $\{p, r\}$ *covers* p and r. Similarly, a thin edge (p, D) *covers* p and the resources in D. A player or a resource is covered by a set of edges if it is covered by some edge in the set. For any $w \geqslant 0$, a thin edge (p, D) is a *w-minimal* if $\sum_{r \in D} v_r \geqslant w$ and $\sum_{r \in D'} v_r < w$ for any $D' \subsetneq D$. For a w-minimal thin edge (p, D), it is not hard to see that $w \leqslant \sum_{r \in D} v_r < w + \lambda$.

Given the above definitions of fat and thin edges, finding the target allocation is equivalent to finding a set of mutually compatible edges that covers all the players.

2.3 A local search idea

The following local search idea is initially proposed by Asadpour et al. [2], and is also used in [1, 9].

Let G be the bipartite graph formed by the players, the fat resources, and the fat edges. We maintain a set M of fat edges and a set $\mathcal{E}$ of thin edges such that: (i) M is a maximum matching of G, (ii) edges in $\mathcal{E}$ are λ-*minimal* and are mutually compatible, and (iii) each player is covered by at most one edge in $M \cup \mathcal{E}$. We call such M and $\mathcal{E}$ a partial allocation. Initially, M is an arbitrary maximum matching of G, and $\mathcal{E}$ is empty. The set $M \cup \mathcal{E}$ is updated and grown iteratively so that one more player is covered in each iteration. The final set $M \cup \mathcal{E}$ covers all the players and induces our target allocation.

Let p_0 be a player not yet covered by $M \cup \mathcal{E}$. We need to update $M \cup \mathcal{E}$ to cover p_0 without losing any player that are already covered. The simplest case is that we can find a player q_0 such that q_0 is covered by a thin edge a compatible with $\mathcal{E}$ and there is an alternating path [14] with respect to M from p_0 to q_0. Let π be this alternating path. We first update M by taking the symmetric difference $M \oplus \pi$, i.e., remove the edges in $\pi \cap M$ from the matching and add the edges in $\pi \setminus M$ to the matching. $M \oplus \pi$ is also a maximum matching of G. After the update, p_0 becomes matched while q_0 becomes unmatched. Then we add a to $\mathcal{E}$ to cover q_0 again. Here we slight abuse the notion of alternating paths in the sense that wen allow an alternating path with no edge. The $\oplus$ can easily extend to alternating paths with no edge.

It is possible that no edge covering q_0 is compatible with $\mathcal{E}$. Let a be an edge covering q_0. Suppose that b is an edge in $\mathcal{E}$ that is not compatible with a. We say b *blocks* a. Let p_1 be the player covered by b. In order to add a to $\mathcal{E}$, we have to release b from $\mathcal{E}$. But we cannot lose p_1, so before we release b, we need to find another edge to cover p_1. Now p_1 has a similar role as p_0.

2.4 Node-disjoint alternating paths

In order to achieve a polynomial running time, our algorithm updates M using multiple node-disjoint alternating paths from unmatched players to players . In this section, we define a problem of finding a largest set of node-disjoint paths. We also extend the $\oplus$ operation to a set of node-disjoint paths.

For any maximum matching M of G, we define G_M to be the directed graph obtained from G by orienting edges of G from r to p if $\{p, r\} \in M$, and from p to r if $\{p, r\} \notin M$. Let S be a subset of the players not matched by M. Let T be a subset of the players. Finding the largest set of node-disjoint alternating paths from S to T is equivalent to finding the largest set of node-disjoint paths in G_M from S to T. Let $G_M(S, T)$ denote the problem of finding the largest set of node-disjoint paths from S to T in G_M. Let $f_M(S, T)$ denotes the maximum number of such paths. Note that when $S \cap T \neq \emptyset$, a path consisting of a single node is allowed. Such path is called a trivial path. Paths with at least one edge is non-trivial. Let Π be a feasible solution for $G_M(S, T)$. The paths in Π originate from a subset of S, which we call the *sources* and denote as src_Π, and terminate in a subset of T, which we call the *sinks* and denote as $sink_\Pi$. We extend the $\oplus$ operation to Π. Viewing Π as a set of edges, $M \oplus \Pi$ stands for removing the edges in $\Pi \cap M$ from the matching and adding the edges in $\Pi \setminus M$ to the matching. One can see that $M \oplus \Pi$ is a maximum matching of G.

The problem $G_M(S, T)$ can be solved in polynomial time. Please refer to the full version of the paper for more details.

3 An Approximation Algorithm

We discuss below a few techniques used by our algorithm. Some of them are used in [1, 9, 10]. The *limited blocking* strategy is brand new, and is crucial to achieving an approximation ratio of $4 + \delta$. In the following discussion, one can interpret addable edges as thin edges that we hope to add to $\mathcal{E}$, and blocking edges as edges in $\mathcal{E}$ that are not compatible with addable edges. The precise definition will be given later.

Layers. As in [1, 9], we maintain a stack of layers, where each layer consists of addable edges and their blocking edges. The key to achieving a polynomial running time is to guarantee a geometric growth in the number of blocking edges from the bottom to the top of the stack.

Layer-level node-disjoint paths. We require that the players covered by the addable edges in a layer can be simultaneously reached via node-disjoint paths in G_M from the players covered by the blocking edges in the previous layers [10]. It has the same effect as the globally node-disjoint path used in [1]: if lots of addable edges in a layer become unblocked, then a significant update can be made. The advantage of our strategy is that it offers more flexibility when building a new layer.

Lazy update. When having an unblocked addable edge, one may be tempted to update M and $\mathcal{E}$ immediately. However, as in [1], in order to achieve a polynomial running time, we should wait until there are lots of unblocked addable edges, and then a significant update can be made in one step. The laziness is controlled by a small constant μ that will be defined later.

Greedy and Limited Blocking. Recall that the key to achieving a polynomial running time is to guarantee a geometric growth in the number of blocking edges from the bottom to the top of the stack. In [2], every addable edge is λ-minimal, and each blocking edge blocks exactly one addable edge. If using this strategy, in worst case, one may get a layer consisting of one addable edge that is blocked by many blocking edges. After some of these blocking edges are released from $\mathcal{E}$, we may be left with a layer of a single addable edge that is blocked by a single blocking edge, which breaks the geometric growth in the number of blocking edges. To resolve this issue, Annamalai et al. [1] allow a blocking edge to block as many addable edges as possible. However, it brings a new trouble: one may get a layer consisting of many addable edges that are blocked by one blocking edge. As a consequence, they have to introduce another strategy *Greedy*. They require every addable edge to be $\frac{1}{2}$-minimal. If such an addable edge is blocked, at least $\frac{1}{2} - \lambda$ worth of its resources must be occupied by blocking edges. Provided that a blocking edge is λ-minimal and covers at most 2λ worth of resources, the greedy strategy ensures that, in a layer, the number of blocking edges cannot be too small comparing with the number of addable edges. Analysis shows that although the greedy strategy makes the algorithm faster, it deteriorates the approximation ratio. Our strategy is a generalization of those used in [2] and [1]. We allow a blocking edge to block more than one addable edge, but once it shares strictly more than $\beta\lambda$ worth of resources with the addable edges blocked by it, we stop it from blocking more edges. We use greedy too. In our algorithm, addable edges are $(1 + \gamma)\lambda$-minimal for some constant γ.

If we set β, γ, μ to be 0, then our algorithm acts exactly the same as the local search in [2], which achieves a ratio of 4 but may not run in polynomial time. If β, γ are set to be some large constant, then our algorithm acts like the algorithm in [1] which achieves a polynomial running time but a much worse ratio. We show that carefully selected tiny β and tiny γ guarantee a polynomial running time but barely hurt the approximation ratio.

3.1 The algorithm

Let $M \cup \mathcal{E}$ be the current partial allocation. Let p_0 be a player that is not yet covered by $M \cup \mathcal{E}$. The algorithm alternates between two phases to update and extend $M \cup \mathcal{E}$ so that the partial allocation covers p_0 eventually without losing any covered player. In the building phase, it pushes new layers onto a stack, where each layer stores some addable edges and their blocking edges. In the collapse phase, it uses unblocked addable edges to release some blocking edges in some layer from $\mathcal{E}$.

Since we frequently talk about resources covered by thin edges and take sum of values over a set of resources, we define the following notations. Given a thin edge e, R_e denotes the set of resources covered by e. Given a set $\mathcal{S}$ of thin edges, $R(\mathcal{S})$ denotes the set of thin resources covered by $\mathcal{S}$. Given a set D of resources, define $v[D] = \sum_{r \in D} v_r$.

3.1.1 Building phase

The algorithm maintains a stack of layers. The layer index starts with 1 from the bottommost layer in the stack. The i-th layer L_i is a tuple $(\mathcal{A}_i, \mathcal{B}_i, d_i, z_i)$, where $\mathcal{A}_i$ is a set of addable edges that we want to add to $\mathcal{E}$, $\mathcal{B}_i$ is a set of blocking edges that prevent us from doing so, and d_i and z_i are two values maintained for the sake of analysis. The algorithm also maintains a set $\mathcal{I}$ of addable edges that are compatible with $\mathcal{E}$. We will define addable edges and blocking edges later. We use ℓ to denote the number of layers in the current stack. The state of the algorithm is specified by $(M, \mathcal{E}, \mathcal{I}, (L_1, \ldots, L_\ell))$.

For each $\mathcal{A}_i$, we use A_i to denote the set of players covered by $\mathcal{A}_i$. Similarly, B_i and I denote the set of players covered by $\mathcal{B}_i$ and $\mathcal{I}$, respectively. For $i \in [1, \ell]$, define $\mathcal{B}_{\leqslant i} = \bigcup_{j=1}^{i} \mathcal{B}_j$, $B_{\leqslant i} = \bigcup_{j=1}^{i} B_j$, and $\mathcal{A}_{\leqslant i} = \bigcup_{j=1}^{i} \mathcal{A}_j$. We do not define $A_{\leqslant i}$ because although two addable edges in different layers do not share any resource, they may cover the same player. This is a consequence of the layer-level node-disjoint paths technique.

For simplicity, we define the first layer L_1 to be $(\emptyset, \{(p_0, \emptyset)\}, 0, 0)$. That is, $\mathcal{A}_1 = \emptyset$, $\mathcal{B}_1 = \{(p_0, \emptyset)\}$, and $d_1 = z_1 = 0$.

The layers are built inductively. Initially, there is only the layer L_1 and $\mathcal{I} = \emptyset$. Let ℓ be the number of layers in the current stack. Consider the construction of the $(\ell + 1)$-th layer.

▶ **Definition 3.** *Let $\beta \geqslant 0$ be a constant to be specified later. A thin resource r is **inactive** if* (i) *$r \in R(\mathcal{A}_{\leqslant \ell} \cup \mathcal{B}_{\leqslant \ell})$, or* (ii) *$r \in R(\mathcal{A}_{\ell+1} \cup \mathcal{I})$, or* (iii) *$r \in R_b$ for some $b \in \mathcal{B}_{\ell+1}$ and $v[R_b \cap R(\mathcal{A}_{\ell+1})] > \beta\lambda$. If a thin resource is not inactive, then it is **active**.*

We will define addable edges so that they use only active thin resources.

▶ **Definition 4.** *A player p is **addable** if $f_M(B_{\leqslant \ell}, A_{\ell+1} \cup I \cup \{p\}) = f_M(B_{\leqslant \ell}, A_{\ell+1} \cup I) + 1$.*

The activeness of thin resources and the addability of the players depend on $\mathcal{A}_{\ell+1}$ and $\mathcal{I}$ ($A_{\ell+1}$ and I), so they may be affected as we add edges to $\mathcal{A}_{\ell+1}$ and $\mathcal{I}$.

▶ **Definition 5.** *A thin edge (p, D) is **addable** if p is addable and D is a set of **active** thin resources desired by p with $v[D] \geqslant \lambda$. The **blocking edges** of an addable edge (p, D) are $\{e \in \mathcal{E} : R_e \cap D \neq \emptyset\}$. An addable edge (p, D) is **unblocked** if $v[D \setminus R(\mathcal{E})] \geqslant \lambda$.*

Recall that, for any $w > 0$, a thin edge (p, D) is a *w-minimal* if $v[D] \geqslant w$ and $v[D'] < w$ for any $D' \subsetneq D$. Our algorithm considers two kinds of addable edges. The first kind is unblocked addable edges that are λ-minimal. It is easy to see that if an unblocked addable edge is λ-minimal, then it must be compatible with $\mathcal{E}$. We use $\mathcal{I}$ to keep such addable edges. The second kind is blocked addable edges that are $(1 + \gamma)\lambda$-minimal, where γ is a constant

Table 1 Some facts about $\mathcal{I}$ and the layers in the stack.

Fact 1	Edges in $\mathcal{A}_{\leqslant \ell} \cup \mathcal{I}$ are mutually compatible.
Fact 2	Edges in $\mathcal{I}$ are compatible with edges in $\mathcal{E}$.
Fact 3	For any $i \in [1, \ell]$, no two edges in $\mathcal{A}_i \cup \mathcal{I}$ cover the same player.
Fact 4	$\{\mathcal{B}_2, \ldots, \mathcal{B}_\ell\}$ are disjoint subsets of $\mathcal{E}$. Note that $\mathcal{B}_1 = \{(p_0, \emptyset)\}$ does not share any resource with $\mathcal{B}_i$ for $i \in [2, \ell]$.

to be specified later. Such edges will be added to $\mathcal{A}_{\ell+1}$. Once a $(1+\gamma)\lambda$-minimal addable edge (p, D) becomes unblocked, we can easily extract a λ-minimal unblocked addable edge (p, D') with $D' \subseteq D$.

Consider condition (iii) in Definition 3. Let b be a blocking edge in $\mathcal{B}_{\ell+1}$. When R_b and $R(\mathcal{A}_{\ell+1})$ share strictly more than $\beta\lambda$ worth of resources, all resources in R_b become inactive. Any addable edge to be added to $\mathcal{A}_{\ell+1}$ in the future cannot use these inactive resources, and hence, will not be blocked by b. This is how we achieve "limited blocking" mentioned before.

We call BUILD below to construct the $(\ell+1)$-th layer. Note that after adding an addable edge to $\mathcal{A}_{\ell+1}$, we immediately add its blocking edges to $\mathcal{B}_{\ell+1}$ in order to keep the inactive/active status of thin resources up-to-date.

BUILD$(M, \mathcal{E}, \mathcal{I}, (L_1, \cdots, L_\ell))$

1. Initialize $\mathcal{A}_{\ell+1} = \emptyset$ and $\mathcal{B}_{\ell+1} = \emptyset$.
2. While there is an unblocked addable edge that is λ-minimal, add it to $\mathcal{I}$.
3. While there is an addable edge (p, D) that is $(1+\gamma)\lambda$-minimal
   - 3.1 add (p, D) to $\mathcal{A}_{\ell+1}$. (Note that (p, D) must be blocked; otherwise, we could extract from it a λ-minimal unblocked addable edge, which should be added to $\mathcal{I}$ in step 2.)
   - 3.2 add to $\mathcal{B}_{\ell+1}$ the edges in $\mathcal{E}$ that block (p, D).
4. Set $d_{\ell+1} := f_M(B_{\leqslant \ell}, A_{\ell+1} \cup I)$, $z_{\ell+1} := |A_{\ell+1}|$, and $L_{\ell+1} := (\mathcal{A}_{\ell+1}, \mathcal{B}_{\ell+1}, d_{\ell+1}, z_{\ell+1})$.
5. Update $\ell := \ell + 1$

Table 1 lists a few facts about the layers.

3.1.2 Collapse phase

When some layer becomes collapsible, the algorithm enters the collapse phase. Let $(M, \mathcal{E}, \mathcal{I}, (L_1, \cdots, L_\ell))$ be the current state of the algorithm. In order to determine whether a layer is collapsible or not, we need to compute the following decomposition of $\mathcal{I}$. Let $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ be some disjoint subsets of $\mathcal{I}$. Let I_i denote the set of players covered by $\mathcal{I}_i$. For $i \in [1, \ell-1]$, we use $\mathcal{I}_{\leqslant i}$ and $I_{\leqslant i}$ to denote $\bigcup_{j=1}^{i} \mathcal{I}_j$ and $\bigcup_{j=1}^{i} I_j$, respectively.

▶ **Definition 6.** *A collection of disjoint subsets $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ of $\mathcal{I}$ is a **canonical decomposition** of $\mathcal{I}$ if for all $i \in [1, \ell-1]$, $f_M(B_{\leqslant i}, I_{\leqslant i}) = f_M(B_{\leqslant i}, I) = |I_{\leqslant i}|$. A solution Γ for $G_M(B_{\leqslant \ell-1}, I)$ is a **canonical solution** with respect to the canonical decomposition $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ if Γ can be partitioned into disjoint subsets $(\Gamma_1, \ldots, \Gamma_{\ell-1})$ such that for every $i \in [1, \ell-1]$, Γ_i is a set of $|I_i|$ paths from B_i to I_i in G_M.*

Although it is not clear from the definition, invariant 1 in Table 2 implies that $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ is indeed a partition of $\mathcal{I}$. The following lemma is analogous to its counterpart in [1, 9]. Its proof is omitted.

▶ **Lemma 7.** *Let ℓ be the number of layers in the stack. A canonical decomposition of $\mathcal{I}$ and a corresponding canonical solution for $G_M(B_{\leqslant \ell-1}, I)$ can be computed in poly(ℓ, m, n) time.*

All the edges in $\mathcal{I}_i$ are compatible with $\mathcal{E}$, and all the players in I_i can be reached from B_i by node-disjoint paths Γ_i in G_M, so every edge in $\mathcal{I}_i$ can be used to release one blocking edge in $\mathcal{B}_i$ from $\mathcal{E}$. A layer is collapsible if a certain fraction of its blocking edges can be released.

▶ **Definition 8.** *Let μ be a constant to be specified later. A layer L_i is **collapsible** if there is a canonical decomposition $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ of $\mathcal{I}$ such that $|I_i| > \mu |B_i|$.*

Note that although there can be more than one canonical decomposition, the collapsibility of a layer is independent of the choice of canonical decompositions, because by definition, we always have $|I_i| = f_M(B_{\leqslant i}, I) - f_M(B_{\leqslant i-1}, I)$.

When some layer is collapsible, we enter the collapse phase, call Collapse to shrink collapsible layers until no layer is collapsible, and then return to the build phase.

Collapse$(M, \mathcal{E}, \mathcal{I}, (L_1, \cdots, L_\ell))$

1. Compute a canonical decomposition $(\mathcal{I}_1, \ldots, \mathcal{I}_{\ell-1})$ and a corresponding canonical solution $\Gamma_1 \cup \cdots \cup \Gamma_{\ell-1}$ for $G_M(B_{\leqslant \ell-1}, I)$. If no layer is collapsible, go to the build phase; otherwise, let L_t be the collapsible layer with the smallest index.
2. Remove all the layers above L_t from the stack. Set $\mathcal{I} := \mathcal{I}_{\leqslant t-1}$.
3. Recall that $src_{\Gamma_t} \subseteq B_t$ by Definition 6. Let $\mathcal{B}^\Gamma$ denote the set of edges in $\mathcal{B}_t$ that are incident to players in src_{Γ_t}. We use $\mathcal{I}_t$ and Γ_t to release the edges in $\mathcal{B}^\Gamma$.
   - 3.1 Update M by flipping the paths in Γ_t, i.e., set $M := M \oplus \Gamma_t$.
   - 3.2 Add to $\mathcal{E}$ the edges in $\mathcal{I}_t$, i.e., set $\mathcal{E} := \mathcal{E} \cup \mathcal{I}_t$.
   - 3.3 Each player in src_{Γ_t} is now covered by either a fat resource or a thin edge from $\mathcal{I}_t$. If $t = 1$, then p_0 is already covered, and the algorithm terminates. Assume that $t \geqslant 2$. Edges in $\mathcal{B}^\Gamma$ can be safely released from $\mathcal{E}$. Set $\mathcal{E} := \mathcal{E} \setminus \mathcal{B}^\Gamma$ and $\mathcal{B}_t := \mathcal{B}_t \setminus \mathcal{B}^\Gamma$.
4. If $t \geqslant 2$, we need to update $\mathcal{A}_t$ because some edges in $\mathcal{A}_t$ may become unblocked due to the release of blocking edges. For every edge (p, D) in $\mathcal{A}_t$ that becomes unblocked,
   - 4.1 Remove (p, D) from $\mathcal{A}_t$,
   - 4.2 if $f_M(B_{\leqslant t-1}, I \cup \{p\}) = f_M(B_{\leqslant t-1}, I) + 1$, then extract a λ-minimal unblocked addable edge (p, D') from (p, D), and add (p, D') to $\mathcal{I}$.
5. Update $\ell := t$. Go to step 1.

4 Analysis of the approximation algorithm

4.1 Some invariants

Table 2 lists a few invariants, where ℓ is the number of layers in the stack. Lemmas 9 and 10 below have analogous versions in [1, 9] and can be proved similarly. We omit their proofs.

▶ **Lemma 9.** Build *and* Collapse *maintain the invariants in Table 2.*

▶ **Lemma 10.** *Let $(L_1, \ldots, L_\ell)$ be the stack of layers. If no layer is collapsible, then* (i) *$|I| \leqslant \mu |B_{\leqslant \ell-1}|$, and* (ii) *for all $i \in [1, \ell]$, $|A_i| \geqslant z_i - \mu |B_{\leqslant i-1}|$.*

Table 2 Invariants maintained by the algorithm.

Invariant 1	$f_M(B_{\leqslant \ell-1}, I) = \lvert I\rvert$.
Invariant 2	For all $i \in [1, \ell-1]$, $f_M(B_{\leqslant i}, A_{i+1} \cup I) \geqslant d_{i+1}$.
Invariant 3	For all $i \in [1, \ell]$, $\lvert A_i\rvert \leqslant z_i$.
Invariant 4	For all $i \in [1, \ell]$, $d_i \geqslant z_i$.

4.2 Bounding the number of blocking edges

Lemma 11 – 13 are consequences of our greedy and limited blocking strategies. Basically, they bound the number of blocking edges in a layer in terms of the number of addable edges.

▶ **Lemma 11.** *Let $L_i = (\mathcal{A}_i, \mathcal{B}_i, d_i, z_i)$ be an arbitrary layer in the stack. For each edge $b \in \mathcal{B}_i$, there is an edge $a \in \mathcal{A}_i$ such that $v[R_b \cap R(\mathcal{A}_i \setminus \{a\})] \leqslant \beta\lambda$.*

Proof. Let b be an edge in $\mathcal{B}_i$. Sort the edges in $\mathcal{A}_i$ in chronological order of their additions into $\mathcal{A}_i$. Let a be the last edge in $\mathcal{A}_i$ that is blocked by b. By our choice of a, the edges in $\mathcal{A}_i$ that are added after a cannot be blocked by b, so they do not share any common resource with b. Among the edges added before a, let S be the subset of their resources that are also covered by b. We claim that $v[S] \leqslant \beta\lambda$. If not, all resources in R_b would be inactive before the addition of a by definition of inactive resources. So no resource in R_b could be included in a. But $R_a \cap R_b$ must be non-empty as b blocks a, a contradiction. ◀

▶ **Lemma 12.** *Let $L_i = (\mathcal{A}_i, \mathcal{B}_i, d_i, z_i)$ be an arbitrary layer in the stack. We have $\lvert A_i\rvert < (1 + \frac{\beta}{\gamma})\lvert B_i\rvert$.*

Proof. By Lemma 11, for each $b \in \mathcal{B}_i$, we can identify an edge $a_b \in \mathcal{A}_i$ so that $v[R_b \cap R(\mathcal{A}_i \setminus \{a_b\})] \leqslant \beta\lambda$. Let $\mathcal{A}_i^0 = \{a_b : b \in \mathcal{B}_i\}$ be the set of edges identified. $\lvert\mathcal{A}_i^0\rvert \leqslant \lvert B_i\rvert$.

Let $\mathcal{A}_i^1 = \mathcal{A}_i \setminus \mathcal{A}_i^0$. For every $b \in \mathcal{B}_i$, $v[R_b \cap R(\mathcal{A}_i^1)] \leqslant v[R_b \cap R(\mathcal{A}_i \setminus \{a_b\})] \leqslant \beta\lambda$. Taking sum over all edges in $\mathcal{B}_i$, we get $v[R(\mathcal{B}_i) \cap R(\mathcal{A}_i^1)] \leqslant \beta\lambda\lvert B_i\rvert$. On the other hand, each edge a in $\mathcal{A}_i^1$ is $(1+\gamma)\lambda$-minimal and is blocked, so it must have more than $\gamma\lambda$ worth of its resources occupied by edges in $\mathcal{B}_i$, i.e., $v[R(\mathcal{B}_i) \cap R_a] > \gamma\lambda$. Taking sum over all the edges in $\mathcal{A}_i^1$ gives $v[R(\mathcal{B}_i) \cap R(\mathcal{A}_i^1)] > \gamma\lambda\lvert\mathcal{A}_i^1\rvert$. Hence, $\beta\lambda\lvert B_i\rvert \geqslant v[R(\mathcal{B}_i) \cap R(\mathcal{A}_i^1)] > \gamma\lambda\lvert\mathcal{A}_i^1\rvert$.

Finally we get $\lvert B_i\rvert = \lvert\mathcal{A}_i^0\rvert + \lvert\mathcal{A}_i^1\rvert \leqslant \lvert B_i\rvert + \frac{\beta}{\gamma}\lvert B_i\rvert < (1 + \frac{\beta}{\gamma})\lvert B_i\rvert$. ◀

▶ **Lemma 13.** *Let $L_i = (\mathcal{A}_i, \mathcal{B}_i, d_i, z_i)$ be an arbitrary layer in the stack. Let $\mathcal{B}_i'$ be the set of edges in $\mathcal{B}_i$ that share strictly more than $\beta\lambda$ resources with edges in $\mathcal{A}_i$. More precisely, $\mathcal{B}_i' = \{e \in \mathcal{B}_i : v[R_e \cap R(\mathcal{A}_i)] > \beta\lambda\}$. We have $\lvert\mathcal{B}_i'\rvert < \frac{2+\gamma}{\beta}\lvert A_i\rvert$.*

Proof. Taking the sum of $v[R_e \cap R(\mathcal{A}_i)]$ over all edges e in $\mathcal{B}_i'$, we obtain $v[R(\mathcal{B}_i') \cap R(\mathcal{A}_i)] > \beta\lambda\lvert\mathcal{B}'_i\rvert$. On the other hand, $v[R(\mathcal{B}_i') \cap R(\mathcal{A}_i)] \leqslant v[R(\mathcal{A}_i)] < (2+\gamma)\lambda\lvert A_i\rvert$. The last inequality is because that edges in $\mathcal{A}_i$ are $(1+\gamma)\lambda$-minimal. Combining the above two inequality, we obtain $\beta\lambda\lvert\mathcal{B}'_i\rvert < (2+\gamma)\lambda\lvert A_i\rvert \Rightarrow \lvert\mathcal{B}_i'\rvert < \frac{2+\gamma}{\beta}\lvert A_i\rvert$. ◀

4.3 Geometric growth in the number of blocking edges

Now we are ready to prove that the number of blocking edges grow geometrically from bottom to top. Lemma 14 states that there are lots of addable edges in a layer *immediately after* its construction. Previous Lemma 10(ii) ensures that as long as there is no collapsible layer, every layer cannot lose too many addable edges. Therefore, Lemma 14 implies that

when no layer is collapsible, then every layer must have lots of addable edges, even if they are not newly constructed. Then since the number of blocking edges in a layer is lower bounded in terms of the number of addable edges by Lemma 12, we can conclude that there must be lots of blocking edges in a layer when no layer in the stack is collapsible (Lemma 17).

▶ **Lemma 14.** *Let $(M, \mathcal{E}, \mathcal{I}, (L_1, \ldots, L_{\ell+1}))$ be the state of the algorithm **immediately after** the construction of $L_{\ell+1}$. If no layer is collapsible, then $z_{\ell+1} = |\mathcal{A}_{\ell+1}| \geqslant 2\mu|\mathcal{B}_{\leqslant\ell}|$.*

Proof. We give a proof by contradiction. Suppose that $z_{\ell+1} = |\mathcal{A}_{\ell+1}| < 2\mu|\mathcal{B}_{\leqslant\ell}|$. We will show that the dual of $CLP(1)$ is unbounded, which implies that $CLP(1)$ is infeasible, contradicting the assumption that the configuration LP has optimal value $T^* = 1$.

Consider the moment immediately after we finish adding edges to $\mathcal{A}_{\ell+1}$ during the construction of $L_{\ell+1}$. At this moment, there is no $(1+\gamma)\lambda$-minimal addable edge left. The rest of the proof is with respect to this moment.

Let Π be an optimal solution for $G_M(B_{\leqslant\ell}, A_{\ell+1} \cup I)$. Note that $M \oplus \Pi$ is a maximum matching of G. Consider the directed graph $G_{M\oplus\Pi}$ obtained by orienting the edges of G according to whether they are in $M \oplus \Pi$ or not. Let P^+ be the set of players that can be reached in $G_{M\oplus\Pi}$ from $B_{\leqslant\ell} \setminus src_\Pi$. Let R_f^+ be the set of fat resources that can be reached in $G_{M\oplus\Pi}$ from $B_{\leqslant\ell} \setminus src_\Pi$. Let R_t^+ be the set of inactive thin resources.

▷ Claim 15. (i) Players in P^+ are still addable after we finish adding edges to $\mathcal{A}_{\ell+1}$ (ii) Players in P^+ have in-degree at most 1 in $G_{M\oplus\Pi}$. (iii) Resources in R_f^+ have out-degree exactly 1 in $G_{M\oplus\Pi}$.

We define a dual solution $(\{y_p^*\}_{p\in P}, \{z_r^*\}_{r\in R})$ as follows.

$$y_p^* = \begin{cases} 1-(1+\gamma)\lambda & \text{if } p \in P^+, \\ 0 & \text{otherwise.} \end{cases} \qquad z_r^* = \begin{cases} 1-(1+\gamma)\lambda & \text{if } r \in R_f^+, \\ v_r & \text{if } r \in R_t^+, \\ 0 & \text{otherwise.} \end{cases}$$

▷ Claim 16. $(\{y_p^*\}_{p\in P}, \{z_r^*\}_{r\in R})$ is a feasible solution, and it has a positive objective function value.

Suppose that Claim 16 holds. Then $(\{\alpha y_p^*\}_{p\in P}, \{\alpha z_r^*\}_{r\in R})$ is also a feasible solution for any $\alpha > 0$. As α goes to infinity, the objective function value goes to infinity, yielding the contradiction that we look for. ◀

We omit the proof of Claim 15. We give the proof of Claim 16 below.

Feasibility. We need to show that $\forall p \in P$, $\forall C \in \mathcal{C}_p(1)$, $y_p^* \leqslant \sum_{r\in C} z_r^*$. If $p \notin P^+$, then $y_p^* = 0$, and the inequality holds since z_r^* is non-negative. Assume that $p \in P^+$. So $y_p^* = 1-(1+\gamma)\lambda$. Let C be any configuration for p. We show that $\sum_{r\in C} z_r^* \geqslant 1-(1+\gamma)\lambda$.

Case 1: C contains a fat resource r_f. Since p desires r_f, $G_{M\oplus\Pi}$ has either an edge (p, r_f) or an edge (r_f, p). By the definition of P^+, there is a path π in $G_{M\oplus\Pi}$ from $B_{\leqslant\ell} \setminus src_\Pi$ to p. If $G_{M\oplus\Pi}$ has an edge (p, r_f), we can reach r_f from $B_{\leqslant\ell} \setminus src_\Pi$ by following π and then (p, r_f). So $r_f \in R_f^+$. If $G_{M\oplus\Pi}$ has an edge (r_f, p), then p is matched by $M \oplus \Pi$. Since players in $B_{\leqslant\ell} \setminus src_\Pi$ are not matched by $M \oplus \Pi$, $p \notin (B_{\leqslant\ell} \setminus src_\Pi)$. By Claim 15, in $G_{M\oplus\Pi}$, the in-degree of p is at most one, so (r_f, p) is the only edge entering p. To reach p, π must reach r_f first. Hence, we can follow π to reach r_f from $B_{\leqslant\ell} \setminus src_\Pi$, which implies $r_f \in R_f^+$. In both cases, we have $\sum_{r\in C} z_r^* \geqslant z_{r_f}^* = 1-(1+\gamma)\lambda$.

Case 2: C contains only thin resources. By Claim 15, p is still addable after we finish adding edges to $\mathcal{A}_{\ell+1}$. However, when we finish adding edges to $\mathcal{A}_{\ell+1}$, there is no $(1+\gamma)\lambda$-minimal addable edge left. It must be that p does not have enough active resources to form an addable edge. The active thin resources in C must have a total value less than $(1+\gamma)\lambda$. Recall that $v[C] \geqslant 1$. At least $1-(1+\gamma)\lambda$ worth of thin resources in C are inactive. Since $z^*_r = v_r$ for inactive thin resources, $\sum_{r\in C} z^*_r \geqslant 1-(1+\gamma)\lambda$. ◁

Positive Objective Function Value. We need to show that $\sum_{p\in P} y^*_p - \sum_{r\in R} z^*_r > 0$. By our setting of y^*_p and z^*_r, $\sum_{p\in P} y^*_p - \sum_{r\in R} z^*_r = \sum_{p\in P^+} y^*_p - \sum_{r\in R^+_f} z^*_r - \sum_{r\in R^+_t} z^*_r$.

First consider $\sum_{p\in P^+} y^*_p - \sum_{r\in R^+_f} z^*_r$. Since y^*_p and z^*_r have the same value $1-(1+\gamma)\lambda$ for $p\in P^+$ and $r\in R^+_f$, it suffices to bound $|P^+|-|R^+_f|$ from below. For each $r_f\in R^+_f$, by Claim 15, r_f has exactly one out-going edge to some player p in $G_{M\oplus\Pi}$. Since r_f is reachable from $B_{\leqslant\ell}\setminus src_\Pi$, so is p. That is, $p\in P^+$. We charge r_f to p. By Claim 15, each player in P^+ has in-degree at most 1 in $G_{M\oplus\Pi}$, so each of them is charged at most once. Note that players in $B_{\leqslant\ell}\setminus src_\Pi$ obviously belong to P^+ because they can be reached by themselves. Moreover, they have zero in-degree in $G_{M\oplus\Pi}$ as they are not matched by $M\oplus\Pi$, so they are not charged. Therefore, $|P^+|-|R^+_f| \geqslant |B_{\leqslant\ell}\setminus src_\Pi| \geqslant |B_{\leqslant\ell}|-|A_{\ell+1}|-|I|$. The last inequality is because Π is an optimal solution for $G_M(B_{\leqslant\ell}, A_{\ell+1}\cup I)$. In summary,

$$\sum_{p\in P^+} y^*_p - \sum_{r\in R^+_f} z^*_r \geqslant (1-(1+\gamma)\lambda)\left(|B_{\leqslant\ell}|-|A_{\ell+1}|-|I|\right). \tag{1}$$

Now consider $\sum_{r\in R^+_t} z^*_r$. By definition of inactive resources, R^+_t can be divided into three parts: those covered by $\mathcal{A}_{\leqslant\ell}\cup\mathcal{B}_{\leqslant\ell}$, those covered by $\mathcal{A}_{\ell+1}\cup\mathcal{I}$, and those covered by $\mathcal{B}'_{\ell+1} = \{e\in\mathcal{B}_{\ell+1} : v[R_e\cap R(\mathcal{A}_{\ell+1})] > b\lambda\}$. We handle these three parts separately.

Every edge in $\mathcal{A}_{\leqslant\ell}$ is blocked by some edges in $\mathcal{B}_{\leqslant\ell}$, so it has less than λ worth of thin resources not used by $\mathcal{B}_{\leqslant\ell}$. Every edge in $\mathcal{B}_{\leqslant\ell}$ is λ-minimal, so it covers less than 2λ worth of thin resources. Thus, $v[R(\mathcal{A}_{\leqslant\ell}\cup\mathcal{B}_{\leqslant\ell})] < \lambda|\mathcal{A}_{\leqslant\ell}| + 2\lambda|\mathcal{B}_{\leqslant\ell}| \leqslant \left(3+\frac{\beta}{\gamma}\right)\lambda|B_{\leqslant\ell}|$. The last inequality is by Lemma 12. Edges in $\mathcal{A}_{\ell+1}$ are $(1+\gamma)\lambda$-minimal, so each of them covers less than $(2+\gamma)\lambda$ worth of resources. Edges in $\mathcal{I}$ are λ-minimal, so each of them covers less than 2λ worth of thin resources. Therefore, $v[R(\mathcal{A}_{\ell+1}\cup\mathcal{I})] < (2+\gamma)\lambda|A_{\ell+1}| + 2\lambda|I|$. Edges in $\mathcal{B}'_{\ell+1}$ are λ-minimal, so $v[R(\mathcal{B}'_{\ell+1})] < 2\lambda|\mathcal{B}'_{\ell+1}| < \frac{4+2\gamma}{\beta}\lambda|A_{\ell+1}|$. The second inequality is by Lemma 13. Combining the above three parts gives

$$\sum_{r\in R^+_t} z^*_r = \sum_{r\in R^+_t} v_r < \left(3+\frac{\beta}{\gamma}\right)\lambda|B_{\leqslant\ell}| + 2\lambda|I| + \left(2+\gamma+\frac{4+2\gamma}{\beta}\right)\lambda|A_{\ell+1}|. \tag{2}$$

Combining (1) and (2) gives that

$$\begin{aligned}&\sum_{p\in P^+} y^*_p - \sum_{r\in R^+_f} z^*_r - \sum_{r\in R^+_t} z^*_r\\ &> \left(1-\left(4+\gamma+\frac{\beta}{\gamma}\right)\lambda\right)|B_{\leqslant\ell}| - \left(1+\left(1+\frac{4+2\gamma}{\beta}\right)\lambda\right)|A_{\ell+1}| - (1+(1-\gamma)\lambda)\,|I|.\end{aligned}$$

By the contrapositive assumption at the beginning of the proof of Lemma 14, $|A_{\ell+1}| < 2\mu|B_{\leqslant\ell}|$. Moreover, since no layer is collapsible, by Lemma 10(i), $|I| \leqslant \mu|B_{\leqslant\ell}|$. Substituting

these two inequalities into the above gives

$$\begin{aligned}&\sum_{p\in P^+} y_p^* - \sum_{r\in R_f^+} z_r^* - \sum_{r\in R_t^+} z_r^*\\ &> \left((1-3\mu) - \left(4+\gamma+\frac{\beta}{\gamma}+3\mu+\frac{(8+4\gamma)\mu}{\beta}-\gamma\mu\right)\lambda\right)|B_{\leqslant\ell}|.\end{aligned}$$

Let $\beta=\gamma^2$ and $\mu=\gamma^3$. We have

$$\sum_{p\in P^+} y_p^* - \sum_{r\in R_f^+} z_r^* - \sum_{r\in R_t^+} z_r^* > \left(\left(1-3\gamma^3\right) - \left(4+10\gamma+4\gamma^2+3\gamma^3-\gamma^4\right)\lambda\right)|B_{\leqslant\ell}|.$$

Recall that $\lambda=\frac{1}{4+\delta}$ for some $\delta>0$. As $\gamma\to 0$, $\frac{1-3\gamma^3}{4+10\gamma+4\gamma^2+3\gamma^3-\gamma^4}\to\frac{1}{4}$. Hence, there is a sufficiently small γ that makes $\frac{1-3\gamma^3}{4+10\gamma+4\gamma^2+3\gamma^3-\gamma^4}>\frac{1}{4+\delta}=\lambda$, thereby proving $\sum_{p\in P^+} y_p^* - \sum_{r\in R_f^+} z_r^* - \sum_{r\in R_t^+} z_r^* > 0$. Moreover, one can verify that $\frac{1}{\gamma}=O(\frac{1}{\delta})$. ◁

▶ **Lemma 17.** *Let $(M,\mathcal{E},\mathcal{I},(L_1,\ldots,L_\ell))$ be a state of the algorithm. If no layer is collapsible, then for $i\in[1,\ell-1]$, $|B_{i+1}|\geqslant\frac{\gamma^3}{1+\gamma}|B_{\leqslant i}|$.*

Proof. Fix an $i\in[1,\ell-1]$. Consider the period from the *most recent* construction of layer L_{i+1} until now. During this period, none of the layers below L_{i+1} has ever been collapsed; otherwise, L_{i+1} would be removed, contradiction. Hence, blocking edges in the layers below L_{i+1} have never been touched during this period. In other words, at the time L_{i+1} was constructed, the set of blocking edges in the layers below L_{i+1} was exactly $\mathcal{B}_{\leqslant i}$. Also the constant z_{i+1} is unchanged. By Lemma 14, $z_{i+1}\geqslant 2\mu|\mathcal{B}_{\leqslant i}|$. Although addable edges may be removed from the L_{i+1} during this period, there are still lots of addable edges left. By Lemma 10(ii), $|A_{i+1}|\geqslant z_{i+1}-\mu|B_{\leqslant i}|\geqslant\mu|B_{\leqslant i}|$. By Lemma 12, $|B_{i+1}|>\frac{1}{(1+\beta/\gamma)}|A_{i+1}|\geqslant\frac{\mu}{(1+\beta/\gamma)}|\mathcal{B}_{\leqslant i}|$. Recall that we set $\beta=\gamma^2$ and $\mu=\gamma^3$ in the proof of Claim 16. Replacing β by γ^2 and μ by γ^3 proves the lemma. ◀

▶ **Lemma 18.** *In $poly(m,n)\cdot n^{poly(\frac{1}{\delta})}$ time, the algorithm extends $M\cup\mathcal{E}$ to cover one more player.*

Given Lemma 17, Lemma 18 can be proved in a way similar to that of [1, 9]. We sketch the proof here. Consider all non-collapsible states ever reached by the algorithm. By non-collapsible, we mean that no layer is collapsible in this state. Let $h=\frac{\gamma^3}{1+\gamma}$. For each non-collapsible state $(M,\mathcal{E},\mathcal{I},(L_1,\ldots,L_\ell))$, we define its signature vector $(s_1,\ldots,s_\ell,\infty)$ where $s_i=\log_{1/(1-\mu)}\frac{|B_i|}{h^{i+1}}$. One can verify that the coordinates of the signature vector are non-decreasing, and that as the algorithm goes from one non-collapsible state to another, the signature vector decreases lexicographically. Moreover, the sum of the coordinates is bounded by U^2 where $U=\log n\cdot O(\frac{1}{\mu h}\log\frac{1}{h})$. Each signature can be regarded as a partition of an integer less than or equal to U^2. Summing up the number of partitions of an integer i over all $i\in[1,U^2]$, we get the upper bound of $n^{O(\frac{1}{uh}\log\frac{1}{h})}$ on the number of distinct signatures. Recall that $u=\gamma^3$, $h=\frac{\gamma^3}{1+\gamma}$, and $\frac{1}{\gamma}=O(\frac{1}{\delta})$. As a consequence, the number of non-collapsible states ever reached by the algorithm is bounded by $n^{poly(\frac{1}{\delta})}$. Between two consecutive non-collapsible states, there is one Build and at most $\log_{h+1} n$ Collapse, which take $poly(m,n)\cdot n^{poly(\frac{1}{\delta})}$ time in total. The total running time is thus $poly(m,n)\cdot n^{poly(\frac{1}{\delta})}$.

Abstract

The Minimum Circuit Size Problem (MCSP) asks if a given truth table of a Boolean function f can be computed by a Boolean circuit of size at most θ, for a given parameter θ. We improve several circuit lower bounds for MCSP, using pseudorandom generators (PRGs) that are local; a PRG is called *local* if its output bit strings, when viewed as the truth table of a Boolean function, can be computed by a Boolean circuit of small size. We get new and improved lower bounds for MCSP that almost match the best-known lower bounds against several circuit models. Specifically, we show that computing MCSP, on functions with a truth table of length N, requires

- $N^{3-o(1)}$-size de Morgan formulas, improving the recent $N^{2-o(1)}$ lower bound by Hirahara and Santhanam (CCC, 2017),
- $N^{2-o(1)}$-size formulas over an arbitrary basis or general branching programs (no non-trivial lower bound was known for MCSP against these models), and
- $2^{\Omega\left(N^{1/(d+2.01)}\right)}$-size depth-$d$ AC^0 circuits, improving the superpolynomial lower bound by Allender et al. (SICOMP, 2006).

The AC^0 lower bound stated above matches the best-known AC^0 lower bound (for PARITY) up to a small *additive* constant in the depth. Also, for the special case of depth-2 circuits (i.e., CNFs or DNFs), we get an almost optimal lower bound of $2^{N^{1-o(1)}}$ for MCSP.

1 Introduction

Given the truth table of some Boolean function f and a size parameter θ, the minimum circuit size problem (MCSP) asks whether f can be computed by a circuit of size at most θ. Understanding the exact complexity of MCSP is an important open problem in computational complexity theory, dating back to the 1950s [20].

It is easy to see that MCSP is in NP. A popular conjecture is that MCSP is also NP-hard. However, despite serious efforts over the years, such a proof is still unknown. Given that it is difficult to show that MCSP is hard, perhaps the problem is easy? It turns out that this cannot be the case under some plausible cryptographic assumptions. More specifically, it is known that if one-way functions exist, then MCSP is not in P [11]. As proving an *unconditional* lower bound for MCSP seems far beyond the reach of currently known techniques, can we at least prove unconditional lower bounds for MCSP against some restricted computational models?[1]

Two of the most studied restricted computational models in complexity theory are constant-depth circuits (AC^0) and de Morgan formulas. For AC^0 circuits, the best-known lower bound is about PARITY: PARITY on N variables requires depth-d AC^0 circuits of size $2^{\Omega\left(N^{1/(d-1)}\right)}$ [6]. For de Morgan formulas, the state-of-the-art lower bound is almost cubic, namely $N^{3-o(1)}$, for some polynomial-time computable function [7, 18, 19, 5].

Notably, there are also lower bounds against these models for MCSP. Allender et al. [2] showed that MCSP, on functions represented as a truth table of length N, cannot be computed by polynomial-size constant-depth AC^0 circuits. In fact, by a more careful analysis of their argument, one can get a lower bound of $2^{N^{1/(c\cdot d+O(1))}}$, for a constant $c \geq 2$. However, such a lower bound still has a worse dependence on the depth compared to the PARITY lower bound. For de Morgan formulas, Hirahara and Santhanam [9] showed that computing MCSP requires de Morgan formulas of size $N^{2-o(1)}$.

Given these two MCSP lower bounds and the best-known lower bounds against these two models, it is natural to ask whether we can get MCSP lower bounds against small-depth circuits and de Morgan formulas that match the state-of-the-art lower bounds against these models. More specifically, can we show that computing MCSP requires depth-d AC^0 circuits of size $2^{N^{1/(d+O(1))}}$ and de Morgan formulas of size $N^{3-o(1)}$? Furthermore, can we show lower bounds for MCSP against some other restricted models that match their state-of-the-art lower bounds? In this paper, we answer these questions in the affirmative.

1.1 Our results

Our first result is an almost-cubic de Morgan formula lower bound for MCSP.

▶ **Theorem 1.** *Any de Morgan formula computing* MCSP *on truth tables of length N must have size at least $N^3/2^{O\left(\log^{2/3} N\right)}$.*

We also get almost-quadratic lower bounds against formulas over an arbitrary basis as well as general branching programs; these almost match the best-known lower bounds against these models [12].

▶ **Theorem 2.** *Let C be either a formula over any basis or a branching program that computes* MCSP *on truth tables of length N. Then C must have size at least $N^2/2^{O\left(\sqrt{\log N}\right)}$.*

[1] A recent line of research on *hardness magnification* [16, 14] provides another motivation for proving relatively weak lower bounds for restricted circuit models against certain "gap variants" of MCSP. Such lower bounds are shown to imply much stronger (superpolynomial) lower bounds.

For small-depth circuits, we have the following improved lower bound for MCSP, which its dependence on the depth matches the one in the PARITY lower bound, up to a small additive constant.

▶ **Theorem 3.** *For every $d > 2$ and every constant $\gamma > 0$, any depth-d AC^0 circuit computing* MCSP *on truth tables of length N must have size $2^{\Omega\left(N^{1/(d+2+\gamma)}\right)}$.*

For the special case of depth-2 circuits, we can have an almost optimal lower bound.

▶ **Theorem 4.** *Any CNF or DNF computing* MCSP *on truth tables of length N must have size $2^{N/\widetilde{O}\left(\log^2 N\right)}$.*

Also, in this paper (in the full version), we give a fine-grained analysis of the approach of obtaining MCSP lower bounds from average-case hardness via the Nisan-Wigderson framework.

1.2 Our techniques

For a class $\mathfrak{C}$ of N-variate Boolean functions, a pseudorandom generator (PRG) against $\mathfrak{C}$ is a deterministic efficiently-computable function G mapping short binary strings (seeds) to longer binary strings so that every function in $\mathfrak{C}$ accepts G's output on a uniformly random seed with about the same probability as that for an actual uniformly random string. A key notion in this work is that of a local PRG. We say that a PRG is *local* if its N-bit output (viewed as the truth table of some function) has small circuit complexity. More precisely, for any fixed seed to the PRG, there exists a small circuit such that, given $j \in [N]$ as an input, the circuit computes the j-th bit of the PRG output, where the size of the circuit is measured relative to its input length, namely $\log N$.

Local PRGs in the context of MCSP (and related problems) have been studied in previous works (see, e.g., [2, 15, 9, 8]). In this work, we refine the previous approaches, and obtain stronger circuit lower bounds by establishing strong locality properties of certain PRGs.[2]

MCSP lower bounds from local PRGs. Suppose we have a local PRG against some class of circuits $\mathfrak{C}$ of size s, and we want to show that MCSP cannot be computed by any size-s circuit in $\mathfrak{C}$. Suppose some size-s circuit C in $\mathfrak{C}$ computes MCSP. Using the fact that a random function has almost maximum circuit complexity, we have that C will output FALSE on most of its inputs (by setting the size parameter θ to be a non-trivial quantity that is asymptotically smaller than $2^n/n$, where n is the input length of the function). If we replace the uniformly random inputs with the outputs of the local PRG, then, by the definition of PRGs, C will still output FALSE with large probability. However, since the PRG is local, all of its outputs have circuit complexity smaller than the size parameter θ, and hence must be accepted by C. A contradiction.

To get a strong lower bound, we would like to make the above argument to work for large s. Note that the local complexity of the PRG, $\lambda(s)$, is a function on the size of the circuit C, and we need this local complexity to be "non-trivial" in order to reach a contradiction. Therefore, we want to choose s so that this local complexity remains asymptotically smaller than $2^n/n$. As a result, the final lower bound (i.e., the largest s that we can choose) is determined by the local complexity λ. So the main question we study in our paper is: What is the smallest local complexity of a PRG against a given circuit class?

[2] Note that, as one of our reviewers pointed out, the notion of a local PRG can be also found in the context of cryptography [4], where a PRG $G : \{0,1\}^n \to \{0,1\}^m$ is called *k-local*, for some constant $k > 0$, if every output PRG bit $G(x)_j$, for any $x \in \{0,1\}^n$ and $j \in [m]$, depends only on k input bits $x_{i_1}, \ldots, x_{i_k}$, for $i_1, \ldots, i_k \in [n]$. In our work, however, locality refers to the circuit complexity of the PRG at hand and the output bits of our PRGs may depend on a superconstant number of input bits.

MCSP lower bound against de Morgan formulas. Our formula lower bound for MCSP is obtained by applying the framework described above to a local PRG against formulas. The state-of-the-art PRG against formulas is given by Impagliazzo, Meka, and Zuckerman [10], which we refer to as the IMZ PRG. Their PRG has a seed length of $s^{1/3+o(1)}$ for size s formulas (note that such a PRG is useful against sub-cubic formulas only). If we want to utilize the IMZ PRG to get an MCSP lower bound against formulas, we will need to argue that the IMZ PRG is local.

In fact, in order to get an almost-cubic lower bound, we will need such a PRG to be strongly local in the sense that any single output bit of the PRG (on any given fixed seed) can be computed by a circuit of size comparable to its seed length, which is $s^{1/3+o(1)}$. However, by inspecting the construction, the IMZ PRG does not seem to have such a property, and a straightforward implementation seems to require a circuit of size at least $s^{2/3}$ (see the full version for more details), which yields a weaker lower bound for MCSP.

To overcome this issue, we present an alternative PRG useful against sub-cubic formulas which is strongly local. The construction of this PRG can be viewed as a modification of the IMZ PRG. At a high level, it is based on the Ajtai-Wigderson construction [1], which is a framework for constructing PRGs against computations that can be simplified under (pseudo)random restrictions. This framework is then combined with the ideas of reducing (recycling) random bits using an extractor, by exploiting communication bottlenecks in computations [13]. Our modification, particularly the utilization of the Ajtai-Wigderson construction, allows us to compute any output bit of the PRG efficiently by reducing the number of calls to the extractor. Using some crucial observations on the circuit complexity of certain pseudorandom objects, we get a PRG that is locally computable by a $s^{1/3+o(1)}$-size circuit.[3]

MCSP lower bounds against formulas over an arbitrary basis or branching programs. The MCSP lower bounds against formulas over an arbitrary basis or branching programs are obtained similarly to those for de Morgan formulas. The idea is to construct strongly local PRGs against these models by modifying the PRGs in [10]. Then, by applying our "MCSP circuit lower bounds from local PRGs" framework, we get the desired lower bounds.

MCSP lower bounds against AC^0. We use a local PRG against AC^0 to get MCSP lower bounds. To get a lower bound matching the one in Theorem 3, we can use the state-of-the-art PRG against AC^0 by Trevisan and Xue [21], which has a seed length of $(\log s)^{d+O(1)}$ for size-s depth-d AC^0 circuits. By a careful analysis of the construction of this PRG, we can show that the Trevisan-Xue PRG is strongly local and can be used to get an MCSP lower bound that is close to the one stated in Theorem 3. However, in this paper, we will present a more direct proof of such a lower bound by using the pseudorandom switching lemma for constant-depth circuits, which is due to Trevisan and Xue [21], as well, and is a key ingredient in their PRG.

The idea is to show that for any small-depth circuit of size less than the claimed lower bound, there is some locally computable restriction that turns the circuit into a constant function, but leaves many variables unrestricted. However, MCSP cannot be constant under such a restriction, because depending on the partial assignment to the unrestricted variables, the resulting input function (which is composed of the restriction and the partial assignment) can be either easy or hard. Such an approach based on pseudorandom restrictions can also be applied to depth-2 circuits and yield almost optimal CNF (and DNF) MCSP lower bounds.

[3] It is also possible to use the original IMZ PRG to obtain an almost-cubic formula lower bound for MCSP. We can show that the IMZ PRG, although not fully strongly local, is "almost strongly local" in the sense that *most* of its outputs have very small circuit complexity; see the full version.

1.3 Remainder of the paper

We give the necessary background in Section 2. In Section 3, we describe our framework of using local PRGs to obtain lower bounds for MCSP. We prove the almost-cubic de Morgan formula lower bound for MCSP (Theorem 1) in Section 4, and the almost-quadratic lower bound against formulas over an arbitrary basis and branching programs (Theorem 2) in Section 5. The improved AC^0 lower bounds for MCSP (Theorem 3 and Theorem 4) are proved in Section 6. Finally, we give some open problems in Section 7. Due to space limitations we relegated some material to the full version, like some omitted proofs and the framework of proving MCSP lower bounds from average-case hardness.

2 Preliminaries

2.1 Notation

For any computational model, we use the term *size* to refer to its complexity measure. For example, if the model is circuits of some fixed depth, then the size is the number of gates in the circuit.

For a positive integer n, that is a power of two, we use the following notation: $[n]$ denotes the set $\{1, 2, \ldots, n\} \cong \{0,1\}^{\log n}$, $\mathbb{F}_n$ denotes the field with n elements, where the elements in $\mathbb{F}_n$ are represented by $(\log n)$-bit strings, U_n denotes the uniform distribution over $\{0,1\}^n$, and, for a function $f\colon \{0,1\}^n \to \{0,1\}$, $\mathtt{tt}(f) \in \{0,1\}^{N=2^n}$ denotes the truth table of f.

2.2 Pseudorandomness

▶ **Definition 5** (Pseudorandom generators). *Let $G\colon \{0,1\}^r \to \{0,1\}^n$ be a function, $\mathcal{F}$ be a class of Boolean functions, and $0 < \varepsilon < 1$. We say that G is a* pseudorandom generator of seed length r that ε-fools $\mathcal{F}$ *if, for every function $f \in \mathcal{F}$, it is the case that*

$$\left|\mathbb{E}_{z\sim\{0,1\}^r}[f(G(z))] - \mathbb{E}_{x\sim\{0,1\}^n}[f(x)]\right| \leq \varepsilon.$$

▶ **Definition 6** (k-wise independence). *A distribution X over $[m]^n$ is called* k-wise independent *if for any $1 \leq i_1 \leq i_2 \leq \cdots \leq i_k \leq n$ and every $b_1, b_2, \ldots, b_k \in [m]$, we have*

$$\mathbf{Pr}[X_{i_1} = b_1, X_{i_2} = b_2, \ldots, X_{i_k} = b_k] = m^{-k}.$$

The following simple fact (proved in the full version) will be convenient for us.

▶ **Lemma 7.** *Let X and Y be two random variables that take values in $\{0,1\}$ and $\mathcal{E}$ be some event. If $|\mathbb{E}[X \mid \mathcal{E}] - \mathbb{E}[Y \mid \mathcal{E}]| \leq \varepsilon_1$ and $\mathbf{Pr}[\neg\mathcal{E}] \leq \varepsilon_2$, then $|\mathbb{E}[X] - \mathbb{E}[Y]| \leq \varepsilon_1 + \varepsilon_2$.*

2.3 Random restrictions

A restriction for a n-variate Boolean function f, usually denoted as $\rho \in \{0,1,*\}^n$, specifies a way of fixing the values of some subset of variables for f. We denote by f_ρ the restricted function after the variables are restricted according to ρ, and denote by $\rho^{-1}(*)$ the set of unrestricted variables. A random restriction is then a distribution over restrictions, which can be specified by a pair $(\sigma, \beta) \in \{0,1\}^n \times \{0,1\}^n$, where σ (as a characteristic string) specifies the set of unrestricted variables, and β specifies the values for fixing the restricted variables. We say that a random restriction (or random selection) is p-regular if each variable is left unrestricted with probability p. One way to generate a p-regular random restriction is to leave each variable, independently, unrestricted with probability p, and otherwise assign to it a 0 or

a 1, uniformly at random. Such a random restriction is called a *(truly) p-random restriction*. Note that to sample such a restriction, we can first pick a string in $\{0,1\}^{n\cdot\log(1/p)} \cong [1/p]^n$ to specify the selection of the unrestricted variables, where a coordinate is unrestricted if and only if all of its corresponding $\log(1/p)$ bits are 0, and then a string in $\{0,1\}^n$ to specify the values assigned to each of the restricted variables. So sampling a restriction in this way requires $n \cdot \log(1/p) + n$ random bits.

We can also generate a restriction in a pseudorandom manner, which may use fewer random bits. For example, one way to do this is to use a limited-independence distribution over $[1/p]^n$, so that each variable is left unrestricted with probability p and any k variables are independent. Also, we can let each variable be assigned a 0 or a 1, uniformly at random, in a way such that any k of the variables are independent; this again can be done using a k-wise independent distribution on $\{0,1\}^n$.

2.4 Simple facts about Boolean circuits

▶ **Proposition 8.** *A Boolean circuit of size s can be specified using $O(s \log s)$ bits. Hence there are at most $2^{O(s \log s)} = s^{O(s)}$ distinct circuits of size at most s.*

▶ **Theorem 9** ([17])**.** *The fraction of functions on n variables that have a circuit of size less than $2^n/(3n)$ is $o(1)$.*

The following lemma is proved in the full version.

▶ **Lemma 10.** *For any integer $t > 0$, there exists a circuit C of size $\widetilde{O}(t)$ such that, given any string $x \in \{0,1\}^t$, the circuit does the following: If $x = 0^t$, then C outputs $(0, 0^{\log t})$ and if $x \neq 0^t$, then C outputs $(1, q)$, where $q \in \{0,1\}^{\log t}$ is the index of the first bit in x that is not 0.*

The following circuit upper bound for the addressing (storage access) function is well-known (see, e.g., [22]); we include a proof, in the full version, for completeness.

▶ **Lemma 11.** *For any integers $t, m > 0$, there exists a circuit of size $O(tm)$ such that, given any string $y = (y_1, y_2, \ldots, y_t)$, where $y_i \in \{0,1\}^m$ for each i, and an index $i \in \{0,1\}^{\log t}$, the circuit outputs y_i.*

3 The "MCSP circuit lower bounds from local PRGs" framework

We first describe how to use local PRGs to obtain MCSP lower bounds.

▶ **Definition 12** (Local PRGs)**.** *Let $\lambda\colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ be a size function. For any Boolean computational model and size $s > 0$, we say that a function $G\colon \{0,1\}^{r=r(N,s)} \to \{0,1\}^N$ is a $(N, s, \lambda(N,s))$-local PRG against the model if G 1/3-fools every device f on N variables of size s in the model; that is,*

$$\left|\mathbb{E}_{z\sim\{0,1\}^r}[f(G(z))] - \mathbb{E}_{x\sim\{0,1\}^N}[f(x)]\right| \leq 1/3,$$

and for any seed $z \in \{0,1\}^r$, the function $g\colon \{0,1\}^{\log N} \to \{0,1\}$, defined as $g_z(j) = G(z)_j$, can be computed by a general circuit of size at most $\lambda(N,s)$.

Note that $\lambda(N,s)$ is at least $r(N,s)$, by a counting argument (neglecting $\log \lambda(N,s)$ factors). This is to ensure that, for any function g, on n variables, which may be output by G, there is some $\lambda(N,s)$-size circuit that computes g.

▶ **Theorem 13.** *There exists a constant $c > 0$ such that the following holds. For any computational model, let s be such that* MCSP *on truth tables of length N can be computed by a device of size s in the model. If there exists some $(N, s, \lambda(N, s))$-local PRG against the model, then $\lambda(N, s) \geq \frac{N}{c \log N}$.*

Proof. Let C be a device in the computational model such that C computes MCSP on truth tables of length N. Suppose C has size s, and let G be a $(N, s, \lambda(N, s))$-local PRG against C with some seed length r.

For the sake of contradiction, suppose that $\lambda(N, s) < \frac{N}{c \log N}$. On the one hand, since most functions require circuits of size greater than $\frac{N}{c \log N}$ (Theorem 9) and C computes MCSP, we have $\mu = \mathbf{Pr}_{\mathtt{tt}(f) \sim \{0,1\}^N}[C(\mathtt{tt}(f), \lambda(N, s)) = 0] \geq 1/2$. Also, since G fools C, we have $\mathbf{Pr}_{z \sim \{0,1\}^r}[C(G(z), \lambda(N, s)) = 0] \geq \mu - 1/3 \geq 1/6$. On the other hand, because G is $(N, s, \lambda(N, s))$-local, we must have $C(G(z), \lambda(N, s)) = 1$, for every z. A contradiction. ◀

4 Almost-cubic de Morgan formula lower bounds for MCSP

In this section, we present our almost-cubic de Morgan formula lower bound for MCSP. By saying "formula" within this section, we refer to formulas over the de Morgan basis (AND, OR, and NOT). By *size* of a formula, we mean its usual leaf complexity, i.e., the number of leaves in the tree representation of the formula.

▶ **Theorem 14** (Theorem 1 restated)**.** *Any de Morgan formula computing* MCSP *on truth tables of length N must have size at least $N^3/2^{O\left(\log^{2/3} N\right)}$.*

We will construct a strongly local PRG useful against sub-cubic formulas. That is, given as input an index j, the j-th bit of the PRG can be computed by a circuit of size that is comparable to its seed length, which in our case is around $s^{1/3}$ for size s formulas.

▶ **Lemma 15.** *For any $s \geq N$, there exists a $\left(N, s, s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}\right)$-local PRG against de Morgan formulas.*

Given the local PRG in Lemma 15, we can combine it with our Theorem 13 to obtain a formula lower bound for MCSP.

Proof of Theorem 14. Let s be such that MCSP on truth tables of length N can be computed by some formula of size s. We can assume that $s \leq N^3$ since, otherwise, the result trivially holds. By Theorem 13 and Lemma 15, we have $s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)} \geq N/(c \log N)$; then, $s \geq N^3 / \left(2^{O\left(\log^{2/3} N\right)} c^3 \log^3 N\right)$. ◀

The rest of this section is devoted to proving Lemma 15.

4.1 Almost-linear-size k-independent generators

The PRG in Lemma 15 will use k-wise independent distributions. Recall that a multidimensional distribution is called *k-wise independent* if any k coordinates of the distribution are uniformly distributed (see Definition 6). We say that a function G is a *k-independent generator* if, for random inputs, the distribution of the outputs of G is k-wise independent.

We will need a k-independent generator that is strongly local.

▶ **Lemma 16.** *For any integer $k > 0$, there exists a k-independent generator $G\colon \{0,1\}^r \to [m]^N$, with $r = k \cdot \max\{\log N, \log m\}$, such that the following holds. There exists a circuit of size $k \cdot \max\{\widetilde{O}(\log N), \widetilde{O}(\log m)\}$ such that, given $j \in \{0,1\}^{\log N}$ and a seed $z \in \{0,1\}^r$, the circuit computes the j-th coordinate of $G(z)$ (as an element of $\{0,1\}^{\log m}$).*

The above k-independent generator is constructed using finite fields (see the full version). Its efficiency crucially depends on the fact that finite field arithmetic can be done using *almost linear-size* Boolean circuits.

4.2 Almost-linear-size extractors

Our PRG will make use of randomness extractors. Here, we describe an extractor that is computable by a circuit of size that is almost linear in the length of its input. We start by reviewing the definitions of some basic notions regarding extractors.

▶ **Definition 17** (ε-closeness and statistical distance). *Let $0 \leq \varepsilon \leq 1$. We say two distributions X and Y (over some universe D) are* ε-close *if their* statistical distance, *defined as*

$$\max_{T:D\to\{0,1\}} \left|\mathbf{Pr}[T(X)=1] - \mathbf{Pr}[T(Y)=1]\right|,$$

is at most ε.

▶ **Definition 18** (Min-entropy). *Let X be a random variable. The* min-entropy *of X, denoted by $H_\infty(X)$, is the largest real number k such that $\mathbf{Pr}[X=x] \leq 2^{-k}$ for every x in the range of X. If X is a distribution over $\{0,1\}^\aleph$ with $H_\infty(X) \geq k$, then X is called a* $(\aleph, k)$-source.

▶ **Definition 19** (Extractors). *A function $E\colon \{0,1\}^\aleph \times \{0,1\}^d \to \{0,1\}^m$ is an* (k,ε)-extractor *if, for any $(\aleph,k)$-source X, the distribution $E(X,U_d)$ is ε-close to U_m.*

We now state the extractor, which for a high min-entropy source extracts a constant fraction of min-entropy, using seeds of polylogarithmic length. The construction and circuit complexity of this extractor are presented in the full version.

▶ **Lemma 20** (Almost-linear-size extractors, following [13]). *There exists some randomness extractor $E\colon \{0,1\}^\aleph \times \{0,1\}^d \to \{0,1\}^m$ that is an $(\aleph/2,\varepsilon)$-extractor with $m = \Omega(\aleph)$ and $d = \mathsf{polylog}(\aleph/\varepsilon)$. Moreover, E can be computed by a circuit of size $\aleph \cdot \mathsf{polylog}(\aleph/\varepsilon)$.*

4.3 Strongly local PRG useful against sub-cubic de Morgan formulas

For a formula F, let $L(F)$ denote the size (which is measured by the number of leaves) of F. We need the following pseudorandom shrinkage lemma for de Morgan formulas, which says that there exists a p-regular restriction, where the unrestricted variables are selected pseudorandomly and the restricted variables are fixed truly-randomly, such that *with high probability* the size of the restricted formula will "shrink" by a factor of p^2.

▶ **Lemma 21** (Pseudorandom shrinkage lemma, Lemma 4.8 of [10][4]). *There exists a constant $c_0 > 0$ such that the following holds. For any constant $c > c_0$, any $s \geq N$, $p \geq s^{-1/2}$, and any de Morgan formula F on N variables of size s, there exists a p-regular pseudorandom selection $\mathcal{D}$ over N variables, that is samplable using $r = 2^{O(\log^{2/3} s)}$ random bits, such that*

$$\mathbf{Pr}_{\sigma\sim\mathcal{D}, x\sim\{0,1\}^N}\left[L\big(F_{(\sigma,x)}\big) \geq 2^{3\cdot c\cdot \log^{2/3} s} \cdot p^2 \cdot s\right] \leq s^{-c}.$$

Moreover, there exists a circuit of size $2^{O(\log^{2/3} s)}$ such that, given $j \in \{0,1\}^{\log N}$ and a seed $z \in \{0,1\}^r$, the circuit computes the j-th bit of $\mathcal{D}(z)$.

[4] The pseudorandom shrinkage lemma in [10] is not stated in this form, but rather selects the unrestricted variables and fixes the restricted variables both pseudorandomly (based on limited independence). However, our version here follows from the proof of the original version in Section 4.2 of [10] by noting that limited-independence distributions can be computed locally.

We are now ready to show our PRG in Lemma 15.

Proof of Lemma 15. The construction is as follows: We first sample a p-regular pseudorandom selection from Lemma 21. Then, we fill the star coordinates, specified by the pseudorandom selection, in the output string with the output of some extractor which takes a min-entropy source sample and a short seed (in fact, it is the output of some limited-independence generator that takes the output of the extractor as a seed). We then sample another pseudorandom selection, and fill the star coordinates specified by this pseudorandom selection but this time only for those that have not been filled in previous steps, again with the output of the same extractor using the *same min-entropy source sample* but a *different short seed*. We continue this way until all the coordinates are filled.

More formally, our PRG uses the following parameters:[5]

- $p = 1/s^{1/3}$, the expected fraction of unrestricted variables in each of the pseudorandom selections;
- $\varepsilon = 1/\mathsf{poly}(N)$ and $\varepsilon_0 = \varepsilon/(10t)$, which specify the error of the PRG;
- $t = \ln(2N/\varepsilon)/p = s^{1/3} \cdot O(\log N)$, the number of steps needed so that all the coordinates will be filled with probability except $\varepsilon/2$;
- $s_0 = p^2 \cdot s \cdot 2^{O\left(\log^{2/3} s\right)} = s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}$, the size of the formula after being simplified by a pseudorandom restriction;
- $k \geq s_0 = s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}$, the amount of independence needed to fool the simplified formula, and $r_k = k \cdot \log N$ the seed length for the k-independent generator;
- $\aleph$, the length of the min-entropy source for the extractor, which is such that $\aleph \geq 2 \cdot (\log(1/\varepsilon_0) + c \cdot s_0 \cdot \log s_0)$, where $c > 0$ is some constant, and that $\aleph = \Omega(r_k)$. We can take $\aleph = s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}$;
- $d = \mathsf{polylog}(\aleph/\varepsilon_0) = \mathsf{polylog}(N)$, the seed length of the extractor;
- $\ell = 2^{O(\log^{2/3} s)}$, the number of random bits for sampling a pseudorandom selection.

Construction. The PRG takes a seed $(X, Y_1, Y_2, \ldots, Y_t, \gamma_1, \gamma_2, \ldots, \gamma_t) \in \{0,1\}^r$, where

- $X \in \{0,1\}^{\aleph}$ is the min-entropy source sample of an extractor,
- $Y_i \in \{0,1\}^{\mathsf{polylog}(N)}$, for each $i \in [t]$, is the seed of an extractor, and
- $\gamma_i \in \{0,1\}^{\ell}$, for each $i \in [t]$, is the seed for sampling a pseudorandom selection.

The construction of the PRG proceeds in the following two stages.

1. Compute a sequence of t p-regular pseudorandom selections $\sigma_1, \ldots, \sigma_t$, using Lemma 21, with the seeds $\gamma_1, \ldots, \gamma_t$. Below, we denote the star coordinates in σ_i by $\sigma_i^{-1}(*)$. Let $S_1, \ldots, S_t \subseteq [N]$ be t disjoint sets defined by

$$S_i = \sigma_i^{-1}(*) \setminus (S_1 \cup S_2 \cup \cdots \cup S_{i-1}).$$

2. Define $Z_1, Z_2, \ldots, Z_t \in \{0,1\}^N$ by

$$Z_i = G_k(E(X, Y_i)),$$

where $E\colon \{0,1\}^{\aleph} \times \{0,1\}^d \to \{0,1\}^{\Omega(\aleph)}$ is an $(\aleph/2, \varepsilon_0)$-extractor and $G_k\colon \{0,1\}^{r_k} \to \{0,1\}^N$ is a k-independent generator. The final output of our PRG is the binary string that has the values $Z_i|_{S_i}$ in the positions indexed by S_i, for all $i \in [t]$, where $Z_i|_{S_i}$ denotes the bit values of Z_i projected to the set S_i. (We fix those positions that are not in any of the S_i's to be 0.) Stage 2 of the PRG construction is depicted in Figure 1.

[5] In fact, there are mainly two types of parameters here. Those that are close to $s^{1/3}$, which are $1/p, t, s_0, k, N$, and those that are close to $N^{o(1)}$, which are d and ℓ.

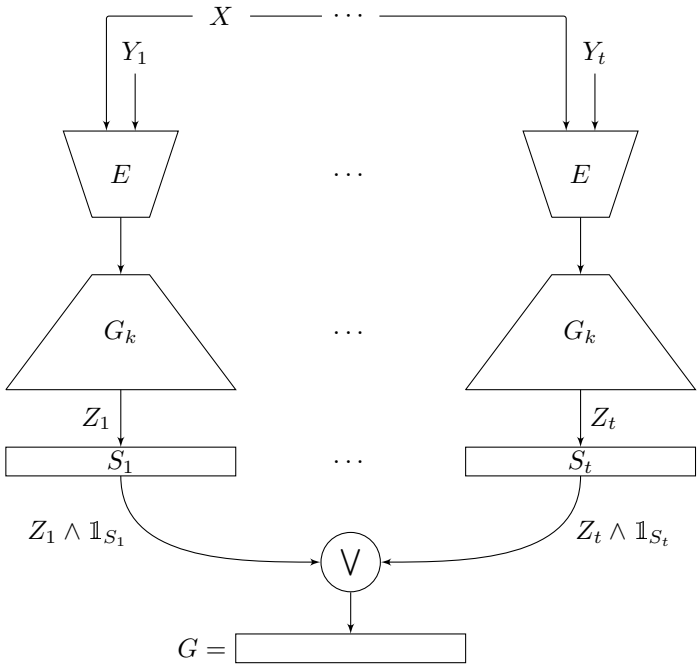

Figure 1 Construction of the PRG in Lemma 15, Stage 2. For each $i \in [t]$, $\mathbb{1}_{S_i} \in \{0,1\}^N$ denotes the characteristic Boolean vector of the set S_i, where $S_i \subseteq [N]$ is the set of star coordinates in the i-th pseudorandom selection that did not appear in the preceding sets $S_1, \ldots, S_{i-1}$. Also, $\wedge$ denotes a coordinate-wise AND operation (i.e., coordinate-wise *multiplication* of Boolean vectors) and $\bigvee$ is a coordinate-wise OR operation.

Correctness. Next, we show that the above PRG ε-fools N-variate formulas f of size s. First, note that, by our choice of t, with probability except $\varepsilon/2$, $S_1 \cup S_2 \cup \cdots \cup S_t$ covers all coordinates. For the rest of the argument, we will assume that this is the case. By Lemma 7, conditioning on this assumption contributes at most $\varepsilon/2$ to the error of the constructed PRG.

We continue the correctness analysis using a *hybrid argument*. Let G denote the distribution given by the PRG described above. Let U be the uniform distribution. Note that if in the above construction we replace Z_i, for all $i \in [t]$, with U, then we would get a uniform distribution. Now we can start from there and gradually replace U with the Z_i's step-by-step for a total of t steps. We will argue that after each replacement step, the expected value of the function does not change by much. Let A_i be the distribution so that we have replaced U with Z_i in the first i steps. That is,

$$A_i = \left(Z_1|_{S_1}, \ldots, Z_i|_{S_i}, U|_{S_{i+1}}, \ldots, U|_{S_t} \right) = \left(Z_1|_{S_1}, \ldots, Z_i|_{S_i}, U|_{S_{i+1} \cup \cdots \cup S_t} \right).$$

For the sake of contradiction, suppose there exists an N-variate size-s formula f such that

$$|\mathbb{E}[f(U)] - \mathbb{E}[f(G)]| = |\mathbb{E}[f(A_0)] - \mathbb{E}[f(A_t)]| > \varepsilon/2.$$

By the triangle inequality, there exists an $0 \leq i < t$ such that

$$|\mathbb{E}[f(A_i)] - \mathbb{E}[f(A_{i+1})]| > \varepsilon/(2t). \tag{1}$$

Let us say that the expectations in Equation (1) are over $\sigma_1, \ldots, \sigma_{i+1}, Y_1, \ldots, Y_{i+1}, X, U$, and we may remove the absolute value without loss of generality. Then, we have

$$\mathbb{E}_{\substack{\sigma_1,\ldots,\sigma_i,\\ Y_1,\ldots,Y_i,\\ X}} \left[\mathbb{E}_{\sigma_{i+1},Y_{i+1},U} \left[f(A_i) \right] - \mathbb{E}_{\sigma_{i+1},Y_{i+1},U} \left[f(A_{i+1}) \right] \right] > \varepsilon/(2t). \tag{2}$$

Let $W_i = (\sigma_1, \ldots, \sigma_i, Y_1, \ldots, Y_i, X)$, and let f' be the random function (where the randomness is over W_i) defined as $f' = f(Z_1|_{S_1}, \ldots, Z_i|_{S_i}, \quad \cdot \quad)$. That is, f' is the restricted function after the first i steps. Then, the left hand side of Equation (2) becomes

$$\mathbb{E}_{W_i}\left[\mathbb{E}_{\sigma_{i+1},U}\left[f'(U|_{S_{i+1}}, U|_{\ S_{i+2}\cup\cdots\cup S_t})\right] - \mathbb{E}_{\sigma_{i+1},Y_{i+1},U}\left[f'(Z_{i+1}|_{S_{i+1}}, U|_{\ S_{i+2}\cup\cdots\cup S_t})\right]\right]. \tag{3}$$

Note that, at this point, we can view $\rho_{i+1} = (\sigma_{i+1}, U)$ as a pseudorandom restriction (in the sense of Lemma 21) applied to f'. Next, let f'' be the random function defined as the restricted function of f' under ρ_{i+1} (note that the randomness is over W_i, and also the pseudorandom restriction ρ_{i+1}). Now Equation (3) becomes

$$\mathbb{E}_{W_i,\rho_{i+1}}\left[\mathbb{E}_U\left[f''(U)\right] - \mathbb{E}_{Y_{i+1}}\left[f''(Z_{i+1})\right]\right]. \tag{4}$$

Note that in the above, we abuse notation and use U and Z_{i+1} to denote $U|_{S_{i+1}}$ and $Z_{i+1}|_{S_{i+1}}$, respectively.

Next we want to show that the difference between the two expectations in Equation (4) is at most $3\varepsilon_0 = 3\varepsilon/(10t) \leq \varepsilon/(2t)$, which would give a contradiction, by Equation (2). The intuition is the following. On the one hand, f'' is obtained by a pseudorandom restriction ρ_{i+1}, and so, with high probability, it has size at most s_0. On the other hand, Z_{i+1} is obtained using an extractor that is supposed to extract enough random bits for an s_0-independent generator.

The issue, however, is that f'' depends on X, the source sample of the extractor. Therefore, f'' may contain information about X, so that X is not truly random anymore. Nonetheless, being a formula of size at most s_0, f'' cannot contain too much information, and so cannot take too much entropy away from X. We make this argument more formal next.

Let us define the set of good functions for f'', namely

$$\mathcal{F} = \left\{g \mid L(g) \leq s_0 \quad \text{and} \quad \mathbf{Pr}_{W_i,\rho_{i+1}}[f'' = g] \geq \varepsilon_0/s_0^{cs_0}\right\},$$

where c is some constant. Let $\mathcal{E}$ denote the event $f'' \in \mathcal{F}$. We first show the following.

▷ Claim 22. It is the case that $\mathbf{Pr}[\neg\mathcal{E}] \leq 2\varepsilon_0$.

Proof of Claim 22. We have

$$\begin{aligned}\mathbf{Pr}[\neg\mathcal{E}] &= \mathbf{Pr}[(f'' \notin \mathcal{F}) \wedge (L(f'') > s_0)] + \mathbf{Pr}[(f'' \notin \mathcal{F}) \wedge (L(f'') \leq s_0)] \\ &\leq \mathbf{Pr}[(L(f'') > s_0)] + \mathbf{Pr}[(f'' \notin \mathcal{F}) \wedge (L(f'') \leq s_0)].\end{aligned}$$

Note that, by the pseudorandom shrinkage lemma (Lemma 21), we have $\mathbf{Pr}[L(f'') > s_0] \leq \varepsilon_0$. Also note that under the condition that $L(f'') \leq s_0$, there can be at most $s_0^{O(s_0)}$ choices for f'', since a formula of size s_0 can be specified using $O(s_0 \log s_0)$ bits (Proposition 8). Therefore, $\mathbf{Pr}[(f'' \notin \mathcal{F}) \wedge (L(f'') \leq s_0)] \leq s_0^{O(s_0)} \cdot \varepsilon_0/s_0^{cs_0} \leq \varepsilon_0$. ◁

Let us now analyze Equation (4) while conditioning on the event $\mathcal{E}$. We show the following.

▷ Claim 23. It is the case that $\mathbb{E}\left[f''(U) \mid \mathcal{E}\right] - \mathbb{E}\left[f''(Z_{i+1}) \mid \mathcal{E}\right] \leq \varepsilon_0$.

Proof of Claim 23. First note that conditioning on $\mathcal{E}$, X still has large min-entropy. More precisely, for every $g \in \mathcal{F}$ it is the case that $H_\infty(X \mid f'' = g) \geq \aleph/2$. This is because, for every x in the range of X, we have

$$\mathbf{Pr}[X = x \mid f'' = g] \leq \frac{\mathbf{Pr}[X = x]}{\mathbf{Pr}[f'' = g]} \leq \frac{2^{-\aleph}}{\varepsilon_0/s_0^{c\cdot s_0}} = 2^{-(\aleph - \log(1/\varepsilon_0) - c\cdot s_0 \cdot \log s_0)} \leq 2^{-\aleph/2}.$$

Then, by the definition of the extractor, we have $\mathbb{E}\left[f''(G_k(U)) \mid \mathcal{E}\right] - \mathbb{E}\left[f''(Z_{i+1}) \mid \mathcal{E}\right] \leq \varepsilon_0$. Finally, note that $\mathbb{E}\left[f''(G_k(U)) \mid \mathcal{E}\right] = \mathbb{E}\left[f''(U) \mid \mathcal{E}\right]$, since s_0-wise independent distributions fool size-s_0 formulas. ◁

Combining Claim 22, Claim 23, and Lemma 7, we get that the quantity in Equation (4) is at most $3\varepsilon_0$, which leads to a contradiction. This completes the proof of correctness.

Locality. To see that the j-th bit of the PRG can be computed using a circuit of size $s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}$, we observe the following equivalent construction:

1. Compute the j-th bits of the t pseudorandom selections $(\sigma_1)_j, (\sigma_2)_j, \ldots, (\sigma_t)_j$.
2. Retrieve Y_q, where q is the smallest integer such that $(\sigma_q)_j$ is a star.
3. Compute $(Z_q)_j = G_k(E(X, Y_q))_j$, as the j-th bit of the PRG.

Note that Step 1 can be done using a circuit of size $t \cdot 2^{O\left(\log^{2/3} s\right)} = s^{1/3} \cdot 2^{O\left(\log^{2/3} s\right)}$, by the pseudorandom shrinkage lemma (Lemma 21). Also, Step 2 can be done by first computing q from the sequence $((\sigma_i)_j)_{i\in[t]}$, using a circuit of size $\widetilde{O}(t)$ (Lemma 10), and then outputting Y_q from $(Y_i)_{i\in[t]}$, using a circuit of size $t \cdot \mathsf{polylog}(N)$ (Lemma 11). Finally, Step 3 can be done by a circuit of size $\widetilde{O}(\aleph)$, using the efficient extractor (Lemma 20) and the limited-independence generator (Lemma 16). ◀

5 Almost-quadratic lower bounds against arbitrary basis formulas and branching programs

The MCSP lower bounds against formulas, over an arbitrary basis, and branching programs are obtained similarly to those for de Morgan formulas in the previous section. The idea is to construct strongly local PRGs against these models by modifying the PRGs in [10].

▶ **Lemma 24.** *For any $s \geq n$, there exists a $\left(N, s, s^{1/2} \cdot 2^{O\left(\sqrt{\log s}\right)}\right)$-local PRG against size-$s$ formulas over an arbitrary basis (or branching programs).*

The MCSP lower bound in Theorem 2 follows from Lemma 24 and Theorem 13.

6 Improved AC^0 lower bounds for MCSP

In this section, we show improved lower bounds for MCSP against constant-depth circuits.

6.1 The case of depth $d > 2$

We first show the improved lower bound against circuits of depth $d > 2$ that almost matches the lower bound for PARITY.

▶ **Theorem 25** (Theorem 3 restated). *For every $d > 2$ and every constant $\gamma > 0$, any depth-d AC^0 circuit computing MCSP on truth tables of length N must have size $2^{\Omega\left(N^{1/(d+2+\gamma)}\right)}$.*

The above result is proved using the following structural property of small-depth circuits, which says that for any such circuit, there exists some locally computable restriction that simplifies the circuits to be a constant while leaving many variables unrestricted.

▶ **Lemma 26.** *For any size-s depth-d circuit C, there exists a restriction $\rho \in \{0,1,*\}^N$ such that C_ρ is a constant function, $\left|\rho^{-1}(*)\right| \geq \frac{N}{O(\log s)^{d-2}} - \log s$, and there exists a circuit of size $d \cdot \log(N) \cdot \widetilde{O}\left(\log^3 s\right)$ such that, given $j \in \{0,1\}^{\log N}$, the circuit computes the j-th coordinate of ρ.*

The proof of Lemma 26, presented in the full version, uses the pseudorandom switching lemma due to Trevisan and Xue [21], which says that a depth-2 circuit is likely to be simplified after hit by a pseudorandom restriction. We now prove Theorem 25.

Proof of Theorem 25. Let C be a depth-d AC^0 circuit on $\{0,1\}^N \times \{0,1\}^{\log N}$ such that C computes MCSP on truth tables of length N, and let s be the size of C.

For a size parameter $\lambda = d \cdot \log(N) \cdot \widetilde{O}\left(\log^3 s\right)$, let $C' = C(\cdot, \lambda)$. Let ρ be a restriction from Lemma 26 for C'. By Lemma 26, we have that C'_ρ is a constant function. First note that $C'_\rho(0^{|\rho^{-1}(*)|}) = 1$. To see this, note that $C'_\rho(0^{|\rho^{-1}(*)|}) = C(\mathtt{tt}(f), \lambda)$, where C computes MCSP and $f\colon \{0,1\}^{\log N} \to \{0,1\}$ is the following:

$$f(j) = \begin{cases} 0, & \text{if } \rho_j = 0 \text{ or } \rho_j = *, \\ 1, & \text{else if } \rho_j = 1. \end{cases}$$

By Item 3 of Lemma 26, such a function f can be computed by a λ-size circuit. On the other hand, there can be $2^{|\rho^{-1}(*)|}$ different functions corresponding to the different partial assignments to the unrestricted variables. Since there are at most $O(\lambda \log \lambda)$ different circuits of size at most λ, in order for C'_ρ to be the constant 1, we must have $2^{O(\lambda \log \lambda)} \geq 2^{|\rho^{-1}(*)|} = 2^{\frac{N}{O(\log s)^{d-2}} - \log s}$, which, by a simple calculation, implies $s = 2^{\Omega\left(N^{1/(d+2+\gamma)}\right)}$, for any $\gamma > 0$. ◀

6.2 The case of depth 2

Here we show that computing MCSP requires depth-2 circuits of almost maximum size.

▶ **Theorem 27** (Theorem 4 restated). *Any CNF or DNF computing* MCSP *on truth tables of length N must have size $2^{N/\widetilde{O}\left(\log^2 N\right)}$.*

The proof uses a variant of Lemma 26 which says that a depth-2 circuit can be made constant via a more efficient restriction. Given such a local restriction, it is straightforward to prove Theorem 27 following the argument in the proof of Theorem 25.

7 Open problems

Our de Morgan formula lower bound for MCSP is still slightly weaker than the state-of-the-art de Morgan formula lower bound due to Tal [19], which is $\Omega\left(N^3/\left(\log N \cdot (\log\log N)^2\right)\right)$. Can the MCSP lower bound be improved? Are there better constructions of local PRGs against formulas? Or, are there alternative proofs that do not rely on local PRGs?

A similar question can be asked for small-depth circuits. In particular, can we show that MCSP requires depth-2 circuits (i.e., CNFs or DNFs) of size $2^{\Omega(N)}$, as in the case of PARITY?

What are other restricted models of computation against which we can show MCSP lower bounds using local PRGs? The recent "random walk PRG" by Chattopadhyay, Hatami, Hosseini, and Lovett [3] is also local and can be used to get MCSP lower bounds. However, as a general PRG that can be used to fool a variety of restricted models, it has sub-optimal usefulness (which is determined by its seed length) compared to the best-known lower bounds for most of those models.

The Norms of Graph Spanners

Abstract

A t-spanner of a graph G is a subgraph H in which all distances are preserved up to a multiplicative t factor. A classical result of Althöfer et al. is that for every integer k and every graph G, there is a $(2k-1)$-spanner of G with at most $O(n^{1+1/k})$ edges. But for some settings the more interesting notion is not the number of edges, but the degrees of the nodes. This spurred interest in and study of spanners with small maximum degree. However, this is not necessarily a robust enough objective: we would like spanners that not only have small maximum degree, but also have "few" nodes of "large" degree. To interpolate between these two extremes, in this paper we initiate the study of graph spanners with respect to the ℓ_p-norm of their degree vector, thus simultaneously modeling the number of edges (the ℓ_1-norm) and the maximum degree (the ℓ_∞-norm). We give precise upper bounds for all ranges of p and stretch t: we prove that the greedy $(2k-1)$-spanner has ℓ_p norm of at most $\max(O(n), O(n^{\frac{k+p}{kp}}))$, and that this bound is tight (assuming the Erdős girth conjecture). We also study universal lower bounds, allowing us to give "generic" guarantees on the approximation ratio of the greedy algorithm which generalize and interpolate between the known approximations for the ℓ_1 and ℓ_∞ norm. Finally, we show that at least in some situations, the ℓ_p norm behaves fundamentally differently from ℓ_1 or ℓ_∞: there are regimes ($p = 2$ and stretch 3 in particular) where the greedy spanner has a provably superior approximation to the generic guarantee.

1 Introduction

Graph spanners are subgraphs which approximately preserve distances. Slightly more formally, given a graph $G = (V, E)$ (possibly with lengths on the edges), a subgraph H of G is a *t-spanner* of G if $d_G(u, v) \leq d_H(u, v) \leq t \cdot d_G(u, v)$ for all $u, v \in V$, where d_G denotes shortest-path distances in G (and d_H in H). The value t is called the *stretch* of the spanner.

Graph spanners were originally introduced in the context of distributed computing [27, 26], but have since proved to be a fundamental building block that is useful in a variety of applications, from property testing [7] to network routing [28]. When building spanners there are many objectives which we could try to optimize, but probably the most popular is the number of edges (the *size* or the *sparsity*). Not only is sparsity important in many applications, it also admits a beautiful tradeoff with the stretch, proved by Althöfer et al. [2]:

▶ **Theorem 1** ([2]). *For every integer $k \geq 1$ and every weighted graph $G = (V, E)$ with $|V| = n$, there is a $(2k-1)$-spanner H of G with at most $O(n^{1+1/k})$ edges.*

While understanding the tradeoff between the size and the stretch was a seminal achievement, for many applications (particularly in distributed computing) we care not just about the size, but also about the *maximum degree*. Unfortunately, unlike the size, there is no possible tradeoff between the stretch and the maximum degree. This is trivial to see: if G is a star, then the only spanner of G with non-infinite stretch has maximum degree of $n-1$. In general, if G has maximum degree Δ, then all we can say is the trivial fact that G has a spanner with maximum degree at most Δ. Nevertheless, given the importance of the maximum degree objective, there has been significant work on building spanners that minimize the maximum degree from the perspective of *approximation algorithms* [23, 10, 9]. From this perspective, we are given a graph G and stretch value t and are asked to find the "best" t-spanner of G (where "best" means minimizing the maximum degree).

While this has been an interesting and productive line of research, clearly there are problems with the maximum degree objective as well. For example, if it is unavoidable for there to be some node of large degree d, the maximum degree objective allows us to make every other vertex also of degree d, with no change in the objective function. But clearly we would prefer to have fewer high-degree nodes if possible!

So we are left with a natural question: can we define a notion of "cost" of a spanner which discourages very high degree nodes, but if there are high degree nodes, still encourages the rest of the nodes to have small degree? There is of course an obvious candidate for such a cost function: the ℓ_p norm of the degree vector. That is, given a spanner H, we can define $\|H\|_p$ to be the ℓ_p-norm of the n-dimensional vector in which the coordinate corresponding to a node v contains the degree of v in H. Then $\|H\|_1$ is just (twice) the total number of edges, and $\|H\|_\infty$ is precisely the maximum degree. Thus the ℓ_p-norm is an interpolation between these two classical objectives. Moreover, for $1 < p < \infty$, this notion of cost has precisely the properties that we want: it encourages low-degree nodes rather than high-degree nodes, but if high-degree nodes are unavoidable it still encourages the rest of the nodes to be as low-degree as possible. These properties, of interpolating between the average and the maximum, are why the ℓ_p-norm has appeared as a popular objective for a variety of problems, ranging from clustering (the famous k-means problem [22, 24]), to scheduling [4, 3, 1], to covering [21].

1.1 Our Results and Techniques

In this paper we initiate the study of graph spanners under the ℓ_p-norm objective. We prove a variety of results, giving upper bounds, lower bounds, and approximation guarantees. Our main result is the analog of Theorem 1 for the ℓ_p-norm objective, but we also characterize universal lower bounds as part of an effort to understand the generic approximation ratio for the related optimization problem. We also show that in some ways the ℓ_p-norm can behave fundamentally differently than the traditional ℓ_1 or ℓ_∞ norms, by proving that the greedy algorithm can have an approximation ratio that is *strictly better* than the generic guarantee, unlike the ℓ_1 or ℓ_∞ settings.

1.1.1 Upper Bound

We begin by proving our main result: a universal upper bound (the analog of Theorem 1) for ℓ_p-norm spanners. Recall the classical greedy algorithm for constructing a t-spanner H of a graph $G = (V, E)$. Consider the edges in nondecreasing order of edge length, and when considering edge $\{u, v\}$, add it to H if currently $d_H(u, v) > t \cdot d_G(u, v)$. We call H the *greedy*

t-spanner of G. It is trivial to show that the greedy t-spanner has girth at least $t+2$. This is the algorithm that was used to prove Theorem 1, and it has since received extensive study (see, e.g., [20, 8]) and will form the basis of our upper bound:

▶ **Theorem 2.** *Let $k \geq 1$ be an integer, let $G = (V, E)$ be a graph (possibly with lengths on the edges), and let $H = (V, E_H)$ be the greedy $(2k-1)$-spanner of G. Then $\|H\|_p \leq \max\left(O(n), O\left(n^{\frac{k+p}{kp}}\right)\right)$ for all $p \geq 1$.*

In other words, if $p \geq \frac{k}{k-1}$ then our upper bound is $O(n)$, and otherwise it is $O\left(n^{\frac{k+p}{kp}}\right)$. Clearly this interpolates between $p = 1$ and $p = \infty$: when $p = 1$ this is the same bound as Theorem 1, while if $p = \infty$ this gives $O(n)$ which is the only possible bound in terms of n. To get some more intuition for this bound, note that $n^{\frac{k+p}{kp}}$ would be the ℓ_p-norm of H if H had the size guaranteed by Theorem 1 and was also regular. So one way to think of this bound is that while the greedy spanner can be non-regular, its ℓ_p-norm still acts as if it were regular.

It is also straightforward to prove that this bound is tight if we again assume the Erdős girth conjecture [19]; for completeness, we do this in the full version [12].

The proof of Theorem 1 from [2] is relatively simple: the greedy $(2k-1)$-spanner has girth at least $2k+1$, and any graph with more than $n^{1+1/k}$ edges must have a cycle of length at most $2k$. Generalizing this to the ℓ_p-norm is significantly more complicated, since it is not nearly as easy to show a relationship between the girth and the ℓ_p-norm. But this is precisely what we do.

It turns out to be easiest to prove Theorem 2 for stretch 3: it just takes one more step beyond [2] to split the vertices of the high-girth graph (the spanner) into "low" and "high" degrees, and show that each vertex set does not contribute too much to the ℓ_p norm. However for larger stretch values this approach does not work: the main lemma used for stretch 3 (Lemma 5) is simply false when generalized to larger stretch bounds. Instead, we need a much more involved decomposition into "low", "medium", and "high"-degree nodes. This decomposition is very subtle, since the categories are not purely about the degree, but rather about how the degree relates to expansion at some particular distances from the node. We also need to further decompose the "high"-degree nodes into sets determined by which distance level we consider the expansion of. We then separately bound the contribution to the p-norm of each class in the decomposition; for "low"-degree nodes this is quite straightforward, but for medium and high-degree nodes this requires some subtle arguments which strongly use the structure of large-girth graphs.

1.1.2 Universal Lower Bounds

To motivate our next set of results, consider the optimization problem of finding the "best" t-spanner of a given input graph. When "best" is the smallest ℓ_1-norm this is known as the Basic t-Spanner problem [16, 5, 15, 18], and when "best" is the smallest ℓ_∞-norm this is the Lowest-Degree t-Spanner problem [23, 10, 9]. It is natural to consider this problem for the ℓ_p-norm as well. It is also natural to consider how well the greedy algorithm (used to prove the upper bound of Theorem 2) performs as an approximation algorithm.

To see an obvious way of analyzing the greedy algorithm as an approximation algorithm, consider the ℓ_1-norm. Theorem 1 implies that the greedy algorithm always returns a spanner of size at most $O(n^{1+1/k})$, while clearly *every* spanner must have size at least $\Omega(n)$ (assuming that the input graph is connected). Thus we immediately get that the greedy algorithm is an $O(n^{1/k})$-approximation. By dividing a universal upper bound (an upper bound on the size of the greedy spanner that holds for every graph) by a universal lower bound (a lower bound on the size of *every* spanner in every graph), we can bound the approximation ratio in a way that is generic, i.e., that is essentially independent of the actual graph.

Now consider the ℓ_∞-norm. The generic approach seems to break down here: the universal upper bound is only $\Theta(n)$ (as shown by the star graph), while the universal lower bound is only $\Theta(1)$ (as shown by the path). So it seems like the generic guarantee is just the trivial $\Theta(n)$. But this is just because n is the wrong parameter in this setting: the correct parameterization is based on Δ, the maximum degree of G (i.e., $\Delta = \|G\|_\infty$). With respect to Δ, the greedy algorithm (or any algorithm) returns a spanner with maximum degree at most Δ, while *any* t-spanner of a graph with maximum degree Δ must have maximum degree at least $\Omega(\Delta^{1/t})$ (assuming the graph is unweighted). So there is still a "generic" guarantee which implies that the greedy algorithm is an $O(\Delta^{1-1/t}) \leq O(n^{1-1/t})$-approximation.

This suggests that for $1 < p < \infty$, we will need to parameterize by *both* the number of nodes n and the ℓ_p-norm Λ of G. We can define both universal upper bounds and universal lower bounds with respect to this dual parameterization:

$$\mathrm{UB}_t^p(n,\Lambda) = \max_{\substack{G=(V,E):|V|=n,\|G\|_p=\Lambda, \\ \text{and } G \text{ is connected}}} \min_{H:\ H \text{ is a } t\text{-spanner of } G} \|H\|_p$$

$$\mathrm{LB}_t^p(n,\Lambda) = \min_{\substack{G=(V,E):|V|=n,\|G\|_p=\Lambda, \\ \text{and } G \text{ is connected}}} \min_{H:\ H \text{ is a } t\text{-spanner of } G} \|H\|_p$$

With this notation, we can define the generic guarantee $g_t^p(n,\Lambda) = \mathrm{UB}_t^p(n,\Lambda)/\mathrm{LB}_t^p(n,\Lambda)$, and if we want a guarantee purely in terms of n we can define the generic guarantee $g_t^p(n) = \max_\Lambda g_t^p(n,\Lambda)$. Our upper bound of Theorem 2 can then be restated as the claim that $\mathrm{UB}_{2k-1}^p(n,\Lambda) \leq \min\left\{\Lambda, \max\left\{O(n), O(n^{\frac{k+p}{kp}})\right\}\right\}$ for all n,k,p,Λ. So in order to understand the generic guarantees $g_{2k-1}^p(n,\Lambda)$ or $g_{2k-1}^p(n)$, we need to understand the universal lower bound quantity $\mathrm{LB}_{2k-1}^p(n,\Lambda)$.

Surprisingly, unlike the ℓ_1 and ℓ_∞ cases, the universal lower bound for other values of p is extremely complex. Understanding its value, and understanding the structure of the extremal graphs which match the bound given by $\mathrm{LB}_t^p(n,\Lambda)$, are the most technically involved results in this paper. However, while the analysis and even the exact formulation of the lower bound is quite complex, it turns out to be easily computable from a simple linear program:

▶ **Theorem 3.** *There is an explicit linear program of size $O(t)$ which calculates $\mathrm{LB}_t^p(n,\Lambda)$ for any $t \in \mathbb{N}, p \geq 1$. The bound given by the program is tight up to a factor of $\log(n)^{O(t)}$.*

Our linear program and the proof of Theorem 3 appear in the full version [12]. In fact, our linear program not only calculates a lower bound on the ℓ_p-norm of any t-spanner, it also gives the parameters which define an extremal graph of ℓ_p-norm Λ with a t-spanner whose ℓ_p-norm matches this lower bound. While the structure of these extremal graphs is simple, the dependence of the parameters of these graphs on t and p is quite complex. Nevertheless, we give a complete explicit description of these graphs for every possible value of p, t.

Interestingly, despite the fact that $\mathrm{LB}_t^p(n,\Lambda)$ is fundamentally a question of extremal graph theory (although as discussed our motivation is the generic guarantee on approximation algorithms), our techniques are in some ways more related to approximation algorithms. We give a linear program which computes the LB function, and we reason about it by explicitly constructing dual solutions. This is, to the best of our knowledge, the first time that structural bounds on spanners (as opposed to approximation bounds) have been derived using linear programs. Moreover, the structure of the extremal graphs is fundamentally related to a quantity which we call the *p-log density* of the input graph. This is a generalization of the notion of "log-density", which was introduced as the fundamental parameter when designing approximation algorithms for the Densest k-Subgraph (DkS) problem [6], and has since proved useful in many approximation settings (see, e.g., [10, 11, 14, 13]).

1.1.3 Greedy Can Do Better Than The Generic Bound

As discussed, when $p = 1$ or $p = \infty$, the approximation ratio of the greedy algorithm can be bounded by the generic guarantee. But it turns out that the connection is actually even closer: when $p = 1$ and $p = \infty$, for every n and Λ the approximation ratio of the greedy algorithm is *equal* to the generic guarantee $g^p_{2k-1}(n, \Lambda)$. In other words, greedy is no better than generic in the traditional settings (we prove this for completeness, but it is essentially folklore). In fact, for the ℓ_1 objective, giving *any* approximation algorithm which is better than the generic guarantee $g^1_{2k-1}(n)$ is a long-standing open problem [18] which has only been accomplished for stretch 3 [5] and stretch 4 [18], while for the ℓ_∞ objective such an improvement was only shown recently [9] (and not with the greedy algorithm).

We show that, at least in some regimes of interest, ℓ_p-norm graph spanners exhibit fundamentally different behavior from ℓ_1 and ℓ_∞: the greedy algorithm has approximation ratio which is *better* than the generic guarantee, even though the universal upper bound is proved via the greedy algorithm! In particular, we consider the regime of stretch 3, $p = 2$, and $\Lambda = \Theta(n)$. This is a very natural regime, since $p = 2$ is the most obvious and widely-studied norm other than ℓ_1 and ℓ_∞, and stretch 3 is the smallest value for which nontrivial sparsification can occur.

Our theorems about UB and LB imply that $g^2_3(n) = g^2_3(n, n) = \Theta(\sqrt{n})$. But we show that in this setting (and in fact for any Λ as long as $p = 2$ and the stretch is 3) the greedy algorithm is an $O(n^{63/128})$-approximation. Thus we show that, unlike ℓ_1 and ℓ_∞, for $p = 2$ the greedy algorithm provides an approximation guarantee that is strictly better than the generic bound, both for specific values of Λ and when considering the worst case Λ.

1.2 Outline

We begin in Section 2 with some basic definitions and preliminaries. In order to illustrate the basic concepts in a simpler and more understandable setting, we then focus in Section 3 on the special case of stretch 3: we prove the stretch-3 version of Theorem 1 in Section 3.1, and then show that the greedy algorithm has approximation ratio better than the generic guarantee in Section 3.2. We then prove our upper and lower bounds in full generality: the upper bound (i.e., the proof of Theorem 2) in Section 4, and then our universal lower bound in Section 5. Due to space constraints, all missing proofs can be found in the appendices.

2 Definitions and Preliminaries

Let $G = (V, E)$ be a graph, possibly with lengths on the edges. For any vertex $u \in V$, we let $d(u)$ denote the degree of u and let $N(u)$ denote the neighbors of u. We will also generalize this notation slightly by letting $N_i(u)$ denote the set of vertices that are exactly i hops away from u (i.e., their distance from u if we ignore lengths is exactly i), and we let $d_i(u) = |N_i(u)|$. Note that by definition, $N_0(u) = \{u\}$ and $d_0(u) = 1$ for all $u \in V$. We will sometimes use $B(v, r) = \cup_{i=0}^{r} N_i(v)$ to denote the ball around v of radius r.

We let $d_G : V \times V \to \mathbb{R}_{\geq 0}$ denote the shortest-path distances in G. A subgraph $H = (V, E_H)$ of a graph $G = (V, E)$ is a *t-spanner* of G if $d_H(u, v) \leq t \cdot d_G(u, v)$ for all $u, v \in E$. Recall that $\|\vec{x}\|_p = (\sum_{i=1}^{n} x_i^p)^{1/p}$ for any $p \geq 1$ and $\vec{x} \in \mathbb{R}^n$. To measure the "cost" of a spanner, for any graph $G = (V, E)$, let $\vec{d_G}$ denote the vector of degrees in G and for any $p \geq 1$, let $\|G\|_p = \|\vec{d_G}\|_p$. For any subset $S \subseteq V$, we let $\|S\|_p$ denote the ℓ_p norm of the vector obtained from $\vec{d_G}$ by removing the coordinate of every node not in S (note that we do not remove the nodes from the graph, i.e., $\|S\|_p$ is the norm of the degrees in G of the nodes in S, not in the subgraph induced by S).

3 Warmup: Stretch 3

We begin by analyzing the special case of stretch 3, particularly for the ℓ_2-norm. More specifically, we will focus on bounding $\text{UB}_3^p(n, \Lambda)$. This is one of the simplest cases, but demonstrates (at a very high level) the outlines of our upper bound. Moreover, in this particular case we can prove that the greedy algorithm performs better than the generic guarantee, showing a fundamental difference between the ℓ_2 norm and the more traditional ℓ_1 and ℓ_∞ norms.

3.1 Upper Bound

Recall that *greedy spanner* is the spanner obtained from the obvious greedy algorithm: starting with an empty graph as the spanner, consider the edges one at a time in nondecreasing length order, and add an edge if the current spanner does not span it (within the given stretch requirement). It is obvious that when run with stretch parameter t this algorithm does indeed return a t-spanner, and moreover it will return a t-spanner that has girth at least $t+2$ (if there is a $(t+1)$-cycle then the algorithm would not have added the final edge).

Our main goal in this section will be to prove the following theorem.

▶ **Theorem 4.** *Let $G = (V, E)$ be a graph and let $H = (V, E_H)$ be the greedy 3-spanner of G. Then $\|H\|_p \leq \max(O(n), O(n^{(2+p)/(2p)}))$ for all $p \geq 1$.*

In other words, when $1 \leq p \leq 2$ the greedy 3-spanner H has $\|H\|_p \leq O(n^{(2+p)/(2p)})$, and when $p \geq 2$ we get that that $\|H\|_p \leq O(n)$.

To prove this theorem, we will first show that nodes with "large" degree cannot be incident with too many edges in any graph of girth at least 5 (like the greedy 3-spanner). This is the most important step, since for $p > 1$ the p-norm of a graph gives greater "weight" to nodes with larger degree.

▶ **Lemma 5.** *Let $G = (V, E)$ be a graph with girth at least 5. Then $\sum_{v \in V : d(v) \geq 2\sqrt{n}} d(v) \leq 2n$.*

Proof. Suppose for the sake of contradiction that these vertices have total degree greater than $2n$, and let $\{v_1, \ldots, v_{\ell+1}\}$ be a minimal set with this property. That is, all these vertices have degree at least $2\sqrt{n}$, and furthermore $\sum_{i=1}^{\ell} d(v_i) \leq 2n < \sum_{i=1}^{\ell+1} d(v)$.

Because G has girth at least 5, any two vertices v_i, v_j in this set have at most one common neighbor. That is, $|N(v_i) \cap N(v_j)| \leq 1$. Thus, for every $j \in [\ell+1]$, the number of "new" neighbors contributed by $N(v_j)$ is $\left|N(v_j) \setminus \left(\bigcup_{i=1}^{j-1} N(V_i)\right)\right| \geq |N(v_j)| - \sum_{i=1}^{j-1} |N(v_i) \cap N(v_j)| \geq d(v_j) - (j-1) \geq d(v_j) - \ell$.

On the other hand, we have $2n \geq \sum_{i=1}^{\ell} d(v_i) \geq \ell \cdot 2\sqrt{n}$, and so we have $\ell \leq \sqrt{n}$. Thus, every v_j contributes at least $d(v_j) - \ell \geq d(v_j) - \sqrt{n} \geq d(v_j)/2$ new neighbors, and so we get $n \geq \left|\bigcup_{j=1}^{\ell+1} N(v_j)\right| = \sum_{j=1}^{\ell+1} \left|N(v_j) \setminus \left(\bigcup_{i=1}^{j-1} N(v_i)\right)\right| \geq \sum_{j=1}^{\ell+1} d(v_j)/2$, which contradicts our assumption that $\sum_{j=1}^{\ell+1} d(v_j) > 2n$. ◀

We can now prove Theorem 4.

Proof of Theorem 4. Let $V_{low} = \{v \in V : d(v) \leq 2\sqrt{n}\}$, and let $V_{high} = \{v \in V : d(v) > 2\sqrt{n}\}$. Since H has girth at least 5, we can apply Lemma 5. So using this lemma and

standard algebraic inequalities, we get that

$$\|H\|_p = \left(\sum_{v\in V_{low}} d(v)^p + \sum_{v\in V_{high}} d(v)^p\right)^{\frac{1}{p}} \leq \left(\sum_{v\in V_{low}} d(v)^p\right)^{\frac{1}{p}} + \left(\sum_{v\in V_{high}} d(v)^p\right)^{\frac{1}{p}}$$
$$\leq \left(\sum_{v\in V_{low}} (2\sqrt{n})^p\right)^{\frac{1}{p}} + \sum_{v\in V_{high}} d(v) \leq \left(n\cdot 2^p n^{p/2}\right)^{\frac{1}{p}} + \sum_{v\in V_{high}} d(v) \leq 2n^{\frac{2+p}{2p}} + 2n,$$

which implies the theorem. ◀

It is easy to show that the above bound is tight: for every $p \geq 1$ there are graphs in which every 3-spanner has size at least $\max(\Omega(n), \Omega(n^{\frac{2+p}{2p}}))$. In fact, we can generalize slightly to also account for different values of Λ. Theorem 2 can be interpreted as claiming that $\mathrm{UB}_3^p(n,\Lambda) \leq O(\min(\max(n, n^{\frac{2+p}{2p}}), \Lambda))$. In the full version [12] we show that this is tight: $\mathrm{UB}_3^p(n,\Lambda) \geq \Omega(\min(\max(n, n^{\frac{2+p}{2p}}), \Lambda))$ for all $p \geq 1$ and $\Omega(n^{1/p}) \leq \Lambda \leq O(n^{\frac{1+p}{p}})$.

3.2 Greedy vs Generic

It is not hard to show that in the traditional settings in which spanners have been studied, the ℓ_1 and ℓ_∞ norms, the greedy algorithm does no better than the generic guarantee, for all relevant parameter regimes. In slightly more detail, for ℓ_∞ it is relatively easy to show that $\mathrm{UB}_t^\infty(n,\Lambda) = \Theta(\Lambda)$, while $\mathrm{LB}_t^\infty(n,\Lambda) = \Theta(\Lambda^{1/t})$. Thus the generic guarantee $g_t^\infty(n,\Lambda) = \Theta(\Lambda^{1-\frac{1}{t}})$, and moreover we can build graphs in which the approximation ratio of the greedy algorithm is also $\Theta(\Lambda^{1-\frac{1}{t}})$. Similarly, for the ℓ_1-norm, classical results on spanners imply that $\mathrm{UB}_{2k-1}^1(n,\Lambda) = \Theta(\min(n^{1+\frac{1}{k}}, \Lambda))$ and $\mathrm{LB}_{2k-1}^1(n,\Lambda) = \Theta(n)$, so the generic guarantee is $g_{2k-1}^1(n,\Lambda) = \Theta(\min(n^{1+\frac{1}{k}}, \Lambda)/n)$ and there are graphs for all parameter regimes where this is the approximation ratio achieved by greedy.

We show that the behavior of the greedy spanner in intermediate ℓ_p-norms is fundamentally different: in some parameter regimes of interest, greedy *outperforms* the generic guarantee!

To demonstrate this, consider the regime of stretch 3 with the ℓ_2 norm and with $\Lambda = n$ in unweighted graphs. In this regime, the results of Section 3.1 imply that $\mathrm{UB}_3^2(n,n) = \Theta(n)$. On the other hand, our results on the universal lower bound from Section 5 (Corollary 19 in particular) directly imply that $\mathrm{LB}_3^2(n,n) = \tilde{\Theta}(\sqrt{n})$. Thus the generic guarantee is $g_3^2(n,n) = \tilde{\Theta}(\sqrt{n})$, and this is the worst case over Λ and thus $g_3^2(n) = \tilde{\Theta}(\sqrt{n})$. However, we show that the greedy algorithm is a strictly better approximation, even without parameterizing by Λ.

▶ **Theorem 6.** *The greedy algorithm is an $O(n^{63/128})$-approximation for the problem of computing the 3-spanner with smallest ℓ_2-norm (where the input is an unweighted graph).*

To prove this, let $G = (V, E)$ be a graph with $|V| = n$, let H be the greedy 3-spanner of G, and let H^* be a 3-spanner of G with minimum ℓ_2-norm. Let $\alpha = \log_n \|H^*\|_2$, so $\|H^*\|_2 = n^\alpha$; note that $\alpha \geq 1/2$. We first prove a lemma which uses $\|H^*\|_2$ to bound neighborhoods.

▶ **Lemma 7.** *$|B_{H^*}(v,r)| \leq n^{2\alpha(1-2^{-r})}$ for all $v \in V$ and $r \in \mathbb{N}$.*

Proof. We use induction on r. For the base case $r = 1$, since $\|H^*\|_2 = n^\alpha$ we know that v has degree less than n^α, and thus $|B_{H^*}(v,1)| \leq n^\alpha = n^{2\alpha(1-2^{-r})}$.

Now suppose that the theorem is true for some integer $r-1$. Let $|B_{H^*}(v,r-1)| = n^\gamma \leq n^{2\alpha(1-2^{-(r-1)})}$ (by induction). Since $\|H^*\|_2 = n^\alpha$, the average degree (in H^*) of the nodes in $B_{H^*}(v,r-1)$ is at most $n^{\alpha-(\gamma/2)}$. Thus we get that $|B_{H^*}(v,r)| \leq n^\gamma \cdot n^{\alpha-(\gamma/2)} = n^{\alpha+(\gamma/2)} \leq n^{\alpha+\alpha(1-2^{-(r-1)})} = n^{2\alpha(1-2^{-r})}$, as claimed. ◀

Using this lemma, we can now prove Theorem 6.

Proof of Theorem 6. Lemma 7 implies that $|B_{H^*}(v,6)| \leq n^{(63/32)\alpha}$ for all $v \in V$. Since H^* is a 3-spanner of G, every vertex in $B_G(v,2)$ must be in $B_{H^*}(v,6)$, and thus $|B_G(v,2)| \leq n^{(63/32)\alpha}$. Now we can use this to bound the number of 2-paths in H. Let $P_2(H)$ denote the number of paths of length 2 in H. Since H is the greedy 3-spanner of G it must have girth at least 5. This means that every path of length 2 in H which starts from v must have a different other endpoint: there cannot be two different paths of the form $v-w-u$ and $v-x-u$ in H, or else H would have girth at most 4. Thus the number of 2-paths in H which start from v is bounded by $|B_H(v,2)| \leq |B_G(v,2)| \leq n^{(63/32)\alpha}$, and thus $P_2(H) \leq n^{1+(63/32)\alpha}$.

On the other hand, note that instead of counting 2-paths in H by their starting vertex, we could instead count them by their middle vertex. The number of 2-paths where v is the *middle* node is $\binom{d_H(v)}{2} \geq d_H(v)^2/4$, and thus $P_2(H) \geq \sum_{v \in V}(d_H(v)^2/4) = \|H\|_2^2/4$. Combining these two inequalities implies that $\|H\|_2 \leq 4n^{\frac{1}{2}+\frac{63}{64}\alpha}$, and hence the greedy spanner has approximation ratio of at most $\frac{\|H\|_2}{\|H^*\|_2} \leq \frac{4n^{\frac{1}{2}+\frac{63}{64}\alpha}}{n^\alpha} = 4n^{\frac{1}{2}-\frac{1}{64}\alpha} \leq 4n^{\frac{1}{2}-\frac{1}{128}} = 4n^{63/128}$. ◀

4 Upper Bound: General Stretch

We now want to generalize the bounds from Section 3 to hold for larger stretch ($2k-1$ in particular) in order to prove Theorem 2. A natural approach would be an extension of the stretch 3 analysis: if in Lemma 5 we replaced the bound of $2\sqrt{n}$ with $2n^{1/k}$, then the proof of Theorem 4 could easily be extended to prove Theorem 2. Unfortunately this is impossible: there are graphs of girth at least $2k+1$ where it is not true that the number of edges incident with nodes of degree at least $2n^{1/k}$ is at most $O(n)$. This can be seen from, e.g., [25] for $k=3$.

So we cannot just break the vertices into "high-degree" and "low-degree" as we did for stretch 3. Instead, our decomposition is more complicated. We will still have low-degree nodes, which can be analyzed trivially. But our definition of "high" will actually be parameterized by a distance j, and we will define a node to be "high-degree" at distance j if its degree is large relative to the expansion of its neighborhood at approximately distance j. We will also introduce a new type of "medium-degree" node. In Section 4.1 we define this decomposition and prove that it is a full decomposition of V, and then in Sections 4.2 and 4.3 we show that no part in this decomposition can contribute too much to the overall cost.

First, though, we make one simple observation that will allow us to simplify notation by only considering one particular value of p. While we could analyze general values of p as we did for stretch 3 in Section 3.1, it is actually sufficient to prove the bound for the special case of k and p where the two terms in the maximum are equal, i.e., when $\frac{k+p}{kp} = 1$.

▶ **Lemma 8.** *Let $k \geq 1$ be an integer, let $G=(V,E)$ be a graph, and let $H=(V,E_H)$ be the greedy $(2k-1)$-spanner of G. If $\|H\|_{p'} = O(n)$ for $p' = k/(k-1)$ then $\|H\|_p \leq \max\left(O(n), O\left(n^{\frac{k+p}{kp}}\right)\right)$ for all $p \geq 1$.*

Proof. First note that $p' = k/(k-1)$ if and only if $\frac{k+p'}{kp'} = 1$. So we break into two cases, one for $p > p'$ and one for $1 \leq p < p'$. For the first case, where $p > p'$, the result follows simply because of the monotonicity of p-norms: $\|H\|_p \leq \|H\|_{p'} = O(n) = \max(O(n), O(n^{\frac{k+p}{kp}}))$.

For the second case, where $1 \leq p < p'$, let q be the value such that $1 \leq p \leq p'$ and $\frac{1}{p'} + \frac{1}{q} = \frac{1}{p}$. Recall that $\vec{d_H}$ is the degree vector of H. Then Hölder's inequality implies that $\|\vec{d_H}\|_p \leq \|\vec{d_H}\|_{p'}\|1\|_q = n^{\frac{1}{p}-\frac{1}{p'}}\|\vec{d_H}\|_{p'}$. Since by assumption we have $\|\vec{d_H}\|_{p'} \leq O(n)$, this implies that $\|H\|_p \leq O(n^{1+\frac{1}{p}-\frac{1}{p'}}) = O(n^{\frac{1}{p}-\frac{k-1}{k}+1}) = O(n^{\frac{k+p}{kp}})$, as claimed. ◀

4.1 Graph Decomposition

Recall that $d_i(v)$ denotes the number of vertices at distance exactly i from v. This will let us define the following vertex sets.

▶ **Definition 9.** *Let $G = (V, E)$ be a graph of girth at least $2k + 1$, with $k \geq 3$. Then define*

$$V_{low} = \{v \in V : d_1(v) \leq n^{1/k}\}$$
$$V_{med} = \{v \in V : n^{(k-2)/(k-1)} d_1(v)^{1/(k-1)} \leq d_{k-1}(v)\}$$
$$V_{high,j} = \{v \in V : d_{k-2j-1}(v) \leq n^{1/(k-1)} d_{k-2j-3}(v) d_1(v)^{(k-2)/(k-1)}\},$$

where $0 \leq j \leq \lfloor (k-3)/2 \rfloor$.

It is not hard to see that this notion of high still corresponds to a deviation from regularity, as in the stretch 3 setting; the difference is that this deviation is relative to the size of the neighborhood at distance $k - 2j - 1$ vs the neighborhood at distance $k - 2j - 3$.

As we will see in Sections 4.2 and 4.3, analyzing the contribution of $V_{high,j}$ to the p-norm of the greedy spanner is in some sense the "main" technical step: analyzing V_{low} is straightforward, and analyzing V_{med}, while nontrivial, turns out to be easier than the case for $V_{high,j}$. Before we do this, though, we will show that we have a full decomposition of V:

▶ **Theorem 10.** *Let $G = (V, E)$ be a graph of girth at least $2k + 1$, with $k \geq 3$. Then $V = V_{low} \cup V_{med} \cup \left(\cup_{0 \leq j \leq \lfloor (k-3)/2 \rfloor} V_{high,j}\right)$.*

Proof. We prove the case when k is odd. The even case is similar. Assume that $v \notin \cup_{0 \leq j \leq \lfloor (k-3)/2 \rfloor} V_{high,j}$. Then by the definition of $V_{high,j}$, we know that $d_{k-2j-1}(v) > n^{1/(k-1)} d_{k-2j-3}(v) d_1(v)^{(k-2)/(k-1)}$ for all j. Then a straightforward induction on j implies that

$$d_{k-1}(v) > n^{1/2} d_1(v)^{(k-2)/2}. \tag{1}$$

If further we assume that $v \notin V_{low}$, then $d_1(v) > n^{1/k}$, and thus

$$(d_1(v))^{k(k-3)/(2(k-1))} > n^{(k-3)/(2(k-1))}. \tag{2}$$

Finally, assuming that $v \notin V_{med}$ implies that

$$n^{(k-2)/(k-1)} (d_1(v))^{1/(k-1)} > d_{k-1}(v). \tag{3}$$

If we then multiply inequalities (1), (2) and (3), after some elementary algebra we find that $1 > 1$, a contradiction. Thus $v \in V_{low} \cup V_{med} \cup \left(\cup_{0 \leq j \leq \lfloor (k-3)/2 \rfloor} V_{high,j}\right)$. ◀

4.2 Structural Lemmas for High-Girth Graphs

With Theorem 10 in hand, it remains to bound the contribution to the p-norm of the spanner of these different vertex sets. In order to do this, we start with a few useful lemmas (proofs can be found in the full version [12]). We first give a simple lemma: if the girth is large enough, then the neighborhoods around a node can be bounded by the neighborhoods around its neighbors.

▶ **Lemma 11.** *Let $G = (V, E)$ have girth at least $2k+1$ with $k \geq 2$. Then $\sum_{w \in N_1(v)} d_{k-1}(w) \leq d_k(v) + d_1(v) d_{k-2}(v)$ for all $v \in V$.*

With this lemma in hand, we will now prove a more complicated technical lemma which will likewise hold for all high-girth graphs. For a given v, w with $v \in N(w)$, we can consider the fraction of the k-neighborhood of w which is also contained in the $(k-1)$-neighborhood of v. Then if we sum this fraction over all neighbors v of w, we would of course get 1 since the girth constraint would imply that any two neighbors of v cannot both be first hops on paths to the same node in $N_k(w)$. But what if we consider the slightly different ratio of $d_{k-1}(v)/d_k(w)$? This is notably different since it includes in the numerator not just $N_{k-1}(v) \cap N_k(w)$, but also $N_{k-1}(v) \cap N_{k-2}(w)$. It will prove useful for us to reason about these values, so we show that "on average" they behave approximately the same: if we sum over the neighbors of any given node then these fractions can add up to something quite large (not 1), but overall they only add up to $O(n)$.

▶ **Lemma 12.** *Let $k \geq 1$ be an integer, and let $G = (V, E)$ have girth at least $2k+1$ and minimum degree at least 4. Then $\sum_{w \in V} \sum_{v \in N(w)} \frac{d_{k-1}(v)}{d_k(w)} \leq 2n$.*

The proof of this lemma is quite technical, but is done with an induction on k and careful use of the arithmetic-harmonic mean inequality. While Lemma 12 is the main structural result that we will use to bound the "high" degree nodes, the following corollary makes it slightly simpler to use.

▶ **Corollary 13.** *Let $k \geq 2$ be an integer, and let $G = (V, E)$ have girth at least $2k+1$ and minimum degree at least 4. Then $\sum_{v \in V} \frac{(d_1(v))^2 d_{k-2}(v)}{d_k(v) + d_1(v) d_{k-2}(v)} \leq 2n$.*

4.3 Proving Theorem 2

We can now finally prove Theorem 2 by analyzing the contribution of the different sets in the decomposition to any graph of girth at least $2k+1$ (in particular, the greedy $(2k-1)$-spanner). All missing proofs can be found in the full version [12].

The analysis of the low nodes is straightforward, while the analysis of the medium nodes is slightly more complex. But the main difficulty is in the high nodes.

▶ **Lemma 14.** *Let $k \geq 2$ be an integer, let $p = \frac{k}{k-1}$, and let $G = (V, E)$ have girth at least $2k+1$. Then $\|V_{low}\|_p \leq n$.*

We next bound the medium nodes.

▶ **Lemma 15.** *Let $k \geq 2$ be an integer, let $p = \frac{k}{k-1}$, and let $G = (V, E)$ have girth at least $2k+1$. Then $\|V_{med}\|_p \leq n$.*

We now bound the high nodes, with one degree assumption which we will later remove.

▶ **Lemma 16.** *Let $G = (V, E)$ be a graph of girth at least $2k+1$ with $k \geq 3$. Further assume that the graph has minimum degree at least 4. Then $\|V_{high,j}\|_{k/(k-1)} = O(n)$ for all $0 \leq j \leq \lfloor (k-3)/2 \rfloor$.*

Proof. We will break the high nodes into the following two sets:

$$V'_{high,j} = \{v \in V_{high,j} : d_{k-2j-1}(v) \geq d_{k-2j-3}(v) d_1(v)\}$$
$$V''_{high,j} = \{v \in V_{high,j} : d_{k-2j-1}(v) < d_{k-2j-3}(v) d_1(v)\}.$$

Obviously $V_{high,j} = V'_{high,j} \cup V''_{high,j}$, so we can bound each of the two sets separately. For the first set, we get that

$$\|V'_{high,j}\|_{\frac{k}{k-1}} = \left(\sum_{v \in V'_{high,j}} (d_1(v))^{\frac{k}{k-1}} \right)^{\frac{k-1}{k}} \leq \left(\sum_{v \in V'_{high,j}} \frac{n^{\frac{1}{k-1}} d_1(v)^2 d_{k-2j-3}(v)}{d_{k-2j-1}(v)} \right)^{\frac{k-1}{k}}$$
$$\leq \left(2 \sum_{v \in V'_{high,j}} \frac{n^{\frac{1}{k-1}} d_1(v)^2 d_{k-2j-3}(v)}{d_{k-2j-1}(v) + d_1(v) d_{k-2j-3}(v)} \right)^{\frac{k-1}{k}} \leq 4n.$$

The first inequality is from the definition of V_{high}, the second is from the definition of V'_{high}, and the final inequality is from Corollary 13.

To analyze V''_{high}, note that $d_{k-2j-1}(v) + d_1(v) d_{k-2j-3}(v) < 2 d_1(v) d_{k-2j-3}(v)$ by definition for all $v \in V''_{high,j}$. Combining this with Corollary 13 implies that

$$\|V''_{high,j}\|_{k/(k-1)} \leq \|V''_{high,j}\|_1 = \sum_{v \in V''_{high,j}} d_1(v) = \sum_{v \in V''_{high,j}} \frac{d_1(v)^2 d_{k-2j-3}(v)}{d_1(v) d_{k-2j-3}(v)}$$
$$\leq 2 \sum_{v \in V''_{high,j}} \frac{d_1(v)^2 d_{k-2j-3}(v)}{d_{k-2j-1}(v) + d_1(v) d_{k-2j-3}(v)} \leq 4n.$$

Thus $\|V_{high,j}\|_{k/(k-1)} \leq \|V'_{high,j}\|_{k/(k-1)} + \|V''_{high,j}\|_{k/(k-1)} \leq 8n$. ◀

Putting this all together gives the following theorem.

▶ **Theorem 17.** *Let $G = (V, E)$ have girth at least $2k+1$, $k \geq 2$ and minimum degree at least 4. Then $\|G\|_p \leq O(kn)$ for $p = \frac{k}{k-1}$.*

Proof. We know from Theorem 10 that $V = V_{low} \cup V_{med} \cup \left(\cup_{0 \leq j \leq \lfloor (k-3)/2 \rfloor} V_{high,j} \right)$ for $k \geq 3$. Thus $\|G\|_p \leq \|V_{low}\|_p + \|V_{med}\|_p + \sum_{j=0}^{\lfloor (k-3)/2 \rfloor} \|V_{high,j}\|_p \leq O(kn)$, where we used Lemmas 14, 15, 16, to bound the contribution of each set. If $k = 2$ then $V_{med} = V$ and the proof is similar (alternatively see Theorem 4). ◀

We can now remove the degree assumption and the restriction to $p = \frac{k}{k-1}$, to finally prove Theorem 2.

Proof of Theorem 2. The case of $k = 1$ is trivial since every graph H has $\|H\|_p \leq O(n^{\frac{p+1}{p}})$. For $k \geq 2$, by Lemma 8, we may assume that $p = \frac{k}{k-1}$. We will use induction on the number of vertices of degree less than 4. If H has no vertices with degree less than 4, then Theorem 17 implies Theorem 2. Otherwise, let $v \in V$ be a vertex of degree at most 3, and let $G' = G - v$ be the graph obtained by removing v. Then it is easy to see that $\|\vec{d_G} - \vec{d_{G'}}\|_1 \leq 6$, since one entry in the degree vector of value at most 3 gets removed and at most three other entries get decreased by 1. Thus we can use triangle inequality and monotonicity of norms to get that $\|G\|_p - \|G'\|_p \leq \|\vec{d_G} - \vec{d_{G'}}\|_p \leq \|\vec{d_G} - \vec{d_{G'}}\|_1 \leq 6$. Hence by the induction hypothesis we get that $\|G\|_p \leq O(kn)$ as required. ◀

5 Universal Lower Bound

As stated in Theorem 3, our lower bound can be calculated by a simple linear program of size $O(t)$ (where t is the stretch). We give this linear program formally in the full version [12]. The linear program assumes that the graph has a fairly regular structure. In particular, it

assumes that the extremal t-spanner H is a layered graph with $t+1$ layers $V_0, \ldots, V_t$, such that the subgraph induced on every two subsequent layers V_i, V_{i+1} is bipartite and biregular (in each side, all vertices have the same degree), and that the original extremal graph G (the graph whose spanner H achieves the lower bound) in addition has a biregular graph between V_0 and V_t which contributes most of the p-norm of G, and is spanned by the layered graph H. Such a spanner H can be briefly described by the cardinalities of the layers V_i and the degrees of the bipartite graphs connecting every two consecutive layers.

As we show, this assumption is without loss of generality, in the sense that pruning any graph to obtain this structure can change the p-norm of the graph or its spanner by at most a polylogarithmic factor. The linear program captures the constraints that the parameters of a spanner with such a regular structure must satisfy. These constraints are also sufficient in the sense that given any solution to the linear program, we can construct a graph G and spanner H of this form with the parameters given by this LP solution.

In fact, the extremal spanners which match our lower bound have a fairly specific structure with consistent properties:

- The layers in the extremal can be partitioned into three sections: an initial section in which we have layers of decreasing size $|V_0| \geq |V_1| \ldots \geq |V_L|$, a middle section consisting of equal size layers $|V_L| = \ldots = |V_{L+C}|$, and a final section with layers of increasing size $|V_{L+C}| \leq \ldots \leq |V_{L+C+R}|$. In some cases one of the first two sections may be missing.
- The bipartite graphs between every two consecutive layers in the spanner have the same contribution to the p-norm of the spanner.
- In addition to the edges in the spanner, the original graph also contains a biclique between the outer layers V_0 and V_t, so that $\|G\|_p = \Theta(|V_0|^{1/p}|V_t|)$.

The structure of these spanners has the property that given the lengths of the three sections, we can derive the exact structure of the spanner, and hence the exact value of the lower bound. In our analysis, we focus on this specific family of graphs, and show that it suffices to describe our lower bound.

While the lower bound for $p = 1$ or $p = \infty$ is simple, it turns out that the lower bound for intermediate values of p is quite complex, and depends on the stretch t, the norm parameter p, and the p-norm of the input graph Λ in a highly non-trivial way. To identify the extremal spanners and prove their optimality, we look at the dual of our linear program, and for every graph in our family of candidate extremal spanners, examine whether there exists a dual solution which satisfies complementary slackness w.r.t. the primal LP solution corresponding to our spanner. With this approach, for every p, t, Λ, we are able to identify the exact constraints that the parameters of an optimal spanner from our family must satisfy, and give an explicit solution, which gives our lower bound.

As an example, our analysis identifies the lower bound for relatively low values of p.

▶ **Theorem 18.** *If t is even, then for all $p \in [1, \varphi]$ (where $\varphi = \frac{1+\sqrt{5}}{2}$ is the golden ratio),*

$$\mathrm{LB}_t^p(n, \Lambda) = \tilde{\Theta}\left(\max\left\{n^{1/p}, \Lambda^{\alpha}\right\}\right) \text{ for } \alpha = 1/\left((p+1)\left(1 - ((p-1)/p)^{t/2}\right)\right).$$

If t is odd, then for all $p \in [1, 2]$,

$$\mathrm{LB}_t^p(n, \Lambda) = \tilde{\Theta}\left(\max\left\{n^{1/p}, \Lambda^{\beta}\right\}\right) \text{ for } \beta = 1/\left(1 + p\left(1 - ((p-1)/p)^{(t-1)/2}\right)\right).$$

▶ **Corollary 19.** *For all $p \in [1, \varphi]$, we have $\mathrm{LB}_2^p(n, \Lambda) = \tilde{\Theta}\left(\max\left\{n^{1/p}, \Lambda^{p/(p+1)}\right\}\right)$. For all $p \in [1, 2]$, we have $\mathrm{LB}_3^p(n, \Lambda) = \tilde{\Theta}\left(\max\left\{n^{1/p}, \sqrt{\Lambda}\right\}\right)$.*

Note that the dependence on n for this range of parameters is minimal. In fact, the only dependence on n is due to the fact that any connected n-vertex graph (such as the spanner of a connected n-vertex graph) must have p-norm at least $n^{1/p}$. If we remove the condition that the graph must be connected, the lower bounds in Theorem 18 become $\tilde{\Theta}(\Lambda^{\alpha})$ and $\tilde{\Theta}(\Lambda^{\beta})$.

For higher values of p, the lower bound becomes more complex. In particular, the parameters which determine the extremal spanner depend not only on p and t, but also on the *p-log density* of the graph, which we define to be $\log_n(\Lambda) = \log_n(\|G\|_p)$. This parameter generalizes the notion of log-density, which is at the heart of several recent breakthroughs in approximation algorithms [6, 10, 11, 14, 13], in which log-density was used to mean p-log density for $p = 1$ or $p = \infty$. As in that line of work, the structure and parameters of the graphs of interest here (the extremal spanners) is a function of the p-log density of our graph which does not depend on n. The complete technical details of our lower bound appear in the full version of the paper [12].

6 Future Work

In this paper we have initiated the study of graph spanners with cost defined by the ℓ_p-norm of the degree vector, since this provides an interesting interpolation between the ℓ_1-norm (only caring about the number of edges) and the ℓ_∞-norm (only caring about the maximum degree). But we have only scratched the surface: many of the hundreds of results on graph spanners can be extended or reexamined with respect to the ℓ_p-norm. There are also some very interesting direct extensions of this paper that would be interesting to study. In particular, we showed that the approximation ratio achieved by the greedy algorithm is strictly better than the generic guarantee for the ℓ_2-norm with stretch 3, unlike the ℓ_1 and ℓ_∞ norms. This suggests further study of the greedy algorithm in general, but also suggests extending the recent line of work on approximation algorithms for graph spanners (mostly using convex relaxations and rounding) to general ℓ_p-norms. The approaches taken for the ℓ_1-norm in the past [16, 17, 5, 18] have been quite different from the approaches used for the ℓ_∞-norm [23, 10, 9]; is there a way of interpolating between them to get even better approximations for intermediate ℓ_p-norms?

On the Fixed-Parameter Tractability of Capacitated Clustering

Vincent Cohen-Addad
CNRS & Sorbonne Université, Paris, France

Jason Li
Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

We study the complexity of the classic capacitated k-median and k-means problems parameterized by the number of centers, k. These problems are notoriously difficult since the best known approximation bound for high dimensional Euclidean space and general metric space is $\Theta(\log k)$ and it remains a major open problem whether a constant factor exists.

We show that there exists a $(3+\epsilon)$-approximation algorithm for the capacitated k-median and a $(9+\epsilon)$-approximation algorithm for the capacitated k-means problem in general metric spaces whose running times are $f(\epsilon,k)n^{O(1)}$. For Euclidean inputs of arbitrary dimension, we give a $(1+\epsilon)$-approximation algorithm for both problems with a similar running time. This is a significant improvement over the $(7+\epsilon)$-approximation of Adamczyk et al. for k-median in general metric spaces and the $(69+\epsilon)$-approximation of Xu et al. for Euclidean k-means.

1 Introduction

Clustering under capacity constraints is a fundamental problem whose complexity is still poorly understood. The capacitated k-median and k-means problems have attracted a lot of attention over the recent years (*e.g.*: [4, 22, 23, 24, 13, 3, 8, 6]), but the best known approximation algorithm for capacitated k-median remains a somewhat folklore $O(\log k)$-approximation using the classic technique of embeddings the metric space into trees that follows from the work of Charikar et al [5] on the uncapacitated version, see also [1] for a complete exposition.

Arguably, the hardness of the problem comes from having both a hard constraint on the number of clusters, k, and on the number of clients that can be assigned to each cluster. Indeed, constant factor approximation algorithms are known if the capacities [22, 23] or the number of clusters can be violated by a $(1+\epsilon)$ factor [4, 13], for constant ϵ. Moreover, the capacitated facility location problem admits constant factor approximation algorithms with no capacity violation. On the other hand and perhaps surprisingly, the best known lower bound for capacitated k-median is not higher than the $1+2/e$ lower bound for the uncapacitated version of the problem.

Thus, to improve the understanding of the problem a natural direction consists in obtaining better approximation algorithms in some specific metric spaces, or through the fixed-parameter complexity of the problem. For example, a quasi-polynomial time approximation scheme (QPTAS) for capacitated k-median in Euclidean space of fixed dimension with $(1+\epsilon)$ capacity violation was known since the late 90's [2]. This has been recently improved to a PTAS for $\mathbb{R}^2$ and a QPTAS for doubling metrics without capacity violation [9]. It remains an interesting open question to obtain constant factor approximation for other metrics such as planar graphs or Euclidean space of arbitrary dimension.

For many optimization problems are at least W[1]-hard and so obtaining exact fixed-parameter tractable (FPT) algorithms is unlikely. However, FPT algorithms have recently shown that they can help break long-standing barriers in the world of approximation algorithms. FPT approximation algorithms achieving better approximation guarantees than the best known polynomial-time approximation algorithms for some classic W[1]- and W[2]-hard problems have been designed. For example, for k-cut [15], for k-vertex separator [21] or k-treewidth-deletion [16].

For the fixed-parameter tractability of the k-median and k-means problems, a natural parameter is the number of clusters k. The FPT complexity of the classic uncapacitated k-median problem, parameterized by k, has received a lot of attention over the last 15 years. From a lower bound perspective, the problem is known to be W[2]-hard in general metric spaces and assuming the exponential time hypothesis (ETH), even for points in $\mathbb{R}^4$, there is no exact algorithm running in time $n^{o(k)}$ [10]. For $\mathbb{R}^2$ there exists an exact $n^{O(\sqrt{k})}$ which is the best one can hope for assuming ETH [10], see also [26].

From an upper bound perspective, *coreset* constructions and PTAS with running time $f(k,\epsilon)n^{O(1)}$ have been known since the early 00's [12, 19, 17, 18, 14]. In the language of fixed-parameter tractability, a coreset is essentially an "approximate kernel" for the problem: given a set P of n points in a metric space, a coreset is, loosely speaking, a mapping from the points in P to a set of points Q of size $(k \log n\epsilon^{-1})^{O(1)}$ such that any clustering of Q of cost γ can be converted into a clustering of P of cost at most $\gamma \pm \epsilon\mathsf{cost}(\mathrm{OPT})$, through the inverse of the mapping (where OPT is the optimal solution for P). See Definition 9 for a more complete definition.

In Euclidean space, several coreset constructions for uncapacitated k-median are independent of the input size and of the dimension and so are truly approximate kernels. Thus approximation schemes can simply be obtained by enumerating all possible partitions of the coreset points into k parts, evaluating the cost of each of them and outputing the one of minimum cost. However, obtaining similar results in general metric spaces seems much harder and is likely impossible. In fact, obtaining an FPT approximation algorithm with approximation guarantee less than $1 + 2/e$ is impossible assuming Gap-ETH, see [11].

For the capacitated k-median and k-means problems much less is known. First, the coreset constructions or the classic FPT-approximation schemes techniques of [20, 12] do not immediately apply. Thus, very little was known until the recent result of Adamczyk et al. [1] who proposed a $(7+\epsilon)$-approximation algorithm running in time $k^{O(k)}n^{O(1)}$. More recently, a $(69+\epsilon)$-approximation algorithm for the capacitated k-means problem with similar running time has been proposed by Xu et al. [28].

1.1 Our Results

We present a coreset construction for the capacitated k-median and k-means problems, with general capacities, and in general metric spaces (Theorem 11). For an n points set, the coreset has size $\mathrm{poly}(k\epsilon^{-1}\log n)$.

From this we derive a $(3+\epsilon)$-approximation for the k-median problem and a $(9+\epsilon)$-approximation for the k-means problem in general metric spaces.

▶ **Theorem 1.** *For any $\epsilon > 0$, there exists a $(3+\epsilon)$-approximation algorithm for the capacitated k-median problem and a $(9+\epsilon)$-approximation algorithm for the capacitated k-means problem running in time $(k\epsilon^{-1}\log n)^{O(k)}n^{O(1)}$. This running time can also be bounded by $(k/\epsilon)^{O(k)}n^{O(1)}$.*

This results in a significant improvement over the recent results of Adamczyk et al. [1] for k-median and Xu et al. [28] for (Euclidean) k-means, in the same asymptotic running time.

Moreover, combining with the techniques of Kumar et al. [20], we obtain a $(1+\epsilon)$-approximation algorithm for points in $\mathbb{R}^d$, where d is arbitrary. We believe that this is an interesting result: while it seems unlikely that one can obtain an FPT-approximation better than $1+2/e$ in general metrics, it is possible to obtain an FPT-$(1+\epsilon)$-approximation in Euclidean metrics of arbitrary dimension. This works for both the *discrete* and *continuous* settings: in the former, the set of centers must be chosen from a discrete set of candidate centers in $\mathbb{R}^d$ and the capacities may not be uniform, while in the latter the centers can be placed anywhere in $\mathbb{R}^d$ and the capacities are uniform.

▶ **Theorem 2.** *For any $\epsilon > 0$, there exists a $(1+\epsilon)$-approximation algorithm for the discrete, Euclidean, capacitated k-means and k-median problems which runs in time $(k\epsilon^{-1}\log n)^{k\epsilon^{-O(1)}}$ $n^{O(1)}$. This running time can also be bounded by $(k\epsilon^{-1})^{k\epsilon^{-O(1)}}$ $n^{O(1)}$.*

▶ **Theorem 3.** *For any $\epsilon > 0$, there exists a $(1+\epsilon)$-approximation algorithm for the continuous, Euclidean, capacitated k-means and k-median problems running in time $(k\epsilon^{-1}\log n)^{k\epsilon^{-O(1)}}$ $n^{O(1)}$. This running time can also be bounded by $(k\epsilon^{-1})^{k\epsilon^{-O(1)}}n^{O(1)}$.*

These two results are a major improvement over the 69-approximation algorithm of Xu et al. [28].

1.2 Preliminaries

We now provide a more formal definition of the problems.

▶ **Definition 4.** *Given a set of points V in a metric space with distance function d, together with a set of* clients *$C \subseteq V$, a set of* centers *$\mathbb{F} \subseteq V$ with a* capacity *$\eta_f \in \mathbb{Z}_+$ for each $f \in \mathbb{F}$, and an integer k, the* capacitated k-median problem *asks for a set $F \subseteq \mathbb{F}$ of k* centers *and an assignment $\mu : C \mapsto F$ such that $\forall f \in F$, $|\{c \mid \mu(c) = f\}| \leq \eta_f$ and that minimizes $\sum_{c\in C} d(c, \mu(c))$. We abbreviate the capacitated k-median instance as $((V,d), C, \mathbb{F}, k)$.*

▶ **Definition 5.** *The* capacitated k-means problem *is identical, except we seek to minimize $\sum_{c\in C} d(c,\mu(c))^2$.*

In the literature, centers are sometimes called *facilities*, but we will use *centers* throughout for consistency.

In the case of the capacitated Euclidean k-median and k-means, our approach works for the two main definitions. First, the definition of [28, 20]: $P = \mathbb{R}^d$ and capacities are uniform, namely $\eta_f = \eta_{f'}$, $\forall f, f' \in \mathbb{R}^d$. Second, P is some specific set of points in $\mathbb{R}^d$, and for each $f \in P$, the input specifies a specific capacity η_f

▶ **Definition 6.** *Given a capacitated k-median instance $((V,d), C, \mathbb{F}, k)$ and a set of chosen centers $F \subseteq \mathbb{F}$, define* $\mathsf{CapKMed}(C, F)$ *as the cost of the optimal assignment of the clients to the chosen centers. If it is impossible, i.e., the sum of the capacities of the centers is less than $|C|$, then* $\mathsf{CapKMed}(C, F) = \infty$.

In our analysis, we will also encounter formulations where the clients have positive *real* weights. In this case, we define a *fractional* variant of capacitated k-median, where the assignment μ is allowed to be fractional.

▶ **Definition 7.** *Suppose the clients also have weights, so we are given clients C and a weight function $w : C \to \mathbb{R}_+$. Let $W \subseteq C \times \mathbb{R}_+$ be the set of pairs $\{(c, w(c)) : c \in C\}$. Then,* $\mathsf{FracCapKMed}(W, F)$ *is the minimum value of $\sum_{c \in C, f \in F} \mu(c, f)\, d(c, f)$ over all "fractional assignments" $\mu : C \times F \to \mathbb{R}_+$ such that:*

1. *$\forall c \in C$, $\sum_{f \in F} \mu(c, f) = w(c)$, i.e., μ is a proper assignment of clients, and*
2. *$\forall f \in F$, $\sum_{c \in C} \mu(c, f) \leq \eta_f$, i.e., μ satisfies capacity constraints at all centers.*

▶ **Definition 8.** *We define* $\mathsf{CapKMeans}(C, F)$ *and* $\mathsf{FracCapKMeans}(W, F)$ *similarly, except our objective functions are $\sum_{c \in C} d(c, \mu(c))^2$ and $\sum_{c \in C, f \in F} \mu(c, f)\, d(c, f)^2$, respectively.*

It is well-known that, given a set $F \subseteq \mathbb{F}$ of centers, the problem of finding the optimum μ is an (integral) *minimum-cost flow* problem, which can be solved in polynomial time. Therefore, we assume that every time we have a set $F \subseteq \mathbb{F}$, we can evaluate $\mathsf{CapKMed}(C, F)$ and $\mathsf{CapKMeans}(C, F)$ in polynomial time. Similarly, FracCapKMed and FracCapKMeans can be solved through fractional min-cost flow, or even an LP, in polynomial time. Furthermore, if W is exactly the set C of clients with weight 1, i.e., $W = \{(c, 1) : c \in C\}$, then $\mathsf{CapKMed}(C, F) = \mathsf{FracCapKMed}(W, F)$, since the min-cost flow formulation of FracCapKMed has integral capacities and therefore integral flows as well.

We now formally state our definition of coresets, sometimes called *strong* coresets in the literature.

▶ **Definition 9.** *A (strong) coreset for a capacitated k-median instance $((V, d), C, \mathbb{F}, k)$ is a set of weighted clients $W \subseteq C \times \mathbb{R}_+$ such that for every set of centers $F \subseteq \mathbb{F}$ of size k,*

$$\mathsf{FracCapKMed}(W, F) \in (1 - \epsilon, 1 + \epsilon) \cdot \mathsf{CapKMed}(C, F).$$

The definition is identical for capacitated k-means, except CapKMed *and* FracCapKMed *are replaced by* CapKMeans *and* FracCapKMeans *above.*

▶ **Fact 10.** *Let W be a coreset for a capacitated k-median instance $((V, d), C, \mathbb{F}, k)$. We have*

$$\min_{\substack{F \subseteq \mathbb{F} \\ |F| = k}} \mathsf{FracCapKMed}(W, F) \in (1 - \epsilon, 1 + \epsilon) \cdot \min_{\substack{F \subseteq \mathbb{F} \\ |F| = k}} \mathsf{CapKMed}(C, F),$$

In particular, an α-approximation of $\min_{F \subseteq \mathbb{F}, |F| = k} \mathsf{FracCapKMed}(W, F)$ implies a $(1 + O(\epsilon))\alpha$-approximation to the capacitated k-median instance. The same holds in the capacitated k-means case, with FracCapKMed *and* CapKMed *replaced by* FracCapKMeans *and* CapKMeans*, respectively.*

For a capacitated k-median or k-means instance $((V, d), C, \mathbb{F}, k)$, the *aspect ratio* is the ratio of the maximum and minimum distances between any two points in $C \cup F$. It is well-known that we may assume, with a multiplicative error of $(1 + o(1))$ in the optimal solution, that the instance has $\mathrm{poly}(n)$ aspect ratio.[1] Therefore, we will make this assumption throughout the paper.

[1] For example, the following modification to the distances d does the trick. First, compute an $O(\log k)$-approximation [5] to the problem, and let that value be M. For any two points $u, v \in C \cup F$ with $d(u, v) > Mn^{10}$, truncate their distance to exactly Mn^{10}. Then, add Mn^{-10} distance to each pair of points $u, v \in C \cup F$. The aspect ratio is now bounded by $O(n^{20})$.

Lastly, we define $\mathbb{R}_+$ and $\mathbb{Z}_+$ as the set of positive reals and positive integers, respectively. As usual, we define *with high probability (w.h.p.)* as with probability $1-n^{-Z}$ for an arbitrarily large positive constant Z, fixed beforehand.

2 Coreset for k-median

In this section, we prove our main technical result for the k-median case: constructing a coreset for capacitated k-median of size $\text{poly}(k \log n\, \epsilon^{-1})$.

▶ **Theorem 11.** *For any small enough constant $\epsilon \geq 0$, there exists a Monte Carlo algorithm that, given an instance $((V,d), C, \mathbb{F}, k)$ of capacitated k-median, outputs a (strong) coreset $W \subseteq C$ with size $O(k^2 \log^2 n/\epsilon^3)$ in polynomial time, w.h.p.*

▶ **Theorem 12.** *For any small enough constant $\epsilon \geq 0$, there exists a Monte Carlo algorithm that, given an instance $((V,d), C, \mathbb{F}, k)$ of capacitated k-means, outputs a (strong) coreset $W \subseteq C$ with size $O(k^5 \log^5 n/\epsilon^3)$ in polynomial time, w.h.p.*

Our inspiration for the coreset construction is Chen's algorithm [7] based on random sampling. Our algorithm is essentially the same, with slightly worse bounds in the sampling step, although our analysis is a lot more involved. We describe the full algorithm in pseudocode below (see Algorithm 1).

At a high level, the algorithm first partitions the client set C into $\text{poly}(k, \log n)$ many subsets, called *rings*, with the help of a polynomial-time approximate solution (see line 1). The sets are called rings because they are of the form $C_i \cap (\mathsf{ball}(f_i', R) \setminus \mathsf{ball}(f_i', R/2))$ for some subset of clients $C_i \subseteq C$, some facility $f_i' \in \mathbb{F}$, and some positive number R (see line 7). Then, for each ring $C_{i,R}$, if $|C_{i,R}|$ is small enough, the algorithm adds the entire ring into the coreset (each with weight 1); otherwise, the algorithm takes a random sample of $r = \text{poly}(k, \log n)$ many clients in $C_{i,R}$, weights each sampled client by $|C_{i,R}|/r$, and adds the weighted sample to the coreset. The weighting ensures that the total weight of the sampled points is always equal to $|C_{i,R}|$. To prove that the algorithm produces a coreset w.h.p., Chen union bounds over all $\binom{|\mathbb{F}|}{k}$ choices of a set of k facilities, and shows that for each choice $F \subseteq \mathbb{F}$, with probability at least $1 - n^{-\Omega(k)}$, the total cost to assign the coreset points to F is approximately the total cost to assign the original clients C to F; this statement is proved through standard concentration bounds. More details and intuition for the algorithm can be found in Section 3 of Chen's paper [7].

2.1 Single ring case

We first restrict ourselves to sampling from a *single* ring $C_{i,R} \subseteq C$. That is, while we still consider the cost of serving the clients outside of $C_{i,R}$, we only perform the sampling (lines 12–13) on one ring $C_{i,R}$. The general case of $O(k \log n)$ many rings is more complicated than simply treating each ring separately. Due to space constraints, we only consider the single ring case in this extended abstract, and the rest is deferred to the full version.

Fix an arbitrary ring $C_{i,R}$ throughout this section, and define $C' := C_{i,R}$ for convenience. Let $N := |C'|$ be the number of clients, and let $f' := f_i'$ be the ring center of C' (line 4). Let W' be the (weighted) centers in $C_{i,R}$ sampled by the algorithm (lines 12–13), together with the (unweighted) centers in $C \setminus C'$, which have weight 1. Our goal is to show that $\mathsf{FracCapKMed}(W', F)$, the cost after sampling only from C', is close to the original cost $\mathsf{CapKMed}(C, F)$.

Algorithm 1 CoreSet(I).

1: $F' = \{f'_1, \ldots, f'_{O(k)}\} \leftarrow$ an $(O(1), O(1))$ bicriteria solution to instance I, namely a capacitated $O(k)$-median solution with total cost $ALG' \leq O(OPT)$ ▷ using, e.g., [23]
2: $W \leftarrow \emptyset$ ▷ $W \subseteq C \times \mathbb{R}_+$ is the final coreset at the end of the algorithm
3: Define $d_{\min}$ and $d_{\max}$ as the minimum and maximum distances, respectively, between any two points in $C \cup \mathbb{F}$ ▷ $d_{\max}/d_{\min}$ is the aspect ratio
4: **for** each center f'_i **do** ▷ $O(k)$ centers
5: $C_i \leftarrow$ the clients in C assigned to center f'_i
6: **for** each R, a power of 2 in the range $[d_{\min}, 2d_{\max}]$ **do** ▷ $O(\log n)$ iterations, assuming poly(n) aspect ratio
7: $C_{i,R} \leftarrow C_i \cap (\mathsf{ball}(f'_i, R) \setminus \mathsf{ball}(f'_i, R/2))$ ▷ We call the sets $C_{i,R}$ *rings*, with *ring center* f'_i. The rings $C_{i,R}$ over all i, R partition the client set C.
8: $r \leftarrow \gamma k \log n/\epsilon^3$ for sufficiently large (absolute) constant γ
9: **if** $|C_{i,R}| \leq r$ **then**
10: add $(c, 1)$ to W for each $c \in C_{i,R}$ ▷ $C_{i,R}$ small enough: add everything into coreset
11: **else**
12: sample r random centers in $C_{i,R}$ (without replacement)
13: add $(c, \frac{|C_{i,R}|}{r})$ to W for each sampled center c ▷ weighted so that total weight is still $|C_{i,R}|$

▶ **Lemma 13.** *W.h.p., for any set of k centers $F \subseteq \mathbb{F}$ satisfying* $\mathsf{CapKMed}(C, F) < \infty$,

$$|\mathsf{FracCapKMed}(W', F) - \mathsf{CapKMed}(C, F)| \leq \epsilon NR. \tag{1}$$

It is clear that the output W has size $O(k^2 \log^2 n/\epsilon^3)$. The rest of this section focuses on proving that W is indeed a coreset, w.h.p.

The intuition behind the ϵNR additive error is that we can "charge" this error to the cost of the bicriteria solution (line 1) that C' is responsible for. In particular, the total cost of assigning clients in C' to ring center f' in the bicriteria solution is at least $N \cdot R/2$, since all clients in C' are distance at least $R/2$ to f'. Therefore, we charge an additive error of ϵNR to a $NR/2$ portion of ALG', which is a "rate" of 2ϵ to 1. If we can do the same for all rings, then since the portions of ALG' sum to ALG', our total additive error is at most $2\epsilon \cdot ALG' = O(\epsilon) \cdot OPT$. Finally, replacing ϵ with a small enough $\Theta(\epsilon)$ gives the desired additive error of $\epsilon \cdot OPT$; note that this is where we use that the approximation ratio of ALG' is $O(1)$, and that the specific approximation ratio is not important (as long as it is constant). The formalization of this intuition is deferred to the full version; the argument is identical to Chen's [7], so we claim no novelty here.

We now prove Lemma 13. First of all, if $N = |C'| \leq r$ (line 9), then sampling changes nothing, and $\mathsf{FracCapKMed}(W', F) = \mathsf{CapKMed}(C, F)$. Therefore, for the rest of the proof, we assume that $N > r = \gamma k \log n/\epsilon^3$, with the γ taken to be a large enough constant.

Our high-level strategy is the same as Chen's: we union bound over all sets of centers $F \subseteq \mathbb{F}$ of size k, and prove that for a fixed set F, the probability of violating (1) is at most $n^{-(k+10)}$.[2] Union bounding over all $\leq \binom{n}{k}$ choices of F gives probability $\leq n^{-10}$ of

[2] For simplicity of presentation, we will focus on a success probability of $1 - n^{-10}$. The constants can be easily tweaked so that the algorithm succeeds w.h.p., i.e., with probaility $1 - n^{-Z}$ for any positive constant Z.

violating (1), proving the lemma. Therefore, from now on, we focus on a single, arbitrary set $F \subseteq \mathbb{F}$ of size k satisfying $\mathsf{CapKMed}(C, F) < \infty$, and aim to show that (1) fails with probability $\leq n^{-(k+10)}$.

For our analysis, we define a function $g : \mathbb{R}_+^{C'} \to \mathbb{R}_+$ as follows. For an input vector $\mathbf{d} \in \mathbb{R}_+^{C'}$ (indexed by clients in C'), consider a min-cost flow instance $\mathsf{FlowInstance}(\mathbf{d})$ on the graph metric with the following demands: set demand d_c at each client $c \in C'$, demand 1 at each client $c \in C \setminus C'$, and demand $N - \sum_{c \in C'} d_c$ (this demand can be negative) at ring center $f' = f'_i$ (so we are effectively treating f' as a special client with possibly negative demand, not a facility). Observe that $\mathsf{FlowInstance}(\mathbf{d})$ is a feasible min-cost flow instance, because the sum of demands is exactly

$$\sum_{c \in C'} d_c + |C \setminus C'| + \left(N - \sum_{c \in C'} d_c \right) = |C \setminus C'| + N = |C|,$$

which is the same as the sum of demands in the instance $\mathsf{CapKMed}(C, F)$, which is feasible by assumption.

Given this setup for an input vector $\mathbf{d} \in \mathbb{R}_+^{C'}$, we define the function $g(\mathbf{d})$ as the min-cost flow of $\mathsf{FlowInstance}(\mathbf{d})$. Observe that $g(\mathbb{1})$ is exactly $\mathsf{CapKMed}(C, F)$.

Now define a random vector $X \in \mathbb{R}_+^{C'}$ as follows. Each coordinate of X is independently N/r with probability r/N and 0 otherwise, so that $\mathbb{E}[X] = \mathbb{1}$. Note that X does not accurately represent our sampling of r clients, since this process is not guaranteed to sample exactly r clients. Nevertheless, it is intuitively clear that with probability $\Omega(1/n)$, X will indeed have exactly r nonzero entries, since r is the expected number; we prove this formally in the following simple claim (with $p = r/N$), whose routine proof is deferred to the full version. And if we *condition* on this event, then $g(X)$ and $\mathsf{CapKMed}(C, F)$ are now identically distributed.

▷ Claim 14. Let N be a positive integer, and let $p \in (0, 1)$ such that pN is an integer. The probability that $\mathsf{Binomial}(N, p) = pN$ is at least $\Omega(1/\sqrt{N})$.

In light of all this, our main argument has two steps. First, we show that $g(X)$ is concentrated around $\mathbb{E}[g(X)]$ using martingales. However, what we really need is concentration around $g(\mathbb{E}[X]) = g(\mathbb{1}) = \mathsf{CapKMed}(C, F)$, so our second step is to show that $\mathbb{E}[g(X)] \approx g(\mathbb{E}[X])$ (with probability 1). We formally state the lemmas below which, as discussed, together imply Lemma 13.

▶ **Lemma 15.** *Assume that $|C'| > \Theta(k \log n/\epsilon^3)$. With probability $\geq 1 - n^{-(k+20)}$, we have $|g(X) - \mathbb{E}[g(X)]| \leq \epsilon NR/2$.*

▶ **Lemma 16.** *Assume that $|C'| > \Theta(k \log n/\epsilon^3)$. Then, $|\mathbb{E}[g(X)] - g(\mathbb{E}[X])| \leq \epsilon NR/2$.*

2.1.1 Proof of Lemma 15: concentration around $\mathbb{E}[g(X)]$ via martingales.

To show that $g(X)$ is concentrated around its mean, we show that g is sufficiently Lipschitz (w.r.t. the ℓ_1 distance in $\mathbb{R}_+^{C'}$), and then apply standard martingale tools.

▷ Claim 17. The function g is R-Lipschitz w.r.t. the ℓ_1 distance in $\mathbb{R}_+^{C'}$.

Proof. Fix a client $c \in C'$, and consider two vectors $\mathbf{d}, \mathbf{d}' \in \mathbb{R}_+^{C'}$ with $\mathbf{d}' = \mathbf{d} + \delta \cdot \mathbb{1}_c$. By definition of $\mathsf{FlowInstance}$, the only difference between $\mathsf{FlowInstance}(\mathbf{d})$ and $\mathsf{FlowInstance}(\mathbf{d}')$ is that in $\mathsf{FlowInstance}(\mathbf{d}')$, client c has δ more demand and "special client" f' has δ less

demand. Therefore, if we begin with the min-cost flow of $\mathsf{FlowInstance}(\mathbf{d})$, and then add δ units of flow from c to f', then we now have a feasible flow for $\mathsf{FlowInstance}(\mathbf{d}')$.[3] This means that

$$g(\mathbf{d}') \leq g(\mathbf{d}) + \delta R.$$

Similarly, starting from a min-cost flow of $\mathsf{FlowInstance}(\mathbf{d}')$ and then adding δ units of flow from f' to c, we obtain a feasible flow for $\mathsf{FlowInstance}(\mathbf{d})$, so

$$g(\mathbf{d}) \leq g(\mathbf{d}') + \delta R.$$

Together, these two inequalities show that g is R-Lipschitz. ◁

We state the following Chernoff bound for Lipschitz functions, which can be proven by adapting the standard (multiplicative) Chernoff bound proof to a martingale.

▶ **Theorem 18.** *Let $x_1, \ldots, x_n$ be independent random variables taking value b with probability p and value 0 with probability $1-p$, and let $g : [0,1]^n \to \mathbb{R}$ be a L-Lipschitz function in ℓ_1 norm. Define $X := (x_1, \ldots, x_n)$ and $\mu := \mathbb{E}[g(X)]$. Then, for $0 \leq \epsilon \leq 1$:*

$$\Pr\left[\left|g(X) - \mathbb{E}[g(X)]\right| \geq \epsilon pnbL\right] \leq 2e^{-\epsilon^2 pn/3}$$

We apply Theorem 18 on the L-Lipschitz function g with the randomly sampled demands. Set $p := r/N$ as the sampling probability, so that $X \in \{0, 1/p\}^N$ is the random demand vector. Setting $n := N$, $b := 1/p$, and $L := R$, we obtain

$$\begin{aligned}
&\Pr\left[\left|g(X) - \mathbb{E}[g(X)]\right| \geq (\epsilon/2)NR\right] \\
&\quad = \Pr\left[\left|g(X) - \mathbb{E}[g(X)]\right| \geq (\epsilon/2)pnbL\right] \\
&\quad \leq 2\exp\left(\frac{-(\epsilon/2)^2 pn}{3}\right) \\
&\quad = 2\exp\left(\frac{-(\epsilon/2)^2 (r/N)N}{3}\right) = \exp\left(-\Theta(\epsilon^2 r)\right) = \exp\left(-\Omega(\epsilon^2 \cdot \frac{k\log n}{\epsilon^2})\right) \\
&\quad \leq n^{-(k+20)}
\end{aligned}$$

for sufficiently large γ in the definition of $r = \gamma k \log n/\epsilon^2$. This concludes Lemma 15.

2.1.2 Proof of Lemma 16: relating $\mathbb{E}[g(X)]$ with $g(\mathbb{E}[X])$.

We have obtained concentration about $\mathbb{E}[g(X)]$, but we really need concentration around $g(\mathbb{E}[X]) = \mathsf{CapKMed}(C', F)$. We establish this by proving Lemma 16.

We first show the easy direction, that $g(\mathbb{E}[X]) \leq \mathbb{E}[g(X)]$, which essentially follows from the convexity of min-cost flow: Suppose the outcomes of random variable X are $\mathbf{d}_1, \mathbf{d}_2, \ldots$ with respective probabilities $\mu_1, \mu_2, \ldots$, so that $\mathbb{E}[g(X)] = \sum_i \mu_i g(\mathbf{d}_i)$. Now consider the flow obtained by adding up, for each i, the min-cost flow of $\mathsf{FlowInstance}(\mathbf{d}_i)$ scaled by μ_i. This flow is a feasible flow to $\mathsf{FlowInstance}(\mathbb{E}[X])$ and has cost at most $\mathbb{E}[g(X)]$. Since the min-cost flow of $\mathsf{FlowInstance}(\mathbb{E}[X])$ can only be lower, we have $g(\mathbb{E}[X]) \leq \mathbb{E}[g(X)]$.

We now prove the other direction: $\mathbb{E}[g(X)] \leq g(\mathbb{E}[X]) + \epsilon NR/2$.

[3] We define demand so that if a vertex v has $d > 0$ demand, then d flow must exit v in a feasible flow, and if it has $d < 0$ demand, then $|d|$ flow must enter v.

▷ Claim 19. With probability 1, $g(X) \le g(\mathbb{E}[X]) + nNR$.

Proof. Since $X \in [0, N/r]^N$, and since g is R-Lipschitz, the entire range of $g(X)$ is contained in some interval of length $N \cdot N/r \cdot R \le N \cdot n \cdot R$. Since $\mathbb{E}[X] \in [0, N/r]^N$ as well, the value $g(\mathbb{E}[X])$ is also contained in that interval. The statement follows. ◁

▶ **Lemma 20.** *With probability* $\ge 1 - n^{-10}$, $g(X) \le g(\mathbb{E}[X]) + 0.49\epsilon NR$.

Due to space constraints, the proof of Lemma 20, which is long and technical, is deferred to the full version. Assuming Lemma 20, we now show how Claim 19 and Lemma 20 together imply Lemma 16: we have

$$\begin{aligned}\mathbb{E}[g(X)] &\le n^{-10} \cdot \big(g(\mathbb{E}[X]) + nNR\big) + (1 - n^{-10})\big(g(\mathbb{E}[X]) + 0.49\epsilon NR\big) \\ &= g(\mathbb{E}[X]) + \big(n^{-10} \cdot n + (1 - n^{-10}) \cdot 0.49\epsilon\big)NR \\ &\le g(\mathbb{E}[X]) + (\epsilon/2)NR,\end{aligned}$$

finishing the proof of Lemma 16.

2.2 $(3+\epsilon)$- and $(9+\epsilon)$-approximation – Proof of Theorem 1

In this section, we finish the algorithm for Theorem 1. We will focus mainly on the k-median case, since the k-means case is nearly identical.

Suppose we run the coreset for the capacitated k-median instance with parameter ϵ_0 (to be set later), obtaining a coreset $W \subseteq C \times \mathbb{R}^+$ of size $\text{poly}(k \log n\, \epsilon_0^{-1})$. We now want to compute some $F \subseteq \mathbb{F}$ of size k and an assignment μ of the clients in W to F minimizing $\sum_{(c,w)\in W} w \cdot d(c, \mu(c))$. By definition of coreset, if we compute an α-approximation to this problem, then we compute a $(1+\epsilon_0)\alpha$-approximation to the original capacitated k-median problem.

The strategy is similar to that in [11]: we guess a set of *leaders* and *distances* that match the optimal solution. More formally, let $F^* = \{f_1^*, \ldots, f_k^*\} \subseteq \mathbb{F}$ be the optimal solution with assignment μ^*. For each $f_i^* \in F^*$, let $(\mu^*)^{-1}(f_i^*)$ be the clients in the coreset assigned by μ^* to f_i^*, and let ℓ_i be the client in $(\mu^*)^{-1}(f_i^*)$ closest to f_i^*. We call ℓ_i the *leader* of the client set $(\mu^*)^{-1}(f_i^*)$. Also, let R_i be the distance $d(f_i^*, \ell_i)$, rounded down to the closest integer power of $(1+\epsilon_1)$ for some ϵ_1 we set later.

The algorithm begins with an enumeration phase. There are $|W|^k$ choices for the set $\{\ell_1, \ldots, \ell_k\}$, and $O(\epsilon_1^{-1} \log n)^k$ choices for the values $R_1, \ldots, R_k$, since we assumed that the instance has aspect ratio $\text{poly}(n)$. So by enumerating over $|W|^k O(\epsilon_1^{-1} \log n)^k = (k \log n\, \epsilon_0^{-1} \epsilon_1^{-1})^{O(k)}$ choices, we can assume that we have guessed the right values ℓ_i and R_i.

For each leader ℓ_i, define $\mathbb{F}_i$ as the centers $f \in \mathbb{F}$ satisfying $d(\ell_i, f) \in [1, 1+\epsilon_1) \cdot R_i$. Note that $f_i^* \in \mathbb{F}_i$ for each i. Next, the algorithm wants to pick the center in each $\mathbb{F}_i$ with the largest capacity. This way, even if it doesn't pick f_i^* for $\mathbb{F}_i$, it picks a center not much farther away that has at least as much capacity.

The most natural solution is to *greedily* choose the center with largest capacity in each $\mathbb{F}_i$. One immediate issue with this approach is that we might choose the same center twice, since the sets $\mathbb{F}_i$ are not necessarily disjoint. Note that this issue is not as pronounced in the uncapacitated k-median problem, since in that case, we can always imagine choosing the same center twice and then throwing out one copy, which changes nothing. In the capacitated case, choosing the same center twice effectively doubles the capacity at that center, so throwing out a copy affects the capacity at that center.

One simple fix to this issue is the simple idea of *color-coding*, common in the FPT literature: for each center $f \in \mathbb{F}$, independently assign a uniformly random label in $\{1, 2, 3, \ldots, k\}$. With probability $1/k^k$, each $f_i^* \in F^*$ is assigned label i. Moreover, repeating this routine $O(k^k \log n)$ times ensures that w.h.p., this will happen in some iteration. So with a $O(k^k \log n)$ multiplicative overhead in the running time, we may assume that each f_i^* is assigned label i.

The algorithm now chooses, from each $\mathbb{F}_i$, the center with the largest capacity among all centers with label i. Since f_i^* is an option for each $\mathbb{F}_i$, the center chosen can only have larger capacity. Let the center chosen from $\mathbb{F}_i$ be f_i. Let $F := \{f_1, \ldots, f_k\}$ be our chosen centers.

We now claim that F is a $(3+\epsilon_1)$-approximation. Recall μ^*, the optimal assignment to the centers F^*; we construct an assignment μ to F as follows: for each client c in the coreset, if μ^* assigns c to center f_i^*, then we set $\mu(c) = f_i$. Observe that if $\mu^*(c) = f_i^*$, then

$$d(c, f_i) \le d(c, f_i^*) + d(f_i^*, \ell_i) + d(\ell_i, f_i) \le d(c, f_i^*) + 2(1+\epsilon_1)R_i \le d(c, f_i^*) + 2(1+\epsilon_1) \cdot d(c, f_i^*),$$

where the first inequality follows from triangle inequality, the second follows since both f_i^* and f_i are approximately R_i away from ℓ_i, and the third follows from $d(c, f_i^*) \ge d(\ell_i, f_i^*) \ge R$ by our choice of ℓ_i. Therefore, we have $d(c, \mu(c)) = d(c, f_i) \le (3 + 2\epsilon_1) d(c, f_i^*) = (3 + 2\epsilon_1) d(c, \mu^*(c))$. Altogether, the total cost of the assignment μ is

$$\sum_{(c,w) \in W} w \cdot d(c, \mu(c)) \le \sum_{(c,w) \in W} w \cdot (3 + 2\epsilon_1) d(c, \mu^*(c)) = (3 + 2\epsilon_1)\, OPT.$$

The optimal assignment can only be better, hence the $(3+2\epsilon_1)$-approximation. This implies a $(1+\epsilon_0)(3+2\epsilon_1)$-approximation in time $\text{poly}(k \log n\, \epsilon_0^{-1} \epsilon_1^{-1})^{O(k)}$. Finally, setting $\epsilon_0, \epsilon_1 := \Theta(\epsilon)$, for $\Theta(\cdot)$ small enough, guarantees a $(3+\epsilon)$-approximation in time $(k \log n\, \epsilon^{-1})^{O(k)} n^{O(1)}$.

Lastly, we show that the $(\log n)^{O(k)}$ factor in the running time can be upper bounded by $k^{O(k)} n^{O(1)}$, proving the second running time in Theorem 1. If $k < \frac{\log n}{\log \log n}$, then $(\log n)^{O(k)} = (\log n)^{\frac{\log n}{\log \log n}} = n^{O(1)}$; otherwise, $k > \frac{\log n}{\log \log n} \ge \sqrt{\log n}$, so $(\log n)^{O(k)} \le (k^2)^{O(k)}$. Therefore, the running time in Theorem 1 is at most $O(k/\epsilon)^{O(k)} n^{O(1)}$.

For k-means, the algorithm and analysis are identical, except that the total cost is now

$$_{(c,w) \in W} w \cdot d(c, \mu(c))^2 \le \sum_{(c,w) \in W} w \cdot \big((3 + 2\epsilon_1) d(c, \mu^*(c))\big)^2 = (9 + O(\epsilon_1))\, OPT,$$

implying a $(9+\epsilon)$-approximation. This concludes the proof of Theorem 1.

3 A $(1+\epsilon)$-Approximation for Euclidean Inputs

3.1 The Continuous (Uniform-Capacity) Case – Proof of Theorem 3

In this section we consider the continuous case: namely the case where centers can be located at arbitary position in $\mathbb{R}^d$ and the capacities are uniform and $\eta \ge n/k$.

Let $\epsilon > 0$. Given a set of points P, denote by $\text{OPT}_1(P)$ the location of the optimal center of P (namely, the centroid of P in the case of the k-means problem or the median of P in the case of the k-median problem). We will make us of the following lemma of [20].

▶ **Lemma 21** (Lemma 5.3 in [20]). *Let P be a set of points in $\mathbb{R}^d$ and X be a random sample of size $O(\epsilon^{-3} \log(1/\epsilon))$ from P and a and b such that $a \le \mathsf{cost}(P, OPT_1(P)) \le b$. Then, we can construct a set Y of $O(2^{1/\epsilon^{O(1)}} \log(b/\epsilon a))$ points such that with constant probability there is at least one point $z \in X \cup Y$ satisfying $\mathsf{cost}(P, \{z\}) \le (1 + 2\epsilon)\mathsf{cost}(P, OPT_1(P))$. Further, the time taken to construct Y from X is $O(2^{1/\epsilon^{O(1)}} \log(b/\epsilon a) d)$.*

Our algorithm for obtaining a $(1+\epsilon)$-approximation is as follows:

1. Compute a coreset C for capacitated k-median as described by Lemma 21, and an estimate γ of the value of OPT using the classic $O(\log n)$-approximation.
   In the remaining, we assume that the minimum pairwise distance between pairs of points of C is at least $\epsilon\gamma/(n\log n)$ since otherwise one can simply take a net of the input and the additive error is at most ϵOPT (see e.g.: [11]). Moreover, we assume that there is no cluster containing only one point of the coreset since these clusters can be "guessed" and dealt with separately.
2. Start with $\mathcal{C}=\emptyset$, then for each subset S of C of size $O(\epsilon^{-3}\log(k/\epsilon))$, for each $s=(1+\epsilon)^i$ in the interval $[\epsilon\gamma/(n\log n),\gamma]$ apply the procedure of Lemma 21 with $a=s$ and $b=(1+\epsilon)a$ and add the output of the procedure to $\mathcal{C}$. We refer to $\mathcal{C}$ as a set of approximate candidate centers.
3. Consider all subsets of size k of $\mathcal{C}$. For each subset, compute the cost of using this set of centers for the capacitated k-median instance by using a min cost flow computation. Output the set of centers of minimum cost.

We first discuss the running time of the algorithm. The time for computing the coreset is polynomial by Theorem 11. Generating $\mathcal{C}$ takes $|C|^{O(\epsilon^{-3}\log(1/\epsilon))}\cdot 2^{1/\epsilon^{O(1)}}\log((1+\epsilon)/\epsilon)d$ time. For the last part, namely enumerating all subsets of $\mathcal{C}$ of size k, the running time is $|C|^{O(k\epsilon^{-3}\log(1/\epsilon))}\cdot 2^{k/\epsilon^{O(1)}}\log^k((1+\epsilon)/\epsilon)$. Theorem 11 implies that $|C|=\text{poly}(k\log n\,\epsilon^{-1})$ and so, the algorithm has running time $(k\log n\,\epsilon^{-1})^{k\epsilon^{-O(1)}}n^{O(1)}$. Again, the $(\log n)^{k\epsilon^{-O(1)}}$ factor can be upper bounded by $(k/\epsilon)^{k\epsilon^{-O(1)}}$ or $n^{O(1)}$ based on whether or not $k\epsilon^{-O(1)}<\frac{\log n}{\log\log n}$, hence the improved running time in Theorem 3.

We show that this algorithm provides a $(1+O(\epsilon))$-approximation. Theorem 11 immediately implies that the solution found for the coreset C can be lifted to a solution for the original input at a cost of an additive $O(\epsilon\text{OPT})$. For any (possibly weighted) set of client A and set of centers B, we define $\mathsf{cost}(A,B)$ to be the cost of the best assignment of the clients in A to the centers of B.

▶ **Lemma 22.** *The $\mathcal{C}$ computed by the algorithm contains a set of centers $\tilde{S}$ that is such that $\mathsf{cost}(C,\tilde{S})\leq(1+\epsilon)\mathsf{cost}(C,OPT)$.*

Proof. This follows almost immediately from Lemma 21. By Lemma 21, for each cluster C_i^* of OPT, there exists a set $S_i^*\subseteq C_i^*$ of size at most $O(\epsilon^{-3}\log(k/\epsilon))$ such that applying the procedure of Lemma 21 with the correct value of a to S_i^* yields a set of points containing a point z_i such that $\mathsf{cost}(C_i^*,z_i)\leq(1+2\epsilon)\mathsf{cost}(C_i^*,\text{OPT})$. Since the algorithm iterates over all subsets of size $O(\epsilon^{-3}\log(k/\epsilon))$, and that the pairwise distance is at least $\epsilon\text{OPT}/n$, it follows that S_i^* is one of the subset considered by the algorithm, and so z_i is part of $\mathcal{C}$. ◀

Finally, since the algorithm iterates over all subsets of $\mathcal{C}$ of size at most k, Lemma 22 implies that there exists a set $\{z_1,\ldots,z_k\}$ that is considered by the algorithm and on which solving a min cost flow instance yields a solution of cost at most $(1+O(\epsilon))\mathsf{cost}(\mathcal{P},\text{OPT})$.

3.2 The Non-Uniform Case – Proof of Theorem 2

We now consider the non-uniform case. In this setting, the input consists of a set of points in $\mathbb{R}^d$ together with a set of candidate centers in $\mathbb{R}^d$ and a capacity η_f for each such candidate center. We make use of the following lemma. As slightly worse bound for the lemma can also be found in [25].

▶ **Lemma 23** ([27]). *Let $\epsilon \in (0,1)$ and $X \subseteq \mathbb{R}^d$ be arbitrary with X having size $n > 1$. There exists $f : \mathbb{R}^d \mapsto \mathbb{R}^m$ with $m = O(\epsilon^{-2} \log n)$ such that $\forall x \in X$, $\forall y \in \mathbb{R}^d$, $||x-y||_2 \leq ||f(x)-f(y)||_2 \leq (1+\epsilon)||x-y||_2$.*

We describe a polynomial-time approximation scheme. Let $\epsilon > 0$. The algorithm is as follows. The first step of the algorithm is identical to the continous case.

1. Compute a coreset C for capacitated k-median as described by Theorem 21, and an estimate γ of the value of OPT using the classic $O(\log n)$-approximation.
   In the remaining, we assume that the minimum pairwise distance between pairs of points of C is at least $\epsilon\gamma/(n \log n)$ since otherwise one can simply take a net of the input and the additive error is at most ϵOPT (see e.g.: [11]). Moreover, we assume that there is no cluster containing only one point of the coreset since these clusters can be "guessed" and dealt with separately.
2. Apply Lemma 23 to the points of the coreset to obtain a set of points in a Euclidean space of dimension $\frac{\log k + \log\log n}{\epsilon^{O(1)}}$. Let C^* and A^* be respectively the image of the coreset points and of the candidate centers through the projection.
3. Start with $\mathcal{V} = \emptyset$ For each point p of the coreset do the following: For each $i \in \{1, 2, \ldots, n^2\}$, consider the ith-*ring* defined by $\mathsf{ball}(p, (1+\epsilon)^i \epsilon\gamma/(n \log n)) \setminus \mathsf{ball}(p, (1+\epsilon)^{i-1}\epsilon\gamma/(n \log n))$ and choose an $\epsilon \cdot (1+\epsilon)^i \epsilon\gamma/(n \log n)$-net. Consider the Voronoi diagram induced by the points of the net. Then, for each Voronoi cell, add to $\mathcal{V}$ the k candidate centers of A^* in the cell that are of maximum capacity.
4. Enumerate all possible subset of $\mathcal{V}$ of size k and output the one that leads to the solution of minimum cost.

3.2.1 Correctness

Theorem 11 implies that finding a near-optimal solution for the coreset points yields a near-optimal solution for the input point set.

Lemma 23 immediately implies that, given the coreset construction C, and the projection of the coreset points onto a $\frac{\log k + \log\log n}{\epsilon^{O(1)}}$-dimensional Euclidean space, finding a near-optimal set of centers in A^* yields a near-optimal set of centers in A through the inverse of the projection.

Therefore, it remains to show that the set $\mathcal{V}$ contains a set of candidate centers that yields a near-optimal solution. To see this, consider each center of the optimal solution in A^*. For each such optimal center f, consider the closest coreset point $c(f)$ together with the ring of $c(f)$ containing f. Let j be the index of this ring, namely $f \in \mathsf{ball}(p, (1+\epsilon)^j \epsilon\gamma/(n \log n)) \setminus \mathsf{ball}(p, (1+\epsilon)^{j-1}\epsilon\gamma/(n \log n))$.

By definition of the net, there exists a point p of the net at distance at most $\epsilon \cdot \mathsf{ball}(p, (1+\epsilon)^j \epsilon\gamma/(n \log n)) \leq 2\epsilon||c - c(f)||_2$ from $c(f)$. Therefore, consider the Voronoi cell of p and the top-k candidate centers in terms of capacity. If f is part of this top-k, then f is part of $\mathcal{V}$ and we are done. Otherwise, it is possible to associate to f a center f^* that has capacity at least the capacity of f, and so for all the optimal centers simultaneously since we consider the top-k. Therefore, consider replacing f by f^* in the optimal solution. The change in cost is at most, by the triangle inequality, $4\epsilon||c - c(f)||_2$ since both centers are in the Voronoi cell of p. Finally, since c is the closest client to $c(f)$, the cost increases by a factor at most $(1+4\epsilon)$ for each client and the correctness follows.

3.2.2 Running time

We now bound the running time. The first two steps are clearly polynomial time. An $\epsilon \cdot (1+\epsilon)^i \epsilon\gamma/(n \log n)$-net of a ball of radius $(1+\epsilon)^i \epsilon\gamma/(n \log n)$ has size $\epsilon^{-O(d)}$ and so in this context, after Step 2, a size $\epsilon^{-(\frac{\log k + \log\log n}{\epsilon^{O(1)}})}$. Since for each element of the net, k centers are chosen and since the number of rings is, by Step 1, at most $O(\epsilon^{-2} \log n)$, the total size of $\mathcal{V}$ is at most $|C| k \epsilon^{-2} \log n \epsilon^{-(\frac{\log k + \log\log n}{\epsilon^{O(1)}})}$ which is at most $|C| \epsilon^{-2} (k \log n)^{\epsilon^{-O(1)}} = (k\epsilon^{-1} \log n)^{\epsilon^{-O(1)}}$. Enumerating all subsets of size k takes time $(k\epsilon^{-1} \log n)^{k\epsilon^{-O(1)}}$ and the theorem follows.

Abstract

We investigate the fine-grained complexity of approximating the classical k-Median/k-Means clustering problems in general metric spaces. We show how to improve the approximation factors to $(1 + 2/e + \varepsilon)$ and $(1 + 8/e + \varepsilon)$ respectively, using algorithms that run in fixed-parameter time. Moreover, we show that we cannot do better in FPT time, modulo recent complexity-theoretic conjectures.

1 Introduction

How well can we approximate the k-Median and k-Means clustering problems? This question has been intensively studied over the past two decades, and many interesting algorithmic techniques have been developed and refined in an attempt to understand these problems. Let us elaborate for the k-Median problem; the story for k-Means is much the

same. Recall that in the k-Median problem, given a metric space (V, d) with n points and clients at some of the points, the goal is to open k *facilities* such that the sum of distances from the clients to their closest facilities is minimized.

The first constant-factor approximation algorithm for k-Median was given by Charikar et al. [6]. After many interesting developments (e.g., primal-dual schemes, sophisticated LP rounding schemes, and pseudo-approximations), today the best approximation guarantee is 2.611 [3]. The best lower bound, however, is still the $(1 + 2/e)$-hardness from 1998, due to Guha and Khuller [16]. In this paper, we ask: can we do better if we give ourselves more resources? The problem can be solved exactly by brute-force enumeration in time $n^{k+O(1)}$, but what can we do, say, in FPT time $f(k)n^{O(1)}$?

We cannot hope to solve the problem exactly in FPT time: the reduction of Guha and Khuller also shows a $W[2]$-hardness for finding the optimal solution for k-Median/k-Means exactly. Naturally, we then ask what we can achieve by combining the two approaches together, and whether good approximation algorithms can be given in FPT time.

Our Results. Our main algorithmic result is a positive result in this direction:

▶ **Theorem 1** (Algorithm for k-Median/k-Means)**.** *For every $\varepsilon > 0$, there is a $(1+2/e+\varepsilon)$-approximation algorithm for the k-Median problem, that runs in time FPT time, i.e., in $f(k, \varepsilon)n^{O(1)}$ time. For the k-Means problem, we can achieve a $(1 + 8/e + \varepsilon)$-approximation in the same runtime.*

The approximation guarantees in Theorem 1 match the NP-hardness results for the two problems implied by [16]. However, since we are allowing ourselves FPT time and not just $\text{poly}(n, k)$ time, can we do even better and go past this NP-hardness barrier? Our second main result shows that this is not possible, at least under recent complexity-theoretic conjectures. We prove that the results in Theorem 1 are essentially tight, assuming the Gap-Exponential Time Hypothesis [12, 24, 5]:

▶ **Theorem 2** (Hardness)**.** *There exists a function $g : \mathbb{R}^+ \to \mathbb{R}^+$ such that assuming the Gap-ETH, for any $\varepsilon > 0$, any $(1 + 2/e - \varepsilon)$-approximation algorithm for k-Median, and any $(1 + 8/e - \varepsilon)$-approximation for k-Means, must run in time at least $n^{k^{g(\varepsilon)}}$.*

The basic component of the above hardness result is an FPT-hardness of a factor of $(1 - 1/e)$ for the Max k-Coverage problem, again using the Gap-ETH (Theorem 15). Composing that hardness result with the reduction of Guha and Khuller [16] gives us Theorem 2 above.

Matroid Median. Finally, using our algorithmic techniques, we are able to also give an improved approximation for the matroid-median problem, which is a generalization of the k-Median problem.

▶ **Theorem 3** (Algorithm for Matroid Median)**.** *There is a $(2+\varepsilon)$-approximation algorithm for the* Matroid Median *problem, that runs in time FPT time, i.e., in $f(k, \varepsilon)n^{O(1)}$ time.*

Since the Matroid Median problem is a generalization of the k-Median problem, the $(1 + 2/e - \varepsilon)$-hardness from Theorem 2 translates immediately to Matroid Median. It remains an open problem to close the gap between this lower bound and the $(2 + \varepsilon)$-approximation in Theorem 3. We can also use our ideas to get an $(3 - \frac{2}{p+1} + \varepsilon)$ for the p-Matroid Median problem.

Facility Location. Facility Location is a problem closely related to k-Median, where each facility has an opening cost and the goal is to open facilities to minimize the sum of distances from clients to their closest facilities plus the sum of the total opening costs. For this problem, the best known hardness ratio is $\alpha_{\mathsf{FL}} \approx 1.463$ [16], which is defined to be $\max_{x \geq 0} \left(1 + \frac{x}{1+x} \ln \frac{2}{x}\right)$. On the other hand, the best algorithm achieves an 1.488-approximation [21]. When the parameter k denotes the number of facilities open in the optimal solution, we prove that our techniques also give an FPT algorithm for Facility Location whose approximation ratio matches the hardness ratio of [16].

▶ **Theorem 4** (Algorithm for Facility Location). *There is a $(\alpha_{\mathsf{FL}} + \varepsilon)$-approximation algorithm for the* Facility Location *problem, that runs in time FPT time, i.e., in $f(k, \varepsilon) n^{O(1)}$ time.*

Roadmap. In Section 2, we describe the approximation algorithms for these problems. We assume throughout that the aspect ratio is polynomially bounded. (In the full version of the paper, we show that this assumption is without loss of generality, in the case we consider where the clients have unit weights.) In Section 3, we then give the hardness results for FPT Max k-Coverage, k-Median, and k-Means.

1.1 Our Techniques

The algorithm is inspired by the hardness result from [16]: it relies on the result of Feige [13] that Max k-Coverage is hard to approximate better than $(1 - 1/e)$. Hence, if we build a "factor graph" with sets on one side and elements on another, with edges indicating inclusion, picking k sets covers $(1 - 1/e)$ elements at distance 1, and the remaining at distance at least 3 – hence $1 + 2/e$. Now what if we have a general instance, with different distances? We show how to do limited enumeration (in FPT) time to restrict our choices to picking one facility each from k disjoint sets. Moreover, via a surprisingly clean idea we can model the objective as submodular maximization (subject to a partition matroid constraint). And this problem can be approximated well: the factor again is $(1 - 1/e)$, hence giving the same factor upto additive ε terms!

The matching hardness result is via showing an FPT hardness for Max k-Coverage assuming the Gap-ETH. Firstly, we show that assuming the Gap-ETH, there is no FPT approximation algorithm for Label Cover problem parameterized by the number of vertices k on one side of the bipartition. (Trying all labelings on one side takes time $O(n^{k+O(1)})$, and doing much better is hard.) To do this, we construct a *variable-clause game* from a 3-SAT instance, merge *clause vertices* into ℓ super-vertices, and then use r rounds of parallel repetition. (The number of clause vertices becomes $k := \ell^r$.) Then we compose this with the classical reduction from Label Cover to Max k-Coverage [13]. Due to some technical details (e.g., our Label Cover instance is not guaranteed to be regular) and for the sake of completeness, we provide a formal proof in Lemma 19. While our techniques are similar to recent FPT hardnesses for the related k-Dominating Set problem [5, 10], some technical details (e.g., the *projection property* of Label Cover instances) prevent us from directly using prior results to get $(1 - 1/e + \varepsilon)$-hardness for Max k-Coverage.

1.2 Related Work

We briefly survey the state-of-the-art for k-Median and k-Means; please see references below for more historical context. For general metric spaces, the best approximation ratio for k-Median is 2.611 [3] by Byrka et al., building on work of Li and Svensson [22]. Kanungo et al. [17] gave a $(9 + \varepsilon)$-approximation algorithm for k-Means in general metric spaces, which

was later improved to 6.357 by Ahmadian et al. [1]. The first constant factor approximation algorithm for Matroid Median was given by Krishnaswamy et al. [18], which was improved by Swamy [26] to 8.

For Euclidean spaces, the problems are better approximable, at least when either k or the dimension d are fixed; we restrict this discussion to parameterizing by k. Specifically, PTASs for both k-Median and k-Means with running time $f(k,\varepsilon)\operatorname{poly}(n,d)$ were given by Kumar et al. [19]. The running times were improved by Chen [7] to $O(nkd + d^2 n^\sigma 2^{(k/\varepsilon)^{O(1)}})$ for any $\sigma > 0$ for k-Median, and by Feldman et al. [15] to $O(nkd + d\operatorname{poly}(k/\varepsilon) + 2^{\tilde{O}(k/\varepsilon)})$ for k-Means. Both these latter results were based on the notion of coresets. The k-Means problem is APX hard even in Euclidean space, if both k and d are allowed to be arbitrary [2, 20].

A result of direct interest to this work is that of Czumaj and Sohler [11], for the *min-sum clustering problem*. They give a $(4+\varepsilon)$-approximation on general metrics in FPT time. They construct a small (strong) core-set for the related Balanced k-Median problem, and enumerate over all choices of centers inside this core-set. In the full version, we show that their approach extends to give a 2-approximation for the *non-bipartite case* of k-Median– in this special case of k-Median a facility may be opened at any client location, and hence $C \subseteq \mathbb{F}$. Theorem 1 above shows how to get a better guarantee for a more general case. (As an aside, the hardness for this special non-bipartite case is only $(1+1/e)$; closing this gap is another interesting open question.)

Hardness-of-approximation results for parameterized problems have been actively studied recently. Lin [23] proved $W[1]$-hardness of approximation for k-Biclique. Chen and Lin [9] proved $W[1]$-hardness of approximation for k-Dominating Set in any constant factor, which was later improved to any function $f(k)$ in [5, 10]. Chalermsook et al. [5] also proved that there is no FPT $o(k)$-approximation algorithm for k-Clique assuming the Gap-ETH.

1.3 Preliminaries

An instance $\mathcal{I}$ of the k-Median problem is defined by a tuple $((V,d), C, \mathbb{F}, k)$, where (V,d) is a metric space over a set of points V with $d(i,j)$ denoting the distance between two points i, j in V. Further, C and $\mathbb{F}$ are subsets of V and are referred as "clients" and "facility locations", and k is a positive parameter. The goal is to find a subset F of k facilities in $\mathbb{F}$ to minimize

$$\mathsf{cost}(C,F) := \sum_{j \in C} d(j,F).$$

In the *weighted* version of k-Median, every client $j \in C$ has an associated weight w_j, and the goal is to find a subset F of $\mathbb{F}$ of size k such that $\mathsf{cost}(C,F) := \sum_{j\in C} w_j d(j,F)$ is minimized.

The k-Means problem is defined similarly except that the objective function gets modified to $\mathsf{cost}(C,F) := \sum_{j\in C} d(j,F)^2$ (and analogously for the weighted version). The names of the two problems come from the fact that if the metric space is the real line and $k=1$, the optimal solution is the median and the mean respectively. In the Matroid Median problem, we are given a matroid on the set $\mathbb{F}$, and the set of open facilities must be an independent set in the matroid. Again, the goal is to minimize the assignment cost of clients to the nearest open facility.

In the Facility Location problem, an instance is not given k, but additionally has $\mathsf{open} : \mathbb{F} \to \mathbb{R}^+$ that indicates the opening cost of each facility. The goal is to find a subset $F \subseteq \mathbb{F}$ (without any restriction on $|F|$) that minimizes $\mathsf{open}(F) + \mathsf{cost}(C,F)$ where $\mathsf{open}(F) := \sum_{f\in F} \mathsf{open}(f)$.

Finally, the *aspect ratio* of a metric space (V,d) is $\Delta := \frac{\max_{x,y\in V} d(x,y)}{\min_{x,y\in V} d(x,y)}$.

2 The Approximation Algorithm

We now give the $(1+2/e+\varepsilon)$-approximation algorithm for k-Median, where $\varepsilon > 0$ is a fixed parameter throughout this section. The running time of the algorithm is $f(k,\varepsilon) \cdot \text{poly}(n)$, where $f(k,\varepsilon) = O(\varepsilon^{-2} k \log k)^k$. We then indicate the alterations to get algorithms for k-Means and Matroid Median.

2.1 The Intuition

We focus on k-Median for now; the ideas for the other problems are analogous. The first idea is to reduce the size of the client set C to $O(\varepsilon^{-2} k \log n)$– this can be done by results on core-sets for k-Median, which consolidate the clients into a small number of distinct locations [8, 14]. The consolidated clients now have weights, but this extension to weighted k-Median does not pose a problem.

The next idea is to carefully enumerate over the structure of an optimal solution. Consider an optimal solution $F^\star = \{f_1^\star, \ldots, f_k^\star\}$. For a facility $f_i^\star \in F^\star$, let "cluster" $C_i^\star$ be the clients assigned to $f_i^\star$, i.e., the subset of clients C for which $f_i^\star$ is closest open facility. Let ℓ_i be the client in $C_i^\star$ closest to $f_i^\star$ – we call it the *leader* of cluster $C_i^\star$. Let R_i be the distance $d(f^\star, \ell_i)$, suitably discretized. Our algorithm guesses the leaders ℓ_i and the distances R_i for each $i \in [k]$. Since the size of C is $O(\varepsilon^{-2} k \log n)$, there are $(O(\varepsilon^{-2} k \log n))^k$ choices for leaders,[1] and a similar number of choices for the distances; moreover, this quantity can be shown to be $f(k,\varepsilon) \cdot n^{O(1)}$.

Assume now that we have correctly guessed the leaders ℓ_i and distances R_i. For each leader ℓ_i, let F_i be the facilities at distance about R_i from ℓ_i – this set F_i contains $f_i^\star$. By making copies, assume the sets F_i are disjoint. Now our task is to select one facility from each set F_i such that the total (weighted) assignment cost of the clients in C is minimized. As such, this seems like a decreasing *supermodular minimization* problem with a (partition) matroid constraint. (Observe that choosing an arbitrary center in each F_i gives us a 3-approximation in FPT time, but we want to do much better.)

The last idea is to convert this into a monotone submodular maximization problem, again with a partition matroid constraint. For each set F_i, we add a *fictitious facility* f_i' such that (i) the assignment cost of clients to the fictitious facilities is at most $3OPT$, and (ii) for a subset S of facilities, the "improvement" $\mathsf{cost}(C, F') - \mathsf{cost}(C, F' \cup S)$, where F' is the set of fictitious facilities, is a monotone submodular function. We finally show that a $(1-1/e)$-approximation for this submodular maximization problem gives the desired approximation guarantee. The next two sections describe the algorithm for k-Median in detail. The extension to k-Means, Matroid Median and Facility Location then appears in the full version of the paper.

2.2 Client Reduction via Coresets

Consider an instance $\mathcal{I} = ((V,d), C, \mathbb{F}, k)$ of the k-Median problem. Let $\varepsilon > 0$ be a fixed constant. We now define the notion of core-sets and use known results to reduce the size of C to (a weighted) a set of size $O(\varepsilon^{-2} k \log n)$.

[1] Our analysis will tighten this bound to $O(\varepsilon^{-2} \log n)^k$, but this improvement can be ignored for this intuition section.

▶ **Definition 5** (Core-set). *A* (strong) core-set *for $\mathcal{I}$ is a set of clients $C' \subseteq V$ along with weights w_j for all $j \in C'$, such that*

$$\sum_{j \in C'} w_j \, d(j, F) \in (1-\varepsilon, 1+\varepsilon) \cdot \sum_{j \in C} d(j, F),$$

for every $F \subseteq \mathbb{F}$ with $|F| = k$.

A similar definition holds for a strong core-set for the k-Means problem. Since we deal only with strong core-sets in this paper, we drop the modifier and refer to them only as core-sets. The first core-sets for metric k-Median were given by Chen [8]; the following result is the best current construction:

▶ **Theorem 6** ([14], Theorem 15.4). *For $0 \leq \varepsilon, \delta \leq 1/2$, there exists a Monte Carlo algorithm that for each instance I of k-Median on a general metric, outputs a core-set $C' \subseteq C$ with size*

$$|C'| = O\Big(\frac{k \log n + \log 1/\delta}{\varepsilon^2}\Big)$$

with probability $1-\delta$, where $n = |V|$. Moreover, the algorithm runs in time $O(k(n+k) + \log^2(1/\delta) \log^2 n)$. For k-Means, the core-set is of size $|C'| = O\big(\frac{k \log n + \log 1/\delta}{\varepsilon^4}\big)$, and the runtime remains the same.

The power of core-sets lies in the following fact.

▷ Fact 7. Consider a k-Median/k-Means instance $\mathcal{I} = ((V,d), C, \mathbb{F}, k)$, and let C' be a (strong) core-set with weights w. Consider the weighted instance $\mathcal{I}' = ((V,d), C', \mathbb{F}, k, w)$, which is the instance $\mathcal{I}$ with its clients replaced by the weighted clients in the core-set. Then, for any $\beta \geq 1$, a β-approximate solution $F \subseteq \mathbb{F}$ to $\mathcal{I}'$ is a $\beta(1+O(\varepsilon))$-approximate solution to $\mathcal{I}$.

Therefore, in order to find a $(1+2/e+O(\varepsilon))$-approximation to a k-Median $\mathcal{I}$, it suffices to find a $(1+2/e+O(\varepsilon))$-approximation to $\mathcal{I}'$, and analogously for k-Means. Henceforth, we restrict our attention to the core-set instance $\mathcal{I}'$. In other words, we assume that our instances have only a small number of clients, but now the clients have associated weights. In the following sections, we show how to approximate such weighted k-Median/k-Means instances in FPT time.

2.3 Reduction to Submodular Maximization

Given Fact 7, we only consider instances $\mathcal{I} = ((V,d), C, \mathbb{F}, k, w)$ of weighted k-Median, where clients in C have weights in the range $[1, n]$ and $|C|$ is bounded by $O(\varepsilon^{-2} k \log n)$. In this section we prove the following approximation guarantee for k-Median; this, combined with Fact 7, proves the k-Median statement in Theorem 1.

▶ **Theorem 8.** *Let ε be a fixed parameter. Given a k-Median instance $\mathcal{I} = ((V,d), C', \mathbb{F}, k, w)$ with $|C'| = O(\varepsilon^{-2} k \log n)$, there is a $(1+2/e+O(\varepsilon))$-approximation algorithm that runs in $f(k,\varepsilon) n^{O(1)}$ time.*

By scaling, assume the minimum distance between points in V is 1, so the aspect ratio Δ is the maximum distance between two points in V. For a positive integer a, define $[\![a]\!] := (1+\varepsilon)^{\lceil \log_{(1+\varepsilon)} a \rceil}$ as the smallest power of $(1+\varepsilon)$ larger than or equal to a. Here, ε is the same fixed parameter as the one used in the core-set.

The formal algorithm follows the intuition in §2.1 and is described in Algorithm 2.1; let us step through it now. We iterate over all possible values $\ell_1, \ldots, \ell_k$ for the leaders, and $R_1, \ldots, R_k$ for the corresponding distances. The same vertex could appear several times in the subset $\{\ell_1, \ldots, \ell_k\}$, and so the latter should be thought of as a multi-set. In Step 7, we add k new fictitious facilities: for each i, the new facility f_i' is at distance $2R_i$ from all the facilities in F_i. The distance to all other points is determined by triangle inequality in Step 8. Claim 9 shows that this forms a valid metric. In Step 9, we define the "improvement" function $\mathsf{improv}(S)$ as the reduction in cost due to adding in the facilities in S. Claim 10 shows this function is monotone submodular. This means we can use the $(1 - 1/e)$-approximation algorithm [4] for monotone submodular function maximization subject to a matroid constraint to find a set S which contains exactly one facility from each of the sets F_i, since this is a partition matroid constraint. Observe that the function $\mathsf{improv}(\cdot)$ can be computed efficiently. This completes the description of the algorithm.

Algorithm 2.1 `FindCenters`.

1: **for** every multi-set $\{\ell_1, \ell_2, \ldots, \ell_k\} \subseteq C$ **do**
2: **for** every $R_1, \ldots, R_k$ such that $R_i \in [1, \ldots, \lceil\Delta\rceil]$ and R_i is a power of $(1+\varepsilon)$ **do**
3: $F_i \leftarrow \{f \in F \mid \lceil d(f, \ell_i)\rceil = R_i\}$
4: make copies of facilities to ensure that $F_1, \ldots, F_k$ are disjoint
5: Initialize $F' \leftarrow \varnothing$; F' will be the set of fictitious facilities
6: **for** $i = 1, \ldots, k$ **do**
7: add a new fictitious facility f_i' to F' and set $d(f_i', f) := 2R_i$ for all $f \in F_i$
8: define $d(f_i', v) := \min_{f \in F_i}(d(f_i', f) + d(f, v))$ for all other points v
9: define $\mathsf{improv}(S) := \mathsf{cost}(C, F') - \mathsf{cost}(C, S \cup F')$ for every set $S \subseteq \mathbb{F}$
10: find $S \subseteq \mathbb{F}$ approximately maximizing $\mathsf{improv}(S)$, such that $|S \cap F_i| = 1$
11: among all sets S computed in line 10, output S for which $\mathsf{cost}(C, S)$ is minimized.

To prove correctness of the algorithm, we need to show two things: the distance function defined on $F' \cup V$ in Step 8 is a metric, and the function improv defined in Step 9 is monotone and submodular. We defer the simple proofs to the full version of the paper.

▷ Claim 9. Consider the set F' defined during an iteration of the algorithm. The distance function defined on $F' \cup V$ is a metric.

▷ Claim 10. The function $\mathsf{improv}(S)$ defined in Step 9 is monotone and submodular with $\mathsf{improv}(\varnothing) = 0$.

Now to bound the runtime. Since $|C| = O(\varepsilon^{-2} k \log n)$, there are at most $\binom{O(\varepsilon^{-2} k \log n)+k-1}{k} = (O(\varepsilon^{-2} \log n))^k$ different multi-sets of size k with elements in C. In addition, there are $\log_{1+\varepsilon} \Delta$ many choices for R_i for each $i \in [k]$. Therefore, the number of iterations in Step 1 of the algorithm can be bounded by

$$(O(\varepsilon^{-2} \log n))^k \cdot (\log_{1+\varepsilon} \Delta)^k \leq \left(O\left(\frac{(\log \Delta)(\log n)}{\varepsilon^2}\right)\right)^k. \tag{2.1}$$

Since we started with the unweighted k-Median problem, the aspect ratio Δ can be assumed to polynomially bounded in n, and so the number of iterations can be bounded by $(O(\log n/\varepsilon^2))^k$, which is at most $n \cdot (O(\varepsilon^{-2} k \log k))^k$. Indeed, in case $k < \frac{\log n}{\log\log n}$, $(O(\log n/\varepsilon^2))^k \leq (O(1/\varepsilon^2))^k \cdot (\log n)^{\frac{\log n}{\log\log n}} = (O(1/\varepsilon^2))^k \cdot n$. Else $\log n \leq O(k \log k)$, and hence $(O(\log n/\varepsilon^2))^k = (O(k \log k/\varepsilon^2))^k$.

The algorithm for submodular maximization subject to a matroid constraint takes polynomial time, given a value oracle for the function [4, Theorem 1.1]: in fact it can be sped up for the case of partition matroid constraints [4, §3.3]. The value oracle for $\mathsf{improv}(S)$ can itself be implemented in polynomial time. Hence each iteration of the algorithm can be run in time polynomial in n.

The submodular maximization algorithm is a randomized Monte-Carlo algorithm that succeeds with only probability $1 - 1/n^2$, but we can easily boost the success probability by repetition: by running it $\tau := \mathrm{poly}(\varepsilon^{-1} k \log n)$ times for each input S and returning the maximum value obtained, we can ensure that with high probability it succeeds in all the calls we make.

2.3.1 Approximation Ratio

We now argue about the approximation ratio of the algorithm. We fix an optimal solution to the instance. Let $F^\star = \{f_1^\star, \ldots, f_k^\star\}$ be the centers opened by this solution. Define $C_i^\star$ as the clients for which the closest open center is $f_i^\star$, i.e., $C_i^\star := \{j \in C : d(j, f_i^\star) = d(j, F^\star)\}$. We define the notion of leaders with respect to this solution.

▶ **Definition 11** (Leader). *For each $i \in [k]$, call a client $j \in C_i^\star$ that minimizes $d(j, f_i^\star)$ over all $j \in C_i^\star$ the* leader *$\ell_i^\star$ of center $f_i^\star$. If there are multiple clients $j \in C_i^\star$ achieving the minimum, declare an arbitrary one to be the leader. Note that a client can be the leader of multiple centers $f_i^\star$. The* leaders *w.r.t. the solution $F^\star$ is the multi-set $\{\ell_1^\star, \ldots, \ell_k^\star\}$. For each leader $\ell_i^\star$, the* radius *$R_i^\star$ is defined as $\lceil d(\ell_i^\star, f_i^\star) \rceil$.*

Consider the iteration of Algorithm 2.1 where $\ell_1, \ldots, \ell_k$ are equal to $\ell_1^\star, \ldots, \ell_k^\star$ respectively, and $R_1, \ldots, R_k$ are equal to $R_1^\star, \ldots, R_k^\star$ respectively. Let $S^\star$ be the set output in Step 10 of the algorithm. It suffices to show that $\mathsf{cost}(C, S^\star) \le (1 + 2/e + \varepsilon)\mathsf{cost}(C, F^\star)$. We proceed to show this in the rest of the section.

As in the algorithm, define

$$F_i := \{f \in F \mid \lceil d(f, \ell_i^\star) \rceil = R_i^\star\},$$

so that $f_i^\star \in F_i$ for each $i \in [k]$. (Recall that the sets F_i are disjoint by duplicating facilities.) Let $F' = \{f_1', \ldots, f_k'\}$ be the set of fictitious facilities defined in the algorithm.

We are interested in the solutions S that consist of one center from each F_i, since one such solution is the desired $F^\star$. More formally, define a solution S to be *valid* if the set S can be listed as $(f_1, \ldots, f_k)$ so that $f_i \in F_i$ for each $i \in [k]$.

▷ Claim 12. For every valid S, $\mathsf{cost}(C, F' \cup S) = \mathsf{cost}(C, S)$.

Proof. List the set S as $(f_1, \ldots, f_k)$, where $f_i \in F_i$ for each $i \in [k]$. Informally, this claim amounts to showing that the fictitious facilities F' do not improve the solution S. To formalize this idea, fix a client $j \in C$ and a fictitious facility f_i', and let $f \in F_i$ be a closest center to j in F_i. Below, we show that in fact, client j is closer to $f_i \in S$ than to $f_i' \in F'$:

$$d(j, f_i) \overset{(\triangle \text{ ineq.})}{\le} d(j, f) + d(f, \ell_i^\star) + d(\ell_i^\star, f_i) \le d(j, f) + R_i^\star + R_i^\star = d(j, f) + d(f, f_i') = d(j, f_i').$$

Therefore, we have $d(j, F') \ge d(j, S)$ for all clients j, so

$$\mathsf{cost}(C, F' \cup S) = \sum_{j \in C'} w_j \, d(j, F' \cup S) = \sum_{j \in C'} w_j \, d(j, S) = \mathsf{cost}(C, S),$$

as desired. ◁

We now bound the cost of the solution which opens facilities at F'.

▷ Claim 13. $\mathsf{cost}(C, F') \le (3+2\varepsilon)\,\mathsf{cost}(C, F^\star)$.

Proof. It suffices to show that $d(j, F') \le (3+2\varepsilon)\,d(j, F^\star)$ for each client $j \in C$. Fix a client $j \in C$, and let $f_i^\star \in F^\star$ be a center achieving $d(j, f_i^\star) = d(j, F^\star)$. Since $\ell_i^\star$ is the leader of center $f_i^\star$, we have

$$d(j, f_i^\star) \ge d(\ell_i, f_i^\star) \ge \frac{R_i^\star}{1+\varepsilon}. \tag{2.2}$$

Recall that $f_i^\star \in F_i$. Therefore,

$$\begin{aligned} d(j, F') \le d(j, f_i') &\overset{(\triangle)}{\le} d(j, f_i^\star) + d(f_i^\star, f_i') = d(j, f_i^\star) + 2R_i^\star \\ &\overset{(2.2)}{\le} d(j, f_i^\star) + 2(1+\varepsilon)\,d(j, f_i^\star) \le (3+2\varepsilon)\,d(j, F^\star), \end{aligned}$$

as desired. ◁

Let $S^\star$ be the set output in Step 11. Since the algorithm of [4] is $(1-1/e)$-approximation,

$$\mathsf{improv}(S^\star) \ge (1-1/e)\mathsf{improv}(F^\star) \tag{2.3}$$

▶ **Lemma 14.** *The solution $S^\star$ in (2.3) satisfies* $\mathsf{cost}(C, S^\star) \le (1+2/e+O(\varepsilon))\,\mathsf{cost}(C, F^\star)$.

Proof. We bound the cost associated with this solution as follows.

$$\begin{aligned} \mathsf{cost}(C, S^\star) &\overset{(\text{Lem } 12)}{=} \mathsf{cost}(F' \cup S^\star) = \mathsf{cost}(C, F') - \mathsf{improv}(S^\star) \\ &\overset{(2.3)}{\le} \mathsf{cost}(C, F') - (1-1/e)\,\mathsf{improv}(F^\star) \\ &= \mathsf{cost}(C, F') - (1-1/e)\,(\mathsf{cost}(C, F') - \mathsf{cost}(C, F^\star)) \\ &= (1/e)\,\mathsf{cost}(C, F') + (1-1/e)\,\mathsf{cost}(C, F^\star) \\ &\overset{(\text{Lem } 13)}{\le} (3+2\varepsilon)(1/e)\,\mathsf{cost}(C, F^\star) + (1-1/e)\,\mathsf{cost}(C, F^\star) \\ &= (1+2/e+O(\varepsilon))\,\mathsf{cost}(C, F^\star). \end{aligned} \tag{2.4}$$

Hence the proof. ◀

2.3.2 Putting it all together

Our algorithm is a Monte Carlo randomized algorithm: both our subroutines use randomness. The first is the core-set construction in §2.2, and the second is the submodular maximization procedure in Step 10 of the algorithm. For each, we can make the error probability $1/\operatorname{poly}(n)$. Since each iteration of the algorithm can be implemented in $\operatorname{poly}(n)$ time, the runtime is dominated by the number of iterations, which is $(O(\varepsilon^{-2}k\log k)^k \operatorname{poly}(n))$. Moreover, combining the two steps of finding the core-set and the submodular maximization, the approximation ratio is $(1+\varepsilon)(1+2/e+O(\varepsilon)) = 1+2/e+O(\varepsilon)$. This proves Theorem 1 for the k-Median problem.

3 Gap-ETH Hardness of Max k-Coverage

In this section, we show that assuming the Gap Exponential Time Hypothesis (Gap-ETH) [12, 24], for any $\varepsilon > 0$, there is no FPT-approximation algorithm that approximates Max k-Coverage better than a factor $(1-1/e+\varepsilon)$.

▶ **Theorem 15** (Hardness for Max-Coverage). *There exists a function $g : \mathbb{R}^+ \to \mathbb{R}^+$ such that assuming the Gap-ETH, for any $\varepsilon > 0$, any $(1 - 1/e + \varepsilon)$-approximation algorithm for* Max k-Coverage *with n elements and m sets must run in time at least $(n+m)^{k^{g(\varepsilon)}}$.*

Using the reduction of Guha and Khuller [16], this immediately implies Theorem 2. The rest of the section is devoted to the proof of Theorem 15. The proof has two main components: the first part shows under the Gap-ETH, it takes at least $n^{h(k)}$ time to approximate the Label Cover problem even when one side of the bipartition has only k vertices; here $h(\cdot)$ is some increasing function depending on the quality of approximation. This reduction is inspired by the recent progress on the hardness of parameterized problems [5, 10] and was communicated to us by Pasin Manurangsi. The second part is the classical reduction from Label Cover to Max k-Coverage given by Feige [13].

3.1 Hardness of Label Cover from Gap-ETH

We begin with the standard definition of Label Cover.

▶ **Definition 16** (Label Cover). *An instance of* Label Cover $\mathcal{L}$ *consists of a bipartite graph $G = (U \cup V, E)$ with possibly parallel edges, two label sets Σ_U, Σ_V, and a projection $\pi_e : \Sigma_U \to \Sigma_V$ for each $e \in E$. Given a labeling $\sigma : (U \cup V) \to (\Sigma_U \cup \Sigma_V)$, an edge $e = (u, v) \in E$ is satisfied when $\pi_e(\sigma(u)) = \sigma(v)$. The goal of* Label Cover *is to find a labeling σ that maximizes the number of satisfied edges. Let $\mathsf{OPT}(\mathcal{L})$ be the maximum fraction of edges simultaneously satisfied by any labeling.*

Note that we include the *projection property* in the definition; all Label Cover instances in the paper will have this property. For a vertex $u \in U \cup V$, let d_u be the degree of u, and let d_U (resp. d_V) be the maximum degree of U (resp. V). We also call an instance *U-regular* (resp. *V-regular*) if all vertices in U (resp. V) have the same degree. All subsequent Label Cover instances will be U-regular, though the lack of V-regularity will require us to do a little more work in §3.2.

Given a 3-SAT formula ϕ, let $\mathsf{OPT}(\phi)$ be the maximum fraction of clauses that can be satisfied by any assignment. The Gap-ETH [12, 24] states that there exist some constants $\delta > 0, s < 1$ for which no algorithm, given a 3-SAT formula ϕ on n variables and $m = O(n)$ clauses, can distinguish whether $\mathsf{OPT}(\phi) = 1$ or $\mathsf{OPT}(\phi) < s$ in time $O(2^{\delta n})$. The main result of this subsection is the following lemma.

▶ **Lemma 17.** *For every $\ell, r \in \mathbb{N}$, there is a reduction that, given 3-SAT formula ϕ with n variables and m clauses, outputs a U-regular* Label Cover *instance $\mathcal{L}$ such that*

- *(Completeness)* $\mathsf{OPT}(\phi) = 1 \implies \mathsf{OPT}(\mathcal{L}) = 1$, *and*
- *(Soundness)* $\mathsf{OPT}(\phi) < s \implies \mathsf{OPT}(\mathcal{L}) < s^{\Omega(r)}$,

where $|U| = \ell^r, |V| = n^r, |\Sigma_U| = 2^{O(mr/\ell)}, |\Sigma_V| = 2^{O(r)}, d_V \le m^r$. The running time of this reduction is $m^{O(r)} \cdot |\Sigma_U|$.

In particular, assuming Gap-ETH, for any $\eta > 0$, if we let $r = \Theta(\log(1/\eta))$ so that

$$|\Sigma_U|^{|U|^{O(1/\log(1/\eta))}} = |\Sigma_U|^{|U|^{1/2r}} = |\Sigma_U|^{\ell^{1/2}} = 2^{O(mr/\sqrt{\ell})},$$

no algorithm can take a Label Cover *instance $\mathcal{L}$ and can decide whether $\mathsf{OPT}(\mathcal{L}) = 1$ or $\mathsf{OPT}(\mathcal{L}) < \eta$ in time $|\Sigma_U|^{|U|^{O(1/\log(1/\eta))}}$.*

Note that a brute-force algorithm that tries every assignment to U and chooses the best assignment for V for it runs in $O(|\Sigma_U|^{|U|})$ times a polynomial. Lemma 17 shows that assuming the Gap-ETH, even approximately solving Label Cover requires significant time.

Lemma 17 is proved by a series of well-known transformations between Label Cover instances. We start with the following basic hardness result for Label Cover assuming the Gap-ETH, which follows from essentially restating Gap-ETH as a *clause-variable* game:

▶ **Theorem 18** (Theorem 4.1 of [5]). *There is a reduction that, given 3-SAT formula ϕ with n variables and m clauses, outputs a U-regular* Label Cover *instance $\mathcal{L}$ such that*

- *(Completeness)* $\mathsf{OPT}(\phi) = 1 \implies \mathsf{OPT}(\mathcal{L}) = 1$, *and*
- *(Soundness)* $\mathsf{OPT}(\phi) < s' \implies \mathsf{OPT}(\mathcal{L}) < s = 1 - (1 - s')/3$,

where $|U| = m, |V| = n, |\Sigma_U| = 7, |\Sigma_V| = 2, d_V \leq m$, and G is U-regular with $d_U = 3$. In particular, assuming the Gap-ETH, there exist constants $\delta > 0$, $s < 1$ such that no algorithm can take a Label Cover *instance $\mathcal{L}$ and can decide whether $\mathsf{OPT}(\mathcal{L}) = 1$ or $\mathsf{OPT}(\mathcal{L}) < s$ in $O(2^{\delta|U|})$ time.*

Let ℓ be a parameter that will be related to k in Max k-Coverage later. We can ensure ℓ divides $|U|$ by taking an arbitrary vertex in U and making $\ell\lceil|U|/\ell\rceil - |U|$ copies of it. This does not change any of the properties in Theorem 18 except to increase the soundness s by $o_n(1)$; however, the soundness still remains bounded away from 1.

Since we want few vertices on the left, we construct a new Label Cover instance $\mathcal{L}_1$ by partitioning U into ℓ groups and creating super-vertices for each one. Formally, index the vertices of u as $U = \{u_{i,j}\}_{i\in[\ell],j\in[m/\ell]}$, and let the i^{th} part be $S_i := \{u_{i,j}\}_{j\in[m/\ell]}$. The new instance $\mathcal{L}_1 = ((U_1 \cup V_1, E_1), \Sigma_{U_1}, \Sigma_{V_1}, \{\pi^1_e\}_{e\in E_1})$ is constructed as follows.

- $V_1 = V$ and $\Sigma_{V_1} = \Sigma_V$ (the RHS remains unchanged),
- $U_1 = \{S_1, \ldots, S_\ell\}$. $\Sigma_{U_1} = (\Sigma_U)^{m/\ell}$ (the LHS has one super-vertex for each group), and
- for each $e = (u, v) \in E$ such that $u = u_{i,j}$, add an edge $e' = (S_i, v)$ to E_1 with the projection $\pi^1_{e'}(\sigma_1, \ldots, \sigma_{m/\ell}) := \pi_e(\sigma_j)$ where the latter π_e denotes the projection in $\mathcal{L}$. (Recall we allow parallel edges with different projections.)

Since the set of possible labelings and the set of edges remain the same except for syntactic changes, the completeness c and the soundness s do not change. The parameters become $|U_1| = \ell, |V_1| = |V|, |\Sigma_{U_1}| = 2^{O(m/\ell)}, |\Sigma_{V_1}| = O(1)$. It still maintains U-regularity and $d_{V_1} = d_V \leq m$.

The final transformation is the powerful *parallel repetition* step, which shows that the soundness decreases exponentially as we take the natural graph power. Fix $r \in \mathbb{N}$. The instance $\mathcal{L}_2 = ((U_2 \cup V_2, E_2), \Sigma_{U_2}, \Sigma_{V_2}, \{\pi^2_e\}_{e\in E_2})$ is constructed as follows.

- $U_2 = (U_1)^r$ and $\Sigma_{U_2} = (\Sigma_{U_1})^r$.
- $V_2 = (V_1)^r$ and $\Sigma_{V_2} = (\Sigma_{V_1})^r$.
- $E_2 = (E_1)^r$. For each $e = (e_i)_{i\in[r]} \in E_2$ with $e_i = (u_i, v_i) \in E_1$ and $(\sigma_1, \ldots, \sigma_r) \in \Sigma^r_{U_1}$, $\pi^2_e(\sigma_1, \ldots, \sigma_r) = (\pi^1_{e_1}(\sigma_1), \ldots, \pi^1_{e_r}(\sigma_r))$.

The parameters become $|U_2| = \ell^r, |V_2| = |V|^r = n^r, |\Sigma_{U_2}| = 2^{O(mr/\ell)}, |\Sigma_{V_2}| = 2^{O(r)}, d_{V_2} \leq d^r_{V_1} \leq m^r$, and $\mathcal{L}_2$ maintains U-regularity. The completeness c still remains 1, and by the parallel repetition theorem [25], the soundness drops $s = 2^{-\Theta(r)}$, where the constant hiding in the Θ depends on the original soundness. This proves Lemma 17.

3.2 Hardness of Max k-Coverage from Label Cover

Given the "nice" Label Cover instance from Lemma 17 we now show how to reduce this to Max k-Coverage. This reduction is standard and closely follows the classical one given by Feige [13], modulo some minor issues arising from it not being V-regular.

Recall that an instance of $\mathcal{I}$ of Max k-Coverage consists of an underlying universe $\mathcal{U}$, a family $\mathcal{S}$ of subsets, and an integer k. The goal is to find a subfamily $\mathcal{S}' \subseteq \mathcal{S}$ with $|\mathcal{S}'| = k$ that covers the largest number of elements. For notational simplicity, we prove the hardness

of the *weighted version* of Max k-Coverage where each element $e \in \mathcal{U}$ has weight $w(e)$ and we want to maximize the total weight of the covered elements. Note that weighted instances can be easily converted to unweighted instances by duplicating elements according to their weights. In our reduction, the ratio between the maximum and the minimum weight will be bounded by the number of elements. The proof appears in the full version of the paper.

▶ **Lemma 19** (Reduction #2). *There exist functions $a : \mathbb{R}^+ \to \mathbb{N}$ and $f : \mathbb{R}^+ \to \mathbb{R}^+$ such that for any $\varepsilon > 0$, there exists a polynomial-time reduction that takes a* Label Cover *instance $\mathcal{L} = ((U \cup V, E), \Sigma_U, \Sigma_V, \{\pi_e\}_{e \in E})$ that is U-regular and has the maximum V-degree d_V, and produces a* Max k-Coverage *instance $\mathcal{I} = (\mathcal{U}, \mathcal{S}, k)$ such that*

- *(Completeness)* $\mathsf{OPT}(\mathcal{L}) = 1 \implies \mathsf{OPT}(\mathcal{I}) = w(\mathcal{U})$.
- *(Soundness)* $\mathsf{OPT}(\mathcal{L}) < f(\varepsilon) \implies \mathsf{OPT}(\mathcal{I}) \le (1 - 1/e + \varepsilon) \cdot w(\mathcal{U})$.

The reduction satisfies $|\mathcal{U}| \le |V| \cdot |d_V|^{a(\varepsilon)} \cdot a(\varepsilon)^{\Sigma_V}$, $|\mathcal{S}| = a(\varepsilon) \cdot |U| \cdot |\Sigma_U|$, and $k = a|U|$.

We can now finish the proof of Theorem 15 based on Lemma 17 and Lemma 19.

Proof of Theorem 15. Fix $\varepsilon > 0$ that determines $a(\varepsilon)$ and $f(\varepsilon)$ in Lemma 19. Let $r \in \mathbb{N}$ in Lemma 17 so that the soundness $2^{-\Omega(r)} \le f(\varepsilon)$.

With ℓ still being a free parameter, Lemma 17 shows a reduction from an initial 3-SAT instance ϕ with n variables and $m = O(n)$ clauses to a Label Cover instance with $|U| = \ell^r, |V| = n^r, |\Sigma_U| = 2^{O(mr/\ell)}, |\Sigma_V| = 2^{O(r)}$, and $d_V \le m^r$. Lemma 19 with this Label Cover instance produces a Max k-Coverage instance with

$$\begin{aligned} |\mathcal{U}| &\le |V| \cdot |d_V|^a \cdot a^{\Sigma_V} = n^{O(ar)} \cdot a^{2^{O(r)}} \\ |\mathcal{S}| &= a \cdot |U| \cdot |\Sigma_U| = a\ell^r \cdot 2^{O(nr/\ell)} \\ k &= a|U| = a\ell^r. \end{aligned}$$

An $(1 - 1/e + \varepsilon)$-approximation algorithm for Max k-Coverage that runs in time $|\mathcal{S}|^{k^{1/2r}}$ will distinguish whether $\mathsf{OPT}(\phi) = 1$ or $\mathsf{OPT}(\phi) < s'$ for some s' in time

$$2^{O((nr/\ell) \cdot k^{1/2r})} = 2^{O((nr/\ell) \cdot \sqrt{\ell})} = 2^{O(nr/\sqrt{\ell})},$$

which will contradict the Gap-ETH for large enough ℓ. Observe that $|\mathcal{S}| \gg |\mathcal{U}|$; if we set $g(\varepsilon) := 1/2r$, we get the same implication from an algorithm that runs in time $|\mathcal{U}|^{k^{g(\varepsilon)}}$, which proves the theorem. ◀

Abstract

In the group testing problem we aim to identify a small number of infected individuals within a large population. We avail ourselves to a procedure that can test a group of multiple individuals, with the test result coming out positive iff at least one individual in the group is infected. With all tests conducted in parallel, what is the least number of tests required to identify the status of all individuals? In a recent test design [Aldridge et al. 2016] the individuals are assigned to test groups randomly, with every individual joining an equal number of groups. We pinpoint the sharp threshold for the number of tests required in this randomised design so that it is information-theoretically possible to infer the infection status of every individual. Moreover, we analyse two efficient inference algorithms. These results settle conjectures from [Aldridge et al. 2014, Johnson et al. 2019].

1 Introduction

1.1 Background and motivation

The group testing problem goes back to the work of Dorfman from the 1940s [19]. Among a large population a few individuals are infected with a rare disease. The objective is to identify the infected individuals effectively. At our disposal we have a testing procedure capable of

not merely testing one individual, but several. The test result will be positive if any one individual in the test group is infected, and negative otherwise; all tests are conducted in parallel. We are at liberty to assign a single individual to several test groups. The aim is to devise a test design that identifies the status of every single individual correctly while requiring as small a number of tests as possible.

A recently proposed test design allocates the individuals to tests randomly [7, 10, 11, 28, 32]. To be precise, given integers $n, m, \Delta > 0$ we create a random bipartite multi-graph by choosing independently for each of the n vertices $x_1, \ldots, x_n$ "on the left" Δ neighbours among the m vertices $a_1, \ldots, a_m$ "on the right" uniformly at random with replacement. The vertices $x_1, \ldots, x_n$ represent the individuals, the $a_1, \ldots, a_m$ represent the test groups and an individual joins a test group iff the corresponding vertices are adjacent. The wisdom behind this construction is that the expansion properties of the random bipartite graph precipitate virtuous correlations, facilitating inference.

Given n and (an estimate of) the number k of infected individuals, what is the least m for which, with a suitable choice of Δ, the status of every individual can be inferred correctly from the test results with high probability? Like in many other inference problems the answer comes in two instalments. First, we might ask for what m it is *information-theoretically* possible to detect the infected individuals. In other words, regardless of computational resources, do the test results contain enough information in principle to identify the infection status of every individual? Second, for what m does this problem admit *efficient algorithms*?

The first main result of this paper resolves the information-theoretic question completely. Specifically, Aldridge, Johnson and Scarlett [11] obtained a function $m_{\inf} = m_{\inf}(n, k)$ such that for any fixed $\varepsilon > 0$ the inference problem is information-theoretically infeasible if $m < (1-\varepsilon)m_{\inf}$. They conjectured that this bound is tight, i.e., that for $m > (1+\varepsilon)m_{\inf}(n, k)$ there is an (exponential) algorithm that correctly identifies the infected individuals with high probability. We prove this conjecture.

Furthermore, concerning the algorithmic question, Johnson, Aldridge and Scarlett [28] obtained a function $m_{\mathrm{alg}} = m_{\mathrm{alg}}(n, k)$ that exceeds $m_{\inf}$ by a modest constant factor such that for $m > (1 + \varepsilon)m_{\mathrm{alg}}$ certain efficient algorithms successfully identify the infected individuals with high probability. They conjectured that `SCOMP`, their most sophisticated algorithm, actually succeeds for smaller values of m. We refute this conjecture and show that `SCOMP` fails to outperform a much simpler algorithm called `DD`.

A technical novelty of the present work is that we investigate the group testing problem from a new perspective. While most prior contributions rely either on elementary calculations and/or information-theoretic arguments [10, 11, 28, 38, 39], here we bring to bear techniques from the theory of random constraint satisfaction problems [5, 31]. Indeed, group testing can be viewed naturally as a constraint satisfaction problem: the tests provide the constraints and the task is to find all possible ways of assigning a status ("infected" or "not infected") to the n individuals in a way consistent with the given test results. Since the allocation of individuals to tests is random, this question is similar in nature to, e.g., the random k-SAT problem that asks for a Boolean assignment that satisfies a random collection of clauses [4, 6, 16, 18]. Apart from obtaining the aforementioned new results, this novel perspective allows for short proofs of results that were established more laboriously in prior work. It also puts the group testing problem in the same framework as the considerable body of recent work on other inference problems on random graphs such as the stochastic block model (e.g., [1, 15, 17, 34, 35, 41]).

We proceed to state the main results of the paper precisely, followed by a detailed discussion of the prior literature on group testing. An outline of the proof strategy follows in Section 2.

1.2 The information-theoretic threshold

Throughout the paper we labour under the assumptions commonly made in the context of group testing; we will revisit their merit in Section 1.4. Specifically, we assume that the number k of infected individuals satisfies $k \sim n^\theta$ for a fixed $0 < \theta < 1$. Moreover, let $\boldsymbol{\sigma} \in \{0,1\}^{\{x_1,\ldots,x_n\}}$ be a vector of Hamming weight k chosen uniformly at random. The (one-)entries of $\boldsymbol{\sigma}$ indicate which of the n individuals are infected. Moreover, let $\boldsymbol{G} = \boldsymbol{G}(n, m, \Delta)$ signify the aforementioned random bipartite graph. Then $\boldsymbol{\sigma}$ induces a vector $\hat{\boldsymbol{\sigma}} \in \{0,1\}^{\{a_1,\ldots,a_m\}}$ that indicates which of the m tests come out positive. To be precise, $\hat{\boldsymbol{\sigma}}_i = 1$ iff test a_i is adjacent to an individual x_j with $\boldsymbol{\sigma}_{x_j} = 1$. For what m is it possible to recover $\boldsymbol{\sigma}$ from $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$? Here, we settle an important open question [28] on the sharpness of the information-theoretic threshold. (Throughout the paper all logarithms are base e.)
