▶ **Theorem 1.** *Suppose that $0 < \theta < 1$, and $\varepsilon > 0$ and let*

$$m_{\inf} = m_{\inf}(n,\theta) = \frac{n^\theta(1-\theta)\log(n)}{\min\left\{1, \frac{1-\theta}{\theta}\log 2\right\}\log 2}.$$

- **(i)** *If $m < (1-\varepsilon)m_{\inf}(n,\theta)$, then there does not exist any algorithm that given $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}, k$ outputs $\boldsymbol{\sigma}$ with a non-vanishing probability.*
- **(ii)** *If $m > (1+\varepsilon)m_{\inf}(n,\theta)$, then there exists an algorithm that given $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$ outputs $\boldsymbol{\sigma}$ with high probability.*

Since for $\theta \le \log(2)/(1+\log(2))$ the first part of Theorem 1 readily follows from a folklore argument [20], the interesting regime is $\theta > \log(2)/(1+\log(2)) \approx 0.41$. In this regime Theorem 1 strengthens a result from [11], who showed that for $m < (1-\varepsilon)m_{\inf}$ any inference algorithm has a strictly positive error probability. By comparison, Theorem 1 shows that any algorithm fails with *high* probability.

But the main contribution of Theorem 1 is the second, positive statement. While the case $\theta > 1/2$ is easy because a plain greedy algorithms succeeds [28], the case $\theta < 1/2$ proved more challenging and was so far only heuristically justified using techniques from statistical physics [32] and for $\theta < 1/3$ for a different test design [38, 39]. Indeed, Aldridge et al. [10] conjectured that in this case inferring $\boldsymbol{\sigma}$ from $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$ is equivalent to solving a hypergraph minimum vertex cover problem. The proof of Theorem 1 vindicates this conjecture. Specifically, the vertex set of the hypergraph comprises all "potentially infected" individuals, i.e., those that do not appear in any negative test. The hyperedges are the neighbourhoods ∂a_i of the positive tests a_i in $\boldsymbol{G}$. Exhaustive search solves this vertex cover problem in time $\exp(O(n^\theta \log n))$. But how about efficient algorithms for general θ?

1.3 Efficient algorithms for group testing

Several polynomial time group testing algorithms have been proposed. A very simple greedy strategy called `DD` (for "definitive defectives") first labels all individuals that are members of negative test groups as healthy. Subsequently it checks for positive tests in which all individuals but one have been identified as healthy in the first step. Clearly, the single as yet unlabelled individual in such a test group must be infected. Up to this point all decisions made by `DD` are correct. But in the final step `DD` marks all as yet unclassified individuals as healthy, possibly causing false negatives. In fact, the output of `DD` may be inconsistent with the test results as possibly some positive tests may fail to spot an individual classified as "infected".

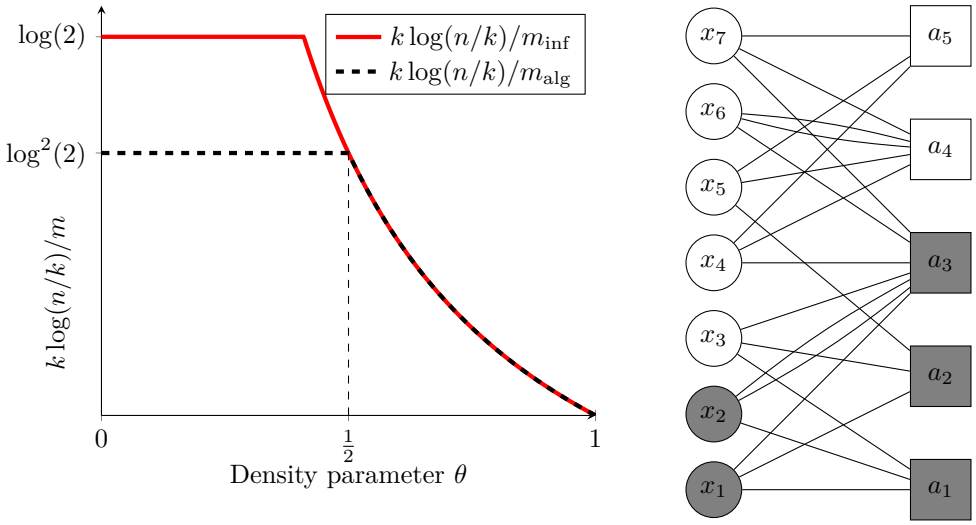

Figure 1 The left diagram displays $m_{\mathrm{inf}}, m_{\mathrm{alg}}$. The red line shows the information theoretic threshold m_{inf}, the dashed black line signifies the bound m_{alg} which is achieved by the both the SCOMP and the DD algorithm. The graph on the right illustrates a small example of a group testing instance, with the individuals $x_1, \dots, x_7$ on the left and the tests $a_1, \dots, a_5$ on the right. Infected individuals and positive tests are coloured in grey.

The more sophisticated SCOMP algorithm is roughly equivalent to the well-known greedy algorithm for the hypergraph vertex cover problem applied to the hypergraph from the previous paragraph. Specifically, in its first step SCOMP proceeds just like DD, classifying all individuals that occur in negative tests as healthy. Then SCOMP identifies as infected all unmarked individuals that appear in at least one test whose other participants are already known to be healthy. Subsequently the algorithm keeps picking an individual that appears in the largest number of as yet "unexplained" (viz. uncovered) positive tests and marks that individual as infected, with ties broken randomly, until every positive test contains an individual classified as infected. Clearly, SCOMP may produce false positives as well as false negatives. But at least the output is consistent with the test results.

Analysing SCOMP has been prominently posed as an open problem in the group testing literature [8, 10, 28]. Indeed, Aldridge et al. [10] opined that "the complicated sequential nature of SCOMP makes it difficult to analyse mathematically". On the positive side, [10] proved that SCOMP succeeds in recovering $\boldsymbol{\sigma}$ correctly given $(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ if $m > (1+\varepsilon)m_{\mathrm{alg}}(n,\theta)$ w.h.p., where

$$m_{\mathrm{alg}} = m_{\mathrm{alg}}(n,\theta) = \frac{n^{\theta}(1-\theta)\log(n)}{\min\left\{1, \frac{1-\theta}{\theta}\right\}\log^2 2}. \tag{1.1}$$

However, the algorithm succeeds for a trivial reason; namely, for $m > (1+\varepsilon)m_{\mathrm{alg}}$ even DD suffices to recover $\boldsymbol{\sigma}$ w.h.p. Yet based on experimental evidence [10, 28] conjectured that SCOMP strictly outperforms DD. The following theorem refutes this conjecture.

▶ **Theorem 2.** *Suppose that $0 < \theta < 1$ and $\varepsilon > 0$. If $m < (1-\varepsilon)m_{\mathrm{alg}}(n,\theta)$, then given $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$ w.h.p. both SCOMP and DD fail to output $\boldsymbol{\sigma}$.*

For $\theta < 1/2$ the information-theoretic bound provided by Theorem 1 and the algorithmic bound m_{alg} supplied by Theorem 2 remain a modest constant factor apart; see Figure 1. In some other inference problems on random graphs such as the stochastic block model similar

gaps appear between the information-theoretic and the algorithmic bounds [1, 17, 34, 41]. There have been attempts at investigating to what extent these gaps are due to genuine computational barriers, i.e., [23, 24, 25, 26]. Whether there actually exists a computationally hard regime for group testing, or whether the gap can be closed by smarter algorithms, remains an exciting question for future research.

1.4 Discussion and related work

Dorfman's original group testing scheme, intended to test the American army for syphilis, was *adaptive*. In a first round of tests each soldier would be allocated to precisely one test group. If the test result came out negative, none of the soldiers in the group were infected. In a second round the soldiers whose group was tested positively would then be tested individually. Of course, Dorfman's scheme was not information-theoretically optimal. An optimal adaptive scheme that involves several test stages, with the tests conducted in the present stage governed by the results from the previous stages, is known [20, 12]. In the adaptive scenario the information-theoretic threshold works out to be

$$m_{\mathrm{inf}}^{\mathrm{adapt}}(n,k) = \frac{n^\theta(1-\theta)\log(n)}{\log 2}.$$

The lower bound, i.e., that no adaptive design gets by with $(1-\varepsilon)m_{\mathrm{inf}}^{\mathrm{adapt}}(n,k)$ tests, follows from a very simple information-theoretic consideration. Namely, with a total of m tests at our disposal there are merely 2^m possible test outcomes, and we need this number to exceed the count $\binom{n}{k}$ of possible vectors $\boldsymbol{\sigma}$.

More recently there has been a great deal of interest in non-adaptive group testing, where the infection status of each individual is to be determined after just one round of tests [7, 9, 10, 11, 14, 22, 28, 32, 38, 39]. This is the version of the problem that we deal with in the present paper. An important advantage of the non-adaptive scenario is that tests, which may be time-consuming, can be conducted in parallel. Indeed, some of today's most popular applications of group testing are non-adaptive such as DNA screening [14, 30, 37] or protein interaction experiments [36, 40] in computational molecular biology. The randomised test design that we deal with here is the best currently known non-adaptive design (in terms of the number of tests required).

The most interesting regime for the group testing problem is when the number k of infected individuals scales as a power n^θ of the entire population. Mathematically this is because in the linear regime $k = \Omega(n)$ the optimal strategy is to perform n individual tests [9]. Thus, for k linear in n there is nothing interesting to do. But the sublinear case is also of practical relevance, as witnessed by Heap's law in epidemiology [13] or biological applications [22].

Apart from the randomised test design $\boldsymbol{G}$ where each individual chooses precisely Δ tests (with replacement), the so-called Bernoulli design assigns each individual to every test with a certain probability independently. A considerable amount of attention has been devoted to this model, and its information-theoretic threshold as well as the thresholds for various algorithms have been determined [8, 7, 10, 38, 39]. However, the Bernoulli test design, while easier to analyse, is provably inferior to the test design $\boldsymbol{G}$ that we study here. This is because in the Bernoulli design there are likely quite a few individuals that participate in far fewer tests than expected due to random degree fluctuations.

1.5 Notation

Throughout the paper $\boldsymbol{G} = \boldsymbol{G}(n, m, \Delta)$ denotes the random bipartite graph that describes which individuals take part in which test groups, the vector $\boldsymbol{\sigma} \in \{0,1\}^{\{x_1,\dots,x_n\}}$ encodes which individuals are infected, and $\hat{\boldsymbol{\sigma}} \in \{0,1\}^{\{a_1,\dots,a_m\}}$ indicates the test results. Moreover, $k \sim n^\theta$ signifies the number of infected individuals. Additionally, we write $V = V_n = \{x_1, \dots, x_n\}$ for the set of all individuals and $V_0 = \{x_i \in V : \boldsymbol{\sigma}_{x_i} = 0\}$, $V_1 = V \setminus V_0$ for the set of healthy and infected individuals, respectively. For an individual $x \in V$ we write ∂x for the set of tests a_i adjacent to x. Analogously, for a test a_i we denote by ∂a_i the set of individuals that take part in the test. Finally, all asymptotic notation refers to the limit $n \to \infty$. Thus, $o(1)$ denotes a term that vanishes in the limit of large n, while $\omega(1)$ stands for function that diverges to ∞ as $n \to \infty$.

2 Outline

We give an overview of the main arguments upon which the proofs of Theorems 1 and 2 rest.

2.1 The Nishimori identity

The very first item on the agenda is to get a handle on the posterior distribution of $\boldsymbol{\sigma}$ given $\boldsymbol{G}$ and $\hat{\boldsymbol{\sigma}}$. To this end, let $S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ be the set of all vectors $\sigma \in \{0,1\}^V$ of Hamming weight k such that

$$\hat{\boldsymbol{\sigma}}_{a_i} = \mathbf{1}\{\exists x \in \partial a_i : \sigma_x = 1\} \qquad \text{for all } i \in [m].$$

In words, $S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ contains the set of all vectors σ with k ones that label the individuals infected/healthy in a way consistent with the test results. Let $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = |S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})|$. The following proposition shows that the posterior of $\boldsymbol{\sigma}$ given $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$ is uniform on $S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$.

▶ **Proposition 3** ([7]).
For all $\tau \in \{0,1\}^{\{x_1,\dots,x_n\}}$ *we have* $\mathbb{P}[\boldsymbol{\sigma} = \tau \mid \boldsymbol{G}, \hat{\boldsymbol{\sigma}}] = \dfrac{\mathbf{1}\{\tau \in S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})\}}{Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})}$.

Adopting the jargon of the recent literature on inference problems on random graphs, we refer to Proposition 3 as the *Nishimori identity* [15, 41]. The proposition shows that apart from the actual test results, there is no further "hidden information" about $\boldsymbol{\sigma}$ encoded in $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$. In particular, the information-theoretically optimal inference algorithm just outputs a uniform sample from $S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$. In effect, we obtain the following.

▶ **Corollary 4.**
1. *If* $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = \omega(1)$ *w.h.p., then for any algorithm* $\mathcal{A}$ *we have*

$$\mathbb{P}[\mathcal{A}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}, k) = \boldsymbol{\sigma}] = o(1).$$

2. *If* $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 1$ *w.h.p., then there is an algorithm* $\mathcal{A}$ *such that*

$$\mathbb{P}[\mathcal{A}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}, k) = \boldsymbol{\sigma}] = 1 - o(1).$$

Both the positive and the negative part of Corollary 4 assume that the precise number k of infected individuals is known to the algorithm. This assumption makes the negative part stronger, but weakens the positive part. Yet we will see in due course how in the positive scenario the assumption that k be known can be removed. The upshot is that we need to get a handle on $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$.

2.2 The information-theoretic threshold

We proceed to discuss the proof of Theorem 1. The proofs of the first, negative statement and of the second, positive statement hinge on two separate arguments. We begin with the negative statement that w.h.p. $\boldsymbol{\sigma}$ cannot be inferred if $m < (1-\varepsilon)m_{\inf}$.

2.2.1 The information-theoretic lower bound

In light of Corollary 4 in order to prove the first part of Theorem 1 we need to show that the number $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ of assignments consistent with the test results $\hat{\boldsymbol{\sigma}}$ is unbounded w.h.p. The proof of this fact is based on a very simple idea: we just identify a biggish number of individuals whose infection status could be flipped without affecting the test results. To be precise, let $V_0^+ = V_0^+(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ be the set of all healthy individuals x_i such that every test in which x_i occurs is positive; in symbols,

$$V_0^+ = \{x_i \in V_0 : \forall a \in \partial x_i \exists y \in \partial a : \boldsymbol{\sigma}_y = 1\}. \tag{2.1}$$

Similarly, let V_1^+ be the set of all infected individuals x_i such that every test in which x_i occurs features another infected individual; in symbols,

$$V_1^+ = \{x_i \in V_1 : \forall a \in \partial x_i \exists y \in \partial a \setminus \{x_i\} : \boldsymbol{\sigma}_y = 1\}.$$

We think of the individuals in V_0^+ as the "potential false positives". Indeed, if for any $x_i \in V_0^+$ we obtain $\boldsymbol{\sigma}'$ from $\boldsymbol{\sigma}$ by setting x_i to one, then $\boldsymbol{\sigma}'$ will render the same test results as $\boldsymbol{\sigma}$. Similarly, the individuals in V_1^+ are potential false negatives.

The following lemma yields a bound on m below which potential false positives and negatives abound. A simple (omitted) calculation also yields the value of Δ that is optimal to facilitate inference, namely $\Delta = \lceil \frac{m}{k} \log 2 \rceil$.

▶ **Lemma 5.** *Let $\varepsilon > 0$ and $0 < \theta < 1$ and assume that*

$$m < \frac{(1-\varepsilon)\theta}{(1-\theta)\log^2 2} n^\theta (1-\theta) \log n$$

Then even with the optimal choice $\Delta = \lceil \frac{m}{k} \log 2 \rceil$ we have $|V_0^+|, |V_1^+| = n^{\Omega(1)}$ w.h.p.

The proof of Lemma 5 relies on a basic random graphs argument. As an immediate application we obtain the following information-theoretic lower bound.

▶ **Corollary 6.** *Let $\varepsilon > 0$ and $0 < \theta < 1$ and assume that*

$$m < \frac{(1-\varepsilon)\theta}{(1-\theta)\log^2 2} n^\theta (1-\theta) \log n \tag{2.2}$$

Then $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = \omega(1)$ w.h.p.

Proof. We need to exhibit alternative vectors $\boldsymbol{\sigma}' \in \{0,1\}^V$ with Hamming weight k that render the same test results as $\boldsymbol{\sigma}$. Thus, pick any $x_i \in V_0^+$ and any $x_j \in V_1^+$ and obtain $\boldsymbol{\sigma}'$ from $\boldsymbol{\sigma}$ by setting $\boldsymbol{\sigma}'_{x_i} = 1$ and $\boldsymbol{\sigma}'_{x_j} = 0$. By construction, $\boldsymbol{\sigma}'$ has Hamming weight k and renders the same test results. Hence, Lemma 5 shows that $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) \geq |V_0^+ \times V_1^+| = \Omega(n^{2\theta}) \gg 1$ w.h.p. ◀

The bound (2.2) matches $m_{\inf}$ for $\theta \gtrapprox 0.41$. A simpler, purely information-theoretic argument covers the remaining θ.

▶ **Lemma 7.** *Let $\varepsilon > 0$, $0 < \theta < 1$. If $m < \frac{1-\varepsilon}{\log 2} n^\theta (1-\theta) \log n$, then $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = \omega(1)$ w.h.p.*

We thus conclude that for all $0 < \theta < 1$, w.h.p. $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = \omega(1)$ if $m < (1-\varepsilon)m_{\inf}$. Therefore, the desired information-theoretic lower bound follows from Corollary 4.

2.2.2 The information-theoretic upper bound

The proof of the information-theoretic upper bound is the principal achievement of the present work. The proof rests upon techniques that have come to play an important role in the theory of random constraint satisfaction problems. Specifically, we need to show that $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 1$ w.h.p., i.e., that $\boldsymbol{\sigma}$ is the only assignment compatible with the test results w.h.p. We establish this result by combining two separate arguments. First, we use a moment calculation to show that w.h.p. there are no other solutions that have a small "overlap" with $\boldsymbol{\sigma}$. Then we use an expansion argument to show that w.h.p. there are no alternative solutions with a big overlap. Both these arguments are variants of the arguments that have been used to study the solution space geometry of random constraint satisfaction problems such as random k-SAT or random k-XORSAT [3, 4, 21], as well as the freezing thresholds of random constraint satisfaction problems [2, 33]. Yet to our knowledge these methods have thus far not been applied to the group testing problem.

Formally, we define

$$Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = |\{\sigma \in S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) : \langle \boldsymbol{\sigma}, \sigma \rangle = \ell\}|$$

as the number of assignments $\sigma \in S_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ whose *overlap* $\langle \boldsymbol{\sigma}, \sigma \rangle = \sum_{i=1}^{n} \mathbf{1}\{\sigma_{x_i} = \boldsymbol{\sigma}_{x_i} = 1\}$ with $\boldsymbol{\sigma}$ is equal to ℓ. The following two propositions rule out assignments with a small and a big overlap, respectively. In either case we choose $\Delta = \lceil \frac{m}{k} \log 2 \rceil$ to take its optimal value.

▶ **Proposition 8.** *Let $\varepsilon > 0$ and $0 < \theta < 1$ and assume that $m > (1+\varepsilon) m_{\inf}(k, \theta)$. W.h.p. we have $Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 0$ for all $\ell < (1 - 1/\log n)k$.*

▶ **Proposition 9.** *Let $\varepsilon > 0$ and $0 < \theta < 1$ and assume that $m > (1+\varepsilon) m_{\inf}(k, \theta)$. W.h.p. we have $Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 0$ for all $(1 - 1/\log n)k \leq \ell < k$.*

We defer the proofs of Propositions 8 and 9 to Sections 3 and 4, respectively.

Propositions 8 and 9 readily imply that $Z_k(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 1$ w.h.p. if $m > (1+\varepsilon) m_{\inf}(k, \theta)$. Hence, Corollary 4 shows that there exists an inference algorithm that given $\boldsymbol{G}, \hat{\boldsymbol{\sigma}}$ *and* k outputs $\boldsymbol{\sigma}$ w.h.p. However, up to now this algorithm relies on exactly knowing the number of infected individuals k, which in practice could be rather difficult to learn.

Fortunately this assumption can be removed. Namely, the following proposition shows that w.h.p. there is no assignment σ that is compatible with the test results and that has Hamming weight less than k.

▶ **Proposition 10.** *Let $\varepsilon > 0$ and $0 < \theta < 1$ and assume that $m > (1+\varepsilon) m_{\inf}(k, \theta)$. W.h.p. we have $\sum_{k' < k} Z_{k'}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) = 0$.*

As an immediate consequence of Proposition 10 we conclude that for $m > (1+\varepsilon) m_{\inf}(k, \theta)$ the problem of inferring $\boldsymbol{\sigma}$ boils down to a minimum vertex cover problem, as previously conjectured by Aldridge, Baldassini and Johnson [10]. Namely, let $\mathcal{P}$ be the set of all positive tests, i.e., all tests a_i, $i \in [m]$, with $\hat{\boldsymbol{\sigma}}_{a_i} = 1$. Moreover, let V^+ be the set of all variables $x_i \in V$ such that $\partial x_i \subseteq \mathcal{P}$; in words, x_i takes part in positive tests only. We set up a hypergraph $\boldsymbol{H}$ with vertex set V^+ and hyperedges $\partial a_i \cap V^+$, $a_i \in \mathcal{P}$. Clearly, the set of all individuals x_i with $\boldsymbol{\sigma}_{x_i} = 1$ provides a valid vertex cover of $\boldsymbol{H}$ (as any positive test must feature an infected individual). Conversely, Propositions 8 and 9 show that w.h.p. this is the unique vertex cover of size k, and Proposition 10 shows that there is no strictly smaller vertex cover w.h.p. Therefore, w.h.p. we can infer $\boldsymbol{\sigma}$ even without prior knowledge of k by way of solving this minimum vertex cover instance.

2.3 The SCOMP algorithm

For $\theta \geq 1/2$ we have $m_{\mathrm{alg}} = m_{\mathrm{inf}}$ and thus Theorem 1 implies that SCOMP fails to infer $\boldsymbol{\sigma}$ w.h.p. for $m < (1-\varepsilon)m_{\mathrm{alg}}$. Therefore, we are left to establish Theorem 2 for $\theta < 1/2$, in which case

$$m_{\mathrm{alg}} = \frac{n^{\theta}(1-\theta)\log(n)}{\log^2 2}. \tag{2.3}$$

The proof of Theorem 2 for $\theta < 1/2$ hinges on two lemmas. First we show that below m_{alg}, the set V_1^{--} of infected individuals that the second step of SCOMP identifies correctly is empty. Formally, with V_0^+ from (2.1),

$$V_1^{--} = \left\{x \in V_1 : \exists a \in \partial x : \partial a \setminus \{x\} \subseteq V_0 \setminus V_0^+\right\}.$$

▶ **Lemma 11.** *Suppose that $0 < \theta < 1/2$ and $\varepsilon > 0$. If $m < (1-\varepsilon)m_{\mathrm{alg}}$, then for all $\Delta > 0$ we have $V_1^{--}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}^*) = \emptyset$ w.h.p.*

With the second step of SCOMP failing to 'explain' (viz. cover) any positive tests, the greedy vertex cover algorithm takes over. This algorithm is applied to the hypergraph whose vertices are the as yet unclassified individuals and whose edges are the neighbourhoods of the positive tests. Our second lemma shows that the set $V^{+,\Delta}$ of potententially false positive individuals $x \in V_0^+$ that participate in the maximum number Δ of different test is far greater than the actual number k of infected individuals. Formally, let

$$V_0^{+,\Delta} = \left\{x \in V_0^+ : |\partial x| = \Delta\right\}.$$

▶ **Lemma 12.** *Suppose that $0 < \theta < 1/2$ and $\varepsilon > 0$. If $m < (1-\varepsilon)m_{\mathrm{alg}}$, then for all $\Delta > 0$ we have $V_0^{+,\Delta} \geq k \log n$ w.h.p.*

The proofs of Lemmas 11 and 12 are based on moment calculations that turn out to be mildly subtle due to the potentially very large degrees of the underlying graph $\boldsymbol{G}$. We complete the proof of Theorem 2 as follows.

Proof of Theorem 2. The first step of SCOMP (correctly) marks all individuals that appear in negative tests as healthy. Moreover, Lemma 11 implies that the second step of SCOMP is void w.h.p., because there is no single infected individual that appears in a test whose other individuals have already been identified as healthy by the first step. Consequently, SCOMP simply applies the greedy vertex cover algorithm. Now, thanks to Lemma 12 it suffices to prove that SCOMP will fail w.h.p. if $V_0^+ = \omega(k)$. Because they belong to positive tests only, all the individuals of V_0^+ are present in the vertex cover instance that SCOMP attempts to solve. Moreover, in the hypergraph no vertex has degree greater than Δ, because the degrees of $x_1, \ldots, x_n$ in $\boldsymbol{G}$ are equal to Δ. (Some of the hypergraph degrees may be strictly smaller than Δ because $\boldsymbol{G}$ is a multi-graph.) Therefore, since $|V_0^+| \geq k \log n$ while the actual set of infected individuals only has size k, w.h.p. the individual classified as infected by the very first step of the greedy set cover algorithm belongs to V_0^+. Hence, this individual is not actually infected, i.e., SCOMP errs w.h.p. ◀

Since the success probability of the SCOMP algorithm is at least as high as of the DD algorithm, we can prove the conjecture of [28] regarding the upper bound of the DD algorithm.

▶ **Corollary 13.** *If $m < (1-\varepsilon)m_{\mathrm{alg}}$, the DD algorithm will fail to retrieve the correct set of infected individuals w.h.p..*

3 Proof of Proposition 8

For $i \in [m]$ let Γ_i be the degree of a_i in $\boldsymbol{G}$, i.e., the number of edges incident with a_i; this number may exceed the number of different individuals that participate in test a_i as $\boldsymbol{G}$ may feature multi-edges. Let $\mathcal{G}$ be the σ-algebra generated by the random variables $(\Gamma_i)_{i\in[m]}$.

Given $\mathcal{G}$ we can generate $\boldsymbol{G}$ from the well-known *pairing model* [27]. Specifically, we create a set $\{x_i\} \times [\Delta]$ of Δ clones of each individual as well as sets $\{a_i\} \times [\Gamma_i]$ of clones of the tests. Then we draw a perfect matching of the complete bipartite graph on the vertex sets $\bigcup_{i=1}^{n} \{x_i\} \times [\Delta]$, $\bigcup_{i=1}^{m} \{a_i\} \times [\Gamma_i]$ uniformly at random. For each matching edge linking a clone of x_i with a clone of a_j we insert an i-j-edge. The resulting bipartite random multi-graph has the same distribution as $\boldsymbol{G}$ given $\mathcal{G}$. As an immediate application of this observation we obtain the following estimate.

▶ **Lemma 14.** *For every integer $0 \le \ell < k$ we have*

$$\mathbb{E}[Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) \mid \mathcal{G}] \le O(1) \cdot \binom{k}{\ell}\binom{n-k}{k-\ell} \prod_{i=1}^{m} 1 - 2(1-k/n)^{\Gamma_i} + 2\left(1 - 2k/n + \ell/n\right)^{\Gamma_i} \tag{3.1}$$

Proof. We use the linearity of expectation. The product of the two binomial coefficients simply accounts for the number of assignments σ that have overlap ℓ with $\boldsymbol{\sigma}$. Hence, with $\mathcal{S}$ the event that one specific $\sigma \in \{0,1\}^V$ that has overlap ℓ with $\boldsymbol{\sigma}$ belongs to $S_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$, we need to show that

$$\mathbb{P}\left[\mathcal{S} \mid \mathcal{G}\right] \le \prod_{i=1}^{m} 1 - 2(1-k/n)^{\Gamma_i} + 2\left(1 - 2k/n + \ell/n\right)^{\Gamma_i}. \tag{3.2}$$

By symmetry we may assume that $\boldsymbol{\sigma}_{x_i} = \mathbf{1}\{i \le k\}$ and that $\sigma_{x_i} = \mathbf{1}\{i \le \ell\} + \mathbf{1}\{k < i \le 2k - \ell\}$.

To establish (3.2) we harness the pairing model. Namely, given $\mathcal{G}$ we can think of each test a_i as a bin of capacity Γ_i. Moreover, we think of each clone (x_i, h), $h \in [\Delta]$, of an individual as a ball. The ball is labelled $(\boldsymbol{\sigma}_{x_i}, \sigma_{x_i}) \in \{0,1\}^2$. The random matching that creates $\boldsymbol{G}$ effectively tosses the Δn balls randomly into the bins. Hence, for $i \in [m]$ and for $j \in [\Gamma_i]$ let us write $\boldsymbol{A}_{i,j} = (\boldsymbol{A}_{i,j,1}, \boldsymbol{A}_{i,j,2}) \in \{0,1\}^2$ for the label of the jth ball that ends up in bin number i. Then we are left to calculate

$$\mathbb{P}\left[\mathcal{S} \mid \mathcal{G}\right] = \mathbb{P}\left[\forall i \in [m] : \max_{j\in[\Gamma_i]} \boldsymbol{A}_{i,j,1} = \max_{j\in[\Gamma_i]} \boldsymbol{A}_{i,j,2} \,\middle|\, \mathcal{G}\right], \tag{3.3}$$

i.e., the probability that a test a_i is positive with respect to first assignment $(\boldsymbol{A}_{i,j,1})_{j\in[\Gamma_i]}$ iff it is positive with respect to the second assignment $(\boldsymbol{A}_{i,j,2})_{j\in[\Gamma_i]}$.

To calculate this probability we borrow a trick from the analysis of the random k-SAT model [16]. Namely, we consider a new set $\{0,1\}^2$-valued random variables $\boldsymbol{A}'_{i,j} = (\boldsymbol{A}'_{i,j,1}, \boldsymbol{A}''_{i,j,2})$ such that $(\boldsymbol{A}'_{i,j})_{i\in[m],j\in[\Gamma_i]}$ are mutually independent and such that

$$\mathbb{P}\left[\boldsymbol{A}'_{i,j} = (1,1)\right] = \ell/n, \qquad \mathbb{P}\left[\boldsymbol{A}'_{i,j} = (0,1)\right] = \mathbb{P}\left[\boldsymbol{A}'_{i,j} = (1,0)\right] = (k-\ell)/n,$$
$$\mathbb{P}\left[\boldsymbol{A}'_{i,j} = (0,0)\right] = (n - 2k + \ell)/n$$

for all i, j. Now, let $\mathcal{R}$ be the event that

$$\sum_{i=1}^{m}\sum_{j=1}^{\Gamma_i}\mathbf{1}\left\{\boldsymbol{A}'_{i,j}=(1,1)\right\}=\ell\Delta, \qquad \sum_{i=1}^{m}\sum_{j=1}^{\Gamma_i}\mathbf{1}\left\{\boldsymbol{A}'_{i,j}=(0,0)\right\}=(n-2k+\ell)\Delta,$$
$$\sum_{i=1}^{m}\sum_{j=1}^{\Gamma_i}\mathbf{1}\left\{\boldsymbol{A}'_{i,j}=(1,0)\right\}=\sum_{i=1}^{m}\sum_{j=1}^{\Gamma_i}\mathbf{1}\left\{\boldsymbol{A}'_{i,j}=(0,1)\right\}=(k-\ell)\Delta,$$

i..e, that all of the sums on the l.h.s. are *precisely* equal to their expected values. Then $\boldsymbol{A}'=(\boldsymbol{A}'_{i,j})_{i,j}$ given $\mathcal{R}$ is distributed precisely as $\boldsymbol{A}=(\boldsymbol{A}_{i,j})_{i,j}$. Hence, (3.3) yields

$$\mathbb{P}\left[\mathcal{S}\mid\mathcal{G}\right]=\mathbb{P}\left[\forall i\in[m]:\max_{j\in[\Gamma_i]}\boldsymbol{A}'_{i,j,1}=\max_{j\in[\Gamma_i]}\boldsymbol{A}'_{i,j,2}\mid\mathcal{G},\mathcal{R}\right]. \tag{3.4}$$

Thus, let $\mathcal{A}=\left\{\forall i\in[m]:\max_{j\in[\Gamma_i]}\boldsymbol{A}'_{i,j,1}=\max_{j\in[\Gamma_i]}\boldsymbol{A}'_{i,j,2}\right\}$. Because the $(\boldsymbol{A}'_{i,j})_{i,j}$ are mutually independent, we can easily compute the unconditional probability $\mathcal{A}$: by inclusion/exclusion,

$$\mathbb{P}\left[\mathcal{A}\mid\mathcal{G}\right]=\prod_{i=1}^{m}1-2(1-k/n)^{\Gamma_i}+2(1-2k/n+\ell/n)^{\Gamma_i} \tag{3.5}$$

(the probability that $\max\boldsymbol{A}'_{i,j,1}=\max\boldsymbol{A}'_{i,j,2}=1$, i.e., both tests positive, equals one minus the probability that $\max\boldsymbol{A}'_{i,j,1}=0$ minus the probability that $\max\boldsymbol{A}'_{i,j,2}=0$ plus the probability that $\max\boldsymbol{A}'_{i,j,1}=\max\boldsymbol{A}'_{i,j,2}=0$; then add the probability that $\max\boldsymbol{A}'_{i,j,1}=\max\boldsymbol{A}'_{i,j,2}=0$, i.e., both tests negative).

Finally, to deal with the conditioning we use Bayes' rule:

$$\mathbb{P}\left[\mathcal{A}\mid\mathcal{R},\mathcal{G}\right]=\frac{\mathbb{P}\left[\mathcal{A}\mid\mathcal{G}\right]\mathbb{P}\left[\mathcal{R}\mid\mathcal{A},\mathcal{G}\right]}{\mathbb{P}\left[\mathcal{R}\mid\mathcal{G}\right]}. \tag{3.6}$$

Since the $(\boldsymbol{A}'_{i,j})_{i,j}$ are independent, the Local Limit Theorem for sums of independent variables [29] yields $\mathbb{P}\left[\mathcal{R}\mid\mathcal{G}\right]=\Theta(\Delta n)^{-3/2}$, $\mathbb{P}\left[\mathcal{R}\mid\mathcal{A},\mathcal{G}\right]=\Theta(\Delta n)^{-3/2}$. Hence, (3.2) follows from (3.4)–(3.6). ◀

Proof of Proposition 8. The Chernoff bound implies that $\Gamma_i\geq\Gamma_{\min}=\Delta n/m-\sqrt{\Delta n/m}\log n$ for all $i\in[m]$ w.h.p. Further, assuming that the Γ_i satisfy this bound, we perform an elementary calculation to check that

$$\sum_{0\leq\ell\leq(1-1/\log n)k}\binom{k}{\ell}\binom{n-k}{k-\ell}\prod_{i=1}^{m}1-2(1-k/n)^{\Gamma_i}+2\left(1-2k/n+\ell/n\right)^{\Gamma_i}=o(1). \tag{3.7}$$

Therefore, the proposition follows from Lemma 14 and Markov's inequality. ◀

4 Proof of Proposition 9

The argument from Section 3 does not extend large overlaps (close to k) because the expression on the r.h.s. of (3.1) gets too large. In other words, merely just computing the expected number of solutions with a given overlap does not do the trick. This "lottery phenomenon" is ubiquitous in random constraint satisfaction problems: for big overlap values rare solution-rich instances drive up the expected number of solutions [4, 5]. In order to cope with this issue we take another leaf out of the random CSP literature [2, 33]. Namely, we show that the solution $\boldsymbol{\sigma}$ is locally rigid. That is, the expansion properties of the random bipartite graph $\boldsymbol{G}$ preclude the existence of other solutions that have a big overlap with $\boldsymbol{\sigma}$. The following lemma holds the key to this effect.

▶ **Lemma 15.** *For any $\varepsilon > 0$ there exists $\delta = \delta(\varepsilon) > 0$ such that for all $m > (1+\varepsilon)m_{\inf}$ the following is true. Let $\mathcal{R}$ be the event that for every x_i with $\boldsymbol{\sigma}_{x_i} = 1$ there are at least $\delta\Delta$ tests $a \in \partial x_i$ such that $\partial a \setminus \{x_i\} \subseteq V_0$. Then $\mathbb{P}[\mathcal{R}] = 1 - o(1)$.*

Hence, w.h.p. any infected individual appears in plenty of tests where all the other individuals are healthy. This property causes $\boldsymbol{\sigma}$ to be locally rigid. To see why, consider the repercussions of just changing the status of a single individual x_i from infected to healthy. Because given $\mathcal{R}$ the individual x_i appears as the only infected individual in at least $\delta\Delta$ tests, in order to maintain the same tests results we will also need to flip at least one individual in each of these tests from healthy to infected. Since tests typically have relatively few individuals in common, the necessary number of flips from 0 to 1 will be $\Omega(\Delta) = \Omega(\log n)$. But then in order to keep the total number of infected individuals constant k, we will need to perform another $\Omega(\Delta)$ flips from 1 to 0. Yet given $\mathcal{R}$ each of these "second generation" individuals that we flip from infected to healthy is itself the only infected individual in many tests. Thus, the single flip that we started from triggers a veritable avalanche of flips, which will stop only after the overlap has dropped significantly. The next lemma formalises this intuition. The lemma shows that while the unconditional expectation of $Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ is "too big", the conditional expectation of $Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ given $\mathcal{R}$ is much smaller. Let $\boldsymbol{m}_0 = \boldsymbol{m}_0(\boldsymbol{G}, \hat{\boldsymbol{\sigma}})$ be the total number of negative tests.

▶ **Lemma 16.** *Suppose that $(1 - 1/\log n)k \le \ell < k$ and let $\Gamma_{\min} = \min_{i\in[m]} \Gamma_i$, $\Gamma_{\max} = \max_{i\in[m]} \Gamma_i$. Then*

$$\mathbb{E}[Z_{k,\ell}(\boldsymbol{G}, \hat{\boldsymbol{\sigma}}) \mid \mathcal{G}, \mathcal{R}, \boldsymbol{m}_0] \le$$
$$O(1)\binom{k}{\ell}\binom{n-k}{k-\ell}\left(1 - \left(1 - \frac{k-\ell}{n}\right)^{\Gamma_{\max}}\right)^{\delta\Delta(k-\ell)}\left(\frac{n-2k+\ell}{n-k}\right)^{\Gamma_{\min}\boldsymbol{m}_0} = o(1) \qquad (4.1)$$

The proof of Lemma 16 requires some mildly delicate manoeuvres to cope with the stochastic dependences that are inherent in the random bipartite graph model.

Proof of Proposition 9. Standard tail bound arguments show that $\Gamma_{\max}, \Gamma_{\min} = \min_{i\in[m]} \Gamma_i = \Delta n/m + O(\sqrt{\Delta n/m \log n})$ w.h.p. Plugging these estimates into (4.1) and summing on $\ell > (1 - 1/\log n)k$ completes the proof. ◀

Abstract

We consider the Membership and the Half-Space Reachability problems for matrices in dimensions two and three. Our first main result is that the Membership Problem is decidable for finitely generated sub-semigroups of the Heisenberg group over rational numbers. Furthermore, we prove two decidability results for the Half-Space Reachability Problem. Namely, we show that this problem is decidable for sub-semigroups of $\mathrm{GL}(2,\mathbb{Z})$ and of the Heisenberg group over rational numbers.

1 Introduction

The algorithmic theory of matrix groups and semigroups is a staple of computational algebra [3] with numerous applications to automata theory and program analysis [7, 10, 12, 19, 20, 27] and has been influential in developing the notion of interactive proofs in complexity theory [1].

Two central decision problems on matrix semigroups are the *Membership* and *Half-Space Reachability* (see, e.g., [6]). For the Membership Problem the input is a finite set of generators $A_1, \ldots, A_k$ and a target matrix A, with all matrices being square and of the same dimension. The question is whether A lies in the semigroup generated by $A_1, \ldots, A_k$. We emphasize that we consider membership in finitely generated *sub-semigroups*, i.e., we seek to recover A as a non-empty product of generators. In a related *subgroup* membership problem one additionally allows to take inverses of generators. The subgroup membership can clearly be reduced to the sub-semigroup membership and tends to be more tractable (e.g., the subgroup membership for polycyclic groups is well-known to be decidable [38], and the subgroup membership for the modular group $\mathrm{PSL}(2,\mathbb{Z})$ is in PTIME [15]). For the Half-Space Reachability Problem the target matrix is replaced by vectors $\boldsymbol{u}$, $\boldsymbol{v}$ and a scalar λ, and the question is now whether there exists a matrix A in the semigroup generated by $A_1, \ldots, A_k$ such that $\boldsymbol{u}^\top A \boldsymbol{v} \geq \lambda$. Geometrically the question is whether the orbit of $\boldsymbol{v}$ under the action of the semigroup reaches a certain half-space with normal $\boldsymbol{u}$. Closely related to these problems are the Vector Reachability and the Hyperplane Reachability[1] problems, which ask whether there exists a matrix A in the semigroup generated by $A_1, \ldots, A_k$ such that $A\boldsymbol{v} = \boldsymbol{u}$ or such that $\boldsymbol{u}^\top A \boldsymbol{v} = \lambda$, respectively.

Undecidability of the Membership Problem has long been known (indeed, this was one of the earliest undecidability results – see A. Markov [28]). Subsequently a number of positive decidability results were obtained in the case of semigroups generated by commuting matrices over infinite fields [2, 20]. More recently, attention has focussed on integer matrices in dimension two. A classical result of [10] shows decidability of the Membership Problem for sub-semigroups of $\mathrm{GL}(2,\mathbb{Z})$ – the group of 2×2 integer matrices with integer inverses (equivalently, with determinants equal to ± 1). Moreover, the semigroup membership for the identity matrix was shown to be NP-complete for $\mathrm{SL}(2,\mathbb{Z})$ [4]. Furthermore, the Membership Problem is decidable for 2×2 integer matrices with nonzero determinant [32] and for 2×2 integer matrices with determinants equal to 0 and ± 1 [33]. However it is still unknown whether the Membership Problem is decidable for all 2×2 integer matrices.

Going beyond dimension two, it has long been known that the Membership Problem is undecidable for general 3×3 integer matrices [31]. However the status of the Membership Problem for $\mathrm{GL}(3,\mathbb{Z})$ is currently an outstanding open problem. Related to this, it was shown in [23] that for a two-element alphabet Σ, the monoid $\Sigma^* \times \Sigma^*$ cannot be embedded in $\mathrm{GL}(3,\mathbb{Z})$. This fact suggests that undecidability proofs of the Membership Problem in other settings (such as [31]), which are based on encodings of the Post Correspondence Problem, are unlikely to carry over to $\mathrm{GL}(3,\mathbb{Z})$. It is classical that the Membership Problem for $\mathrm{GL}(4,\mathbb{Z})$ is undecidable [29, 5, 23]; thus it can reasonably be said that dimension three lies on the borderline between decidability and undecidability.

Our first main result (Theorem 7) concerns the Membership Problem for a simple subgroup of $\mathrm{GL}(3,\mathbb{Z})$: the so-called *Heisenberg group* $\mathrm{H}(3,\mathbb{Z})$, which comprises upper triangular integer matrices with ones along the diagonal. Since the Heisenberg group is polycyclic, the sub*group* membership problem is decidable [38]. It was moreover recently shown in [23] how to decide membership of the identity matrix in finitely generated sub-semigroups of $\mathrm{H}(3,\mathbb{Z})$. Our main theorem strengthens this last result to show decidability of the Membership Problem for $\mathrm{H}(3,\mathbb{Z})$. In fact, like in [23], our argument works for Heisenberg groups of any dimension and even over the field of rational numbers, that is, for $\mathrm{H}(n,\mathbb{Q})$.

[1] In the literature the Hyperplane Reachability Problem is also called the Scalar Reachability Problem.

Our proof relies on arguments developed in [23] but contains several significant new elements, including the use of linear programming, integer register automata, and matrix logarithms. The following algebraic property of $\mathrm{H}(3,\mathbb{Z})$ is important for our construction: the subgroup generated by commutators of matrices from a given subset $\mathcal{G} \subseteq \mathrm{H}(3,\mathbb{Z})$ is isomorphic to a subgroup of $\mathbb{Z}$. Such property does not hold for the direct product of two Heisenberg groups $\mathrm{H}(3,\mathbb{Z})^2$ or for the group of 4×4 upper unitriangular matrices $\mathrm{UT}(4,\mathbb{Z})$. This makes it challenging to generalize our argument to show decidability of the Membership Problem for $\mathrm{H}(3,\mathbb{Z})^2$, $\mathrm{UT}(4,\mathbb{Z})$ or other similar matrix groups.

In [24] a related problem was studied, called the Knapsack Problem. Namely, it was proved that the Knapsack Problem is decidable for $\mathrm{H}(3,\mathbb{Z})$, that is, given matrices $A_1,\ldots,A_k$ and A from $\mathrm{H}(3,\mathbb{Z})$ one can decide whether there are non-negative integers $n_1,\ldots,n_k$ such that $A_1^{n_1}\cdots A_k^{n_k} = A$. Decidability of the Knapsack Problem is shown by reduction to the problem of solving a single quadratic equation in integer numbers (proved to be decidable in [13, 14]). By contrast, our decision procedure for the Membership Problem relies only on linear programming and integer linear arithmetic. As far as we can tell, there is no straightforward reduction in either direction between the Membership and Knapsack Problems for $\mathrm{H}(3,\mathbb{Z})$.

The Vector Reachability, Hyperlane Reachability, and Half-Space Reachabilty Problems are all known to be undecidable in general (see [9, 16, 17]). The Vector and Hyperplane Reachability problems are known to be decidable for $\mathrm{GL}(2,\mathbb{Z})$, as shown in [34]. For matrix semigroups with a single generator, the Half-Space Reachability Problem is equivalent to the *Positivity Problem* for linear recurrence sequences: a longstanding and apparently difficult open problem [30, 36]. Our second main result is that the Half-Space Reachability Problem is decidable for both $\mathrm{GL}(2,\mathbb{Z})$ (Theorem 17) and $\mathrm{H}(n,\mathbb{Q})$ (Theorem 20). For $\mathrm{GL}(2,\mathbb{Z})$ we build on automata-theoretic techniques developed in [10], with the key insight being that the set of matrices in $\mathrm{GL}(2,\mathbb{Z})$ with a positive value in a given entry can be represented as a regular language over the generators of $\mathrm{GL}(2,\mathbb{Z})$. For $\mathrm{H}(n,\mathbb{Q})$ we rely on a nontrivial result about the nonnegativity of quadratic forms over the integers from [13, 14] (related to the result used in [24] to solve the Knapsack Problem).

2 Preliminaries

The Heisenberg Group

We use notations I_n and 0_n for the identity matrix and for the zero matrix of size $n \times n$, respectively. For $n \geq 3$, the *Heisenberg group* of dimension n is the group $\mathrm{H}(n,\mathbb{R})$ of $n \times n$ real matrices of the form

$$A = \begin{pmatrix} 1 & \boldsymbol{a}^\top & c \\ 0 & I_{n-2} & \boldsymbol{b} \\ 0 & 0 & 1 \end{pmatrix}, \tag{1}$$

where $\boldsymbol{a},\boldsymbol{b} \in \mathbb{R}^{n-2}$, $c \in \mathbb{R}$. For brevity, we will often denote a matrix A as in (1) by the triple $(\boldsymbol{a},\boldsymbol{b},c) \in \mathbb{R}^{n-2} \times \mathbb{R}^{n-2} \times \mathbb{R}$. It is easy to check that the product operation is given by

$$(\boldsymbol{a},\boldsymbol{b},c)\cdot(\boldsymbol{a}',\boldsymbol{b}',c') = (\boldsymbol{a}+\boldsymbol{a}',\boldsymbol{b}+\boldsymbol{b}',c+c'+\boldsymbol{a}^\top\boldsymbol{b}').$$

We use ψ to denote the group homomorphism $\psi : \mathrm{H}(n,\mathbb{R}) \to \mathbb{R}^{2n-4}$ given by $\psi(\boldsymbol{a},\boldsymbol{b},c) = (\boldsymbol{a},\boldsymbol{b})$.

The Heisenberg group $\mathrm{H}(n,\mathbb{R})$ is a Lie group whose corresponding Lie algebra $\mathfrak{h}(n,\mathbb{R})$ comprises the vector space of $n \times n$ real matrices of the form

$$B = \begin{pmatrix} 0 & \boldsymbol{a}^\top & c \\ 0 & 0_{n-2} & \boldsymbol{b} \\ 0 & 0 & 0 \end{pmatrix}, \tag{2}$$

where $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{R}^{n-2}$ and $c \in \mathbb{R}$, together with the binary *Lie bracket* operation $[A,B] := AB - BA$ for $A, B \in \mathfrak{h}(n,\mathbb{R})$. Note that $[A,B]$ has only zero entries except for the $(1,n)$-entry. From this it is easy to check that $[[A,B],C] = 0_n$ for all $A, B, C \in \mathfrak{h}(n,\mathbb{R})$.

Given $A \in \mathrm{H}(n,\mathbb{R})$, as shown in (1), we define its logarithm $\log(A) \in \mathfrak{h}(n,\mathbb{R})$ to be

$$\log(A) := (A-I) - \frac{(A-I)^2}{2} = \begin{pmatrix} 0 & \boldsymbol{a}^\top & c - \frac{1}{2}\boldsymbol{a}^\top\boldsymbol{b} \\ 0 & 0_{n-2} & \boldsymbol{b} \\ 0 & 0 & 0 \end{pmatrix}.$$

Conversely, given $B \in \mathfrak{h}(n,\mathbb{R})$, as shown in (2), we define its exponential $\exp(B) \in \mathrm{H}(n,\mathbb{R})$ to be $\exp(B) := I + B + \frac{B^2}{2} = (\boldsymbol{a}, \boldsymbol{b}, c + \frac{1}{2}\boldsymbol{a}^\top\boldsymbol{b})$. It is easy to verify that log and exp are mutually inverse and together induce a bijection between $\mathrm{H}(n,\mathbb{R})$ and $\mathfrak{h}(n,\mathbb{R})$.

The following is a specialisation to $\mathrm{H}(n,\mathbb{R})$ of the Baker-Campbell-Hausdorff product formula (see [18, Chapter 5] for a details). Given a sequence of matrices $B_1, \ldots, B_m \in \mathrm{H}(n,\mathbb{R})$, we have

$$\log(B_1 \cdots B_m) = \sum_{i=1}^{m} \log(B_i) + \frac{1}{2} \sum_{1 \le i < j \le m} [\log(B_i), \log(B_j)]\,. \tag{3}$$

Regular subsets of $\mathbf{GL(2,\mathbb{Z})}$

We will use the notation $\mathrm{GL}(2,\mathbb{Z})$ for the general linear group of 2×2 integer matrices, that is, $\mathrm{GL}(2,\mathbb{Z}) = \{M \in \mathbb{Z}^{2\times 2} : \det(M) = \pm 1\}$. A matrix is called *singular* if its determinant is zero and *nonsingular* otherwise.

We will use the following encoding of the matrices from $\mathrm{GL}(2,\mathbb{Z})$ by words in alphabet $\Sigma = \{X, N, S, R\}$. First, we define a mapping $\varphi : \Sigma \to \mathrm{GL}(2,\mathbb{Z})$ as follows:

$$\varphi(X) = -I_2 = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix},\ \varphi(N) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},\ \varphi(S) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},\ \varphi(R) = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}.$$

We can extend φ to a morphism $\varphi : \Sigma^* \to \mathrm{GL}(2,\mathbb{Z})$ in a natural way. It is a well-known fact that morphism φ is surjective, that is, for every $M \in \mathrm{GL}(2,\mathbb{Z})$ there is a word $w \in \Sigma^*$ such that $\varphi(w) = M$. This presentation is not unique because of identities such as $\varphi(SS) = \varphi(RRR) = \varphi(X)$. However, as explained below, every matrix $M \in \mathrm{GL}(2,\mathbb{Z})$ is represented by a unique word in the *canonical* form.

In the following definition, for n a positive integer and $V \in \Sigma$, V^n is the word consisting of n copies of V, while V^0 denotes the empty word.

▶ **Definition 1.** *A word $w \in \Sigma^*$ is called* canonical *if it has the form*

$$w = N^\delta X^\gamma S^\beta R^{\alpha_1} S R^{\alpha_2} \cdots S R^{\alpha_n} S^\varepsilon,$$

where $\beta, \gamma, \delta, \varepsilon \in \{0,1\}$ and $\alpha_i \in \{1,2\}$ for $i = 1, \ldots, n$. In other words, w is canonical *if it does not contain subwords SS or RRR. Moreover, letter N may appear only once in the first position, and letter X may appear only once either in the first position or after N.*

The next proposition is a well-known fact.

▶ **Proposition 2** ([25, 26, 32, 35]). *For every matrix $M \in \mathrm{GL}(2,\mathbb{Z})$, there is a unique canonical word w such that $M = \varphi(w)$.*

▶ **Definition 3.** *A subset $\mathcal{S} \subseteq \mathrm{GL}(2,\mathbb{Z})$ is called* regular *if there is a regular language $L \subseteq \Sigma^*$ such that $\mathcal{S} = \varphi(L)$.*

▶ **Definition 4.** *Two words w_1 and w_2 from Σ^* are* equivalent*, denoted $w_1 \sim w_2$, if $\varphi(w_1) = \varphi(w_2)$. Two languages L_1 and L_2 in the alphabet Σ are* equivalent*, denoted $L_1 \sim L_2$, if*

(i) *for each $w_1 \in L_1$, there exists $w_2 \in L_2$ such that $w_1 \sim w_2$, and*
(ii) *for each $w_2 \in L_2$, there exists $w_1 \in L_1$ such that $w_2 \sim w_1$.*

In other words, $L_1 \sim L_2$ if and only if $\varphi(L_1) = \varphi(L_2)$. Two finite automata $\mathcal{A}_1$ and $\mathcal{A}_2$ with alphabet Σ are equivalent*, denoted $\mathcal{A}_1 \sim \mathcal{A}_2$, if $L(\mathcal{A}_1) \sim L(\mathcal{A}_2)$.*

The following theorem is a crucial ingredient of our decidability results.

▶ **Theorem 5** ([32]). *For any automaton $\mathcal{A}$ over the alphabet $\Sigma = \{X, N, S, R\}$, there exists an automaton $\mathrm{Can}(\mathcal{A})$ such that $\mathrm{Can}(\mathcal{A})$ is equivalent to $\mathcal{A}$ and $\mathrm{Can}(\mathcal{A})$ accepts only canonical words. Furthermore, $\mathrm{Can}(\mathcal{A})$ can be constructed from $\mathcal{A}$ in polynomial time.*

The proof of the following corollary is given in the full version [11].

▶ **Corollary 6.** *Regular subsets of $\mathrm{GL}(2,\mathbb{Z})$ are effectively closed under Boolean operations. Namely, given two regular languages $L, L' \subseteq \Sigma^*$, we can algorithmically construct in polynomial time regular languages $L^\cup$, $L^\cap$ and L^c such that $\varphi(L^\cup) = \varphi(L) \cup \varphi(L')$, $\varphi(L^\cap) = \varphi(L) \cap \varphi(L')$, and $\varphi(L^c) = \mathrm{GL}(2,\mathbb{Z}) \setminus \varphi(L)$.*

Decision problems for matrix semigroups

If $\mathcal{G}$ is a finite collection of matrices, then $\langle\mathcal{G}\rangle$ denotes the semigroup generated by $\mathcal{G}$, that is, $A \in \langle\mathcal{G}\rangle$ if and only if there are matrices $A_1, \ldots, A_t \in \mathcal{G}$ such that $A = A_1 \cdots A_t$.

In this paper we will consider the following decision problems for matrix semigroups:

- **The Membership Problem:** Given a finite collection of matrices $\mathcal{G}$ and a "target" matrix A, decide whether A belongs to $\langle\mathcal{G}\rangle$.
- **The Half-Space Reachability Problem:** Given a finite collection of matrices $\mathcal{G}$, two vectors $\boldsymbol{u}, \boldsymbol{v}$ and a scalar λ, decide whether there exists a matrix $A \in \langle\mathcal{G}\rangle$ such that $\boldsymbol{u}^\top A \boldsymbol{v} \geq \lambda$. In other words, decide whether it is possible to reach the half-space $\mathcal{H} = \{\boldsymbol{x} : \boldsymbol{u}^\top \boldsymbol{x} \geq \lambda\}$ using matrices from $\mathcal{G}$ starting from an initial vector $\boldsymbol{v}$.

When we talk about *the Membership Problem for* $\mathrm{GL}(2,\mathbb{Z})$ *or for the Heisenberg group* $\mathrm{H}(n,\mathbb{Q})$, we mean that A and the matrices from $\mathcal{G}$ belong to $\mathrm{GL}(2,\mathbb{Z})$ or $\mathrm{H}(n,\mathbb{Q})$, respectively. Similarly, in *the Half-Space Reachability Problem for* $\mathrm{GL}(2,\mathbb{Z})$ *or* $\mathrm{H}(n,\mathbb{Q})$ we assume that $\mathcal{G}$ is a finite subset of $\mathrm{GL}(2,\mathbb{Z})$ or $\mathrm{H}(n,\mathbb{Q})$, respectively, and furthermore we assume that the vectors $\boldsymbol{u}, \boldsymbol{v}$ have rational coefficients and λ is a rational number.

3 The Membership Problem for the Heisenberg Group

Let $\mathrm{H}(n,\mathbb{Z})$ and $\mathrm{H}(n,\mathbb{Q})$ be subgroups of $\mathrm{H}(n,\mathbb{R})$ comprising all matrices with integer and rational entries, respectively. In this section we will prove our first main result.

▶ **Theorem 7.** *The Membership Problem for $\mathrm{H}(n,\mathbb{Z})$ is decidable.*

We first give an overview of our decision procedure. Let $\mathcal{G} = \{A_1, \ldots, A_k\}$ be a finite set of generators from $\mathrm{H}(n, \mathbb{Z})$ and $A \in \mathrm{H}(n, \mathbb{Z})$ be a target matrix. The idea is to partition the set of generators $\mathcal{G}$ into two sets $\mathcal{G}_+$ and $\mathcal{G}_0$. The definition of $\mathcal{G}_+$ is such that there is a computable upper bound on the number of occurrences of a matrix from $\mathcal{G}_+$ in any string of generators whose product equals the target matrix A. The definition of $\mathcal{G}_0$ is such that the image of the semigroup generated by $\mathcal{G}_0$ under the homomorphism ψ is a sub*group* of $\mathbb{R}^{2n-4}$ (i.e., the image is closed under inverses). We then proceed by a case analysis according to whether or not $\mathcal{G}_0$ is a commutative set of matrices. If $\mathcal{G}_0$ is commutative then the Membership Problem can be reduced to solving a system of linear equations over non-negative integer variables. If $\mathcal{G}_0$ is not commutative then we reduce the Membership Problem to a reachability query in an integer register automaton.

Partitioning the Set of Generators

In the rest of this section we work with an instance of the Membership Problem in which the generators are $A_i = (\boldsymbol{a}_i, \boldsymbol{b}_i, c_i)$, for $i = 1, \ldots, k$, and the target matrix is $A = (\boldsymbol{a}, \boldsymbol{b}, c)$. Recalling the homomorphism $\psi : \mathrm{H}(n, \mathbb{Z}) \to \mathbb{Z}^{2n-4}$, let us define $\boldsymbol{v}_i := \psi(A_i) = (\boldsymbol{a}_i, \boldsymbol{b}_i)$, for $i = 1, \ldots, k$, and $\boldsymbol{v} := \psi(A) = (\boldsymbol{a}, \boldsymbol{b})$.

A set $C \subseteq \mathbb{R}^n$ is called a *cone* if $\sum_{i=1}^{k} r_i \boldsymbol{u}_i \in C$ for all $r_1, \ldots, r_k \in \mathbb{R}_{\geq 0}$ and $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k \in C$. The *dual* of a cone $C \subseteq \mathbb{R}^n$ is the cone defined as

$$C^* := \{\boldsymbol{x} \in \mathbb{R}^n : \boldsymbol{x}^\top \boldsymbol{y} \geq 0 \text{ for all } \boldsymbol{y} \in C\}.$$

We will use the fact that $C = C^{**}$, i.e., a cone is equal to its double dual [8, Chapter 2.6.1].

We write $\mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$ for the cone generated by the vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$. We now partition the set of generators $\mathcal{G}$ into two disjoint sets $\mathcal{G}_0, \mathcal{G}_+$, where

$$\begin{aligned} \mathcal{G}_0 &:= \left\{A_i : \forall \boldsymbol{u} \in \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)^* \quad \boldsymbol{v}_i^\top \boldsymbol{u} = 0\right\} \\ \mathcal{G}_+ &:= \left\{A_i : \exists \boldsymbol{u} \in \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)^* \quad \boldsymbol{v}_i^\top \boldsymbol{u} > 0\right\} . \end{aligned}$$

We can determine the sets $\mathcal{G}_0$ and $\mathcal{G}_+$ using linear programming [37]. Without loss of generality we can assume that $\mathcal{G}_0 = \{A_1, \ldots, A_\ell\}$ for some $\ell \geq 0$.

We show how to compute a bound $\beta > 0$ such that for every sequence $\mathcal{S} = B_1, \ldots, B_m$ of elements of $\mathcal{G}$ whose product is equal to the target matrix A, the number of indices i such that $B_i \in \mathcal{G}_+$ is at most β. By definition of $\mathcal{G}_+$, for each $i \in \{1, \ldots, \ell\}$, there exists $\boldsymbol{u}_i \in \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)^*$ such that $\boldsymbol{v}_i^\top \boldsymbol{u}_i > 0$. Since $\boldsymbol{v}_j^\top \boldsymbol{u}_i \geq 0$ for all $j \neq i$, $\mathcal{S}$ contains at most $\frac{\boldsymbol{v}^\top \boldsymbol{u}_i}{\boldsymbol{v}_i^\top \boldsymbol{u}_i}$ occurrences of matrix A_i (or no occurrences if $\boldsymbol{v}^\top \boldsymbol{u}_i \leq 0$). Thus we may define $\beta := \sum_i \frac{\boldsymbol{v}^\top \boldsymbol{u}_i}{\boldsymbol{v}_i^\top \boldsymbol{u}_i}$ where the sum is take over the indices $i = 1, \ldots, \ell$ such that $\boldsymbol{v}^\top \boldsymbol{u}_i > 0$

We now consider two cases according to whether $\mathcal{G}_0$ is a commutative set of matrices.

Case I: $\mathcal{G}_0$ is commutative

Consider a sequence $\mathcal{S} = B_1, \ldots, B_m$ of elements of $\mathcal{G}$. Let $B_{i_1}, \ldots, B_{i_s}$ be the subsequence of $\mathcal{S}$ containing all occurrences of elements of $\mathcal{G}_+$ in $\mathcal{S}$, where $0 = i_0 < i_1 < \ldots < i_s < i_{s+1} = m + 1$. For $i \in \{1, \ldots, \ell\}$ and $j \in \{1, \ldots, s+1\}$, write $n_{i,j}$ for the number of occurrences of $A_i \in \mathcal{G}_0$ in the subsequence of $\mathcal{S}$ lying strictly between $B_{i_{j-1}}$ and B_{i_j} (where B_0 is interpreted as the beginning of $\mathcal{S}$ and B_{m+1} as the end of $\mathcal{S}$). The idea is to write a formula for $\log(B_1 \cdots B_m)$ that is a linear form in the variables $n_{i,j}$.

Indeed by Equation (3), writing $C_{i_j} := \log(B_{i_j})$ for $j = 1, \ldots, s$ and $D_i := \log(A_i)$ for $i = 1, \ldots, \ell$, we have

$$\log(B_1 \cdots B_m) = \sum_{j=1}^{s} C_{i_j} + \sum_{i=1}^{\ell} \sum_{j=1}^{s+1} n_{i,j} D_i + \sum_{1 \le j < j' \le s} [C_{i_j}, C_{i_{j'}}] + \sum_{i=1}^{\ell} \sum_{1 \le j \le j' \le s} n_{i,j} [D_i, C_{i_{j'}}] + \sum_{i=1}^{\ell} \sum_{1 \le j < j' \le s+1} n_{i,j'} [C_{i_j}, D_i] \quad (4)$$

An important observation is that the above formula has no quadratic terms due to commutativity of $\mathcal{G}_0$. Now $B_1 \cdots B_m = A$ if and only if $\log(B_1 \cdots B_m) = \log(A)$. Setting the right-hand-side of (4) equal to $\log(A)$ yields a linear Diophantine equation in variables $n_{i,j}$. The form of this equation is determined by the subsequence of matrices $B_{i_1}, \ldots, B_{i_s}$ lying in $\mathcal{G}_+$. Recall that we can without loss of generality restrict attention to the case that $s \le \beta$ and thus we reduce the question of whether A lies in the semigroup generated by $\mathcal{G}$ to the solubility of finitely many linear equations in nonnegative integers.

Case II: $\mathcal{G}_0$ is not commutative

Let $\mathcal{G}_0 = \{A_1, \ldots, A_\ell\}$ for some $\ell \ge 2$ such that A_1 and A_2 do not commute. Recall that by definition of $\mathcal{G}_0$ it holds that $\boldsymbol{v}_i^\top \boldsymbol{u} = 0$ for all $\boldsymbol{u} \in \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)^*$ and $i = 1, \ldots, \ell$. Therefore,

$$\mathrm{Span}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_\ell) \subseteq \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)^{**} = \mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)\,. \quad (5)$$

Following ideas from [23], we will show that there exist integers $p > 0$ and $q < 0$ such that $M_+ = (\mathbf{0}, \mathbf{0}, p)$ and $M_- = (\mathbf{0}, \mathbf{0}, q)$ and both lie in the semigroup generated by $\mathcal{G}$.

Indeed, from Equation (5) it follows that $-(\boldsymbol{v}_1 + \boldsymbol{v}_2)$ lies in $\mathrm{Cone}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k)$. Thus there exist $r_1, \ldots, r_k \in \mathbb{R}_{\ge 0}$ with r_1, r_2 strictly positive such that $\sum_{i=1}^{k} r_i \boldsymbol{v}_i = \mathbf{0}$. But since the vectors $\boldsymbol{v}_i$ have integer coefficients we can solve the above equation in natural numbers $r_1, \ldots, r_k$ with $r_1, r_2 > 0$. Taking a sequence of matrices $B_1, \ldots, B_m$, drawn from $\mathcal{G}$, such that $B_1 = A_1$, $B_2 = A_2$ and such that matrix A_i appears r_i times in the sequence for $i \in \{1, \ldots, k\}$, we obtain $\psi(B_1 \cdots B_m) = \mathbf{0}$. Since ψ is a homomorphism to a commutative group we have that $\psi(B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t) = \mathbf{0}$ for all $t \ge 1$ and permutations $\sigma \in S_m$.

Write $C_i = \log(B_i)$ for $i = 1, \ldots, m$. Applying the Baker-Campbell-Hausdorff Formula (3), we have that for any positive integer t and permutation $\sigma \in S_m$

$$\log(B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t) = t \sum_{i=1}^{m} C_{\sigma(i)} + \frac{t^2}{2} \sum_{i<j} [C_{\sigma(i)}, C_{\sigma(j)}]. \quad (6)$$

We show that we can obtain the desired matrices M_+ and M_- as $M_+ := B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t$ and $M_- := B_{\sigma(m)}^t \cdots B_{\sigma(1)}^t$ for some permutation $\sigma \in S_m$ and large enough t.

Let $\sigma_0 \in S_m$ be the permutation that transposes 1 and 2. Write also $\mathrm{id} \in S_m$ for the identity permutation. Defining $\delta_\sigma := \sum_{i<j} [C_{\sigma(i)}, C_{\sigma(j)}]_{1,n}$, we have $\delta_{\mathrm{id}} - \delta_{\sigma_0} = 2[C_1, C_2]_{1,n} \neq 0$ since B_1, B_2 do not commute. Hence there exists $\sigma \in \{\mathrm{id}, \sigma_0\}$ with $\delta_\sigma \neq 0$. Defining the reverse permutation $\sigma' \in S_m$ by $\sigma'(i) = \sigma(m + 1 - i)$ for $i = 1, \ldots, m$, we moreover have $\delta_{\sigma'} = -\delta_\sigma$, and thus we may suppose that $\delta_\sigma > 0$ and $\delta_{\sigma'} < 0$. It remains to note, by inspection of (6), that for t sufficiently large, if $\delta_\sigma \neq 0$ then the sign of the $(1, n)$-entry of $\log(B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t)$ is equal to the sign of δ_σ. But since $\log(B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t)$ has zeros in all entries, except for the $(1, n)$-entry, this entry is in fact equal to the $(1, n)$-entry of $B_{\sigma(1)}^t \cdots B_{\sigma(m)}^t$.

So, under the assumption that $\mathcal{G}_0$ is not commutative we have shown that one can compute integers $p > 0$ and $q < 0$ such that $M_+ = (\mathbf{0}, \mathbf{0}, p)$ and $M_- = (\mathbf{0}, \mathbf{0}, q)$ are in $\mathcal{G}$. It follows that $\langle \mathcal{G} \rangle$ contains the group $\mathcal{N} = \{(\mathbf{0}, \mathbf{0}, c) \in \mathrm{H}(n, \mathbb{Z}) : c \equiv 0 \pmod{m}\}$, where $m = \gcd(p, q)$. Since

$$(\boldsymbol{a}, \boldsymbol{b}, c) \cdot (\mathbf{0}, \mathbf{0}, c') = (\mathbf{0}, \mathbf{0}, c') \cdot (\boldsymbol{a}, \boldsymbol{b}, c) = (\boldsymbol{a}, \boldsymbol{b}, c + c'),$$

we have the following equivalence for the target matrix $A = (\boldsymbol{a}, \boldsymbol{b}, c)$:

$$\begin{aligned} A = (\boldsymbol{a}, \boldsymbol{b}, c) \in \langle \mathcal{G} \rangle \quad & \text{iff} \quad \exists B \in \langle \mathcal{G} \rangle \text{ such that } AB^{-1} \in \mathcal{N} \\ & \text{iff} \quad \exists B \in \langle \mathcal{G} \rangle \text{ such that } B = (\boldsymbol{a}, \boldsymbol{b}, c') \text{ and } c' \equiv c \pmod{m}. \end{aligned}$$

To decide whether $\langle \mathcal{G} \rangle$ contains a matrix $B = (\boldsymbol{a}, \boldsymbol{b}, c')$ with $c' \equiv c \pmod{m}$, we will use register automata. Let $d = n-2$ and consider the following finite automaton with $2d$ registers:

$$\mathbf{Q} = (\{A_1, \ldots, A_k\}, S, R_1, \ldots, R_d, T_1, \ldots, T_d, s_0, \delta, F),$$

where the alphabet of $\mathbf{Q}$ is equal to the set of generator matrices $\mathcal{G} = \{A_1, \ldots, A_k\}$, and the set of states S is equal to

$$S = \{(s_1, \ldots, s_d, t_1, \ldots, t_d, u) \ : \ s_i, t_i, u \in \{0, \ldots, m-1\} \text{ for } i = 1, \ldots, d\}.$$

Intuitively, $(2d+1)$-tuples from S store the values of a vector $(\boldsymbol{a}, \boldsymbol{b}, c)$ modulo m, and the registers $R_1, \ldots, R_d$ and $T_1, \ldots, T_d$ store the values of $\boldsymbol{a}$ and $\boldsymbol{b}$, respectively.

The initial state of $\mathbf{Q}$ is $s_0 = (0, \ldots, 0)$, and the initial values of all the registers are zeros. The transition function δ is defined as follows. Suppose $\mathbf{Q}$ is in a state $(s_1, \ldots, s_d, t_1, \ldots, t_d, u)$, and the current values of R_i and T_i are r_i and t_i, respectively, for $i = 1, \ldots, d$. If $\mathbf{Q}$ reads a letter $A_\ell = (a_1^\ell, \ldots, a_d^\ell, b_1^\ell, \ldots, b_d^\ell, c^\ell)$, then it moves to the state $(s'_1, \ldots, s'_d, t'_1, \ldots, t'_d, u')$, where for each $i = 1, \ldots, d$:

$s'_i \equiv s_i + a_i^\ell \pmod{m}$ and $t'_i \equiv t_i + b_i^\ell \pmod{m}$,
$u' \equiv u + c^\ell + s_1 b_1^\ell + \cdots + s_d b_d^\ell \pmod{m}$.
Also, the new value of R_i is $r_i + a_i^\ell$ and the new value of T_i is $t_i + b_i^\ell$.

The set F of final states consists of one state that corresponds to the values of the target matrix $A = (\boldsymbol{a}, \boldsymbol{b}, c) = (a_1, \ldots, a_d, b_1, \ldots, b_d, c)$ modulo m, that is

$$F = \{(s_1, \ldots, s_d, t_1, \ldots, t_d, u) \ : \ s_i \equiv a_i, \ t_i \equiv b_i, \ u \equiv c \pmod{m} \ \text{ for } i = 1, \ldots, d\}.$$

The automaton $\mathbf{Q}$ accepts a word $w \in \{A_1, \cdots, A_k\}^*$ if after reading w it reaches the final state from F and the values of the registers $R_1, \ldots, R_d$ and $T_1, \ldots, T_d$ are equal to $a_1, \ldots, a_d$ and $b_1, \ldots, b_d$, respectively. By construction, the language of $\mathbf{Q}$ in non-empty if and only if $\langle \mathcal{G} \rangle$ contains a matrix $B = (\boldsymbol{a}, \boldsymbol{b}, c')$ with $c' \equiv c \pmod{m}$.

Note that after reading any letter the registers of $\mathbf{Q}$ are changed by constant values, and the transitions have no guards or zero checks. Let $\mathcal{S}$ be the set of values that the registers of $\mathbf{Q}$ can have when it reaches the final state. It is well-known that for a register automaton of this type the set $\mathcal{S}$ is effectively semilinear (see [22, 21] for details). In particular, we can decide whether $\mathcal{S}$ contains the vector $(\boldsymbol{a}, \boldsymbol{b})$, and so the emptiness problem for $\mathbf{Q}$ is decidable. Hence, in the case when $\mathcal{G}_0$ is not commutative the Membership Problem for $\mathrm{H}(n, \mathbb{Z})$ is decidable.

▶ **Corollary 8.** *The Membership Problem for* $\mathrm{H}(n, \mathbb{Q})$ *is decidable.*

Proof. Let $A_i = (\boldsymbol{a}_i, \boldsymbol{b}_i, c_i)$, for $i = 1, \ldots, k$, and $A = (\boldsymbol{a}, \boldsymbol{b}, c)$ be the given generators and the target matrix from $\mathrm{H}(n, \mathbb{Q})$. Let N be a natural number such that $A_i = (\frac{1}{N}\boldsymbol{a}'_i, \frac{1}{N}\boldsymbol{b}'_i, \frac{1}{N^2}c'_i)$, for $i = 1, \ldots, k$, and $A = (\frac{1}{N}\boldsymbol{a}', \frac{1}{N}\boldsymbol{b}', \frac{1}{N^2}c')$, where $\boldsymbol{a}'_i, \boldsymbol{b}'_i, c'_i$, for $i = 1, \ldots, k$, and $\boldsymbol{a}', \boldsymbol{b}', c'$ are integer vectors and numbers. It is easy to check that

$$(\tfrac{1}{N}\boldsymbol{x}, \tfrac{1}{N}\boldsymbol{y}, \tfrac{1}{N^2}c) \cdot (\tfrac{1}{N}\boldsymbol{x}', \tfrac{1}{N}\boldsymbol{y}', \tfrac{1}{N^2}c') = (\tfrac{1}{N}(\boldsymbol{x} + \boldsymbol{x}'), \tfrac{1}{N}(\boldsymbol{y} + \boldsymbol{y}'), \tfrac{1}{N^2}(c + c' + \boldsymbol{x}^\top \boldsymbol{y}')) .$$

Hence $A \in \langle A_1, \ldots, A_k \rangle$ iff $A' \in \langle A'_1, \ldots, A'_k \rangle$, where $A' = (\boldsymbol{a}', \boldsymbol{b}', c')$ and $A'_i = (\boldsymbol{a}'_i, \boldsymbol{b}'_i, c'_i)$, for $i = 1, \ldots, k$, are matrices with integer entries, that is, from $\mathrm{H}(n, \mathbb{Z})$. By Theorem 7 we can decide whether $A' \in \langle A'_1, \ldots, A'_k \rangle$. ◀

4 The Half-Space Reachability Problem for $\mathrm{GL}(2, \mathbb{Z})$

In this section we will show that the Half-Space Reachability Problem for $\mathrm{GL}(2, \mathbb{Z})$ is decidable (Theorem 17).

▶ **Definition 9.** *For an integer n, the sign of n as follows:* $\mathrm{sg}(n) = 1$ *if* $n > 0$, $\mathrm{sg}(n) = -1$ *if* $n < 0$, *and* $\mathrm{sg}(n) = *$ *if* $n = 0$.

For a matrix $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathbb{Z}^{2\times 2}$, *define* $\mathrm{sg}(A) := \begin{pmatrix} \mathrm{sg}(a) & \mathrm{sg}(b) \\ \mathrm{sg}(c) & \mathrm{sg}(d) \end{pmatrix}$.

If A and B are two expressions whose values are in the set $\{1, -1, *\}$, then the notation $A \simeq B$ means that $A = B$ or $A = *$ or $B = *$.

▶ **Proposition 10.** *Suppose w is a canonical word of the form $w = SR^{\alpha_1}SR^{\alpha_2}\cdots SR^{\alpha_n}$, where $\alpha_i \in \{1, 2\}$ for $i = 1, \ldots, n$. Then* $\mathrm{sg}(\varphi(w)) \simeq \begin{pmatrix} (-1)^n & (-1)^n \\ (-1)^n & (-1)^n \end{pmatrix}$.

Proof. The proof is by induction on n. For $n = 1$, we have

$$\mathrm{sg}(\varphi(SR)) = \mathrm{sg}\begin{pmatrix} -1 & -1 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} \mathrm{sg}(-1) & \mathrm{sg}(-1) \\ \mathrm{sg}(0) & \mathrm{sg}(-1) \end{pmatrix} \simeq \begin{pmatrix} -1 & -1 \\ -1 & -1 \end{pmatrix} \quad \text{and}$$

$$\mathrm{sg}(\varphi(SR^2)) = \mathrm{sg}\begin{pmatrix} -1 & 0 \\ -1 & -1 \end{pmatrix} = \begin{pmatrix} \mathrm{sg}(-1) & \mathrm{sg}(0) \\ \mathrm{sg}(-1) & \mathrm{sg}(-1) \end{pmatrix} \simeq \begin{pmatrix} -1 & -1 \\ -1 & -1 \end{pmatrix}$$

Suppose the statement of the proposition is true for $w = SR^{\alpha_1}SR^{\alpha_2}\cdots SR^{\alpha_n}$ and consider the words wSR and wSR^2. Assume that $\varphi(w) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ and $\mathrm{sg}(\varphi(w)) = \begin{pmatrix} \mathrm{sg}(a) & \mathrm{sg}(b) \\ \mathrm{sg}(c) & \mathrm{sg}(d) \end{pmatrix} \simeq \begin{pmatrix} (-1)^n & (-1)^n \\ (-1)^n & (-1)^n \end{pmatrix}$. Then we have

$$\varphi(wSR) = \varphi(w)\varphi(SR) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}\begin{pmatrix} -1 & -1 \\ 0 & -1 \end{pmatrix} = \begin{pmatrix} -a & -a-b \\ -c & -c-d \end{pmatrix} \quad \text{and}$$

$$\varphi(wSR^2) = \varphi(w)\varphi(SR^2) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}\begin{pmatrix} -1 & 0 \\ -1 & -1 \end{pmatrix} = \begin{pmatrix} -a-b & -b \\ -c-d & -d \end{pmatrix}.$$

From these formulas it not hard to see that $\mathrm{sg}(\varphi(wSR)) \simeq \begin{pmatrix} (-1)^{n+1} & (-1)^{n+1} \\ (-1)^{n+1} & (-1)^{n+1} \end{pmatrix}$ and $\mathrm{sg}(\varphi(wSR^2)) \simeq \begin{pmatrix} (-1)^{n+1} & (-1)^{n+1} \\ (-1)^{n+1} & (-1)^{n+1} \end{pmatrix}$. ◀

▶ **Proposition 11.** *Let w be a canonical word of the form $w = S^\beta R^{\alpha_1} S R^{\alpha_2} \cdots S R^{\alpha_n} S^\varepsilon$, where $\beta, \varepsilon \in \{0,1\}$ and $\alpha_i \in \{1,2\}$, $i = 1, \ldots, n$. Then* $\operatorname{sg}(\varphi(w)) \simeq \begin{pmatrix} (-1)^n & (-1)^{n+\varepsilon} \\ (-1)^{n-1+\beta} & (-1)^{n-1+\beta+\varepsilon} \end{pmatrix}$.

Proof. First, consider the case when $\varepsilon = 0$. Suppose $\varphi(SR^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n}) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$. Then by Proposition 10 we have

$$\operatorname{sg}(\varphi(SR^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n})) = \begin{pmatrix} \operatorname{sg}(a) & \operatorname{sg}(b) \\ \operatorname{sg}(c) & \operatorname{sg}(d) \end{pmatrix} \simeq \begin{pmatrix} (-1)^n & (-1)^n \\ (-1)^n & (-1)^n \end{pmatrix}.$$

On the other hand, $\varphi(R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n}) =$

$$= -\varphi(S)\varphi(SR^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n}) = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} c & d \\ -a & -b \end{pmatrix}.$$

Hence $\operatorname{sg}(\varphi(R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n})) = \begin{pmatrix} \operatorname{sg}(c) & \operatorname{sg}(d) \\ \operatorname{sg}(-a) & \operatorname{sg}(-b) \end{pmatrix} \simeq \begin{pmatrix} (-1)^n & (-1)^n \\ (-1)^{n-1} & (-1)^{n-1} \end{pmatrix}$. Thus, for $\beta \in \{0,1\}$, we showed that

$$\operatorname{sg}(\varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n})) \simeq \begin{pmatrix} (-1)^n & (-1)^n \\ (-1)^{n-1+\beta} & (-1)^{n-1+\beta} \end{pmatrix}. \tag{7}$$

Now assume $\varepsilon = 1$ and let $\varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n}) = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$. Then

$$\begin{aligned} \varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n} S) &= \varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n})\varphi(S) \\ &= \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} b & -a \\ d & -c \end{pmatrix}. \end{aligned} \tag{8}$$

From equations (7) and (8) we obtain

$$\operatorname{sg}(\varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n} S)) = \begin{pmatrix} \operatorname{sg}(b) & \operatorname{sg}(-a) \\ \operatorname{sg}(d) & \operatorname{sg}(-c) \end{pmatrix} \simeq \begin{pmatrix} (-1)^n & (-1)^{n+1} \\ (-1)^{n-1+\beta} & (-1)^{n-1+\beta+1} \end{pmatrix}. \tag{9}$$

Equations (7) and (9) imply that for any $\beta, \varepsilon \in \{0,1\}$ $\operatorname{sg}(\varphi(S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n} S^\varepsilon)) \simeq \begin{pmatrix} (-1)^n & (-1)^{n+\varepsilon} \\ (-1)^{n-1+\beta} & (-1)^{n-1+\beta+\varepsilon} \end{pmatrix}$. ◀

From Proposition 11 and the equalities

$$\varphi(X) \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} -a & -b \\ -c & -d \end{pmatrix} \quad \text{and} \quad \varphi(N) \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} a & b \\ -c & -d \end{pmatrix}$$

we obtain the following proposition.

▶ **Proposition 12.** *Let w be a canonical word of the form $w = N^\delta X^\gamma S^\beta R^{\alpha_1} SR^{\alpha_2} \cdots SR^{\alpha_n} S^\varepsilon$, where $\beta, \gamma, \delta, \varepsilon \in \{0,1\}$ and $\alpha_i \in \{1,2\}$ for $i = 1, \ldots, n$. Then*

$$\operatorname{sg}(\varphi(w)) \simeq \begin{pmatrix} (-1)^{n+\gamma} & (-1)^{n+\gamma+\varepsilon} \\ (-1)^{n-1+\beta+\gamma+\delta} & (-1)^{n-1+\beta+\gamma+\delta+\varepsilon} \end{pmatrix}.$$

▶ **Theorem 13.** *The set of matrices in* $\mathrm{GL}(2,\mathbb{Z})$ *whose particular entry is nonnegative forms a regular subset. In other words, for all* $i,j \in \{1,2\}$*, the following subset of* $\mathrm{GL}(2,\mathbb{Z})$ *is regular:*

$$\mathrm{Pos}_{ij} = \left\{ \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ a_{ij} \geq 0 \right\}.$$

Proof. Suppose $i = j = 2$ as other cases are similar. Let A be a matrix from $\mathrm{GL}(2,\mathbb{Z})$ and let $w = N^\delta X^\gamma S^\beta R^{\alpha_1} S R^{\alpha_2} \cdots S R^{\alpha_n} S^\varepsilon$, where $\beta,\gamma,\delta,\varepsilon \in \{0,1\}$ and $\alpha_i \in \{1,2\}$ for $i = 1,\ldots,n$, be a canonical word that represents A, that is, $A = \varphi(w)$. From Proposition 12 we see that $\mathrm{sg}(a_{22}) \simeq (-1)^{n-1+\beta+\gamma+\delta+\varepsilon}$. Hence

$$a_{22} \geq 0 \quad \text{if and only if} \quad n - 1 + \beta + \gamma + \delta + \varepsilon \equiv 0 \pmod 2. \tag{10}$$

To finish the proof, we note that the set of all canonical words is regular. Furthermore, given a canonical word of the form $w = N^\delta X^\gamma S^\beta R^{\alpha_1} S R^{\alpha_2} \cdots S R^{\alpha_n} S^\varepsilon$, a finite automaton can read off the values of $\beta,\gamma,\delta,\varepsilon$ and determine the parity of number n. From this data an automaton can decide whether $a_{22} \geq 0$ by the above mentioned equivalence (10). Hence the set of canonical words w such that $\varphi(w) \in \mathrm{Pos}_{22}$ can be recognised by a finite automaton. ◀

Next theorem was proved in [33].

▶ **Theorem 14.** *For every* $k \in \mathbb{Z}$*, the following subset of* $\mathrm{GL}(2,\mathbb{Z})$ *is regular:*

$$\mathrm{S}_{ij}(k) = \left\{ \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ a_{ij} = k \right\}.$$

As a corollary from Theorems 13 and 14 we obtain:

▶ **Theorem 15.** *For every* $k \in \mathbb{Z}$*, the following subsets of* $\mathrm{GL}(2,\mathbb{Z})$ *are regular:*

$$\mathrm{S}_{ij}(\geq k) = \left\{ \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ a_{ij} \geq k \right\} \quad \textit{and}$$

$$\mathrm{S}_{ij}(\leq k) = \left\{ \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \in \mathrm{GL}(2,\mathbb{Z}) \ : \ a_{ij} \leq k \right\}.$$

Proof. Since $\mathrm{S}_{ij}(\leq k)$ is the complement of $\mathrm{S}_{ij}(\geq k+1)$, it suffices to prove that the sets $\mathrm{S}_{ij}(\geq k)$ are regular.

If $k = 0$, then it follows from Theorem 13 that $\mathrm{S}_{ij}(\geq 0) = \mathrm{Pos}_{ij}$ is regular. Furthermore,

$$\mathrm{S}_{ij}(\geq k) = \mathrm{Pos}_{ij} \ \setminus \bigcup_{n=0}^{k-1} M_{ij}(n) \text{ if } k > 0 \quad \text{and} \quad \mathrm{S}_{ij}(\geq k) = \mathrm{Pos}_{ij} \ \cup \bigcup_{n=k}^{-1} M_{ij}(n) \text{ if } k < 0.$$

Since by Corollary 6 regular subsets of $\mathrm{GL}(2,\mathbb{Z})$ are closed under Boolean operations, we conclude that $\mathrm{S}_{ij}(\geq k)$ is a regular set for any $k \in \mathbb{Z}$. ◀

▶ **Theorem 16.** *Let* $\lambda \in \mathbb{Q}$ *and* $\boldsymbol{u},\boldsymbol{v} \in \mathbb{Q} \times \mathbb{Q}$*. Then the set* $\mathcal{S}(\boldsymbol{u},\boldsymbol{v},\lambda) = \{\, M \in \mathrm{GL}(2,\mathbb{Z}) \ : \ \boldsymbol{u}^\top M \boldsymbol{v} \geq \lambda \,\}$ *is a regular subset of* $\mathrm{GL}(2,\mathbb{Z})$*.*

Proof. Note that if $\boldsymbol{u} = \boldsymbol{0}$ or $\boldsymbol{v} = \boldsymbol{0}$, then $\boldsymbol{u}^\top M \boldsymbol{v} = 0$. In this case $\mathcal{S}(\boldsymbol{u},\boldsymbol{v},\lambda)$ equals either the empty set or $\mathrm{GL}(2,\mathbb{Z})$, both of which are regular subsets. Hence we will assume that both $\boldsymbol{u} = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$ and $\boldsymbol{v} = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}$ are nonzero vectors. By multiplying the inequality $\boldsymbol{u}^\top M \boldsymbol{v} \geq \lambda$

by the least common multiple of the denominators of u_1, u_2, v_1, v_2, we can assume that $\boldsymbol{u}$ and $\boldsymbol{v}$ have integer coefficients. Furthermore, we can divide $\boldsymbol{u}^\top M\boldsymbol{v} \geq \lambda$ by $\gcd(u_1, u_2)$ and $\gcd(v_1, v_2)$ and so assume from now on that $\gcd(u_1, u_2) = \gcd(v_1, v_2) = 1$.

Finally, note that the inequality $\boldsymbol{u}^\top M\boldsymbol{v} \geq \lambda$ is equivalent to $\boldsymbol{u}^\top M\boldsymbol{v} \geq \lceil\lambda\rceil$, where $\lceil\lambda\rceil = \min\{n \in \mathbb{Z} \ : \ n \geq \lambda\}$. So, we can assume that λ is also an integer number.

Since $\gcd(u_1, u_2) = \gcd(v_1, v_2) = 1$, there are integers s_1, s_2, t_1, t_2 such that $s_1u_1 + s_2u_2 = 1$ and $t_1v_1 + t_2v_2 = 1$. Hence the matrices $A = \begin{pmatrix} u_1 & -s_2 \\ u_2 & s_1 \end{pmatrix}$ and $B = \begin{pmatrix} v_1 & -t_2 \\ v_2 & t_1 \end{pmatrix}$ belong to $\mathrm{GL}(2, \mathbb{Z})$, and we have that $\boldsymbol{u} = A\boldsymbol{e}_1$ and $\boldsymbol{v} = B\boldsymbol{e}_1$. Therefore, the inequality $\boldsymbol{u}^\top M\boldsymbol{v} \geq \lambda$ is equivalent to $\boldsymbol{e}_1^\top A^\top MB\boldsymbol{e}_1 \geq \lambda$. In other words,

$$M \in \mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda) \iff A^\top MB \in \mathrm{S}_{11}(\geq\lambda) \iff M \in (A^\top)^{-1} \cdot \mathrm{S}_{11}(\geq\lambda) \cdot B^{-1}.$$

By Theorem 15, $\mathrm{S}_{11}(\geq \lambda)$ is a regular subset of $\mathrm{GL}(2, \mathbb{Z})$. Let L be a regular language and let w_1, w_2 be canonical words such that $\varphi(L) = \mathrm{S}_{11}(\geq \lambda)$ and $\varphi(w_1) = (A^\top)^{-1}$ and $\varphi(w_2) = B^{-1}$. Then $\{w_1\} \cdot L \cdot \{w_2\}$ is a regular language such that $\varphi(\{w_1\} \cdot L \cdot \{w_2\}) = (A^\top)^{-1} \cdot \mathrm{S}_{11}(\geq\lambda) \cdot B^{-1} = \mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda)$. ◀

▶ **Theorem 17.** *The Half-Space Reachability Problem for* $\mathrm{GL}(2, \mathbb{Z})$ *is decidable.*

Proof. Let $\mathcal{G} = \{A_1, \ldots, A_k\}$ be a finite collection of matrices from $\mathrm{GL}(2, \mathbb{Z})$, λ be a rational number and $\boldsymbol{u}, \boldsymbol{v}$ be vectors from $\mathbb{Q}^2$. Define $\mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda) := \{\, M \in \mathrm{GL}(2, \mathbb{Z}) \ : \ \boldsymbol{u}^\top M\boldsymbol{v} \geq \lambda \,\}$. By Theorem 16, $\mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda)$ is a regular subset of $\mathrm{GL}(2, \mathbb{Z})$. Let $L_{\mathcal{S}}$ be a regular language such that $\mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda) = \varphi(L_{\mathcal{S}})$. It is not hard to see that the semigroup $\langle\mathcal{G}\rangle$ is also a regular subset. Indeed, consider a regular language $L_{\mathcal{G}} = (w_1 \cup \cdots \cup w_k)^+$, where $w_1, \ldots, w_k$ are canonical words that correspond to the matrices $A_1, \ldots, A_k$, respectively. Then $\langle\mathcal{G}\rangle = \varphi(L_{\mathcal{G}})$.

By Corollary 6, we can algorithmically construct a regular language $L^\cap$ such that $\varphi(L^\cap) = \varphi(L_{\mathcal{S}}) \cap \varphi(L_{\mathcal{G}}) = \mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda) \cap \langle\mathcal{G}\rangle$. Now we have the following equivalence:

$$\text{there is } M \in \langle\mathcal{G}\rangle \text{ such that } \boldsymbol{u}^\top M\boldsymbol{v} \geq \lambda \quad \text{iff} \quad \mathcal{S}(\boldsymbol{u}, \boldsymbol{v}, \lambda) \cap \langle\mathcal{G}\rangle = \varphi(L^\cap) \neq \emptyset.$$

The last condition is equivalent to $L^\cap \neq \emptyset$. Therefore, we reduced the Half-Space Reachability Problem for $\mathrm{GL}(2, \mathbb{Z})$ to the emptiness problem for regular languages. ◀

5 The Half-Space Reachability Problem for the Heisenberg Group

▶ **Definition 18.** *Let* $\mathcal{S} := B_1, \ldots, B_m$ *be a sequence in* $\mathrm{H}(n, \mathbb{Q})$ *and* A *a particular matrix in* $\mathrm{H}(n, \mathbb{Q})$*. A pair* $i, j \in \{1 \ldots, m\}$ *with* $i \leq j$ *is called an* A-block *of* $\mathcal{S}$ *if*

1. $B_k = A$ *for all* $k \in \{i, \ldots, j\}$,
2. *either* $i = 1$ *or* $B_{i-1} \neq A$,
3. *either* $j = m$ *or* $B_{j+1} \neq A$.

We say that $\mathcal{S}$ *is* pure *if it has at most one* A*-block for every matrix* A*.*

Given a sequence $\mathcal{S} = B_1, \ldots, B_m \in \mathrm{H}(n, \mathbb{Q})$, define $C_i := \log(B_i)$ for $i = 1, \ldots, m$, $\Delta(\mathcal{S}) := \sum_{1 \leq i < j \leq m} [C_i, C_j]$, and $\delta(\mathcal{S}) := \Delta(\mathcal{S})_{1,n}$. Recall that using the Baker-Campbell-Hausdorff formula (3) we can express the product of the sequence $\mathcal{S}$ as follows

$$B_1 \cdots B_m = \exp\Big(\sum_{i=1}^{m} C_i + \frac{1}{2} \underbrace{\sum_{1 \leq i < j \leq m} [C_i, C_j]}_{\Delta(\mathcal{S})}\Big) \tag{11}$$

▶ **Proposition 19.** *For any sequence of matrices $\mathcal{S} = B_1, \ldots, B_m \in \mathrm{H}(n, \mathbb{Q})$, there is a permutation $\pi \in S_m$ such that sequence $\mathcal{S}' := B_{\pi(1)}, \ldots, B_{\pi(m)}$ is pure and $\delta(\mathcal{S}) \leq \delta(\mathcal{S}')$.*

The proof of Proposition 19 can be found in the full version [11].

▶ **Theorem 20.** *The Half-Space Reachability Problem for $\mathrm{H}(n, \mathbb{Q})$ is decidable.*

Proof. Consider an instance of the Half-Space Reachability Problem, given by a finite set $\mathcal{G} = \{A_1, \ldots, A_k\} \subseteq \mathrm{H}(n, \mathbb{Q})$ of generators, vectors $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{Q}^n$ and a scalar $\lambda \in \mathbb{Q}$.

Given a sequence $\mathcal{S} = B_1, \ldots, B_m$ of elements of $\mathcal{G}$ and a permutation $\sigma \in \mathrm{Sym}_m$, define $\mathcal{S}_\sigma = B_{\sigma(1)}, \ldots, B_{\sigma(m)}$. It follows from Equation (11) that the entries of the product $B_{\sigma(1)} \cdots B_{\sigma(m)}$ do not depend on the choice of $\sigma \in \mathrm{Sym}_m$, except for the $(1, n)$-entry which is equal to $\frac{1}{2}\Delta(\mathcal{S}_\sigma)_{1,n}$ plus a constant that also does not depend on σ. So, the permutation σ that maximises $\boldsymbol{u}^\top B_{\sigma(1)} \cdots B_{\sigma(m)} \boldsymbol{v}$ is the same which maximises or minimises $\Delta(\mathcal{S}_\sigma)_{1,n}$ depending on the sign of the coefficient at $\Delta(\mathcal{S}_\sigma)_{1,n}$ in the expression $\boldsymbol{u}^\top \Delta(\mathcal{S}_\sigma) \boldsymbol{v}$, namely, on the sign of $\boldsymbol{u}_1 \boldsymbol{v}_n$. By Proposition 19 we may assume without loss of generality that the optimal permutation σ is such that $\mathcal{S}_\sigma$ is pure.

By the reasoning above, to decide the given instance of the Half-Space Reachability Problem it suffices to restrict attention to pure sequences of generators. Equivalently we must decide whether there exist nonnegative integers $n_1, \ldots, n_k$ and a permutation $\sigma \in \mathrm{Sym}_k$ such that $\boldsymbol{u}^\top A_{\sigma(1)}^{n_1} \cdots A_{\sigma(k)}^{n_k} \boldsymbol{v} \geq \lambda$. Write $C_i = \log A_i$ for $i = 1, \ldots, k$. Then

$$\begin{aligned} \boldsymbol{u}^\top A_{\sigma(1)}^{n_1} \cdots A_{\sigma(k)}^{n_k} \boldsymbol{v} &= \boldsymbol{u}^\top \exp\left(\sum_{i=1}^{k} n_i C_{\sigma(i)} + \frac{1}{2} \sum_{i<j} n_i n_j [C_{\sigma(i)}, C_{\sigma(j)}] \right) \boldsymbol{v} \\ &= Q(n_1, \ldots, n_k) \end{aligned}$$

for some quadratic polynomial $Q(x_1, \ldots, x_k)$ with rational coefficients.

In the work of Grunewald and Segal [14] an algorithm is given for solving the following problem: does there exist integers $n_1, \ldots, n_k$ that satisfy a given quadratic equation $Q(n_1, \ldots, n_k) = 0$ (with rational coefficients) and a finite number of linear inequalities on $n_1, \ldots, n_k$ (also with rational coefficients).

By introducing a "dummy" variable we can use the Grunewald and Segal algorithm to decide whether $Q(n_1, \ldots, n_k) \geq \lambda$ for some nonnegative integers $n_1, \ldots, n_k$. Hence the Half-Space Reachability Problem for $\mathrm{H}(n, \mathbb{Q})$ is decidable. ◀

Abstract

We consider the maximal and maximum independent set problems in three models of graph streams:

- In the edge model we see a stream of edges which collectively define a graph; this model is well-studied for a variety of problems. We show that the space complexity for a one-pass streaming algorithm to find a maximal independent set is quadratic (i.e. we must store all edges). We further show that it is not much easier if we only require approximate maximality. This contrasts strongly with the other two vertex-based models, where one can greedily find an exact solution in only the space needed to store the independent set.
- In the "explicit" vertex model, the input stream is a sequence of vertices making up the graph. Every vertex arrives along with its incident edges that connect to previously arrived vertices. Various graph problems require substantially less space to solve in this setting than in edge-arrival streams. We show that every one-pass c-approximation streaming algorithm for maximum independent set (MIS) on explicit vertex streams requires $\Omega(\frac{n^2}{c^6})$ bits of space, where n is the number of vertices of the input graph. It is already known that $\tilde{\Theta}(\frac{n^2}{c^2})$ bits of space are necessary and sufficient in the edge arrival model (Halldórsson *et al.* 2012), thus the MIS problem is not significantly easier to solve under the explicit vertex arrival order assumption. Our result is proved via a reduction from a new multi-party communication problem closely related to pointer jumping.
- In the "implicit" vertex model, the input stream consists of a sequence of objects, one per vertex. The algorithm is equipped with a function that maps pairs of objects to the presence or absence of edges, thus defining the graph. This model captures, for example, geometric intersection graphs such as unit disc graphs. Our final set of results consists of several improved upper and lower bounds for interval and square intersection graphs, in both explicit and implicit streams. In particular, we show a gap between the hardness of the explicit and implicit vertex models for interval graphs.

1 Introduction

The streaming model supposes that, rather than being loaded into memory all at once, the input is received piece-by-piece over a period of time. Only a sublinear amount of memory (in the input size) is made available, preventing any algorithm from "seeing" even a constant fraction of the whole input at once.

In graph streams (see [19] for an excellent survey), we distinguish between the "edge-arrival" model, where the stream consists of individual edges arriving in any order, and the "vertex-arrival" model, where the stream consists of batches of edges incident to a particular vertex – as each vertex "arrives" we are given all the edges from the new vertex to previously arrived vertices. We will shorten the names to edge streams and vertex streams, respectively. Problems are always at least as hard on edge streams as on vertex streams (as any vertex stream is also a valid edge stream).

There is a further variant which we will call "implicit" vertex streams (as opposed to the normal explicit representation). In this model, the stream consists of a series of small (polylog(n)-sized) identifiers – one per vertex. We are additionally provided with some symmetric function or oracle which maps a pair of identifiers to a Boolean output indicating whether the two vertices are connected or not. This implicitly defines a graph over the list of identifiers received. Geometric intersection graphs, received as a stream of geometric objects, are the most natural members of this class. For example, a unit interval intersection graph can be given by a set of points in $\mathbb{R}$. Then a pair of vertices x, y are adjacent if and only if $|x - y| \leq 1$.

Explicit and implicit vertex streams are closely related but distinct, with neither being strictly "harder" than the other. For example: it is easy to count exactly the number of edges in $\tilde{O}(1)$ space[1] for an explicit vertex stream, however, doing so for an implicit stream requires linear space – otherwise we cannot hope to know how many edges are incident to the final vertex. On the other hand: implicit vertex streams can be stored entirely in $\tilde{O}(n)$ space, whereas explicit vertex streams require $\Omega(n^2)$ space to store the full structure.

Maximum Independent Set (MIS) is an important problem on graphs. The task is to find a largest subset of vertices which have no edges between them. The size of a MIS in a graph G is denoted $\alpha(G)$, the independence number of G. Unfortunately, it is NP-hard to find a maximum independent set in a general graph [16], and even hard to approximate within a factor of $n^{1-\epsilon}$, for any $\epsilon > 0$ [20]. It is also known to be hard in the edge-arrival streaming model: Halldórsson *et al.* [15] showed that space $\tilde{\Theta}(\frac{n^2}{c^2})$ is necessary (and sufficient) for computing a c-approximation on an n-vertex graph, despite being allowed unlimited computation.

Our Results. In this paper, we study the hardness of approximate MIS in the explicit and implicit vertex streaming models. Since many problems are significantly easier to solve in vertex streams than in edge streams, we ask whether this is also the case for the MIS problem. As our main result, we answer this question in the negative:

▶ **Theorem 1.** *Any constant error one-pass c-approximation streaming algorithm for* MIS *(or the size of a* MIS*) in the explicit vertex stream model requires $\Omega\left(\frac{n^2}{c^6}\right)$ bits of space.*

[1] All space bounds in this paper are given as number of bits. We use $\tilde{O}$, $\tilde{\Theta}$, and $\tilde{\Omega}$ to mean O, Θ, and Ω (respectively) with log factors suppressed.

Space Bound	Approx. MIS $\tilde{O}(\alpha(G))$	Approx. $\alpha(\mathbf{G})$ poly$(\log n)$	$\Omega(n)$
Unit Interval	2 (Greedy alg.)	$O\left(\frac{\log^2 n}{\log\log n}\right)$ [9]	$< 5/3$

Figure 1 Approximation factors for explicit vertex streams.

Space Bound	Approx. MIS $\tilde{O}(\alpha(G))$	Approx. $\alpha(\mathbf{G})$ poly$(\log n, \epsilon^{-1})$	$\Omega(n)$
Unit Interval	3/2 [11]	$3/2+\epsilon$ [7]	$< 3/2$ [11]
Interval	2 [11]	$2+\epsilon$ [7]	< 2 [11]
Unit Square	3	$3+\epsilon$	$< 5/2$

Figure 2 Approximation factors for implicit vertex streams. The first column concerns algorithms that output independent sets themselves, while the second columns concerns algorithms that output estimations of the maximum independent set size. Results from this paper are highlighted.

Our lower bound also holds for the Minimum Vertex Coloring (MVC) problem, where the objective is to color the vertices of the input graph such that adjacent vertices have different colors, using the fewest colors possible. This quantity is the chromatic number and denoted by $\chi(G)$. Our result is the first lower bound known for this problem, even for edge streams (in particular, the work by Halldórsson *et al.* [15] does not imply such a result).

Next, we show that the situation is very different for the related *maximal* independent set problem, where we need to find a subset of non-adjacent vertices that cannot be enlarged. While it is easy to maintain a maximal independent set in vertex arrival streams (both explicit and implicit) using space $\tilde{O}(\alpha(G)) = \tilde{O}(n)$, we prove that $\Omega(n^2)$ space is required in the edge-arrival model. We further show that even if we relax the maximality constraint to *approximate maximality* and allow for a slightly sublinear number of vertices that are not adjacent to vertices of the independent set then space $\Omega(n^{2-o(1)})$ is still required.

Finally, we show various improved upper and lower bounds for certain geometric intersection graph classes in both vertex streaming models: unit interval intersection graphs given as explicit vertex streams require $\Omega(n)$ space to get a better than $\frac{5}{3}$-approximation to $\alpha(G)$, making them harder than their implicit vertex stream equivalents; and we can 3-approximate MIS for a stream of unit squares in the plane using $\tilde{O}(\alpha(G))$ space, but achieving better than a $\frac{5}{2}$-approximation to $\alpha(G)$ requires $\Omega(n)$ space. Figures 2 and 1 shows these results in the context of previously known bounds.

Techniques. Halldórsson *et al.* [15] proved their space lower bound for MIS in edge streams via the *one-way two-party communication framework*. Two parties, denoted Alice and Bob, each hold a subset of the edges of the input graph. Alice sends a single message to Bob, who, upon receipt, outputs a large independent set. Via a reduction from a well-known communication problem, they showed that if Bob outputs a c-approximate MIS then Alice must send a message of size $\tilde{\Omega}(\frac{n^2}{c^2})$ to Bob. A common reduction then implies that the same lower bound holds for the space complexity of one-pass streaming algorithms.

Proving a similar result in vertex streams is significantly harder since the two-party communication abstraction cannot yield the desired result. When partitioning the vertices of a vertex stream between Alice and Bob both parties hold *vertex-induced subgraphs*, as opposed to the *spanning subgraphs* obtained when partitioning the edges of an edge stream. Since an independent set in an induced subgraph is also an independent set in the whole

graph, and since either Alice or Bob holds at least half the vertices of any MIS, one of them must already know a 2-approximation to the MIS. Using the same reasoning, it is trivial to compute a p-approximation in the one-way p-party communication setting. To obtain our lower bound result, we therefore need to consider multi-party communication with $\Omega(c)$ parties.

To this end, we define a new k-party communication problem denoted $\textsc{Chain}_k$ – which can be seen as chaining together multiple two-party instances of the well-known Index problem (see Definition 2) that are guaranteed to have the same answer. We first give a $\Omega(\frac{n}{k^2})$ lower bound for $\textsc{Chain}_k$ by showing a reduction from a multi-party pointer jumping problem [8]. We then improve this lower bound to $\Omega(\frac{n}{k})$ for k up to $\tilde{O}\left(\sqrt[4]{n}\right)$ using the same party elimination techniques described in [8]. The actual reduction from $\textsc{Chain}_k$ to MIS relies on an involved graph construction using erasure codes based on affine planes.

Our lower bound for the computation of a maximal independent set in edge streams is obtained via a reduction from the Index problem in the two-party communication framework. This construction is then extended to yield results for approximate maximality via a construction involving Ruzsa-Szemerédi graphs.

Our upper bound results on 2D geometric intersection graphs are obtained by generalizing 1D bounds, with more work to cover the increased number of cases that occur in 2D. The lower bounds involve intricate packing arguments to show that knowledge of $\alpha(G)$ can be used to recover encoded information, which is used in conjunction with our multiparty $\textsc{Chain}_k$ problem to demonstrate approximation hardness.

Further Related Work. Grouping the three streaming models:

- *Edge Streams.* As previously mentioned, Halldórsson *et al.* [15] showed that for general graphs in the edge-arrival model $\tilde{\Omega}\left(\frac{n^2}{c^2}\right)$ space is required to obtain a c-approximation to the maximum independent set size (or maximum clique size). A corresponding $\tilde{O}\left(\frac{n^2}{c^2}\right)$ space random sampling algorithm shows that this is tight up to logarithmic factors. Braverman *et al.* [6] showed that space $\Omega(\frac{m}{c^2})$ is needed, even if $c = o(\log n)$, where m is the number of edges of the input graph, though this bound only holds for small m.
- *Explicit Vertex Streams.* The work of Halldórsson *et al.* [13] gives an $O(n \log n)$ space streaming algorithm which can find an independent set of expected size at least $\beta(G) = \sum_{v \in V} \frac{1}{\deg(v)+1}$. On general graphs, this only gives a $\Theta(n)$-approximation, but for polynomially bounded independence graphs, this gives a polylog(n)-approximation [14]. In our prior work, we showed how to return an estimate $\gamma \in \Omega\left(\frac{\beta(G)}{\log n}\right)$ with $\gamma \leq \alpha(G)$ from an explicit vertex arrival stream using only $O(\log^3 n)$ space [9]. This result, for example, gives a $O(\frac{\log^2 n}{\log \log n})$-approximation on unit interval graphs (see Figure 1). However, the technique samples vertices based on their degree and does not extend to implicit vertex streams.

  Braverman *et al.* [6] showed that in a variant of the vertex arrival model, where every vertex arrives together with *all* its incident edges (as opposed to only the edges incident to previously arrived vertices), space $\Omega(\frac{m}{c^3})$ is required for computing a c-approximate MIS. In their construction the input graph has $\Theta(nc)$ edges, which thus yields a lower bound of $\Omega(\frac{n}{c^2})$. Observe that our lower bound for explicit vertex streams is $\Omega(\frac{n^2}{c^6})$, a quadratic improvement for constant c.
- *Implicit Vertex Streams.* In [11], it was shown that it is possible to $\frac{3}{2}$-approximate MIS for the intersection graph of a unit interval stream using $\tilde{O}(\alpha(G))$ space. In the same space, a 2-approximation is possible for arbitrary interval streams. Both are shown to

be tight: any $(\frac{3}{2}-\epsilon)$-approximation for unit intervals, or $(2-\epsilon)$ for general intervals, requires $\Omega(n)$ space. By clever use of sampling, the result can be adapted to provide an approximation of $\alpha(G)$ of $\frac{3}{2}+\epsilon$ for unit intervals and $2+\epsilon$ for general intervals with only polylog(n, ϵ^{-1}) space [7].

Concurrent Work. Independently of, and concurrently with, an earlier version of this paper [10, v1], Assadi *et al.* [3] also gave an $\Omega(n^2)$ lower bound for maximal independent set in edge streams using a similar construction.

Outline. We present our main result, the lower bound for MIS in vertex streams, in Section 2. Our lower bounds for maximal and approximately maximal independent sets in edge streams are given in Section 3. Section 4 covers our results on interval and square graphs, and we give a brief conclusion in Section 5.

2 Maximum Independent Set in Explicit Vertex Streams

We first introduce and show the hardness of a "chained index" problem, which we then use to show the hardness of approximating the size $\alpha(G)$ – and hence also for finding an approximate MIS.

2.1 Chained Index Communication Problem

We define a multi-party communication problem $\textsc{Chain}_k$, which allows us to prove new lower bounds on several streaming problems. The problem is closely related to pointer jumping and generalizes the classic two-party Index communication problem to more parties by "chaining" together multiple instances which have the same answer but are otherwise independent. Index is defined as follows:

▶ **Definition 2.** *In the two-party communication problem* Index*, Alice holds an n-bit string $X \in \{0,1\}^n$ and Bob holds an index $\sigma \in [n]$. Alice sends a single message to Bob who, upon receipt, outputs X_σ.*

It is well known that Alice essentially needs to send all n bits to Bob (see [18]):

▶ **Theorem 3.** *The randomized constant error communication complexity of* Index *is $\Omega(n)$.*

In $\textsc{Chain}_k$, each party (except the last) holds a binary vector that contains a special bit which is the answer to the instance. Each party (except the first) knows where the answer bit is located in the previous party's vector. Communication is one-way and private, with each player receiving a message from the previous player and then sending a message to the next player. Formally:

▶ **Definition 4.** *The k-party chained index problem $\textsc{Chain}_k$ consists of $(k-1)$ n-bit binary vectors $\{X^{(i)}\}_{i=1}^{k-1}$, along with corresponding indices $\{\sigma_i\}_{i=1}^{k-1}$ from the range $[n]$. We have the promise that the entries $\{X^{(i)}_{\sigma_i}\}_{i=1}^{k-1}$ are all equal to the desired answer bit $z \in \{0,1\}$. The input is initially allocated as follows:*

- *The first party P_1 knows $X^{(1)}$*
- *Each intermediate party P_p for $1 < p < k$ knows $X^{(p)}$ and σ_{p-1}*
- *The final party P_k knows just σ_{k-1}*

Communication proceeds as follows: P_1 sends a single message to P_2, then P_2 communicates to P_3, and so on, with each party sending exactly one message to its immediate successor. After all messages are sent, P_k must correctly output z, succeeding with probability at least $2/3$. If the promise condition is violated, any output is considered correct.

There is a trivial communication upper bound of $O(n)$ bits: for instance, simply have the penultimate party send $X^{(k-1)}$ to the final party who can then return $X^{(k-1)}_{\sigma_{k-1}}$.

We claim two bounds on the communication complexity of this problem.

▶ **Theorem 5.** *Any communication scheme $\mathcal{B}$ which solves $\textsc{Chain}_k$ must communicate at least $\Omega(\frac{n}{k^2})$ bits in total.*

This first bound is shown by reducing instances of another problem (conservative pointer jumping [8]) to instances of our problem.

▶ **Theorem 6.** *There is a constant $C > 0$ such that any communication scheme $\mathcal{B}$ which solves $\textsc{Chain}_k$ for $k \leq C\left(\frac{n}{\log n}\right)^{\frac{1}{4}}$ must communicate at least $\Omega(\frac{n}{k})$ bits in total.*

This second bound is shown by a lengthy and technical proof based on the structure of the pointer jumping bound given in [8]. Due to space restrictions we omit both proofs here – they can be found in the full paper.

In particular, for constant k, we have a tight bound on the communication complexity of the k-party chained index problem of $\Theta(n)$. We conjecture that a dependence on k is not necessary.

▶ **Conjecture 1.** *Any communication scheme for $\textsc{Chain}_k$ requires $\Omega(n)$ communication.*

2.2 MIS Hardness in Explicit Vertex Streams

We show a new lower bound for the vertex streaming space complexity of approximate MIS.

▶ **Theorem 1** (restated)**.** *Any algorithm for the explicit vertex stream model which finds a c-approximation to $\alpha(G)$ with probability at least $2/3$ requires $\Omega\left(\frac{n^2}{c^6}\right)$ space.*

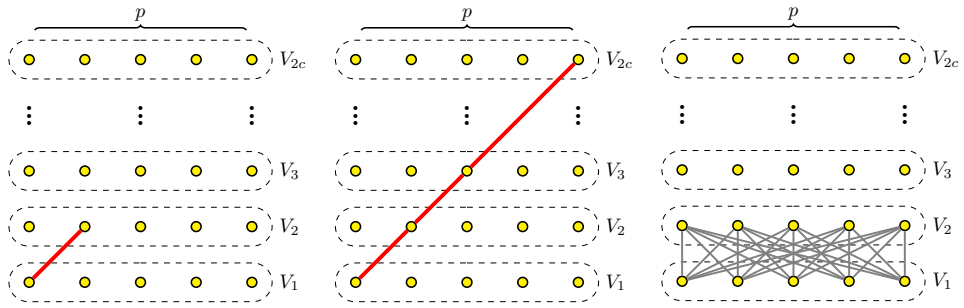
For ease of argument, we will actually prove an equivalent result for the problem of clique number approximation, and then note that the complement of the constructed graph can be used with the same arguments to prove Theorem 1. To see this equivalence, note that an MIS of a graph is a maximum clique in its complement.

▶ **Theorem 7.** *Any algorithm for the explicit vertex stream model which finds a c-approximation to the size of the largest clique $\omega(G)$ with probability at least $2/3$ requires $\Omega\left(\frac{n^2}{c^6}\right)$ space.*

The heart of our construction is to use an erasure code to encode a length $\Theta(\frac{n^2}{c^4})$ binary vector on $\Theta(\frac{n}{c})$ vertices, with each bit corresponding to the presence or absence of a clique of size $2c$. The use of the erasure code is to ensure that no pair of these cliques can share an edge. We can then chain together $2c$ such gadgets to encode an instance of $\textsc{Chain}_{2c}$ such that if the correct answer is 1, the resulting graph has an independent set of size $4c^2$, while if the correct answer is 0 the graph has no independent set larger than $4c - 1$. Any (one-sided) c-approximation algorithm could distinguish these two cases, which proves the result.

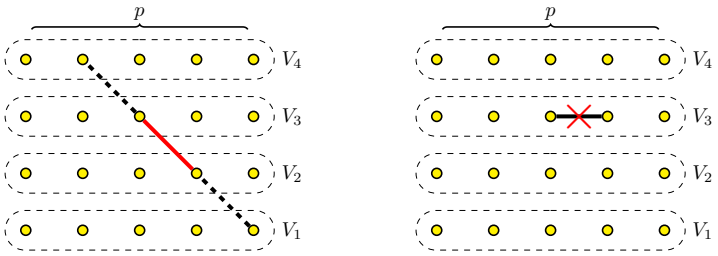
First we define our clique gadget.

▶ **Lemma 8.** *For any positive integers n and $c^2 < \frac{n}{8}$, there exists a graph on n vertices containing $\frac{n^2}{16c^2}$ edge-disjoint cliques of size $2c$ and no cliques of size larger than $2c$.*



(a) Select an edge. **(b)** Extend linearly to size $2c$. **(c)** Can make p^2 such cliques.

Figure 3 Clique gadget construction in Lemma 8.



(a) No edge belongs to two different lines (cliques).

(b) No edges within layers, so no cliques larger than $2c$.

Figure 4 Clique gadget proof sketch for Theorem 7.

Proof. We construct the sets from an erasure code with block size $2c$ and message size 2. Choose a prime p such that $\frac{n}{4c} \leq p \leq \frac{n}{2c}$ (which is guaranteed to exist). Now take $2c < p$ groups of vertices, each of size p. Label the groups V_i (for $i \in [2c]$) and label the items in each group V_i as v_j^i (for $j \in [p]$). Leftover vertices are added to the final graph as isolated vertices.

For each polynomial $\mathcal{P} \in \mathrm{GF}(p^2)$ we define $K_{\mathcal{P}}$ to be the clique over vertices $\{v^i_{\mathcal{P}(i)} | i \in [2c]\}$. This can be viewed as taking each of the p^2 possible edges between V_1 and V_2 and extending them "linearly" to the other layers (see Figure 3). In other words, the cliques correspond to non-horizontal lines in the affine plane of order p. Clearly $\mathcal{K} = \{K_{\mathcal{P}} | \mathcal{P} \in \mathrm{GF}(p^2)\}$ consists of $p^2 > \frac{n^2}{16c^2}$ cliques, each of size $2c$. We next show that they are pairwise edge-disjoint and that their union contains no larger cliques.

Each clique contains exactly one vertex from each group V_i, so for two cliques to share an edge there must be distinct polynomials $\mathcal{P}, \mathcal{Q} \in GF(p^2)$ that have the same value at two different points: $\mathcal{P}(i) = \mathcal{Q}(i)$ and $\mathcal{P}(j) = \mathcal{Q}(j)$ for $i \neq j$ – a contradiction. Finally, because no clique contains a pair of vertices from a single V_i, their union can contain no internal edges on any V_i. So any clique can contain at most 1 vertex from each V_i, giving a maximum size of $2c$. Hence, $\bigcup_{\mathcal{P} \in \mathrm{GF}(p^2)} K_{\mathcal{P}}$ is a graph with the required properties. ◀

Proof of Theorem 7. Suppose we have an algorithm $\mathcal{C}$ for explicit vertex streams which can, with probability at least $\frac{2}{3}$, produce a c-approximation to $\omega(G)$, the size of the largest clique. We will show that such an algorithm can be used to solve $\textsc{Chain}_{2c}$, by communicating its state $2c - 1$ times.

Fix an instance of $\textsc{Chain}_{2c}$ with vectors of length $b = \frac{n^2}{64c^4}$. Our lower bound in Theorem 6 implies that any algorithm that can solve this must send at least one message of size $\Omega\left(\frac{b}{c^2}\right) = \Omega\left(\frac{n^2}{c^6}\right)$ bits. Take n vertices and partition the nodes into $2c$ groups of size $\frac{n}{2c}$. Each group will be added to the stream by one of the parties.

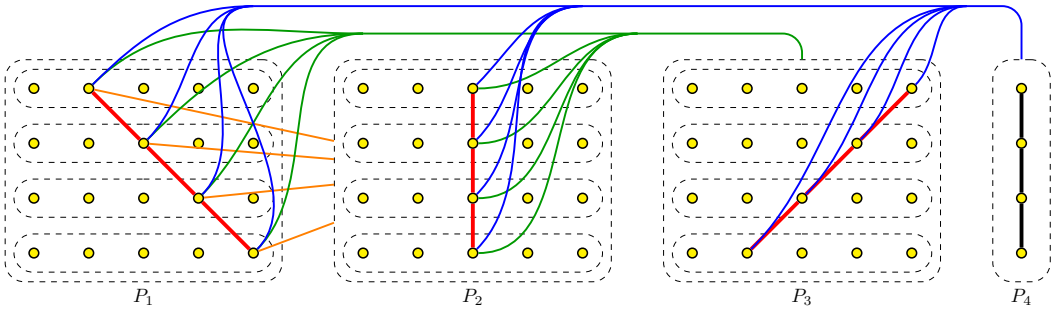


Figure 5 Example lower bound instance with 4 players for Theorem 7. Cliques corresponding to σ_1, σ_2, and σ_3 are shown in bold red – other cliques are omitted.

Intra-party edges. First, consider the group of nodes associated with party P_i. We will encode the bits of $X^{(i)}$ onto the internal edges of this group using the construction from Lemma 8. The size $\frac{n}{2c}$ sub-graph can fit b cliques of size $2c$. We include the edges of clique j if and only if $X^{(i)}_j = 1$. This is well defined as the cliques are edge-disjoint. Label the clique in party P_i corresponding to bit j of $X^{(i)}$ as $\mathcal{K}^i_j$. The final party P_{2c} has no associated vector. Instead, it constructs a single clique of size $2c$ and leaves the other vertices isolated.

Inter-party edges. We also need edges between the sub-graphs associated with different parties. Each party P_i will connect all its vertices to some of the vertices belonging to previous parties (P_j for $j < i$). These edges are considered to belong to party P_i, as they will be added by this party in the vertex streaming model. For each $j < i$ the party P_i connects every one of its vertices to all of $\mathcal{K}^j_{\sigma_j}$ (the clique corresponding to index σ_j). For this to happen, P_i must know all σ_j for $j < i$. This information is not known initially, but can be appended to the communications between players with only $O(c)$ overhead.

Now that we have our construction, we need to show bounds on $\omega(G)$ for the two cases. First, consider when every $X^{(i)}_{\sigma_i} = 1$. In this case we have each of the cliques $\mathcal{K}^i_{\sigma_i}$ present and connected together, forming a clique of size $4c^2$. Now consider the case when every $X^{(i)}_{\sigma_i} = 0$. Consider a clique $\mathcal{K}$ in the graph. If $\mathcal{K}$ contains multiple vertices belonging to one party P_i, then it can contain none from any subsequent party P_j ($j > i$), and at most one from each preceding party P_l ($l < i$). Hence the size of any clique is bounded by $4c - 1$. To see why this holds, observe that for any $i < 2c$, our clique can contain only one vertex from $\mathcal{K}^i_{\sigma_i}$, as none of its edges are included in the graph. So to contain multiple vertices from party P_i, the clique $\mathcal{K}$ must contain a vertex v from some $\mathcal{K}^i_j$ with $j \neq \sigma_i$. But then all subsequent parties P_j ($j > i$) will have no vertices adjacent to v, so cannot contribute anything to $\mathcal{K}$. So the best we can do is include one vertex from each $\mathcal{K}^i_{\sigma_i}$ and then $2c$ from party P_{2c} giving a clique of size $4c - 1$.

To complete the proof, observe that this gap in clique sizes can be distinguished by a c-approximation algorithm, and any streaming algorithm gives a communication protocol by having each party update the algorithm state with their information and then pass it to the next party. ◀

Interestingly, the same construction gives us hardness for approximating the chromatic number of a graph. This is notably not possible in the 2-party edge stream construction in [15], as the random graphs used as gadgets have large chromatic number w.h.p. (see [5]).

▶ **Corollary 9.** *Any explicit vertex streaming algorithm to find a c-approximation to $\chi(G)$ (the chromatic number), succeeding with probability at least 2/3 requires $\Omega\left(\frac{n^2}{c^6}\right)$ space.*

Proof. Consider the construction in the proof of Theorem 1. In the case of all $X_{\sigma_i}^{(i)} = 1$, the graph contains a clique of size $4c^2$, so it requires at least as many colours.

Conversely, in the case of every $X_{\sigma_i}^{(i)} = 0$, we can construct a $4c$-coloring of the graph. First color each of the nodes in each $\mathcal{K}_{\sigma_i}^i$ with the i^{th} color (this is allowed, as they have no internal edges). The remaining vertices in each party are then not adjacent to any uncolored vertices from other parties, so we simply need to be able to complete the coloring of each party in isolation with $2c$ new colors and we are finished. This is easily done, as each party's sub-graph is $2c$-partite by construction. ◀

3 Maximal Independent Set in Edge Streams

In this section, we consider streaming algorithms for the *maximal* independent set problem. Vertex streams (both explicit and implicit) are well-suited to the maximal independent set problem, since they allow the implementation of the Greedy algorithm for independent sets, which greedily adds every incoming vertex v to an initially empty independent set I if this is possible, i.e., if $I \cup \{v\}$ is an independent set. The algorithm only stores the computed independent set. This yields the following result:

▶ **Fact 1.** *The* Greedy *algorithm for independent sets is a one-pass $\tilde{O}(\alpha(G)) = \tilde{O}(n)$ space maximal independent set algorithm in vertex streams (both implicit and explicit).*

This raises the question of how well we can solve the maximal independent set problem in edge streams. We show that computing a maximal independent set in one pass in the edge-arrival model is not possible using sublinear space, i.e., space $\Omega(n^2)$ is required. This result is obtained through a reduction from the Index problem in two-party communication complexity. This proof is available in the full version of the paper.

▶ **Theorem 10.** *Every randomized constant error one-pass streaming algorithm in the edge-arrival model that computes a maximal independent set requires $\Omega(n^2)$ space.*

Since computing a maximal independent set with sublinear space is impossible in edge streams, we ask whether we can compute an *approximately maximal* independent set instead:

▶ **Definition 11** (Approximate Maximality)**.** *Let $G = (V, E)$ be an n-vertex graph, and let $I \subseteq V$ be an independent set. Then I is δ-maximal, if $|I \cup \Gamma_G[I]| \geq \delta n$.*

A δ-maximal independent set I covers a δ-fraction of the vertices, or, in other words, when removing I and its neighbors $\Gamma_G[I]$ from the graph, then at most $(1-\delta)n$ vertices are remaining. We will next show that establishing approximate maximality in edge streams requires strictly more space than computing a maximal independent set in vertex streams (i.e., $\omega(n)$ space), even if $\delta = \frac{24}{25}$. Regarding stronger approximate maximality, our lower bound yields that computing a $(1 - \frac{1}{n^\epsilon})$-maximal independent set requires space $\Omega(n^{2-o(1)})$, for every $\epsilon > 0$.

Central to our construction are *Ruzsa-Szemerédi graphs*, which have previously been used for the construction of streaming space lower bounds for maximum matching [12, 17, 4]:

▶ **Definition 12** (Ruzsa-Szemerédi graph)**.** *A bipartite graph G is an (r, s)*-Ruzsa-Szemerédi graph *if its edge set can be partitioned into r induced matchings each of size s.*

Recall that a matching $M \subseteq E$ in a graph $G = (V, E)$ is induced, if the edge set of the vertex-induced subgraph $G[V(M)]$ equals M, i.e., there are no other edges interconnecting $V(M)$ different from M.

Our lower bound for approximate maximality is obtained by a reduction from the two-party communication problem RS-Index, defined as follows:

▶ **Definition 13** (RS-Index). *Let H be an (r, s)-Ruzsa-Szemerédi graph with induced matchings $M_1, M_2, \ldots, M_r$. For each induced matching M_i, let $M_i' \subseteq M_i$ be a uniform random subset of size $s/2$ (we assume that s is even). The* RS-Index *problem is a one-way two-party communication problem, where H, and, in particular, $M_1, M_2, \ldots, M_r$ are known by both parties. In addition, Alice holds the graph $G = H[\cup_i M_i']$, and Bob holds a uniform random index $i \in \{1, 2, \ldots, r\}$. Alice sends a single message to Bob, who, upon receipt, outputs at least $C \cdot s$ edges of M_i', for an arbitrary small constant C.*

Observe that this problem is similar in spirit to Index: In Index, Bob needs to learn one uniform random bit, while in RS-Index, Bob needs to learn the presence of many edges of M_i'. A lower bound on the communication complexity of RS-Index is implicit in [12] [2]:

▶ **Theorem 14** ([12]). *The randomized constant error communication complexity of* RS-Index *is $\Omega(r \cdot s)$.*

Equipped with the RS-Index problem, we now give a reduction to approximate maximality from RS-Index, which yields our lower bound for streaming algorithms:

▶ **Lemma 15.** *Let r, s, n be integers such that there is an n-vertex (r, s)-Ruzsa-Szemerédi graph. Then, every randomized constant error one-pass streaming algorithm in the edge-arrival model that computes a $(1 - \frac{s}{6n})$-maximal independent set requires $\Omega(r \cdot s)$ space.*

Proof. Let H be an n-vertex (r, s)-Ruzsa-Szemerédi graph, and let G be Alice's input graph for the RS-Index problem derived from H. Let $M_1, M_2, \ldots, M_r$ denote the induced matchings in H, let $V_i = V(M_i)$, and let $M_i' \subseteq M_i$ denote the subset of edges of matching M_i that is included in G. Let i be Bob's input. Furthermore, let $\mathcal{A}$ be a constant error randomized one-pass streaming algorithm for the edge-arrival model that computes a $(1-\frac{s}{6N})$-maximal independent set on a graph on N vertices. We now show how $\mathcal{A}$ can be used to solve RS-Index:

Given G, let $\tilde{G}$ be the graph obtained from G, where every induced matching M_i' in G is replaced by edges $\tilde{M}_i' := M_i \setminus M_i'$ (observe that $E(G) \cup E(\tilde{G}) = E(H)$). Alice now constructs two disjoint copies G_1 and G_2 of $\tilde{G}$, runs algorithm $\mathcal{A}$ on $G_1 \dot{\cup} G_2$ (on an arbitrary ordering of their edges), and sends the memory state to Bob. Bob constructs the edge set F that connects every vertex $v_1 \in V(G_1) \setminus V_{i1}$ with every vertex $v_2 \in V(G_2) \setminus V_{i2}$, where V_{i1} and V_{i2} are the copies of the vertices V_i in graphs G_1 and G_2, respectively, and continues the execution of $\mathcal{A}$ on F. Let I be the independent set produced by algorithm $\mathcal{A}$.

Observe that the graph processed by algorithm $\mathcal{A}$ contains $N = 2n$ vertices. Since I is $(1 - \frac{s}{6N})$-maximal, we have $|V \setminus \Gamma[I]| \leq N - (1 - \frac{s}{6N})N = s/6$. This allows us to identify $\Omega(s)$ edges of M_i' as follows:

Let a, b be the incident vertices to an arbitrary edge of M_i', let a_1, b_1 be the copies of a, b in G_1, and let a_2, b_2 be the copies of a, b in G_2. Observe that a_1 and b_1 are not connected in G_1, and a_2 and b_2 are not connected in G_2. We now claim that if all vertices a_1, b_1, a_2, b_2

[2] In [12] a lower bound is given for the task of computing a maximum matching. Their hardness stems from the fact that it is hard to learn many edges of M_i' under the distribution described in the definition of RS-Index.

are covered by I, i.e., $\{a_1, b_1, a_2, b_2\} \subseteq \Gamma[I]$, then either $\{a_1, b_1\} \subseteq I$ or $\{a_2, b_2\} \subseteq I$ (or both). Indeed, suppose that this is not the case. Then there are vertices $x_1 \in \{a_1, b_1\}$ and $x_2 \in \{a_2, b_2\}$ with $x_1, x_2 \notin I$. Let $y_1 \in I$ be a vertex incident to x_1, and let $y_2 \in I$ be a vertex incident to x_2. By the construction of the input graph, $y_1 \in V(G_1) \setminus V_{i1}$, and $y_2 \in V(G_2) \setminus V_{i2}$. Observe, however, that the edge y_1y_2 was included by Bob, which implies that y_1, y_2 are not independent: a contradiction. Hence, either $\{a_1, b_1\} \subseteq I$ or $\{a_2, b_2\} \subseteq I$ (or both) hold. This implies that the algorithm identified that there is no edge between a_1, b_1, which in turn implies that we learned one edge of M'_i. Hence, for every pair of vertices a, b of M'_i, either at least one vertex among $\{a_1, b_1, a_2, b_2\}$ is not covered by I, or we learn one edge of M'_i. Since there are $s/2$ edges in M'_i, and at most $s/6$ vertices of the input graph are not covered by I, we learn at least $s/2 - s/6 = \Omega(s)$ edges of M'_i, which thus solves RS-Index. By Theorem 14, algorithm $\mathcal{A}$ therefore requires space $\Omega(r \cdot s)$. ◀

In [12] it is shown that there are n-vertex $(n^{\Theta(\frac{1}{\log\log n})}, (\frac{1}{4} - \epsilon)n)$ Ruzsa-Szemerédi graphs, for every $\epsilon > 0$, and in [2], it is shown that there are such graphs with $\Theta(n^{2-o(1)})$ edges such that each matching is of size $n^{1-o(1)}$. Combined with Lemma 15, we obtain:

▶ **Theorem 16.** *Every randomized constant error one-pass streaming algorithm that computes a $\frac{24}{25}$-maximal independent set requires space $n^{1+\Omega(\frac{1}{\log\log n})}$, and every such algorithm computing a $(1 - \frac{1}{n^\epsilon})$-maximal independent set requires space $\Omega(n^{2-o(1)})$, for every $\epsilon > 0$.*

Last, interestingly, if we allow an algorithm to perform multiple passes, then sublinear space algorithms can be obtained. Such algorithms are in fact immediately implied by the correlation clustering algorithms given in [1]. Their result yields the following theorem:

▶ **Theorem 17.** *There is a $O(\log\log n)$-pass streaming algorithm for maximal independent set that uses space $\tilde{O}(n)$.*

4 Maximum Independent Set in Geometric Intersection Graphs

We now present a collection of results around geometric intersection graphs, in one and two dimensions, given as explicit or implicit vertex streams. We consider intervals and squares.

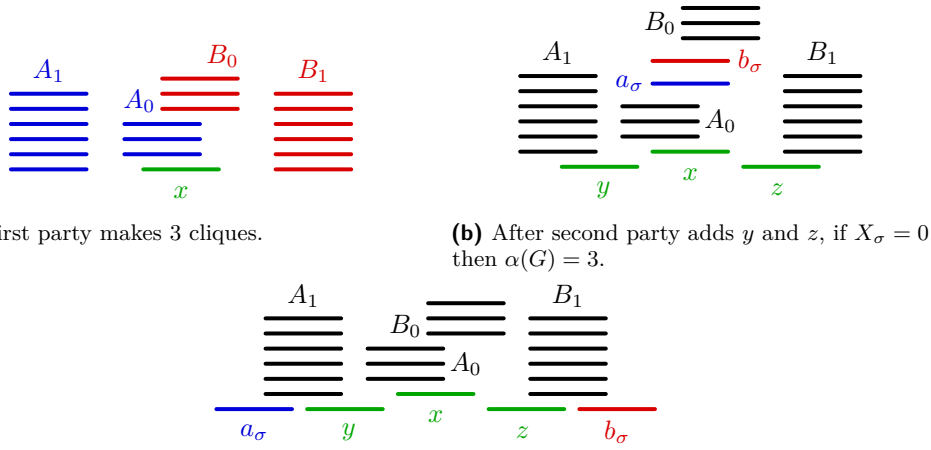
A geometric intersection graph is a graph where nodes correspond to geometric objects, and edges indicate whether or not a particular pair of objects intersect. These graphs can be described implicitly as the collection of geometric objects, or explicitly as a collection of vertices and edges under the promise that some geometric representation exists.

For implicit representations, we assume that intervals and squares are presented by their centers and their lengths. We assume that the center is a value in $[M]^d$ ($d = 1$ for intervals, and $d = 2$ for squares), and the length is in $[M]$, for some $M \in$ poly n.

4.1 Unit Interval Graphs: $\mathrm{d} = 1$

As discussed in Section 1, given a stream of unit intervals we can compute a $\frac{3}{2}$-approximation to MIS in $\tilde{O}(\alpha(G))$ space, and any better approximation requires $\Omega(n)$ space. A natural question is how this compares with the space complexity for an interval intersection graph given as an explicit vertex stream:

▶ **Theorem 18.** *Any algorithm with constant error probability that returns a $(\frac{5}{3} - \epsilon)$-approximation of $\alpha(G)$ for a unit interval intersection graph given as an explicit vertex stream requires $\Omega(n)$ space.*



(a) First party makes 3 cliques.

(b) After second party adds y and z, if $X_\sigma = 0$ then $\alpha(G) = 3$.

(c) Conversely, if $X_\sigma = 1$ then $\alpha(G) = 5$.

Figure 6 Interval representations for the construction in theorem 18. Horizontal positioning represents the location of the intervals in $\mathbb{R}$, vertical positioning is for clarity only.

Proof. We will show this bound by a reduction from the 2-party INDEX communication problem. Consider an instance of INDEX with bit vector $X \in \{0,1\}^n$ and index to be queried $\sigma \in [n]$. We will construct a $2n+3$ vertex graph as an explicit vertex stream.

Label the vertices x, y, z and a_i, b_i for $i \in [n]$. Split the a_i's into two sets based on the bit vector X: $A_1 = \{a_i\}_{X_i=1}$ and $A_0 = \{a_i\}_{X_i=0}$. Similarly let $B_1 = \{b_i\}_{X_i=1}$ and $B_0 = \{b_i\}_{X_i=0}$. Now the first party creates the following subgraph in the stream: a clique consisting of all the vertices in A_1, a second clique made from B_1, and a third clique containing $A_0 \cup B_0 \cup \{x\}$.

So far this represents a valid interval graph, which can be interpreted as three adjacent "stacks" of intervals. Now, the second player adds y with edges to every a_i except a_σ and then adds z with edges to every b_i except b_σ. This can still be viewed as a valid interval graph, but we now require some intervals from each stack to be "shifted" to overlap with the two new intervals.

In the case of $X_\sigma = 0$, the resulting graph has $\alpha(G) = 3$. Otherwise, $\alpha(G) = 5$. Hence, any algorithm giving a better than $\frac{5}{3}$-approximation factor could distinguish them and solve INDEX. ◀

This shows that MIS for interval graphs is strictly more difficult in explicit vertex streams than implicit ones.

4.2 Square Graphs: $\mathrm{d} = 2$

We obtain several improved bounds for the 2D case. Full details can be found in the extended paper, but we briefly summarise here.

Our first result for 2D is a 3-approximation algorithm for MIS on a unit square stream. This is a generalization of the algorithm of [7] for unit interval streams – we perform a decomposition of the plane into 2-by-3 strips, similar to their decomposition of the line into length 3 segments.

▶ **Theorem 19.** *There is a 3-approximation streaming algorithm for* MIS *on a stream of unit squares (implicit vertex stream) using $\tilde{O}(\alpha(G))$ space.*

As in [7] for unit intervals, this immediately leads to a sublinear space algorithm for estimating $\alpha(G)$ with only a $(1+\epsilon)$ factor loss in approximation factor, through a combination of counting distinct elements and clever sampling.

▶ **Corollary 20.** *We can $(3+\epsilon)$-approximate $\alpha(G)$ with constant probability in a stream of unit squares using $O(\epsilon^{-2}\log\epsilon^{-1}+\log n)$ space.*

One might speculate whether this decomposition approach could afford a better approximation factor based on some different partitioning of the plane. We give evidence for the negative, since any larger strip size results in the fixed-size sub-problems not being solvable exactly, as the following result shows.

▶ **Theorem 21.** *Given a stream of w-by-w squares contained in a $(2+\delta)w$-by-$(2+\delta)w$ region, achieving a $(\frac{3}{2}-\epsilon)$-approximation to $\alpha(G)$, with constant probability of success for any $\epsilon,\delta>0$ requires $\Omega(n)$ space.*

Our next result for two dimensions is a stronger lower bound for approximating $\alpha(G)$ of a stream of unit squares in an unrestricted region, based on a reduction from the chained index communication problem used in our main result in Section 2.

▶ **Theorem 22.** *Achieving a $(\frac{5}{2}-\epsilon)$-approximation of $\alpha(G)$, with constant probability of success, on a unit square stream requires $\Omega(n)$ space for any $\epsilon>0$.*

If we are allowed a combination of large and small balls, we can slightly improve the lower bound up to the maximum possible for a 3-party construction.

▶ **Theorem 23.** *Achieving a $(3-\epsilon)$-approximation of $\alpha(G)$, with constant probability of success, on a stream of squares or arbitrary side lengths requires $\Omega(n)$ space for any $\epsilon>0$.*

5 Conclusion

We have looked at the complexity of Maximal and Maximum Independent Set (and various relaxations and related problems) under three natural models of graph streams: edge-arrival, explicit vertex-arrival, and implicit vertex-arrival.

By making use of a new communication problem $\textsc{Chain}_k$, we showed that MIS is not significantly easier on explicit vertex streams than edge streams. However, the question of whether they have exactly the same complexity is left open. Improving the communication bound on $\textsc{Chain}_k$ to $\Omega(n)$, as we conjectured, would improve our MIS lower bound to $\Omega\left(\frac{n^2}{c^5}\right)$, but we do not know of any vertex stream upper bounds better than the $\tilde{O}\left(\frac{n^2}{c^2}\right)$ algorithm for general edge streams.

There are a number of other open questions that naturally follow from our study:

- Is there a multi-pass lower bound for *maximal* independent set in edge streams?
- Are there $o(\alpha(G))$ space algorithms for achieving constant factor approximations to $\alpha(G)$ for classes of geometric intersection graphs given as *explicit* vertex streams?
- Can we close the gap between the 3 and 5/2 factors of the upper and lower bounds for approximating MIS in a unit square stream?
- Is there an $O(\alpha(G))$ space constant factor approximation algorithm for MIS on streams of arbitrary sized squares?
- Can $\textsc{Chain}_k$ be used to form novel lower bounds for other kinds of problems?

Abstract

We study fundamental graph parameters such as the Diameter and Radius in directed graphs, when distances are measured using a somewhat unorthodox but natural measure: the distance between u and v is the *minimum* of the shortest path distances from u to v and from v to u. The center node in a graph under this measure can for instance represent the optimal location for a hospital to ensure the fastest medical care for everyone, as one can either go to the hospital, or a doctor can be sent to help.

By computing All-Pairs Shortest Paths, all pairwise distances and thus the parameters we study can be computed exactly in $\tilde{O}(mn)$ time for directed graphs on n vertices, m edges and nonnegative edge weights. Furthermore, this time bound is tight under the Strong Exponential Time Hypothesis [Roditty-Vassilevska W. STOC 2013] so it is natural to study how well these parameters can be *approximated* in $O(mn^{1-\varepsilon})$ time for constant $\varepsilon > 0$. Abboud, Vassilevska Williams, and Wang [SODA 2016] gave a polynomial factor approximation for Diameter and Radius, as well as a constant factor approximation for both problems in the special case where the graph is a DAG. We greatly improve upon these bounds by providing the first constant factor approximations for Diameter, Radius and the related Eccentricities problem in general graphs. Additionally, we provide a hierarchy of algorithms for Diameter that gives a time/accuracy trade-off.

1 Introduction

The diameter, radius and eccentricities of a graph are fundamental parameters that have been extensively studied [13, 20, 12, 18, 3, 14, 11, 17, 5, 6, 26, 27, 9, 19, 24, 23, 10, 1, 7] (and many others). The eccentricity of a vertex v is the largest distance between v and any other vertex. The diameter is the maximum eccentricity of a vertex in the graph, thus measuring how far apart two nodes can be, and the radius is the minimum eccentricity, measuring the maximum distance to the most central node.

The distance between two vertices in an undirected graph is just the shortest path distance $d(\cdot,\cdot)$ between them. For directed graphs, however, this notion of distance d is no longer necessarily symmetric, and rather than being a distance *between* two nodes, it measures the distance in a given direction. Several related notions of pairwise distance that are symmetric have been studied. These include the roundtrip distance [15] which for two vertices u and v is just $d(u,v)+d(v,u)$, the max-distance [2] which is $\max\{d(u,v),d(v,u)\}$, and the min-distance [2] which is $\min\{d(u,v),d(v,u)\}$.

Each of these notions of distance has a particular application. For instance, one would have to pay the roundtrip distance when going to the store and back. On the other hand, if one needs medical assistance, one could either go to the hospital, or have a physician come to the home – the time to receive care is then measured by the min-distance. Another example of min-distance is in symmetric-key encryption: any pair of parties can create a shared private key by using only one-way communication.

For each notion of distance, the diameter, radius and eccentricity parameters are well-defined. Given the shortest path distances $d(\cdot,\cdot)$ for all vertices, the parameters for each distance measure can be computed in $O(n^2)$ time in n vertex graphs. The fastest known algorithms for All-Pairs Shortest Paths (APSP) [25, 21, 22] give the fastest known algorithms to compute these parameters exactly, running in $n^3/\exp(\sqrt{\log n})$ time and $O(mn+n^2\log\log n)$, respectively on m-edge, n-vertex graphs. Furthermore, under the Strong Exponential Hypothesis, there is no $O(m^{2-\varepsilon})$ time algorithm for Diameter in unweighted graphs (and thus also for any of these notions of Diameter and Eccentricities in directed graphs) [23]. For Radius, the same lower bound holds but under the "Hitting Set" conjecture [2].

As exact computation is expensive, it makes sense to resort to approximation algorithms. For the shortest path distance versions of Diameter, Eccentricities and Radius, there are several fast algorithms that achieve various small constant approximation ratios [23, 10, 8, 4]. For instance, for Diameter, a folklore linear time algorithm can achieve a 2-approximation, and an $\tilde{O}(m^{3/2})$ time[1] algorithm can achieve a 3/2-approximation [23, 10].

Many of these algorithms [23, 10, 4] work for any distance measure that satisfies the triangle inequality. Thus they work for the shortest paths distance, max-distance and roundtrip distance. The min-distance however does not satisfy the triangle inequality: e.g. you might have edges (x,y) and (z,y), and thus the min-distance between x and y and between y and z are both 1, yet there may be no directed path between x and z in any direction, so that the min-distance between them may be ∞.

This issue makes it much more difficult to design fast approximation algorithms for Min-Diameter, Min-Radius and Min-Eccentricities (the parameters of interest under the min-distance). The only known nontrivial algorithms are by Abboud et al. [2]. For Min-Diameter [2] gives a near-linear time 2-approximation algorithm if the input is a directed acyclic graph. For general graphs, the only nontrivial fast approximation algorithm is an

[1] We use $\tilde{O}$ notation to hide polylogarithmic factors.

$\tilde{O}(mn^{1-\varepsilon})$ time n^{ε}-approximation algorithm for any constant $\varepsilon > 0$. (No constant factor approximation algorithm is known that runs significantly faster than just computing APSP.) For Min-Radius, [2] gives an $\tilde{O}(m\sqrt{n})$ time 3-approximation algorithm for directed acyclic graphs. For general graphs, they only achieve a very weak n-approximation in near-linear time that checks if the Min-Radius is finite. There are no known approximation algorithms for Min-Eccentricities faster than just computing APSP.

1.1 Our Results

The main goal of our paper is to obtain new fast, $O(mn^{1-\varepsilon})$ time for some constant $\varepsilon > 0$, algorithms for Min-Diameter, Min-Radius and Min-Eccentricities (thus beating the $\tilde{O}(mn)$ time of exact computation). We achieve this by developing powerful new techniques that can handle the complications that arise due to the fact that the min-distance does not satisfy the triangle inequality.

Our results are as follows. For Min-Diameter we achieve a hierarchy of algorithms trading off running time with approximation accuracy.

▶ **Theorem 1.** *For any integer $0 < \ell \leq O(\log n)$, there is an $\tilde{O}(mn^{1/(\ell+1)})$ time randomized algorithm that, given a directed weighted graph G with edge weights non-negative and polynomial in n, can output an estimate $\tilde{D}$ such that $D/(4\ell - 1) \leq \tilde{D} \leq D$ with high probability, where D is the min-diameter of G.*

When we set $\ell = 1$, we obtain an $\tilde{O}(m\sqrt{n})$ time 3-approximation algorithm, and when we set $\ell = \lceil \log n \rceil$, we get an $\tilde{O}(m)$ time $O(\log n)$-approximation.

Our tradeoff achieves the first constant factor approximation algorithms for Min-Diameter in general graphs that run in $O(mn^{1-\varepsilon})$ time for constant $\varepsilon > 0$. Such a result was only known for directed acyclic graphs, whereas for general graphs the only known efficient algorithm could achieve an n^{ε}-approximation.

For Min-Radius, we also achieve the first constant factor approximation algorithm for general graphs running in $O(mn^{1-\varepsilon})$ time for some constant $\varepsilon > 0$. Such a result was only known for directed acyclic graphs, whereas for general graphs the only known efficient algorithm could only check if the Min-Radius is finite.

▶ **Theorem 2.** *For any constant δ with $1 > \delta > 0$, there is an $\tilde{O}(m\sqrt{n}/\delta)$ time randomized algorithm, that given a directed weighted graph G with edge weights positive and polynomial in n, can output an estimate R' such that $R \leq R' \leq (3+\delta)R$ with high probability, where R is the min-radius of G.*

Finally, we obtain the first $O(mn^{1-\varepsilon})$ time (for constant $\varepsilon > 0$) constant factor approximation algorithms for the Min-Eccentricities of all vertices in a graph. For unweighted graphs we are able to obtain a close to 3 approximation in $\tilde{O}(m\sqrt{n})$ time. For weighted graphs, our approximation factor grows to 5, while the running time is the same. Previously, the only algorithm to approximate the Min-Eccentricities computed them exactly via an APSP computation.

▶ **Theorem 3.** *For any constant δ with $1 > \delta > 0$, there is an $\tilde{O}(m\sqrt{n}/\delta)$ time randomized algorithm, that given a directed weighted graph $G = (V, E)$ with weights positive and polynomial in n, can output an estimate $\varepsilon'(s)$ for every vertex $s \in V$ such that $\varepsilon(s) \leq \varepsilon'(s) \leq (5+\delta)\varepsilon(s)$ with high probability, where $\varepsilon(s)$ is the min-eccentricity of vertex s in G.*

▶ **Theorem 4.** *For any constant δ with $1 > \delta > 0$, there is an $\tilde{O}(m\sqrt{n}/\delta^2)$ time randomized algorithm, that given a directed unweighted graph $G = (V, E)$, can output an estimate $\varepsilon'(s)$ for every vertex $s \in V$ such that $\varepsilon(s) \leq \varepsilon'(s) \leq (3+\delta)\varepsilon(s)$ with high probability, where $\varepsilon(s)$ is the min-eccentricity of the vertex s in G.*

1.2 Our Techniques

To obtain our results, we develop powerful new techniques which we outline below.

Partial search graphs. The idea of partial search graphs is used in the algorithms of [2] for Min-Radius and Min-Diameter on DAGs. These algorithms use the following high-level framework: perform Dijkstra's algorithm from some vertices and then perform a *partial* Dijkstra's algorithm from *every* vertex. The partial search from a vertex v is with respect to a carefully defined partial search graph $G_v \subset G$. The crux of the analysis for the algorithms on DAGs is to argue that if the executions of Dijkstra's algorithm on the full graph did not find a good estimate for the desired quantity (either min-diameter or min-radius), then the partial search from some vertex v returns a good estimate of the min-eccentricity of v, which in turn is a good estimate for the desired quantity. In DAGs it is natural to define the partial search graphs G_v by considering a topological ordering of the vertices and letting each G_v be some interval containing v (though defining the exact intervals requires some work). For general graphs it is completely unclear how to even define such intervals since there is no natural notion of an ordering of the vertices, and thus figuring out what the G_v's should be is nontrivial. Our approach to overcoming this hurdle is to carefully define a DAG-like structure in general graphs. Such a structure may be of independent interest.

Defining a DAG-like structure in general graphs. It would be ideal to directly reduce the problem on general graphs to the problem on DAGs, however it is very unclear how to do this. Instead, we recognize that it suffices to define a *DAG-like* structure in general graphs. As a first step, we use the following idea. Suppose we have performed Dijkstra's algorithm from a vertex v. We let $S_v = \{u : d(u,v) < d(v,u)\}$ and we let $T_v = \{u : d(u,v) > d(v,u)\}$[2]. Then, we partially order the vertices so that the vertices in S_v appear before v and those in T_v appear after v. We note that this partial ordering is "DAG-like" because it is consistent with the topological ordering of a DAG; that is, if we apply this partition into S_v and T_v to a DAG then there trivially exists a topological ordering such that every vertex in S_v appears before v and every vertex in T_v appears after v. After partitioning into S_v and T_v, we recursively partition each set to create a more precise partial ordering. Importantly, we show that by recursively sampling vertices randomly, we can guarantee that our partitioning is approximately balanced which is crucial for the runtime analysis. The obtained partial ordering is the starting point for all of our algorithms.

Min-Diameter: graph augmentation. The Min-Diameter algorithm on DAGs from [2] relies heavily on the following key property of DAGs. Consider a topological ordering and the graphs induced by the first and second halves of the ordering; which are defined with respect to the middle vertex in the ordering. For all pairs of vertices in the same half of the ordering, their min-distance in the graph induced by this half is the same as their min-distance in the full graph. As previously mentioned, if we sample a vertex v, we can make sure that S_v and T_v are approximately balanced, so that we can think of S_v and T_v as corresponding to the first and second half of a DAG topological ordering, respectively. However it is unclear how to obtain a property of S_v and T_v analogous to the above key property of DAGs. In particular, the min-distance between a pair of vertices in the graph induced by S_v could be wildly different from their min-distance in the full graph, since paths whose endpoints are

[2] u's with $d(u,v) = d(v,u)$ are added to either S_v or T_v as specified in the formal definition later

in S_v can contain vertices outside of S_v. To overcome this hurdle, we *augment* the graph induced by S_v and the graph induced by T_v by carefully adding edges so that distances within these augmented graphs approximate distances in the original graph.

Min-Radius: refined DAG-like structure. Our Min-Radius algorithm is much more delicate than our Min-Diameter algorithm due to the fact that for Min-Radius we care about small distances instead of large distances. In particular, the graph augmentation idea from our Min-Diameter algorithm does not help for Min-Radius because although the augmentations do not distort large distances much, they heavily distort small distances. Furthermore, the previously mentioned DAG-like structure for general graphs does not suffice for Min-Radius. However we use it as a starting point to define a more refined DAG-like partial ordering. Most of our algorithm is concerned with precisely arranging vertices in this partial ordering. Specifically, we structure the partial ordering to satisfy *roughly* the following property: for every pair of vertices u, v such that u appears before v in the partial ordering, $d(v,u)$ is large while $d(u,v)$ is small.

1.3 Notation

Given a graph $G=(V,E)$, $n=|V|$ and $m=|E|$. Graphs are directed and have non-negative weights polynomial in n unless otherwise specified. For any pair of vertices u and v, the *distance from u to v* $d(u,v)$ is the length of the shortest directed path from u to v. When the context is not clear, we write $d_G(u,v)$ to specify the graph G. The *min-distance* between a pair of vertices u and v is $d_{min}(u,v)=\min\{d(u,v),d(v,u)\}$. The *min-diameter* of a graph is $\max_{u,v\in V} d_{min}(u,v)$. The *min-radius* of a graph is $\min_{v\in V}\max_{u\in V} d_{min}(u,v)$. For any vertex v, the *min-eccentricity* of v is $\varepsilon(v)=\max_{u\in V} d_{min}(u,v)$. When the context is not clear, we say $\varepsilon_G(v)$ to specify the graph G. Note that we do not use the *min* subscript to denote the min-eccentricity of a vertex. For an algorithm with input size n we use *with high probability* to denote the probability $>1-1/n^c$ for all constants c. We say some quantity is *poly*(n) to mean it is $O(n^c)$ for some fixed constant c. We use $\tilde{O}$ notation to hide polylogarithmic factors.

1.4 Organization

In Section 2 we give an overview of all of our algorithms, in Section 3 we describe a graph partitioning procedure that begins all of our algorithms, in Section 4 we describe our Min-Diameter algorithms. We defer the time/accuracy tradeoff algorithm for Min-Diameter, the Min-Radius algorithm and the Min-Eccentricities algorithm to the full version [16].

2 Overview of Algorithms

We use the algorithms from [2] for Min-Diameter and Min-Radius on DAGs as inspiration. For each problem, we first outline the DAG algorithm and then provide intuition for how to apply these ideas to general graphs.

2.1 Min-Diameter

Algorithm for DAGs

We begin by outlining the $\tilde{O}(n+m)$ time 2-approximation algorithm for Min-Diameter on DAGs from [2]. Consider a topological ordering of the vertices and perform Dijkstra's algorithm from the middle vertex v. Then recurse on the graphs induced by the vertices in

the first half (before v) and in the second half (after v). A key observation in the analysis is that if the true endpoints s^* and t^* of the min-diameter fall on opposite sides of v in the ordering, then the min-eccentricity $\varepsilon(v)$ of v is a 2-approximation for the min-diameter D. This is because if $\varepsilon(v) < D/2$ and s^* and t^* fall on opposite sides of v in the ordering, then $d(s^*, v) < D/2$ and $d(v, t^*) < D/2$ so $d(s^*, t^*) < D$, a contradiction. So, suppose (without loss of generality) that s^* and t^* both fall before v in the ordering. Since the graph is a DAG, every path between s^* and t^* only uses vertices before v in the ordering. Thus, the min-distance between s^* and t^* in the graph induced by the first half of the graph is still D.

Algorithm for general graphs

We now outline a precursor to our Min-Diameter algorithm for general graphs that mimics the algorithm for DAGs. This $\tilde{O}(n+m)$ time algorithm does not achieve a constant approximation factor, however it provides intuition for our constant-factor approximation algorithms. We begin by performing Dijkstra's algorithm from a vertex v and constructing S_v and T_v as defined in the previous section. Analogously to the DAG algorithm if the true min-diameter endpoints s^* and t^* fall into different sets S_v, T_v then the min-eccentricity $\varepsilon(v)$ is a 2-approximation. This is because if $\varepsilon(v) < D/2$, $s^* \in S_v$, and $t^* \in T_v$ then $d(s^*, v) < D/2$ and $d(v, t^*) < D/2$ so $d(s^*, t^*) < D$, a contradiction. However, unlike the DAG algorithm, we cannot simply recurse independently on the graphs induced by S_v and T_v since the shortest path between a pair of vertices in S_v may not be completely contained in S_v (and analogously for T_v).

To overcome this hurdle, before recursing we first augment the graphs induced by S_v and T_v by carefully adding edges so that distances within these augmented graphs approximate distances in the original graph. Specifically, for every vertex $u \in S_v$, we add the directed edge (u, v) with weight 0 and the directed edge (v, u) with weight $\max\{0, d(v, u) - \varepsilon(v)\}$. This choice of edges allows us to argue that the distances within the augmented graphs are approximations of the distances in G up to an additive error of $2\varepsilon(v)$. Then, by returning the maximum of $\varepsilon(v)$ and the min-diameter estimates from recursing on the augmented graphs, we get an approximation guarantee, which turns out to be a logarithmic factor. Intuitively, the approximation factor is not constant because the recursion causes the distance distortion to compound at each level of recursion.

To reduce the approximation factor to a constant, we would like to decrease the number of recursion levels. To achieve this, we initially partition the graph into more than just two parts S_v and T_v, by sampling more vertices. For our $\tilde{O}(m\sqrt{n})$ time 3-approximation, we perform a full Dijkstra's algorithm from $\tilde{O}(\sqrt{n})$ vertices to define an ordered partition of the vertices into $\tilde{O}(\sqrt{n})$ parts of $\tilde{O}(\sqrt{n})$ vertices each. Then we apply the above idea of adding weighted edges within each part, however we must refine the definition of the graph augmentation to take into account *all* of the $\tilde{O}(\sqrt{n})$ vertices we initially perform Dijkstra's algorithm from, instead of just v. Finally we use brute force (without recursion) on each part in the partition by running an exact all-pairs shortest paths algorithm.

To achieve our time-accuracy trade-off algorithm, we carefully combine ideas from the logarithmic factor approximation and the 3-approximation algorithms. Specifically, we initially perform Dijkstra's algorithm from fewer than $\sqrt{n}$ vertices to define an ordered partition with larger parts than in the 3-approximation. Then we augment the graph induced by each part and carry out a constant number of recursion levels to further partition the graph before applying brute-force.

2.2 Min-Radius

Algorithm for DAGs

We begin by outlining the $\tilde{O}(m\sqrt{n})$ time 3-approximation algorithm for Min-Radius on DAGs from [2], which is very different from and more involved than the Min-Diameter algorithm on DAGs. We begin by considering a topological ordering of the vertices and performing Dijkstra's algorithm from a set W of $\tilde{O}(\sqrt{n})$ evenly spaced vertices including the first and last vertex. If a vertex $v \in W$ has min-eccentricity at most twice the true min-radius R then we have obtained a 2-approximation. (We do not know R in advance but we repeatedly run the algorithm with different values of R to perform a binary search on R.)

Otherwise, we will define intervals in the ordering such that the min-center c cannot be contained in any of these intervals. A key observation is that if there is a pair of vertices (u, v) such that u appears before v in the topological ordering and $d(u, v) > 2R$, then the min-center c cannot fall between u and v in the topological ordering. This is because if it did, then $d(u, c) \leq R$ and $d(c, v) \leq R$, so $d(u, v) \leq 2R$, a contradiction. We define the intervals that cannot contain c as follows: for all $v \in W$ we let a_v be the first vertex in the ordering such that $d(a_v, v) > 2R$ (if it exists, otherwise $a_v = v$) and define b_v to be the last vertex in the ordering such that $d(v, b_v) > 2R$ (if it exists, otherwise $b_v = v$). Then, the key observation implies that c cannot fall in the interval $[a_v, b_v]$ in the ordering. Now, we have a set of possibly overlapping intervals that cannot contain c. We take the union of these intervals to get a set of disjoint intervals that cannot contain c.

Every vertex u that does not appear in such an interval, falls between two consecutive intervals I_u and I'_u. We define the partial search graph of u to be the graph induced by the set of vertices in I_u or I'_u or between I_u and I'_u. After performing the partial searches, the algorithm returns 3 times the minimum min-radius of all partial search graph. Next we give the idea of the analysis, which demystifies the factor of 3 in the returned value.

We claim that if the min-eccentricity of a vertex with respect to its partial search graph is at most R, then its min-eccentricity with respect to the full graph is at most $3R$, and the min-eccentricity of the true min-center with respect to its partial search graph is at most R (because for any path in a DAG whose starting and ending points are in a certain interval, every vertex in the path is in that interval). Thus, assuming the claim, $3R$ is a 3-approximation for the min-radius. We now outline the proof of the claim. Let u be the min-center with the minimum min-radius R of all partial search graphs. Let $v \in W$ such that a_v is the first vertex (in the topological order) of I_u, then $v \in I_u$ and $d(v, u) \leq R$. Furthermore, by the definition of a_v, all vertices that appear before the beginning of the interval I_u have distance at most $2R$ to v, and thus distance at most $3R$ to u. A symmetric argument holds for vertices that appear after the end of the interval I'_u. Hence the min-eccentricity of u with respect to the full graph is at most $3R$.

This algorithm runs in time $O(m\sqrt{n})$ because the vertices of W are evenly spaced so there are no more than $\sqrt{n}$ vertices between each pair of consecutive intervals. This implies that in the partial searches, each edge is only scanned $O(\sqrt{n})$ times. (Furthermore, repeatedly running the algorithm to binary search for R adds a logarithmic factor to the runtime.)

Algorithm for general graphs

We now give a high-level outline of our $\tilde{O}(m\sqrt{n})$ time 3-approximation algorithm for Min-Radius. This algorithm is much more delicate than our Min-Diameter algorithm, hence more of the details are deferred to the full description. We begin by running Dijkstra's algorithm

from a set W of $\tilde{O}(\sqrt{n})$ randomly sampled vertices to recursively partition the vertices into S_v and T_v as outlined in Section 1.2. This defines an initial DAG-like structure, however our analysis requires constructing a much more refined DAG-like structure.

Perhaps counter-intuitively, it makes sense to place vertices that are *far* from each other in the graph *close* to each other in the DAG-like structure. The reason for this is illuminated by the Min-Radius algorithm on DAGs, in which we find pairs of vertices u, v that are far from each other and apply the key observation that the min-center cannot be between u and v in the topological ordering. Intuitively, it is as if we collapse the interval between u and v in the DAG since we do not have to search within this interval for the min-center. An analogous key observation is true for general graphs: if there is a pair of vertices (u, v) with $d_{min}(u, v) > 2R$, then either $c \in S_u \cap S_v$ or $c \in T_u \cap T_v$. This is because if $c \in T_u \cap S_v$, then $d(u, c) \leq R$ and $d(c, v) \leq R$ so $d(u, v) \leq 2R$, a contradiction; the last case $c \in S_u \cap T_v$ is symmetric. In our algorithm for general graphs, we ensure that far vertices are near each other in the DAG-like structure by doing the following: we let the *far graph* G_{far} be an undirected graph on V with an edge between $u \in W$ and $v \in V$ if $d_{min}(u, v) > 2R$. All vertices in W that are in the same connected component in G_{far} will be grouped in the DAG-like structure. We let F_i be the set of vertices in W that are in the i^{th} connected component of G_{far}.

To construct the DAG-like structure, we show that precisely chosen groups of F_is can be merged to create *supercomponents*, which constitute a DAG-like structure in the following sense: there is an ordering of supercomponents such that for every pair of vertices $u, v \in W$ where the supercomponent containing u appears before that containing v, $d(u, v)$ is small and $d(v, u)$ is large. Specifically, we define the *close graph* H whose vertex set is the set of F_is. We add a directed edge between a pair of vertices in H if there exists a short path (length $\leq 5R$) between the corresponding F_is. Then we merge all F_is that appear in the same strongly connected component of H into a supercomponent. This contraction of strongly connected components of H results in a DAG, which defines the ordering of the supercomponents.

Now that we have arranged the vertices in W into a DAG-like structure, we would like to fit every vertex in the graph into this structure. Based on the precise way that we have defined the supercomponents, we can use an intricate argument to show *roughly* the following property: for every vertex v there exists an i such that for every vertex $u \in W$ in the first i supercomponents, $d(u, v)$ is small and for every vertex $u \in W$ in the remaining supercomponents, $d(v, u)$ is small.

After fitting every vertex into the refined DAG-like ordering, we can define each partial search graph to be an interval in the ordering that is large enough to contain several supercomponents. In the algorithm for DAGs, there were two important properties of the partial search graphs: (1) the min-eccentricity of the true min-center with respect to its partial search graph is at most R, and (2) if the min-eccentricity of a vertex with respect to its partial search graph is at most R then its min-eccentricity with respect to the full graph is at most $3R$. We show that due to the precise structure of the supercomponents, refinements of properties (1) and (2) are also true for general graphs.

Intuitively, property (1) is roughly true because for every pair of vertices $u, v \in W$ such that u's supercomponent appears before v's in the ordering, $d(v, u) > 5R$, since otherwise this pair of supercomponents would be in the same strongly connected component of H and would have been merged into a single supercomponent. This implies that paths of length at most R to or from the min-center cannot stray beyond its partial search graph. Intuitively, property (2) is roughly true because for every pair of vertices $u, v \in W$ such that u's supercomponents appears before v's in the ordering, $d(u, v) \leq 2R$ because otherwise, u

and v would be in the same component of G_{far} and thus be in the same supercomponent. Thus, like the argument for DAGs, for all u, all vertices that appear before u's partial search graph G_u have distance at most $2R$ to each supercomponent in G_u, and thus distance at most $3R$ to u. A symmetric argument holds for vertices after u in the ordering.

2.3 Min-Eccentricities

Our Min-Eccentricities algorithm is a modification of our Min-Radius algorithm. In our Min-Radius algorithm, we identify a vertex whose min-eccentricity is at most about $3R$, where R is the true min-radius. In our Min-Eccentricities algorithm, we show that with some extra bookkeeping, the algorithm can identify *all* vertices with min-eccentricity at most about 5ρ for any ρ. We run the algorithm repeatedly, increasing ρ by a factor of $(1+\delta)$ at each execution until we have estimated the min-eccentricity of every vertex.

The major modification of the Min-Radius algorithm here is that if one of the vertices that we run Dijkstra from has min-eccentricity at most 3ρ, we cannot stop running the algorithm, as we can in the Min-Radius algorithm. Instead, we use this vertex as a tool to find vertices with min-eccentricity at most 5ρ.

3 Preliminary Graph Partitioning

In this section we describe a graph partitioning procedure we use as a first step in our Min-Diameter, Min-Radius, and Min-Eccentricities algorithms. The goal of this partitioning is to define a DAG-like structure in general directed graphs.

▶ **Definition 5.** *Assign each vertex a unique ID from* $[n]$*. For each vertex* v*, let* $S_v = \{u \in V : d(u,v) < d(v,u) \vee [d(u,v) = d(v,u) \wedge ID(u) < ID(v)]\}$*. Let* $T_v = V \setminus (S_v \cup \{v\})$*.*

The runtime of our algorithms relies on whether the partition into S_v and T_v is *balanced*. Using the observation that if $u \in S_v$, then $v \in T_u$, the following lemma shows that for most vertices, the partition is indeed approximately balanced.

▶ **Lemma 6.** *For any* n*-vertex graph, there are* $> \frac{n}{2}$ *vertices* v *such that* $\frac{|S_v|}{8} \leq |T_v| \leq 8 \cdot |S_v|$*.*

More generally, for any $U \subseteq V$*, there are more than* $\frac{|U|}{2}$ *vertices* $v \in U$ *such that* $\frac{|S_v \cap U|}{8} \leq |T_v \cap U| \leq 8|S_v \cap U|$*.*

Lemma 6 is proved in the full version [16]. Next, we describe how we use Lemma 6 to recursively construct a balanced partition of the vertices into a given number of of sets.

▶ **Lemma 7.** *Given an* n*-vertex graph* $G = (V, E)$ *and a constant* $c > 0$*, in* $\tilde{O}(mn^{1-c})$ *time one can split* V *into disjoint sets* $W, V_1, V_2, \ldots, V_{q+1}$*, where* $q = |W| = n^{1-c}$*, such that with high probability:*

1. *for all* i*,* $|V_i| = \Theta(\frac{n}{q})$*;*
2. *for all* $i \neq j$*, there exists* $w \in W$ *such that either* $V_i \subseteq S_w$,$V_j \subseteq T_w$*, or* $V_i \subseteq T_w$,$V_j \subseteq S_w$*;*
3. *for all* $U \subseteq W$*, let* $V_U = \left(\bigcap_{w \in U} S_w\right) \bigcap \left(\bigcap_{w \in W \setminus U} T_w\right)$*, then* $V_U \subseteq V_i$ *for some* $i \in [q+1]$*.*

Proof. We begin with $W = \emptyset$ and we will iteratively populate W with vertices. We let $\mathcal{V}_0 = \{V\}$ and for all $i \in [q]$ when we add the i^{th} vertex to W, we will construct $\mathcal{V}_i$ from $\mathcal{V}_{i-1}$ by partitioning the largest set in $\mathcal{V}_{i-1}$ into two parts. After adding q vertices to W we will have constructed $\mathcal{V}_q = \{V_1 \ldots V_{q+1}\}$.

For all $i \in [q]$, let A_i, B_i be the largest and smallest sets in $\mathcal{V}_i$, respectively.

We describe how to construct W and $\mathcal{V}_q$ inductively. Suppose $|W| = r - 1$ and we have constructed $\mathcal{V}_{r-1}$. By Lemma 6, if we randomly sample $O(\log^2 n)$ vertices from A_{r-1}, with probability at least $1 - 2^{-\log^2 n} = 1 - n^{-\log n}$ we will sample a vertex w_r such that $A_S = A_{r-1} \cap S_{w_r}$ and $A_T = A_{r-1} \cap T_{w_r}$ differ by a factor of at most 8. We add w_r to W and let $\mathcal{V}_r = \mathcal{V}_{r-1} \cup \{A_S, A_T\} \setminus \{A_{r-1}\}$.

By union bound over the $q = n^{1-c}$ partitionings, with probability at least $1 - n^{1-c-\log n}$, every partitioning produces two sets that differ in size by a factor of at most 8.

We prove property 1 by induction on $|W| = r$. Specifically, we will show that for all $r \in [q]$, $|A_r| \leq 9|B_r|$. This implies that $|A_q| = O(|B_q|)$, and property 1 follows. Lemma 6 implies that $|A_1| \leq 9|B_1|$. Assume inductively that $|A_{r-1}| \leq 9|B_{r-1}|$. Since no subset grows in size, $|A_r| \leq |A_{r-1}|$ and $|B_r| \leq |B_{r-1}|$. If $|B_r| = |B_{r-1}|$, then $|A_r| \leq |A_{r-1}| \leq 9|B_{r-1}| = 9|B_r|$. Otherwise, $|B_r| < |B_{r-1}|$, which implies that B_r is one of the two sets obtained by partitioning A_{r-1}. Then by Lemma 6, $|A_{r-1}| \leq 9|B_r|$. Hence $|A_r| \leq |A_{r-1}| \leq 9|B_r|$, completing the induction.

Property 2 follows from the partitioning procedure: for any $i \neq j$, if for all $w \in W$, $V_i, V_j \subseteq S_w$ or $V_i, V_j \subseteq T_w$ then $V_i \cup V_j$ would never have been partitioned.

Property 3 also follows from the partitioning procedure: observe that for all $w \in W$ and all $U \subseteq W$, $V_U \subseteq S_w$ or $V_U \subseteq T_w$, so V_U is never partitioned and thus $V_U \subseteq V_i$ for some $i \in [q+1]$.

Since we sample $n^{1-c}\log^2 n$ vertices and for all v finding S_v, T_v takes $O(m)$ time, the runtime is $\tilde{O}(mn^{1-c})$. ◀

4 Min-Diameter Algorithm

Throughout this section, let D be the min-diameter, and let s^*, t^* the endpoints of the min-diameter. In this section we prove the time/accuracy trade-off theorem for Min-Diameter.

▶ **Theorem 8.** *For any integer $0 < \ell \leq O(\log n)$, there is an $\tilde{O}(mn^{1/(\ell+1)})$ time randomized algorithm that, given a directed weighted graph G with edge weights non-negative and polynomial in n, can output an estimate $\tilde{D}$ such that $D/(4\ell - 1) \leq \tilde{D} \leq D$ with high probability, where D is the min-diameter of G.*

We first prove a special case of Theorem 8 where $\ell = 1$, and the rest of the proof can be found in the full version [16].

4.1 An $\tilde{O}(m\sqrt{n})$ time 3-approximation

▶ **Theorem 9** (Theorem 8 with $\ell = 1$)**.** *There is an $\tilde{O}(m\sqrt{n})$ time randomized algorithm, that given a directed weighted graph $G = (V, E)$ with edge weights non-negative and polynomial in n, can output an estimate $\tilde{D}$ such that $D/3 \leq \tilde{D} \leq D$ with high probability, where D is the min-diameter of G.*

4.1.1 Algorithm Description

Applying Lemma 7 with $q = \sqrt{n}$ we obtain a partition of the vertices into $W, V_1, V_2, \ldots, V_{\sqrt{n}+1}$.

We perform Dijkstra's algorithm from every vertex in W and define $D' = \max_{w \in W} \varepsilon(w)$. We will later show that D' is a good approximation of the Min-Diameter when s^* and t^* are not in the same vertex set V_i.

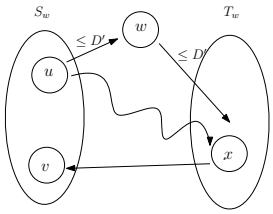

Figure 1 The case where $u, v \in S_w$ and the shortest path from u to v contains a node $x \in T_w \cup \{w\}$.

For every $i \in [\sqrt{n}+1]$, define $W_i^S = \{w \in W : V_i \subseteq S_w\}$, and $W_i^T = \{w \in W : V_i \subseteq T_w\}$. Then, for every i, we construct two graphs G_i^S and G_i^T. The first graph G_i^S contains all vertices of V_i and an additional node w_i^S. It has the following edges:

1. For every directed edge $(u, v) \in E$ such that $u, v \in V_i$, add this edge to G_i^S.
2. Add a directed edge from w_i^S to every $v \in V_i$, with weight $\max\left\{\min_{w \in W_i^S} d(w, v) - D', 0\right\}$, and a directed edge from every $v \in V_i$ to w_i^S with weight 0.

The second graph G_i^T is symmetric to G_i^S. It contains all vertices in V_i and an additional node w_i^T. It has the following edges:

1. For every directed edge $(u, v) \in E$ such that $u, v \in V_i$, add this edge to G_i^T.
2. Add a directed edge from every $v \in V_i$ to w_i^T, with weight $\max\left\{\min_{w \in W_i^T} d(v, w) - D', 0\right\}$, and add a directed edge from w_i^T to every $v \in V_i$ with weight 0.

For all i, we run an exact all-pairs shortest paths algorithm on G_i^S and G_i^T. This allows us to compute for all i and all $u, v \in V_i$ the quantity $\min\{d_{G_i^S}(u, v), d_{G_i^T}(u, v)\}$, which we denote by $d_i'(u, v)$.

We choose the larger between D' and $\max_{i \in [\sqrt{n}+1], u, v \in V_i} \min\{d_i'(u, v), d_i'(v, u)\}$ as our final estimate for the min-diameter.

4.1.2 Analysis

The following lemma will be used to show that D' is a good estimate for the min-diameter if s^* and t^* happen to fall into different sets V_i

▶ **Lemma 10.** *For all vertices v, if either $s^* \in S_v$, $t^* \in T_v$, or $t^* \in S_v$, $s^* \in T_v$, then $\varepsilon(v) \geq D/2$.*

Proof. We only consider the case when $s^* \in S_v$ and $t^* \in T_v$ as the other case is symmetric. By way of contradiction, assume that $\varepsilon(v) < D/2$, then we have $d_{\min}(s^*, v) < D/2$ and $d_{\min}(t^*, v) < D/2$. Since $s^* \in S_v$, $d(s^*, v) = d_{\min}(s^*, v) < D/2$; similarly, since $t^* \in T_v$, $d(v, t^*) = d_{min}(t^*, v) < D/2$. Therefore, by the triangle inequality, $d(s^*, t^*) < D$, a contradiction. ◀

The next two lemmas are used for the case where s^* and t^* fall into the same set V_i.

▶ **Lemma 11.** *For every i, and every pair of vertices $u, v \in V_i$, $d_i'(u, v) \leq d(u, v)$; that is, $\min\{d_{G_i^S}(u, v), d_{G_i^T}(u, v)\} \leq d(u, v)$.*

Proof. Take any shortest path in the original graph G from u to v. If this path does not leave V_i, then this path also exists in G_i^S and G_i^T, and thus the inequality is true.

It remains to prove for the case when the shortest u, v path in the original graph leaves V_i. Let $x \notin V_i$ be any vertex on a shortest u, v path. By Lemma 7, property 2, there exists $w \in W$ such that $x \in S_w \cup \{w\}$ and $V_i \subseteq T_w$, or $x \in T_w \cup \{w\}$ and $V_i \subseteq S_w$. We first assume $x \in T_w \cup \{w\}$ and $V_i \subseteq S_w$ as shown in Figure 1, and the other case is symmetric.

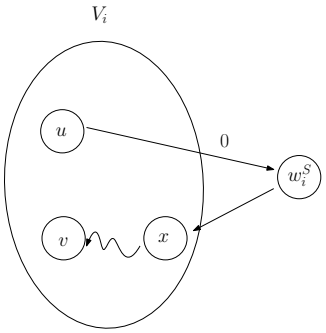

Figure 2 A shortest u, v path in G_i^S that contains w_i^S. The path goes from u, directly to w_i^S using a weight 0 edge, then directly to a vertex x, and finally reaches v.

Since x is on the shortest path from u to v, we have $d(u, v) \geq d(x, v)$. Also, we have $d(w, x) \leq D'$, by definition of D'. Therefore,

$$d(u, v) \geq d(x, v) \geq d(x, v) + (d(w, x) - D') \geq d(w, v) - D'. \tag{1}$$

Now consider the path $u \to w_i^S \to v$ in G_i^S. The first part $u \to w_i^S$ costs 0, because there is an edge from u to w_i^S with weight 0; the second part $w_i^S \to v$ costs at most $\max\{0, d(w, v) - D'\}$. If $d(w, v) < D'$, then $d'_i(u, v) \leq d_{G_i^S}(u, v) = 0 \leq d(u, v)$; otherwise, $d'_i(u, v) \leq d_{G_i^S}(u, v) \leq d(w, v) - D' \leq d(u, v)$, where the last step is Equation 1.

When $x \in S_w \cup \{w\}$, and $V_i \subseteq T_w$, we have a symmetric argument: $d(u, v) \geq d(u, x) \geq d(u, x) + (d(x, w) - D') \geq d(u, w) - D'$. Consider the path $u \to w_i^T \to v$ in G_i^T. The second part $w_i^T \to v$ costs 0, because there is an edge from w_i^T to v with weight 0; the first part $u \to w_i^T$ costs at most $\max\{0, d(u, w) - D'\}$. If $d(u, w) < D'$, then $d'_i(u, v) \leq d_{G_i^T}(u, v) = 0 \leq d(u, v)$; otherwise, $d'_i(u, v) \leq d_{G_i^T}(u, v) \leq d(u, w) - D' \leq d(u, v)$. ◀

▶ **Lemma 12.** *For every i, and every pair of vertices $u, v \in V_i$, $d'_i(u, v) \geq d(u, v) - 2D'$; that is, $d_{G_i^S}(u, v) \geq d(u, v) - 2D'$ and $d_{G_i^T}(u, v) \geq d(u, v) - 2D'$.*

Proof. We only provide full proof for $d_{G_i^S}(u, v) \geq d(u, v) - 2D'$. The inequality for G_i^T can be proved by a symmetrical argument. If the shortest path from u to v in G_i^S does not contain w_i^S, then this path also exists in the original graph G, and thus the inequality is true.

Otherwise, the shortest path from u to v in G_i^S contains w_i^S, as shown in Figure 2. All edges on the shortest path from w_i^S to v exist in the original graph G except for the first edge from w_i^S to some node x, since a shortest path cannot use the vertex w_i^S more than once. That is, $d_{G_i^S}(x, v) = d(x, v)$.

By the definition of w_i^S and the edges incident to it, there exists a $w \in W_i^S$ such that $d(w, x) \leq d_{G_i^S}(w_i^S, x) + D'$. Thus, we have

$$\begin{aligned}
d_{G_i^S}(u, v) &= d_{G_i^S}(u, w_i^S) + d_{G_i^S}(w_i^S, x) + d_{G_i^S}(x, v) \\
&= d_{G_i^S}(w_i^S, x) + d_{G_i^S}(x, v) && \text{since } d_{G_i^S}(u, w_i^S) = 0 \text{ by construction} \\
&= d_{G_i^S}(w_i^S, x) + d(x, v) && \text{from argument above} \\
&\geq d(w, x) - D' + d(x, v) && \text{by the definition of } w \\
&\geq d(w, v) - D' && \text{by the triangle inequality} \\
&\geq (d(w, v) - D') + (d(u, w) - D') && \text{since } d(u, w) \leq D' \text{ by definition} \\
&\geq d(u, v) - 2D' && \text{by the triangle inequality}
\end{aligned}$$

◀

We are now ready to prove our approximation ratio guarantee: $D/3 \leq \tilde{D} \leq D$. Clearly $D' \leq D$ because D' is the min-eccentricity of a vertex. By Lemma 11 $\max_{i,u\in V_i,v\in V_i} \min\{d'_i(u,v), d'_i(v,u)\} \leq \max_{i,u\in V_i,v\in V_i} d_{min}(u,v) \leq D$. Therefore, we never over estimate the Min-Diameter.

If $s^* \in W$ or $t^* \in W$, then since we run Dijkstra from all vertices in W we have $D' = D$. So assuming that $s^*, t^* \notin W$, we have two cases.

Case 1: s^* and t^* are not in the same vertex set V_i. By Lemma 7, property 2, there exists $w \in W$ such that one of s^* and t^* is in S_w and the other is in T_w, so by Lemma 10, $\varepsilon(w) \geq D/2$. Since $D' \geq \varepsilon(w)$, we have $D' \geq D/2$.

Case 2: s^* and t^* are in the same vertex set V_i for some i. By Lemma 12, $\min(d'_i(s^*,t^*), d'_i(t^*,s^*)) \geq d_{min}(s^*,t^*) - 2D' = D - 2D'$. Since $\max\{D-2D', D'\} \geq D/3$, we get a 3-approximation.

Runtime analysis

It takes $\tilde{O}(m\sqrt{n})$ time to perform the partitioning from Lemma 7 and to perform Dijkstra's algorithm from all $w \in W$ since $|W| = O(\sqrt{n})$.

For all i, the number of vertices in G_i^S is $|V_i| + 1 = O(\sqrt{n})$ with high probability by property 1 of Lemma 7 and the number of edges is $m_i + O(\sqrt{n})$ where m_i is the number of edges in the graph induced by V_i. Hence we can run an all-pairs shortest paths algorithm on G_i^S in time $\tilde{O}((m_i + \sqrt{n})\sqrt{n})$. Summing over all i gives us $\tilde{O}(m\sqrt{n})$. The same analysis also works for G_T^i.

Abstract

Some of the most fundamental and well-studied graph parameters are the Diameter (the largest shortest paths distance) and Radius (the smallest distance for which a "center" node can reach all other nodes). The natural and important ST-variant considers two subsets S and T of the vertex set and lets the ST-diameter be the maximum distance between a node in S and a node in T, and the ST-radius be the minimum distance for a node of S to reach all nodes of T. The *bichromatic* variant is the special case in which S and T partition the vertex set.

In this paper we present a comprehensive study of the *approximability* of ST and Bichromatic Diameter, Radius, and Eccentricities, and variants, in graphs with and without directions and weights. We give the first nontrivial approximation algorithms for most of these problems, including time/accuracy trade-off upper and lower bounds. We show that nearly *all* of our obtained bounds are tight under the Strong Exponential Time Hypothesis (SETH), or the related Hitting Set Hypothesis.

For instance, for Bichromatic Diameter in undirected weighted graphs with m edges, we present an $\tilde{O}(m^{3/2})$ time [1] 5/3-approximation algorithm, and show that under SETH, neither the running time, nor the approximation factor can be significantly improved while keeping the other unchanged.

1 Introduction

A fundamental and very well studied problem in algorithms is the Diameter of a graph, where the output is the largest (shortest path) distance over all pairs of vertices. Over the years many different algorithms have been developed for the problem, both in theory (e.g. [3, 21, 24, 8, 4]) and in practice (e.g. [10, 25, 20]).

A very natural variant is the so called ST-Diameter problem [4]: given a graph and two subsets S and T of its vertex set, determine the largest distance between a vertex of S and a vertex of T. In the Subset version of ST-Diameter, we have $S = T$. Bichromatic Diameter is the version of ST-Diameter for which S and T partition the vertex set. Besides Diameter, the Radius (the smallest distance for which a "center" node can reach all other nodes) and Eccentricities (the largest distance out of every vertex) problems are also very well studied, and analogous ST, Subset, and Bichromatic versions are easy to define.

All of these parameters are simple to compute by computing all pairwise distances in the graph, i.e. by solving All-Pairs Shortest Paths (APSP). In sparse n-node graphs, where the number of edges m is $\tilde{O}(n)$, APSP still needs $\Omega(n^2)$ time, as this is the size of the output, whereas it is apriori unclear whether this much time is needed for computing the Diameter, Radius and Eccentricities or their ST and bichromatic variants, as the output is small.

A related extremely well-studied problem in computational geometry is Bichromatic Diameter on point sets (commonly known as Bichromatic Farthest Pair), where one seeks to determine the farthest pair of points in a given set of points in space (see e.g. [29, 13, 28, 2, 17]). Another related problem is the Subset version of spanners (e.g. [19, 11]), as well as the ST version of spanners (e.g. [9, 18]). Furthermore, the ST, Subset, and Bichromatic versions of many problems have been of great interest; for instance Steiner Tree, Subset TSP, and a number of problems in computational geometry such as Bichromatic Matching (e.g. [16]) and Bichromatic Line Segment Intersection (e.g. [7]).

There are several known approximation algorithms for the standard version of Diameter, most of which have been developed in the last 6 years. Trivially, running Dijkstra's algorithm from an arbitrary vertex gives a simple $\tilde{O}(m)$ time 2-approximation algorithm for directed and weighted graphs. Non-trivial algorithms achieve an improved approximation factor with an increased runtime: Building on Aingworth et al. [3], Roditty and Vassilevska W. [24] showed for instance that an "almost" 1.5 approximation for Diameter can be computed in $\tilde{O}(m\sqrt{n})$ time in m-edge n-vertex directed weighted graphs – the approximation factor is 1.5 if the Diameter is divisible by 3, and there is a slight additive error otherwise. Chechik et al. [8] gave a true 1.5 approximation at the expense of increasing the runtime to $\tilde{O}(mn^{2/3})$, and Cairo, Grossi and Rizzi [5] generalized the approach giving an $\tilde{O}(mn^{1/(k+1)})$ time, "almost" $2 - 1/2^k$ approximation algorithm for all $k \geq 1$ which works only in undirected graphs.

In STOC'18, Backurs et al. [4] gave the first non-trivial approximation algorithms for ST-Diameter: an $\tilde{O}(m^{3/2})$ time 2-approximation and an $\tilde{O}(m)$ time 3-approximation. They also showed that these algorithms cannot be improved significantly, unless the Strong Exponential Time Hypothesis (SETH) fails. Backurs et al. did not provide algorithms for ST-Eccentricities or ST-Radius, and they did not study the natural Subset and Bichromatic versions. They also only focused on undirected graphs.

We study the following natural and fundamental questions:

How well can ST-Eccentricities and ST-Radius be approximated? Are any interesting approximation algorithms possible for directed graphs for any of the ST-variants? Does the approximability of the problems change when one turns to the Subset versions in which $S = T$, or the Bichromatic versions in which S and T are required to partition the vertex set?

1.1 Our Results

We present a comprehensive study of the approximability of the ST, Subset and Bichromatic variants of the Diameter, Radius and Eccentricities problems in graphs, both with and without directions and weights. We obtain the first non-trivial approximation algorithms for most of these problems, including time/accuracy trade-off upper and lower bounds. We show that nearly *all* of our approximation algorithms are tight under SETH (or under the related Hitting Set Hypothesis for Radius). Additionally, we study a parameterized version of these problems.

Our results are summarized in Tables 1-4.

Table 1 Bichromatic undirected results. All of our parameterized algorithms and near-linear time algorithms, except for directed Subset Radius and Eccentricities, are deterministic. The rest are randomized and work with high probability[2]. Our lower bounds for Diameter and Eccentricities are under SETH and our lower bounds for Radius are under the Hitting Set (HS) Hypothesis, defined later. All of our lower bounds hold even for unweighted graphs. The trade-off lower bounds in terms of k hold for any integer $k \geq 2$. δ is any constant > 0. B and B' are parameters defined in our parameterized algorithms. The lower bound constructions for the parameterized algorithms have $|B| = \tilde{O}(1)$.
* Multiplicative approximation factor is tight, but not runtime.

APSP algorithms [6, 23, 22] as they run in $\tilde{O}(mn)$ time. The $m\sqrt{n}$ time of the algorithms that allow small additive error beat the APSP algorithms for every graph sparsity.

Bichromatic Diameter and Radius

Our first contribution is an algorithm with the same running time as the 2-approximation ST-Diameter algorithm of [4], achieving a better, 5/3 approximation for Bichromatic Diameter. In other words, when S and T partition the vertex set of the graph, ST-Diameter can be approximated much better! Moreover, we show that under SETH, neither the runtime nor the approximation factor of our algorithm can be improved. The result is summarized in Theorem 1 below, and proven in Theorems 11 and 12.

▶ **Theorem 1.** *There is a randomized $\tilde{O}(m^{3/2})$ time algorithm, that given an undirected graph $G = (V, E)$ with nonnegative integer edge weights and $S \subseteq V, T = V \setminus S$, can output an estimate D' such that $3D_{ST}/5 \leq D' \leq D_{ST}$ with high probability, where D_{ST} is the ST-Diameter of G.*

Moreover, if there is an $O(m^{3/2-\varepsilon})$ time 5/3-approximation algorithm for some $\varepsilon > 0$, or if there is an $O(m^{2-\varepsilon})$ time $(5/3 - \varepsilon)$-approximation algorithm for the problem, then SETH is false.

We also obtain an $\tilde{O}(m\sqrt{n})$ time algorithm that achieves an "almost" 5/3-approximation: the guarantee for unweighted graphs is $3D_{ST}/5 - 6/5 \leq D' \leq D_{ST}$. We also obtain a near-linear time algorithm for weighted graphs that returns an estimate D' with $D_{ST}/2 - W/2 \leq D' \leq D_{ST}$ where W is the minimum weight of a $S \times T$ edge. Using our general theorem 12, we get that this result is also essentially tight, as a $(2 - \varepsilon)$-approximation for $\varepsilon > 0$ running in near-linear time would refute SETH.

To obtain our improvements for Bichromatic Diameter over the known ST-Diameter algorithms, we crucially exploit the basic fact that as S, T partition V any path that starts

from a vertex $s \in S$ and ends in a vertex $t \in T$ must cross a (u, v) edge such that $u \in S, v \in T$. While this fact is clear, it not at all obvious how one might try to exploit it.

We explain our technique in more detail for the bichromatic diameter problem, and similar ideas are used for our algorithms for the other problems. Let $s^* \in S$ and $t^* \in T$ be end-points of an ST-Diameter path. Similarly to prior Diameter algorithms, our goal is to run Dijkstra's algorithm from some $s \in S$ which is close to s^*, and hence far from t^*, or from some $t \in T$ which is close to t^* and hence far from s^* (by the triangle inequality). Our 5/3-approximation algorithms are a delicate combination of two themes: (1) randomly sample nodes in S and nodes in T – similarly to prior works, the sampling works well if there are many nodes of S that are close to s^*, or if there are many nodes of T that are close to t^*. If (1) is not good enough, in theme (2) we show that we can find a node $w \in S$ close to t^* for which we can "catch" an $S \times T$ edge (s, t) on the shortest $w \to t^*$ path, such that t is close to t^*. Theme (2) is our new contribution. Because of theme (2), our algorithms are more complicated than the ST-Diameter algorithms, but run in asymptotically the same time, and achieve a better approximation guarantee. In order to better separate the ideas in our algorithms, we explain them in several steps, where Theme (1) can be seen in the first steps and Theme (2) appears towards the last steps.

Following a similar approach to our Bichromatic Diameter algorithms, we develop similar algorithms for Bichromatic Radius. First, we give a simple near-linear time almost 2-approximation algorithm, and then we adapt the 5/3-approximation for Bichromatic Diameter to also give a 5/3-approximation for Bichromatic Radius. Moreover, we show that any better approximation factor requires essentially quadratic time, under the Hitting Set (HS) Hypothesis of [1] (see also [14]).

▶ **Theorem 2.** *There is a randomized $\tilde{O}(m^{3/2})$ time algorithm, that given an undirected graph $G = (V, E)$ with nonnegative integer edge weights and $S \subseteq V, T = V \setminus S$, can output an estimate R' such that $R_{ST} \leq R' \leq 5R_{ST}/3$ with high probability, where R_{ST} is the ST-Radius of G. Moreover, if there is a $5/3 - \varepsilon$ approximation algorithm running in $O(m^{2-\delta})$ time for any $\varepsilon, \delta > 0$, then the HS Hypothesis is false.*

Similarly to the Bichromatic Diameter algorithm, if one is satisfied with a slight additive error, one can improve the runtime to $\tilde{O}(m\sqrt{n})$.

ST-Eccentricities and ST-Radius

Prior work only considered ST-Diameter but did not consider the more general ST- Eccentricities problem in which one wants to approximate for every $s \in S$, $\varepsilon_{ST}(s) := \max_{t \in T} d(s, t)$.

Here we show that one can achieve exactly the same approximation factors for ST-Eccentricities as for ST-Diameter. Since any conditional lower bound for ST-Diameter also applies for the ST-Eccentricities problem, the algorithms we obtain are conditionally optimal, similarly to the ST-Diameter algorithms in [4]. Interestingly, we show that the same conditional lower bounds apply for Bichromatic Eccentricities (see the full version [12]), and therefore our ST-Eccentricities algorithms are optimal even for the Bichromatic case.

▶ **Theorem 3.** *There is a randomized $\tilde{O}(m^{3/2})$ time algorithm, that given an undirected graph $G = (V, E)$ with nonnegative integer edge weights and $S, T \subseteq V$, can output for every $s \in S$, an estimate $\varepsilon'(s)$ such that $\varepsilon_{ST}(s)/2 \leq \varepsilon'(s) \leq \varepsilon_{ST}(s)$ with high probability. Moreover, if there is a $2 - \varepsilon$ approximation algorithm running in $O(m^{2-\delta})$ time for any $\varepsilon, \delta > 0$ or a 2-approximation algorithm running in $O(m^{3/2-\varepsilon})$ time for $\varepsilon > 0$, even for the Bichromatic case when $T = V \setminus S$, then SETH is false.*

Again, as before, one can improve the runtime to $\tilde{O}(m\sqrt{n})$ with a slight additive error, and there is a simple near-linear time 3-approximation algorithm which is tight under SETH, similar to the one in [4] for ST-Diameter. A simple argument shows that these algorithms imply algorithms with the same running time and approximation factor for ST-Radius.

Bichromatic and ST Problems in Directed Graphs

Using simple reductions we first show that there can be no $O(m^{2-\varepsilon})$ time (for $\varepsilon > 0$) algorithms that achieve any finite approximation for ST-Diameter or ST-Eccentricities (under SETH), or ST-Radius (under HS). Interestingly, the same holds for Bichromatic Eccentricities (under SETH, see the full version [12]) and Bichromatic Radius (under HS, see [12]), but not Bichromatic Diameter! Surprisingly, unlike those two problems, Bichromatic Diameter does admit a finite, in fact 2-approximation algorithm running in subquadratic time, and this algorithm is conditionally optimal:

▶ **Theorem 4.** *There is a randomized $\tilde{O}(m^{3/2})$ time algorithm, that given a directed graph $G = (V, E)$ with nonnegative integer edge weights and $S \subseteq V, T = V \setminus S$, can output an estimate D' such that $D_{ST}/2 \leq D' \leq D_{ST}$ with high probability, where D_{ST} is the ST-Diameter of G.*

Moreover, if there is an $O(m^{2-\varepsilon})$ time $2-\delta$-approximation algorithm for the problem for some $\varepsilon, \delta > 0$, then SETH is false.

The previously known techniques for approximating Diameter in directed graphs fail here. The main issue is that the prior techniques were general enough that they also gave algorithms for Eccentricities and Radius as a byproduct. In the Bichromatic case, however, there is a genuine difference between Diameter and Radius, as we noted above, and new techniques are needed. Here again it turns out that combining theme (2) with a delicate argument is sufficient to get conditionally tight algorithms under SETH.

Subset Versions

Recall that Subset Diameter, Radius, and Eccentricities are the versions of the corresponding ST problems with the constraint that $S = T$. Interestingly, Subset Diameter, Radius, and Eccentricities all exhibit the same sharp threshold behavior. For all three problems, there are near-linear time algorithms that achieve a 2 (or almost 2) approximation, as well as conditional lower bounds that show that there is no $2-\delta$ approximation in $m^{2-o(1)}$ time.

Parameterized Algorithms

We consider the Bichromatic Diameter, Radius, and Eccentricities problems parameterized by the size of the *boundary* between the S and T sets. If S' is the set of vertices in S that have a neighbor in T, and T' is the set of vertices in T that have a neighbor in S, then the boundary B is whichever of S' or T' is smaller in size. Our lower bound constructions already have small boundary so they rule out algorithms even for graphs with small boundary. However, interestingly we obtain near-linear time algorithms for graphs with small boundary that achieve *better* multiplicative approximation factors than the optimal non-parameterized algorithms. This is not a contradiction because our parameterized algorithms have a constant additive error, while the apparently contradictory lower bounds do not tolerate additive error.

2 Preliminaries

Given a graph $G = (V, E)$ (directed or undirected, weighted or unweighted), let $d(u, v)$ denote the distance from $u \in V$ to $v \in V$. For a subset $X \subseteq V$ and $v \in V$, define $d(v, X) := \min_{x \in X} d(v, x)$. Similarly $d(X, v) := \min_{x \in X} d(x, v)$.

Unless otherwise stated, m denotes the number of edges and n the number of vertices of the underlying graph. Without loss of generality, we can assume that all undirected graphs are connected, and all directed graphs are weakly connected, so that $m \geq n - 1$.

The *Eccentricity* $\varepsilon(v)$ of a vertex $v \in V$ is $\max_{u \in V} d(v, u)$. The *Diameter* $D(G)$ of G is $\max_{v \in V} \varepsilon(v)$, and the *Radius* $R(G)$ of G is $\min_{v \in V} \varepsilon(v)$.

Given $S, T \subseteq V$, we define analogous parameters as follows. The ST-Eccentricity $\varepsilon_{ST}(v)$ of $v \in S$ is $\max_{u \in T} d(v, u)$. The ST-Diameter $D_{ST}(G)$ is $\max_{v \in S} \varepsilon_{ST}(v)$, and the ST-Radius $R_{ST}(G)$ is $\min_{v \in S} \varepsilon_{ST}(v)$.

The above parameters are called *Bichromatic* Eccentricities, Diameter, and Radius if S and T form a partition of V, i.e. $T = V \setminus S$.

The above parameters are called *Subset* Eccentricities, Diameter, and Radius if $S = T$ and are notated with subscript S instead of ST.

2.1 Preliminaries for algorithms

▶ **Lemma 5.** *Let $G = (V, E)$ be a (possibly directed and weighted graph) and let $W \subseteq V$. Let $g \geq \Omega(\ln n)$ be an integer. Let $S \subseteq W$ be a random subset of $c(|W|/g) \ln n$ vertices for some constant $c > 1$. For every $v \in V$, let $W(v)$ be the set of vertices $x \in W$ for which $d(v, x) < d(v, S)$. Then with probability at least $1 - 1/n^{c-1}$, for every $v \in V$, $|W(v)| \leq g$, and moreover, if one takes the closest g vertices of W to v, they will contain $W(v)$.*

Proof. For each $v \in V$, imagine sorting the nodes $x \in W$ according to $d(v, x)$. Define Q_v to be the first g nodes in this sorted order - those are the nodes of W closest to v (in the $v \to x$ direction).

We pick S randomly by selecting each vertex of W with probability $(c \ln n)/g$. The probability that a particular $q \in Q_v$ is not in S is $1 - (c \ln n)/g$, and the probability that no $q \in Q_v$ is in S is $(1 - (c \ln n)/g)^g \leq 1/n^c$. By a union bound, with probability at least $1 - 1/n^{c-1}$, for every $v \in V$, we have that $Q_v \cap S \neq \emptyset$.

Now, for each particular v, say that $w(v)$ is a node in $Q_v \cap S$. Since all nodes $x \in W$ with $d(v, x) < d(v, w(v))$ must be in Q_v, and since $d(v, w(v)) \geq d(v, S)$, we must have that $W(v) \subseteq Q_v$. Hence, with probability at least $1 - 1/n^{c-1}$, for every $v \in V$, $|W(v)| \leq g$ and $W(v) \subseteq Q_v$. ◀

▶ **Lemma 6.** *Let $G = (V, E)$ be a (possibly directed and weighted) graph. Let $M, W \subseteq V$ and let $S \subseteq W$ be a random subset of $c(n/g) \ln n$ vertices for some large enough constant c and some integer $g \geq 1$.*

Then, for any $D > 0$ and for any $w \in M$ with $d(w, S) > D$, if one takes the closest g vertices of W to w, they will contain all nodes of W at distance $< D$ from w, with high probability.

Proof. Let Q be the closest g vertices of W to w. By Lemma 5, with high probability Q contains all nodes of W at distance $< d(w, S)$ from w, and hence Q contains all nodes of W at distance $< D$ from w, with high probability. ◀

We sometimes sample edges instead of vertices, so analogous lemmas to Lemmas 5 and 6 hold when the sample is from a set of edges. Here is the analogue of Lemma 6. The other lemma is similar.

▶ **Lemma 7.** *Let $G = (V, E)$ be a (possibly directed and weighted graph) and let $M, W \subseteq V$. Let $E' \subseteq E$ be a random subset of $c(|E|/g) \ln n$ edges for some large enough constant c and some integer $g \geq 1$. Let Q be the endpoints of edges in E' that are in W.*

Then, for any $D > 0$, and for any w with $d(w, S) > D$, if one takes the closest g edges of E' to w wrt the distance from their W endpoints, they will contain all edges of E' whose W endpoints are at distance $< D$ from w, with high probability.

2.2 Preliminaries for lower bounds

The Strong Exponential Time Hypothesis (SETH) asserts that on a Word-RAM with $O(\log n)$ bit words, there is no $(2-\varepsilon)^n$ time (possibly randomized) algorithm for some constant $\varepsilon > 0$ that can determine whether a given CNF-Formula with n variables and $O(n)$ clauses is satisfiable. (This version of SETH is equivalent to the original formulation by Impagliazzo, Paturi and Zane [15].) By a result of Williams [27], the following Orthogonal Vectors (OV) Problem requires $n^{2-o(1)}\text{poly}(d)$ time (on a word-RAM with $O(\log n)$ bit words), unless SETH fails: given two sets $U, V \subseteq \{0,1\}^d$ with $|U| = |V| = n$ and $d = \omega(\log n)$, determine whether there are $u \in U, v \in V$ with $u \cdot v = 0$.

Given an arbitrary instance of OV with $d = \tilde{O}(1)$ (while respecting $d = \omega(\log n)$, e.g. $d = \Theta(\log^2 n)$), consider the following graph representation, which we call the *OV-graph*: the vertex set consists of a node for every $u \in U$, for every $v \in V$ and for every coordinate $c \in [d] = C$, and there is an edge $(x \in U \cup V, c \in C)$ if and only if $x[c] = 1$. OV is then equivalent to the question of whether there exist $u \in U, v \in V$ such that $d(u, v) > 2$. In fact, it is equivalent to distinguishing whether for every $u \in U, v \in V$, $d(u, v) = 2$ (no OV-solution), or there is some $u \in U, v \in V$ such that $d(u, v) \geq 4$ (OV-solution). In other words, if we set $S = U, T = V$, the ST-Diameter of the OV-graph is 2 if and only if there is no OV-solution and at least 4 otherwise. Because the OV graph has $m = \tilde{O}(n)$, under SETH, any $(2-\delta)$-approximation algorithm for ST-Diameter requires $m^{2-o(1)}$.

A related problem to OV is the Hitting Set (HS) problem [1, 14, 26]: given two sets $U, V \subseteq \{0,1\}^d$ with $|U| = |V| = n$ and $d = \omega(\log n)$, determine whether there is $u \in U$ such that for all $v \in V$, $u \cdot v \neq 0$. A common hypothesis is that (on the word-RAM) HS requires $n^{2-o(1)}$ time.

If we form the OV-graph on the HS instance input, then the HS problem becomes equivalent to determining whether there is some $u \in U$ such that for all $v \in V$, $d(u, v) \leq 2$. In other words, if we set $S = U, T = V$, the ST-Radius of the OV-graph is 2 if and only if there is a HS-solution and at least 4 otherwise. Thus, under the HS hypothesis, any $(2-\delta)$-approximation algorithm for ST-Radius requires $m^{2-o(1)}$.

Additionally for our constructions we assume that if there is a HS solution u' then for all $c \in C$, $d(u', c) \leq 3$. This is because for every coordinate index i there must be $v \in V$ with $v[i] = 1$ as otherwise we can just delete the i^{th} bit from all vectors.

Let $k \geq 2$ be an integer. Then, a generalization of the OV problem is k-OV: given k sets $U_1, \ldots, U_k \subseteq \{0,1\}^d$, are there $u_1 \in U_1, \ldots, u_k \in U_k$ so that $\sum_{c=1}^{d} \prod_{i=1}^{k} u_i[c] = 0$? It is known that, under SETH, when $d = \omega(\log n)$, there is no $n^{k-o(1)}$ time algorithm for k-OV (in the word RAM model) [27].

Similar to the OV-graph, Backurs et al. [4] define a graph for k-OV which we will refer to as the k-OV-graph. We do not explicitly define the k-OV-graph here; instead we list its properties in the following theorem.

▶ **Theorem 8** ([4]). *Let $k \geq 2$. Given a k-OV instance consisting of sets $W_0, W_1, \ldots, W_{k-1} \subseteq \{0,1\}^d$, each of size n, we can in $O(kn^{k-1}d^{k-1})$ time construct an unweighted, undirected graph with $O(n^{k-1} + kn^{k-2}d^{k-1})$ vertices and $O(kn^{k-1}d^{k-1})$ edges that satisfies the following properties.*

1. *The graph consists of $k+1$ layers of vertices $L_0, L_1, L_2, \ldots, L_k$. The number of nodes in the sets is $|L_0| = |L_k| = n^{k-1}$ and $|L_1|, |L_2|, \ldots, |L_{k-1}| \leq n^{k-2}d^{k-1}$.*
2. *L_0 consists of all tuples $(a_0, a_1, \ldots, a_{k-2})$ where for each i, $a_i \in W_i$. Similarly, L_k consists of all tuples $(b_1, b_2, \ldots, b_{k-1})$ where for each i, $b_i \in W_i$.*
3. *If the k-OV instance has no solution, then $d(u,v) = k$ for all $u \in L_0$ and $v \in L_k$.*
4. *If the k-OV instance has a solution $a_0, a_1, \ldots, a_{k-1}$ where for each i, $a_i \in W_i$ then if $\alpha = (a_0, \ldots a_{k-2}) \in L_0$ and $\beta = (a_1, \ldots, a_{k-1}) \in L_k$, then $d(\alpha, \beta) \geq 3k-2$.*
5. *For all i from 1 to $k-1$, for all $v \in L_i$ there exists a vertex in L_{i-1} adjacent to v and a vertex in L_{i+1} adjacent to v.*

2.3 Organization

In Section 3 we present our algorithms and conditional lower bound for undirected bichromatic diameter. We defer the rest of our algorithms and conditional lower bounds to the full version [12].

3 Algorithms and Lower Bound for Undirected Bichromatic Diameter

We begin with a simple near-linear time algorithm.

▶ **Proposition 9.** *There is an $O(m + n \log n)$ time algorithm, that given an undirected graph $G = (V, E)$ and $S \subseteq V, T = V \setminus S$, can output an estimate D' such that $D_{ST}(G)/2 - W/2 \leq D' \leq D_{ST}$, where W is the minimum weight of an edge in $S \times T$.*

Proof. Let (s,t) be a minimum weight edge of G with $s \in S$ and $t \in T$. Run Dijkstra's algorithm from s and from t. Let $D' = \max\{\max_{t' \in T} d(s,t'), \max_{s' \in S} d(s',t)\}$. Let $s^* \in S, t^* \in T$ be endpoints of an ST-Diameter path, i.e. $d(s^*, t^*) = D_{ST}$. Then, suppose that $\max_{t' \in T} d(s,t') < D_{ST}/2 - W/2$. In particular, $d(s,t^*) < D_{ST}/2 - W/2$, and hence $d(s,s^*) > D_{ST}/2 + W/2$ by the triangle inequality. Also by the triangle inequality,

$$D_{ST}/2 + W/2 < d(s,t) + d(t,s^*) \leq w(s,t) + \max_{s' \in S} d(s',t).$$

Hence, $D' > D_{ST}/2 - W/2$, where W is the minimum weight of an edge in $S \times T$. ◀

Now we turn to our 5/3-approximation algorithms. Our first theorem is for unweighted graphs. Later on, we modify the algorithm in this theorem to obtain an algorithm for weighted graphs as well, and at the same time remove the small additive error that appears in the theorem below.

▶ **Theorem 10.** *There is an $\tilde{O}(m\sqrt{n})$ time algorithm, that given an unweighted undirected graph $G = (V, E)$ and $S \subseteq V, T = V \setminus S$, can output an estimate D' such that $3D_{ST}(G)/5 \leq D' \leq D_{ST}(G)$ if $D_{ST}(G)$ is divisible by 5, and otherwise $3D_{ST}(G)/5 - 6/5 \leq D' \leq D_{ST}(G)$.*

Proof. Let $D = D_{ST}(G)$ and let us assume that D is divisible by 5. If D is not divisible by 5, the estimate we return will have a small additive error. For clarity of presentation, we omit the analysis of the case where D is not divisible by 5. However, we include such analyses in our proofs for Bichromatic Radius and ST-Eccentricities (see ARXIV) and the analysis for Diameter is analogous.

Suppose the (bichromatic) ST-Diameter endpoints are $s^* \in S$ and $t^* \in T$ and that the ST-Diameter is D. The algorithm does not know D, but we will use it in the analysis.

(Algorithm Step 1): The algorithm first samples $Z \subseteq S$ of size $c\sqrt{n}\ln n$ uniformly at random. For every $z \in Z$, run BFS, and let $D_1 = \max_{z\in Z, t\in T} d(z,t)$.

(Analysis Step 1): If for some $s' \in Z$ we have that $d(s^*, s') \leq 2D/5$, then $D_1 \geq d(s', t^*) \geq D - d(s^*, s') \geq 3D/5$.

(Algorithm Step 2): Now, sample a set X from T of size $C\sqrt{n}\ln n$ uniformly at random for large enough constant C. For every $t \in X$, run BFS and find the closest node $s(t)$ of S to t. Run BFS from every $s(t)$. Let $D_2 = \max_{t\in X, t'\in T} d(s(t), t')$.

(Analysis Step 2): If s^* is at distance $\leq D/5$ from some node t of X, then $d(s^*, s(t)) \leq 2D/5$ (since $s(t)$ is closer to t than s^*), and so $D_2 \geq d(s(t), t^*) \geq 3D/5$.

If neither D_1, nor D_2 are good approximations, it must be that $d(s^*, X) > D/5$ and $d(s^*, Z) > 2D/5$. Consider the nodes M of S that are at distance $> 2D/5$ from Z, then the node $w \in M$ that is furthest from X among all nodes of M. If neither D_1, nor D_2 was a good approximation, $s^* \in M$ and since $d(s^*, X) > D/5$, we must have that $d(w, X) > D/5$ (and also $d(w, Z) > 2D/5$). In the next step we will look for such a w.

(Algorithm Step 3): For each $s \in S$ define D_s to be the biggest integer which satisfies $d(s, X) > D_s/5$ and $d(s, Z) > 2D_s/5$. Let $w = \arg\max D_s$ and $D' = \max D_s$.

(Analysis Step 3): By Lemma 6 we have that whp, the number of nodes of T at distance $\leq D'/5$ from w and the number of nodes of S at distance $\leq 2D'/5$ from w are both $\leq \sqrt{n}$. Also if neither D_1, nor D_2 are good approximations, it must be that $d(s^*, X) > D/5$ and $d(s^*, Z) > 2D/5$ and hence $D' \geq D$.

(Algorithm Step 4): Run BFS from w. Take all nodes of S at distance $\leq 2D'/5$ from w, call these S_w, and run BFS from them. Whp, $|S_w| \leq \sqrt{n}$, so that this BFS run takes $O(m\sqrt{n})$ time. Let $D_3 := \max_{s\in S_w, t\in T} d(s,t)$.

For every $s \in S_w$, let $t(s)$ be the closest node of T to s (breaking ties arbitrarily). Run BFS from each $t(s)$. Let $D_4 := \max_{s\in S_w, s'\in S} d(s', t(s))$.

(Analysis Step 4): If $D_3 \geq 3D/5$ or $D_4 \geq 3D/5$, we are done, so let us assume that $D_3, D_4 < 3D/5$. Since $D_3 < 3D/5$, and since $D_3 \geq d(w, t^*)$, it must be that $d(w, t^*) < 3D/5$. Let P_{wt^*} be the shortest w to t^* path. Consider the node b on P_{wt^*} for which $d(w, b) = 2D/5$. If $b \in S$, then since $D' \geq D$, $b \in S_w$ and hence we ran BFS from $t(b)$. But since $d(b, t^*) = d(w, t^*) - 2D/5 < D/5$, and $d(b, t(b)) \leq d(b, t^*)$ we have that $d(t(b), t^*) \leq 2D/5$ and hence $D_4 \geq d(s^*, t(b)) \geq D - d(t(b), t^*) \geq 3D/5$. Thus, if $D_4 < 3D/5$, it must be that $b \in T$.

(Algorithm Step 5): Take all nodes of T at distance $\leq D'/5$ from w, call these T_w and run BFS from them. Since $d(w, X) > D'/5$, whp $|T_w| \leq \sqrt{n}$, so this step runs in $O(m\sqrt{n})$ time. Let $D_5 = \max_{t\in T_w, s\in S} d(t, s)$.

(Analysis Step 5): If $D_5 \geq 3D/5$, we would be done, so assume that $D_5 < 3D/5$. Let a be the node on the shortest w to t^* path P_{wt^*} with $d(w, a) = D/5$. Suppose that $a \in T$. Since $D' \geq D$, $a \in T_w$ and we ran BFS from it. However, also $d(a, t^*) = d(w, t^*) - d(w, a) < 3D/5 - D/5 = 2D/5$, and hence $D_5 \geq d(a, s^*) \geq d(t^*, s^*) - d(t^*, a) \geq D - 2D/5 = 3D/5$. Since $D_5 < 3D/5$, it must be that $a \in S$.

Now, since $a \in S$ and $b \in T$, somewhere on the a to b shortest path P_{ab}, there must be an edge (s', t') with $s' \in S, t' \in T$. Since s' is before b, $d(w, s') \leq 2D/5 \leq 2D'/5$, and hence $s' \in S_w$. Thus we ran BFS from $t(s')$. Since s' has an edge to $t' \in T$, $d(s', t(s')) \leq d(s', t') = 1$.

Also, since $d(w,s') \geq d(w,a) = D/5$ and $d(w,t^*) \leq 3D/5 - 1$, $d(s',t^*) \leq 2D/5 - 1$. Thus,

$$\begin{aligned} D_4 \geq d(t(s'),s^*) &\geq d(s^*,t^*) - d(t(s'),t^*) \\ &\geq D - d(t(s'),s') - d(s',t^*) \\ &\geq D - 1 - 2D/5 + 1 = 3D/5. \end{aligned}$$

Hence if we set $D'' = \max\{D_1, D_2, D_3, D_4, D_5\}$, we get that $3D/5 \leq D'' \leq D$. ◀

We now modify the algorithm for unweighted graphs, both making the algorithm work for weighted graphs and removing the additive error, at the expense of increasing the runtime to $\tilde{O}(m^{3/2})$.

▶ **Theorem 11.** *There is an $\tilde{O}(m^{3/2})$ time algorithm, that given an undirected graph $G = (V,E)$ with nonnegative integer edge weights and $S \subseteq V, T = V \setminus S$, can output an estimate D' such that $3D_{ST}(G)/5 \leq D' \leq D_{ST}$.*

Proof. Suppose as before the (bichromatic) ST-Diameter endpoints are $s^* \in S$ and $t^* \in T$ and that the ST-Diameter is D.

(Algorithm Modified Step 1): The algorithm here samples $E' \subseteq E$ of size $c\sqrt{m}\ln n$ uniformly at random, for large enough c. Let Z be the endpoints of edges in E' that are in S. For every $z \in Z$, run Dijkstra's algorithm, and let $D_1 = \max_{z \in Z, t \in T} d(z,t)$.

(Analysis Step 1): If for some $s' \in Z$ we have that $d(s^*,s') \leq 2D/5$, then $D_1 \geq d(s',t^*) \geq D - d(s^*,s') \geq 3D/5$. Let us then assume that $d(s^*,Z) > 2D/5$.

(Algorithm Modified Step 2): Let X be the endpoints of edges in E' that are in T. For every $t \in X$, run Dijkstra's algorithm and find the closest node $s(t)$ of S to t. Run Dijkstra's algorithm from every $s(t)$. Let $D_2 = \max_{t \in X, t' \in T} d(s(t),t')$.

(Analysis Step 2): If s^* is at distance $\leq D/5$ from some node t of X, then $d(s^*,s(t)) \leq 2D/5$ (since $s(t)$ is closer to t than s^*), and so $D_2 \geq d(s(t),t^*) \geq 3D/5$. Let us then assume that $d(s^*,X) > D/5$.

As before, if we consider the nodes M of S that are at distance $> 2D/5$ from Z, then the node $w \in M$ that is furthest from X among all nodes of M, would have both $d(w,Z) > 2D/5$ and $d(w,X) > D/5$, as s^* is in M and satisfies $d(s^*,X) > D/5$. We will find a node w with these properties in the next step.

(Algorithm Unmodified Step 3): Perform exactly the same Step 3 as before, finding the largest integer D' such that there is some node $w \in S$ with $d(w,Z) > 2D'/5$ and $d(w,X) > D'/5$.

(Analysis Step 3): Let $w \in S$ be the node we found such that $d(w,X) > D'/5, d(w,Z) > 2D'/5$. By Lemma 7 we have that whp, the number of edges (s,g) where $s \in S, g \in V$ and $d(w,s) \leq 2D'/5$ and the number of edges (t,g') where $t \in T, g' \in V$ and $d(w,t) \leq D'/5$ is at most $\sqrt{m}$. Also, if $D_1, D_2 < 3D/5$, then $D' \geq D$, so that we also have that the number of edges (s,b) where $s \in S$ and $d(w,s) \leq 2D/5$ and the number of edges (t,b') where $t \in T$ and $d(w,t) \leq D/5$ is at most $\sqrt{m}$, whp.

(Algorithm Modified Step 4): Run Dijkstra's algorithm from w. Take all edges incident to nodes of S at dist $\leq 2D'/5$ from w. Call these edges E_S and their endpoints S_w. Run Dijkstra's algorithm from both of their end points. Whp, $|E_S| \leq \sqrt{m}$ and so $|S_w| \leq 2\sqrt{m}$, so that this Dijkstra run takes $\tilde{O}(m^{3/2})$ time. Let $D_3 := \max_{t \in S_w \cap T, s \in S} d(s,t)$.

For every $s \in S_w \cap S$, determine a closest node $t(s) \in T$ to s, and run Dijkstra's algorithm from $t(s)$ as well. This search also takes $O(m^{3/2})$ time. Let $D_4 := \max_{s \in S_w \cap S, s' \in S} d(s', t(s))$.

(Analysis Step 4): If $d(w,t^*) \geq 3D/5$, or $D_3 \geq 3D/5$ or $D_4 \geq 3D/5$, we are done, so let us assume that $d(w,t^*), D_3, D_4 < 3D/5$.
Now consider the node b on the shortest w to t^* path P_{wt^*} for which $d(w,b) \leq 2D/5$, but such that the node b' after it on P_{wt^*} has $d(w,b') > 2D/5$.
Suppose that $b \in S$. Then since $D' \geq D$, we have $d(w,b) \leq 2D'/5$ and hence $(b,b') \in E_S$. Let us consider $d(b',t^*) = d(w,t^*) - d(b',w)$. Since $d(w,t^*) < 3D/5$ and $d(b',w) > 2D/5$, $d(b',t^*) < D/5$. If $b' \in T$, then since we ran Dijkstra's algorithm from b', we got $D_3 \geq D - D/5 = 4D/5$. If $b' \in S$, then we ran Dijkstra's algorithm from $t(b')$ and $d(t(b'),t^*) \leq d(t(b'),b') + d(b',t^*) \leq 2d(b',t^*) < 2D/5$, and hence $D_4 \geq d(t(b),s^*) \geq D - 2D/5 = 3D/5$. Thus if neither $d(w,t^*)$, D_3, nor D_4 are good approximations, then $b \in T$.

(Algorithm Modified Step 5): Take all edges incident to nodes of T at dist $\leq D'/5$ from w. Call these edges E_T and their endpoints that are in T, T_w. Run Dijkstra's algorithm from all nodes in T_w.
Since $d(w,X) > D'/5$, whp $|T_w| \leq 2\sqrt{m}$, so this step runs in $O(m^{3/2})$ time. Let $D_5 = \max_{t \in T_w, s \in S} d(t,s)$.

(Analysis Step 5): If $D_5 \geq 3D/5$, we would be done, so assume that $D_5 < 3D/5$. Let a be the node on P_{wt^*} with $d(w,a) \leq D/5$ but so that the node a' after a on P_{wt^*} has $d(w,a') > D/5$. Suppose that $a' \in T$. Since $D' \geq D$, $(a,a') \in E_T$, $a' \in T_w$ and we ran Dijkstra's algorithm from a'. However, also $d(a',t^*) = d(w,t^*) - d(w,a') < 3D/5 - D/5 = 2D/5$, and hence $D_5 \geq d(a,s^*) \geq d(t^*,s^*) - d(t^*,a') \geq D - 2D/5 = 3D/5$. Since $D_5 < 3D/5$, it must be that $a' \in S$.

Now, since $a' \in S$ and $b \in T$, somewhere on the a' to b shortest path P_{ab}, there must be an edge (s',t') with $s' \in S, t' \in T$. However, since s' is before b, we have that $d(w,s') \leq d(w,b) \leq 2D/5 \leq 2D'/5$. Thus, $(s',t') \in E_S$ and we ran Dijkstra's algorithm from t'. However, $d(t',t^*) = d(w,t^*) - d(w,t') \leq d(w,t^*) - d(w,a') < 3D/5 - D/5 = 2D/5$, and hence $D_3 \geq d(t',s^*) \geq d(s^*,t^*) - d(t',t^*) > 3D/5$.

Hence if we set $D'' = \max\{d(w,t^*), D_1, D_2, D_3, D_4, D_5\}$, we get that $3D/5 \leq D'' \leq D$. ◀

Conditional Lower Bound

The following theorem implies that our algorithms for undirected Bichromatic Diameter from Theorem 11 and Proposition 9 are tight under SETH.

▶ **Theorem 12.** *Under SETH, for every $k \geq 2$, every algorithm that can distinguish between Bichromatic Diameter $2k-1$ and $4k-3$ in undirected unweighted graphs requires $m^{1+1/(k-1)-o(1)}$ time.*

In particular setting $k = 2$ and 3 in Theorem 12 implies that our $m^{3/2}$ time 5/3-approximation algorithm from Theorem 11 is tight in approximation factor and runtime, respectively. Furthermore, setting k to be arbitrarily large implies that our $\tilde{O}(m)$ time almost 2-approximation algorithm from Proposition 9 is tight under SETH.

Theorem 12 follows from the following lemma.

▶ **Lemma 13.** *Let $k \geq 2$ be any integer. Given a k-OV instance, we can in $O(kn^{k-1}d^{k-1})$ time construct an unweighted, undirected graph with $O(kn^{k-1} + kn^{k-2}d^{k-1})$ vertices and $O(kn^{k-1}d^{k-1})$ edges that satisfies the following two properties.*

1. *If the k-OV instance has no solution, then for* all *pairs of vertices $u \in S$ and $v \in T$ we have $d(u,v) \leq 2k-1$.*

2. *If the k-OV instance has a solution, then there exists a pair of vertices $u \in S$ and $v \in T$ such that $d(u, v) \geq 4k - 3$.*

Proof.

Construction of the graph. We begin with the k-OV-graph from Theorem 8. Additionally, we add $k - 1$ new layers of vertices $L_{k+1}, \ldots, L_{2k-1}$, where each new layer contains n^{k-1} vertices and is connected to the previous layer by a matching. That is, each new layer contains one vertex for every tuple $(a_1, \ldots, a_{k-1})$ where $a_i \in W_i$ for all i, and each $(a_1, \ldots, a_{k-1}) \in L_j$ is connected to its counterpart $(a_1, \ldots, a_{k-1}) \in L_{j-1}$ by an edge, for all j.

We let $S = L_0$ and we let T contain the rest of the vertices in the graph.

Correctness of the construction.

Case 1: The k-OV instance has no solution. By property 3 of Theorem 8 for all $u \in S$ and $v \in L_k$, $d(u, v) = k$. Then, since $L_k, \ldots, L_{2k-1}$ form a series of matchings, for all $u \in S$ and $v \in L_{k+1} \cup \cdots \cup L_{2k-1}$, $d(u, v) \leq 2k - 1$. Furthermore, property 5 of Theorem 8 implies that for all $u \in S$ and $v \in L_1 \cup \cdots \cup L_{k-1}$, $d(u, v) \leq 2k - 1$. Thus, we have shown that for all $u \in S$ and $v \in T$ we have $d(u, v) \leq 2k - 1$.

Case 2: The k-OV instance has a solution. Let $(a_0, a_1, \ldots, a_{k-1})$ be a solution to the k-OV instance where $a_i \in W_i$ for all i. We claim that $d((a_0, \ldots, a_{k-2}) \in S, (a_1, \ldots, a_{k-1}) \in L_{2k-1})) \geq 4k - 3$. Since $L_k, \ldots, L_{2k-1}$ form a series of matchings, every path from $(a_0, \ldots, a_{k-2}) \in S$ to $(a_1, \ldots, a_{k-1}) \in L_{2k-1}$ contains the vertex $(a_1, \ldots, a_{k-1}) \in L_k$. By property 4 of Theorem 8, $d((a_0, \ldots, a_{k-2}) \in S, (a_1, \ldots, a_{k-1}) \in L_k) \geq 3k - 2$. Thus, $d((a_0, \ldots, a_{k-2}) \in S, (a_1, \ldots, a_{k-1}) \in L_{2k-1})) \geq 4k - 3$. ◀

Abstract

In this paper, we present an improved algorithm for the All Pairs Non-decreasing Paths (APNP) problem on weighted simple digraphs, which has running time $\tilde{O}(n^{\frac{3+\omega}{2}}) = \tilde{O}(n^{2.686})$. Here n is the number of vertices, and $\omega < 2.373$ is the exponent of time complexity of fast matrix multiplication [Williams 2012, Le Gall 2014]. This matches the current best upper bound for $(\max, \min)$-matrix product [Duan, Pettie 2009] which is reducible to APNP. Thus, further improvement for APNP will imply a faster algorithm for $(\max, \min)$-matrix product. The previous best upper bound for APNP on weighted digraphs was $\tilde{O}(n^{\frac{1}{2}(3+\frac{3-\omega}{\omega+1}+\omega)}) = \tilde{O}(n^{2.78})$ [Duan, Gu, Zhang 2018]. We also show an $\tilde{O}(n^2)$ time algorithm for APNP in undirected simple graphs which also reaches optimal within logarithmic factors.

1 Introduction

Given a directed or undirected graph $G = (V, E)$ with arbitrary real edge weights, a *non-decreasing path* is a path on which edge weights form a non-decreasing sequence [11]. We define the weight of a non-decreasing path to be the weight of its last edge, which we want to minimize. The motivation of this definition comes from train scheduling [13]. Suppose each train station is mapped to a vertex of a directed graph, and a train from station v_1 to station v_2 scheduled at time w is mapped to a directed edge (v_1, v_2) with weight w. If we neglect the time trains spent on their way, a trip from s to t is just a non-decreasing path from s to t in the constructed graph, and the earliest time arriving at t equals the minimum weight of such non-decreasing path. If we consider the train starts from v_1 at time w_1 and arrives at v_2 at time w_2, we can add a vertex u and two edges $(v_1, u), (u, v_2)$, then gives edge weights w_1, w_2 on them, respectively.

The *Single Source Non-decreasing Paths* (SSNP) problem, first studied by Minty [11] in 1958, is to find the minimum weight non-decreasing path from a given source s to all $t \in V$. The first linear time algorithm for SSNP problem in RAM model was given by Williams [13]. She also gave an $O(m \log \log n)$ time algorithm in the standard addition-comparison model. (m is the number of edges.)

The *All Pairs Non-decreasing Paths* (APNP) problem is the all-pairs version of the above problem, asking for the minimum weight non-decreasing path between *all* pairs of vertices in the graph. Williams [13] gave the first truly sub-cubic time algorithm of APNP. The original time complexity of the algorithm was $\tilde{O}(n^{(15+\omega)/6})$, obtained by using an $\tilde{O}(n^{2+\omega/3})$-time $(\min, \leq)$-matrix product[1] algorithm [12] as a subroutine. Here $\omega < 2.373$ is the exponent of time complexity of fast matrix multiplication [2, 14, 8]. Recently, Duan et al. [5] obtained a faster algorithm for APNP in $\tilde{O}(n^{\frac{1}{2}(3+\frac{3-\omega}{\omega+1}+\omega)}) = \tilde{O}(n^{2.78})$, by using a simple balancing technique introduced in [6]. We also adapt this technique in our algorithm.

Computing APNP is at least as hard as the *All Pair Bottleneck Paths* (APBP) problem [13], which asks for the maximum bottleneck path between every pair of vertices, where the bottleneck of a path is defined as the minimum weight (capacity) among all edges on this path [12, 15, 6, 9]. APBP is shown to have the same complexity as the $(\max, \min)$-matrix product ($C_{i,j} = \max_k\{\min(A_{i,k}, B_{k,j})\}$) [1, 12]. The current fastest algorithm for $(\max, \min)$-matrix product runs in $\tilde{O}(n^{(3+\omega)/2}) = \tilde{O}(n^{2.686})$ time [6]. Our algorithm for APNP matches this running time, so any further improvement on APNP will imply a faster algorithm for APBP and $(\max, \min)$-matrix product as well.

The *vertex-weighted* APNP problem on directed graphs, a restricted version of APNP, is computationally equivalent to the problem of *Maximum Witness for Boolean Matrix Multiplication* (MWBMM) [13]. An algorithm of $O(n^{2+\mu})$ time for MWBMM was given by Czumaj et al. [3], where μ satisfies the equation $\omega(1, \mu, 1) = 1 + 2\mu$ and $\omega(1, \mu, 1)$ is the exponent of multiplying an $n \times n^{\mu}$ matrix with an $n^{\mu} \times n$ matrix. Currently, the best bounds on rectangular matrix multiplication by Le Gall and Urrutia [7] imply that $\mu < 0.5286$.

1.1 Our results

In this paper we describe a faster algorithm for directed APNP problem running in $\tilde{O}(n^{(3+\omega)/2})$ time, which reaches optimal if the algorithm for APBP cannot be improved.

▶ **Theorem 1.** *The all pairs non-decreasing paths (APNP) problem on directed simple graphs can be solved in $\tilde{O}(n^{(3+\omega)/2})$ time.*

As in Dijkstra search [4] we can maintain a priority queue of current non-decreasing paths we have found, then the minimum unvisited one is the optimal paths between its endpoints. Every time we visit an optimal path, we "relax" all edges following that path. In [5] they partition the edge set into some parts by increasing order. For low-degree vertices in one part, trivially relax all of its outgoing edges, while for high-degree ones, use matrix multiplication to accelerate. Our algorithm adapt this idea, but we recursively divide the edges to $O(\log n)$ levels. In order the optimize the running time, a careful analysis of matrix multiplication is needed, and we need new ideas to use fast matrix multiplication to "predetermine" some of the useless edges from high-degree vertices.

We also give a $\tilde{O}(n^2)$ time algorithm for undirected APNP using the dynamic sequence data structure [10], which also reaches optimal within logarithmic factors.

▶ **Theorem 2.** *The all pairs non-decreasing paths (APNP) problem on undirected simple graphs can be solved in $\tilde{O}(n^2)$ time.*

[1] The $(\min, \leq)$-product of two matrices A, B is defined as $C_{i,j} = \min_k\{B_{k,j} : A_{i,k} \leq B_{k,j}\}$.

1.2 Organization of this paper

In Section 2, we introduce some terminologies used throughout this paper, and discuss how to recursively divide the edges. Then Section 3 and 4 will discuss our APNP algorithm for directed graphs in detail, where Section 3 explains the main techniques used, and Section 4 describes our whole algorithm and its analysis using procedures in Section 3 as subroutines. Due to page limit, the algorithm for undirected graphs will be discussed in the full version of this paper[2].

2 Preliminaries

2.1 Basic definitions

APNP problem

Let $G = (V, E)$ be a directed simple graph with edge weight $w(e)$ for each edge $e \in E$. We denote $n = |V|$ and $m = |E| = O(n^2)$.

A path is a sequence of edges $e_1, e_2, \ldots, e_l$. A non-decreasing path is a path satisfying $\forall 1 \leq i \leq l-1$, $w(e_i) \leq w(e_{i+1})$, and the weight of this non-decreasing path is defined to be $w(e_l)$, the weight of the last edge. All pairs non-decreasing paths problem asks to determine the minimum weight non-decreasing path between every pair of vertices. Let $OPT(i, j)$ denote the optimal (minimum) non-decreasing path between i and j. In contrast, during the algorithm, we use $d(i, j)$ to denote the current minimum non-decreasing path that our algorithm has found so far. In our algorithm, instead of explicitly maintaining the paths, we only need to maintain the weights of the paths $d(i, j)$ and $OPT(i, j)$ (and their last edges if we want to retrieve the paths), so we will also use $d(i, j)$ and $OPT(i, j)$ to denote the weights of corresponding paths $d(i, j)$ and $OPT(i, j)$, respectively. (Remember that $w(j, k)$ denotes the weight of the edge (j, k).)

Notation for String and Subgraph

Without loss of generality[3], we assume all edges have distinct edge weights ranged from 0 to $2^b - 1$, where $b = \lceil \log_2 |E| \rceil \leq 2 \log_2 n + O(1)$, so $2^b = O(n^2)$. Then every edge weight $w(e)$ corresponds to a b-bit 0-1 string $[w(e)]$ which is its binary representation, with the rightmost bit being the lowest bit.

To distinguish between values and strings, string s is written as $[s]$. $LCP([w_1], [w_2])$ (which is also a binary string) is the longest common prefix of $[w_1]$ and $[w_2]$. For example $LCP([100], [101]) = [10]$, and $LCP([000], [100]) = [\,]$(empty string). $|[w]|$ denotes the length of the string $[w]$, and $[x][y]$ denotes the concatenation of two strings $[x]$ and $[y]$. $[x] < [y]$ means that the lexicographical order of $[x]$ is smaller. For example, $[0111] < [101] < [1010]$.

We define $E_{[x]} = \{e \in E \mid [w(e)] \text{ has prefix } [x]\}$ to be the set of all edges whose weight has prefix $[x]$ (also call the edges have prefix $[x]$), and similarly the subgraph $G_{[x]} = (V, E_{[x]})$. For convenience, an edge set or a subgraph with subscript $[x]$ means all of the edges in it have prefix $[x]$.

[3] See the full version of this paper for the proof.

Rectangular Matrix Multiplication

We use $M(m,n,p)$ to denote the asymptotic time complexity of multiplying an $m \times n$ matrix with an $n \times p$ matrix. We denote $M(n,n,n) = O(n^\omega)$, where $\omega < 2.373$ [2, 14, 8]. In this paper, rectangular matrix multiplications are straightforwardly reduced to square matrix multiplications. So we will only use the following fact. (Here $\min(x_1, \cdots, x_k)$ means the minimum number in $\{x_1, \cdots, x_k\}$.)

▶ **Lemma 3.** $M(m,n,p) = O\left(\frac{mnp}{\min(m,n,p)^{3-\omega}}\right)$.

Proof. The rectangular matrices are decomposed into $\min(m,n,p) \times \min(m,n,p)$ square matrices, then standard fast square matrix multiplication is applied. ◀

2.2 Naïve Algorithm

Let us first take a look at the naïve algorithm for APNP, a simple Dijkstra-type search [4]. Initially set $d(i,j) = w(i,j)$ for all edges $(i,j) \in E$, and $d(i,j) = +\infty$ otherwise. Each time we visit the minimum unvisited $d(i,j)$ and enumerate every out-going edge (j,k) of vertex j. If $d(i,j)$ and (j,k) form a nondecreasing path, then we update $d(i,k) \leftarrow \min(d(i,k), w(j,k))$. (See Algorithm 1.) We refer to this update step as *relaxing* edge (j,k) w.r.t. $d(i,j)$. By the greedy nature of Dijkstra search, when we visit $d(i,j)$, $d(i,j) = OPT(i,j)$. Namely, it is optimal.

Algorithm 1 Relaxing edges naïvely.

```
1: while there exists unvisited d(i,j) do
2:     visit the minimum unvisited d(i,j)
3:     for every (j,k) such that w(j,k) > d(i,j) do
4:         perform update d(i,k) ← min(d(i,k), w(j,k))
```

For clarity, our usages of symbols i, j, k stick to the following convention: $d(i,k)$ refers to the path being updated by the concatenation of path $d(i,j)$ and edge (j,k).

The naïve algorithm takes $O(n^3)$ time when edge weights are integers from 0 to $2^b - 1$, since a bucket heap is enough to maintain unvisited $d(i,j)$.

2.3 Classifying edges according to degrees

In order to avoid relaxing all edges when visiting $d(i,j)$, our algorithm will classify the edges based on the degrees of their two endpoints, and partition the edges whose both endpoints have high degrees into two sets by the order of their weights, then recursively deal with these two sets. We relax different types of edges by different approaches. First, we define "high-degree" and "low-degree" vertices in a subgraph.

High degree and low degree

In this paper, sometimes we use a subset of edges $E' \subseteq E$ to denote the subgraph $G' = (V', E')$ where V' is the set of vertices associated with E', namely, vertices in E' refers to vertices in V'. In a subgraph $G' = (V', E')$ of G, a vertex has high outdegree if its outdegree is larger than n^{1-t}, and otherwise, it has low outdegree. Here t is a parameter to be determined later (we will choose $t = \frac{3-\omega}{2}$). Similarly, a vertex has high indegree if its indegree is larger than n^{1-t}, and otherwise, it has low indegree. In our algorithm, edges (j,k) in a subgraph are divided into three types based on the outdegree of j and indegree of k:

- Low edge: if j has low outdegree
- High-high edge: if j has high outdegree and k has high indegree
- High-low edge: if j has high outdegree and k has low indegree

Divide the edges

In this binary partition procedure, starting from the entire edge set $E'_{[\,]} = E$, each time we divide the set of high-high edges $H_{[x]}$ in $E'_{[x]}$ into two parts: $H'_{[x][0]}$ and $H'_{[x][1]}$, based on its next bit after prefix $[x]$, then recursively partition the edge sets $H'_{[x][0]}$ and $H'_{[x][1]}$. Here we use $L_{[x]}$ and $\Gamma_{[x]}$ to denote the low edges and high-low edges with prefix $[x]$ obtained in the algorithm.

Algorithm 2 Divide the edges.

procedure DIVIDE($E'_{[x]}$)
  Consider the indegrees and outdegrees of vertices in the graph $G'_{[x]} = (V, E'_{[x]})$;
  Let $L_{[x]}$ be the set of edges from low outdegree vertices;
  Let $H_{[x]}$ be the set of edges from high outdegree vertices to high indegree vertices;
  Let $\Gamma_{[x]}$ be the set of edges from high outdegree vertices to low indegree vertices;
  Let $H'_{[x][0]} = \{(j,k) \in H_{[x]}$ s.t. $[w(j,k)]$ has prefix $[x][0]\}$ and $H'_{[x][1]} = \{(j,k) \in H_{[x]}$ s.t. $[w(j,k)]$ has prefix $[x][1]\}$.
  DIVIDE($H'_{[x][0]}$)
  DIVIDE($H'_{[x][1]}$)
end procedure

At the beginning we call DIVIDE(E). Since only the edges in $H_{[x]}$ go into the next recursion, every edge can only appear in one of $L_{[x]}$ or $\Gamma_{[x]}$ but can appear in many $H_{[x]}$.

2.4 Outline of our algorithm

In our algorithm, we run a Dijkstra-type procedure. When visiting $d(i,j)$, which is guaranteed to be optimal, we relax all the edges (j,k) in $L_{[x]}$ and $\Gamma_{[x]}$ w.r.t. $d(i,j)$ for all $[x]$ which is a prefix of $[d(i,j)]$. The outdegree of j is small in $L_{[x]}$ but not in $\Gamma_{[x]}$, so to relax $L_{[x]}$, we relax all edges from j as the naïve algorithm. But to relax $\Gamma_{[x]}$, a preprocessing procedure of the edges in $\Gamma_{[x]}$ is needed in order to save time. For edges in $H_{[x]}$, instead of immediately relaxing them, we wait until all optimal paths with prefix $[x][0]$ are visited, then perform a $(\min, \leq)$-matrix product of these paths with the adjacency matrix of $H'_{[x][1]}$ to relax all edges in it. Details of these methods will be given in Section 3.

3 Basic techniques

In this section, we explain the method we use for relaxing edges. Suppose we are trying to relax edges (j,k) w.r.t. $d(i,j)$, it will be based on whether (j,k) is in $L_{[x]}$, $H_{[x]}$, or $\Gamma_{[x]}$.

As explained before, $L_{[x]}$ is easiest. Since j has low outdegree, like the naïve algorithm, we simply relax all of its outgoing edges, which takes $O(n^{1-t})$ time. $H_{[x]}$ and $\Gamma_{[x]}$ are handled by different methods, though they both use the "row/column balancing" technique of matrix proposed in [6]. Instead of considering it as splitting rows/columns on matrix, we describe the balancing technique as splitting vertices so that every vertex has low outdegree/indegree. In the following subsections we describe how to handle $H_{[x]}$ and $\Gamma_{[x]}$.

Table 1 Balancing the indegrees of vertices k.

Balancing the indegrees of vertices
(S1) For every k, sort all the in-coming edges of k in increasing order and obtain the sorted list L_k.
(S2) Split k into vertices $k'_1, k'_2, \cdots k'_p$, and divide L_k into segments each of size n^{1-t} (while the last segment is possibly incomplete). The edges in the r-th segment is assigned to vertex k'_r. Namely, edge (j,k) in the r-th segment now becomes edge (j,k'_r).
(S3) Let $[L(k'_r), R(k'_r)]$ denote the weight range of in-coming edges of k'_r. Namely $L(k'_r)$ is the minimum weight of in-coming edges of k'_r, and $R(k'_r)$ is the maximum. Obviously, $L(k'_1) \le R(k'_1) < L(k'_2) \le R(k'_2) < \cdots < L(k'_p) \le R(k'_p)$.

3.1 Balancing

A graph $G = (V, E)$ contains at most $\frac{|E|}{n^{1-t}}$ vertices with high indegrees or outdegrees. If there are $\Theta(\frac{|E|}{n^{1-t}})$ number of vertices with high degrees, we would expect an average degree of $O(n^{1-t})$. However, the degrees of some vertices may be far greater than n^{1-t}. To balance the indegree (outdegree) of each vertex, we split every vertex into several vertices each of indegree (outdegree) n^{1-t} and one vertex of indegree (outdegree) $\le n^{1-t}$. The number of new vertices with indegree (outdegree) exactly n^{1-t} is bounded by $O\left(\frac{|E|}{n^{1-t}}\right)$, and every original high indegree (outdegree) vertex corresponds to at most one new vertex with indegree (outdegree) $< n^{1-t}$, thus we have at most $O\left(\frac{|E|}{n^{1-t}}\right)$ many new vertices each with indegree (outdegree) $\le n^{1-t}$.

In our algorithm, for edge set $\{(j,k)\}$, we use this technique to either balance the outdegrees of vertices j or the indegrees of vertices k. Here we demonstrate this technique for balancing indegrees of k as an example in Table 1. Denote the set of edges after balancing to be $\bar{E}$, then the graph corresponding to $\bar{E}$ is actually a bipartite graph with edges between vertices j and k'_r. The procedure for balancing outdegrees of j is symmetric.

3.2 High-high edges

The technique for high-high edges solves the following problem: Given a set P of optimal paths of prefix $[x][0]$ and a set $H'_{[x][1]}$ of high-high edges, the problem asks to relax all edges in $H'_{[x][1]}$ w.r.t. paths in P, namely, extend paths in P by a single edge in $H'_{[x][1]}$.

This problem is equivalent with a length-two nondecreasing path problem. As discussed in Section 1, this can be solved by fast $(\min, \le)$-product implied in [6]. But the rectangular version is not covered by [6], so we fully describe the algorithm and its analysis (in graphs).

We have two extra guarantees when we use this procedure in our main algorithm:

- P is the set of optimal paths $OPT(i,j)$ such that $[OPT(i,j)]$ has prefix $[x][0]$, so any path $d(i,j)$ in P can form a nondecreasing path with any edge (j,k) in $H'_{[x][1]}$.
- All $d(i,j)$ satisfying $[d(i,j)] < [x][1]$ are already visited by Dijkstra search. So we can tell whether $[OPT(i,j)] < [x][1]$ or not.

Suppose there are $n_{[x][1]}$ many $[OPT(i,j)]$ which have $[x][1]$ as a prefix. In our algorithm the time complexity will depend on $n_{[x][1]}$.

The first step is to apply the balancing technique in Section 3.1 to indegrees of vertices k in $H'_{[x][1]}$, and let the edge set after balancing be $\bar{H'}_{[x][1]}$. Here each high indegree vertex

k is split into vertices $\{k'_r\}$. We define the following two matrices: (j and k'_r only include vertices having out-going edges and in-coming edges in $\bar{H}'_{[x][1]}$, respectively.)

$$A_{i,j} = \begin{cases} 1 & d(i,j) \in P \\ 0 & \text{otherwise} \end{cases} \qquad B_{j,k'_r} = \begin{cases} 1 & (j,k'_r) \in \bar{H}'_{[x][1]} \\ 0 & \text{otherwise} \end{cases}$$

Then we multiply them with rectangular matrix multiplication. Let $C = AB$, then,

$$C_{i,k'_r} \begin{cases} > 0 & \text{if there is a nondecreasing path from } i \text{ to } k'_r \\ = 0 & \text{otherwise} \end{cases}$$

For every pair (i,k) such that $[OPT(i,k)] \geq [x][1]$ ($d(i,j) \notin P$) and k is an in-coming vertex in $H'[x][1]$, we find the minimum r with $C_{i,k'_r} > 0$ and relax all n^{1-t} incoming edges (j,k'_r) of k'_r w.r.t. $d(i,j)$ if $d(i,j) \in P$. We can skip other $r' > r$ because $OPT(i,k) \leq R(k'_r) < L(k'_{r'})$. Namely, we only have to relax $O(n^{1-t})$ many edges for each (i,k), which is the benefit of balancing. We attribute this $O(n^{1-t})$ cost of relaxations to the $OPT(i,k)$ with prefix $[x][1]$ found in these relaxations, which must exist if $C_{i,k'_r} > 0$.

The procedure above consists of three parts: finding minimum r for each (i,k), relaxation and matrix multiplication. The time cost for the first part is at most enumerating all nonzero elements of C, so it is dominated by the matrix multiplication part.

▶ **Lemma 4.** *The relaxation part takes $O\left(n_{[x][1]} n^{1-t}\right)$ time in total.*

Proof. The cost of relaxation is attributed to each $OPT(i,k)$ with prefix $[x][1]$. Since there are $n_{[x][1]}$ many $OPT(i,k)$ with prefix $[x][1]$, and each corresponds to $O(n^{1-t})$ relaxations, it costs $O(n_{[x][1]} n^{1-t})$ time in total. ◀

▶ **Lemma 5.** *In the matrix multiplication part, A is an $n \times O\left(\min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right)\right)$ matrix, and B is a $O\left(\min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right)\right) \times O\left(\frac{2^{b-|[x]|}}{n^{1-t}}\right)$ matrix, so the time complexity for matrix multiplication is $M\left(n, \min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right), \frac{2^{b-|[x]|}}{n^{1-t}}\right)$.*

Proof. There are at most $\min\left(n, \frac{|H'_{[x][1]}|}{n^{1-t}}\right)$ many j because vertices j have high outdegrees. After balancing, there are at most $O\left(\frac{|H'_{[x][1]}|}{n^{1-t}}\right)$ many k'_r by discussion in Section 3.1. Since each edge in $H'_{[x][1]}$ has prefix $[x][1]$, $|H'_{[x][1]}| \leq 2^{b-|[x]|-1} = O\left(2^{b-|[x]|}\right)$. Plug in the size of $H'_{[x][1]}$ gives the desired bound. ◀

3.3 High-low edges

Now we consider the relaxation of the high-low edges in $\Gamma_{[x]}$ when visiting paths with the same prefix $[x]$. To preprocess high-low edges, we run an initialization step when all optimal paths less than $[x]$ have been visited. As before, we denote the number of $[OPT(i,j)]$ with prefix $[x]$ by $n_{[x]}$.

Since the outdegrees of vertices j are high, we cannot relax edges one by one. But we still want to utilize the property that the indegrees of k are low. As in the last subsection, we denote the set of optimal paths we have found to be P, namely when we visit $d(i,j)$, we add $d(i,j)$ to P. By the nature of Dijkstra search, such $d(i,j)$ is always visited in increasing order. At the initialization step, P is the set of all optimal paths less than $[x]$. During the procedure, optimal paths with prefix $[x]$ are added to P.

We also maintain a dynamic set Q which is initially empty. When we relax an edge (j,k) w.r.t. $d(i,j)$, we put $d(i,k)$ into Q only if $[d(i,k)] \geq [x]$, that is, $d(i,k)$ was not visited at initialization. So Q contains new nondecreasing path but not guaranteed to be optimal.

Initialization by Matrix Multiplication

The first step is to apply the balancing technique to the outdegrees of vertices j in $\Gamma_{[x]}$ such that every vertex j in $\Gamma_{[x]}$ is split into a sequence of vertices $\{j'_r\}$. Suppose the edge set after balancing is $\bar{\Gamma}_{[x]}$. Then, we define the following two matrices: (j'_r and k only include vertices having out-going edges and in-coming edges in $\bar{\Gamma}_{[x]}$, respectively.)

$$A_{i,k} = \begin{cases} 1 & d(i,k) \notin P \cup Q \\ 0 & \text{otherwise} \end{cases} \qquad B_{k,j'_r} = \begin{cases} 1 & (j'_r, k) \in \bar{\Gamma}_{[x]} \\ 0 & \text{otherwise} \end{cases}$$

We compute $C = AB$. Basically speaking, the matrix C can indicate whether we need to relax edges (j'_r, k) from j'_r when visiting $d(i,j)$. Note that when we run initialization, Q is empty, so $d(i,k) \notin Q$ is trivially true. But we will add paths to Q and dynamically update the matrix multiplication later.

We make the following observation about C_{i,j'_r}.

▶ **Observation 1.** *If $d(i,j) < L(j'_r)$ and $C_{i,j'_r} > 0$, there is at least one edge (j'_r, k) such that $d(i,k) \notin P \cup Q$ and $[x]$ is a prefix of $[OPT(i,k)]$.*
Conversely, if $C_{i,j'_r} = 0$, there is no such an edge (j'_r, k).

Proof. Since $C_{i,j'_r} > 0$, at least one vertex k satisfy the following:
- $A_{i,k} > 0$: $d(i,k) \notin P$, so $[OPT(i,k)] \geq [x][0 \cdots 0]$. Also $d(i,k) \notin Q$.
- $B_{k,j'_r} > 0$: $(j'_r, k) \in \bar{\Gamma}_{[x]}$.

Since $d(i,j) < L(j'_r)$, $d(i,j)$ and the original edge of (j'_r, k) form a non-decreasing path. So $[OPT(i,k)] \leq [x][1 \cdots 1]$.

Conversely, if $C_{i,j'_r} = 0$, for every k, at least one of these happens:
- $A_{i,k} = 0$: $d(i,k) \in P \cup Q$
- $B_{k,j'_r} = 0$: edge (j'_r, k) does not exist in $\bar{\Gamma}_{[x]}$. ◀

Update matrix multiplication

When a new path $d(i,k)$ is added to P or Q, the matrix A and product C need to be updated. Adding a new path to P or Q only changes one entry of $A_{i,k}$, so we utilize the low indegree of k. There are at most $O(n^{1-t})$ many j'_r such that $B_{k,j'_r} \neq 0$, since $\Gamma_{[x]}$ contains high-low edges only. So the update of C when changing one element $A_{i,k}$ takes only $O(n^{1-t})$ time by enumerating all nonzero B_{k,j'_r}. This cost can be attributed to each $[OPT(i,k)]$ with prefix $[x]$, since every such path can only be added to $P \cup Q$ once. However, adding $d(i,k)$ to Q does not mean we have found the optimal path $OPT(i,k)$, as it can still be updated. How to deal with this will be discussed later.

Relaxation when visiting $d(i,j)$

When we visit $d(i,j)$, for each split vertex j'_r of j, there are three cases:
1. $d(i,j) > R(j'_r)$: $d(i,j)$ cannot form a non-decreasing path with any out-going edge of j'_r, so we skip j'_r.
2. $d(i,j) \in [L(j'_r), R(j'_r)]$: We relax all out-going edges of j'_r larger than $d(i,j)$.
3. $d(i,j) < L(j'_r)$: Only when $C_{i,j'_r} > 0$, we relax all out-going edges of j'_r one by one.

By Observation 1, when $C_{i,j'_r} = 0$, for each edge (j'_r, k), either $d(i,k) \in P$ or $d(i,k) \in Q$. If $d(i,k) \in P$, it needs no more update. If $d(i,k) \in Q$, roughly speaking, since k has indegree less than n^{1-t}, the updates for $d(i,k)$ can be done "in advance" when it is added to Q. The details will be clear later. This is why we can skip j'_r when $C_{i,j'_r} = 0$.

Since the degree of j'_r is bounded by n^{1-t}, the relaxation takes $O(n^{1-t})$ time for each j'_r. For the second case, it only happens once for each $d(i,j)$ because $[L(j'_r), R(j'_r)]$ are disjoint for different j'_r, so the $O(n^{1-t})$ cost is attributed to $d(i,j)$. For the third case, by Observation 1, there is at least one edge (j'_r, k) such that $OPT(i,k) \notin P \cup Q$ with prefix $[x]$, so the $O(n^{1-t})$ time is attributed to $d(i,k)$. (If there is more than one such k, choose an arbitrary one.) Then $d(i,k)$ is added to Q, and the cost of updating A and C is also bounded by n^{1-t}, dominated by the cost of relaxation.

Because the first path $d(i,k)$ we found for each (i,k) is not necessarily the optimal one, we discuss how to handle all future updates of $d(i,k)$ "in advance" after adding it to Q. We enumerate every in-coming edge $(j'', k) \in \Gamma_{[x]}$ of k. If $d(i,j'')$ is not in P, we add (i,k) to a *waiting list* for (i,j''), denoted by $W(i,j'')$. When $d(i,j)$ is visited in the future, we can go through its waiting list $W(i,j)$ and update $d(i,k)$ for all pair (i,k) in the list. There are only n^{1-t} in-coming edges for k, so the waiting list construction cost is also $O(n^{1-t})$ for every $d(i,k)$.

In conclusion, we follow the procedure in Algorithm 3 when visiting $d(i,j)$ with prefix $[x]$.

Algorithm 3 High-low relaxation when visiting $d(i,j)$.

```
1:  Add d(i,j) to P and update A and C = AB.
2:  for (i,k) in the waiting list W(i,j) do
3:      Relax (j,k) w.r.t. d(i,j) if w(j,k) > d(i,j)
4:  for every j'_r satisfying d(i,j) ∈ [L(j'_r), R(k'_r)] or (d(i,j) < L(j'_r) and C_{i,j'_r} > 0) do
5:      for every outgoing edge (j'_r, k) of j'_r larger than d(i,j) do
6:          if d(i,k) ∉ P ∪ Q then
7:              Relax (the original edge of) (j'_r, k) w.r.t. d(i,j)
8:              Add d(i,k) to Q and update A and C = AB
9:              for incoming edge (j'', k) of k do
10:                 Add (i,k) to the waiting list W(i,j'') if d(i,j'') ∉ P
```

Complexity

This procedure is divided into matrix multiplication part (initialization) and relaxation part (Algorithm 3) as well.

▶ **Lemma 6.** *The relaxation part takes $O\left(n_{[x]}n^{1-t}\right)$ time.*

Proof. From discussion above, the $O(n^{1-t})$ cost of each relaxation is either attributed to optimal $d(i,j)$ with prefix $[x]$ or $d(i,k) \in Q$. For each $d(i,k) \in Q$, $OPT(i,k)$ is of course larger than $[x][0\cdots0]$, and then relaxed by an edge $\leq [x][1\cdots1]$, so the size of Q is also bounded by $n_{[x]}$. Since each $d(i,j)$ can only be added to P and Q once, respectively, the total time is $O\left(n_{[x]}n^{1-t}\right)$.

The total size of all waiting lists $W(i,j)$ is bounded by $O\left(n_{[x]}n^{1-t}\right)$ as well, because each time when an $d(i,k)$ is added to Q, we enumerate $\leq n^{1-t}$ many incoming edges of k, and add (i,k) to waiting list at Line 10. Every waiting list can only be relaxed once, thus, the relaxation of waiting list edges in Line 3 needs $O\left(n_{[x]}n^{1-t}\right)$ in total. ◀

The following lemma is crucial. Although edges (j,k) in $\Gamma_{[x]}$ are high-low edges, the number of k is not directly bounded, but remind that in our binary partition of edges, only high-high edges of previous level can be in this set, thus in fact the number of k *cannot* be asymptotically larger than the number of j'_r.

▶ **Lemma 7.** *In the matrix multiplication part, A is an $n \times O\left(\min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right)\right)$ matrix, and B is an $O\left(\min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right)\right) \times O\left(\frac{2^{b-|[x]|}}{n^{1-t}}\right)$ matrix, so the time complexity of matrix multiplication is $M\left(n, \min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right), \frac{2^{b-|[x]|}}{n^{1-t}}\right)$.*

Proof. Since $|\Gamma_{[x]}| \leq 2^{b-|[x]|}$ (because each edge in it has prefix $[x]$), after balancing, there are at most $O\left(\frac{2^{b-|[x]|}}{n^{1-t}}\right)$ many j'_r.

If $[x] \neq []$, suppose $[x] = [x'][0/1]$, namely $[x']$ is the prefix of $[x]$ which is one bit shorter. If $(j,k) \in \Gamma_{[x]}$, by Algorithm 2, $(j,k) \in H_{[x']}$. Since k has high indegree in $H_{[x']}$, the number of such k is bounded by $O\left(\min\left(n, \frac{|H_{[x']}|}{n^{1-t}}\right)\right)$. Also $|H_{[x']}| = O\left(2^{b-|[x]|}\right)$. Plug it in gives the $O\left(\min\left(n, \frac{2^{b-|[x]|}}{n^{1-t}}\right)\right)$ bound for the number of k. If $[x] = []$, of course the number of k is bounded by n. ◀

4 Main algorithm for directed graphs and analysis

4.1 Main algorithm

Just like in the naïve algorithm, we use a bucket to maintain all $d(i,j)$ we have found, and the minimal *unvisited* $d(i,j)$ is guaranteed to be optimal. Our algorithm enumerates the value x from 0 to $2^b - 1$ and visit $d(i,j)$ if $d(i,j) = x$. We carefully combine techniques introduced in the previous section into this framework.

Recall that in Algorithm 2 of Section 2.3 we define $L_{[x]}$ to be the set of low edges (from low outdegree vertices) and $\Gamma_{[x]}$ to be the set of high-low edges in $H'_{[x]}$, which are high-high edges in higher level, then divide the edge set $H_{[x]}$ of high-high edges in $H'_{[x]}$ to $H'_{[x][0]}$ and $H'_{[x][1]}$ and recursively deal with them. Our main algorithm is presented in Algorithm 4.

Algorithm 4 Main algorithm.

```
d(i,j) = w(i,j) for all edges (i,j) ∈ E, and d(i,j) = +∞ otherwise
for x from 0 to 2^b − 1 do
    for all prefix [y] of [x] do
        if [x] = [y][000···0] then
            Run high-low edge initialization for edges in Γ_[y]
        if [x] = [y][100···0] then
            P_[y][0] = {d(i,j) | [y][0] is a prefix of [d(i,j)]}
            Append high-high edges in H'_[y][1] to paths in P_[y][0]
    for d(i,j) = x do
        Mark d(i,j) as visited, add d(i,j) to P.
        for all prefix [y] of [d(i,j)] do
            Relax edges (j,k) ∈ L_[y]
            Relax edges (j,k) ∈ Γ_[y] by Algorithm 3
```

When visiting an optimal path $d(i,j)$, we need to relax all edges (j,k) which are larger than $d(i,j)$.

▶ **Observation 2.** *For $[d(i,j)] = [x]$, every edge (j,k) larger than $d(i,j)$ must be one of the following three cases: (so $[y]$ is a prefix of both $[x]$ and $[w(j,k)]$.)*

- *$(j,k) \in L_{[y]}$ for some prefix $[y]$ of $[x]$*
- *$(j,k) \in \Gamma_{[y]}$ for some prefix $[y]$ of $[x]$*
- *$(j,k) \in H'_{[y][1]}$ where $[y][0]$ is a prefix of $[x]$*

Proof. Consider the longest common prefix $[y] = LCP([x], [w(j,k)])$. If (j,k) is not in the $L_{[y']}$ or $\Gamma_{[y']}$ for any prefix $[y']$ of $[y]$, it must be in $H_{[y]}$. Since $[y]$ is the longest common prefix and $w(j,k)$ is larger than $d(i,j)$, $[d(i,j)]$ has prefix $[y][0]$ and $[w(j,k)]$ has prefix $[y][1]$, thus (j,k) is in $H'_{[y][1]}$. ◀

Thus, we can simply relax the edges of the first type, and use the method in Section 3.2 to relax the edges in $H'_{[y][1]}$ when all of the optimal paths with prefix $[y][0]$ have been visited. The method for high-low edges $\Gamma_{[y]}$ is like a dynamic data structure: we initialize it when $[x] = [y][0 \cdots 0]$, and update it when relaxing an edge in $\Gamma_{[y]}$.

High-high edges

For high-high edges, when $[x] = [y][100 \cdots 0]$, before those $d(i,j) = x$ are visited, we append edges in $H'_{[y][1]}$ to paths in $P_{[y][0]} = \{d(i,j) \mid [y][0] \text{ is a prefix of } [d(i,j)]\}$ using the technique introduced in Section 3.2. See Line 8, Algorithm 4.

In Section 3.2, we have two guarantees. Now we check them one by one:

- Because each edge in $H'_{[y][1]}$ has prefix $[y][1]$, and each path in $P_{[y][0]}$ has prefix $[y][0]$, the maximum weight in $P_{[y][0]}$ is smaller than the minimum weight of $H'_{[y][1]}$. At the time of $[x] = [y][100 \cdots 0]$, all paths in $P_{[y][0]}$ are optimal.
- Since $[x] = [y][100 \cdots 0]$, all $[d(i,j)] < [y][1]$ are visited, and none of $[d(i,j)] \geq [y][1]$ are visited yet.

High-low edges

We initialize for $\Gamma_{[y]}$ when $[x] = [y][000 \cdots 0]$ before we visit those $d(i,j) = x$. See Line 5 of Algorithm 4. All $[d(i,j)] < [y]$ are visited, and none of $[d(i,j)] \geq [y]$ are visited. Once a $d(i,j)$ within the range $[y][000 \cdots 0] \sim [y][111 \cdots 1]$ is visited, we use the approach in Algorithm 3.

4.2 Correctness

We now prove the correctness of our algorithm. Suppose the last edge of $OPT(i,k)$ is (j,k). Then $d(i,k)$ is correctly computed before it is visited if and only if the following two conditions holds:

- If $i \neq j$, $d(i,j)$ is correctly computed before it is visited.
- After $d(i,j)$ is visited, before we visit $d(i,k)$, $d(i,k)$ is updated by relaxing the edge (j,k) w.r.t. $d(i,j)$.

We prove the second condition holds for every $d(i,j)$, and the first one simply follows from induction.

Suppose $[z] = LCP([OPT(i,j)], [OPT(i,k)]) = LCP([OPT(i,j)], [w(j,k)])$. By Observation 2 the last edge (j,k) must be in one of the three cases, so we check them one by one.

▶ **Lemma 8.** *If (j,k) is in $L_{[y]}$ for some prefix $[y]$ of $[z]$, and $d(i,j)$ is correctly computed before visited, then $d(i,k)$ is also correctly computed before visited.*

Proof. Because $[y]$ is also a prefix of $[OPT(i,j)]$, at Line 12, when we visit $d(i,j)$, $d(i,k)$ is updated by relaxing (j,k). Because $OPT(i,j) < OPT(i,k)$, $d(i,k)$ is not visited yet. ◀

▶ **Lemma 9.** *Suppose (j,k) is in $H'_{[y][1]}$ where $[y][0]$ is a prefix of $[OPT(i,j)]$. If $d(i,j)$ is correctly computed before visited, $d(i,k)$ is also correctly computed before visited.*

Proof. We can see $[y] = [z]$ from the proof of Observation 2. At Line 8, when $[x] = [y][100\cdots0]$, $d(i,k)$ is updated by $d(i,j)$ and (j,k). $d(i,j)$ is already visited before because it has prefix $[y][0]$. $d(i,k)$ will be visited later because it has prefix $[y][1]$. ◀

▶ **Lemma 10.** *If (j,k) is in $\Gamma_{[y]}$ for some prefix $[y]$ of $[z]$, and $d(i,j)$ is correctly computed before visited, then $d(i,k)$ is also correctly computed before visited.*

Proof. Since $[y]$ is a prefix of both $[OPT(i,j)]$ and $[w(j,k)]$, the initialization for $\Gamma_{[y]}$ is done at Line 5 when $[x] = [y][000\cdots0]$. After that, $d(i,k)$ is updated when we visit $d(i,j)$ at Line 13. $d(i,k)$ is not visited yet because $OPT(i,k) > OPT(i,j)$. ◀

▶ **Lemma 11.** *All $d(i,j)$ are correctly computed before visited.*

Proof. This follows from a simple induction. In the base case, for all length 1 optimal paths $OPT(i,j)$, they are obviously correctly computed in Line 1. Then if all length $l-1$ paths $OPT(i,j)$ are correctly computed before visited, by Lemma 8, 9, 10, all length l paths $OPT(i,j)$ are also correctly computed before visited. ◀

4.3 Running time

▶ **Lemma 12.** *The relaxation for low edges ($L_{[x]}$) takes $\tilde{O}\left(n^{3-t}\right)$ time in total. (Line 12)*

Proof. At Line 12, we only enumerate $O(n^{1-t})$ many edges because j has low outdegree in $L_{[y]}$. Since there are only $b = O(\log n)$ many prefix $[y]$ for each $[d(i,j)]$, each $d(i,j)$ takes $\tilde{O}(n^{1-t})$ time. So in total, these updates take $\tilde{O}(n^{3-t})$ time for all $O(n^2)$ many $d(i,j)$. ◀

▶ **Lemma 13.** *The relaxation for high-high edges and high-low edges besides matrix multiplication takes $\tilde{O}\left(n^{3-t}\right)$ time in total.*

Proof. By Lemma 4 and Lemma 6, for each $[y]$, the complexity for relaxation is bounded by $(n_{[y]} + n_{[y][1]})n^{1-t} = O\left(n_{[y]}n^{1-t}\right)$, where $n_{[y]}$ stands for the number of optimal paths with prefix $[y]$. Since an optimal path can be counted in $O(\log n)$ many $n_{[y]}$, the total time is therefore $\tilde{O}(n^{3-t})$. ◀

▶ **Lemma 14.** *The matrix multiplication parts for high-high edge updates and the initialization of high-low edge updates take $\tilde{O}\left(n^{t+\omega}\right)$ time in total.*

Proof. By Lemma 5 and Lemma 7, the complexity for matrix multiplication is at most $M\left(n, \min\left(\frac{2^{b-|[y]|}}{n^{1-t}}, n\right), \frac{2^{b-|[y]|}}{n^{1-t}}\right)$ for each $[y]$. We fix the length of $[y]$, denoted by $l = |[y]|$, then consider the two cases:

- $2^l < n^t$: There are at most 2^l many such $[y]$, and each takes

$$M\left(n, n, \frac{2^{b-l}}{n^{1-t}}\right) = O\left(\frac{n^2 \cdot \frac{2^{b-l}}{n^{1-t}}}{n^{3-\omega}}\right) = O\left(n^{t+\omega} \cdot 2^{-l}\right)$$

  This follows from both Lemma 3 and the fact that $2^b = |E| = O(n^2)$. For each l, the time complexity is exactly $O(n^{t+\omega})$. So the total complexity is $\tilde{O}(n^{t+\omega})$ since $l = O(\log_2(n))$.
- $2^l \geq n^t$: There are at most 2^l many such $[y]$. Each takes

$$\begin{aligned} M\left(n, \frac{2^{b-l}}{n^{1-t}}, \frac{2^{b-l}}{n^{1-t}}\right) &= O\left(n \cdot \left(\frac{2^{b-l}}{n^{1-t}}\right)^{2-(3-\omega)}\right) \\ &= O\left(n^{(t+1)(\omega-1)+1} \cdot 2^{-l(\omega-1)}\right) \end{aligned}$$

So for all $[y]$ of length l, it takes $O\left(n^{(t+1)(\omega-1)+1} \cdot 2^{-l(\omega-2)}\right)$ time. The term $2^{-l(\omega-2)}$ is maximized when l is minimized, so $2^{-l(\omega-2)} \leq n^{-t(\omega-2)}$, and the total time for all lengths of $[y]$ is

$$\tilde{O}\left(n^{(t+1)(\omega-1)+1-t(\omega-2)}\right) = \tilde{O}\left(n^{t+\omega}\right)$$ ◀

▶ **Theorem 15.** *The All Pair Non-decreasing Paths (APNP) problem on directed simple graphs can be solved in* $\tilde{O}\left(n^{\frac{3+\omega}{2}}\right)$ *time. The optimal path of length* l *between any two vertices can also be explicitly found in* $O(l)$ *time if we slightly modify the algorithm.*

Proof. We choose $t = \frac{3-\omega}{2}$. The running time of this algorithm follows from previous lemmas. Since all optimal paths $OPT(i,k)$ are obtained by relaxation of edges (j,k), we can store the last edge (j,k) for each $OPT(i,k)$, so retrieving the optimal path can be done in $O(l)$ time. ◀

Faster Approximation Algorithms for Computing Shortest Cycles on Weighted Graphs

Abstract

Given an n-vertex m-edge graph G with non-negative edge-weights, a *shortest cycle* of G is one minimizing the sum of the weights on its edges. The *girth* of G is the weight of such a shortest cycle. We obtain several new approximation algorithms for computing the girth of weighted graphs:

- For any graph G with polynomially bounded integer weights, we present a deterministic algorithm that computes, in $\tilde{\mathcal{O}}(n^{5/3} + m)$-time[1], a cycle of weight at most twice the girth of G. This matches both the approximation factor and – almost – the running time of the best known subquadratic-time approximation algorithm for the girth of *unweighted* graphs.
- Then, we turn our algorithm into a deterministic $(2+\varepsilon)$-approximation for graphs with arbitrary non-negative edge-weights, at the price of a slightly worse running-time in $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}(1/\varepsilon) + m)$. For that, we introduce a generic method in order to obtain a polynomial-factor approximation of the girth in subquadratic time, that may be of independent interest.
- Finally, if we assume that the adjacency lists are sorted then we can get rid off the dependency in the number m of edges. Namely, we can transform our algorithms into an $\tilde{\mathcal{O}}(n^{5/3})$-time *randomized* 4-approximation for graphs with non-negative edge-weights. This can be derandomized, thereby leading to an $\tilde{\mathcal{O}}(n^{5/3})$-time deterministic 4-approximation for graphs with polynomially bounded integer weights, and an $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}(1/\varepsilon))$-time deterministic $(4+\varepsilon)$-approximation for graphs with non-negative edge-weights.

To the best of our knowledge, these are the first known *subquadratic-time* approximation algorithms for computing the girth of weighted graphs.

1 Introduction

The exciting program of "Hardness in P" aims at proving (under plausible complexity theoretic conjectures) the *exact* time-complexity of fundamental, polynomial-time solvable problems in computer science. In this paper, we consider the Girth problem on edge-weighted undirected graphs, for which almost all what is known in terms of finer-grained complexity

[1] The $\tilde{\mathcal{O}}(\cdot)$ notation suppresses polylogarithmic factors.

only holds for dense graphs ($m = \Omega(n^2)$). We recall that the girth of a given graph G is the minimum weight of a cycle in G – with the weight of a cycle being defined as the sum of the weights on its edges (see Sec. 2 for any undefined terminology in this introduction). For dense graphs this parameter can be computed in time $\mathcal{O}(n^3)$, and Vassilevska Williams and Williams [19] proved a bunch of combinatorial subcubic equivalences between Girth and other path and matrix problems. In particular, for every $\varepsilon > 0$, there cannot exist any *combinatorial* $(4/3 - \varepsilon)$-approximation algorithm for Girth that runs in truly subcubic time unless there exists a truly subcubic combinatorial algorithm for multiplying two boolean matrices. Roditty and Tov completed this above hardness result with an $\tilde{\mathcal{O}}(n^2/\varepsilon)$-time $(4/3 + \varepsilon)$-approximation algorithm [15], thereby essentially completing the picture of what can be done combinatorially in subcubic time. However, the story does not end here for at least two reasons. A first simple but important observation is that as the graphs considered get sparser, the complexity for computing their girth falls down to $\mathcal{O}(n^2)$. In fact, when the edge-weights are integers bounded by some constant M, there is a non-combinatorial algorithm for computing the girth of *any* n-vertex graph G in time $\tilde{\mathcal{O}}(Mn^\omega)$ where ω stands for the the exponent of square matrix multiplication over a ring [16]. It is widely believed that $\omega = 2$ [13], and if true, that would imply we can compute the *exact* value of the girth in quasi *quadratic* time – at least when edge-weights are bounded. So far, all the *approximation* algorithms for Girth on weighted graphs run in $\tilde{\Omega}(n^2)$-time [10, 15]. This leads us to the following, natural research question:

Does there exist a subquadratic approximation algorithm for Girth *on weighted graphs?*

In this paper, we answer to this above question in the affirmative.

1.1 Our contributions

We present new approximation algorithms for the girth of graphs with non-negative real edge-weights. These are the first algorithms to break the quadratic barrier for this problem – at the price of a slightly worse approximation factor compared to the state of the art [15] – see Sec. 1.2 on the Related work for more details. Our first result is obtained for graphs with bounded integer edge-weights.

▶ **Theorem 1.** *For every $G = (V, E, w)$ with edge-weights in $\{1, \ldots, M\}$, we can compute a deterministic 2-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}M + m)$.*

Our starting point for Theorem 1 is a previous 2-approximation algorithm from Lingas and Lundell [10], that runs in *quadratic* time. Specifically, these two authors introduced an $\tilde{O}(n \log M)$-time procedure that takes as entry a specified vertex of the graph and needs to be applied to *every* vertex in order to obtain the desired 2-approximation of the girth. Inspired by the techniques used for approximate distance oracles [18] we informally modify their algorithm as follows. We only apply their procedure to the vertices in a *random* subset S: where each vertex is present with equal probability $n^{-1/3}$ (we can derandomize our approach by using known techniques from the litterature [14]). Furthermore, for the vertices not in S, we rather apply a modified version of their procedure that is restricted to a small subgraph – induced by some ball of expected size $\mathcal{O}(n^{1/3})$. A careful analysis shows this is a 2-approximation. The reason why this above approach works is that, when we run the procedure of Lingas and Lundell at some arbitrary vertex s, it will always detect a short cycle if there is one passing *close* to s (but not necessarily passing through s itself). This nice property has been noticed and exploited for related algorithms on *unweighted*

graphs [10][2]. However, we think we are the first to prove such a property in the weighted case. We note that one of the two algorithms proposed by Roditty and Tov in [15] also satisfies such a property. We did not find a way to exploit their algorithm in order to improve our approximation factor.

Our approach for graphs with bounded integer edge-weights (see Sec. 3.2) is the cornerstone of all our other results in the paper. We considerably refine this approach so that it also applies to graphs with *arbitrary* non-negative edge-weights.

▶ **Theorem 2.** *For every $\varepsilon > 0$ and $G = (V, E, w)$ with non-negative edge-weights, we can compute a deterministic $(2+\varepsilon)$-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}1/\varepsilon + m)$.*

We note that in [15], Roditty and Tov introduced a nice technique – that we partly reuse in this paper – in order to transpose their results for bounded integer-weights to arbitrary weights. However, we face several new difficulties, not encountered in [15], due to the need to perform all the intermediate operations in *subquadratic* time. As a side contribution of this work, we present an intricate modification of our approach for graphs with bounded integer edge-weights that we use in order to approximate the girth of graphs with arbitrary non-negative edge-weights up to a polynomial-factor. This subquadratic-time routine could be useful to anyone improving our result for the graphs with integer-weights in order to generalize their results to the graphs with non-negative real weights.

Our algorithms are subquadratic in the size of the graph, but they may be quadratic in its order n if there are $m = \Theta(n^2)$ edges. By a folklore application of Moore bounds, any unweighted graph with $\mathcal{O}(n^{1+\frac{1}{\ell}})$ edges has girth at most 2ℓ, and so, we can always output a constant upper-bound on the girth of moderately dense graphs. It implies that the dependency on m can always be removed in the running-time of approximation algorithms for the girth of *unweighted* graphs. However, in the full version of this paper, we prove by using elementary arguments that any approximation algorithm for the girth on weighted graphs must run in $\Omega(m)$-time. We study what happens if we have *sorted* adjacency lists[3].

▶ **Theorem 3.** *Let $G = (V, E, w)$ have sorted adjacency lists.*

1. *If all edge-weights are in $\{1, \ldots, M\}$ then, we can compute a deterministic 4-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}M)$.*
2. *If all edge-weights are non-negative then, we can compute a* randomized *4-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3})$. For every $\varepsilon > 0$, we can also compute a deterministic $(4+\varepsilon)$-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}1/\varepsilon)$.*

We observe that even assuming sorted adjacency lists, it is not clear whether the algorithm of Theorem 1 can be implemented to run in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}M)$. Indeed, this algorithm requires to build several induced subgraphs in time roughly proportional to their size, that requires a different preprocessing on the adjacency lists. We prove that we do not need to construct these induced subgraphs *entirely* in order to derive a constant-factor approximation of the girth. Similarly, for graphs with non-negative edge-weights we cannot use our polynomial-factor approximation algorithm for the girth directly, as it needs to enumerate all edges in the graph. We overcome this difficulty through the help of a classical density result for the C_4-free *unweighted* graphs [4].

[2] There is a subtle difference between our approach for weighted graphs and the one formerly applied to unweighted graphs. Indeed, we need to consider all edges in the *subgraphs* that are induced by some small balls in the graph, that might include some large-weight edges not on any shortest-path in G. For unweighted graphs [10, 16], they mostly consider edges on some shortest-paths in G between a pre-defined vertex and the other vertices in the ball.

[3] Throughout this paper, we call an adjacency list *sorted* if it is sorted by edge-weight, and *ordered* if it is sorted by neighbour index. See also Sec. 2.

1.2 Related work

Approximation algorithms for the girth. Itai and Rodeh were the first to study the Girth problem for *unweighted* graphs [9]. Among other results, they showed how to compute an additive +1-approximation of the girth in time $\mathcal{O}(n^2)$. This was later completed by Lingas and Lundell [10], who proposed a randomized quasi 2-approximation algorithm for this problem that runs in time $\mathcal{O}(n^{3/2}\sqrt{\log n})$. In [17], Roditty and Vassilevska Williams presented the first deterministic approximation algorithm for the girth of unweighted graphs. Specifically, they obtained a 2-approximation algorithm in time $\tilde{\mathcal{O}}(n^{5/3})$, and they conjectured that there does not exist any subquadratic $(2-\varepsilon)$-approximation for Girth. We obtain the same approximation factor for weighted graphs, and we almost match their running time up to polylog factors and to an additional term in $\tilde{O}(m)$. It would be interesting to know whether in our case, this dependency on m can be removed while preserving the approximation factor 2. Very recently, new subquadratic-time approximation algorithms were proposed for Girth in unweighted graphs (see [7]). It is open whether one can achieve a constant-factor approximation for the girth in, say, $\tilde{\mathcal{O}}(n^{1+o(1)})$-time.

Much less is known about the girth of weighted graphs. The first known subcubic approximation was the one of Lingas and Lundell [10], that only applies to graphs with bounded integer edge-weights. Their work somewhat generalizes the algorithm of Itai and Rodeh for unweighted graphs. The approximation factor was later improved to 4/3 by Roditty and Tov, still for the graphs with bounded integer weights, and to $4/3+\varepsilon$ for the graphs with *arbitrary weights* [15]. Our algorithms in this paper are faster than these two previous algorithms, but they use the latter as a routine to be applied on several subgraphs of sublinear size. Therefore, the approximation factors that we obtain cannot outperform those obtained in [10, 15].

More recently, a breakthrough logarithmic approximation of the girth of *directed* weighted graphs was obtained in [11].

Approximate distances. Finally, approximation algorithms for the girth are tightly related to the computation of approximate distances in weighted graphs. In a seminal paper [18], Thorup and Zwick showed that we can compute in expected time $\mathcal{O}(mn^{1/k})$ an approximate distance oracle: that can answer any distance query in time $\mathcal{O}(k)$ with a multiplicative stretch at most $2k-1$. This has been improved in several follow-ups [2, 5, 12, 14, 20]. However, the construction of most oracles already takes (super)quadratic time for moderately dense graphs. A key observation is that we do not need to construct these oracles *entirely* if we just want to approximate the girth. This allows us to avoid a great deal of distance computations, and so, to lower the running time.

1.3 Organization of the paper

We start gathering in Section 2 some known results from the literature that we will use for our algorithm. Then, in Section 3, we give some new insights on the algorithm of Lingas and Lundell [10] before presenting our main result (Theorem 1). Our algorithm is generalized to graphs with arbitrary weights in Section 4. Finally, we remove the dependency on the number of edges in the time complexity of our algorithms in Section 5. We conclude this paper with some open perspectives (Section 6). Due to space restrictions, some of the proofs are omitted. Full proofs can be found in our technical report [8].

2 Preliminaries

We refer to [3] for any undefined graph terminology. Graphs in this study are finite, simple (hence, without any loop nor multiple edges), connected and edge-weighted. Specifically, we denote a weighted graph by a triple $G = (V, E, w)$ where $w : E \to \mathbb{R}^+$ is the edge-weight function of G. The weight of a subgraph $H \subseteq G$, denoted $w(H) := \sum_{e \in E(H)} w_e$, is the sum of the weights on its edges. The girth of G is the minimum weight of a cycle in G. The distance $dist_G(u, v)$ between any two vertices $u, v \in V$ is the minimum weight of an uv-path in G. By extension, for every $v \in V$ and $S \subseteq V$ we define $dist_G(v, S) := \min_{u \in S} dist_G(u, v)$. – We will sometimes omit the subscript if no ambiguity on the graph G can occur. – For any $v \in V$ and $r \geq 0$, we also define the ball $B_G(v, r) := \{u \in V \mid dist_G(u, v) \leq r\}$. Finally, an r-nearest set for v is any r-set $\mathcal{N}_r(v)$ such that, for any $x \in \mathcal{N}_r(v)$ and $y \notin \mathcal{N}_r(v)$, we have $dist_G(v, x) \leq dist_G(v, y)$.

For every $v \in V$, let $N_G(v) = \{u \in V \mid uv \in E\}$ be the (open) neighbourhood of vertex v and let $d_v = |N_G(v)|$ be its degree. Let $Q_v = \{vu \mid u \in N_G(v)\}$ be totally ordered. We call it a *sorted* adjacency list if edges incident to v are ordered by increasing weight, *i.e.*, $Q_v = (vu_1, vu_2, \ldots, vu_{d_v})$ and $w_{vu_i} \leq w_{vu_{i+1}}$ for every $i < d_v$. However, we call it an *ordered* adjacency list if, given some fixed total ordering $\prec$ over V the neighbours of v are ordered according to $\prec$ (*i.e.*, $u_i \prec u_{i+1}$ for every $i < d_v$). Throughout the rest of the paper we will assume that each vertex has access to two copies of its adjacency list: one being sorted and the other being ordered. The latter can always be ensured up to an $\tilde{O}(m)$-time preprocessing.

2.1 The Hitting Set method

We gather many well-known facts in the literature, that can be found, *e.g.*, in [14, 18, 1, 6]. All these facts are combined in order to prove the following useful result for our algorithms:

▶ **Proposition 4.** *For any graph $G = (V, E, w)$ with* sorted *adjacency lists, in $\tilde{O}(n^{5/3})$-time we can compute a set $S \subseteq V$, and the open balls $B_S(v) := \{u \in V \mid dist(v, u) < dist(v, S)\}$ for every $v \in V$, such that the following two properties hold true:*

1. $|S| = \tilde{\mathcal{O}}(n^{2/3})$;
2. *and for every $v \in V$ we have $|B_S(v)| = \mathcal{O}(n^{1/3})$.*

It is well-known that a set S as requested by Proposition 4 can be constructed *randomly* as follows: every vertex in V is added in S with equal probability $n^{-1/3}$ [18]. This construction was derandomized in [14, 18, 1, 6]. In what follows we will not only need the balls $B_S(v)$ for every vertex v, but also the subgraphs these balls induce in G. Next, we observe that all these subgraphs can be obtained almost for free. Namely:

▶ **Lemma 5** (folklore). *For every $G = (V, E, w)$ and $U \subseteq V$ we can compute the subgraph $G[U]$ induced by U in time $\tilde{\mathcal{O}}(|U|^2)$ (assuming* ordered *adjacency lists).*

3 Case of graphs with bounded integer weights

This section is devoted to the proof of Theorem 1. We start presenting some new properties of a previous approximation algorithm for the girth of weighted graphs (Section 3.1) as we will need to use them in our own algorithm. Then, we prove our main result for graphs with bounded integer weights in Section 3.2.

3.1 Reporting a close short cycle

We propose a deeper analysis of an existing approximation algorithm for GIRTH on weighted graphs [10]. Roughly, this algorithm applies a same procedure to every vertex of the graph. In order to derive the approximation factor of their algorithm, the authors in [10] were considering a run that takes as entry some vertex *on a shortest cycle*. This is in contrast with the classical algorithm from Itai and Rodeh on unweighted graphs [9], that also offers provable guarantees on the length of the output assuming there is a shortest cycle passing *close* to the source (but not necessarily passing by this vertex); see [10, Lemma 2]. We revisit the analysis of the algorithm in [10] for weighted graphs, and we prove that this algorithm also satisfies such a "closeness property".

The HBD-algorithm from [10]. Given $G = (V, E, w)$, $s \in V$ and $t \geq 0$, the algorithm $HBD(G, s, t)$ is a relaxed version of Dijkstra's single-source shortest-path algorithm. We are only interested in computing the ball of radius t around s, and so, we stop if there are no more unvisited vertices at a distance $\leq t$ from s. Furthermore, whenever we visit a vertex $u \in B_G(s, t)$, we only relax edges $e = \{u, v\}$ such that $dist(s, u) + w_e \leq t$. Then, a cycle is detected if we already inferred that $dist(s, v) \leq t$ (*i.e.*, using another neighbour of v than u). Overall, the algorithm stops as soon as it encounters a cycle, or all the vertices in $B_G(s, t)$ were visited. Assuming sorted adjacency lists, this algorithm runs in $\tilde{\mathcal{O}}(n)$-time [10].

(a) `HBD`(G, s, t).

```
1: for all v ∈ V do
2:     d(v) ← ∞; π(v) ← NIL
3: d(s) ← 0; Q ← {s}
4: while Q ≠ ∅ do
5:     u ← Extract-min(Q)
6:     Controlled-Relax(u, t)
```

(b) `Controlled-Relax`(u, t).

```
1: Q_u ← sorted adj. list
2: uv ← Extract-min(Q_u)
3: while d(u) + w_uv ≤ t do
4:     RelaxOrStop(u, v)
5:     uv ← Extract-min(Q_u)
```

(c) `RelaxOrStop`(u, v).

```
1: if d(v) ≠ ∞ then
2:     return a cycle and stop
3: else
4:     d(v) ← d(u) + w_uv
5:     Q ← Q ∪ {v}
```

▶ **Lemma 6** ([10]). *If HBD(G, s, t) detects a cycle, then its weight is $\leq 2t$.*

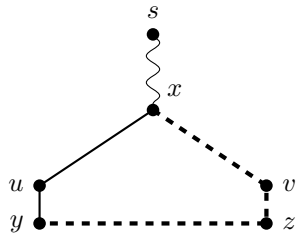
We now complete the analysis of the `HBD`-algorithm in order to derive a generalization of [10, Lemma 2] to weighted graphs. Assuming no cycle has been detected, we first gain more insights on the structure of the ball of radius t centered at s.

▶ **Lemma 7.** *If HBD(G, s, t) does not detect a cycle then, for any $v \in B_G(s, t)$, there exists a unique sv-path of weight $\leq t$.*

Based on Lemma 7, we state some bounds on the weight of the cycle detected using `HBD`. In particular, Corollary 9 will play a key role in the analysis of our algorithms.

▶ **Corollary 8.** *Given $G = (V, E, w)$, let $s \in V$ and let C be a cycle. The minimum t_0 such that HBD(G, s, t_0) detects a cycle satisfies $t_0 \leq dist(s, C) + w(C)$.*

▶ **Corollary 9.** *Given $G = (V, E, w)$, let $s \in V$ and let C be a cycle. Assume the existence of a vertex $x \in V(C)$ such that $\max_{v \in V(C)} dist_C(x, v) \geq dist_G(s, x) > 0$. Then, the minimum t_0 such that HBD(G, s, t_0) detects a cycle satisfies $t_0 \leq w(C)$.*



Proof. Let $B_x = \{v \in V(C) \mid dist_C(x,v) < dist_G(x,s)\}$. Since we assume that we have $\max_{v \in V(C)} dist_C(x,v) \geq dist_G(x,s)$, $B_x \neq V(C)$. Hence there exist $uy, vz \in E(C)$ distinct such that $u, v \in B_x$ but $y, z \notin B_x$. W.l.o.g. $dist_C(x,y) \leq dist_C(x,z)$. We can bipartition $E(C)$ in two edge-disjoint xy-paths P_1 and P_2, with P_1 being the xy-subpath passing by vz (and so, P_2 is the other xy-subpath passing by uy). Note that it implies $dist_C(x,y) = w(P_2) \leq w(C)/2$. Then, by Lemma 7 we have $t_0 \leq dist_G(s,x) + \max\{w(P_1), w(P_2)\} = dist_G(s,x) + w(P_1) \leq dist_C(x,y) + w(P_1) = w(P_2) + w(P_1) = w(C)$. ◀

3.2 Subquadratic-time approximation

Proof of Theorem 1. We analyse the following `Subquadratic-Approx` algorithm:

(a) `Approx-Girth`(G, s, M).

1: Find the minimum $t \in [3; M \cdot |V(G)|]$ such that: `HBD`(G, s, t) detects a cycle.
2: Let C_s be the shortest cycle we so computed.
3: **return** C_s.

(b) `Subquadratic-Approx`(G, M).

1: Let S and $(B_S(v))_{v \in V}$ be as in Prop. 4.
2: **for all** $s \in S$ **do**
3: $\quad C_s \leftarrow$ `Approx-Girth`(G, s, M)
4:
5: **for all** $v \notin S$ **do**
6: $\quad$ Let G'_v be induced by $B_S(v)$.
7: $\quad C_v \leftarrow$ `Approx-Girth`(G'_v, v, M)
8:
9: **return** a shortest cycle in $\{C_v \mid v \in V\}$.

The algorithm starts precomputing a set $S \subseteq V$ and the open balls $(B_S(v))_{v \in V}$ as described in Proposition 4. This takes time $\tilde{\mathcal{O}}(n^{5/3})$, plus an additional preprocessing time in $\tilde{O}(m)$ for sorting the adjacency lists. Then, we process the vertices in S and those in $V \setminus S$ separately: For every $s \in S$, we compute the smallest $t_s \in [3; Mn]$ such that `HBD`(G, s, t_s) detects a cycle by using a dichotomic search (procedure `Approx-Girth`(G, s, M)). We store the cycle C_s outputted by `HBD`(G, s, t_s). Since each test we perform during the dichotomic search consists in a call to the `HBD`-algorithm, this takes time $\tilde{\mathcal{O}}(n \log M)$ per vertex in S, and so, $\tilde{\mathcal{O}}(n|S| \log M) = \tilde{\mathcal{O}}(n^{5/3} \log M)$ in total. We now consider the vertices $v \in V \setminus S$ sequentially. Let G'_v be the subgraph of G induced by the open ball $B_S(v)$. By Lemma 5, this subgraph can be computed in time $\tilde{\mathcal{O}}(|B_S(v)|^2) = \tilde{\mathcal{O}}(n^{2/3})$ – assuming a preprocessing of the graph in time $\mathcal{O}(m)$ for ordering the adjacency lists. We apply the same procedure as for the vertices in S but, we restrict ourselves to the ball $B_S(v)$. That is, we call `Approx-Girth`(G'_v, v, M), and we denote by C_v the cycle outputted by this algorithm. Since we restrict ourselves to a subgraph of order $\mathcal{O}(n^{1/3})$, this takes total time $\tilde{\mathcal{O}}(n \cdot (n^{2/3} + n^{1/3} \log M)) = \tilde{\mathcal{O}}(n^{5/3} \log M)$.

Let $C \in \{C_v \mid v \in V\}$ be of minimum weight. We claim that $w(C)$ is a 2-approximation of the girth of G, that will end proving the theorem. In order to prove this claim, we apply the following case analysis to some arbitrary shortest cycle C_0 of G. If $V(C_0) \cap S \neq \emptyset$ then, let C_S be a shortest cycle among $\{C_s \mid s \in S\}$. We prove as a subclaim that $w(C_S)$ is at most twice the weight of a shortest cycle intersecting S. In order to prove this subclaim,

it suffices to prove that for every $s \in S$, we compute a cycle C_s of weight no more than twice the weight of a shortest cycle passing by s. By Corollary 8, if t_s is the smallest t such that $HBD(G, s, t)$ detects a cycle then, a shortest cycle C passing by s must have weight $\geq t_s$. Furthermore, by Lemma 6 we get $w(C_s) \leq 2t_s$, thereby proving the subclaim. Thus, $w(C_S) \leq 2w(C_0)$ if $V(C_0) \cap S \neq \emptyset$. From now on we assume $V(C_0) \cap S = \emptyset$. Let $v \in V(C_0)$ be arbitrary. There are two subcases:

- If $V(C_0) \subseteq B_S(v)$ then, C_0 is also a cycle in G'_v. Moreover by Corollary 8 applied for $dist(v, C_0) = 0$, the smallest t_v such that $\texttt{HBD}(G'_v, v, t_v)$ detects a cycle satisfies $t_v \leq w(C_0)$. By Lemma 6, $w(C) \leq w(C_v) \leq 2w(C_0)$.
- Otherwise $V(C_0) \not\subseteq B_S(v)$. This implies that we have: $\max_{u \in V(C_0)} dist_{C_0}(u, v) \geq \max_{u \in V(C_0)} dist_G(u, v) \geq dist_G(v, S) > 0$. Furthermore, let $s \in S$ minimize $dist_G(s, v)$. Then, by Corollary 9, the smallest t_s such that $\texttt{HBD}(G, s, t_s)$ detects a cycle satisfies $t_s \leq w(C_0)$. As a result, by Lemma 6 $w(C) \leq w(C_s) \leq 2w(C_0)$.

Summarizing, $w(C) \leq 2w(C_0)$ in all the cases. ◀

4 Generalization to unbounded weights

This section is devoted to the proof of Theorem 2. We divide it into two parts. In Section 4.1 we present a *polynomial-factor* approximation of the girth in subquadratic time. This part is new compared to [15] and the techniques used are interesting in their own right. Then, based on a clever technique from [15], we end up refining this rough estimate of the girth until we obtain a constant-factor approximation (Section 4.2).

Throughout this section, we will use the main result of Roditty and Tov as a subroutine:

▶ **Theorem 10** ([15]). *For every $G = (V, E, w)$ with arbitrary non-negative edge-weights, we can compute a $(4/3 + \varepsilon)$-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^2/\varepsilon)$.*

4.1 A polynomial-factor approximation

For simplicity, we first reduce the general case of graphs with non-negative weights to the subcase of graphs with positive weights. We omit the proof as it quite similar, but simpler, to the one of Proposition 12 (presented next).

▶ **Lemma 11.** *Assume there exists an $T(n, m)$-time α-approximation algorithm for* Girth *for graphs with positive edge-weights, where $T(n, m) = \Omega(m)$. Then, there also exists an $\mathcal{O}(T(n, m))$-time α-approximation algorithm for* Girth *for graphs with non-negative edge-weights.*

We now obtain an approximation of the girth that only depends on the order of the graph. We stress that for weighted graphs, this is already a non-trivial task.

▶ **Proposition 12.** *For every $G = (V, E, w)$ with arbitrary positive edge-weights, we can compute an $\tilde{\mathcal{O}}(n^{2/3})$-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3} + m)$.*

Proof. Let S be as in Proposition 4. We show a significantly more elaborate method that uses S in order to approximate the girth. We divide this method into five main steps.

Step 1: check the small balls. For every $v \notin S$, let G'_v be the subgraph induced by the open ball $B_S(v)$. As before, we first estimate the girth of G'_v. Since this subgraph has order $\mathcal{O}(n^{1/3})$, by Theorem 10 we can compute a constant-factor approximation for its girth in time $\tilde{\mathcal{O}}(n^{2/3})$ (say, a 2-approximation). Overall, this step takes total time $\tilde{\mathcal{O}}(n^{5/3})$. Furthermore, after completing this step the following property (also used in Theorem 1) becomes true:

▷ Claim 13. Let C_v be a shortest cycle passing through v. If $w(C_v) < 2 \cdot dist(v, S)$ then, we computed a cycle of weight $\leq 2w(C_v)$.

Step 2: partitioning into (shortest path) subtrees. Intuitively, what we try to do next is to approximate the weight of a shortest cycle passing close to S. The difference with Theorem 1 is that we cannot use directly the algorithm of Roditty and Tov for that. Indeed, their algorithm has some global steps (*e.g.*, the approximate computation of the girth of some sparse spanner) that we currently do not know how to do in subquadratic time. So, we need to find some new techniques. Specifically, we partition the vertex-set V into shortest-path subtrees $(T_s)_{s \in S}$ such that, for every $s \in S$ and $v \in V(T_s)$ we have $dist(v, s) = dist(v, S)$. As noted, *e.g.*, in [18], a simple way to do that is to add a dummy vertex $x_S \notin V$, edges sx_S for every $s \in S$ with weight 0, then to compute a shortest-path tree rooted at x_S in time $\tilde{\mathcal{O}}(m)$. See Fig. 3 for an example. In what follows, we show how to use this tree structure in order to compute short cycles.

Figure 3 An example of Step 2. The two vertices in S are drawn as rectangles.

Step 3: finding short cycles in a subtree. Let $s \in S$ be fixed. Informally, we try to estimate the weight of a shortest cycle in $V(T_s)$. Note that every such a cycle has an edge that is not contained in T_s. So, we consider all the edges $e = uv$ such that $u, v \in V(T_s)$ but $e \notin E(T_s)$. Adding this edge in T_s closes a cycle. Let $C_{e,s}$ be an (unknown) shortest cycle passing by e and contained in $V(T_s)$. We output $dist(s, u) + w_e + dist(v, s)$ as a rough estimate of $w(C_{e,s})$. Indeed, the latter is a straightforward upper-bound on $w(C_{e,s})$, and this bound is reached if $s \in \{u, v\}$. Overall, this step takes total time $\mathcal{O}(m)$.

▷ Claim 14. Let C^*_s be a shortest cycle contained in $V(T_s)$. After Steps 1-3, we computed a cycle of weight $\leq 2w(C^*_s)$.

Step 4: finding short cycles in two subtrees. We now want to estimate the weight of a shortest cycle in $V(T_s) \cup V(T_{s'})$, for some distinct $s, s' \in S$. We only need to consider the case where this cycle must contain two edges e, e' with an end in $V(T_s)$ and the other end in $V(T_{s'})$ (all other cases have already been considered at Step 3).

1. We scan all the edges $e = uv \in E$ such that u and v are not in a same subtree. Let $s_u, s_v \in S$ such that $u \in V(T_{s_u}), v \in V(T_{s_v})$. We set $\ell(e) = dist(s_u, u) + w_e + dist(v, s_v)$.
2. Group all these above edges with their two ends in the same two subtrees. It takes time $\mathcal{O}(m + |S|) = \mathcal{O}(m + n^{2/3})$ by using, say, a linear-time sorting algorithm.
3. Finally, for every distinct $s, s' \in S$, let $E(s, s')$ contain all the edges with one end in T_s and the other end in $T_{s'}$. If $|E(s, s')| \geq 2$ then, we pick e, e' minimizing $\ell(\cdot)$ and we output $\ell(e) + \ell(e')$. Overall, since the sets $E(s, s')$ partition the edges of G, this last phase also takes time $\mathcal{O}(m)$.

▷ Claim 15. Let $s, s' \in S$ be distinct and let $C^*_{s,s'}$ be a shortest cycle contained in $V(T_s) \cup V(T_{s'})$. After Steps 1-4, we computed a cycle of weight $\leq 3w(C^*_{s,s'})$.

Step 5: the general case. We end up defining a weighted graph $H_S = (S, E_S, w^S)$, where $E_S = \{ss' \mid E(s,s') \neq \emptyset\}$, and for every $ss' \in E_S$:

$$w^S_{ss'} = \min_{e \in E(s,s')} \ell(e) = \min_{uv \in E(s,s')} dist(s,u) + w_{uv} + dist(v,s').$$

Roughly, $w^S_{ss'}$ is the smallest weight of an ss'-path with one edge in $E(s,s')$. We can construct H_S simply by scanning all the sets $E(s,s')$ (computed during Step 4). Overall, since the sets $E(s,s')$ partition the edges of G, this takes total time $\mathcal{O}(m+|S|) = \mathcal{O}(m+n^{2/3})$. Furthermore, by Theorem 10 we can compute a constant-factor approximation of the girth of H_S in time $\tilde{\mathcal{O}}(|S|^2) = \tilde{\mathcal{O}}(n^{4/3})$. The graph H_S is *not* a subgraph of G. However, given a cycle C_H for H_S, we can compute a cycle C^*_H of G as follows. For every $s \in V(C_H)$ let $s', s'' \in V(C_H)$ be its two neighbours. By construction, there exist $e = uv \in E(s',s)$ and $e' = xy \in E(s,s'')$ such that the edges ss' and ss'' in H_S have weights $dist(s',u) + w_e + dist(v,s)$ and $dist(s,x) + w_{e'} + dist(y,s'')$, respectively. – We may assume the edges e, e' to be stored in H_S so that s', s'' will choose the same common edge with s. – Then, we replace s by the vx-path in T_s. It is important to notice that, by construction, we have $w(C^*_H) \leq w(C_H)$. In particular, we can apply this above transformation to the (approximately shortest) cycle of H_S that has been outputted by the algorithm of Roditty and Tov (Theorem 10).

Overall, let $C_{\min}$ be a shortest cycle computed by the algorithm above (*i.e.*, after Steps 1-5). In order to finish the proof, we need to show that $w(C_{\min})$ is an $\tilde{\mathcal{O}}(n^{2/3})$-approximation of the girth of G. By Claims 14 and 15, this is the case if there exists a shortest cycle intersecting at most two subtrees $T_s, s \in S$. From now on assume that any shortest cycle C_0 of G intersects at least three subtrees T_s. Write $C_0 = (v_0, v_1, \ldots, v_{p-1}, v_0)$ and assume w.l.o.g. v_0, v_{p-1} are not contained into the same subtree T_s. We partition the v_i's into the maximal subpaths $P_0, P_1, \ldots, P_{q-1},\ q \leq p$ that are contained into the vertex-set of a same subtree T_s (in particular, $v_0 \in V(P_0)$ and $v_{p-1} \in V(P_{q-1})$). Furthermore for every $j \in \{0,1,\ldots,q-1\}$ let $s_j \in S$ be such $V(P_j) \subseteq V(T_{s_j})$, and let i_j be the largest index such that $v_{i_j} \in V(P_j)$. For instance, $i_{q-1} = p-1$ by construction. Since $P_0 = P_q$ and $q \geq 3$ by the hypothesis, there exist distinct indices j_1, j_2 such that $s_{j_1} = s_{j_2+1}$ and for every $j \in \{j_1, j_1+1, \ldots, j_2\}$ the s_j's are pairwise different (indices are taken modulo q). Then, two cases may arise:

- Case $j_2 = j_1 + 1$. We have: $e_{j_1} := v_{i_{j_1}} v_{i_{j_1}+1},\ e_{j_2} := v_{i_{j_2}+1} v_{i_{j_2}} \in E(s_{j_1}, s_{j_2})$. Furthermore, C_0 goes by $v_{i_{j_1}}$ (by $v_{i_{j_1}+1}, v_{i_{j_2}+1}, v_{i_{j_2}}$, respectively), and so, by Claim 13, either we computed a short cycle of weight $\leq 2w(C_0)$ during Step 1, or we have $w(C_0) \geq 2 \cdot \max\{dist(s_{j_1}, v_{i_{j_1}}), dist(s_{j_1}, v_{i_{j_2}+1}), dist(s_{j_2}, v_{i_{j_1}+1}), dist(s_{j_2}, v_{i_{j_2}})\}$. In the latter case, there exists a cycle of weight: $\leq dist(s_{j_1}, v_{i_{j_1}}) + w_{e_{j_1}} + dist(s_{j_2}, v_{i_{j_1}+1}) + dist(s_{j_2}, v_{i_{j_2}}) + w_{e_{j_2}} + dist(s_{j_1}, v_{i_{j_2}+1}) \leq 3w(C_0)$ that is fully contained in $V(T_{s_{j_1}}) \cup V(T_{s_{j_2}})$. By Claim 15, we so computed a cycle of weight $\leq 9w(C_0)$ at Step 4.

- From now on let us assume $j_2 \neq j_1 + 1$. For every j we have $e_j := v_{i_j} v_{i_j+1} \in E(s_j, s_{j+1})$, and so, the edge $s_j s_{j+1} \in E_S$ has weight no more than $dist(s_j, v_{i_j}) + w_{e_j} + dist(v_{i_j+1}, s_{j+1})$ in H_S (indices are taken modulo q for the s_j's and modulo p for the v_i's). Furthermore, C_0 goes by v_{i_j} (by v_{i_j+1}, respectively), and so, by Claim 13, either we computed a short cycle of weight $\leq 2w(C_0)$ during Step 1, or we have $w(C_0) \geq 2 \cdot \max\{dist(s_j, v_{i_j}), dist(s_{j+1}, v_{i_j+1}\}$ for every j. In the latter case,

$(s_{j_1}, s_{j_1+1}, \ldots, s_{j_2}, s_{j_2+1} = s_{j_1})$ is a cycle in H_S of weight:

$$\leq w(C_0) + \sum_{j=j_1}^{j_2} (dist(v_{i_{j-1}+1}, s_j) + dist(s_j, v_{i_j}))$$
$$\leq w(C_0)(1 + (j_2 - j_1 + 1))$$
$$\leq w(C_0)|S| = \tilde{\mathcal{O}}(n^{2/3} \cdot w(C_0)).$$

Then, let C_H be a cycle of H_S such that $w(C_H) = \tilde{\mathcal{O}}(n^{2/3} \cdot w(C_0))$ (obtained by applying the algorithm of Roditty and Tov to H_S). As explained above, we can derive from C_H a cycle C^*_H of G such that $w(C^*_H) \leq w(C_H) = \tilde{\mathcal{O}}(n^{2/3} \cdot w(C_0))$.

Summarizing, we obtain an $\tilde{\mathcal{O}}(n^{2/3})$-approximation of the girth by outputting a shortest cycle computed during Steps 1,3,4,5. ◀

4.2 Improving the approximation factor

Sketch Proof of Theorem 2. We may assume that all weights are positive by Lemma 11. Let g^* be the $\tilde{\mathcal{O}}(n^{2/3})$-approximation that we computed by using Proposition 12. There exists some (known) constant c such that the girth of G is somewhere between $g^*/(cn^{2/3}\log n)$ and g^*. Then, let $i_{\min}, i_{\max}$ be the smallest nonnegative integers such that $g^*/(cn^{2/3}\log n) \leq (1+\varepsilon/2)^{i_{\min}}$ and in the same way $g^* \leq (1+\varepsilon/2)^{i_{\max}}$. We have that:

$$i_{\max} - i_{\min} = \mathcal{O}\left(\log_{1+\varepsilon/2}\left(\frac{g^*}{g^*/(cn^{2/3}\log n)}\right)\right) = \mathcal{O}(\log n/\log(1+\varepsilon/2)) = \mathcal{O}(\log n/\varepsilon).$$

Let S be as in Proposition 4. For every $v \in V \setminus S$, we compute a 2-approximation of a shortest cycle in G'_v: the subgraph of G induced by the ball $B_S(v)$[4]. By Theorem 10, it can be done in time $\tilde{\mathcal{O}}(n^{2/3})$ for each v, and so, this takes total time $\tilde{\mathcal{O}}(n^{5/3})$. Then, let $T = \{(1+\varepsilon/2)^i \mid i_{\min} \leq i \leq i_{\max}\}$. For every $s \in S$, we compute the smallest $t \in T$ such that $HBD(G, s, t)$ detects a cycle (if any). It can be done in time $\tilde{\mathcal{O}}(|S|n\log|T|) = \tilde{\mathcal{O}}(n^{5/3}\log 1/\varepsilon)$ by using a dichotomic search. Finally, let $g_{\min}$ be the value computed by the above algorithm (with a corresponding cycle). In order to conclude we prove, with a similar case analysis as for Theorem 1, that the girth of G is at least $g_{\min}/(2+\varepsilon)$. ◀

5 A subquadratic algorithm for dense graphs

A drawback of the algorithms in Theorems 1 and 2 is that their time complexity also depends on the number m of edges. It implies that for dense graphs with $m = \Theta(n^2)$ edges we do not achieve any improvement on the running time compared to [10, 15]. The main result of this section is that assuming sorted adjacency lists, the dependency on m can always be discarded (Theorem 3). Due to lack of space, we will only prove the following weaker result:

▶ **Proposition 16.** *For every $G = (V, E, w)$ with non-negative edge-weights and sorted adjacency lists, we can compute:*

1. *a randomized 4-approximation for* Girth *in expected time $\tilde{\mathcal{O}}(n^{5/3})$;*
2. *and, for every $\varepsilon > 0$, a deterministic $(8+\varepsilon)$-approximation for* Girth *in time $\tilde{\mathcal{O}}(n^{5/3}\text{polylog}1/\varepsilon)$.*

[4] In fact, this is already done in the proof of Proposition 12, but we restate it here for completeness of the method.

Roughly, we can prove Theorem 3 by combining this above Proposition 16 with a natural modification of the algorithm presented in Section 3.2.

We will need the following well-known result in graph theory:

▶ **Theorem 17** ([4]). *Every* unweighted *graph with order n and $m \geq \left(\frac{1}{2} + o(1)\right) n^{3/2}$ edges contains a cycle of length four.*

Proof of Proposition 16. If G has $m = \tilde{\mathcal{O}}(n^{5/3})$ edges then, we can simply apply Theorem 2 for $\varepsilon = 2$ (the latter can be easily verified by scanning the adjacency lists until we read the end of it or we reach the desired upper-bound). From now on assume this is not the case and let H be induced by the $\left\lceil \left(\frac{1}{2} + o(1)\right) n^{3/2} \right\rceil$ edges of minimum weight in G.

We claim that H can be constructed in time $\tilde{\mathcal{O}}(n^{3/2})$ by using a priority queue Q. Indeed, initially we set $E(H) = \emptyset$ and for every $v \in V$ we start inserting in Q the edge of minimum-weight that is incident to v. This way, we ensure that a minimum-weight edge of $G \setminus E(H)$ is present in Q (recall that initially, $E(H) = \emptyset$, and so, $G = G \setminus E(H)$). Then, in order to preserve this above invariant, each time a minimum-weight edge uv is extracted from Q and added in H we insert in Q the remaining edge of minimum weight in Q_u and the one in Q_v (if any). – Note that in doing so, a same edge can be added in Q twice, but this has no consequence on the algorithm. –

We now apply Theorem 2 for $\varepsilon' = \varepsilon/4$ to H, and we so obtain a cycle C that is a $(2+\varepsilon/4)$-approximation of the girth of H. We claim that $w(C)$ is also a $(8+\varepsilon)$-approximation of the girth of G. In order to prove this claim, we need to consider two different cases:

- Assume there exists a shortest cycle C_0 of G such that $E(C_0) \subseteq E(H)$. By Theorem 2, $w(C) \leq (2 + \varepsilon/4)w(C_0) < (8 + \varepsilon)w(C_0)$.
- Otherwise, any shortest cycle C_0 of G has at least one edge that is not contained in H. Since edges are added by increasing weights, this implies that every shortest cycle contains an edge of weight at least $w_{\max}$, where $w_{\max}$ denotes the maximum-weight of an edge in H. In particular, the girth of G is at least $w_{\max}$. Furthermore, since H has enough edges by construction, by Theorem 17 it contains a cycle of four vertices; the latter has weight at most $4w_{\max}$. As a result, $w(C) \leq (2 + \varepsilon/4) \cdot 4w_{\max} = (8 + \varepsilon)w_{\max} \leq (8 + \varepsilon)w(C_0)$.

The above proves the claim, and so, the deterministic version of the result. In order to obtain a randomized 4-approximation, it suffices to pick $\varepsilon \leq 2$ and to output any cycle C' of H with four vertices (then, we output any of C, C' that has minimum weight). Up to some constant multiplicative increase of the number of edges to add in H, this can be done by using a randomized algorithm of Yuster and Zwick that runs in expected linear time [21, Theorem 2.9]. Note that this is the only source of randomness in the algorithm. ◀

We recall that any *unweighted* graph with $\mathcal{O}(n^{1+\frac{1}{\ell}})$ edges contains a cycle of length at most 2ℓ. We could use this density result instead of Theorem 17. In doing so, we could use a much sparser subgraph H in the proof of Proposition 16. However, our algorithm would still run in time $\tilde{\mathcal{O}}(n^{5/3})$ because the bottleneck is our call to the algorithm of Theorem 2.

6 Open problems

The most pressing question is whether we can achieve a 4/3-approximation for the girth in subquadratic time. If it is not the case then, what is the best approximation factor we can get in subquadratic time? We note that in [17], Roditty and Vassilevska Williams conjectured that we cannot achieve a $(2 - \varepsilon)$-approximation already for unweighted graphs[5].

[5] They did obtain such an algorithm for *triangle-free* graphs.

If their conjecture is true then, this would imply our algorithm is essentially optimal (at least for the non-dense graphs with $\mathcal{O}(n^{2-\varepsilon})$ edges). However, for the dense graphs with sorted adjacency lists, we left open whether a better approximation-factor than 4 can be obtained in $o(n^2)$-time. Finally, another interesting question is whether a constant-approximation for the girth can be computed in quasi linear time. We recall that this is wide open even for *unweighted* graphs [7].

Abstract

We call *domain* any arbitrary subset of a Cartesian power of the set $\{0, 1\}$ when we think of it as reflecting abstract rationality restrictions on vectors of two-valued judgments on a number of issues. In Computational Social Choice Theory, and in particular in the theory of judgment aggregation, a domain is called a possibility domain if it admits a non-dictatorial aggregator, i.e. if for some k there exists a unanimous (idempotent) function $F : D^k \to D$ which is not a projection function. We prove that a domain is a possibility domain if and only if there is a propositional formula of a certain syntactic form, sometimes called an integrity constraint, whose set of satisfying truth assignments, or models, comprise the domain. We call *possibility* integrity constraints the formulas of the specific syntactic type we define. Given a possibility domain D, we show how to construct a possibility integrity constraint for D efficiently, i.e, in polynomial time in the size of the domain. We also show how to distinguish formulas that are possibility integrity constraints in linear time in the size of the input formula. Finally, we prove the analogous results for local possibility domains, i.e. domains that admit an aggregator which is not a projection function, even when restricted to any given issue. Our result falls in the realm of classical results that give syntactic characterizations of logical relations that have certain closure properties, like e.g. the result that logical relations component-wise closed under logical AND are precisely the models of Horn formulas. However, our techniques draw from results in judgment aggregation theory as well from results about propositional formulas and logical relations.

1 Introduction

We call *domain* any arbitrary subset of a Cartesian power $\{0,1\}^n$ ($n \geq 1$) when we think of it as the set of yes/no ballots, or accept/reject judgment vectors on n issues that are "rational" in the sense manifested by being a member of the subset. A domain D has a non-dictatorial aggregator if for some $k \geq 1$ there is a unanimous (idempotent) function $F : D^k \to D$ that is not a projection function. Such domains are called *possibility domains*. The theory of judgment aggregation was put in this abstract framework by Wilson [19], and then elaborated by several others (see e.g. the work by Dietrich [4] and Dokow and Holzman [6, 5]). It can be trivially shown that non-dictatorial aggregators always exist unless we demand that F is defined on an issue by issue fashion (see next section for formal definitions). Such aggregators are called Independent of Irrelevant Alternatives (IIA). In this work aggregators are assumed to be IIA.

It is a well known fact from elementary Propositional Logic that for every subset D of $\{0,1\}^n$, $n \geq 1$, i.e. for every domain, there is a Boolean formula in Conjunctive Normal Form (CNF) whose set of satisfying truth assignments, or models, denoted by $\mathrm{Mod}(\phi)$, is equal to D (see e.g. Enderton [8, Theorem 15B]). Zanuttini and Hébrard [21] give an algorithm that finds such a formula and runs in polynomial-time with respect to the size of the representation of D as input. Following Grandi and Endriss [11], we call such a ϕ an *integrity constraint* and think of it as expressing the "rationality" of D (the term comes from databases, see e.g. [7]).

We prove that a domain is a possibility domain, if and only if it admits an integrity constraint of a certain syntactic form to be precisely defined, which we call a *possibility* integrity constraint. Very roughly, possibility integrity constraints are formulas that belong to one of three types, the first two of which correspond to "easy" cases of possibility domains: (i) formulas whose variables can be partitioned into two non-empty subsets so that no clause contains variables from both sets and (ii) formulas whose clauses are exclusive OR's of their literals. The most interesting third type is comprised of formulas such that if we change the logical sign of some of their variables, we get formulas that have a Horn part and whose remaining clauses contain only negative occurrences of the variables in the Horn part. We call such formulas *renamable partially Horn*, whereas we call *partially Horn*[1] the formulas that belong to the third type without having to rename any variables. Furthermore, we show that the unified framework of Zanuttini and Hébrard [21] for producing formulas of a specific type that describe a given domain, and which entails the notion of prime formulas (i.e. formulas that we cannot further simplify its clauses; see Definition 2.11) works also in the case of possibility integrity constraints. Actually, in addition to the syntactical characterization of possibility domains, we give two algorithms: the first on input a formula decides whether it is a possibility integrity constraint in time linear in the length of the formula (notice that the definition of possibility integrity constraint entails searching over all subsets of variables of the formula); the second on input a domain D halts in time polynomial in the size of

[1] A weaker notion of Horn formulas has appeared before in the work of Yamasaki and Doshita [20]; however our notion is incomparable with theirs, in the sense that the class of partially Horn formulas in neither a subset nor a superset (nor equal) to the class $\mathbb{S}_0$ they define.

D and either decides that D is not a possibility domain or otherwise returns a possibility integrity constraint that describes D. It should be noted that the satisfiability problem remains NP-complete even when restricted to formulas that are partially Horn. However in Computational Social Choice, domains are considered to be non-empty (see paragraph preceding Example 2.6).

We then consider *local possibility domains*, that is, domains admitting IIA aggregators whose components are all different than any projection function. Such aggregators are called *locally non-dictatorial* (see [15]). Local non-dictatorial domains were introduced in [12] as *uniform possibility domains* (the definition entails also non-Boolean domains). We show that local possibility domains are described by formulas we call *local possibility integrity constraints* and again, we provide a linear algorithm that checks if a formula is a local possibility integrity constraint and a polynomial algorithm that checks if a domain is a local possibility one and, in case it is, constructs a local possibility integrity constraint that describes it.

As examples of similar classical results in the theory of Boolean relations, we mention that domains component-wise closed under $\wedge$ or $\vee$ have been identified with the class of domains that are models of Horn or dual-Horn formulas respectively (see Dechter and Pearl [1]). Also it is known that a domain is component-wise closed under the ternary sum mod 2 if and only if it is the set of models of a formula that is a conjunction of subformulas each of which is an exclusive OR (the term "ternary" refers to the number of bits to be summed). Finally, a domain is closed under the ternary majority operator if and only it is the set of models of a CNF formula where each clause has at most two literals. The latter two results are due to Schaefer [18]. The ternary majority operator is the ternary Boolean function that returns 1 on input three bits if and only if at least two of them are 1. It is also known that the respective formulas for each case can be found in polynomial time with respect to the size of D (see Zanuttini and Hébrard [21]).

Our result can be interpreted as verifying that non-dictatorial voting schemes can always be generated by integrity constraints that have a specific, easily recognizable syntactic form. This can prove valuable for applications in the field of judgment aggregation, where relations are frequently encountered in compact form, as the sets of models of integrity constraints. As examples of such applications, we mention the work of Pigozzi [16] in avoiding the *discursive dilemma*, the characterization of *safe agendas* by Grandi and Endriss [10] and that of Endriss and de Haan [9] concerning the *winner determination problem*. Our proofs draw from results in judgment aggregation theory as well as from results about propositional formulas and logical relations. Specifically, as stepping stones for our algorithmic syntactic characterization we use three results. First, a theorem implicit in Dokow and Holzman [5] stating that a domain is a possibility domain if and only if it either admits a binary (of arity 2) non-dictatorial aggregator or it is component-wise closed under the ternary direct sum. This result was generalized by Kirousis et al. [12] for domains in the non-Boolean framework. Second, a characterization of local possibility domains proven by Kirousis et al. in [12]. Lastly, the "unified framework for structure identification" by Zanuttini and Hébrard [21] (see next section for definitions).

Due to space restrictions, most proofs are omitted and can instead be found in [3].

2 Preliminaries

We first give the notation and basic definitions from Propositional Logic and judgment aggregation theory that we will use.

Let $V = \{x_1, \ldots, x_n\}$ be a set of Boolean variables. A literal is either a variable $x \in V$ (positive literal) or a negation $\neg x$ of it (negative literal). A clause is a disjunction $(l_{i_1} \vee \cdots \vee l_{i_k})$ of literals from different variables. A propositional formula ϕ (or just a "formula", without the specification "propositional", if clear from the context) in Conjunctive Normal Form (CNF) is a conjunction of clauses. A formula is called k-CNF if every clause of it contains exactly k literals. A (truth) assignment to the variables is an assignment of either 0 or 1 to each of the variables. We denote by $a(x)$ the value of x under the assignment a. Truth assignments will be identified with elements of $\{0,1\}^n$, or n-sequences of bits. The truth value of a formula for an assignment is computed by the usual rules that apply to logical connectives. The set of satisfying (returning the value 1) truth assignments, or models, of a formula, is denoted by $\mathrm{Mod}(\phi)$. In what follows, we will assume, except if specifically noted, that n denotes the number of variables of a formula ϕ and m the number of its clauses.

We say that a variable x appears *positively* (resp. *negatively*) in a clause C, if x (resp. $\neg x$) is a literal of C. A variable $x \in V$ is positively (resp. negatively) *pure* if it has only positive (resp. negative) appearances in ϕ.

A Horn clause is a clause with at most one positive literal. A dual Horn is a clause with at most one negative literal. A formula that contains only Horn (dual Horn) clauses is called Horn (dual Horn, respectively). Generalizing the notion of a clause, we will also call clauses sets of literals connected with exclusive OR (or direct sum), the logical connective that corresponds to summation in $\{0,1\}$ mod 2. Formulas obtained by considering a conjunction of such clauses are called affine. Finally, bijunctive are called the formulas whose clauses, in inclusive disjunctive form, have at most two literals. A domain $D \subseteq \{0,1\}^n$ is called Horn, dual Horn, affine or bijunctive respectively, if there is a Horn, dual Horn, affine or bijunctive formula ϕ of n variables such that $\mathrm{Mod}(\phi) = D$. In the previous section, we mentioned efficient solutions to classical syntactic characterization problems for classes of relations with given closure properties on one hand, and formulas of the syntactic forms mentioned above on the other.

We have presented the above notions and results without many details, as they are all classical results. For the notions that follow we give more detailed definitions and examples. The first one, as far as we can tell, dates back to 1978 (see Lewis [13]).

▶ **Definition 2.1.** *A formula ϕ whose variables are among the elements of the set $V = \{x_1, \ldots, x_n\}$ is called* renamable Horn*, if there is a subset $V_0 \subseteq V$ so that if we replace every appearance of every negated literal l from V_0 with the corresponding positive one and vice versa, ϕ is transformed to a Horn formula.*

The process of replacing the literals of some variables with their logical opposite ones, is called a *renaming* of the variables of ϕ.

▶ **Example 2.2.** Consider the formulas $\phi_1 = (x_1 \vee x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_3 \vee x_4) \wedge (\neg x_2 \vee x_3 \vee \neg x_5)$ and $\phi_2 = (\neg x_1 \vee x_2 \vee x_3 \vee x_4) \wedge (x_1 \vee \neg x_2 \vee \neg x_3) \wedge (x_4 \vee x_5)$, defined over $V = \{x_1, x_2, x_3, x_4, x_5\}$.

The formula ϕ_1 is renamable Horn. To see this, let $V_0 = \{x_1, x_2, x_3, x_4\}$. By renaming these variables, we get the Horn formula $\phi_1^* = (\neg x_1 \vee \neg x_2 \vee x_3) \wedge (x_1 \vee \neg x_3 \vee \neg x_4) \wedge (x_2 \vee \neg x_3 \vee \neg x_5)$. On the other hand, it is easy to check that ϕ_2 cannot be transformed into a Horn formula for any subset of V, since for the first clause to become Horn, at least two variables from $\{x_2, x_3, x_4\}$ have to be renamed, which will make the second clause not Horn. ◇

It turns out that whether a formula is renamable Horn can be checked in linear time. There are several algorithms that do that in the literature, with the one of del Val [2] being a relatively recent such example. The original non-linear one was given by Lewis [13].

We now proceed with introducing several syntactic types of formulas:

▶ **Definition 2.3.** *A formula is called* separable *if its variables can be partitioned into two non-empty disjoint subsets so that no clause of it contains literals from both subsets.*

▶ **Example 2.4.** The formula $\phi_3 = (\neg x_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \neg x_2 \vee \neg x_3) \wedge (x_4 \vee x_5)$ is separable. Indeed, for the partition $V_1 = \{x_1, x_2, x_3\}$, $V_2 = \{x_4, x_5\}$ of V, we have that no clause of ϕ_3 contains variables from both subsets of the partition. On the other hand, there is no such partition of V for neither ϕ_1 nor ϕ_2 of the previous example. ◇

The fact that separable formulas can be recognized in linear time is relatively straightforward (see Proposition 3.1 in Subsection 3.1).

We now introduce the following notions:

▶ **Definition 2.5.** *A formula ϕ is called* partially Horn *if there is a nonempty subset $V_0 \subseteq V$ such that (i) the clauses containing only variables from V_0 are Horn and (ii) the variables of V_0 appear only negatively (if at all) in a clause containing also variables not in V_0.*

If a formula ϕ is partially Horn, then any non-empty subset $V_0 \subseteq V$ that satisfies the requirements of Definition 2.5 will be called an *admissible set of variables*. Also the Horn clauses that contain variables only from V_0 will be called *admissible clauses* (the set of admissible clauses might be empty). A Horn clause with a variable in $V \setminus V_0$ will be called *inadmissible* (the reason for the possible existence of such clauses will be made clear in the following example).

Notice that a Horn formula is, trivially, partially Horn too, as is a formula that contains at least one negative pure literal. It immediately follows that the satisfiability problem remains NP-complete even when restricted to partially Horn formulas (just add a dummy negative pure literal). However, in Computational Social Choice, domains are considered to be non-empty as a non-degeneracy condition. Actually, it is usually assumed that the projection of a domain to any one of the n issues is the set $\{0, 1\}$.

▶ **Example 2.6.** We first examine the formulas of the previous examples. ϕ_1 is partially Horn, since it contains the negative pure literal $\neg x_5$. The Horn formula ϕ_1^* is also trivially partially Horn. On the other hand, ϕ_2 and ϕ_3 are not, since for every possible $V_0 \subseteq \{x_1, x_2, x_3, x_4, x_5\}$, we either get non-Horn clauses containing variables only from V_0, or variables of V_0 that appear positively in inadmissible clauses.

The formula $\phi_4 = (x_1 \vee \neg x_2) \wedge (\neg x_1 \vee x_2) \wedge (\neg x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_3 \vee x_4)$ is partially Horn. Its first three clauses are Horn, though the third has to be put in every inadmissible set, since x_3 appears positively in the fourth clause which is not Horn. The first two clauses though constitute an admissible set of Horn clauses. Finally, $\phi_5 = (x_1 \vee \neg x_2) \wedge (x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_3 \vee x_4)$ is not partially Horn. Indeed, since all its variables appear positively in some clause, we need at least one clause to be admissible. The first two clauses of ϕ_5 are Horn, but we will show that they both have to be included in an inadmissible set. Indeed, the second has to belong to every inadmissible set since x_3 appears positively in the third, not Horn, clause. Furthermore, x_2 appears positively in the second clause, which we just showed to belong to every inadmissible set. Thus, the first clause also has to be included in every inadmissible set, and therefore ϕ_5 is not partially Horn. ◇

Accordingly to the case of renamable Horn formulas, we define:

▶ **Definition 2.7.** *A formula is called* renamable partially Horn *if some of its variables can be renamed (in the sense of Definition 2.1) so that it becomes partially Horn.*

Observe that any Horn, renamable horn or partially Horn formula is trivially renamable partially Horn. Also, a formula with at least one pure positive literal is renamable partially Horn, since by renaming the corresponding variable, we get a formula with a pure negative literal.

▶ **Example 2.8.** All formulas of the previous examples are renamable partially Horn: ϕ_1^*, ϕ_1 and ϕ_4 correspond to the trivial cases we discussed above, whereas ϕ_2, ϕ_3 and ϕ_5 all contain the pure positive literal x_4.

Lastly, we examine two more formulas: $\phi_6 = (\neg x_1 \vee x_2 \vee x_3 \vee x_4) \wedge (x_1 \vee \neg x_2 \vee \neg x_3) \wedge \neg x_4$ is easily not partially Horn, but by renaming x_4, we obtain the partially Horn formula $\phi_6^* = (\neg x_1 \vee x_2 \vee x_3 \vee \neg x_4) \wedge (x_1 \vee \neg x_2 \vee \neg x_3) \wedge x_4$, where $V_0 = \{x_4\}$ is the set of admissible variables. One the other hand, the formula $\phi_7 = (\neg x_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \neg x_2 \vee \neg x_3)$ is not renamable partially Horn. Indeed, whichever variables we rename, we end up with one Horn and one non-Horn clause, with at least one variable of the Horn clause appearing positively in the non-Horn clause. ◇

We prove, by Theorem 3.3 in Subsection 3.1 that checking whether a formula is renamable partially Horn can be done in linear time in the length of the formula.

▶ Remark 2.9. Let ϕ be a renamable partially Horn formula, and let ϕ^* be a partially Horn formula obtained by renaming some of the variables of ϕ, with V_0 being the admissible set of variables. Let also $\mathcal{C}_0$ be an admissible set of Horn clauses in ϕ^*. We can assume that only variables of V_0 have been renamed, since the other variables are not involved in the definition of being partially Horn. Also, we can assume that a Horn clause of ϕ^* whose variables appear only in clauses in $\mathcal{C}_0$ belongs to $\mathcal{C}_0$. Indeed, if not, we can add it to $\mathcal{C}_0$. ◇

▶ **Definition 2.10.** *A formula is called a* possibility integrity constraint *if it is either separable, or renamable partially Horn or affine.*

From the above and the fact that checking whether a formula is affine is easy we get Theorem 3.4 in Subsection 3.1, which states that checking whether a formula is a possibility integrity constraint can be done in polynomial time in the size of the formula.

Now, given a clause C of a formula ϕ, we say that a *sub-clause* of C is any non-empty clause created by deleting at least one literal of C. In Quine [17] and Zanuttini and Hébrard [21], we find the following definitions:

▶ **Definition 2.11.** *A clause C of a formula ϕ is a* prime implicate *of ϕ if no sub-clause of C is logically implied by ϕ. Furthermore, ϕ is* prime *if all its clauses are prime implicates of it.*

In sub-section 3.2, we use this notion in order to efficiently construct formulas whose set of models is a possibility domain.

We now come to some notions from Social Choice Theory (for an introduction, see e.g. List [14]). In the sequel, we will deal with k sequences of n-bit-vectors, each of which belongs to a fixed domain $D \subseteq \{0,1\}^n$. It is convenient to present such sequences with an $k \times n$ matrix $x_j^i, i = 1, \ldots, k, j = 1, \ldots, n$ with bits as entries. The rows of this matrix are denoted by $x^i, i = 1, \ldots, k$ and the columns by $x_j, j = 1, \ldots, n$. Each row represents a row-vector of 0/1 decisions on n issues by one of k individuals. Each column represents the column-vector of the positions of all k individuals on a particular issue.

In Social Choice Theory, $D \subseteq \{0,1\}^n$ is said to have a k-ary (of arity k) unanimous aggregator if there are exists a sequence of n k-ary Boolean functions $(f_1, \ldots, f_n)$, $f_j : \{0,1\}^k \to \{0,1\}, j = 1, \ldots, n$ such that

- all f_j are unanimous, i.e if $b_1 = \cdots = b_k$ are equal bits, then

  $$f_j(b_1, \ldots, b_k) = b_1 = \cdots = b_k, \text{ and}$$

- if for a matrix $(x^i_j)_{i,j}$ that represents the opinions of k individuals on n issues we have that the row-vectors $x^i \in D$ for all $i = 1, \ldots, k$, then

  $$(f_1(x_1), \ldots, f_n(x_n)) \in D.$$

Notice that in the second bullet above, the f_j's are applied to column-vectors, which have dimension k. The f_j's are called the *components* of the aggregator $(f_1, \ldots, f_n)$. Intuitively, an aggregator is a sequence of functions that when applied onto some rational opinion vectors of k individuals on n issues, in a issue-by-issue fashion, they return a row-vector that is still rational. From now on, we will refer to unanimous aggregators, simply as aggregators. We will also sometimes say that F is an aggregator, meaning that F is a sequence of n functions $(f_1, \ldots, f_n)$ as above.

An aggregator $(f_1, \ldots, f_n)$ is called *dictatorial* if there is a $d = 1 \ldots, k$ such that $f_1 = \cdots = f_n = \mathrm{pr}^k_d$, where $\mathrm{pr}^k_d : (b_1, \ldots, b_k) \mapsto b_d$ is the k-ary projection function on the d'th coordinate.

A k-ary aggregator is called a *projection* aggregator if each of its components is a projection function pr^k_d, for some $d = 1, \ldots, m$.

Notice that it is conceivable to have non-dictatorial aggregators that are projection aggregators.

A binary (of arity 2) Boolean function $f : \{0,1\}^2 \to \{0,1\}$ is called *symmetric* if for all pairs of bits b_1, b_2, we have that $f(b_1, b_2) = f(b_2, b_1)$. A binary aggregator is called symmetric if all its components are symmetric. Let us mention here the easily to check fact that the only unanimous binary functions are the $\wedge$, $\vee$ and the two projection functions $\mathrm{pr}^2_1, \mathrm{pr}^2_2$. Of those four, only the first two are symmetric.

▶ **Definition 2.12.** *A domain D is called a possibility domain if it has a (unanimous) non-dictatorial aggregator of some arity.*

Notice that the search space for such an aggregator is large, as the arity is not restricted. However, from [12, Theorem 3.7] (a result that follows from Dokow and Holzman [5], but without being explicitly mentioned there), we can easily get that:

▶ **Theorem 2.13** (Dokow and Holzman [5])**.** *A domain D is a possibility domain if and only if it admits either: (i) a non-dictatorial binary projection aggregator or (ii) a non-projection binary aggregator (i.e. at least one symmetric component) or (iii) a ternary aggregator all components of which are the binary addition* mod 2*.*

Nehring and Puppe [15] defined a type of non-dictatorial aggregators they called *locally non-dictatorial*. A k-ary aggregator $(f_1, \ldots, f_n)$ is locally non-dictatorial if $f_j \neq \mathrm{pr}^k_d$, for all $d \in \{1, \ldots, k\}$ and $j = 1, \ldots, n$.

▶ **Definition 2.14.** *D is a* local possibility domain (lpd) *if it admits a locally non-dictatorial aggregator.*

Consider the following ternary operators on $\{0,1\}$: (i) $\wedge^{(3)}(x,y,z) := \wedge(\wedge(x,y),z))$ (resp. for $\vee^{(3)}$), (ii) maj, where $\mathrm{maj}(x,y,z) = 1$ if and only if *at least* two elements of its input are 1 and (iii) $\oplus$, where $\oplus(x,y,z) = 1$ if an only if *exactly one or all* of the elements of its input are equal to 1. In [12], the following characterization of lpd's has been proven:

▶ **Theorem 2.15** (Kirousis et al. [12])**.** *$D \subseteq \{0,1\}$ is a local possibility domain if and only if it admits a ternary aggregator $(f_1, \ldots, f_n)$ such that $f_j \in \{\wedge^{(3)}, \vee^{(3)}, \mathrm{maj}, \oplus\}$, for $j = 1, \ldots, n$.*

3 Syntactic characterization of possibility domains by possibility integrity constraints

3.1 Identifying possibility integrity constraints

In this subsection, we show that identifying possibility integrity constraints can be done in time linear in the length of the input formula. By Definition 2.10, it suffices to show that for separable and renamable partially Horn formulas, since the corresponding problem for affine formulas is trivial.

In all that follows, we assume that we have a set of variables $V := \{x_1, \ldots, x_n\}$ and a formula ϕ defined on V that is a conjunction of m clauses $C_1, \ldots, C_m$, where $C_j = (l_{j_1}, \ldots, l_{j_{k_j}})$, $j = 1, \ldots, n$, and l_{j_s} is a positive or negative literal of x_{j_s}, $s = 1, \ldots, k_j$. We denote the set of variables corresponding to the literals of a clause C_j by $\mathrm{vbl}(C_j)$.

We begin with the result for separable formulas:

▶ **Proposition 3.1.** *There is an algorithm that, on input a formula ϕ, halts in time linear in the length of ϕ and either returns that the formula is not separable, or alternatively produces a* partition *of V in two non-empty and disjoint subsets $V_1, V_2 \subseteq V$, such that no clause of ϕ contains variables from both V_1 and V_2.*

Proof. (Sketch; detailed proof provided in [3].) Let the variables of ϕ be the vertices of a simple graph G. We connect two such vertices if they appear consecutively in a common clause of ϕ. The result is then obtained by showing that ϕ is separable if and only if G is not connected. ◀

To deal with renamable partially Horn formulas, we will start with Lewis' idea [13] of creating, for a formula ϕ, a 2SAT formula ϕ' whose satisfiability is equivalent to ϕ being renamable Horn. However, here we need to (i) look for a renaming that might transform only some clauses into Horn and (ii) deal with inadmissible Horn clauses, since such clauses can cause other Horn clauses to become inadmissible too.

▶ **Proposition 3.2.** *For every formula ϕ, there is a formula ϕ' such that ϕ is renamable partially Horn if and only if ϕ' is satisfiable.*

Proof. (Sketch; detailed proof provided in [3].) For each variable $x \in V$, we introduce a new variable x'. Intuitively, setting $x = 1$ means that x is renamed, whereas setting $x' = 1$ means that x is in V_0, but is not renamed. Finally we set both x and x' equal to 0 in case x is not in V_0. Obviously, we should not not allow the assignment $x = x' = 1$ (a variable in V_0 cannot be renamed and not renamed).

Suppose that a clause C of ϕ has the literals $x, \neg y$. If we add x to V_0 without renaming it, we should not rename y, since we would have two positive literals in an admissible clause. Also, we should not leave the latter out of V_0, since we would have a variable of V_0 appearing positively in a clause containing a variable not in V_0. Thus, we have that $x' \to y'$, which is expressed by the equivalent clause $(\neg x' \vee y')$. We add this clause to ϕ' and we proceed in this way for any possible combination of literals in a clause of ϕ. We also introduce the clauses $\neg x \vee \neg x'$, for all $x \in V$, in order to exclude the assignment $x = x' = 1$. Finally, we add the clause $\bigvee_{x \in V'} x$, to ensure that at least one variable is admissible. ◀

To compute ϕ' from ϕ, one would need quadratic time in the length of ϕ. Thus, we introduce the following linear algorithm that decides if a formula ϕ is renamable partially Horn, by tying a property of a graph constructed based on ϕ, with the satisfiability of ϕ'.

▶ **Theorem 3.3.** *There is an algorithm that, on input a formula ϕ, halts in time linear in the length of ϕ and either returns that ϕ is not renamable partially Horn or alternatively produces a subset $V^* \subseteq V$ such that the formula ϕ^* obtained from ϕ by renaming the literals of variables in V^* is partially Horn.*

Proof. (Sketch; detailed proof provided in [3].) To prove Theorem 3.3, we define a *directed bipartite* graph G, i.e. a directed graph whose set of vertices is partitioned in two sets such that no vertices belonging in the same part are adjacent. One set is comprised of the variables of ϕ', and the other of the clauses of ϕ. Each variable is connected with the clauses it appears in. Then, by computing its *strongly connected components (scc)*, i.e. its maximal sets of vertices such that every two of them are connected by a directed path, we show that at least one of them does not contain both a variable x and x' (and thus allows x to be admissible) *if and only if* ϕ is renamable partially Horn. ◀

Because checking whether a formula is affine can be trivially done in linear time, we get:

▶ **Theorem 3.4.** *There is an algorithm that, on input a formula ϕ, halts in linear time in the length of ϕ and either returns that ϕ is not a possibility integrity constraint, or alternatively, (i) either it returns that ϕ is affine or (ii) in case ϕ is separable, it produces two non-empty and disjoint subsets $V_1, V_2 \subseteq V$ such that no clause of ϕ contains variables from both V_1 and V_2 and (iii) in case ϕ is renamable partially Horn, it produces a subset $V^* \subseteq V$ such that the formula ϕ^* obtained from ϕ by renaming the literals of variables in V^* is partially Horn.*

3.2 Syntactic Characterization of possibility domains

In this subsection, we provide a syntactic characterization for possibility domains, by proving they are the models of possibility integrity constraints. Furthermore, we show that given a possibility domain D, we can produce a possibility integrity constraint, whose set of models is D, in time polynomial in the size of D. To obtain the characterization, we proceed as follows. We separately show that each type of a possibility integrity constraint of Definition 2.10 corresponds to one of the conditions of Theorem 2.13: (i) Domains admitting non-dictatorial binary projection aggragators are the sets of models of separable formulas, those admitting non-projection binary aggregators are the sets of models of renamable partially Horn formulas and (iii) affine domains are the sets of models of affine formulas.

We will need some additional notation. For a set of indices I, let $D_I := \{(a_i)_{i\in I} \mid a \in D\}$ be the projection of D to the indices of I and $D_{-I} := D_{\{1,\dots,n\}\setminus I}$. Also, for two (partial) vectors $a = (a_1, \dots, a_k) \in D_{\{1,\dots,k\}}$, $k < n$ and $b = (b_1, \dots, b_{n-k}) \in D_{\{k+1,\dots,n\}}$, we define their *concatenation* to be the vector $ab = (a_1, \dots, a_k, b_1, \dots, b_{n-k})$. Finally, given two subsets $D, D' \subseteq \{0,1\}^n$, we write that $D \approx D'$ if we can obtain D by *permuting* the coordinates of D', i.e. if $D = \{(d_{j_1}, \dots, d_{j_n}) \mid (d_1, \dots, d_n) \in D'\}$, where $\{j_1, \dots, j_n\} = \{1, \dots, n\}$.

We begin with characterizing the domains closed under a non-dictatorial projection aggregator as the models of separable formulas.

▶ **Proposition 3.5.** *D admits a binary non-dictatorial projection aggregator $(f_1, \dots, f_n)$ if and only if there exists a separable formula ϕ whose set of models equals D.*

Proof. (Sketch; detailed proof provided in [3].) First prove that D admits a binary non-dictatorial projection aggregator if an only if there exists a partition (I, J) of $\{1, \dots, n\}$ such that $D \approx D_I \times D_J$. To do that, take I to be the indices of the aggregator that are projections to the first coordinate and J that of the indices that are projections to the second coordinate.

Then, take the formulas ϕ_1 and ϕ_2 such that $\mathsf{Mod}(\phi_1) = D_I$ and $\mathsf{Mod}(\phi_2) = D_J$ and prove that $\mathsf{Mod}(\phi_1 \wedge \phi_2) = D$. ◀

We now turn our attention to domains closed under binary non projection aggregators.

▶ **Theorem 3.6.** *D admits a binary aggregator $(f_1, \ldots, f_n)$ which is not a projection aggregator if and only if there exists a renamable partially Horn formula ϕ whose set of models equals D.*

Proof. (Sketch; detailed proof provided in [3].) We first show that any domain D admitting a binary aggregator that has some components being projections to different coordinates, also admits one whose projections are all to the same coordinate. Also, given a domain admitting a binary aggregator with some components being $\vee$, we construct a domain D^* admitting a binary aggregator that all of its symmetric components are $\wedge$.

We then proceed to describing a partially Horn formula $\phi = \phi_0 \wedge \phi_1$, such that ϕ_0 is Horn and describes D_I, the projection of D to the indices corresponding to the symmetric components of $(f_1, \ldots, f_n)$. ϕ_1 is then constructed as the conjunction of smaller formulas that describe the sets of partial vectors that extend those of D_I. We also ensure that any variable of ϕ_0 appears only negatively in ϕ_1. ◀

We thus get:

▶ **Theorem 3.7.** *D is a possibility domain if and only if there exists a possibility integrity constraint ϕ whose set of models equals D.*

Proof. (Sketch; detailed proof provided in [3].) The proof follows by combining the characterization of possibility domains of Theorem 2.13, with Proposition 3.5 for separable formulas, Theorem 3.6, for renamable partially Horn formulas and the fact that an affine domain is described by an affine formula. ◀

To finish this section, we will use Zanuttini and Hébrard's "unified framework" [21]. Recall the definition of a prime formula (Def. 2.11) and consider the following proposition:

▶ **Proposition 3.8.** *Let ϕ_P be a prime formula and ϕ be a formula logically equivalent to ϕ_P. Then:*
1. *if ϕ is separable, ϕ_P is also separable and*
2. *if ϕ is renamable partially Horn, ϕ_P is also renamable partially Horn.*

Proof. (Sketch; detailed proof provided in [3].) Follows from the fact that neither *resolution* nor *omission* can destroy separability or make an admissible variable non-admissible (see also Quine [17]). ◀

We are now ready to prove our main result:

▶ **Theorem 3.9.** *There is an algorithm that, on input $D \subseteq \{0,1\}^n$, halts in time $O(|D|^2 n^2)$ and either returns that D is not a possibility domain, or alternatively outputs a possibility integrity constraint ϕ, containing $O(|D|n)$ clauses, whose set of satisfying truth assignments is D.*

Proof. Given a domain D, we first use Zanuttini and Hébrard's algorithm to check if it is affine [21, Proposition 8], and if it is, produce, in time $O(|D|^2 n^2)$ an affine formula ϕ with $O(|D|n)$ clauses, such that $\mathsf{Mod}(\phi) = D$. If it isn't, we use again Zanuttini and Hébrard's algorithm [21] to produce, in time $O(|D|^2 n^2)$, a prime formula ϕ with $O(|D|n)$ clauses, such that $\mathsf{Mod}(\phi) = D$. Then, we use the linear algorithms of Proposition 3.1 and Theorem 3.3 to check if ϕ is separable or renamable partially Horn. If it is either of the two, then ϕ is a possibility integrity constraint and, by Theorem 3.7, D is a possibility domain. Else, by Proposition 3.8, D is not a possibility domain. ◀

4 Local possibility domains

We turn now our attention to local possibility domains. As in the case of possibility domains, we want to characterize lpd's with a syntactic type of formulas.

We will first address a technical issue. Let V, V' be two disjoint sets of variables. By further generalizing the notion of a clause of a CNF formula, we say that a (V, V')-*generalized clause* is a clause of the form:

$$(l_1 \vee \cdots \vee l_s \vee (l_{s+1} \oplus \cdots \oplus l_t)),$$

where the literal l_j corresponds to variable v_j, $j = 1, \ldots, t$, $v_1, \ldots, v_s \in V$, $v_{s+1}, \ldots, v_t \in V'$ and $0 \leq s < t$. Such a clause if falsified by exactly those assignments that falsify every literal l_i, $i = 1, \ldots, s$ and satisfy an even number of literals l_j, $j = s+1, \ldots, t$. An affine clause is trivially a (V, V')-generalized clause, where all its literals correspond to variables from V'.

Consider now the following definition, which is analogous to Definition 2.10.

▶ **Definition 4.1.** *A formula ϕ is a* local possibility integrity constraint (lpic) *if there are three* pairwise disjoint *subsets $V_0, V_1, V_2 \subseteq V$, with $V_0 \cup V_1 \cup V_2 = V$, where no clause contains variables both from V_1 and V_2 and such that:*

1. *by renaming some variables of V_0, we obtain a partially Horn formula ϕ^*, whose set of admissible variables is V_0,*
2. *any clause contains at most two variables from V_1 and*
3. *the clauses containing variables from V_2 are (V_0, V_2)-generalized clauses.*

▶ **Example 4.2.** Easily, every (renamable) Horn, bijunctive or affine formula is an lpic. On the other hand, consider the following possibility integrity constraint:

$$\phi = (\neg x_1 \vee x_2 \vee x_3 \vee x_4) \wedge (\neg x_2 \vee \neg x_3 \vee \neg x_4).$$

ϕ is partially Horn, since it has the pure negative literal $\neg x_1$ and thus a possibility integrity constraint. But, it is not an lpic, since however we define V_0, V_1, either there will be a variable of V_0 with a positive appearence in a non-admissible clause (even after any possible renaming of the variables of V_0) and/or there will be a clause with more than two literals from V_1. ◇

By Definition 4.1, we get the following corollary:

▶ **Corollary 4.3.** *If ϕ is a local possibility integrity constraint, then it is also a possibility integrity constraint.*

Proof. Let V_0, V_1 and V_2 be as in Definition 4.1. If $V_0 \neq \emptyset$, ϕ is partially Horn. Else, if $V_0 = V_1 = \emptyset$, then ϕ is affine. On the other hand, if $V_0 = \emptyset$ and V_1 and V_2 are not, ϕ is separable. Finally, if $V_1 = V$, then ϕ is bijunctive and equivalently, 2-SAT. The result now follows by the fact that any 2-SAT formula is renamable Horn. Indeed, let α be an assignment satisfying ϕ and rename all the variables $x \in V$ such that $\alpha(x) = 1$. Then, every clause of ϕ either has a positive literal that is renamed, or a negative one that is not renamed. ◀

The first theorem we prove is that we can recognize lpic's efficiently.

▶ **Theorem 4.4.** *There is an algorithm that, on input a formula ϕ, halts in linear time in the length of ϕ and either returns that ϕ is not a local possibility constraint, or alternatively, produces the sets V_0, V_1, V_2 described in Definition 4.1.*

Proof. (Sketch; detailed proof provided in [3].) By Theorem 3.3, we check if ϕ is renamable partially Horn in time linear to its length and obtain the set V_0 of admissible variables, in case it is. Then, we can trivially check if any sub-clause, obtained by a non-admissible clause by deleting any variable from V_0 is bijunctive or affine. ◀

We now syntactically characterize lpd's as the sets of models of lpic's.

▶ **Theorem 4.5.** *A domain $D \subseteq \{0,1\}^n$ is a local possibility domain if and only if there is a local possibility integrity constraint ϕ such that $\mathsf{Mod}(\phi) = D$.*

Proof. (Sketch; detailed proof provided in [3].) The proof is a variation of the one for Theorem 3.6. ◀

We end this section by showing that, given an lpd D, we can efficiently construct an lpic ϕ such that $\mathsf{Mod}(\phi) = D$.

▶ **Theorem 4.6.** *There is an algorithm that, on input $D \subseteq \{0,1\}^n$, halts in time $O(|D|^2 n^2)$ and either returns that D is not a local possibility domain, or alternatively outputs a local possibility integrity constraint ϕ, containing $O(|D|n)$ clauses, whose set of satisfying truth assignments is D.*

Proof. (Sketch; detailed proof provided in [3].) Using Zanuttini and Hébrard's unified framework, we compute a prime formula ϕ such that $\mathsf{Mod}(\phi) = D$ in time $O(|D|^2 n^2)$ that contains $O(|D|n)$ clauses. We then check, in linear time to the length of ϕ, whether it is an lpic. ◀

Concluding remarks

It is known that any domain on n issues can be represented either by n formulas $\phi_1, \ldots, \phi_n$ (an agenda), in which case the domain is the set of binary n-vectors, the i-component of which represents the acceptance or rejection of ϕ_i in a consistent way (logic-based approach), or, alternatively, by a single formula ϕ of n variables (an integrity constraint), in which case the domain is the set of models of ϕ. In the former case, there are results, albeit of non-algorithmic nature, that give us conditions on the syntactic form of the ϕ_i's, so that the domain accepts a non-dictatorial aggregator. In this work, we give a necessary and sufficient condition on the syntactic form of a formula to be an integrity constraint of a domain that accepts a (locally) non-dictatorial aggregator. We called such formulas, (local) possibility integrity constraints. Our results are algorithmic, in the sense that (i) recognizing a (local) possibility integrity constraint can be implemented in time linear in the length of the input formula and (ii) given a (local) possibility domain, a corresponding (local) possibility integrity constraint, whose number of clauses is polynomial in the size of the domain, can be constructed in time polynomial in the size of the domain. Our proofs draw from results in judgment aggregation theory as well from results about propositional formulas and logical relations.

Abstract

Geometric Complexity Theory as initiated by Mulmuley and Sohoni in two papers (SIAM J Comput 2001, 2008) aims to separate algebraic complexity classes via representation theoretic multiplicities in coordinate rings of specific group varieties. We provide the first toy setting in which a separation can be achieved for a family of polynomials via these multiplicities.

Mulmuley and Sohoni's papers also conjecture that the vanishing behavior of multiplicities would be sufficient to separate complexity classes (so-called *occurrence obstructions*). The existence of such strong occurrence obstructions has been recently disproven in 2016 in two successive papers, Ikenmeyer-Panova (Adv. Math.) and Bürgisser-Ikenmeyer-Panova (J. AMS). This raises the question whether separating group varieties via representation theoretic multiplicities is stronger than separating them via occurrences. We provide first finite settings where a separation via multiplicities can be achieved, while the separation via occurrences is provably impossible. These settings are surprisingly simple and natural: We study the variety of products of homogeneous linear forms (the so-called Chow variety) and the variety of polynomials of bounded border Waring rank (i.e. a higher secant variety of the Veronese variety).

As a side result we prove a slight generalization of Hermite's reciprocity theorem, which proves Foulkes' conjecture for a new infinite family of cases.

1 Introduction

In two landmark papers [22, 23] Mulmuley and Sohoni suggested the use of representation theoretic multiplicities to separate group varieties that correspond to complexity classes. The goal of this approach, which is called *geometric complexity theory*, is to achieve complexity lower bounds that lead to the separation of algebraic complexity classes such as VP and VNP (see [3] or [28] for the precise definitions, which will not be important in this paper). At the heart of the approach was the hope that so-called *occurrence obstructions* (see Section 2) would be sufficient to separate VP and VNP. In [16, 8] it was shown that occurrence obstructions are too weak to provide the necessary separation, at least for the group varieties that were originally proposed by Mulmuley and Sohoni. But representation theoretic multiplicities might still be able to separate VP and VNP when we look at the finer separation criterion via *multiplicity obstructions* (see also Section 2). Unfortunately, so far all known separations of group varieties via multiplicity obstructions could also in fact be obtained via occurrence obstructions, or at least there is no setting in which multiplicity obstructions are provably stronger than occurrence obstructions, see e.g. [6, 7]. Indeed, little is known about multiplicity obstructions in general, as the required multiplicities are often #P-hard to compute, see e.g. [25, 5, 2], which implies that a polynomial time algorithm for their computation can only exist if P=NP.

Scott Aaronson raised the question about the existence of a setting where multiplicity obstructions are provably more powerful than occurrence obstructions. In this paper we give the first example of such a situation in a finite setting, see Theorem 2.1 below.

Theorem 2.1 is not only about finite settings: For the first time multiplicity obstructions are used to separate families of polynomials, even though the separation is extremely modest. Prior work on obstructions focused on tensors instead of polynomials ([6, 7]).

As a side result we prove a slight generalization of Hermite's reciprocity theorem, which proves Foulkes' conjecture (see (1)) for a new infinite family of cases, see Theorem 3.4.

2 Representation theoretic obstructions

In this section we review how to separate group varieties via representation theoretic multiplicities. The setup is in complete analogy to the geometric complexity theory approach of Mulmuley and Sohoni. We then list our main result, see Theorem 2.1.

Consider the space $\mathbb{A}^n_m := \mathbb{C}[x_1, \ldots, x_m]_n$ of complex homogeneous polynomials of degree n in m variables. Let $V := \mathbb{A}^1_m$ be the space of homogeneous degree 1 polynomials. In this paper we compare two subvarieties of $\mathbb{A}^n_m$. The first is the so-called *Chow variety*

$$\mathsf{Ch}^n_m := \{\ell_1 \cdots \ell_n \mid \ell_i \in V\} \subseteq \mathbb{A}^n_m,$$

which is the set of polynomials that can be written as a product of homogeneous linear forms, see e.g. [20, §8.6]. In algebraic complexity theory this set is known as the set of polynomials that have homogeneous depth-two algebraic circuits of the form $\Pi^n\Sigma$, i.e., circuits that consists of an n-ary top product gate of linear combinations of variables. The second variety is called a *higher secant variety of the Veronese variety* and can be written as

$$\mathsf{Pow}^n_{m,k} := \overline{\{\ell_1^n + \cdots + \ell_k^n \mid \ell_i \in V\}} \subseteq \mathbb{A}^n_m,$$

which is the closure of the set of all sums of k powers of homogeneous linear forms. Note that from a general principle it follows that the Zariski closure equals the Euclidean closure in this case, see e.g. [24, §2.C] where this is shown for every constructible set. The polynomials

in $\mathsf{Pow}^n_{m,k}$ are exactly those that have *border Waring rank at most k*, see e.g. [20, §5.4]. In algebraic complexity theory this set is known as the set of polynomials that can be approximated arbitrarily closely by homogeneous depth-three powering circuits of the form $\Sigma^k\Lambda^n\Sigma$, i.e., a k-ary sum of n-th powers of linear combinations of variables.

$\mathbb{A}^n_m$ is generated as a vector space by the powers v^n, $v \in V$, see e.g. [20, Ex. 2.6.6.2]. Given two elements $g_1, g_2 \in \mathsf{GL}_m := \mathsf{GL}(V)$, and given $v \in V$, we clearly have $g_1(g_2 v) = (g_1 g_2)v$. Thus we say that V admits a GL_m-action. This natural action of GL_m on V lifts canonically to $\mathbb{A}^n_m$ via $g(v^n) := (gv)^n$, $g \in \mathsf{GL}_m$, $v \in V$, and linear continuation. Both varieties Ch^n_m and $\mathsf{Pow}^n_{m,k}$ are closed under this action, i.e., for $g \in \mathsf{GL}_m$ and $v \in \mathsf{Ch}^n_m$ we have $gv \in \mathsf{Ch}^n_m$, and analogously $v \in \mathsf{Pow}^n_{m,k}$ implies $gv \in \mathsf{Pow}^n_{m,k}$. A variety that is closed under the action of GL_m is called a GL_m-variety.

Let $\mathbb{C}[\mathbb{A}^n_m]$ denote the coordinate ring of $\mathbb{A}^n_m$, i.e., the polynomial ring in $\dim \mathbb{A}^n_m = \binom{n+m-1}{n}$ many variables, where these variables are in 1:1 correspondence to the monomials in $\mathbb{A}^n_m$. The action of GL_m on $\mathbb{A}^n_m$ lifts to a linear action of GL_m on $\mathbb{C}[\mathbb{A}^n_m]$ via the canonical pullback as follows: $(gf)(h) := f(g^{-1}h)$, $g \in \mathsf{GL}_m$, $f \in \mathbb{C}[\mathbb{A}^n_m]$, $h \in \mathbb{A}^n_m$. Moreover, the action respects the natural grading of $\mathbb{C}[\mathbb{A}^n_m]$, so that each homogeneous degree d part $\mathbb{C}[\mathbb{A}^n_m]_d$ is a finite dimensional vector space that is closed under the action of GL_m.

Recall that a finite dimensional vector space W that is closed under a linear action of GL_m is called a GL_m-*representation*. This is equivalent to the existence of a group homomorphism $\varrho : \mathsf{GL}_m \to \mathsf{GL}(W)$. If we choose bases, then we can interpret $\mathsf{GL}_m \subseteq \mathbb{C}^{m\times m}$ and $\mathsf{GL}(W) \subseteq \mathbb{C}^{\dim W \times \dim W}$ and ϱ is described by $(\dim W)^2$ many coordinate functions, which are functions in m^2 many variables. If these functions are polynomials, then we call W a *polynomial representation*. Our main representation of interest, $\mathbb{C}[\mathbb{A}^n_m]_d$, is a polynomial representation. A linear subspace of W that is closed under the action of GL_m is called a subrepresentation. Subrepresentations of polynomial representations are clearly polynomial representations again. For every GL_m-representation W we have that W and 0 are two trivial subrepresentations. If W has no other subrepresentations, then we call W *irreducible*. A linear map $\varphi : W_1 \to W_2$ between two GL_m-representations is called *equivariant* if $g\varphi(f) = \varphi(gf)$ for all $f \in W_1$, $g \in \mathsf{GL}_m$. If there exists an equivariant vector space isomorphism from W_1 to W_2, then we say that W_1 and W_2 are *isomorphic* GL_m-representations. An *m-partition* of D is a nonincreasing list of m nonnegative integers that sum up to D. Every irreducible polynomial GL_m-representation has an associated isomorphism type, which is an m-partition, see e.g. [10, Ch. 8]. Two irreducible GL_m-representations are isomorphic iff their isomorphism types coincide. We denote by $\{\lambda\}_m$ the irreducible GL_m-representation corresponding to the m-partition λ. We write $\{\lambda\} = \{\lambda\}_m$ is m is clear from the context.

The group GL_m is *linearly reductive*, which means that every GL_m-representation W decomposes into a direct sum of irreducible GL_m-representations, see e.g. [18, AII.5, Satz 4]. The number of times an irreducible representation of type λ occurs in the decomposition is called the *multiplicity* of λ in W, written $\mathrm{mult}_\lambda(W)$. Even though this decomposition is usually not unique, the notation $\mathrm{mult}_\lambda(W)$ makes sense, because the multiplicities are independent of the actual decompositions.

The multiplicity $a_\lambda(d[n]) := \mathrm{mult}_\lambda(\mathbb{C}[\mathbb{A}^n_m]_d)$ is the infamous *plethysm coefficient*, which is the object of study in Foulkes' conjecture and also in Problem 9 in Stanley's famous list of open problems [30]. If we pad an m-partition λ with $m' - m$ many zeros to obtain the m'-partitions $\lambda' = (\lambda_1, \ldots, \lambda_m, 0, \ldots, 0)$, then $\mathrm{mult}_\lambda(\mathbb{C}[\mathbb{A}^n_m]_d) = \mathrm{mult}_{\lambda'}(\mathbb{C}[\mathbb{A}^n_{m'}]_d)$, see e.g. [14, Lem. 4.3.2]. For the sake of simplicity we identify m-partitions with m'-partitions that arise from padding zeros. This justifies leaving out the parameter m in the notation $a_\lambda(d[n])$ by assuming that m is large enough. Foulkes' conjecture states that

$$\text{Conjecture}: \quad a_\lambda(n[d]) \leq a_\lambda(d[n]) \quad \text{for all } d \geq n. \tag{1}$$

Conjecture (1) is known to be true (moreover, equality holds: $a_\lambda(d[n]) = a_\lambda(n[d])$) for all 2-partitions λ, which is often called *Hermite reciprocity* [13]. We make modest progress on this conjecture by proving it for many families of 3-partitions, see Corollary 4.4.

Let Z be a GL_m-variety, e.g., $Z = \mathsf{Ch}^n_m$ or $Z = \mathsf{Pow}^n_{m,k}$. Then the vanishing ideal $I(Z) := \{f \in \mathbb{C}[\mathbb{A}^n_m] \mid \forall h \in Z : f(h) = 0\}$ is also closed under the action of GL_m, which is easy to verify: If $f(h) = 0$ for all $h \in Z$, then also $(gf)(h) = f(g^{-1}h) = 0$, because $g^{-1}h \in Z$. Since the action respects the grading, each homogeneous degree d part $I(Z)_d$ is a GL_m-representation. The coordinate ring $\mathbb{C}[Z]$ is defined as the quotient algebra $\mathbb{C}[\mathbb{A}^n_m]/I(Z)$ and each homogeneous part $\mathbb{C}[Z]_d = \mathbb{C}[\mathbb{A}^n_m]_d/I(Z)_d$ is a GL_m-representation. Equivalently, we can define $\mathbb{C}[Z]$ as the set of restrictions of functions in $\mathbb{C}[\mathbb{A}^n_m]$ to Z.

For most sets of parameters we have $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$, but there are some exceptions. Clearly $\mathsf{Pow}^n_{m,1} \subseteq \mathsf{Ch}^n_m$. Moreover, $\mathsf{Pow}^n_{1,k} = \mathsf{Ch}^n_1$ for all $n \geq 1$, $k \geq 1$; and $\mathsf{Pow}^1_{m,k} = \mathsf{Ch}^1_m$ for all $m \geq 1$, $k \geq 1$. It is also easy to see that $\mathsf{Pow}^2_{2,2} \subseteq \mathsf{Ch}^2_2$, because $\ell_1^2+\ell_2^2 = (\ell_1+i\ell_2)(\ell_1-i\ell_2)$, where $i^2 = -1$. More generally, $(\ell_1 + \zeta\ell_2)(\ell_1 + \zeta^2\ell_2)\cdots(\ell_1 + \zeta^n\ell_2) = \ell_1^n + \zeta^{\frac{n(n+1)}{2}}\ell_2^n$ for $\zeta^n = 1$, which implies $\mathsf{Pow}^n_{m,2} \subseteq \mathsf{Ch}^n_m$. For $m = 2$, $k \geq 1$, $n \geq 1$, we have $\mathsf{Pow}^n_{m,k} \subseteq \mathsf{Ch}^n_m$ by the fundamental theorem of algebra. These are the only exceptions, as for $n \geq 2$, $m \geq 3$, $k \geq 3$ we have $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$: the polynomial $x^n + y^n + z^n$ of the Fermat curve is in $\mathsf{Pow}^n_{m,k}$ and its irreducibility implies (since $n \geq 2$) that $x^n + y^n + z^n \notin \mathsf{Ch}^n_m$.

We will see that for specific settings of parameters there exist *multiplicity obstructions* that prove $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$, but there do not exist *occurrence obstructions* that prove this fact (see the definitions below). Our approach works as follows and is in complete analogy to the approach proposed in [22, 23] to separate group varieties arising from algebraic complexity theory. If $\mathsf{Pow}^n_{m,k} \subseteq \mathsf{Ch}^n_m$, then the restriction of functions gives a canonical GL_m-equivariant surjection $\mathbb{C}[\mathsf{Ch}^n_m]_d \twoheadrightarrow \mathbb{C}[\mathsf{Pow}^n_{m,k}]_d$. In this case, Schur's lemma (e.g. [11, Lemma 4.1.4]) implies that

$$\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) \geq \mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d). \tag{2}$$

for all m-partitions λ. Therefore, a partition λ that violates (2) proves that $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$. Such a λ is called a *multiplicity obstruction*. If additionally $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) = 0$, then λ is called an *occurrence obstruction*.

Since Ch^n_m and $\mathsf{Pow}^n_{m,k}$ are subvarieties of $\mathbb{A}^n_m$ and since all λ for which $\mathrm{mult}_\lambda(\mathbb{C}[\mathbb{A}^n_m]_d) > 0$ are m-partitions of dn, it follows that if $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) > 0$ or $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d) > 0$, then λ is an m-partition of dn.

▶ **Theorem 2.1** (Main Theorem).

(1) *Asymptotic result: Let $m \geq 3$, $n \geq 2$, $k = d = n + 1$, $\lambda = (n^2 - 2, n, 2)$. We have $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) < \mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d)$, i.e., λ is a multiplicity obstruction that shows $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$.*

(2) *Finite result: In two finite settings we can show a slightly stronger separation:*

- **(a)** *Let $k = 4$, $n = 6$, $m = 3$, $d = 7$, $\lambda = (n^2 - 2, n, 2) = (34, 6, 2)$. Then $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) = 7 < 8 = \mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d)$, i.e., λ is a multiplicity obstruction that shows $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$.*
- **(b)** *Similarly, for $k = 4$, $n = 7$, $m = 4$, $d = 8$, $\lambda = (n^2 - 2, n, 2) = (47, 7, 2)$ we have $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) < 11 = \mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d)$, i.e., λ is a multiplicity obstruction that shows $\mathsf{Pow}^n_{m,k} \not\subseteq \mathsf{Ch}^n_m$.*

Both separations (a) *and* (b) *cannot be achieved using occurrence obstructions, even for arbitrary k: for all m-partitions μ that satisfy $a_\mu(d[n]) > 0$ we have $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_{d'}) > 0$ in these settings.*

One would like to show that there are no occurrence obstructions in all cases (1), but this is wrong if n is not large enough with respect to m, see Prop. 3.11. Even for $m = 3$ or $m = 4$ ruling out occurrence obstructions as in (2) is done by a large-scale computer calculation which is only suitable for a finite case, but not for sequences as in (1). The papers [16, 8] rule out occurrence obstructions for families, but only in ranges where they would give very strong new algebraic circuit lower bounds, so that we expect it to be difficult to find multiplicity obstructions in those cases. Note also that [16, 8] are only dealing with *padded polynomials*, for which [17] guarantees λ to have a very restricted shape.

We expect multiplicity obstructions to be more powerful than occurrence obstructions in most cases relevant for geometric complexity theory, and Theorem 2.1 resolves the challenge of finding a setting in which the corresponding multiplicities and occurrences could actually be computed in a reasonable amount of time, while the setting is also involved enough so that a difference between occurrence obstructions and multiplicity obstructions could be witnessed.

▶ Remark 2.2. The partition $(n^2-2, n, 2)$ is known to be the type of one of Brill's classical set-theoretic equations for Ch^n_m, see [12].

3 Proof of the main theorem

The main theorem (Theorem 2.1) makes a statement about the finite situations $k = 4$, $n = 6$, $m = 3$, $d = 7$ and $k = 4$, $n = 7$, $m = 4$, $d = 8$, as well as the general situation $m \geq 3$, $n \geq 2$, $k = d = n + 1$. As a first step, in all these cases we show that

$$\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d) = a_\lambda(d[n]). \tag{3}$$

In the finite cases the following computer calculation suffices to prove (3).

▶ **Proposition 3.1.** $\mathrm{mult}_{(34,6,2)}(\mathbb{C}[\mathsf{Pow}^6_{3,4}]_7) = 8 = a_{(34,6,2)}(7[6])$ *and* $\mathrm{mult}_{(47,7,2)}(\mathbb{C}[\mathsf{Pow}^7_{3,4}]_8) = 11 = a_{(47,7,2)}(8[7])$.

Proof. The plethysm coefficient computations were performed with the LiE software. The rest is a small computer calculation completely analogous to the ones in [8, Sec. 6]. The details can be found in the full version of this paper. ◀

For the general situation the equality (3) is a consequence of the following result on power sums proved in [8, Prop. 3.2]:

▶ **Proposition 3.2.** *If λ is an m-partition of dn and $k \geq d$, then* $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}^n_{m,k}]_d) = a_\lambda(d[n])$.

As a second step we will use the following lemma for $\lambda = (n^2-2, n, 2)$.

▶ **Lemma 3.3** (see also [19, Sec. 9.2.3])**.** *Let λ be an m-partition and $n \geq m$. Then* $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) \leq a_\lambda(n[d])$.

Proof. Let $\mathsf{GL}_n(x_1 \cdots x_n) := \{g(x_1 \cdots x_n) \mid g \in \mathsf{GL}_n\} \subseteq \mathbb{A}^n_n$ denote the GL_n-orbit of $x_1 \cdots x_n$. We denote by $\overline{\mathsf{GL}_n(x_1 \cdots x_n)}$ the Zariski closure of this orbit, which equals its Euclidean closure by the same principles as in Section 2. Choose bases and embed $\mathbb{A}^n_m \subseteq \mathbb{A}^n_n$, so that Ch^n_m is the intersection of $\mathbb{A}^n_m$ and $\overline{\mathsf{GL}_n(x_1 \cdots x_n)}$. This implies (via argument analogous to that for the plethysm coefficient ([14, Lem. 4.3.2])) that the multiplicity of the irreducible GL_m-representation $\{\lambda\}_m$ in $\mathbb{C}[\mathsf{Ch}^n_m]_d$ equals the multiplicity of the irreducible GL_n-representation $\{\lambda\}_n$ in $\mathbb{C}[\overline{\mathsf{GL}_n(x_1 \cdots x_n)}]$. In other words $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}^n_m]_d) = \mathrm{mult}_\lambda(\mathbb{C}[\overline{\mathsf{GL}_n(x_1 \cdots x_n)}]_d)$. The vector space $\mathbb{C}[\overline{\mathsf{GL}_n(x_1 \cdots x_n)}]_d$ consists of exactly the restrictions of polynomials in $\mathbb{C}[\mathbb{A}^n_n]_d$ to

the orbit $\mathsf{GL}_n(x_1 \cdots x_n)$. The coordinate ring $\mathbb{C}[\mathsf{GL}_n(x_1 \cdots x_n)]$ is also graded and its homogeneous degree d part $\mathbb{C}[\mathsf{GL}_n(x_1 \cdots x_n)]_d$ consists of *all* homogeneous degree d regular functions on $\mathsf{GL}_n(x_1 \cdots x_n)$, in particular $\mathrm{mult}_\lambda(\mathbb{C}[\overline{\mathsf{GL}_n(x_1 \cdots x_n)}]_d) \leq \mathrm{mult}_\lambda(\mathbb{C}[\mathsf{GL}_n(x_1 \cdots x_n)]_d)$. The right-hand side can be understood via geometric invariant theory as follows (see [14, Sec. 3.4(A)]): $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{GL}_n(x_1 \cdots x_n)]_d) = \mathrm{mult}_{\lambda^*}(\mathbb{C}[\mathsf{GL}_n]_d^H)$, where $H = \{\mathrm{diag}(\alpha_1, \ldots, \alpha_n) \mid \prod_{i=1}^n \alpha_1 = 1\} \rtimes \mathfrak{S}_n \subseteq \mathsf{GL}_n$ is the stabilizer of $x_1 \cdots x_n$. The algebraic Peter-Weyl theorem (see e.g. [18, II.3.1 Satz 3], [11, Thm. 4.2.7], or [27, Ch. 7, 3.1 Thm.]) states that $\mathbb{C}[\mathsf{GL}_n] = \bigoplus_\lambda \{\lambda\} \otimes \{\lambda^*\}$ and we conclude $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{GL}_n]_d^H) = \dim\{\lambda\}^H$. There are several ways of seeing that $\dim\{\lambda\}^H = a_\lambda(n[d])$, see e.g. [19, Sec. 9.2.3] or [15, Prop. 3.3]. This proves the lemma. ◀

Now an argument using symmetric functions is used to prove the following theorem.

▶ **Theorem 3.4.** $a_{(n^2-2,n,2)}(n+1[n]) = 1 + a_{(n^2-2,n,2)}(n[n+1])$.

Theorem 3.4 is a corollary of more general results, see Corollary 4.4 in the appendix.

This finishes the proof that $(n^2-2, n, 2)$ is a multiplicity obstruction in all cases of Theorem 2.1.

No occurrence obstructions

To finish the proof of Theorem 2.1(2), it remains to show that there are no occurrence obstructions in the finite situation $n = 6$, $m = 3$ and $n = 7$, $m = 4$. We will primarily go into more detail for the first case and the second one will be proven similarly. We will do this by showing that

$$a_\mu(d[n]) > 0 \text{ implies } \mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}_m^n]_d) > 0 \quad \text{for } n = 6,\ m = 3. \tag{4}$$

Note that this claim is independent of k. We start proving (4) by giving a complete classification of when $a_\mu(d[n]) > 0$ for the case $n = 6$, $m = 3$.

First, the following lemma states that for a few special μ the plethysm coefficient always vanishes.

▶ **Lemma 3.5.** *Let $\bar{\lambda} := (\lambda_2, \lambda_3, \ldots)$ denote λ without its first row. If λ is an m-partition of dn and $\bar{\lambda} \in \{(3,3), (3,1), (2,1), (1,1), (1)\}$, then $a_\lambda(d[n]) = 0$.*

Proof. This is proved by a finite calculation for all cases but $(3,3)$ as Thm 1.10(a) in [16]. Exactly the same calculation can be used to also prove the result for the additional partition $(3,3)$. ◀

For characterizing the set of all μ for which $a_\mu(d[n])$ is positive, we observe that they form a finitely generated *semigroup* and hence we only need to find the semigroup's generators:

$$\text{If } a_\mu(d[n]) > 0 \text{ and } a_\nu(d'[n]) > 0, \text{ then } a_{\mu+\nu}(d+d'[n]) > 0. \tag{5}$$

A detailed proof of (5) can be found for example in [1, Prop. 21.2.6].

▶ **Proposition 3.6.** *Define the set*

$X := \{(6),\ (6,6),\ (8,4),\ (10,2),\ (6,6,6),\ (8,6,4),\ (10,4,4),\ (9,6,3),\ (8,8,2),\ (10,6,2),\ (11,5,2),\ (10,7,1),\ (12,4,2),\ (11,6,1),\ (10,8),\ (14,2,2),\ (13,4,1),\ (13,5),\ (15,3),\ (8,8,8),\ (10,8,6),\ (11,7,6),\ (10,9,5),\ (11,8,5),\ (10,10,4),\ (12,7,5),\ (11,9,4),\ (13,6,5),\ (12,8,4),\ (11,10,3),\ (13,7,4),\ (12,9,3),\ (13,8,3),\ (12,10,2),\ (15,5,4),\ (14,7,3),\ (13,9,2),\ (13,10,1),\ (16,5,3),\ (15,7,2),\ (14,9,1),\ (17,4,3),\ (15,8,1),\ (15,9),\ (19,3,2),\ (18,5,1),\ (17,7),\ (10,10,10),\ (11,10,9),\ (12,10,8),\ (13,9,8),\ (12,11,7),\ (13,10,7),\ (14,9,7),\ (13,11,6),\ (15,8,7),\ (13,12,5),\ (16,7,7),\ (15,9,6),\ (14,11,5),\ (13,13,4),\ (15,10,5),\ (15,11,4),\ (14,13,3),\ (16,11,3),\ (15,13,2),\ (15,14,1),\ (17,13),\ (13,12,11),\ (14,11,11),\ (13,13,10),\ (15,11,10),\ (14,13,9),\ (16,11,9),\ (15,13,8),\ (15,14,7),\ (18,9,9),\ (15,15,6),\ (17,17,2),\ (18,17,1),\ (26,5,5),\ (15,14,13),\ (16,13,13),\ (15,15,12),\ (17,17,8),\ (18,15,15),\ (17,17,14),\ (25,23),\ (45,45)\}$.

Here we truncated trailing zeros from the 3-partitions. The set X is the set of generators of the semigroup of 3-partitions μ that have $a_\mu(d[6]) > 0$.

The proof of Proposition 3.6 proceeds in several steps.

A direct computation with the LiE software verifies $a_\mu(d[6]) > 0$ for all $\mu \in X \setminus \{(45,45)\}$. The case $d = 15$ runs into memory problems when using LiE. Other software such as Schur stops working when $d = 8$. We used the formula [32, Cor. 4.2.8] to verify $a_{(45,45)}(15[6]) > 0$.

We call the number of nonzero parts the *length* of a partition. We use a brute-force computer verification and a direct computation with LiE to show that for $d \leq 26$ every partition μ of length ≤ 2 with $a_\mu(d[6]) > 0$ is a sum of partitions from the set X. The same computation is done for all 3-partitions, but only up to $d \leq 14$. The following proposition states that these finite computations completely describe all cases.

▶ **Proposition 3.7.** *If λ is a 3-partition of $6d$, $d \geq 15$, and $\bar{\lambda} \notin \{(3,3),(3,1),(2,1),(1,1),(1)\}$, then λ is a sum of partitions from X.*

Proof. For $15 \leq d \leq 17$ we use a computer calculation to show that we can write every such partition λ as a sum of partitions from X. For $d > 17$ we prove this inductively by showing that we can write every 3-partition λ of $6d$ with $\bar{\lambda} \notin \{(3,3),(3,1),(2,1),(1,1),(1)\}$ as a sum of one of the partitions $(6),(6,6)$ or $(6,6,6)$ and a smaller λ' with again $\bar{\lambda'} \notin \{(3,3),(3,1),(2,1),(1,1),(1)\}$.

Let c_i denote the number of columns in λ with exactly i boxes for $i \in \{1,2,3\}$. Since we have at least 108 boxes in λ, the pigeonhole principle implies that at least one must be true: $c_1 \geq 6$, $c_2 \geq 10$ or $c_3 \geq 10$.

In the case $c_1 \geq 6$ we have $\lambda = \lambda' + (6)$ with λ' being a sum of elements from X since $\bar{\lambda'} = \bar{\lambda}$. In the case $c_2 \geq 10$ we have $\lambda = \lambda' + (6,6)$ with λ' being a sum of elements from X as $\lambda'_2 \geq 4$. In the case $c_3 \geq 10$ we have $\lambda = \lambda' + (6,6,6)$ with λ' being a sum of elements from X as $\lambda'_3 \geq 4$. ◀

This finishes the proof of Proposition 3.6.

To prove (4) it is sufficient (and necessary) to show that $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^n_m]_d) > 0$ for all $\mu \in X$, because a semigroup property analogous to (5) holds (the same proof applies, e.g. [1, Prop. 21.2.6]):

$$\text{If } \mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^n_m]_d) > 0 \text{ and } \mathrm{mult}_\nu(\mathbb{C}[\mathsf{Ch}^n_m]_{d'}) > 0, \text{ then } \mathrm{mult}_{\mu+\nu}(\mathbb{C}[\mathsf{Ch}^n_m]_{d+d'}) > 0. \tag{6}$$

If the length of μ is at most 2, we use the following general result.

▶ **Proposition 3.8.** *Let μ be a 3-partition of length at most 2. If $a_\mu(d[n]) > 0$, then $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^n_m]_d) > 0$.*

Proof. We use an inheritance result: If for a 2-partition μ we have $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^n_2]_d) > 0$, and ν is the 3-partition that arises from μ by adding a single 0, then $\mathrm{mult}_\nu(\mathbb{C}[\mathsf{Ch}^n_3]_d) > 0$. The proof is completely analogous to other inheritance results, see e.g. [14, Lemma 4.3.2 or Sec. 5.3]. Now for 2-partitions μ we have $a_\mu(d[n]) = \mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^n_2]_d)$, because every homogeneous polynomial in 2 variables decomposes as a product of homogeneous linear polynomials by the fundamental theorem of algebra, see also e.g. [19, Exa. 9.1.1.8]. This is how the Hermite reciprocity can be proved. An even simpler argument works if μ has length 1. ◀

We finish the proof of (4) by using a computer calculation to verify that for all 3-partitions $\mu \in X$ of length 3 we have $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}^6_3]) > 0$, see Proposition 5.1.

This finishes the proof of Theorem 2.1(2a). The proof of Theorem 2.1(2b) is completely analogous as follows. Let $m = 4$, $n = 7$.

▶ **Lemma 3.9.** *Let* $\bar{\lambda} := (\lambda_2, \lambda_3, \ldots)$ *denote* λ *without its first row. If* λ *is an* m*-partition of* dn *and* $\bar{\lambda} \in Y$ *for* $Y := \{(1), (1,1), (1,1,1), (2,1), (2,1,1), (2,2,1), (3,1), (3,1,1), (3,2,1), (3,3), (3,3,1), (3,3,2), (3,3,3), (4,1,1), (4,3,3), (5,1,1), (5,5,5), (6,1,1)\}$*, then* $a_\lambda(d[n]) = 0$.

Proof. This is proven exactly like Lemma 3.5. ◀

The semigroup of 4-partitions λ that have $a_\lambda(d[7]) > 0$ has 948 generators, listed in the full version of this paper. They form a set that we call X.

We again use a direct computation with the LiE software to verify $a_\mu(d[7]) > 0$ for all $\mu \in X \setminus \{(49,49), (24,24,23,23)\}$. For both the remaining partitions $\mu \in \{(49,49), (24,24,23,23)\}$ we prove $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}_4^7]_d) > 0$ using our computer calculations which also implies $a_\mu(d[7]) > 0$.

To prove those are all the generators we use the following proposition which is proved completely analogously to Proposition 3.7.

▶ **Proposition 3.10.** *If* λ *is a* 4*-partition of* $7d$*,* $d \geq 14$*, and* $\bar{\lambda} \notin Y$*, then* λ *is a sum of partitions from* X*.*

For the next finite case ($n = 7$, $k = d = 8$, $m = 5$) we reached the computational limit of our implementation. Here we were able to find 5016 generating partitions of the semigroup of 4-partitions μ that have $a_\mu(d[7]) > 0$. Unfortunately these do not generate everything excluding the exceptions yet. We were able to verify for 5000 generating partitions μ that $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}_m^n]_d) > 0$. For the remaining ones, we used up to 200 GB of RAM, but this was not sufficient.

Some occurrence obstructions

As we degenerate the parameter settings and let n get closer to m, multiplicity obstructions tend to become occurrence obstructions. More precisely, for $m = 3$ and values of $n < 6$, and for $(m, n) = (4, 6)$, some multiplicity obstructions are actually also occurrence obstructions, as the following proposition shows.

▶ **Proposition 3.11.** *The following partitions give occurrence obstructions that show* $\mathsf{Pow}_{m,d}^n \not\subseteq \mathsf{Ch}_m^n$.

m	n	λ	d	$a_\lambda(d[n])$	$a_\lambda(n[d])$
3	2	$(2,2,2)$	3	1	0
3	3	$(7,3,2)$	4	1	0
3	4	$(11,9,8)$	7	1	0
3	5	$(12,9,9)$	6	1	0
4	6	$(14,14,13,13)$	9	11	0

Proof. The plethysm coefficient computations were performed with the LiE software. Lemma 3.3 implies that $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Ch}_m^n]_d) \leq a_\lambda(n[d]) = 0$. Proposition 3.2 implies $\mathrm{mult}_\lambda(\mathbb{C}[\mathsf{Pow}_{m,d}^n]_d) > 0$. ◀

See [4, Prop. 4] for additional occurrence obstructions in the case $n = 3$.

4 Plethysm inequalities

We are interested in the plethysm coefficients $a_\lambda(d[m])$ for certain values of λ and d, m. Here we compute such values for infinite families of parameters and in particular, prove Theorem 3.4.

We will work over the ring of symmetric functions Λ, defined as the ring of formal power series (in finitely or infinitely many variables) which are invariant under any transposition of the variables. For the definitions and main identities see e.g. [29]. Plethysms of symmetric functions are described also there in Appendix 2 of Chapter 7, here we review the necessary definitions.

The characters of the irreducible GL_r–module W_λ are the Schur functions $s_\lambda(x_1, \ldots, x_r)$, where $x_1, \ldots, x_r$ correspond to the eigenvalues of the conjugacy class representative from GL_r. Their combinatorial interpretation is as the generating function over all semi-standard Young tableaux with entries $1, ..., r$, but we will use certain determinantal formulas as described below. The complete homogeneous symmetric functions h_ℓ are defined as $s_{(\ell)}$ and are the characters of the Sym^ℓ module. The $\mathrm{Sym}^d(\mathrm{Sym}^n(\mathbb{C}^r))$ module is obtained as the composition of the two representations. The image in $\mathrm{Sym}^n(\mathbb{C}^r)$ of a diagonal matrix from GL_r with entries (i.e. eigenvalues) $x_1, \ldots, x_r$ on the diagonal has eigenvalues all the $N := \binom{n+r-1}{r-1}$ degree n monomials in $x_1, \ldots, x_r$. Hence, the character of the representation $\mathrm{Sym}^d(\mathrm{Sym}^n(\mathbb{C}^r))$ of GL_N can be obtained by evaluating the character h_d of Sym^d at the monomials, i.e. the eigenvalues above. This gives us the definition of the *symmetric function plethysm* $h_d[h_n(x_1, \ldots, x_r)]$, that is, the evaluation of h_d on the variables consisting of all degree n monomials, i.e. $h_d[h_n(x_1, \ldots, x_r)] := h_d(x_1^n, x_1^{n-1}x_2, x_1^{n-1}x_3, \ldots, x_1^{\alpha_1} \cdots x_r^{\alpha_r}, \ldots)$, where $\alpha = (\alpha_1, \ldots, \alpha_r)$ runs over all compositions of n.

In general, knowing the character of a representation contains all the information to obtain the multiplicities of the irreducible decomposition via the inner product of characters. As the Schur functions s_λ are the irreducible characters for GL_r, the inner product is equivalent to an inner product in the ring Λ, where $\{s_\lambda\}_\lambda$ is an orthonormal basis. In other words, the multiplicity of the Weyl module of weight λ is given by the multiplicity of the Schur function s_λ in the expansion of $h_d[h_m]$. We will now compute this via the inner product in the ring Λ of symmetric functions, using some basic properties of this ring as found in [29] and [21].

We have that $a_\lambda(d[n])$ is the multiplicity of $\{\lambda\}$ in $\mathrm{Sym}^d\mathrm{Sym}^n$, translated into characters this is also the coefficient at s_λ of the expansion of $h_d[h_n]$ in Schur function. By their orthonormalitiy, this is the same as

$$a_\lambda(d[n]) = \langle s_\lambda, h_d[h_n] \rangle \tag{7}$$

We now invoke various symmetric function identities in order to compute the above inner product. The Schur functions s_λ can be expressed via the Jacobi-Trudi formula (see again [29, Ch. 7]) as a signed sums of homogeneous symmetric functions, namely

$$s_\lambda = \det\left[h_{\lambda_i - i + j}\right]_{i,j=1}^{\ell(\lambda)}, \tag{8}$$

the inner product (7) can then be computed via a signed sum of inner products of the form $\langle h_\mu, h_d[h_n] \rangle$. We remark that the orthogonal dual basis for the complete homogeneous symmetric functions is the monomial symmetric functions, i.e. $\langle h_\mu, m_\nu \rangle = \delta_{\mu,\nu}$, so we need to express $h_d[h_n]$ in terms of the monomial symmetric functions, defined by

$$m_\nu(x_1, \ldots, x_r) := \sum_{\sigma \in S_r(\nu)} x_1^{\nu_{\sigma(1)}} x_2^{\nu_{\sigma(2)}} \cdots x_r^{\nu_{\sigma(r)}},$$

where the sum ranges over all distinct permutations of $(\nu_1, \nu_2, \ldots, \nu_r)$ and ν is completed with 0s to the length r. Since he monomial symmetric functions form a basis for Λ, we can expand any symmetric function in it uniquely. Let $h_d[h_m] = \sum_\nu c_\nu m_\nu$, for some constants c_ν (i.e. the coefficients in this expansion). Since each m_ν has a unique leading monomial (in the lexicographic order) $x_1^{\nu_1}x_2^{\nu_2}\cdots$, finding c_ν is equivalent to extracting the coefficient at the single monomial $x_1^{\nu_1}\cdots$ from the monomial expansion of the corresponding symmetric function as a polynomial, i.e. $c_\nu = (x_1^{\nu_1}x_2^{\nu_2}\ldots)@h_d[h_n(x_1, x_2, \ldots)]$, where to avoid confusion with the plethysm notation we denote by $(X)@f$ the coefficient of the monomial X in the monomial expansion of the polynomial f.

Let ν be a partition of length ℓ. By the above remarks we need to consider only the truncated expansion $h_d[h_n(x_1, \ldots, x_\ell)]$ as only the monomials in $x_1, \ldots, x_\ell$ will be relevant.

We have the following formula for the h's, see e.g. [29]:

$$h_N(x_1, \ldots, x_r) = \sum_{(b):b_1+b_2+\cdots=N} x_1^{b_1}x_2^{b_2}\cdots,$$

where $(b) = (b_1, b_2, \ldots, b_r)$ runs over all (weak) compositions of N. Hence, assuming some total ordering for compositions α^i of n, we have

$$h_d[h_n(x_1, \ldots, x_r)] = h_d[\ldots, x^{\alpha^i}, \ldots] = \sum_{(b):|b|=d} x^{\sum_i b_i\alpha^i}.$$

Thus for the coefficients c_ν we have:

$$c_\nu(d, n) := (x^\nu)@h_d[h_n] = \langle h_\nu, h_d[h_n]\rangle = \#\{(b) : |b| = d, \sum_i b_i\alpha^i = \nu\} \tag{9}$$

By the Jacobi-Trudi identity (8) this gives a formula for computing the plethysm coeff. as

$$a_\lambda(d[n]) = \langle \det\left[h_{\lambda_i-i+j}\right]_{i,j=1}^{\ell(\lambda)}, h_d[h_n]\rangle = \sum_{\pi\in S_{\ell(\lambda)}} sgn(\pi)c_{\lambda+\pi-(1,2,\ldots)}(d, n), \tag{10}$$

where the permutations π are viewed as vectors with entries $1, 2, \ldots, \ell(\lambda)$

We now turn towards the proof of Theorem 3.4 and consider s_λ for $\lambda = (\lambda_1, \lambda_2, 2)$ for some $k \geq 2$. By the Jacobi-Trudi identity (10) we need to compute only c_ν for ν having at most 3 parts, with $\nu_3 = 0, 1, 2$. Let $p_r(a, b)$ denote the number of partitions of r which fit inside an $a \times b$ rectangle, it's generating function is the q-binomial coefficient (see [31]): $\binom{a+b}{a}_q = \frac{(1-q)\cdots(1-q^{a+b})}{(1-q)\cdots(1-q^a)(1-q)\cdots(1-q^b)} = \sum_{r=0}^{ab} p_r(a, b)q^r$

▶ **Proposition 4.1.** *We have the following generating function identities for $c_\nu(d, n)$, where $\ell(\nu) \leq 3$ and $\nu_3 \leq 2$:*

$$c_{(L,k,2)} = (q^k)@\left(\tbinom{n}{1}_q\tbinom{n+d-2}{n}_q + \tbinom{n-1}{1}_q\tbinom{n+d-1}{n}_q + q\tbinom{n}{2}_q\tbinom{n+d-2}{n}_q\right)$$
$$c_{(L,k,1)} = (q^k)@\tbinom{n}{1}_q\tbinom{n+d-1}{n}_q$$
$$c_{(L,k,0)} = (q^k)@\tbinom{n+d}{n}_q = p_k(n, d)$$

Proof. By formula (9), we have $c_{(L,k,0)} = \#\{(b) : |b| = d, \sum b_i\alpha^i = (L, k)\}$.

Hence, the only α^i involved are of the form $\alpha^i = (n - a_i, a_i)$, and after renumerating, we can assume $a_i = i$. So we are counting compositions b of d, s.t. $\sum_i b_i i = k$ for $i = 0 \ldots n$. This is exactly the same as specifying an integer partition γ of k by the number of its parts, i.e. $\gamma = (0^{b_0}, 1^{b_1}, \ldots, n^{b_n})$, such that $b_0 + \cdots + b_n = d$. These restrictions are equivalent to γ fitting inside an $n \times d$ box, and the number of such γ is exactly $p_k(d, n)$.

Next, when the second part in ν is 1, we have the following. Since $\nu_3 = 1$, the condition $\sum_i b_i\alpha_3^i = \nu_3 = 1$ implies that there is a single i, such that $b_i\alpha_3^i \neq 0$, and in fact must be 1, so $b_i = \alpha_3^i = 1$. After renumeration, we can assume that $i = 0$ (for separation purposes) with $b_0 = \alpha_3^0 = 1$ and $\alpha^0 = (n-1-r, r, 1)$ for $r = 0 \dots n-1$. For the remaining bs and αs we have $\sum_i b_i\alpha^i = (L,k) - (n-1-r, r) = (L+r-n+1, k-r)$ with $b_1 + \dots = d-1$, and $|\alpha^i| = n$. This number is now, by the previous case, $(q^{k-r})@\binom{n+d-1}{n}_q$. The total number is thus

$$c_{(L,k,1)} = \sum_{r=0}^{n-1}(q^{k-r})@\tbinom{n+d-1}{n}_q = (q^k)@\sum_{r=0}^{n-1} q^r\tbinom{n+d-1}{n}_q = (q^k)@\tbinom{n}{1}_q\tbinom{n+d-1}{n}_q.$$

Finally, when $\nu_3 = 2$ we have the following two distinct options:

Either there is an index i, such that $b_i\alpha_3^i = \nu_3 = 2$, or $i < j$ with $b_i\alpha_3^i = 1$ and $b_j\alpha_3^j = 1$.

In the first case we have $b_i\alpha_i^3 = 2$ – either $b_i = 2$, in which case $\alpha^i = (n-1-r, 1)$ and the rest of the b's sum to $d - b_i = d-2$, which brings us to the previous case (of $(L,k,1)$), so the number is

$$(q^k)@\tbinom{n}{1}_q\tbinom{n+d-2}{n}_q.$$

Otherwise, $b_i = 1$ and $\alpha_3^i = 2$. As in the case $\nu_3 = 1$, let $i = 0$ and $\alpha^0 = (n-2-r, r, 2)$, $b_0 = 1$, so we are looking for the number of $(b_1, \dots)$ with $|b| = d-1$ and such that $\sum_i b_i\alpha^i = (L-n+r+2, k-r)$ for all possible $r = 0, \dots, n-2$. So this is

$$\sum_{r=0}^{n-2}(q^{k-r})@\tbinom{n+d-1}{n}_q = (q^k)@\tbinom{n-1}{1}_q\tbinom{n+d-1}{n}_q$$

Last, when there are $i < j$ with $b_i\alpha_3^i = 1$ and $b_j\alpha_3^j = 1$, let $i = -1$, $j = 0$ (again, renumerating for simplicity), with $\alpha^{-1} = (n-1-r_1, r_1, 1)$ and $\alpha^0 = (n-1-r_2, r_2, 1)$ with $0 \le r_1 < r_2 \le n-1$. We thus have for the remaining α and bs that $b_1 + \dots = d-2$, and $\sum_i b_i\alpha^i = (L-(n-1-r_1)-(n-1-r_2), k-r_1-r_2)$. By the first case, this is $(q^{k-r_1-r_2})@\binom{n+d-2}{n}_q$. Summing over all possible $0 < r_1 < r_2 \le n-1$, we have

$$\begin{aligned}(q^k)@\sum_{0\le r_1<r_2\le n-1} q^{r_1+r_2}\binom{n+d-2}{n}_q &= (q^k)@q\sum_{0\le r_1\le r_2-1\le n-2} q^{r_1+(r_2-1)}\binom{n+d-2}{n}_q \\ &= (q^k)@q\binom{n-2+2}{2}_q\binom{n+d-2}{n}_q,\end{aligned}$$

where the last identity follows from interpreting (r_2-1, r_1) as a partition in the $2 \times n-2$ rectangle. Summing over all the cases considered here, we get the desired total coefficient. ◀

▶ **Proposition 4.2.** *The plethysm coefficient for $\lambda = (L, r, 2)$ is equal to*

$$a_\lambda(d[n]) = (q^{r+1})@\left(\tbinom{n+d-2}{n}_q\tfrac{q(1-q^n)(1-q^2+q-q^n)}{1-q^2} + \tbinom{n+d-1}{n}_q(q^{n+1}-1) + (1-q)\tbinom{n+d}{n}_q\right)$$

Proof. Following equation (10), we have that
$a_\lambda(d[n]) = c_{(L,r,2)} - c_{(L,r+1,1)} - c_{(L+1,r-1,2)} + c_{(L+1,r+1,0)} + c_{(L+2,r-1,1)} - c_{(L+2,r,0)}$.
Substituting the formulas for the c's from Proposition 4.1, and observing that $(q^{r+j})@f = (q^r)@q^{-j}f$ for any j, we have that

$$\begin{aligned}a_\lambda(d[n]) = (q^{r+1})@\big((q-q^2)\big(\tbinom{n}{1}_q\tbinom{n+d-2}{n}_q + \tbinom{n-1}{1}_q\tbinom{n+d-1}{n}_q + q\tbinom{n}{2}_q\tbinom{n+d-2}{n}_q\big) \\ +(q^2-1)\tbinom{n}{1}_q\tbinom{n+d-1}{n}_q + (1-q)\tbinom{n+d}{n}_q\big)\end{aligned}$$

Simplifying the above expression by grouping terms for the same binomial coefficients together we obtain
$a_\lambda(d[n]) = (q^{r+1})@\left(\tbinom{n+d-2}{n}_q\tfrac{q(1-q^n)(1-q^2+q-q^n)}{1-q^2} + \tbinom{n+d-1}{n}_q(q^{n+1}-1) + (1-q)\tbinom{n+d}{n}_q\right)$. ◀

▶ **Proposition 4.3.** *Let $\lambda = (L, r, 2)$. We have that*

$$a_\lambda(d[n]) - a_\lambda(n[d]) = (q^r) \mathbin{@} \tbinom{n+d-2}{n-1}_q (q^n - q^d) \tfrac{(1-q^{d-1})(1-q^{n-1})}{(1-q^d)(1-q^n)}.$$

Proof. Set $[a]!_q := (1-q)\cdots(1-q^a)$, a variant of the usual factorial q-analogue but multiplied by $(1-q)^a$, and consider the desired difference via the formula in Proposition 4.2:

$$\begin{aligned} a_\lambda(d[n]) - a_\lambda(n[d]) = (q^{r+1}) \mathbin{@} & \\ \Big\{ & \Big(\tbinom{n+d-2}{n}_q \tfrac{q(1-q^n)(1-q^2+q-q^n)}{1-q^2} + \tbinom{n+d-1}{n}_q (q^{n+1}-1) \\ & - \tbinom{n+d-2}{d}_q \tfrac{q(1-q^d)(1-q^2+q-q^d)}{1-q^2} - \tbinom{n+d-1}{d}_q (q^{d+1}-1) \Big) \\ & = \tfrac{[n+d-2]!_q}{[n-2]!_q[d-2]!_q} \tfrac{q(q^{n-1}-q^{d-1})}{(1-q^{n-1})(1-q^{d-1})} - \tfrac{[n+d-1]!_q}{[n-1]!_q[d-1]!_q} \tfrac{(1-q)(q^n-q^d)}{(1-q^n)(1-q^d)} \\ & = \tbinom{n+d-2}{n-1}_q (q^n - q^d) \left(1 - \tfrac{(1-q^{n+d-1})(1-q)}{(1-q^n)(1-q^d)}\right) \\ & = \tbinom{n+d-2}{n-1}_q (q^n - q^d) \tfrac{q(1-q^{d-1})(1-q^{n-1})}{(1-q^d)(1-q^n)} \Big\} \end{aligned}$$

Finally, observe that the RHS is a polynomial divisible by q, so the coefficient at q^{r+1} is the same as the coefficient at q^r after dividing by q. ◀

We are now ready to prove Theorem 3.4 as a Corollary of the above computations:

▶ **Corollary 4.4.** *[Theorem 3.4] Let $d = n+1$ and $\lambda = (n^2+n-2-r, r, 2)$. Then $a_\lambda((n+1)[n]) - a_\lambda(n[n+1]) \geq 0$, with*

$$a_\lambda((n+1)[n]) - a_\lambda(n[n+1]) = \begin{cases} 0, & \text{when } r < n, \\ 1, & \text{when } r = n, \\ > 0, & \text{when } r > n \text{ and } n \geq 7, \end{cases}$$

with the exception in the last case when $n = 8$, and $r = 35$ when $a_{(35,35,2)}(9[8]) = a_{(35,35,2)}(8[9])$.

Proof. Then by the Proposition 4.3 we have

$$\begin{aligned} a_\lambda(n+1[n]) - a_\lambda(n[n+1]) &= (q^r) \mathbin{@} \tbinom{2n-1}{n-1}_q (q^n - q^{n+1}) \tfrac{(1-q^n)(1-q^{n-1})}{(1-q^{n+1})(1-q^n)} \\ &= (q^r) \mathbin{@} \tbinom{2n-1}{n-1}_q (q^n - q^{n+1}) \tfrac{(1-q^{n-1})}{1-q^{n+1}} = (q^r) \mathbin{@} \tbinom{2n-1}{n-2}_q (q^n - q^{n+1}) \end{aligned}$$

The last line follows by absorbing the fraction into the q-binomial coefficient. It is now evident, that since the q-binomial coefficient expands into a polynomial of q (with coefficients given by $p_*(n-2, n+1)$), multiplying it with q^n or q^{n+1} gives two polynomials whose lowest order terms are q^n and q^{n+1} respectively. So if $r < n$, there is no term of such degree, and the coefficient is 0. when $r = n$ we see that such term can only come from the first polynomial's first (lowest order) term, which is exactly q^n since $\tbinom{2n-1}{n-2}_q q^n = q^n(1 + q + 2q^2 + \cdots) = q^n + O(q^{n+1})$. Therefore we obtain the case $r = n$.

Let now $r > n$, and set $r = n + k + 1$ for some $k \geq 0$. We have that

$$\begin{aligned} a_\lambda((n+1)[n]) - a_\lambda(n[n+1]) &= (q^{k+1}) \mathbin{@} \tbinom{2n-1}{n-2}_q - (q^k) \mathbin{@} \tbinom{2n-1}{n-2}_q \\ &= p_{k+1}(n+1, n-2) - p_k(n+1, n-2) \\ &= g((n^2-n-3-k, k+1), (n+1)^{n-2}, (n+1)^{n-2}) > 0, \end{aligned}$$

where g denotes the Kronecker coefficient for the symmetric group $\mathfrak{S}_n$ for the 3 given partititons, and the last identity and the strict positivity are shown to hold for $n \geq 9$ in [26], and the other cases are verified by direct expansion of the q-binomial coefficients. In particular, we have that $p_{26}(9,6) = 227 = p_{27}(9,6)$ which gives the only exceptional 0 plethysm. ◀

5 Computer calculations

▶ **Proposition 5.1.** *If X is defined as in Proposition 3.6, then for all $\mu \in X$ of length 3 we have* $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}_3^6]) > 0$.

If X is the set of generators of the semigroup of 4-partitions μ that have $a_\mu(d[7]) > 0$ (see full version of this paper), then for all $\mu \in X$ we have $\mathrm{mult}_\mu(\mathbb{C}[\mathsf{Ch}_4^7]) > 0$.

Proof. Proposition 5.1 is proved by a computer calculation that is a refinement and speedup of the computation performed in [9]. Indeed, a run of the method from [9] would take significantly too long to prove Proposition 5.1 in any reasonable time. Our new method makes extensive use of memory resources, while the method from [9] uses almost no memory. The description of the computation can be found in the full version of this paper. ◀

Abstract

In this paper, we revisit the problem of sampling edges in an unknown graph $G = (V, E)$ from a distribution that is (pointwise) almost uniform over E. We consider the case where there is some a priori upper bound on the arboriciy of G. Given query access to a graph G over n vertices and of average degree d and arboricity at most α, we design an algorithm that performs $O\left(\frac{\alpha}{d} \cdot \frac{\log^3 n}{\varepsilon}\right)$ queries in expectation and returns an edge in the graph such that *every* edge $e \in E$ is sampled with probability $(1 \pm \varepsilon)/m$. The algorithm performs two types of queries: degree queries and neighbor queries. We show that the upper bound is tight (up to poly-logarithmic factors and the dependence in ε), as $\Omega\left(\frac{\alpha}{d}\right)$ queries are necessary for the easier task of sampling edges from any distribution over E that is close to uniform in total variational distance. We also prove that even if G is a tree (i.e., $\alpha = 1$ so that $\frac{\alpha}{d} = \Theta(1)$), $\Omega\left(\frac{\log n}{\log\log n}\right)$ queries are necessary to sample an edge from any distribution that is pointwise close to uniform, thus establishing that a poly$(\log n)$ factor is necessary for constant α. Finally we show how our algorithm can be applied to obtain a new result on approximately counting subgraphs, based on the recent work of Assadi, Kapralov, and Khanna (ITCS, 2019).

1 Introduction

Let $G = (V, E)$ be a graph over n vertices and m edges. We consider the problem of sampling an edge in G from a pointwise-almost-uniform distribution over E. That is, for each edge $e \in E$, the probability that e is returned is $(1 \pm \varepsilon)/m$, where ε is a given approximation parameter. An algorithm for performing this task has random access to the vertex set $V = \{1, \ldots, n\}$ and can perform queries to G. The allowed queries are (1) *degree queries*

denoted $\mathsf{deg}(v)$ (what is the degree, $d(v)$, of a given vertex v) and (2) *neighbor queries* denoted $\mathsf{nbr}(v,i)$ (what is the i^{th} neighbor of v).[1] We refer to this model as *the uniform vertex sampling model*.

Sampling edges almost uniformly is a very basic sampling task. In particular it gives the power to sample vertices with probability approximately proportional to their degree, which is a useful primitive. Furthermore, there are sublinear algorithms that are known to work when given access to uniform edges (e.g., [1, 2]) and can be adapted to the case when the distribution over the edges is almost uniform (see Section 1.4 for details). An important observation is that in many cases it is crucial that the sampling distribution is pointwise-close to uniform rather than close with respect to the Total Variation Distance (henceforth TVD) – see the discussion in [15, Sec. 1.1].

Eden and Rosenbaum [15] recently showed that $\Theta^*(\sqrt{m}/d)$ queries are both sufficient and necessary for sampling edges almost uniformly, where $d = 2m/n$ denotes the average degree in the graph. (We use the notation O^* to suppress factors that are polylogarithmic in n and polynomial in $1/\varepsilon$.) The instances for which the task is difficult (i.e., for which $\Omega(\sqrt{m}/d)$ queries are necessary), are characterized by having very dense subgraphs, i.e., a subgraph with average degree $\Theta(\sqrt{m})$. Hence, a natural question is whether it is possible to achieve lower query complexity when some a apriori bound on the density of subgraphs is known. A well studied measure for bounded density "everywhere" is the graph *arboricity* (see Definition 1.2 below). Indeed there are many natural families of graphs that have bounded arboricity such as graphs of bounded degree, bounded treewidth or bounded genus, planar graphs, graphs that exclude a fixed minor and many other graphs. In the context of social networks, preferential attachment graphs and additional generative models exhibit bounded arboricity [3, 6, 5], and this has also been empirically validated for many real-world graphs [18, 16, 22].

We describe a new algorithm for sampling edges almost uniformly whose runtime is $O^*(\alpha/d)$ where α is an upper bound on the arboricity of G. In the extremal case that $\alpha = \Theta(\sqrt{m})$, the runtime of our algorithm is the same as that of [15] (up to poly-log factors). For smaller α, our algorithm is strictly faster. In particular for $\alpha = O(1)$, the new algorithm is *exponentially* faster than that of [15]. We also prove matching lower bounds, showing that for all ranges of α, our algorithm is query-optimal, up to polylogarithmic factors and the dependence in $1/\varepsilon$.

Furthermore, while not as simple as the algorithm of [15], our algorithm is still easy to implement and does not incur any large constants in the query complexity and running time, thus making in it suitable for practical applications.

1.1 Problem definition

In order to state our results precisely, we define the notion of pointwise-closeness of probability distributions (cf. [15]) and arboricity of a graph.

▶ **Definition 1.1.** *Let D be a fixed probability distribution on a finite set X. We say that a probability distribution $\widehat{D}$ is **pointwise ε-close** to D if for all $x \in X$,*

$$\left|\widehat{D}(x) - D(x)\right| \leq \varepsilon D(x)\,, \quad \textit{or equivalently} \quad 1-\varepsilon \leq \frac{\widehat{D}(x)}{D(x)} \leq 1+\varepsilon\,.$$

[1] If $i > d(v)$ then a special symbol, e.g. $\perp$, is returned.

If $D = U$, the uniform distribution on X, then we say that $\widehat{D}$ is ***pointwise ε-close to uniform****.*

For the sake of conciseness, from this point on, unless explicitly stated otherwise, when we refer to an edge sampling algorithm, we mean an algorithm that returns edges according to a distribution that is pointwise-close to uniform.

▶ **Definition 1.2.** *Let $G = (V, E)$ be an undirected graph. A forest $F = (V_F, E_F)$ (i.e., a graph containing no cycles) with vertex set $V_F = V$ and edge set $E_F \subseteq E$ is a* ***spanning forest*** *of G. We say that a family of spanning forests $F_1, F_2, \ldots, F_k$* ***covers*** *G if $E = \bigcup_{i=1}^{k} E_{F_i}$. The* ***arboricity*** *of G, denoted $\alpha(G)$, is the minimum k such that there exists a family of spanning forests of size k that covers G.*

An edge-sampling algorithm is given as input an approximation parameter $\varepsilon \in (0, 1)$ and a parameter α which is an upper bound on the arboricity of G. The algorithm is required to sample edges according a distribution that is pointwise ε-close to uniform. To this end the algorithm is given query access to G. In particular we consider the aforementioned uniform vertex sampling model.

1.2 Results

We prove almost matching upper and lower bounds on the query complexity of sampling an edge according to a distribution that is pointwise-close to uniform when an upper bound on the arboricity of the graph is known. The first lower bound stated below (Theorem 2) holds even for the easier task of sampling from a distribution that is close to uniform in TVD.

▶ **Theorem 1.** *There exists an algorithm $\mathcal{A}$ that for any n, m, α, and graph $G = (V, E)$ with n nodes, m edges, and arboricity at most α, satisfies the following. Given n and α, $\mathcal{A}$ returns an edge $e \in E$ sampled from a distribution $\widehat{U}$ that is pointwise ε-close to uniform using $O\left(\frac{\alpha}{d} \cdot \frac{\log^3 n}{\varepsilon}\right)$ degree and neighbor queries in expectation, where $d = m/n$.*

In Section 1.5.1 we provide a high-level presentation of the algorithm referred to in Theorem 1 and discuss how it differs from the algorithm in [15] (for the case that there is no given upper bound on the arboricity).

We next state our lower bound, which matches the upper bound in Theorem 1 up to a polylogarithmic dependence on n (for constant ε).

▶ **Theorem 2.** *Fix $\varepsilon \leq 1/6$ and let n, m and α be parameters such that $\alpha = \alpha(n) \leq \sqrt{m}$ and $m \leq n\alpha$. Let $\mathcal{G}^{\alpha}_{n,m}$ be the family of graphs with n vertices, m edges and arboricity at most α. Then any algorithm $\mathcal{A}$ that for any $G \in \mathcal{G}^{\alpha}_{n,m}$ samples edges in G from a distribution that is ε-close to uniform in total variation distance – and in particular, any distribution that is pointwise ε-close to uniform – requires $\Omega(\alpha/d)$ queries in expectation.*

When α is a constant then (assuming that $m = \Omega(n)$) the lower bound in Theorem 2 is simply $\Omega(1)$, while Theorem 1 gives an upper bound of $O(\log^3 n)$ (for constant ϵ). We prove that an almost linear dependence on $\log n$ is necessary, even for the case that $\alpha = 1$ (where the graph is a tree).

▶ **Theorem 3.** *Fix $\varepsilon \leq 1/6$, and let $\mathcal{T}_n$ be the family of trees on n vertices. Then any algorithm $\mathcal{A}$ that for any $G \in \mathcal{T}_n$ samples edges in G from a distribution that is pointwise ε-close to uniform requires $\Omega\left(\frac{\log n}{\log\log n}\right)$ queries in expectation.*

We note that both of our lower bounds hold when the algorithm is also given access to *pair queries*, $\mathsf{pair}(u, v)$, which state whether u and v share an edge.

1.3 Discussion of the results

Comparison to known results. The simplest algorithm for sampling edges uniformly is based on rejection sampling. Namely, it repeats the following until an edge is output: Sample a uniform vertex u, flip a coin with bias $d(u)/d_{\max}$, where $d_{\max}$ is the maximum degree, and if the outcome is HEADS, then output a random edge (u, v) incident to u. The expected complexity of rejection sampling grows like $d_{\max}/d$, that is, linearly with the maximum degree. As noted earlier, Eden and Rosenbaum [11] show that this dependence on the maximum degree is not necessary (for approximate sampling), as $O^*(\sqrt{m}/d)$ queries and time always suffice, even when the maximum degree is not bounded (e.g., is $\Theta(n)$). However, if the maximum degree is bounded, and in particular if $d_{\max} = o(\sqrt{m})$, then rejection sampling has lower complexity than the [11] algorithm (e.g., in the case that the graph is close to regular, so that when $d_{\max} = O(d)$, we get complexity $O(1)$).

Since the arboricity of a graph is both upper bounded by $d_{\max}$ and by $\sqrt{m}$, our algorithm can be viewed as "enjoying both worlds". Furthermore, our results can be viewed as showing that the appropriate complexity measure for sampling edges is not the maximum degree but rather the maximum average degree (recall that the arboricity α measures the maximum density of any subgraph of G – for a precise statement, see Theorem 4).

Sampling vs. Estimating. As shown by Eden, Ron and Seshadhri [11], $\Theta^*(\alpha/d)$ is also the complexity of estimating the number of edges in a graph when given a bound α on the arboricity of the graph. Their algorithm improves on the previous known bound of $O^*(\sqrt{m}/d)$ by Feige [17] and Goldreich and Ron [19] (when the arboricity is $o(\sqrt{m})$). However, other than the complexity, our algorithm for sampling edges and the algorithm of [11] for estimating the number of edges do not share any similarities, in particular, as the result of [11] is allowed to "ignore" an ε-fraction of the graph edges.

Furthermore, while the complexity of sampling and of approximate counting of edges are the same (up to $\log n$ and $1/\varepsilon$ dependencies), we have preliminary results showing that for other subgraphs this is not necessarily the case. Specifically, there exist graphs with constant arboricity for which estimating the number of triangles can be done using $O^*(1)$ queries, but pointwise-close to uniform sampling requires $\Omega(n^{1/4})$ queries in expectation.

On the necessity of being provided with an upper bound on the arboricity. While our algorithm does not require to be given any bound on the average degree d, it must be provided with an upper bound α on the arboricity of the given graph. To see why this is true, consider the following two graphs. The first graph consists of a perfect matching between its vertices, so that both its average degree and its arboricity are 1. For $\tilde{\alpha} > 1$, the second graph consists of a perfect matching over $n - n/\tilde{\alpha}$ vertices and an $\tilde{\alpha}$-regular graph over the remaining $n/\tilde{\alpha}$ vertices. This graph has an average degree of roughly 2, and arboricity $\tilde{\alpha}$. If an edge-sampling algorithm is not provided with an appropriate upper bound on the arboricity, but is still required to run in (expected) time that grows like the ratio between the arboricity and the average degree, then the algorithm can be used to distinguish between the two graphs. However, assuming a random labeling of the vertices of the two graphs, this cannot be done in time $o(\tilde{\alpha})$.[2]

Pointwise closeness vs. closeness with respect to the TVD. The lower bound of Theorem 2 holds for sampling from a distribution that is close to uniform with respect to TVD,

[2] We note that this construction can be extended to work for any $d \leq \tilde{\alpha}$.

and *a fortiori* to sampling from pointwise-almost-uniform distributions. In contrast, the lower bound of Theorem 3 does not apply to sampling edges from a distribution that is ε-close to uniform in TVD. Indeed, a simple rejection sampling procedure (essentially ignoring all nodes with degrees greater than $1/\varepsilon$) can sample edges from a distribution that is ε-close to uniform in TVD using $O(1/\varepsilon)$ queries in expectation. Thus, Theorem 3 gives a separation between the tasks of sampling from distributions that are pointwise-close to uniform versus close to uniform in TVD. The general upper and lower bounds of Theorems 1 and 2 show that the separation between the complexity of these tasks can be at most poly-logarithmic for any graph.

1.4 An application to approximately counting subgraphs

In a recent paper [2], Assadi, Kapralov, and Khanna made significant progress on the question of counting arbitrary subgraphs in a graph in sublinear time. Specifically, they provide an algorithm that estimates the number of occurrences of any arbitrary subgraph H in G, denoted by $\#H$, to within a $(1 \pm \varepsilon)$-approximation with high probability. The running time of their algorithm is $O^*\left(\frac{m^{\rho(H)}}{\#H}\right)$, where $\rho(H)$ is the fractional edge cover of H.[3] Their algorithm assumes access to uniform edge samples in addition to degree, neighbor and pair queries. As noted in [2], their algorithm can be adapted to work with edge samples that are pointwise ε-close to uniform (where this is not true for edge samples that are only ε-close to uniform in TVD – e.g., when all the occurrences of H are induced by an ε-fraction of the edges). Invoking the algorithm of [2], and replacing each edge sample with an invocation of Sample-edge results in the following corollary.

▶ **Corollary 1.** *Let G be a graph $G = (V, E)$ with n nodes, m edges, and arboricity at most α. There exists an algorithm that, given $n, \alpha, \varepsilon \in (0, 1)$, a subgraph H and query access to G, returns a $(1 \pm \varepsilon)$ approximation of the number of occurrences of H in G, denoted $\#H$. The expected query complexity and running time of the algorithm are*

$$O^*\left(\min\left\{m, \frac{n\alpha \cdot m^{\rho(H)-1}}{\#H}\right\}\right) \quad \text{and} \quad O^*\left(\frac{n\alpha \cdot m^{\rho(H)-1}}{\#H}\right),$$

respectively, where $\rho(H)$ denotes the fractional edge cover of H, and the allowed queries are degree, neighbor and pair queries.

Thus, by combining our result with [2], we extend the known results for approximately counting the number of subgraphs in a graph in the uniform vertex sampling model. Furthermore, for graphs in which $m = \Theta(n\alpha)$, we obtain the same query complexity and running time of [2] without the assumption that the algorithm has access to uniform edge samples.

1.5 A high-level presentation of the algorithm and lower bounds

1.5.1 The algorithm

While our results concern *un*directed graphs $G = (V, E)$, it will be helpful to view each edge $\{u, v\} \in E$ as a pair of *ordered* edges (u, v) and (v, u). Sampling an edge (almost) uniformly is equivalent to sampling a vertex with probability (almost) proportional to its degree. Hence

[3] The fractional edge cover of a graph $H = (V_H, E_H)$ is a mapping $\psi : E_H \to [0, 1]$ such that for each vertex $a \in V_H$, $\sum_{e \in E_H, a \in e} \psi(e) \geq 1$. The fractional edge-cover number $\rho(H)$ of H is the minimum value of $\sum_{e \in E_H} \psi(e)$ among all fractional edge covers ψ.

we focus on the latter task. A single iteration of the algorithm we describe either returns a vertex or outputs FAIL. We show that the probability that it outputs FAIL is not too large, and that conditioned on the algorithm returning a vertex, each vertex v is returned with probability proportional to its degree, up to a factor of $(1 \pm \varepsilon)$.

Our starting point is a structural decomposition result for graphs with bounded arboricity (Lemma 2.3). Our decomposition defines a partition of the graph's vertices into *levels* $L_0, L_1, \ldots, L_\ell$. For parameters θ and β, the first layer L_0 consists of all vertices with degree at most θ, and for $i > 0$, level L_i contains all vertices v that do not belong to previous levels $L_0, \ldots, L_{i-1}$, but have at least $(1-\beta)d(v)$ neighbors in these levels. We prove that that for any graph with arboricity at most α, for $\theta = \Theta(\alpha \log n/\varepsilon)$ and $\beta = \Theta(\varepsilon/\log n)$, there exists such a partition into layers with $\ell = O(\log n)$ levels. We stress that the algorithm does not actually construct such a partition, but rather we use the partition in our analysis of the algorithm.[4]

In order to gain intuition about the algorithm and its analysis, suppose that all vertices in L_0 have degree exactly θ, and that all edges in the graph are between vertices in consecutive layers. Consider the following *random walk* algorithm. The algorithm first selects an index $j \in [0, \ell]$ uniformly at random. It then selects a vertex u_0 uniformly at random. If $u_0 \in L_0$, then it performs a random walk of length j starting from u_0 (otherwise it outputs FAIL). If the walk did not pass through any vertex in L_0 (with the exception of the starting vertex u_0), then the algorithm returns the final vertex reached.

First observe that for every $u \in L_0$, the probability that u is returned is $\frac{1}{\ell+1} \cdot \frac{1}{n}$ (the probability that the algorithm selected $j = 0$ and selected u as u_0). This equals $\frac{d(u)}{(\ell+1)\cdot\theta\cdot n}$ (by our assumption that $d(u) = \theta$ for every $u \in L_0$). Now consider a vertex $v \in L_1$. The probability that v is returned is at least $\frac{1}{\ell+1} \cdot \frac{(1-\beta)d(v)}{n} \cdot \frac{1}{\theta} = \frac{(1-\beta)d(v)}{(\ell+1)\cdot\theta\cdot n}$ (the probability that the algorithm selected $j = 1$, then selected one of v's neighbors $u \in L_0$, and finally selected to take the edge between u and v). In general, our analysis shows that for every i and every $v \in L_i$, the probability that v is returned is at least $\frac{(1-\beta)^i d(v)}{(\ell+1)\cdot\theta\cdot n}$. On the other hand, we show that for every vertex v, the probability that v is returned is at most $\frac{d(v)}{(\ell+1)\cdot\theta\cdot n}$. By the choice of θ and β we get that each vertex v is returned with probability in the range $[(1-\varepsilon)d(v)\rho(\varepsilon, n), d(v)\rho(\varepsilon, n)]$ for $\rho(\varepsilon, n) = \Theta(\varepsilon/(\alpha n \log^2 n))$. By repeating the aforementioned random-walk process until a vertex is returned – $\Theta\left(\frac{\alpha n}{m} \cdot \frac{\log^2 n}{\varepsilon}\right) = \Theta\left(\frac{\alpha}{d} \cdot \frac{\log^2 n}{\varepsilon}\right)$ times in expectation – we obtain a vertex that is sampled with probability proportional to its degree, up to $(1 \pm \varepsilon)$.

We circumvent the assumption that $d(u) = \theta$ for every $u \in L_0$ by rejection sampling: In the first step, if the algorithm samples $u_0 \in L_0$, then it continues with probability $d(u)/\theta$ and fails otherwise. The assumption that all edges are between consecutive levels is not necessary for the analysis described above to hold. The crucial element in the analysis is that for every vertex $v \notin L_i$, where $i > 0$, at least $(1-\beta)$ of the neighbors of v belong to $L_0, \ldots, L_{i-1}$. This allows us to apply the inductive argument for the lower bound on the probability that v is returned when we average over all choices of j (the number of steps in the random walk). For precise details of the algorithm and its analysis, see Section 2.

We briefly discuss the relation between our algorithm for bounded-arboricity graphs, which we denote by $\mathcal{A}_{ba}$ and the algorithm presented in [15] (for the case that no upper bound is given on the arboricity), which we denote by $\mathcal{A}_{ua}$. The algorithm $\mathcal{A}_{ua}$ can be

[4] This decomposition is related to the forest decomposition of Barenboim and Elkin [4]. The main difference, which is essential for our analysis, is that the partition we define is based on the number of neighbors that a vertex has in lower levels *relative* to its degree, while in [4] the partition is based on the absolute number of neighbors in higher levels.

viewed as considering a partition of the graph vertices into just two layers according to a degree threshold of roughly $\sqrt{m/\varepsilon}$. It performs a random walk similarly to $\mathcal{A}_{ba}$, but where the walk has either length 0 or 1. This difference in the number of layers and the length of the walk, is not only quantitative. Rather, it allows $\mathcal{A}_{ua}$ to determine to which layer a vertex belongs simply according to its degree. This is not possible in the case of $\mathcal{A}_{ba}$ (with the exception of vertices in L_0). Nonetheless, despite the apparent "blindness" of $\mathcal{A}_{ba}$ to the layers it traverses in the random walk, we can show the following: Choosing the length of the random walk uniformly at random and halting in case the walk returns to L_0, ensures that each vertex is output with probability approximately proportional to its degree.

1.5.2 The lower bounds

In order to prove Theorem 2, we employ the method of [14] – which builds upon the paradigm introduced in [7] – based on communication complexity. The idea of the proof is to reduce from the two-party communication complexity problem of computing the disjointness function. The reduction is such that (1) any algorithm that samples edges from an almost-uniform distribution reveals the value of the disjointness function with sufficiently large probability, and (2) every allowable query can be simulated in the two-party communication setting using little communication.

As opposed to the proof of the lower bound for general α, in the case of $\alpha = 1$ we did not find a way to employ the communication-complexity method. Instead, we design a direct, albeit somewhat involved, proof from first-principles.

Specifically, in order to prove Theorem 3, we consider a complete tree in which each internal vertex has degree $\log n$ (so that its depth is $\Theta\left(\frac{\log n}{\log\log n}\right)$). We then consider the family of graphs that correspond to all possible labelings of such a tree. As noted in Section 1.5.1, sampling edges almost uniformly is equivalent to sampling vertices with probability approximately proportional to their degree. In particular, in our construction, the label of the root should be returned with probability approximately $\log n/n$. We show that any algorithm that succeeds in returning the label of the root of the tree with the required probability must perform $\Omega\left(\frac{\log n}{\log\log n}\right)$ queries.

To this end we define a *process* $\mathcal{P}$ that interacts with any algorithm $\mathcal{A}$, answering $\mathcal{A}$'s queries while constructing a uniform random labeling of the vertices and edges in the tree. The vertices of the tree are assigned random labels in $[n]$, and for each vertex v in the tree, its incident edges are assigned random labels in $[d(v)]$. We say that $\mathcal{A}$ *succeeds*, if after the interaction ends, $\mathcal{A}$ outputs the label of the root of the tree, as assigned by $\mathcal{P}$.

Let $L = \frac{\log n}{C \cdot \log\log n}$ be the lower bound we would like to prove, where C is a sufficiently large constant (so that in particular, L is a (small) constant fraction of the depth of the tree). Intuitively, $\mathcal{A}$ would like to "hit" a vertex at depth at most L and then "walk up the tree" to the root. There are two sources of uncertainty for $\mathcal{A}$. One is whether it actually hits a vertex at depth at most L, and the second is which edges should be taken to go up the tree. Our lower bound argument mainly exploits the second uncertainty, as we sketch next.

The process P starts with an unlabeled tree (of the aforementioned structure), and assigns labels to its vertices and edges in the course of its interaction with $\mathcal{A}$. Recall that $\mathcal{P}$ answers the queries of $\mathcal{A}$ while constructing a uniform labeling. Therefore, whenever $\mathcal{A}$ asks a query involving a *new* label (i.e., that has not yet appeared in its queries or answers to them), the vertex to which this label is assigned, should be uniformly selected among all vertices that are not yet labeled. We shall say that a vertex is *critical* it its depth is at most L. As long as no critical vertex is hit, $\mathcal{A}$ cannot reach the root. This implies that if no critical vertex is

hit in the course of its queries, then the probability that $\mathcal{A}$ succeeds is $O(1/n)$.

While the probability of hitting a critical vertex is relatively small, it is not sufficiently small to be deemed negligible. However, suppose that $\mathcal{A}$ hits a critical vertex u at depth $\Delta < L$, which occurs with probability roughly $(\log n)^{\Delta}/n$. Then, conditioned on this event, each of the $(\log n)^{\Delta}$ edge-labeled paths from u is equally likely to lead to the root, and the labels of vertices on these paths are uniformly distributed, thus intuitively conveying no information regarding the "right path".

A subtlety that arises when formalizing this argument is the following. Suppose that in addition to hitting a critical vertex u, $\mathcal{A}$ hits another vertex, v, which is not necessarily critical, but is at distance less than L from u (and in particular has depth at most $2L$, which we refer to as *shallow*). Then, a path starting from v might meet a path starting from u, hence adding a conditioning that makes the above argument (regarding uniform labelings) imprecise. We address this issue by upper bounding the probability of such an event (i.e., of hitting both a critical vertex and a shallow vertex), and accounting for an event of this type as a success of $\mathcal{A}$.

1.6 Related work

Some of the works presented below were already mentioned earlier in the introduction, but are provided in this subsection for the sake of completeness.

The work most closely related to the present work is the recent paper of Eden and Rosenbaum [15]. In [15], the authors proved matching upper and lower bounds of $\Theta^*(\sqrt{m}/d)$ for the problem of sampling an edge from an almost-uniform distribution in an arbitrary graph using degree, neighbor, and pair queries.

The problem of sampling edges in a graph is closely related to the problem of estimating m, the number of edges in the graph. In [17], Feige proved an upper bound of $O^*(\sqrt{m}/d)$ for obtaining a $(2+\varepsilon)$-factor multiplicative approximation of m using only degree queries,[5] and shows that it is not possible to go below a factor of 2 with a sublinear number of degree queries. In [19], Goldreich and Ron showed that $\Theta^*(\sqrt{m}/d)$ queries are necessary and sufficient to obtain a $(1+\varepsilon)$-factor approximation of m if neighbor queries are also allowed.

Several works prove matching upper and lower bounds on the query complexity of counting the number of triangles [8], cliques [13], and star-graphs of a given size [20] using degree, neighbor, and pair queries (when the latter are necessary). Eden, Ron, and Seshadhri devised algorithms for estimating the number of k-cliques [12] and moments of the degree distribution [11] whose runtimes are parameterized by the arboricity α of the input graph (assuming a suitable upper bound for α is given to the algorithm as input). These algorithms outperform the lower bounds of [13] and [20] (respectively) in the case where $\alpha \ll \sqrt{m}$. In [9], Eden, Levi, and Ron described an efficient algorithm for distinguishing graphs with arboricity at most α from those that are far from any graph with arboricity 3α.

Two recent works [1, 2] consider a query model that allows uniform random edge sampling in addition to degree, neighbor, and pair queries. In this model, Aliakbarpour et al. [1] described an algorithm for estimating the number of star subgraphs. In the same model, Assadi et al. [2] devised an algorithm that relies on uniform edge samples as a basic query to approximately count the number of instances of an arbitrary subgraph in a graph. The

[5] To be precise, Feige [17] shows that, given a lower bound d_0 on the average degree, $O(\sqrt{n/d_0}/\varepsilon)$ degree queries are sufficient. If such a lower bound is not provided to the algorithm, then a geometric search can be performed, as shown in [19].

results in [1] and [2] imply that uniform edge samples afford the model strictly more power: the sample complexity of the algorithm of [1] outperforms the lower bound of [20] for the same task, and the sample complexity of the algorithm of [2] outperforms the lower bound of [13] for estimating the number of cliques. (The results of [20, 13] are in the uniform vertex sampling model.)

Organization

Due to space constraints, in this extended abstract we provide full details only for the proof of our upper bound (Theorem 1). The proofs of Theorems 2 and 3 can be found in [10].

2 The Algorithm

In this section we describe an algorithm that samples an edge e from an arbitrary graph G with arboricity at most α, according to a pointwise almost uniform distribution. Theorem 1 follows from our analysis of the algorithm. In what follows, for integers $i \leq j$, we use $[i, j]$ to denote the set of integers $\{i, \ldots, j\}$, and for a vertex v we let $\Gamma(v)$ denote its set of neighbors.

As noted in the introduction, sampling edges from a uniform distribution is equivalent to sampling vertices proportional to their degrees. Indeed, if each vertex v is sampled with probability $d(v)/2m$, then choosing a random neighbor $w \in \Gamma(v)$ uniformly at random returns the (directed) edge $e = (v, w)$ with probability $1/2m$. Thus, it suffices to sample each vertex $v \in V$ with probability (approximately) proportional to its degree.

2.1 Decomposing graphs of bounded arboricity

Before describing the algorithm, we describe a decomposition of a graph G into *layers* depending on its arboricity. We begin by recalling the following characterization of arboricity due to Nash-Williams [21].

▶ **Theorem 4** (Nash-Williams [21]). *Let $G = (V, E)$ be a graph. For a subgraph H of G, let n_H and m_H denote the number of vertices and edges, respectively, in H. Then $\alpha(G) = \max_H \{\lceil m_H/(n_H - 1)\rceil\}$, where the maximum is taken over all subgraphs H of G.*

▶ **Definition 2.1.** *Let $G = (V, E)$ be a graph, and $\theta \in \mathbf{N}$, $\beta \in (0, 1)$ parameters. We define a (θ, β)-**layering** in G to be the sequence of non-empty disjoint subsets $L_0, L_1, \ldots, L_\ell \subseteq V$ defined by $L_0 = \{v \in V \mid d(v) \leq \theta\}$ and for $i \geq 1$,*

$$L_{i+1} = \left\{v \notin L_0 \cup L_1 \cup \cdots \cup L_i \;\middle|\; |\Gamma(v) \cap (L_0 \cup \cdots \cup L_i)| \geq (1 - \beta)d(v)\right\}.$$

*That is, L_0 consists of all vertices of degree at most θ, and a vertex v is in L_{i+1} if i is the smallest index for which a $(1 - \beta)$-fraction of v's neighbors resides in $L_0 \cup L_1 \cup \cdots \cup L_i$. We say that G admits a (θ, β)-**layered partition of depth** ℓ if we have $V = L_0 \cup L_1 \cup \cdots \cup L_\ell$.*

▶ **Notation 2.2.** *For a fixed i, we denote $L_{\leq i} = L_0 \cup L_1 \cup \cdots \cup L_i$, and similarly for $L_{<i}$, $L_{\geq i}$, and $L_{>i}$. We use the notation $d_i(v)$ to denote $|\Gamma(v) \cap L_i|$ and similarly for $d_{\leq i}(v)$ and $d_{\geq i}(v)$.*

▶ **Lemma 2.3.** *Suppose G is a graph with arboricity at most α. Then G admits a (θ, β)-layered partition of depth ℓ for $\theta = 4\alpha\lceil \log n\rceil/\varepsilon$, $\beta = \varepsilon/2\lceil \log n\rceil$, and $\ell \leq \lceil \log n\rceil$.*

Proof. For each i, let $W_i = V \setminus (L_0 \cup L_1 \cup \cdots \cup L_{i-1})$ be the set of vertices not in levels $0, 1, \ldots, i - 1$. Let $m(W_i)$ denote the number of edges in the subgraph of G induced by W_i.

For any fixed i and $v \in W_{i+1}$, we have $d_{<i}(v) < (1-\beta)d(v)$ because $v \notin L_{\leq i}$. Therefore, v has at least $\beta d(v) > \beta\theta$ neighbors in W_i. Summing over vertices $v \in W_{i+1}$ gives

$$m(W_i) = \frac{1}{2}\sum_{v\in W_i} d_{\geq i}(v) \geq \frac{1}{2}\sum_{v\in W_{i+1}} d_{\geq i}(v) > \frac{1}{2}\,|W_{i+1}| \cdot \beta\theta\,. \tag{1}$$

On the other hand, since G has arboricity at most α, Theorem 4 implies that $m(W_i) \leq \alpha\,|W_i|$. Plugging this into Equation (1), we find that $\frac{|W_{i+1}|}{|W_i|} \leq \frac{2\alpha}{\beta\theta} = \frac{1}{2}$, where the inequality is by the choice of β and θ. Therefore, for $\ell \leq \lceil \log n \rceil$, we have that $W_{\ell+1} = \emptyset$, implying that $V = L_0 \cup L_1 \cup \cdots \cup L_\ell$. ◀

2.2 Algorithm description

The algorithm exploits the structure of graphs G with arboricity at most α described in Lemma 2.3. More precisely, as the algorithm does not have direct access to this structure, the structure is used explicitly only in the analysis of the algorithm. Let $L_0, L_1, \ldots, L_\ell$ be a (θ,β)-layered partition of V with $\theta = 4\alpha\lceil\log n\rceil/\varepsilon$, $\beta = \varepsilon/\lceil\log n\rceil$, and $\ell = \lceil\log n\rceil$. Vertices $v \in L_0$ are sampled with probability exactly proportional to their degree using a simple rejection sampling procedure, Sample-$L_0(G,\theta)$. In order to sample vertices in layers L_i for $i > 0$, our algorithm performs a random walk starting from a random vertex in L_0 chosen with probability proportional to its degree. Specifically, the algorithm Sample-edge(G,α) chooses a length j to the random walk uniformly in $[0,\ell]$. The subroutine Random-walk(G,θ,j) performs the random walk for j steps, or until a vertex $v \in L_0$ is reached in some step $i > 0$. If the walk returns to L_0, the subroutine aborts and does not return any vertex. (This behavior ensures that samples are not too biased towards vertices in lower layers.) Otherwise, Random-walk returns the vertex at which the random walk halts. Our analysis shows that the probability that the random walk terminates at any vertex $v \in V$ is approximately proportional to $d(v)$ (Corollary 2.7), although Sample-edge may fail to return any edge with significant probability. Finally, we repeat Sample-edge until it successfully returns a vertex.

Sample-edge(G,α,ε)

1. Let $\theta = 4\alpha\lceil\log n\rceil/\varepsilon$ and let $\ell = \lceil\log n\rceil$.
2. Choose a number $j \in [0,\ell]$ uniformly at random.
3. Invoke Random-walk(G,θ,j) and let v be the returned vertex if one was returned. Otherwise, **return** FAIL.
4. Sample a uniform neighbor w of v and **return** $e = (v,w)$.

Random-walk(G,θ,j)

1. Invoke Sample-$L_0(\theta)$ and let v_0 be the returned vertex if one was returned. Otherwise, **return** FAIL.
2. For $i = 1$ to j do
   a. Sample a random neighbor v_i of v_{i-1}.
   b. If $v_i \in L_0$ then **return** FAIL.
3. **Return** v_j.

Sample-$L_0(G,\theta)$

1. Sample a vertex $u \in V$ uniformly at random and query for its degree.
2. If $d(u) > \theta$ **return** FAIL.
3. **Return** u with probability $\frac{d(u)}{\theta}$, and with probability $1 - \frac{d(u)}{\theta}$ **return** FAIL.

▶ **Definition 2.4.** *We let $P_j[v]$ denote the probability that* Random-walk *returns v, when invoked with parameters G, θ and $j \in [0,\ell]$. We also let $P_{\leq j}[v] \stackrel{def}{=} \sum_{i=0}^{j} P_i[v]$ and similarly for $P_{\geq j}$.*

▶ **Lemma 2.5.** *Let ℓ be as set in Step 1 of* Sample-edge *and let $P_{\leq j}$ be as defined in Definition 2.4. For all $v \in V$, $P_{\leq \ell}[v] \leq \frac{d(v)}{n\theta}$.*

Proof. We argue by induction on j that for any $j \in [0,\ell]$, $P_{\leq j}[v] \leq d(v)/n\theta$. For the case $j = 0$, it is immediate from the description of Random-walk and Sample-L_0 that $P_0[v] = d(v)/(n\theta)$ if $v \in L_0$ and $P_0[v] = 0$ otherwise. Further, for $v \in L_0$, due to Step 2b, $P_i(v) = 0$ for all $i > 0$, so that the lemma holds for all $v \in L_0$. Now suppose that for all $v \in V$ we have $P_{\leq j-1}(v) \leq d(v)/n\theta$. Then for any fixed $v \notin L_0$ we compute

$$P_{\leq j}[v] = \sum_{i=1}^{j} P_i[v] = \sum_{i=1}^{j} \sum_{u\in\Gamma(v)} P_{i-1}[u]\frac{1}{d(u)} = \sum_{u\in\Gamma(v)} \frac{1}{d(u)} \sum_{i=0}^{j-1} P_i[u]$$
$$= \sum_{u\in\Gamma(v)} \frac{1}{d(u)} P_{\leq j-1}[u] \leq \sum_{u\in\Gamma(v)} \frac{1}{d(u)} \frac{d(u)}{n\theta} = \frac{d(v)}{n\theta}.$$

The second equality holds by the definition of Random-walk, and the one before the last inequality holds by the inductive hypothesis. ◀

▶ **Lemma 2.6.** *Let ℓ be as set in Step 1 of* Sample-edge*. For every $j \in [\ell]$, $v \in L_j$ and $k \in [j,\ell]$, we have $P_{\leq k}[v] \geq \frac{(1-\beta)^j d(v)}{n\theta}$.*

Proof. We prove the claim by induction on j. For $j = 0$ and $k = 0$, by the description of Random-walk and Sample-L_0, for every $v \in L_0$,

$$P_0[v] = \frac{d(v)}{n\theta} . \tag{2}$$

For $j = 0$ and $0 < k \leq \ell$,

$$P_{\leq k}[v] = \sum_{i=0}^{k} P_i[v] = P_0[v] + \sum_{i=1}^{k} P_i[v] = \frac{d(v)}{n\theta} , \tag{3}$$

where the last equality is due to Step 2b in Random-walk.

For $j = 1$ and $1 \leq k \leq \ell$, for every $v \in L_1$, according to Step 2b in the procedure Random-walk, $P_0[v] = 0$. Also, for every $u \notin L_0$, $P_0[u] = 0$, since by Step 2 in Sample-L_0 it always holds that v_0 is in L_0. Therefore,

$$P_1[v] = \sum_{u\in\Gamma(v)} P_0[u]\cdot\frac{1}{d(u)} = \sum_{u\in\Gamma(v)\cap L_0} P_0[u]\cdot\frac{1}{d(u)} = \sum_{u\in\Gamma(v)\cap L_0} \frac{d(u)}{n\theta}\cdot\frac{1}{d(u)} = \frac{d_0(v)}{n\theta}, \tag{4}$$

where the second to last inequality is by Equation (2). By the definition of L_1, for every $v \in L_1$, $d_0(v) \geq (1-\beta)d(v)$, and it follows that $P_{\leq k}[v] \geq P_1[v] \geq (1-\beta)d(v)/(n\theta)$.

We now assume that the claim holds for all $i \leq j-1$ and $k \in [i,\ell]$, and prove that it holds for j and for every $k \in [j,\ell]$. By the induction hypothesis and the definition of L_j, for any $v \in L_j$ we have

$$P_{\leq k}[v] \geq P_{\leq j}[v] = \sum_{u\in\Gamma(v)} P_{\leq j-1}[u]\cdot\frac{1}{d(u)} \geq \sum_{i=0}^{j-1} \sum_{u\in\Gamma(v)\cap L_i} P_{\leq j-1}[u]\cdot\frac{1}{d(u)}$$
$$\geq \sum_{i=0}^{j-1} \sum_{u\in\Gamma(v)\cap L_i} \frac{(1-\beta)^i d(u)}{n\theta}\cdot\frac{1}{d(u)} \geq \frac{(1-\beta)^{j-1} d_{\leq j-1}(v)}{n\theta} \geq \frac{(1-\beta)^j d(v)}{n\theta}.$$

Hence, the claim holds for every $j \in [\ell]$ for every $k \in [j,\ell]$. ◀

▶ **Corollary 2.7.** *For any graph G with arboricity at most α, the procedure Sample-edge when invoked with G, α and ε, returns each edge in the graph with probability in the range $\left[\frac{1-\varepsilon/2}{\rho}, \frac{1}{\rho}\right]$ for $\rho = n\theta(\ell+1)$, $\theta = 4\alpha\lceil\log n\rceil/\varepsilon$ and $\ell = \lceil\log n\rceil$.*

Proof. Consider a specific edge $e^* = (v^*, w^*)$, and let i be the index such that $v^* \in L_i$. By the description of the procedure Sample-edge, the procedure Random-walk is invoked with an index j that is chosen uniformly in $[0, \ell]$. Hence, the probability that v^* is returned by Random-walk in Step 3 is $\Pr[v = v^*] = \frac{1}{\ell+1}\sum_{j=0}^{\ell} P_j[v] = \frac{1}{\ell+1}P_{\leq\ell}[v]$. By Lemma 2.5, $P_{\leq\ell}[v] \leq \frac{d(v)}{n\theta}$, and by Lemma 2.6, $P_{\leq\ell}[v^*] \geq \frac{(1-\beta)^\ell d(v^*)}{n\theta}$, where the probability is over the random coins of the procedures Sample-edge and Random-walk. Hence,

$$\Pr[v = v^*] \in [(1-\beta)^\ell, 1] \cdot \frac{d(v^*)}{n\theta(\ell+1)},$$

implying that for $\rho = n\theta(\ell+1)$,

$$\Pr[(v^*, w^*) \text{ is the returned edge}] \in [(1-\beta)^\ell, 1] \cdot \frac{1}{n\theta(\ell+1)} \in \left[\frac{1-\varepsilon/2}{\rho}, \frac{1}{\rho}\right], \tag{5}$$

where the last inequality is by the setting of $\beta = \varepsilon/2\lceil\log n\rceil$. ◀

Proof of Theorem 1. Consider the algorithm that repeatedly calls Sample-edge(G, α) until an edge e is successfully returned. For a single invocation of Sample-edge and fixed edge e let A_e denote the event that Sample-edge returns e. By Corollary 2.7 we have that $\Pr[A_e] \geq (1-\varepsilon)/n\theta(\ell+1)$. Further, for any edge $e' \neq e$ the events A_e and $A_{e'}$ are disjoint, so we bound

$$\Pr[\text{Sample-edge returns an edge}] \;=\; \Pr\left[\bigcup_{e\in E} A_e\right] \;=\; \sum_{e\in E}\Pr[A_e] \;\geq\; \frac{(1-\varepsilon)m}{n\theta(\ell+1)}\,.$$

The expected number of iterations until Sample-edge succeeds is the reciprocal of this probability, so

$$\mathbf{E}[\#\text{ invocations until success}] \leq \frac{n\theta(\ell+1)}{(1-\varepsilon)m} = O\left(\frac{n\alpha}{m\varepsilon}\cdot\log^2 n\right).$$

Since each invocation of Sample-edge uses $O(\log n)$ queries, the expected number of queries before an edge is returned is $O(\frac{n\alpha}{\varepsilon m}\cdot\log^3 n)$.

Finally, when conditioned on a successful invocation of Sample-edge, Corollary 2.7 implies that for any $e, f \in E$ the probabilities p_e, p_f of returning e and f, respectively, satisfy

$$1 - \varepsilon/2 \leq \frac{p_e}{p_f} \leq \frac{1}{1-\varepsilon/2} \leq 1 + \varepsilon.$$

Therefore, the induced distribution P over edges returned by a successful invocation of Sample-edge is pointwise ε-close to uniform, which gives the desired result. ◀

Abstract

We consider the problem of maximizing a monotone submodular function subject to a knapsack constraint. Our main contribution is an algorithm that achieves a nearly-optimal, $1 - 1/e - \epsilon$ approximation, using $(1/\epsilon)^{O(1/\epsilon^4)} n \log^2 n$ function evaluations and arithmetic operations. Our algorithm is impractical but theoretically interesting, since it overcomes a fundamental running time bottleneck of the multilinear extension relaxation framework. This is the main approach for obtaining nearly-optimal approximation guarantees for important classes of constraints but it leads to $\Omega(n^2)$ running times, since evaluating the multilinear extension is expensive. Our algorithm maintains a fractional solution with only a constant number of entries that are strictly fractional, which allows us to overcome this obstacle.

1 Introduction

A set function $f : 2^V \to \mathbb{R}$ is *submodular* if for every $A, B \subseteq V$, we have $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$. Submodular functions naturally arise in a variety of contexts, both in theory and practice. Submodular functions capture many well-studied combinatorial functions including cut functions of graphs and digraphs, weighted coverage functions, as well as continuous functions including the Shannon entropy and log-determinants. Submodular functions are used in a wide range of application domains from machine learning to economics. In machine learning, it is used for document summarization [9], sensor placement [7], exemplar clustering [3], potential functions for image segmentation [4], etc. In an economics context, it can be used to model market expansion [2], influence in social networks [5], etc. The core mathematical problem underpinning many of these applications is the meta problem of maximizing a submodular objective function subject to some constraints.

A common approach to submodular maximization is a two-step framework based on the multilinear extension F of f, a continuous function that extends f to the domain $[0,1]^V$. The program first (1) maximizes $F(x)$ subject to a continuous relaxation of the constraint and then (2) rounds the solution x to an integral vector satisfying the constraint. This paradigm has been very successful and it has led to the current best approximation algorithms for a wide variety of constraints including cardinality constraints, knapsack constraints, matroid constraints, etc. One downside with this approach is that in general, evaluating the multilinear extension is expensive and it is usually approximately evaluated. To achieve the desirable approximation guarantees, the evaluation error needs to be very small and in a lot of cases, the error needs to be $O(n^{-1})$ times the function value. Thus, even an efficient algorithm with $O(n)$ queries to the multilinear extension would require $\Omega(n^2)$ running time.

In this work, we develop a new algorithm that achieves $1 - 1/e - \epsilon$ approximation for maximizing a monotone submodular function subject to a knapsack constraint. The basic approach is still based on the multilinear extension but the algorithm ensures that the number of fractional coordinates is constant, which allows evaluating the multilinear extension exactly in constant number of queries to the original function. This approach allows us to bypass the obstructions discussed above and get nearly linear running time.

▶ **Theorem 1.** *There is an algorithm for maximizing a monotone submodular function subject to a knapsack constraint that achieves a $1 - 1/e - \epsilon$ approximation using $(1/\epsilon)^{O(1/\epsilon^4)} n \log n$ function evaluations and $(1/\epsilon)^{O(1/\epsilon^4)} n \log^2 n$ arithmetic operations.*

For simplicity, when stating running times, we assume that each call to the value oracle of f takes constant time, since for the algorithms discussed the number of evaluations dominates the running time up to logarithmic factors. Previously, Wolsey [11] gives an algorithm with a $1 - 1/e^\beta \approx 0.35$ approximation, where β is the unique root of the equation $e^x = 2 - x$. Building on the work of Khuller *et al.* for the maximum k-coverage problem [6], Sviridenko [10] gives an algorithm with a $1 - 1/e$ approximation that runs in $O(n^5)$ time. Badanidiyuru and Vondrak [1] give an algorithm with a $1 - 1/e - \epsilon$ approximation running in $n^2(\log n/\epsilon)^{O(1/\epsilon^8)}$ time. Our work builds on [1] and we discuss the relationship between the two algorithms in more detail in Section 1.1.

Kulik *et al.* [8] obtain a $1 - 1/e - \epsilon$ approximation for d knapsack constraints in time $\Omega(n^{d/\epsilon^4})$ that comes from enumerating over d/ϵ^4 items. The techniques in this paper could likely be extended to obtain an algorithm for the continuous problem of maximizing the multilinear extension subject to d knapsack constraints, with a running time that is exponential in d and nearly-linear in n. We leave it as an open problem whether the rounding can also be extended to multiple knapsack constraints.

Remark on the algorithm of [1]. We note that there are some technical issues in the algorithm proposed in [1] for a knapsack constraint. The main issue, which was pointed out by Yoshida [12], arises in the partitioning of the items into large and small items: an item e is small if it has value $f(\{e\}) \leq \epsilon^6 f(\mathrm{OPT})$ and cost $c_e \leq \epsilon^4$, and it is large otherwise. The algorithm enumerates the marginal values of the large items and thus the set of large items was intended to be of size $\mathrm{poly}(1/\epsilon)$. But this may not be true in general, as there could be many items in OPT with singleton value greater than $\epsilon^6 f(\mathrm{OPT})$. On the other hand, the assumption that the small items have small singleton values is crucial to ensuring that the algorithm obtains a good value from the small items. Another issue arises in the rounding algorithm. The fractional solution is rounded using a rounding algorithm for a partition matroid that treats the parts independently. But in this setting an item participates in several parts and we need to ensure that it is not selected more than once.

1.1 Our techniques

As in the classical knapsack problem with a linear objective, the algorithms achieving optimal approximation are based on enumeration techniques. One such approach is to enumerate the most valuable items in OPT (in the submodular problem, we can determine which items of OPT are valuable based on the Greedy ordering of OPT, see (1)) and greedily pack the remaining items based on the marginal gain to cost density. This approach leads to the optimal $1 - 1/e$ approximation provided that we enumerate 3 items [10]. The running time of the resulting algorithm is $O(n^5)$ and it can be improved to $O(n^4 \log(n/\epsilon)/\epsilon)$ time at a loss of ϵ in the approximation.

A different approach, inspired by the algorithms for the classical knapsack problem that use dynamic programming over the (appropriately discretized) profits of the items, is to enumerate over the marginal gains of the valuable items of OPT. Unlike the classical setting with linear profits, it is considerably more challenging to leverage such an approach in the submodular setting. Badanidiyuru and Vondrak [1] propose a new approach based on this enumeration technique and continuous density Greedy with a running time of $n^2 \left(\frac{\log n}{\epsilon}\right)^{O\left(\frac{1}{\epsilon^8}\right)}$, which overcame the $\Omega(n^4)$ running time barrier for the approaches that are based on enumerating items.

In this work, we build on the approach introduced by [1] and we obtain a faster running time of $\left(\frac{1}{\epsilon}\right)^{O\left(\frac{1}{\epsilon^4}\right)} n \log^2 n$. Our algorithm is impractical due to the high dependency on ϵ, but it is theoretically interesting. Obtaining near-optimal approximations in nearly-linear time for submodular maximization has been out of reach for all but a cardinality constraint.

Obtaining a fast running time poses several conceptual and technical challenges, and we highlight some of them here. Let us denote the valuable items of OPT as OPT_1, and let $\mathrm{OPT}_2 = \mathrm{OPT} \setminus \mathrm{OPT}_1$. For our algorithm, the set OPT_1 has $\mathrm{poly}(1/\epsilon)$ items and we can handle them by enumerating over their marginal gains, appropriately discretized. Similarly to [1], we use the guessed marginal gains to pack items that are competitive with OPT_1: for each guessed marginal gain, we find the cheapest item whose marginal gain is at least the guessed value, and we add ϵ of the item to the fractional solution. The continuous approach is necessary for ensuring that we obtain a good approximation, but it is already introducing the following conceptual and technical difficulties:

- *We do not know how much budget is available for the remaining items.* Since we packed the items fractionally, we will need to perform the rounding to find out which of the items will be in the final solution and their total budget. But we cannot do the rounding before packing the remaining items. Additionally, we cannot afford to guess the budget of OPT_1, even approximately.
- *In the continuous setting, evaluating the multilinear extension takes $\Omega(n^2)$ time in general.*
- *We will need to ensure that we can round the resulting fractional solution.*

A key idea in our algorithm, and an important departure from the approach of [1], is to *integrally* pack the remaining items using density Greedy with lazy evaluations to obtain a nearly-linear running time. The resulting fractional solution has only a constant number of entries that are strictly fractional, and we show that this is beneficial both in terms of running time and rounding: we can evaluate the multilinear extension in constant time and we can exploit the special structure of the solution to round. However, the first difficulty mentioned above remains a significant conceptual barrier for realizing this plan: if we cannot get a handle on how much budget to allocate to density Greedy, we will not be able to round the solution without violating the budget or losing value. Our solution here is based on the following insights.

Algorithm 1 KNAPSACK(f, ϵ).

$t \leftarrow 1/\epsilon^3$
$r \leftarrow 1/\epsilon$
$M \leftarrow \Theta(f(\mathrm{OPT}))$
$S_{\mathrm{best}} \leftarrow \emptyset$
Try all possible sequences:
  $\{v_{p,i}\}$: $p \in \{1, 2, \ldots, 1/\epsilon\}$, $i \in \{1, 2, \ldots, t\}$, $v_{p,i} \in \{0, \epsilon M/t, 2\epsilon M/t, \ldots, 1\}$
  $\{W_p\}$: $p \in \{1, 2, \ldots, 1/\epsilon\}$, $W_p \in \{0, \epsilon M, 2\epsilon M, \ldots, M\}$
  $\{w_{p,i}\}$: $p \in \{1, 2, \ldots, 1/\epsilon\}$, $i \in \{1, 2, \ldots, r+1\}$, $w_{p,i} \in \{0, \epsilon^2 W_p/r, 2\epsilon^2 W_p/r, \ldots, W_p\}$
for every choice $\{v_{p,i}\}$, $\{W_p\}$, $\{w_{p,i}\}$ **do**
  $x \leftarrow \mathrm{KNAPSACKGUESS}(f, \epsilon, \{v_{p,i}\}, \{W_p\}, \{w_{p,i}\})$
  $S \leftarrow \mathrm{ROUND}(x)$
  if $f(S) > f(S_{\mathrm{best}})$ **then**
    $S_{\mathrm{best}} \leftarrow S$
  end if
end for
Return S_{best}

First, note that we may assume that every item in OPT_2 has a cost that is small relative to the total budget of OPT_2: there can only be a small number of heavy items and each of them has small marginal gain on top of OPT_1, and thus we can discard them without losing too much in the approximation. Moreover, if there are no heavy items at all, we can show that density Greedy will not exceed the budget. Thus, if we knew the budget of OPT_2, we could remove all of the heavy items and run density Greedy on the remaining items.

Unfortunately, we cannot guess the budget of OPT_2 since there are too many possible choices. Instead, note that, since the cost of an item is its marginal value divided by its density, a heavy item has large value or small density. If it has small density then intuitively Greedy will not pick it. The problematic items are the ones that have large marginal values, as density Greedy may pick them and they may be too heavy. Unfortunately, we cannot filter out all the items with large marginal value, since those items may include items in OPT_2 (note that even though every item in OPT_2 has small marginal value on top of OPT_1, it can have large marginal value on top of our current fractional solution that does not necessarily contain OPT_1). Now the key observation is that the number of such items is small, and we can handle them with additional guessing.

The final step of the algorithm is to round the fractional solution to a feasible integral solution. Here we take advantage of the fact that the only entries that are strictly fractional were introduced in the OPT_1 stages of the algorithm. The fractional items can be mapped to the items in OPT_1 in such a way that every item in OPT_1 is assigned a fractional mass of at most 1 coming from items with smaller or equal cost. Thus, for each item in OPT_1, we want to select one of the items fractionally assigned to it. This is reminiscent of a partition matroid and thus a natural approach is to use a matroid rounding algorithm such as pipage rounding or swap rounding. However, an item may be fractionally assigned to more than one item in OPT_1, and we need to ensure that the rounding does not select the same item for different items in OPT_1. We show that we can do so using a careful application of swap rounding.

Algorithm 2 KnapsackGuess$(f, \epsilon, \{v_{p,i}\}, \{W_p\}, \{w_{p,i}\})$.

$t \leftarrow 1/\epsilon^3$
$r \leftarrow 1/\epsilon$
$x_0 \leftarrow 0$
for $p = 1, 2, \ldots, 1/\epsilon$ **do**
  $y^{(p,0)} \leftarrow x_{p-1}$
  $A_p \leftarrow \emptyset$
  for $i = 1, 2, \ldots, t$ **do**
    $a_{p,i} \leftarrow$ element with minimum size c_e in $\{e \notin A_p \colon F(y^{(p,i-1)} \vee \mathbf{1}_e) - F(y^{(p,i-1)}) \geq v_{p,i}\}$
    $y^{(p,i)} \leftarrow y^{(p,i-1)} + \epsilon \mathbf{1}_{a_{p,i}}$
    $A_p \leftarrow A_p \cup \{a_{p,i}\}$
  end for
  if $W_p = 0$ **then**
    Continue to the next phase $p + 1$
  end if
  $z^{(p,0)} \leftarrow y^{(p,t)}$
  $B_p \leftarrow \emptyset$
  Let r_p be the smallest $i \in \{0, 1, \ldots, r\}$ such that $w_{p,i+1} \leq \epsilon(1-\epsilon)W_p/r$. If no such i exists, let $r_p = r$. ⟨⟨ r_p `is the number of large value elements in` OPT_2 ⟩⟩
  for $i = 1, 2, \ldots, r_p$ **do**
    $b_{p,i} \leftarrow$ element with minimum size c_e in $\{e \colon F(z^{(p,i-1)} \vee \mathbf{1}_e) - F(z^{(p,i-1)}) \geq w_{p,i}\}$
    $z^{(p,i)} \leftarrow z^{(p,i-1)} \vee \mathbf{1}_{b_{p,i}}$
    $B_p \leftarrow B_p \cup \{b_{p,i}\}$
    if $F(z^{(p,i)}) - F(z^{(p,0)}) \geq \epsilon(1 - 12\epsilon)W_p$ **then**
      Set $x_p \leftarrow z^{(p,i)}$ and continue to phase $p + 1$
    end if
  end for
  if $F(z^{(p,r_p)}) - F(z^{(p,0)}) < \epsilon(1 - 12\epsilon)W_p$ **then**
    $V' \leftarrow V \setminus \{e \colon F(z^{(p,r_p)} \vee \mathbf{1}_e) - F(z^{(p,r_p)}) \geq \epsilon W_p/r\}$
    $C_p \leftarrow$ DensityGreedy$(f, z^{(p,r_p)}, \epsilon(1 - 12\epsilon)W_p - F(z^{(p,r_p)}) + F(z^{(p,0)}), V')$
    $x_p \leftarrow z^{(p,r_p)} \vee \mathbf{1}_{C_p}$
  end if
end for
Return $x_{1/\epsilon}$

2 The algorithm

We consider the problem of maximizing a monotone submodular function subject to a single knapsack constraint. Each element $e \in V$ has a cost $c_e \in \mathbb{R}_+$, and the goal is to find a set $\mathrm{OPT} \in \mathrm{argmax}\{f(S) \colon \sum_{e \in S} c_e \leq 1\}$. We assume that the knapsack capacity is 1, which we may assume without loss of generality by scaling the cost of each element by the knapsack capacity. We let $F : [0,1]^V \to \mathbb{R}_+$ denote the multilinear extension f. For every $x \in [0,1]^V$, we have

$$F(x) = \sum_{S \subseteq V} f(S) \prod_{e \in S} x_e \prod_{e \notin S} (1 - x_e) = \mathbb{E}[f(R(x))],$$

where $R(x)$ is a random set that includes each element $e \in V$ independently with probability x_e. For two vectors x and y, we let $x \vee y$ denote the vector such that $(x \vee y)_i = \max\{x_i, y_i\}$ for all $i \in V$.

We fix an optimal solution to the problem that we denote by OPT. We assume that the algorithm knows a constant approximation of $f(\mathrm{OPT})$; such an approximation can be obtained in nearly linear time by taking the best of the following two solutions: the solution obtained by running Density Greedy (implemented using lazy evaluations, similarly to Algorithm 3) and the solution consisting of the best single element. Let $f(\mathrm{OPT}) \geq M \geq (1-\epsilon)f(\mathrm{OPT})$ denote the algorithm's guess for the optimal value. There are $O(1/\epsilon)$ choices for M given the constant approximation of $f(\mathrm{OPT})$.

We order OPT as $o_1, o_2, \ldots, o_{|\mathrm{OPT}|}$, where

$$o_i = \mathrm{argmax}_{o \in \mathrm{OPT}}(f(\{o_1, \ldots, o_{i-1}\} \cup \{o\}) - f(\{o_1, \ldots, o_{i-1}\})) \tag{1}$$

Let $t = O(1/\epsilon^3)$, $\mathrm{OPT}_1 = \{o_1, o_2, \ldots, o_t\}$, and $\mathrm{OPT}_2 = \mathrm{OPT} \setminus \mathrm{OPT}_1$.

We emphasize that we use the above ordering of OPT and the partition of OPT into OPT_1 and OPT_2 only for the analysis and to motivate the choices of the algorithm. In particular, the algorithm does not know this ordering or partition.

It is useful to filter out from OPT_2 the items that have large cost, more precisely, cost greater than $\epsilon^2(1 - c(\mathrm{OPT}_1))$. Since every element $o \in \mathrm{OPT}_2$ satisfies $f(\mathrm{OPT}_1 \cup \{o\}) - f(\mathrm{OPT}_1) \leq \epsilon^3 f(\mathrm{OPT}_1)$ and there are at most $1/\epsilon^2$ such elements, this will lead to only an $\epsilon f(\mathrm{OPT})$ loss. For ease of notation, we use OPT_2 to denote the set without these elements, i.e., we assume that $c_o \leq \epsilon^2(1 - c(\mathrm{OPT}_1))$ for every $o \in \mathrm{OPT}_2$.

Algorithm 1 gives a precise description of the algorithm. The algorithm guesses a sequence of values as follows.

Guessed values. Throughout the paper, we assume for simplicity that $1/\epsilon$ is an integer. Recall that $t = 1/\epsilon^3$. Let $r = 1/\epsilon$ (r is an upper bound on the number of items of OPT_2 that have large marginal value in each phase).

- A sequence $\{v_{1,1}, v_{1,2}, \ldots, v_{1/\epsilon,t}\}$ where $v_{p,i} \in \{0, \epsilon M/t, 2\epsilon M/t, \ldots, M\}$ is an integer multiple of $\epsilon M/t$, for all integers p and i such that $1 \leq p \leq 1/\epsilon$ and $1 \leq i \leq t$. The value $v_{p,i}$ is an approximate guess for the marginal value of $o_i \in \mathrm{OPT}_1$ during phase p. There are $t/\epsilon + 1 = 1/\epsilon^4 + 1$ choices for each $v_{p,i}$ and thus there are $(1/\epsilon^4 + 1)^{1/\epsilon^4} = (1/\epsilon)^{O(1/\epsilon^4)}$ possible sequences.
- A sequence $\{W_1, W_2, \ldots, W_{1/\epsilon}\}$ where $W_p \in \{0, \epsilon M, 2\epsilon M, \ldots, M\}$ is an integer multiple of ϵM, for all integers p such that $1 \leq p \leq 1/\epsilon$. The value W_p is an approximate guess for the total marginal value of OPT_2 in phase p. There are $1/\epsilon + 1$ choices for each W_p and thus there are $(1/\epsilon + 1)^{1/\epsilon}$ possible sequences.
- A sequence $\{w_{1,1}, w_{1,2}, \ldots, w_{1/\epsilon,1/\epsilon+1}\}$ where $w_{p,i} \in \{0, \epsilon^2 W_p/r, 2\epsilon^2 W_p/r, \ldots, W_p\}$ is an integer multiple of $\epsilon^2 W_p/r$, for all integers p and i such that $1 \leq p, i \leq 1/\epsilon$ (the value W_p is the same as in the sequence above). The values $w_{p,i}$, where $i \in \{1, 2, \ldots, 1/\epsilon\}$, are approximate guesses for the marginal values of the items in OPT_2 with large marginal value in phase p. There are $r/\epsilon^2 + 1 = 1/\epsilon^3 + 1$ choices for each $w_{p,i}$ and thus there are $(1/\epsilon)^{O(1/\epsilon^2)}$ possible sequences.

The algorithm enumerates all possible such sequences. For each choice, the algorithm works as follows. Let $\{v_{p,i}\}$, $\{W_p\}$, and $\{w_{p,i}\}$ denote the current sequences. The algorithm performs $1/\epsilon$ phases. Each phase is comprised of three stages, executed in sequence in this order: an OPT_1 stage, a stage for the large value items in OPT_2, and a Density Greedy stage. We describe each of these stages in turn.

The $\mathbf{OPT_1}$ stage of phase p. This stage uses the values $\{v_{p,i} : 1 \le i \le t\}$ as follows. We perform t iterations. In each iteration i, we consider the items not selected in previous iterations that have marginal value at least $v_{p,i}$ on top of the current solution, i.e., $F(x \vee \mathbf{1}_e) - F(x) \ge v_{p,i}$. Among these items, we select the item with minimum cost and increase its fractional value by ϵ. Together, the t iterations select t different items and increase their fractional value by ϵ.

The stage of phase p for the large value items in $\mathbf{OPT_2}$. This stage uses the value W_p and the values $\{w_{p,i} : 1 \le i \le 1/\epsilon\}$ as follows. We perform at most r iterations. In each iteration i, we find the minimum cost element that has marginal value at least $w_{p,i}$ on top of the current solution, and we integrally select this item. (Note that this is similar to the OPT_1 stage, except that we select items integrally.) At the end of the stage, if the items selected in this phase have total marginal gain at least $\epsilon(1-12\epsilon)W_p$, then we end phase p and proceed to the next phase. Otherwise, the algorithm proceeds to the Density Greedy stage.

The Density Greedy stage of phase p. If the previous stage did not reach a total marginal gain of at least $\epsilon(1-12\epsilon)W_p$, we run the discrete Density Greedy algorithm until we reach a gain of $\epsilon(1-12\epsilon)W_p$. Before running Density Greedy, we remove from consideration all elements whose marginal value is at least $\epsilon W_p/r$. In every step, the Density Greedy algorithm fully selects the item with largest density, i.e., ratio of marginal value to cost.

In order to achieve nearly linear time, we implement the Density Greedy algorithm using approximate lazy evaluations as shown in Algorithm 3. We maintain the items in a priority queue sorted by density. We initialize the marginal values and the densities with respect to the initial solution. In each iteration of the algorithm, we find an item whose density with respect to the current solution is within a factor of $(1-\epsilon)$ of the maximum density as follows. We remove the item at the top of the queue. The marginal value of the item may be stale, so we evaluate its marginal gain with respect to the current solution. If the new marginal gain is within a factor of $(1-\epsilon)$ of the old marginal gain, it follows from submodularity that the density of the item is within a factor of $(1-\epsilon)$ of the maximum density, and we select the item. If the marginal gain has changed by a factor larger than $(1-\epsilon)$, we update the density and reinsert the item in the queue. We also keep track of how many times each item's density has been updated and, if an item has been updated more than $2\ln(n/\epsilon)/\epsilon$ times, we discard the item since it can no longer contribute a significant value to the solution.

Rounding the fractional solution. After $1/\epsilon$ phases, we obtain a fractional solution with $O(1/\epsilon^4)$ fractional entries. We round the resulting fractional solution to an integral solution using swap rounding, as shown in Algorithm 4.

The following theorem states our main result for the fractional solution. We will use the second guarantee to obtain a fast rounding algorithm (see Section 3). We defer the proof of the theorem to the full version of the paper.

▶ **Theorem 2.** *There are choices for the guessed values $\{v_{p,i}\}$, $\{W_p\}$, and $\{w_{p,i}\}$ for which Algorithm 2 returns a fractional solution x with the following properties:*

(1) $F(x) \ge \left(1 - \frac{1}{e} - O(\epsilon)\right) f(\mathrm{OPT})$;

(2) *Let E be the set of all items $e \in V$ such that $0 < x_e < 1$. There exists a mapping $\sigma : E \times \{1, 2, \ldots, 1/\epsilon\} \to \mathrm{OPT}_1$ with the following properties:*

- **(a)** *For every element $e \in E$ and every phase $p \in \{1, 2, \ldots, 1/\epsilon\}$ such that $e \in A_p$, $\sigma(e,p)$ is defined and $c(e) \le c(\sigma(e,p))$.*
- **(b)** *For every element $o \in \mathrm{OPT}_1$, there are at most $1/\epsilon$ pairs (e,p) such that $\sigma(e,p) = o$.*

3 Rounding algorithm and analysis of the final solution

In this section, we analyze the rounding algorithm (Algorithm 4) that rounds the fractional solution x guaranteed by Theorem 2. We round the fractional entries of x as follows. We initialize $\hat{x} = x$. For analysis purposes, we initialize $O = \mathrm{OPT}_1$. We sort the fractional elements in non-increasing order according to their cost. While there are fractional elements, we repeatedly move fractional mass between the two elements with highest cost as follows. Let e_1 and e_2 be the fractional elements with the highest and second-highest cost, respectively. We consider two cases:

Case 1: $\hat{x}_{e_1} + \hat{x}_{e_2} \leq 1$. With probability $\hat{x}_{e_1}/(\hat{x}_{e_1} + \hat{x}_{e_2})$, we update $\hat{x}_{e_1} \leftarrow \hat{x}_{e_1} + \hat{x}_{e_2}$ and $\hat{x}_{e_2} \leftarrow 0$; with the remaining probability, we update $\hat{x}_{e_2} \leftarrow \hat{x}_{e_1} + \hat{x}_{e_2}$ and $\hat{x}_{e_1} \leftarrow 0$. If an element becomes integral, we remove it from the list. For analysis purposes, if an element is rounded up to 1, we pair it up with the element $o_1 \in O$ with highest cost, and we update $O \leftarrow O \setminus \{o_1\}$.

Algorithm 4 ROUND(x).

Let $\sigma_1, \ldots, \sigma_k$ be the fractional coordinates of x.
Sort $\sigma_1, \ldots, \sigma_k$ so that $c_{\sigma_1} \leq c_{\sigma_2} \leq \cdots \leq c_{\sigma_k}$.
while $k > 0$ **do**
  if $k = 1$ **then**
    $x_{\sigma_1} \leftarrow 1$
    return x
  end if
  if $x_{\sigma_k} + x_{\sigma_{k-1}} > 1$ **then**
    Pick $u \in \{0, 1\}$ randomly such that $\Pr[u = 1] = \frac{1 - x_{\sigma_{k-1}}}{2 - x_{\sigma_k} - x_{\sigma_{k-1}}}$
    if $u = 1$ **then**
      $x_{\sigma_k} \leftarrow 1$
      $x_{\sigma_{k-1}} \leftarrow x_{\sigma_{k-1}} + x_{\sigma_k} - 1$
      $k \leftarrow k - 1$
    else
      $x_{\sigma_{k-1}} \leftarrow 1$
      $x_{\sigma_k} \leftarrow x_{\sigma_{k-1}} + x_{\sigma_k} - 1$
      $\sigma_{k-1} \leftarrow \sigma_k$
      $k \leftarrow k - 1$
    end if
  else
    Pick $u \in \{0, 1\}$ randomly such that $\Pr[u = 1] = \frac{x_{\sigma_k}}{x_{\sigma_k} + x_{\sigma_{k-1}}}$
    if $u = 1$ **then**
      $x_{\sigma_k} \leftarrow x_{\sigma_{k-1}} + x_{\sigma_k}$
      $x_{\sigma_{k-1}} \leftarrow 0$
      $\sigma_{k-1} \leftarrow \sigma_k$
      $k \leftarrow k - 1$
    else
      $x_{\sigma_{k-1}} \leftarrow x_{\sigma_{k-1}} + x_{\sigma_k}$
      $x_{\sigma_k} \leftarrow 0$
      $k \leftarrow k - 1$
    end if
    if $x_{\sigma_k} = 1$ **then**
      $k \leftarrow k - 1$
    end if
  end if
end while

Case 2: $\hat{x}_{e_1} + \hat{x}_{e_2} > 1$. With probability $(1 - \hat{x}_{e_2})/(2 - \hat{x}_{e_1} - \hat{x}_{e_2})$, we update $\hat{x}_{e_1} \leftarrow 1$ and $\hat{x}_{e_2} \leftarrow \hat{x}_{e_1} + \hat{x}_{e_2} - 1$; with the remaining probability, we update $\hat{x}_{e_2} \leftarrow 1$ and $\hat{x}_{e_1} \leftarrow \hat{x}_{e_1} + \hat{x}_{e_2} - 1$. If an element becomes integral, we remove it from the list. For analysis purposes, if an element is rounded up to 1, we pair it up with an element in O as follows. If the element e_1 with the highest cost is rounded up to 1, we pair up e with the element $o_1 \in O$ with highest cost, and we update $O \leftarrow O \setminus \{o_1\}$. If the element e_2 with the second-highest cost is rounded up to 1, we pair up e_2 with the element $o_2 \in O$ with the second-highest cost, and we update $O \leftarrow O \setminus \{o_2\}$.

If there is only one fractional entry then we can round this entry up to 1 and pair up this element with the element $o_1 \in O$ with highest cost.

We now turn to the analysis of the rounding. We first show that the expected value of the rounded solution is at least $F(x)$. We then show that the cost of the fractional elements that were rounded up to 1 is at most $c(\mathrm{OPT}_1)$, thus ensuring that the final rounded solution is feasible.

▶ **Lemma 3.** $\mathbb{E}[F(\hat{x})] \geq F(x)$.

Proof. Note that each iteration updates the solution as follows: $\hat{x}' = \hat{x} + \delta(\mathbf{1}_{e_1} - \mathbf{1}_{e_2})$, where δ is a random value satisfying $\mathbb{E}_\delta[\hat{x}'] = \hat{x}$. The multilinear extension is convex along the direction $\mathbf{1}_e - \mathbf{1}_{e'}$ for every pair of elements e and e'. Therefore $\mathbb{E}_\delta[F(\hat{x}')] \geq F(\mathbb{E}_\delta[\hat{x}']) = F(\hat{x})$, and the claim follows by induction. ◀

▶ **Lemma 4.** *Let $\hat{E}$ be the set of elements corresponding to the fractional entries that were rounded to* 1. *We have $c(\hat{E}) \leq c(\mathrm{OPT}_1)$.*

Proof. The lemma follows from the following invariant maintained by the algorithm for the partially rounded solution $\hat{x}$ and the set $O \subseteq \mathrm{OPT}_1$:

Invariant: Let $o_1, o_2, \ldots, o_p$ be the elements of O, labeled such that $c_{o_1} \geq c_{o_2} \geq \cdots \geq c_{o_p}$. Let $e_1, e_2, \ldots, e_\ell$ be the elements corresponding to the fractional entries of $\hat{x}$, labeled such that $c_{e_1} \geq c_{e_2} \geq \cdots \geq c_{e_\ell}$. We define the following grouping of the elements $e_1, e_2, \ldots, e_\ell$ where each group contributes a fractional mass of 1 and each element belongs to at most two groups. Consider the interval $[0, \sum_{i=1}^{\ell} x_{e_i}]$ that is divided among the elements as follows: $[0, x_{e_1})$ corresponds to e_1 and, for all $2 \leq i \leq \ell$, $[\sum_{j=1}^{i-1} x_{e_j}, \sum_{j=1}^{i} x_{e_j})$ corresponds to e_i. The elements that overlap with the interval $[i-1, i)$ define the i-th group. The invariant is that $\hat{x}$ and O satisfy the following properties:

(1) $\sum_{i=1}^{\ell} \hat{x}_{e_i} \leq |O|$, and

(2) for every $i \geq 1$ and each element e in the i-th group, we have $c_e \leq c_{o_i}$.

We will show the invariant using induction on the number of iterations. We start by showing the invariant at the beginning of the rounding algorithm. We can show the invariant for x and OPT_1 using Theorem 2.

▷ Claim 5. The invariant holds for x and OPT_1.

Proof. Recall that each phase p of the KnapsackGuess algorithm selects a set A_p of elements and it increases the values of each of these elements by ϵ. Thus the fractional value x_{e_i} of each element $e_i \in E$ is equal to ϵ times the number of phases p such that $e_i \in A_p$. Moreover, by Theorem 2, there is a mapping $\sigma : \{e_1, \ldots, e_\ell\} \times \{1, 2, \ldots, 1/\epsilon\} \to \mathrm{OPT}_1$ such that, for each phase p such that $e_i \in A_p$, $\sigma(e_i, p)$ exists and $c(e_i) \leq c(\sigma(e_i, p))$.

We can think of each element e_i having x_{e_i}/ϵ copies and each element $o \in \mathrm{OPT}_1$ having $|\sigma^{-1}(o)| \leq 1/\epsilon$ copies. By letting $\tilde{E}$ and $\tilde{O}$ be the copies of the elements in E and OPT_1 (respectively), we can equivalently view σ as a bijection between $\tilde{E}$ and $\tilde{O}$ with the property that, if $\sigma((e, i)) = (o, j)$ then $c(e) \leq c(o)$. We may also assume that the elements of O with the highest costs have $1/\epsilon$ copies, i.e., there exists an index p' such that $o_1, \ldots, o_{p'}$ have $1/\epsilon$ copies and $o_{p'+1}, \ldots, o_p$ have zero copies; we can ensure this property by reassigning pairs in $\tilde{E}$ to elements of O with higher cost. Thus, if we sort $\tilde{E}$ and $\tilde{O}$ in non-increasing order according to costs, σ maps the first $1/\epsilon$ elements of $\tilde{E}$ to o_1, the next $1/\epsilon$ elements to o_2, etc. Since the i-th consecutive block of $1/\epsilon$ elements of $\tilde{E}$ represents the fractional mass of the i-th group of elements, the second property of the invariant follows. The first property of the invariant follows from the fact that $\frac{\|x\|_1}{\epsilon} = |\tilde{E}| = |\tilde{O}| \leq \frac{|\mathrm{OPT}_1|}{\epsilon}$. ◁

Now consider some iteration of the rounding algorithm, and suppose that the invariant holds at the beginning of the iteration. The invariant guarantees that the total fractional mass $\|\hat{x}\|_1$ is at most $|O|$ and, if we sort the fractional elements in non-increasing order according to the cost, the first unit of fractional mass can be assigned to the element o_1 with highest cost in O, the next unit of fractional mass can be assigned to the element o_2 with second-highest cost in O, etc. We will use such an assignment to argue that the invariant is preserved.

Suppose we are in Case 1, i.e., $\hat{x}_{e_1} + \hat{x}_{e_2} \leq 1$, where e_1 and e_2 are the fractional elements with the highest and second-highest cost. Let o_1 be the element of O with the highest cost. Since $\hat{x}_{e_1} + \hat{x}_{e_2} \leq 1$, it follows from the invariant that the entire fractional mass of $\hat{x}_{e_1} + \hat{x}_{e_2}$ is assigned to o_1. Since the rounding step moves fractional mass between e_1 and e_2, this property will continue to hold after the rounding step. If neither e_1 nor e_2 is rounded to 1, the updated fractional solution clearly satisfies the invariant. Therefore we may assume that one of e_1, e_2 is rounded to 1, and thus we must have had $\hat{x}_{e_1} + \hat{x}_{e_2} = 1$ before the rounding. Since o_1 is assigned a fractional mass of 1 in total, e_1 and e_2 are the only elements assigned to o_1. Therefore, after removing o_1, e_1, and e_2, the remaining fractional entries and the set $O \setminus \{o_1\}$ satisfy the invariant.

Suppose we are in Case 2, i.e., $1 < \hat{x}_{e_1} + \hat{x}_{e_2} \leq 2$, where e_1 and e_2 are the fractional elements with the highest and second-highest cost, respectively. Let o_1 and o_2 be the elements of O with the highest and second-highest cost, respectively. It follows from the invariant that the fractional mass $\hat{x}_{e_1} + \hat{x}_{e_2}$ is assigned to o_1 and o_2 as follows: the 1 unit of fractional mass assigned to o_1 is comprised of $\hat{x}_{e_1}$ from e_1 and $1 - \hat{x}_{e_2}$ from e_2, and o_2 is assigned the remaining $\hat{x}_{e_1} + \hat{x}_{e_2} - 1$ fractional mass of e_2. The rounding step either rounds e_1 to 1 by moving $1 - \hat{x}_{e_1}$ mass from e_2 to e_1 or it rounds e_2 to 1 by moving $1 - \hat{x}_{e_2}$ mass from e_1 to e_2. In the former case, after removing e_1 and o_1, the remaining fractional entries and the set $O \setminus \{o_1\}$ satisfy the invariant. Therefore we may assume that it is the latter, i.e., we round e_2 to 1 and we remove e_2 and o_2. In this case, the fractional values on the elements $e_3, e_4, \ldots$ move forward by $1 - \hat{x}_{e_2}$ to fill in the space vacated by e_2. We can also move forward their assignment to $O \setminus \{o_2\}$: e_1 remains entirely assigned to o_1 as before, and the assignment of each of the elements $e_3, e_4, \ldots$ is shifted forward. Since we remove one unit from both the total fractional mass and O, every remaining element becomes assigned to an element of $O \setminus \{o_2\}$ whose cost is at least as much as the element of O that it was previously assigned. Therefore the invariant is preserved. ◀

Abstract

We consider fast algorithms for monotone submodular maximization subject to a matroid constraint. We assume that the matroid is given as input in an explicit form, and the goal is to obtain the best possible running times for important matroids. We develop a new algorithm for a *general matroid constraint* with a $1 - 1/e - \epsilon$ approximation that achieves a fast running time provided we have a fast data structure for maintaining an approximately maximum weight base in the matroid through a sequence of decrease weight operations. We construct such data structures for graphic matroids and partition matroids, and we obtain the *first algorithms* for these classes of matroids that achieve a nearly-optimal, $1 - 1/e - \epsilon$ approximation, using a nearly-linear number of function evaluations and arithmetic operations.

1 Introduction

In this paper, we consider fast algorithms for monotone submodular maximization subject to a matroid constraint. Submodular maximization is a central problem in combinatorial optimization that captures several problems of interest, such as maximum coverage, facility location, and welfare maximization. The study of this problem dates back to the seminal work of Nemhauser, Wolsey and Fisher from the 1970's [20, 21, 12]. Nemhauser *et al.* introduced a very natural Greedy algorithm for the problem that iteratively builds a solution by selecting the item with the largest marginal gain on top of previously selected items, and they showed that this algorithm achieves a $1 - 1/e$ approximation for a cardinality constraint and a $1/2$ approximation for a general matroid constraint. The maximum coverage problem is a special case of monotone submodular maximization with a cardinality constraint and it is $1 - 1/e$

hard to approximate [10], and thus the former result is optimal. Therefore the main question that was left open by the work of Nemhauser *et al.* is whether one can obtain an optimal, $1 - 1/e$ approximation, for a general matroid constraint.

In a celebrated line of work [6, 24], Calinescu *et al.* developed a framework based on continuous optimization and rounding that led to an optimal $1 - 1/e$ approximation for the problem. The approach is to turn the discrete optimization problem of maximizing a submodular function f subject to a matroid constraint into a continuous optimization problem where the goal is to maximize the multilinear extension F of f (a continuous function that extends f) subject to the matroid polytope (a convex polytope whose vertices are the feasible integral solutions). The continuous optimization problem can be solved approximately within a $1 - 1/e$ factor using a continuous Greedy algorithm [24] and the resulting fractional solution can be rounded to an integral solution without any loss [1, 6, 8]. The resulting algorithm achieves the optimal $1 - 1/e$ approximation in polynomial time.

Unfortunately, a significant drawback of this approach is that it leads to very high running times. Obtaining fast running times is a fundamental direction both in theory and in practice, due to the numerous applications of submodular maximization in machine learning, data mining, and economics [18, 17, 14, 16, 9]. This direction has received considerable attention [2, 11, 3, 19, 5, 7], but it remains a significant challenge for almost all matroid constraints.

Before discussing these challenges, let us first address the important questions on how the input is represented and how we measure running time. The algorithms in this paper as well as prior work assume that the submodular function is represented as a value oracle that takes as input a set S and returns $f(S)$. For all these algorithms, the number of calls to the value oracle for f dominates the running time of the algorithm (up to a logarithmic factor), and thus we assume for simplicity that each call takes constant time.

The algorithms fall into two categories with respect to how the matroid is represented: the *independence oracle* algorithms assume that the matroid is represented using an oracle that takes as input a set S and returns whether S is feasible (independent); the *representable matroid* algorithms assume that the matroid is given as input in an explicit form. The representable matroid algorithms can be used for only a subclass of matroids, namely those that can be represented as a linear matroid over vectors in some field[1], but this class includes practically-relevant matroids such as the uniform, partition, laminar, graphical, and general linear matroids. The oracle algorithms apply to all matroids, but they are *unlikely to lead to the fastest possible running times:* even an ideal algorithm that makes only $O(k)$ independence calls has a running time that is $\Omega(k^2)$ in the independence oracle model (each oracle call needs to read its input, which takes $\Theta(k)$ time in the worst case), even if the matroid is a representable matroid such as a partition or a graphic matroid. This is because Thus there have always been parallel lines of research for representable matroids and general matroids.

This work falls in the first category, i.e., we assume that the matroid is given as input in an explicit form, and the goal is to obtain the best possible running times. Note that, although all the representable matroids are linear matroids, it is necessary to consider each class separately, since they have very different running times to even verify if a given solution is feasible: for simple explicit matroids such as a partition or a graphic matroid, checking whether a solution is feasible takes $O(n)$ time, where n is the size of the ground set of the matroid; for general explicit matroids represented using vectors in some field, checking whether a solution is feasible takes $O(k^\omega)$ time, where k is the rank of the matroid and ω is the exponent for fast matrix multiplication.

[1] In a linear matroid, the ground set is a collection of n vectors and a subset of the vectors is feasible (independent) if the vectors are linearly independent.

Since in many practical settings only nearly-linear running times are feasible, an important question to address is:

For which matroid constraints can we obtain
a nearly-optimal $1 - 1/e - \epsilon$ *approximation in nearly-linear time?*

Prior to this work, the only example of such a constraint was a cardinality constraint. For a partition matroid constraint, the fastest running time is $\Omega(n^{3/2})$ in the worst case when $k = \Omega(n)$ [5]. For a graphical matroid constraint, no faster algorithms are known than a general matroid, and the running time is $\Omega(n^2)$ in the worst case when $k = \Omega(n)$ [3]. Obtaining a best-possible, nearly-linear running time has been very challenging even for these classes of matroids for the following reasons:

The continuous optimization is a significant time bottleneck. The continuous optimization problem of maximizing the multilinear extension subject to the matroid polytope is an integral component in all algorithms that achieve a nearly-optimal approximation guarantee. However, the multilinear extension is expensive to evaluate even approximately. To achieve the nearly-optimal approximation guarantees, the evaluation error needs to be very small and in a lot of cases, the error needs to be $O(n^{-1})$ times the function value. As a result, a single evaluation of the multilinear extension requires $\Omega(n)$ evaluations of f. Thus, even a very efficient algorithm with $O(n)$ queries to the multilinear extension would require $\Omega(n^2)$ running time.

Rounding the fractional solution is a significant time bottleneck as well. Consider a matroid constraint of rank k. The fastest known rounding algorithm is the swap rounding, which requires k swap operations: in each operation, the algorithm has two bases B_1 and B_2 and needs to find $x \in B_1, y \in B_2$ such that $B_1 \setminus \{x\} \cup \{y\}$ and $B_2 \setminus \{y\} \cup \{x\}$ are bases. The typical implementation is to pick some $x \in B_1$ and try all y in B_2, which requires us to check independence for k solutions. Thus, overall, the rounding algorithm checks independence for $\Omega(k^2)$ solutions. Furthermore, each feasibility check takes $\Omega(k)$ time just to read the input. Thus a generic rounding for a matroid takes $\Omega(k^3)$ time.

Thus, in order to achieve a fast overall running time, one needs fast algorithms for both the continuous optimization and the rounding. In this work, we provide such algorithms for partition and graphic matroids, and we obtain the first algorithms with nearly-linear running times. At the heart of our approach is a general, nearly-linear time reduction that reduces the submodular maximization problem to two data structure problems: maintain an approximately maximum weight base in the matroid through a sequence of decrease-weight operations, and maintain an independent set in the matroid that allows us to check whether an element can be feasibly added. This reduction applies to any representable matroid, and thus it opens the possibility of obtaining faster running times for other classes of matroids.

1.1 Our contributions

We now give a more precise description of our contributions. We develop a new algorithm for maximizing the multilinear extension subject to a *general matroid constraint* with a $1 - 1/e - \epsilon$ approximation that achieves a fast running time provided we have fast data structures with the following functionality:

- *A maximum weight base data structure:* each element has a weight, and the goal is to maintain an approximately maximum weight base in the matroid through a sequence of operations, where each operation can only decrease the weight of a single element;

- *An independent set data structure* that maintains an independent set in the matroid and supports two operations: add an element to the independent set, and check whether an element can be added to the independent set while maintaining independence.

▶ **Theorem 1.** *Let f be a monotone submodular function and let $\mathcal{M}$ be a matroid on a ground set of size n. Let F be the multilinear extension of f and $P(\mathcal{M})$ be the matroid polytope of $\mathcal{M}$. Suppose that we have a data structure for maintaining a maximum weight base and independent set as described above. There is an algorithm for the problem $\max_{x \in P(\mathcal{M})} F(x)$ that achieves a $1 - 1/e - \epsilon$ approximation using $O(n \operatorname{poly}(\log n, 1/\epsilon))$ calls to the value oracle for f, data structure operations, and additional arithmetic operations.*

Using our continuous optimization algorithm and additional results that are included in the full version of this paper, we obtain the first nearly-linear time algorithms for both the discrete and continuous problem with a graphic and a partition matroid constraint. In the graphic matroid case, the maximum weight base data structure is a dynamic maximum weight spanning tree (MST) data structure and the independent data structure is a dynamic connectivity data structure (e.g., union-find), and we can use existing data structures that guarantee a poly-logarithmic amortized time per operation [15, 13, 23]. For a partition matroid, we provide data structures with a constant amortized time per operation. We also address the rounding step and provide a nearly-linear time algorithm for rounding a fractional solution in a graphic matroid. A nearly-linear time rounding algorithm for a partition matroid was provided in [5].

▶ **Theorem 2.** *There is an algorithm for maximizing a monotone submodular function subject to a generalized partition matroid constraint that achieves a $1 - 1/e - \epsilon$ approximation using $O(n \operatorname{poly}(1/\epsilon, \log n))$ function evaluations and arithmetic operations.*

▶ **Theorem 3.** *There is an algorithm for maximizing a monotone submodular function subject to a graphic matroid constraint that achieves a $1 - 1/e - \epsilon$ approximation using $O(n \operatorname{poly}(1/\epsilon, \log n))$ function evaluations and arithmetic operations.*

Previously, the best running time for a partition matroid was $\Omega(n^{3/2} \operatorname{poly}(1/\epsilon, \log n))$ in the worst case when $k = \Omega(n)$ [5]. The previous best running time for a graphic matroid is the same as the general matroid case, which is $\Omega(n^2 \operatorname{poly}(1/\epsilon, \log n))$ in the worst case when $k = \Omega(n)$ [3].

As shown by Vondrak [24], there is an efficient reduction from the *submodular welfare maximization* problem to the submodular maximization problem with a partition matroid constraint. Using this reduction and our algorithm for a partition matroid, we obtain a nearly-linear time algorithm for welfare maximization as well.

▶ **Theorem 4.** *There is a $1 - 1/e - \epsilon$ approximation algorithm for submodular welfare maximization using $O(n\text{poly}(1/\epsilon, \log n))$ function evaluations and arithmetic operations.*

We conclude with a formal statement of the contributions made in this paper on which the results above are based.

▶ **Theorem 5.** *There is a dynamic data structure for maintaining a maximum weight base in a partition matroid through a sequence of decrease weight operations with an $O(1)$ amortized time per operation.*

▶ **Theorem 6.** *There is a randomized algorithm based on swap rounding for the graphic matroid polytope that takes as input a point x represented as a convex combination of bases and rounds it to an integral solution S such that $\mathbb{E}[f(S)] \geq F(x)$. The running time of the algorithm is $O(nt \log^2 n)$, where t is the number of bases in the convex combination of x.*

1.2 Technical overview

The starting point of our approach is the work [5]. They observed that the running time of the continuous algorithm using the multilinear extension of [3] depends on the value of the maximum weight base when the value is measured in the modular approximation $f'(S) = \sum_{e \in S} f(e)$. It is clear that this approximation is at least the original function and it can be much larger. They observed that the running time is proportional to the ratio between the maximum weight base when weights are measured using the modular approximation compared with the optimal solution when weights are measured using the original function. On the other hand, in the greedy algorithm, the gain in every greedy step is proportional to the maximum weight base when weights are measured using the modular approximation. Thus, the discrete greedy algorithm makes fast progress precisely when the continuous algorithm is slow and vice versa. Therefore, one can start with the discrete greedy algorithm and switch to the continuous algorithm when the maximum weight solution is small even when weights are measured using the modular approximation.

Our algorithm consists of two key components: (1) a fast dynamic data structure for maintaining an approximate maximum weight base through a sequence of greedy steps, and (2) an algorithm that makes only a small number of queries to the data structure. Even if fast dynamic data structures are available, previous algorithms including that of [5] cannot achieve a fast time, since they require $\Omega(nk)$ queries to the data structure: the algorithm of [5] maintains the marginal gain for every element in the current base and it updates them after each greedy step; since each greedy step changes the marginal gain of every element in the base, this approach necessitates $\Omega(k)$ data structure queries per greedy step.

Our new approach uses random sampling to ensure that the number of queries to the data structure is nearly-linear. After each greedy step, our algorithm randomly samples elements from the base to check and update the marginal gains. Because of sampling, it can only ensure that at least $1/2$ of the elements in every value range have good estimates of their values. However, this is sufficient for maintaining an approximate maximum weight base. The benefit is that the running time becomes much faster: the number of checks that do not result in updates is small and if we make sure that an update only happens when the marginal gain change by a factor $1 - \epsilon$ then the total number of updates is at most $O(n \log n/\epsilon)$. Thus we obtain an algorithm with only a nearly-linear number of data structure queries and additional running time for *any matroid constraint*.

Our approach reduces the algorithmic problem to the data structure problem of maintaining an approximate maximum weight base through a sequence of value updates. In fact, the updates are only decrement in the values and thus can utilize even the decremental data structures as opposed to fully dynamic ones. In the case of a partition matroid constraint, one can develop a simple ad-hoc solution. In the case of a graphic matroid, one can use classical data structures for maintaining minimum spanning trees [15].

In both cases, fast rounding algorithms are also needed. The work [5] gives an algorithm for the partition matroid. We give an algorithm for the graphic matroid based on swap rounding and classical dynamic graph data structures. To obtain fast running time, in each rounding step, instead of swapping a generic pair, we choose a pair involving a leaf of the spanning tree.

1.3 Basic definitions and notation

Submodular functions. Let $f : 2^V \to \mathbb{R}_+$ be a set function on a finite ground set V of size $n := |V|$. The function is *submodular* if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$ for all subsets $A, B \subseteq V$. The function is *monotone* if $f(A) \leq f(B)$ for all subsets $A \subseteq B \subseteq V$. We assume

that the function f is given as a value oracle that takes as input any set $S \subseteq V$ and returns $f(S)$. We let $F : [0,1]^V \to \mathbb{R}_+$ denote the multilinear extension f. For every $x \in [0,1]^V$, we have

$$F(x) = \sum_{S \subseteq V} f(S) \prod_{e \in S} x_e \prod_{e \notin S} (1 - x_e) = \mathbb{E}[R(x)],$$

where $R(x)$ is a random set that includes each element $e \in V$ independently with probability x_e.

Matroids. A matroid $\mathcal{M} = (V, \mathcal{I})$ on a ground set V is a collection $\mathcal{I}$ of subsets of V, called independent sets, that satisfy certain properties (see e.g., [22], Chapter 39). In this paper, we consider matroids that are given to the input to the algorithm. Of particular interest are the partition and graphic matroids. A generalized partition matroid is defined as follows. We are given a partition $V_1, V_2, \ldots, V_h$ of V into disjoint subsets and budgets $k_1, k_2, \ldots, k_h$. A set S is independent ($S \in \mathcal{I}$) if $|S \cap V_i| \leq k_i$ for all $i \in [h]$. We let $k = \sum_{i=1}^{h} k_i$ denote the rank of the matroid. A graphic matroid is defined as follows. We are given a connected graph on $k+1$ vertices and n edges. The independent sets of the matroid are the forests of this graph.

Additional notation. Given a set $S \in \mathcal{I}$, we let f_S denote the function $f_S : 2^{V \setminus S} \to \mathbb{R}_{\geq 0}$ such that $f_S(S') = f(S' \cup S) - f(S)$ for all $S' \subseteq V \setminus S$. We let $\mathcal{M}/S = (V \setminus S, \mathcal{I}')$ denote the matroid obtained by contracting S in $\mathcal{M}$, i.e., $S' \in \mathcal{I}'$ iff $S' \cup S \in \mathcal{I}$. We let $P(\mathcal{M})$ denote the matroid polytope of $\mathcal{M}$: $P(\mathcal{M})$ is the convex hull of the indicator vectors of the bases of $\mathcal{M}$, where a base is an independent set of maximum size.

Constant factor approximation to $f(\mathrm{OPT})$. Our algorithm needs a $O(1)$ approximation to $f(\mathrm{OPT})$. Such an approximation can be computed very efficiently (see e.g. [5], Lemma 3.2).

1.4 Paper organization

In Section 2, we describe our algorithm for the continuous optimization problem of maximizing the multilinear extension subject to a general matroid constraint, with the properties stated in Theorem 1. As discussed in the introduction, our algorithm uses certain data structures to achieve a fast running time. In the full version of the paper, we show how to obtain these data structures for partition and graphic matroids. By combining these data structures with the results of Section 2, we obtain nearly-linear time algorithms for the continuous problem of maximizing the multilinear extension subject to a partition and graphic matroid constraint. To obtain a fast algorithm for the discrete problem, we also need a fast algorithm to round the fractional solution. Buchbinder *et al.* [5] give a nearly-linear time rounding algorithm for a partition matroid. In the full version of the paper, we give a nearly-linear time rounding algorithm for a graphic matroid, and prove Theorem 6. These results together give Theorems 2 and 3.

2 The algorithm for the continuous optimization problem

In this section, we describe and analyze our algorithm for the problem $\max_{x \in P(\mathcal{M})} F(x)$ for a general matroid $\mathcal{M}$, and prove Theorem 1. The algorithm is given in Algorithm 1 and it combines the continuous Greedy algorithm of [3] with a discrete Greedy algorithm that we provide in this paper, building on [5].

Algorithm 1 Algorithm for the continuous problem $\max_{x \in P(\mathcal{M})} F(x)$.

1: **procedure** ContinuousMatroid($f, \mathcal{M}, \epsilon$)
2: $c' = \Theta(1/\epsilon)$, where the Θ hides a sufficiently large absolute constant
3: $S = \text{LazySamplingGreedy}(f, \mathcal{M}, \epsilon)$
4: $x = \text{ContinuousGreedy}(f_S, \mathcal{M}/S, c', \epsilon)$
5: **return** $\mathbf{1}_S \vee x$ $\langle\langle$ $x \vee y$ `is the vector` $(x \vee y)_i = \max\{x_i, y_i\}$ `for all` i $\rangle\rangle$
6: **end procedure**

The continuous Greedy algorithm. The algorithm used on line 4 is the algorithm of [3]. To obtain a fast running time, we use an independent set data structure to maintain the independent sets constructed by the algorithm. The data structure needs to support two operations: add an element to the independent set, and check whether an element can be added to the independent set while maintaining independence. For a partition matroid, such a data structure with $O(1)$ time per operation is trivial to obtain. For a graphic matroid, we can use a union-find data structure [13, 23] with a $O(\log^* k)$ amortized time per operation.

▶ **Lemma 7** (Corollary 3.1 in [5]; [3]). *When run with values c and δ as input,* ContinuousGreedy *uses $O(n \ln(n/\delta)/\delta^2)$ independent set data structure operations, and $O(cn \ln^2(n/\delta)/\delta^4)$ queries to the value oracle of f and additional arithmetic operations. Moreover, if $\max_{S \in \mathcal{I}} \sum_{e \in S} f(e) \leq c \cdot f(\text{OPT})$, where $\text{OPT} \in \text{argmax}_{S \in \mathcal{I}} f(S)$, the solution x returned by the algorithm satisfies $F(x) \geq (1 - \frac{1}{e} - \delta) f(\text{OPT})$.*

The discrete Greedy algorithm is given in Algorithm 2. The algorithm works for any matroid constraint for which we can provide a fast data structure for maintaining a maximum weight base (note that the base is only an approximate maximum weight base, and we drop the word approximate for simplicity). We now describe the properties we require from this data structure. As discussed in the introduction, we give such data structures for a graphic matroid and a partition matroid in the full version of this paper.

The dynamic maximum weight base data structure. Algorithm 2 makes use of a data structure for maintaining the maximum weight base in the matroid, where each element has a weight and the weights are updated through a sequence of updates that can only decrease the weights. The data structure needs to support the following operation: UpdateBase decreases the weight of an element and it updates the base to a maximum weight base for the updated weights. The data structures that we provide in the full version of the paper for a graphic and a partition matroid support this operation in $O(\text{poly}(\log k))$ amortized time.

We note here that the data structure maintains a maximum weight base of the original matroid $\mathcal{M}$, and not the contracted matroid $\mathcal{M}/S$ obtained after picking a set S of elements. This suffices for us, since the discrete Greedy algorithm that we use will not change the weight of an element after it was added to the solution S. Due to this invariant, we can show that the maximum weight base B of $\mathcal{M}$ that the data structure maintains has the property that $S \subseteq B$ at all times, and $B \setminus S$ is a maximum weight base in $\mathcal{M}/S$. This follows from the observation that, if an element e is in the maximum weight base B and the only changes to the weights are such that the weight of e remains unchanged and the weights of elements other than e are decreased, then e remains in the new maximum weight base.

The discrete Greedy algorithm. The algorithm (Algorithm 2) is based on the random residual Greedy algorithm of [4]. The latter algorithm constructs a solution S over k iterations.

Algorithm 2 LazySamplingGreedy$(f, \mathcal{M}, \epsilon)$.

$M = \Theta(f(\mathrm{OPT}))$, $c = \Theta(1/\epsilon)$, $N = 2\ln(k/\epsilon)/\epsilon$
⟨⟨ `maintain cached (rounded) marginal values` ⟩⟩
For each $e \in V$, let $w(e) = (1-\epsilon)^N M$ if $f(\{e\}) \leq (1-\epsilon)^N M$ and $w(e) = (1-\epsilon)^{j-1} M$ if $f(\{e\}) \in ((1-\epsilon)^j M, (1-\epsilon)^{j-1} M]$
⟨⟨ `maintain a base` B `of maximum` $w(\cdot)$ `value in a data structure that supports the` UpdateBase `operation` ⟩⟩
$B = \mathrm{argmax}_{S \in \mathcal{I}} \sum_{e \in S} w(e)$
⟨⟨ `maintain a partition of` B `into buckets` ⟩⟩
$B^{(j)} = \{e \in B \colon w(e) = (1-\epsilon)^{j-1} M\}$ for each $j \in [N]$
$W = \sum_{e \in B} w(e)$
⟨⟨ `main loop` ⟩⟩
$S = \emptyset$
for $t = 1, 2, \ldots, k$ **do**
    Call RefreshValues
    if $W \leq 4cM$ **then**
        return S
    end if
    Sample an element e uniformly at random from B
    $S \leftarrow S \cup \{e\}$
    Remove e from the buckets of B for refreshing purpose so that $w(e)$ is now fixed
end for

procedure RefreshValues ⟨⟨ `Spot check and update values` ⟩⟩
    for $j = 1$ to N **do**
        $T = 0$
        while $T < 4\log_2 n$ **do**
            if $B^{(j)}$ is empty **then**
                Exit the while loop and continue to iteration $j+1$
            end if
            Sample e uniformly at random from $B^{(j)}$
            Let $v(e) = f(S \cup \{e\}) - f(S)$ be the current marginal value of e
            if $v(e) < (1-\epsilon)^j M$ **then**
                $T = 0$
                UpdateBase$(e, j, v(e))$
            else
                $T \leftarrow T + 1$
            end if
        end while
    end for
end procedure

In each iteration, the algorithm assigns a linear weight to each element that is equal to the marginal gain $f(S \cup \{e\}) - f(S)$ on top of the current solution, and it finds a maximum weight base B in $\mathcal{M}/S$. The algorithm then samples an element of B uniformly at random and adds it to the solution. As discussed in Section 1.2, the key difficulty for obtaining a fast running time is maintaining the maximum weight base. Our algorithm uses the following approach for maintaining an approximate maximum weight base. The algorithm maintains

the marginal value of each element (rounded to the next highest power of $(1-\epsilon)$), and it updates it in a lazy manner; at every point, $w(e)$ denotes the cached (rounded) marginal value of the element, and it may be stale.

The algorithm maintains the base B using the data structure discussed above that supports the UpdateBase operation. Additionally, the elements of $B \setminus S$ are stored into buckets corresponding to geometrically decreasing marginal values. More precisely, there are $N = O(\log(k/\epsilon)/\epsilon)$ buckets $B^{(1)}, B^{(2)}, \ldots, B^{(N)}$. The j-th bucket $B^{(j)}$ contains all of the elements of B with marginal values in the range $((1-\epsilon)^j M, (1-\epsilon)^{j-1} M]$, where M is a value such that $f(\mathrm{OPT}) \leq M \leq O(1) f(\mathrm{OPT})$ (we assume that the algorithm knows such a value M, as it can be obtained in nearly-linear time, see e.g. Lemma 3.2 in [5]). The remaining elements of B that do not appear in any of the N buckets have marginal values at most $(1-\epsilon)^N M$; these elements have negligible total marginal gain, and they can be safely ignored.

In order to achieve a fast running time, after each Greedy step, the algorithm uses sampling to (partially) update the base B, the cached marginal values, and the buckets. This is achieved by the procedure RefreshValues, which works as follows. RefreshValues considers each of the buckets in turn. The algorithm updates the bucket $B^{(j)}$ by spot checking $O(\log n)$ elements sampled uniformly at random from the bucket. For each sampled element e, the algorithm computes its current marginal value and, if it has decreased below the range of its bucket, it moves the element to the correct buckets and call UpdateBase to maintain the invariant that B is a maximum weight base.

When the algorithm finds an element whose bucket has changed, it resets to 0 the count for the number of samples taken from the bucket. Thus the algorithm keeps sampling from the bucket until $\Theta(\log n)$ consecutive sampled elements do not change their bucket. The sampling step ensures that, with high probability, in each bucket at least half of the elements are in the correct bucket. (We remark that, instead of resetting the sample count to 0, it suffices to decrease the count by 1, i.e., the count is the total number of samples whose bucket was correct minus the number of samples whose bucket was incorrect. The algorithm then stops when this tally reaches $\Theta(\log n)$. This leads to an improvement in the running time, but we omit it in favor of a simpler analysis.)

After running RefreshValues, the algorithm samples an element e uniformly at random from $B \setminus S$ and adds it to S. The algorithm then removes e from the buckets; this ensures that the weight of e will remain unchanged for the remainder of the algorithm.

2.1 Analysis of the approximation guarantee

Here we show that Algorithm 1 achieves a $1 - 1/e - \epsilon$ approximation. We first analyze the LazySamplingGreedy algorithm. We start with some convenient definitions. Consider some point in the execution of the LazySamplingGreedy algorithm. Consider a bucket $B^{(j)}$. At this point, each element $e \in B^{(j)}$ is in the correct bucket iff its current marginal value $f(S \cup \{e\}) - f(S)$ lies in the interval $((1-\epsilon)^j M, (1-\epsilon)^{j-1} M]$ (its cached marginal value $w(e)$ lies in that interval, but it might be stale). We say that the bucket $B^{(j)}$ is *good* if at least half of the elements in $B^{(j)}$ are in the correct bucket, and we say that the bucket is *bad* otherwise.

The following lemma shows that, with high probability over the random choices of RefreshValues, each run of RefreshValues ensures that every bucket $B^{(j)}$ with $j \in [N]$ is good.

▶ **Lemma 8.** *Consider an iteration in which* LazySamplingGreedy *calls* RefreshValues. *When* RefreshValues *terminates, the probability that the buckets* $\{B^{(j)} : j \in [N]\}$ *are all good is at least* $1 - 1/n^2$.

Proof. We will show that the probability that a given bucket is bad is at most $5 \log n/n^3$; the claim then follows by the union bound, since there are $N \leq n/(5 \log n)$ buckets. Consider a bucket $B^{(j)}$, where $j \in [N]$, and suppose that the bucket is bad at the end of RefreshValues. We analyze the probability the bucket is bad because the algorithm runs until iteration t, which is the last time the algorithm finds an element in $B^{(j)}$ in the wrong bucket, and for $4 \log n$ iterations after t, it always find elements in the right bucket even though only $1/2$ of $B^{(j)}$ are in the right bucket. Since at most half of the elements of $B^{(j)}$ are in the correct bucket and the samples are independent, this event happens with probability at most $(1/2)^{4 \log_2 n} = 1/n^4$. By the union bound over all choices of $t = 1, 2, \ldots, 5n \log n$, the failure probability for bucket $B^{(j)}$ is at most $5 \log n/n^3$. ◀

Since LazySamplingGreedy performs at most $k \leq n$ iterations, it follows by the union bound that all of the buckets $\{B^{(j)} \colon j \in [N]\}$ are all good throughout the algorithm with probability at least $1 - 1/n$. For the remainder of the analysis, we condition on this event. Additionally, we fix an event specifying the random choices made by RefreshValues and we implicitly condition all probabilities and expectations on this event.

Let us now show that B is a suitable approximation for the maximum weight base in $\mathcal{M}/S$ with weights given by the current marginal values $f(S \cup \{e\}) - f(S)$.

▶ **Lemma 9.** *Suppose that every bucket of B is good throughout the algorithm. Let $v(e) = f(S \cup \{e\}) - f(S)$ denote the current marginal values. We have*
(1) *$w(S') \geq v(S')$ for every $S' \subseteq V$;*
(2) *$w(B) \geq w(S')$ for every $S' \subseteq V$;*
(3) *$v(B) \geq \frac{1-\epsilon}{2} \cdot w(B) - \frac{\epsilon^2}{k} \cdot M$.*

Proof. The first property follows from the fact that, by submodularity, the weights $w(\cdot)$ are upper bounds on the marginal values.

The second property follows from the fact that the algorithm maintains the invariant that B is the maximum weight base in $\mathcal{M}/S$ with respect to the weights $w(\cdot)$.

Let us now show the third property. Consider the following partition of B into sets B_1, B_2, and B_3, where: B_1 is the set of all elements $e \in B$ such that e is in one of the buckets $\{B^{(j)} \colon j \in [N]\}$ and moreover e is in the correct bucket (note that $(1-\epsilon)w(e) \leq v(e) \leq w(e)$ for every $e \in B_1$); B_2 is the set of all elements $e \in B$ such that e is in one of the buckets $\{B^{(j)} \colon j \in [N]\}$ but e is not in the correct bucket (i.e., $(1-\epsilon)^N M < w(e)$ but $v(e) < (1-\epsilon)w(e)$); B_3 is the set of all elements $e \in B$ such that $w(e) < (1-\epsilon)^N M \leq (\epsilon/k)^2 M$.

Since $|B_3| \leq k$, we have $w(B_3) \leq |B_3| \cdot \left(\frac{\epsilon}{k}\right)^2 M \leq \frac{\epsilon^2}{k} M$.

Since all of the buckets are good, it follows that the total $w(\cdot)$ weight of the elements that are in the correct bucket is at least $\frac{1}{2} \cdot w(B \setminus B_3)$. Indeed, we have

$$w(B_1) = \sum_{j=1}^{N} w(B_1 \cap B^{(j)}) = \sum_{j=1}^{N} (1-\epsilon)^{j-1} M |B_1 \cap B^{(j)}| \geq \sum_{j=1}^{N} (1-\epsilon)^{j-1} M \frac{|B^{(j)}|}{2} = \frac{w(B \setminus B_3)}{2}.$$

Finally, since $v(e) \geq (1-\epsilon)w(e)$ for every $e \in B_1$, we have

$$v(B) \geq v(B_1) \geq (1-\epsilon)w(B_1) \geq \frac{1-\epsilon}{2} w(B \setminus B_3) \geq \frac{1-\epsilon}{2} w(B) - \frac{\epsilon^2}{k} M. \quad ◀$$

Now we turn to the analysis of the main for loop of LazySamplingGreedy (lines 11–19). Let Z be a random variable equal to the number of iterations where the algorithm executes line 17. We define sets $\{S_t \colon t \in \{0, 1, \ldots, k\}\}$ and $\{\mathrm{OPT}_t \colon t \in \{0, 1, \ldots, k\}\}$ as follows. Let $S_0 = \emptyset$ and $\mathrm{OPT}_0 = \mathrm{OPT}$. Consider an iteration $t \leq Z$ and suppose that

S_{t-1} and OPT_{t-1} have already been defined and they satisfy $S_{t-1} \cup \mathrm{OPT}_{t-1} \in \mathcal{I}$ and $|S_{t-1}| + |\mathrm{OPT}_{t-1}| = k$. Consider a bijection $\pi : B \to \mathrm{OPT}_{t-1}$ so that $\mathrm{OPT}_{t-1} \setminus \{\pi(e)\} \cup \{e\}$ is a base of $\mathcal{M}/S_{t-1}$ for all $e \in B$ (such a bijection always exists, see e.g., Corollary 39.12a in [22]). Let e_t be the element sampled on line 17 and $o_t = \pi(e_t)$. We define $S_t = S_{t-1} \cup \{e_t\}$ and $\mathrm{OPT}_t = \mathrm{OPT}_{t-1} \setminus \{o_t\}$. Note that $S_t \cup \mathrm{OPT}_t \in \mathcal{I}$. For each $t > Z$, we define $S_t = S_Z$ and $\mathrm{OPT}_t = \mathrm{OPT}_Z$.

In each iteration t, the gain in the Greedy solution value is $f(S_t) - f(S_{t-1})$, and the loss in the optimal solution value is $f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_t)$ (when we add an element to S_{t-1}, we remove an element from OPT_{t-1} so that $S_t \cup \mathrm{OPT}_t$ remains a feasible solution). The following lemma relates the two values in expectation.

▶ **Lemma 10.** *For every $t \in [k]$, if all of the buckets $B^{(j)}$ are good, we have* $\mathbb{E}[f(S_t) - f(S_{t-1})] \geq c \cdot \mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_t)]$.

Proof. Consider $t \in [k]$. Recall that Z is the number of iterations where the algorithm executes line 17. If $t > Z$, the inequality is trivially satisfied, since both expectations are equal to 0. Therefore we may assume that $t \leq Z$ and thus $S_t = S_{t-1} \cup \{e_t\}$ and $\mathrm{OPT}_t = \mathrm{OPT}_{t-1} \setminus \{o_t\}$.

Let us now fix an event R_{t-1} specifying the random choices for the first $t-1$ iterations, i.e., the random elements $e_1, \ldots, e_{t-1}$ and $o_1, \ldots, o_{t-1}$. In the following, all the probabilities and expectations are implicitly conditioned on R_{t-1}. Note that, once R_{t-1} is fixed, S_{t-1} and OPT_{t-1} are deterministic.

Let us first lower bound $\mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1})]$. Let w_t, B_t, and W_t denote w, B, and W right after executing RefreshValues in iteration t. Note that, since R_{t-1} and the random choices of RefreshValues are fixed, w_t, B_t, and W_t are deterministic.

Recall that all of the buckets of B_t are good, i.e., at least half of the elements of $B_t^{(j)}$ are in the correct bucket, for every $j \in [N]$. Let B'_t be the subset of B_t consisting of all of the elements that are in the correct bucket, and let B''_t be the subset of B_t consisting of all of the elements that are not in any bucket.

For every $e \in B'_t$, we have $f(S_{t-1} \cup \{e\}) - f(S_{t-1}) \geq (1-\epsilon) w_t(e)$. For every $e \in B''_t$, we have $f(S_{t-1} \cup \{e\}) - f(S_{t-1}) \leq w_t(e) = (1-\epsilon)^N M \leq (\epsilon/k)^2 M$, and therefore $w_t(B''_t) \leq \frac{\epsilon^2}{k} M$. Since all of the buckets are good and $W_t > 4cM$ (the algorithm did not terminate on line 14), we have

$$\begin{aligned}\sum_{e \in B'_t} w_t(e) &= \sum_{j=1}^{N} w_t(B'_t \cap B_t^{(j)}) = \sum_{j=1}^{N} (1-\epsilon)^{j-1} M |B'_t \cap B_t^{(j)}| \geq \sum_{j=1}^{N} (1-\epsilon)^{j-1} M \frac{|B_t^{(j)}|}{2} \\ &= \frac{w_t(B_t \setminus B''_t)}{2} \geq \frac{W_t}{2} - \frac{\epsilon^2}{2k} M \geq \left(2c - \frac{\epsilon^2}{2k}\right) M \geq \left(2c - \frac{\epsilon^2}{2k}\right) f(\mathrm{OPT}).\end{aligned}$$

By combining these observations, we obtain

$$\begin{aligned}&\mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1})] \geq \mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1}) | e_t \in B'_t] \Pr[e_t \in B'_t] \\ &= \mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1}) | e_t \in B'_t] \cdot \frac{|B'_t|}{|B_t|} \geq (1-\epsilon) \mathbb{E}[w_t(e_t) | e_t \in B'_t] \cdot \frac{|B'_t|}{|B_t|} \\ &= (1-\epsilon) w_t(B'_t) \cdot \frac{1}{|B'_t|} \cdot \frac{|B'_t|}{|B_t|} \geq \frac{(1-\epsilon)\left(2c - \frac{\epsilon^2}{2k}\right)}{|B_t|} f(\mathrm{OPT}) \geq \frac{c}{|B_t|} f(\mathrm{OPT})\end{aligned}$$

Let us now upper bound $\mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_t)]$. Recall that e_t is chosen randomly from

B and thus, o_t is chosen uniformly at random from OPT_{t-1} (since π is a bijection). Hence

$$\mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o_t\})] = \sum_{o \in \mathrm{OPT}_{t-1}} (f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o\})) \cdot \frac{1}{|\mathrm{OPT}_{t-1}|}$$

By submodularity, we have

$$f(\mathrm{OPT}_{t-1}) \geq \sum_{j=1}^{m} (f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o_j\}).$$

Therefore

$$\mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o_t\})] \leq \frac{f(\mathrm{OPT}_{t-1})}{|\mathrm{OPT}_{t-1}|} \leq \frac{f(\mathrm{OPT})}{|\mathrm{OPT}_{t-1}|}.$$

To recap, we have shown that:

$$\mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1})] \geq \frac{c \cdot f(\mathrm{OPT})}{|B_t|},$$
$$\mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o_t\})] \leq \frac{f(\mathrm{OPT})}{|\mathrm{OPT}_{t-1}|}.$$

Since $|B_t| = |\mathrm{OPT}_{t-1}|$, we have

$$\mathbb{E}[f(S_{t-1} \cup \{e_t\}) - f(S_{t-1})] \geq c \cdot \mathbb{E}[f(\mathrm{OPT}_{t-1}) - f(\mathrm{OPT}_{t-1} \setminus \{o_t\})].$$

Since the above inequality holds conditioned on every given event R_{t-1}, it holds unconditionally, and the lemma follows. ◀

The following lemma follows from Lemmas 9 and 10.

▶ **Lemma 11.** *If all of the buckets $B^{(j)}$ are good, the* LazySamplingGreedy *algorithm (Algorithm 2) returns a set $S \in \mathcal{I}$ with the following properties.*

(1) $\max_{S' \colon S' \cup S \in \mathcal{I}} \sum_{e \in S'} f_S(e) \leq 4cM = O(1/\epsilon) f(\mathrm{OPT})$.

(2) *There is a random subset $\mathrm{OPT}' \subseteq \mathrm{OPT}$ depending on S with the following properties: $S \cup \mathrm{OPT}' \in \mathcal{I}$ and $\mathbb{E}[f(\mathrm{OPT}')] \geq f(\mathrm{OPT}) - \frac{1}{c} \cdot \mathbb{E}[f(S)] \geq \left(1 - \frac{1}{c}\right) f(\mathrm{OPT})$.*

By combining Lemmas 7 and 11, we obtain:

▶ **Lemma 12.** *The* ContinuousMatroid *algorithm (Algorithm 1) returns a solution $\mathbf{1}_S \vee x \in P(\mathcal{M})$ such that $F(\mathbf{1}_S \vee x) \geq (1 - 1/e - O(\epsilon)) f(\mathrm{OPT})$ with constant probability.*

Proof. Note that, in order to apply Lemma 7, we need the following condition to hold: $\max_{S' \colon S' \cup S \in \mathcal{I}} \sum_{e \in S'} f_S(e) \leq c' f_S(\mathrm{OPT}'')$, where $\mathrm{OPT}'' \in \operatorname{argmax}_{S' \colon S' \cup S \in \mathcal{I}} f_S(S')$.

Using Lemma 11, we can show that the above condition holds with constant probability as follows. Let OPT' be the set guaranteed by Lemma 11. We have $f_S(\mathrm{OPT}') \leq f_S(\mathrm{OPT}'')$ and $f(S \cup \mathrm{OPT}') \geq f(\mathrm{OPT}')$. Therefore $f_S(\mathrm{OPT}'') \geq f_S(\mathrm{OPT}') \geq f(\mathrm{OPT}') - f(S)$.

By Lemma 11, we have $\mathbb{E}[f(\mathrm{OPT}) - f(\mathrm{OPT}')] \leq f(\mathrm{OPT})/c$. Therefore, by the Markov inequality, with probability at least $2/3$, we have $f(\mathrm{OPT}) - f(\mathrm{OPT}') \leq 3f(\mathrm{OPT})/c$. Consider two cases. First, if $f(S) \geq (1 - 1/e) f(\mathrm{OPT})$ then the algorithm can simply return S. Second, if $f(S) < (1 - 1/e) f(\mathrm{OPT})$ then $f_S(\mathrm{OPT}'') \geq f(\mathrm{OPT}') - f(S) \geq (1/e - 3/c) f(\mathrm{OPT})$. Therefore, $\max_{S' \colon S' \cup S \in \mathcal{I}} \sum_{e \in S'} f_S(e) \leq O(c f_S(\mathrm{OPT}'')) \leq c' f_S(\mathrm{OPT}'')$. Thus the conditions of Lemma 7 are satisfied and thus the continuous Greedy algorithm returns a solution $x \in P(\mathcal{M}/S)$ such that

$$F(\mathbf{1}_S \vee x) - f(S) \geq \left(1 - \frac{1}{e} - \epsilon\right) (f(\mathrm{OPT}') - f(S))$$
$$\geq \left(1 - \frac{1}{e} - \epsilon\right) \left(1 - \frac{3}{c}\right) f(\mathrm{OPT}) - f(S) \geq \left(1 - \frac{1}{e} - 2\epsilon\right) f(\mathrm{OPT}) - f(S).$$ ◀

Abstract

Exact string matching in labeled graphs is the problem of searching paths of a graph $G = (V, E)$ such that the concatenation of their node labels is equal to the given pattern string $P[1..m]$. This basic problem can be found at the heart of more complex operations on variation graphs in computational biology, of query operations in graph databases, and of analysis operations in heterogeneous networks.

We prove a conditional lower bound stating that, for any constant $\epsilon > 0$, an $O(|E|^{1-\epsilon}\, m)$-time, or an $O(|E|\, m^{1-\epsilon})$-time algorithm for exact string matching in graphs, with node labels and patterns drawn from a binary alphabet, cannot be achieved unless the Strong Exponential Time Hypothesis (SETH) is false. This holds even if restricted to undirected graphs with maximum node degree two, i.e. to *zig-zag matching in bidirectional strings*, or to *deterministic* directed acyclic graphs whose nodes have maximum sum of indegree and outdegree three. These restricted cases make the lower bound stricter than what can be directly derived from related bounds on regular expression matching (Backurs and Indyk, FOCS'16). In fact, our bounds are tight in the sense that lowering the degree or the alphabet size yields linear-time solvable problems.

An interesting corollary is that exact and approximate matching are equally hard (quadratic time) in graphs under SETH. In comparison, the same problems restricted to strings have linear-time vs quadratic-time solutions, respectively (approximate pattern matching having also a matching SETH lower bound (Backurs and Indyk, STOC'15)).

1 Introduction

String matching is the classical problem of finding the occurrences of a pattern string as a substring of a text string [22]. As most of today's data is linked, it is natural to investigate string matching in labeled graphs. Indeed, large-scale labeled graphs are becoming ubiquitous in several areas, such as graph databases [6, 16, 30, 27], graph mining [19, 12], and computational biology [11]. Applications require sophisticated operations on these graphs, and often rely on primitives that locate paths whose nodes have labels or types matching a pattern given at query time. The most basic pattern is a string and, as we will see, this already poses a challenge when performing string matching in graphs.

Problem Definition

Given an alphabet Σ of symbols, consider a labeled graph $G = (V, E, L)$, where (V, E) represents a directed or undirected graph and $L : V \to \Sigma$ is a function that defines which symbol from Σ is assigned to each node as label.[1] A node labeled with $\sigma \in \Sigma$ is called a *σ-node*, and an edge whose endpoints are labeled σ_1 and σ_2, respectively, is called a *$\sigma_1\sigma_2$-edge*. If G is a directed graph, we say that G is *deterministic* if, for any two out-neighbors of the same node, their labels are different. In the following, we introduce the acronym *3-DDAG* to indicate a deterministic directed acyclic graph (DAG) such that its nodes are labeled with a binary alphabet and the sum of indegree and outdegree of each node is at most 3.

Given a pattern string $P[1..m]$ over Σ, we say that P has a *match* in G if there is a path $u_1, \ldots, u_k$ such that $P = L(u_1) \cdots L(u_k)$ (we also say that P *occurs* in G, and that $u_1, \ldots, u_k$ is an *occurrence* of P).

▶ **Problem 1** (String Matching in Labeled Graphs (SMLG)).
INPUT*: A labeled graph $G = (V, E, L)$ and a pattern string P, both over an alphabet Σ.*
OUTPUT*:* True *if and only if there is at least one occurrence of P in G.*

Results

We give conditional bounds for the SMLG problem using the Orthogonal Vectors (OV) hypothesis [34]. The latter states that for any constant $\epsilon > 0$, no algorithm can solve in $O(n^{2-\epsilon}\text{poly}(d))$ time the OV problem: given two sets $X, Y \subseteq \{0,1\}^d$ such that $|X| = |Y| = n$ and $d = \omega(\log n)$, decide whether there exist $x \in X$ and $y \in Y$ such that x and y are orthogonal, namely, $x \cdot y = 0$. We observe that it is common practice to use the Strong Exponential Time Hypothesis (SETH) [20] but, since SETH implies the OV hypotesis [34], it suffices to use the OV hypothesis in the bounds, as they hold also for SETH.

First, we consider the SMLG problem on directed graphs. Their weakest form is a 3-DDAG, for which we prove in Section 2 that subquadratic time for exact string matching cannot be achieved unless the OV hypothesis is false.

▶ **Theorem 1.** *For any constant $\epsilon > 0$, the String Matching in Labeled Graphs (SMLG) problem for a binary alphabet and a labeled* deterministic *directed acyclic graph (DAG) cannot be solved in either $O(|E|^{1-\epsilon}\, m)$ or $O(|E|\, m^{1-\epsilon})$ time unless the OV hypothesis fails. This holds even if it is restricted to graphs in which the sum of outdegree and indegree of any node is at most three (i.e, 3-DDAGs).*

[1] Note that we can also define the node labels as nonempty strings, but it suffices to use single symbols to show that string matching in graphs is challenging.

Table 1 Legend: V = set of nodes, E = set of edges, occ = number of matches for the pattern in the graph, m = pattern length, N = total length of text in all nodes, *(1)* errors only in the pattern, *(2)* errors in the graph, *(3)* matches span only one edge. The two rows highlighted in gray report the best known bounds for exact and approximate string matching, respectively.

State of the art for SMLG				
Year	**Authors**	**Graph**	**Exact/ Approximate**	**Time**
1992	Manber, Wu [24]	DAG	approximate$^{(1)}$	$O(m\|E\| + occ \lg\lg m)$
1993	Akutsu [2]	tree	exact	$O(N)$

2017	Rautiainen, Marschall [29]	general	approximate$^{(1)}$	$O(N + m\|E\|)$
2019	Jain et al. [21]	general binary alphabet	approximate$^{(2)}$	NP-Hard

Next, we consider the SMLG problem on undirected graphs and introduce the *zig-zag* pattern matching problem in strings, which models searching a string P along a path of an undirected graph. While an exact occurrence of P in a text string is found by scanning the text forward for increasing positions in P, a *zig-zag* occurrence of P can be found by partially scanning forward and backward adjacent text positions, as many times as needed (e.g. for an edge $\{u, v\}$ with $L(u) = \mathtt{a}$ and $L(v) = \mathtt{b}$, all patterns of the form $\mathtt{a}, \mathtt{ab}, \mathtt{aba}, \mathtt{abab}, \ldots$ occur starting from u). We prove in Section 3 the following result.

▶ **Theorem 2.** *The conditional lower bound stated in Theorem 1 holds even if it is restricted to undirected graphs whose nodes have degree at most 2, where the pattern and the node labels are drawn from a binary alphabet.*

Our results can cover arbitrary graphs in this way. Interpreting the graphs from Theorem 2 as directed, we observe that they have nodes with both indegree and outdegree 2. Looking at Theorem 1, we observe that it involves directed graphs with both nodes of indegree at most 1 and outdegree 2, and nodes with outdegree at most 1 and indegree 2. Thus, the only uncovered case is that of directed graphs with only nodes of indegree at most 1, or directed graphs with only nodes of outdegree at most 1. For such graphs, we observe that their edges can be decomposed into forests of directed trees (arborescences), whose roots may be connected in a directed cycle (at most one cycle per forest). In the extended version of this work we will show that the Knuth-Morris-Pratt algorithm [22] can be easily extended to solve exact string matching for these special directed graphs in linear time, thus completing the full picture.

History and Implications

The idea of extending the problem of string matching to graphs, as given in SMLG, is not new. If the nodes $u_1, \ldots, u_k$ are required to be distinct (i.e., to be a *simple* path), this problem is NP-hard as it solves the well-known Hamiltonian Path problem, so this

requirement is removed for this reason. The SMLG problem was studied over 25 years ago as a search problem for hypertext by Manber and Wu [24]. The history of key contributions is given in Table 1, where a common feature of the reported bounds is the appearance of the quadratic term $m\,|E|$ (except for some special cases). The quadratic cost of the approximate matching in graphs is asymptotically optimal under the Strong Exponential Time Hypothesis (SETH) [20] as (i) it solves the approximate string matching as a special case, since a graph consisting of just one directed path of $|E|+1$ nodes and $|E|$ edges is a text string of length $n = |E|+1$, and (ii) it has been recently proved that the edit distance of two strings of length n cannot be computed in $O(n^{2-\epsilon})$ time, for any constant $\epsilon > 0$, unless SETH is false [7]. This conditional lower bound explains why the $O(m|E|)$ barrier has been difficult to cross in the approximate case. Specifically, Amir et al. [4, 5], gave a quadratic-time solution for exact string matching in $O(N + m \cdot |E|)$ time, where $N = \sum_{u \in V} |L(u)|$. Rautiainen and Marschall [29] and Jain et al. [21] recently gave the best bound for errors in pattern only, $O(N + m \cdot |E|)$ time, same as the exact string matching. The two best results for exact and approximate pattern matching, both taking quadratic time in the worst case, are highlighted in Table 1. As allowing errors in the graph makes the problem NP-hard [5], we consider here errors in the pattern only.

In this scenario and the application domains mentioned at the beginning, our results have a number of implications discussed below.

- While we can explain the complexity of *approximate* string matching in graphs, not much is known on the complexity of *exact* string matching in graphs. The classical exact string matching can be solved in linear time [22], so one could expect the corresponding problem on graphs to be easier than approximate string matching. A lower bound (i.e., NP-hard, as mentioned above) exists only in the case when the pattern is restricted to match only simple paths in the graph. Extensions of this type of matching for special graph classes have been studied in [23]. Here we study the general case, where paths can pass through nodes multiple times. Somewhat surprisingly Theorems 1 and 2 imply that *exact and approximate pattern matching are equally hard in graphs*, even if they are 3-DDAGs.
- Our results imply that the algorithm for directed graphs by Amir et al. [4, 5] is essentially the best we can hope for asymptotic bounds unless the OV hyptothesis is false. This also applies to the case of undirected graphs by the simple transformation so that each edge $\{u, v\}$ is transformed into a pair of arcs (u, v) and (v, u). Note that we need also Theorem 2 to explicitly state that this is the best possible also for undirected graphs of maximum degree 2. To complete the picture, we show how to get linear time for the above special case of directed graphs where each node has indegree at most 1, or directed graphs whose nodes have outdegree at most 1.
- Our results also explain why it has been difficult to find indexing schemes for fast exact string matching in graphs, with other than best-case or average-case guarantees [31, 17], except for limited search scenarios [32]. They complement recent findings about *Wheeler graphs* [17, 18, 3]. Wheeler graphs are a class of graphs admitting an index structure that can be constructed in linear time and that supports linear-time exact pattern matching. Gibney and Thankachan [18] claim that it is NP-complete to recognize whether a (non-deterministic) DAG is a Wheeler graph. Alanko et al. [3] claim a linear-time algorithm for recognizing whether a deterministic DAG is a Wheeler graph. Theorem 1 shows that converting an arbitrary deterministic DAG into an equivalent Wheeler graph should take at least quadratic time unless the OV hypothesis is false. In particular, the 3-DDAG obtained in the reduction from OV in the proof of Theorem 1 is not a Wheeler graph.

- We observe that, for any given pattern P, the 3-DDAG obtained by our reduction admits at most one occurrence per node, as it is deterministic and acyclic. When both P and a node u are given, it takes linear time to search P starting from u. Interestingly, if P alone is given, we observe that our results imply that an algorithm reporting whether there exists a node u from which an occurrence of P starts cannot take subquadratic time unless the OV hypothesis is false. Indeed, this hypothetical algorithm would be able to solve the SMLG problem also on that 3-DDAG.
- In the extended version of this work we will describe a simple transformation so that we can see our 3-DDAG and the pattern P as two DFAs, so that our SMLG problem reduces to the emptiness intersection for the string sets recognized by these two DFAs. In this way we give a quadratic conditional lower bound for the latter problem using OV. This adds to the results known in the literature for DFAs (tree automata) under SETH [33] and 3SUM [13]. It is worth noting that our SMLG problem on tree automata takes instead linear time, as will be discussed in the extended version of this work, and this seems to suggest that SMLG could be easier than emptiness intersection for two DFAs under SETH, even though both problems have conditional quadratic lower bounds.

Our reductions share some similarities with those for string problems [7, 10, 1, 8, 9]. The closest connection is with a conditional hardness of several forms of regular expression matching [8]. Especially, one could start with a *non-deterministic finite automaton (NFA)* derived from the regular expression matching of type $|\cdot|$, and add universal "jolly" gadgets (see our reduction) to come up with an OV lower bound for exact pattern matching in directed non-deterministic graphs. (For the interested reader, this is what we have done in an early version of this work [14].) However, to cover the deterministic and bounded degree cases, we build our reduction using a different strategy. This strategy yields a graph of small degree and enables local merging of non-deterministic subgraphs into deterministic counterparts. This locality feature of our reduction is crucial, since converting an NFA into a *deterministic finite automaton (DFA)* can take exponential time [28]. Finally, while this reduction works also for undirected graphs of small degree, it does not cover undirected graphs of degree two. For this case (zig-zag matching in a bidirectional string), we need a more intricate reduction as the underlying graph has less structure.

2 Deterministic Directed Acyclic Graphs

In this section we reduce the OV problem to the SMLG problem for the restricted case of 3-DDAGs. Since any SMLG algorithm for arbitrary directed graphs can be applied also to 3-DDAGs in the same complexity, we will show that a subquadratic-time SMLG algorithm would make the OV hypothesis false. In this scenario, 3-DDAGs are the most restricted case, as otherwise the SMLG problem can be solved in linear time.

Given an OV instance with sets $X = \{x_1, \ldots, x_n\}$ and $Y = \{y_1, \ldots, y_n\}$ of d-dimensional binary vectors, we show how to build a pattern P and a 3-DDAG G such that P will have a match in G if and only if there exists a vector in X orthogonal to one in Y. We first describe how to build P and how to obtain a directed graph whose nodes are labeled with a constant-sized alphabet. Then we discuss how to turn such graph into the 3-DDAG G.

2.1 Pattern

Pattern P is over the alphabet $\Sigma = \{\mathtt{b}, \mathtt{e}, \mathtt{0}, \mathtt{1}\}$, has length $|P| = O(nd)$, and can be built in $O(nd)$ time from the first set of vectors $X = \{x_1, \ldots, x_n\}$. Namely, we define $P = \mathtt{bb}P_{x_1}\mathtt{e}\,\mathtt{b}P_{x_2}\mathtt{e}\ldots\mathtt{b}P_{x_n}\mathtt{ee}$ where P_{x_i} is a string of length d that is associated with $x_i \in X$,

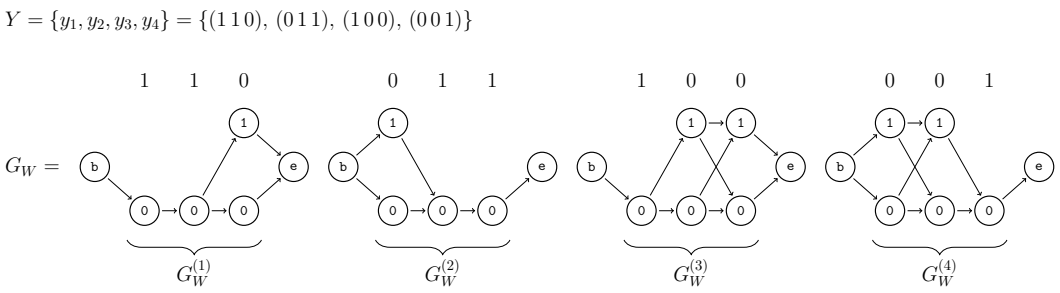

Figure 1 Gadget G_W.

for $1 \leq i \leq n$. The h-th symbol of P_{x_i} is either `0` or `1`, for each $h \in \{1, \ldots, d\}$, such that $P_{x_i}[h] = \texttt{1}$ if and only if $x_i[h] = 1$.[2] We thus view the vectors in X as subpatterns P_{x_i}s which are concatenated by placing separator characters `eb`. Note that P starts with `bb` and ends with `ee`: such strings are found nowhere else in P, marking thus its beginning and its end.

2.2 Directed Graph

The gadget implementing the main logic of the reduction is a directed graph $G_W = (V_W, E_W, L_W)$, illustrated in Figure 1. Starting from the second set of vectors Y, set V_W can be seen as n disjoint *groups* of nodes $V_W^{(1)}, V_W^{(2)}, \ldots, V_W^{(n)}$ (plus some extra nodes), where the nodes in $V_W^{(j)}$ are uniquely associated with vector $y_j \in Y$, for $1 \leq j \leq n$. The corresponding induced subgraph $G_W^{(j)} = (V_W^{(j)}, E_W^{(j)})$ will contain an occurrence of a subpattern P_{x_i} if and only if $x_i \cdot y_j = 0$. We give more details below.

The nodes in $V_W^{(j)}$ are defined as follows. For $1 \leq h \leq d$, we consider entry $y_j[h]$ of vector $y_j \in Y$. If $y_j[h] = 1$, we place just a `0`-node w_{jh}^0 to indicate that we only accept $P_{x_i}[h] = \texttt{0}$ for this h coordinate. Instead, if $y_j[h] = 0$, we place both a `0`-node w_{jh}^0 and a `1`-node w_{jh}^1 to indicate that the value of $P_{x_i}[h]$ does not matter. The nodes in $V_W^{(j)}$ are preceded by a special begin `b`-node $b_W^{(j)}$ and succeeded by a special end `e`-node $e_W^{(j)}$. The overall nodes are thus $V_W = \bigcup_{1 \leq j \leq n} (V_W^{(j)} \cup \{b_W^{(j)}, e_W^{(j)}\})$, and it holds that $|V_W| = O(nd)$.

As for the edges in $E_W^{(j)}$, they properly connect the nodes inside each group $V_W^{(j)}$. Specifically, node $b_W^{(j)}$ is connected to w_{j1}^0 and, if it exists, to w_{j1}^1. Also, we place edges connecting both nodes w_{jd}^0 and w_{jd}^1 (if this exists) to node $e_W^{(j)}$. Moreover, there is an edge for every pair of nodes that are consecutive in terms of h coordinate, for $1 \leq h < d$ (e.g., w_{jh}^1 is connected to $w_{j\,h+1}^0$). The overall edges are thus $E_W = \bigcup_{1 \leq j \leq n} E_W^{(j)}$, where $|E_W| = O(nd)$.

In this way we define the directed graph $G_W = (V_W, E_W, L_W)$, which can be built in $O(nd)$ time from set Y and consists of n connected components $G_W^{(j)}$, one for each vector $y_j \in Y$.

We observe that pattern occurrences in G_W have some useful combinatorial properties. The lemma below is an immediate observation, which follows from the fact that each $G_W^{(j)}$ is acyclic and not connected to any other $G_W^{(j')}$.

▶ **Lemma 3.** *If subpattern* $\texttt{b}P_{x_i}\texttt{e}$ *has a match in* G_W *then the nodes matching* P_{x_i} *share the same* j *coordinate and have distinct and consecutive* h *coordinates.*

Lemma 4 (whose proof will be provided in the extended version of this work) relates the occurrence of a subpattern to the OV problem.

[2] Note that `1` is a symbol of Σ while 1 is the truth value in x_i.

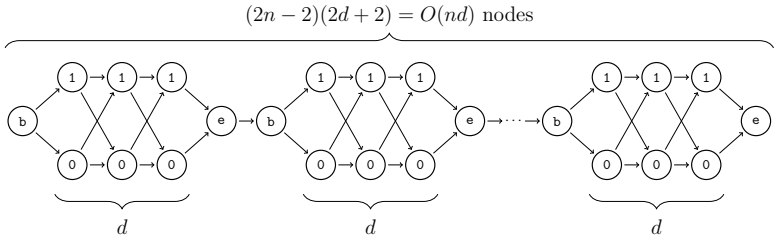

Figure 2 Gadget G_U.

▶ **Lemma 4.** *Subpattern* $\texttt{b}P_{x_i}\texttt{e}$ *has a match in* G_W *if and only if there exist* $y_j \in Y$ *such that* $x_i \cdot y_j = 0$.

In the following we will also use gadget $G_U = (V_U, E_U, L_U)$, the degenerate case of G_W with $2n-2$ (instead of just n) connected components $G_U^{(j)}$ where, for all $1 \leq j \leq 2n-2$ and $1 \leq h \leq d$, we place both a `0`-node and a `1`-node: we call these two nodes u_{jh}^0 and u_{jh}^1, respectively, to distinguish them from those in G_W. Moreover, every `e`-node of this gadget is connected with the next `b`-node, in terms of j coordinate (see Figure 2). As it can be seen, any subpattern P_{x_i} occurs in G_U, so it can be used as a "jolly" gadget.

2.3 Non-deterministic Graph

A possible approach is based on suitably combining one instance of gadget G_W and two instances of gadgets G_U, named G_{U1} and G_{U2}. The idea is that, when $x_i \cdot y_j = 0$, we want P to occur in G, so that the three conditions below hold.

- Instance G_{U1}: P_{x_1} occurs in $G_{U1}^{(n-1+j-(i-1))}$, …, $P_{x_{i-1}}$ occurs in $G_{U1}^{(n-1+j-1)}$.
- Instance G_W: P_{x_i} occurs in $G_W^{(j)}$.
- Instance G_{U2}: $P_{x_{i+1}}$ occurs in $G_{U2}^{(j)}$, …, P_{x_n} occurs in $G_{U2}^{(j+n-i-1)}$.

On the other hand, when $x_i \cdot y_j \neq 0$, we do not want P_{x_i} to occur in $G_W^{(j)}$. We can suitably link the instances G_W, G_{U1} and G_{U2} so that we get the above conditions: we connect the `e`-nodes in G_{U1} to `b`-nodes in G_W, the `e`-nodes in G_W to `b`-nodes in G_{U2} and we place additional starting `b`-nodes and additional ending `e`-nodes, to properly match the `bb` and `ee` prefix and suffix of P, respectively. However, even if G_W, G_{U1} and G_{U2} are deterministic, their resulting composition is not so, because of the out-neighbours of the `e`-nodes.[3] We show below how to obtain a deterministic graph by suitably merging G_W with portions of G_U.

2.4 Deterministic Graph

In order to obtain a *deterministic* DAG, we need to suitably combine one instance of gadget G_W with the two instances G_{U1} and G_{U2} (recall that both G_{U1} and G_{U2} have instances of gadget $G_U^{(j)}$, for all $1 \leq j \leq 2n-2$). While G_{U2} will be used as is, G_{U1} needs to be partially merged with G_W to obtain determinism. We start building our final graph G from G_W by adding parts of G_{U1} when needed, obtaining a deterministic graph called G_{U1W}, as shown in Figure 3. Consider subgraph $G_W^{(j)}$ and assume that the first position in which the `1`-node is lacking is h. We place a partial version of subgraph $G_{U1}^{(j')}, j' := n-1+j$, by adding to the graph the nodes and edges of $G_{U1}^{(j')}$ that are located between position $h+1$ and node

[3] An `e`-node can have two `b`-nodes as out-neighbors when linking G_{U1} to G_W, see [15].

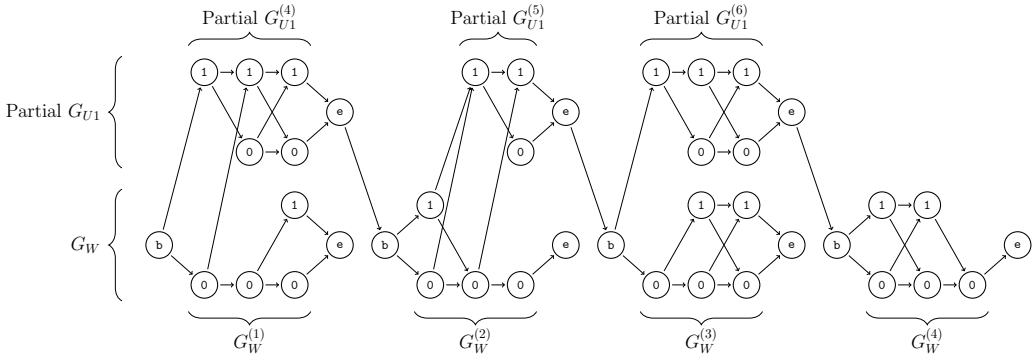

Figure 3 Graph G_{U1W} after merging G_{U1} (from Figure 2) with G_W (from Figure 1).

$e_{U1}^{(j')}$ (included). If $h = d$ we place only node $e_{U1}^{(j')}$. We also place 1-node u_{jh}^1 and we connect the 0-node and the 1-node (if any) of $G_W^{(j)}$ in position $h-1$ to it (if $h > 1$), or we connect $b_W^{(j)}$ to it (if $h = 1$). Moreover, we connect node u_{jh}^1 to the first 0- and 1-node of partial $G_{U1}^{(j')}$. If $h = d$ we connect u_{jh}^1 to $e_{U1}^{(j')}$. Then we scan $G_W^{(j)}$ from left to right looking for those positions h', $h \leq h' < d$, such that there is no 1-node in position $h'+1$. We connect the 0-node and the 1-node (if any) of $G_W^{(j)}$ in position h' to the 1-node of $G_{U1}^{(j')}$ in position $h'+1$. Finally, we place edge $(e_{U1}^{(j')}, b_W^{(j+1)})$. To complete the merging task, we apply the above modification to all $G_W^{(j)}$, for $1 \leq j \leq n-1$, and thus obtain gadget G_{U1W}.

At this point, we place gadget G_{U2} and we connect G_{U1W} to it by placing edges $(e_W^{(j)}, b_{U2}^{(j)})$, for all $1 \leq j \leq n$. Also, for every b-node of G_{U1W} we place an additional b-node as in-neighbor. We do the same for every e-node of G_{U2}, placing an e-node as out-neighbor. Adding subgraphs $G_{U1}^{(1)}, \ldots, G_{U1}^{(n-1)}$ with one additional b-node as in-neighbor of their b-nodes, and connecting the e-node of $G_{U1}^{(n-1)}$ to the b-node of $G_W^{(1)}$, completes the transformation into the wanted deterministic directed acyclic graph, which we call G. Figure 4 gives an overall picture of G.

It is easy to verify that every b- and e-node in G can have no more than two out-neighbours and, in such case, they have different labels. This shows that graph G is deterministic.

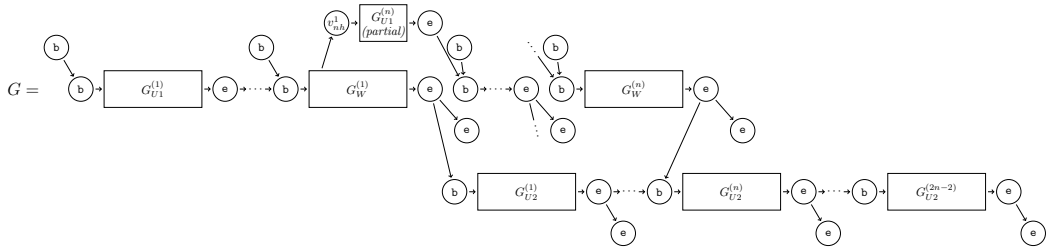

Figure 4 Final deterministic DAG G. In such graph there are $n-1$ instances of $G_{U1}^{(j)}$, $n-1$ partial instances of $G_{U1}^{(j)}$, n instances of $G_W^{(j)}$ and $2n-2$ instances of $G_{U2}^{(j)}$.

The deterministic DAG G has a crucial property which, combined with Lemma 3 and Lemma 4, is key to ensure the correctness of our reduction.

▶ **Lemma 5.** *Pattern P has a match in G if and only if a subpattern $\mathtt{b}P_{x_i}\mathtt{e}$ of P has a match in the underlying subgraph G_W of G_{U1W}.*

Proof. For the ($\Rightarrow$) implication, because of the directed eb-edges, each distinct subpattern $\mathtt{b}P_{x_i}\mathtt{e}$ matches a path from either a distinct portion of G_{U1W} (or from the $G_{U1}^{(j)}$ subgraphs, $1 \leq j \leq n-1$, before it) or G_{U2}. Moreover, each occurrence of P must begin with bb and end with ee. String bb can be matched only in G_{U1W} (or in the $G_{U1}^{(j)}$ subgraphs before it), hence the match must start here. On the other hand, string ee is found either in G_{U1W} or in G_{U2}. Observe that, by construction, once a match for pattern P is started in G_{U1W} (or in the $G_{U1}^{(j)}$ subgraphs before it), the only way to successfully conclude it is either by matching ee within G_{U1W}, or by matching also a portion of G_{U2} and then ee. Because of the structure of the graph, in both cases a subpattern $\mathtt{b}P_{x_i}\mathtt{e}$ of P must match one of the subgraphs $G_W^{(j)}$ that are present in G_{U1W}.

The ($\Leftarrow$) implication is trivial. In fact, if $\mathtt{b}P_{x_i}\mathtt{e}$ has a match in one subgraph $G_W^{(j)}$, then by construction we can match $\mathtt{b}P_{x_1}\mathtt{e}\ldots\mathtt{b}P_{x_{i-1}}\mathtt{e}$ possibly in the $G_{U1}^{(j)}$ subgraphs before G_{U1W}, then possibly in the partial $G_{U1}^{(j)}$ subgraphs of G_{U1W}. We can then match $\mathtt{b}P_{x_{i+1}}\mathtt{e}\ldots\mathtt{b}P_{x_n}\mathtt{e}$ in G_{U2}, and thus have a full match for P in G. ◀

We are now ready to prove our main result.

Proof of Theorem 1. First, we prove that the reduction is correct. Then we analyze its cost and show how a subquadratic-time algorithm for SMLG would contradict the OV hypothesis. Then, we explain how the graph can be modified to become a 3-DDAG using a binary alphabet.

Correctness. We need to ensure that pattern P has a match in G if and only if there exist vectors $x_i \in X$ and $y_j \in Y$ which are orthogonal. This follows from Lemma 5, which guarantees that P has a match in G if and only if a subpattern P_{x_i} has a match in G_W, and the fact that, by Lemma 4, this holds if and only if $x_i \cdot y_j = 0$.

Cost. As observed during the construction in Section 2.1 and Section 2.2, both pattern P and graph G have size $O(nd)$. Indeed, for each one of the n vectors $x_i \in X$ we place in P characters b and e plus d characters that can be either 0 or 1. In graph G, the size of each subgraph is proportional to the dimension d of the vectors and we place $O(n)$ of them.

Using the OV hypothesis. The last step is to show that any $O(|E|^{1-\epsilon}\, m)$-time or $O(|E|\, m^{1-\epsilon})$-time algorithm A for SMLG contradicts the OV hypothesis. Given two sets of vectors X and Y, we can perform our reduction obtaining pattern P and graph G in $O(nd)$ time, by observing that $|E| = O(nd)$ and $m = O(nd)$. No matter whether A has $O(|E|^{1-\epsilon}m)$ or $O(|E|\, m^{1-\epsilon})$ time complexity, we will end up with an algorithm deciding if there exists a pair of orthogonal vectors between X and Y in $O(nd \cdot (nd)^{1-\epsilon}) = O(n^{2-\epsilon}\mathrm{poly}(d))$ time, which contradicts the OV hypothesis.

Maximum sum of indegree and outdegree 3. Observe that every node in G can have at most 2 in-neighbours and 2 out-neighbours. An emblematic case is that of four nodes, say v, w, v', and w', with edges (v,w), (v,w'),(v',w), and (v',w'). To reduce to 1 the outdegree of v and v', and the indegree of w and w', the idea is to add two dummy nodes $\bar{v}$ and $\bar{w}$ connected by an edge $(\bar{v},\bar{w})$, and then replace the four edges above with $(v,\bar{v})$, $(v',\bar{v})$, $(\bar{w},w)$, and $(\bar{w},w')$. The dummy nodes can be labeled e.g. with 0 and then one can do a symmetric modification in the pattern. One needs to apply such transformations between any two consecutive columns of G.

Alphabet size. Our alphabet is of size 4. One can reduce the alphabet size to binary using the encoding $\alpha(\mathtt{0}) = \mathtt{0000}$, $\alpha(\mathtt{1}) = \mathtt{1111}$, $\alpha(\mathtt{b}) = \mathtt{10}$, and $\alpha(\mathtt{e}) = \mathtt{01}$ for both the pattern and the graph. (That is, we replace each σ-node with a path of as many nodes as characters in $\alpha(\sigma)$.) Observe that, after small adjustments that do not weaken our results, there is a bijection from matches before and after applying the encoding. ◀

As discussed in the Introduction, G has both nodes of indegree at most 1 (and outdegree more than 1), and nodes of outdegree at most 1 (and indegree more than 1). In the extended version of this work we will give a linear-time algorithm for directed graphs with nodes of only one such type.

3 Undirected Graphs: Zig-zag Matching

The lower bound given for the SMLG problem can cover the special case of an undirected graph with maximum degree 2. To this end, we need to modify the reduction defining a new alphabet, pattern and graph. The original alphabet $\Sigma = \{\mathtt{b}, \mathtt{e}, \mathtt{0}, \mathtt{1}\}$ is replaced with $\Sigma' = \{\mathtt{b}, \mathtt{e}, \mathtt{A}, \mathtt{B}, \mathtt{s}, \mathtt{t}\}$. Characters `1` and `0` are encoded in the following manner:

$\mathtt{1} = \mathtt{ABA}$ and $\mathtt{0} = \mathtt{ABABABA}$.

When such encoding is applied, character `s` will be used as a separator marking the beginning and the end of the old characters. As an example, the subpattern

$P_{x_i} = \mathtt{1\ 0\ 1}$ will be encoded as $P'_{x_i} = \mathtt{s\ ABA\ s\ ABABABA\ s\ ABA\ s}$.

A new pattern P' is built applying this encoding to each one of the subpatterns P_{x_i}, thus obtaining new subpatterns P'_{x_i}. We then concatenate all the subpatterns P'_{x_i} by placing the new character `t` to separate them, instead of `eb`. Finally, we place characters `bt` at the beginning of the new pattern, and `te` at the end. Here follows an example:

$P = \mathtt{bb\ 100\ e\ b\ 101\ ee}$

$$P' = \mathtt{b\ \ t\ s\ \ \underset{1}{ABA}\ \ s\ \ \underset{0}{ABABABA}\ \ s\ \ \underset{0}{ABABABA}\ \ s\ \ t\ s\ \ \underset{1}{ABA}\ \ s\ \ \underset{0}{ABABABA}\ \ s\ \ \underset{1}{ABA}\ \ s\ \ t\ e}$$

Note that for each subpattern we are introducing a constant number of new characters, hence the size of the entire pattern P' still is $O(nd)$.

An analogous encoding will be applied to the graph. The strategy is to encode G_W in an undirected path by concatenating subpaths representing each $G_W^{(j)}$, one after another.

The positions h in which both a `0`- and a `1`-node are present in $G_W^{(j)}$ are replaced by a path that can be matched both by $\mathtt{0} = \mathtt{ABABABA}$ and $\mathtt{1} = \mathtt{ABA}$. Positions h with only a `0`-node and no `1`-node are encoded instead with a path that can be matched only by $\mathtt{0} = \mathtt{ABABABA}$ (see Figure 5). We use `s`-nodes to separate these paths. We denote by $LG_W^{(j)}$ (*Linear* $G_W^{(j)}$) this linearized version of $G_W^{(j)}$. Moreover, given subgraph $G_W^{(j)}$, two new `t`-nodes will mark the beginning and the ending of its encoding. Figure 6 illustrates this transformation for $G_W^{(j)}$.

In a similar manner, G_U is also encoded as a path. We do not need to encode all its $2n-2$ subgraphs: since the matching path can go through nodes more than once, we only need to encode one of these subgraphs, in the same manner as done for $G_W^{(j)}$. Let LG_U be the linearized version of only one of the "jolly" gadgets that were composing the original G_U.

Then, for each $1 \leq j \leq n$, we build structure $LG^{(j)}$ by placing `t`-nodes, LG_U instances, $LG_W^{(j)}$, a `b`-node on the left and an `e`-node on the right, as in Figure 7. In such structure the `b`-node and the `e`-node delimit the beginning and the end of a viable match for a pattern. The `t`-nodes are separating the LG_U structures from $LG_W^{(j)}$ and, in general, they are marking the beginning and the end of a match for a subpattern P'_{x_i}. The idea behind $LG^{(j)}$ is that a match of P can traverse LG_U from beginning to end, backwards and forwards as many

(a) (b)

Figure 5 New substructures. (a) The old substructure is replaced by an undirected path that can match either `sABAs` (which represents `1`) by going forward only, or `sABABABAs` (which represents `0`), by going forward, backward, and forward again. (b) The an undirected path replacing a `0`-node can match only the string `sABABABAs`.

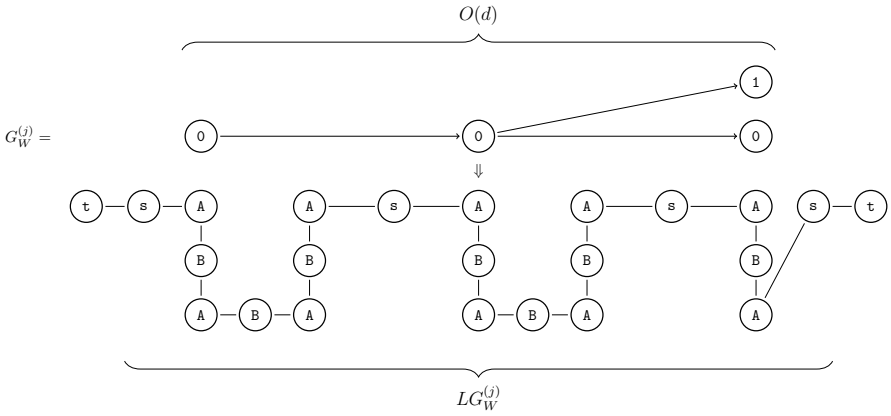

Figure 6 A subgraph $G_W^{(j)}$ is converted into a linear structure $LG_W^{(j)}$ using `s` as separator.

times as needed, before starting a match of some subpattern P'_{x_i} inside $LG_W^{(j)}$. Notice also that this allows only subpatterns on even positions i to match inside $LG_W^{(j)}$. We will address this minor issue at the end (see page 12).

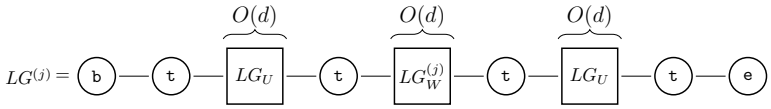

Figure 7 The $LG_W^{(j)}$ structure surrounded by two instances of LG_U. The `t`-nodes establish the beginning and the end of a match for a subpattern $\texttt{t}P'_{x_i}\texttt{t}$ while the `b`- and `e`-nodes are the starting and ending point for a match of the whole pattern P'.

In order to construct the final graph LG we concatenate all $LG^{(1)}$, $LG^{(2)}$, ..., $LG^{(n)}$ into a single undirected path. Figure 8 gives a picture of the end result.

No issues arise regarding the size of the graph, since we are replacing every `0`-node, or every pair of a `0`-node and a `1`-node, with a constant number of new nodes. By construction, the two gadgets LG_U and LG_W both have size $O(d)$, since for each one of the d entries of a vector we place one of the two possible encodings. In LG there are n instances of $LG_W^{(j)}$, each one surrounded by two LG_U instances. Hence the total size of the graph remains $O(nd)$.

In order to prove the correctness of the reduction, we will show some properties on LG by introducing the following lemmas, whose formal proofs will be available in the extended version of this work. We use $t_l LG_W^{(j)} t_r$ to refer to $LG_W^{(j)}$ extended with the `t`-nodes on its left and on its right. When referring to the k-th `s`-character in P'_{x_i} we mean the k-th `s`-character found scanning P'_{x_i} from left to right; in the same manner we refer to the k-th `s`-node in $LG_W^{(j)}$.

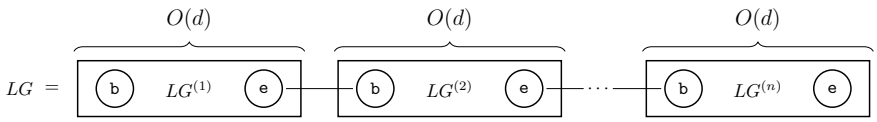

Figure 8 The final graph LG.

▶ **Lemma 6.** *If subpattern* $\mathtt{t}P'_{x_i}\mathtt{t}$ *has a match in* $t_l LG_W^{(j)} t_r$ *starting at* t_l *and ending at* t_r*, then the* k*-th* `s`*-character in* P'_{x_i} *matches the* k*-th* `s`*-node in* $LG_W^{(j)}$*, for all* $1 \leq k \leq d+1$*.*

▶ **Lemma 7.** *Subpattern* $\mathtt{t}P'_{x_i}\mathtt{t}$ *has a match in* $t_l LG_W^{(j)} t_r$ *starting at* t_l *and ending at* t_r *if and only if there exist* $y_j \in Y$ *such that* $x_i \cdot y_j = 0$*.*

The main difference with the original proof resides in assuming that a match for P'_{x_i} starts at t_l and ends at t_r. This feature is crucial for the correctness of the reduction and can be safely exploited since, as shown in the following, the `b`- and `e`-nodes guarantee that in case of a match for P' we will cross the $LG_W^{(j)}$ gadget from left to right at least once.

▶ **Lemma 8.** *Pattern* P' *has a match in* LG *if and only if there exist* i *and* j *such that* i *is even and subpattern* $\mathtt{t}P'_{x_i}\mathtt{t}$ *has a match in* $t_l LG_W^{(j)} t_r$ *starting at* t_l *and ending at* t_r*.*

Proof. For the ($\Rightarrow$) implication, first observe that the `b`- and `e`-nodes in LG are forcing a direction to follow. Let $LG_{Ul}^{(j)}$ and $LG_{Ur}^{(j)}$ be the LG_U gadgets to the left and to the right of $LG_W^{(j)}$, respectively. Since pattern P' starts with a `b` and ends with an `e`, a match can only start at the `b`-node on the left of $LG_{Ul}^{(j)}$ and end at the `e`-node on the right of $LG_{Ur}^{(j)}$, for some j. Hence $LG_W^{(j)}$ needs to be crossed by a match from left to right at least once. Thus, there must exist a subpattern $\mathtt{t}P'_{x_i}\mathtt{t}$ that has a match starting at t_l and ending at t_r. For such a pattern Lemma 7 applies. Moreover, because of our construction, only a subpattern on even position can achieve such a match.

The ($\Leftarrow$) implication is immediate since given a subpattern $\mathtt{t}P'_{x_i}\mathtt{t}$ which has a match in $t_l LG_U^{(j)} t_r$ one can match $\mathtt{bt}P'_{x_1}\mathtt{t}\ldots\mathtt{t}P'_{x_{i-1}}\mathtt{t}$ in $LG_{Ul}^{(j)}$ and $\mathtt{t}P'_{x_{i+1}}\mathtt{t}\ldots\mathtt{t}P'_{x_n}\mathtt{te}$ in $LG_{Ur}^{(j)}$ and have a full match for P' in LG. ◀

Since Lemma 8 gives us a property which holds only if a subpattern is in even position, we need to tweak pattern P' to make the reduction work. Indeed, we define two patterns. The first pattern $P'^{(1)}$ is P' itself; the second pattern $P'^{(2)}$ is obtained by swapping the subpatterns P'_{x_i} on odd position with the next subpatterns $P'_{x_{i+1}}$ on even position, for every $i = 1, 3, \ldots$. For example, if n is even, we will have:

$$P'^{(1)} = \mathtt{bt}\ P'_{x_1}\ \mathtt{t}\ P'_{x_2}\ \mathtt{t}\ P'_{x_3}\ \mathtt{t}\ P'_{x_4}\ \mathtt{t}\ \ldots\ \mathtt{t}\ P'_{x_{n-1}}\ \mathtt{t}\ P'_{x_n}\ \mathtt{te} = P'$$
$$P'^{(2)} = \mathtt{bt}\ P'_{x_2}\ \mathtt{t}\ P'_{x_1}\ \mathtt{t}\ P'_{x_4}\ \mathtt{t}\ P'_{x_3}\ \mathtt{t}\ \ldots\ \mathtt{t}\ P'_{x_n}\ \mathtt{t}\ P'_{x_{n-1}}\ \mathtt{te}$$

While $P'^{(1)}$ checks the even positions of P', $P'^{(2)}$ checks the odd ones. If n is even then the last subpattern would not have the chance to be matched against any $G_W^{(j)}$. In such case we can simply add a dummy subpattern $\bar{P} = \mathtt{s\ ABA\ s\ ABA\ s}\ldots\mathtt{s\ ABA\ s}$ (with d repetitions of `ABA`) at the end of P as it were its last subpattern, so that the number of subpatterns becomes odd. Indeed, observe that $\bar{P}$ corresponds to vector $\bar{x} = (11\ldots1)$, which has null product only with vector $\bar{y} = (00\ldots0)$. Hence if $\bar{y} \notin Y$ then $\bar{P}$ does not have a match in any $LG^{(j)}$, while if $\bar{y} \in Y$ every subpattern P'_{x_i} has a match in the $LG^{(j)}$ built on top of $\bar{y}$. This means that $\bar{P}$ does not disrupt our reduction.

Now we are ready to present the end result.

▶ **Lemma 9.** *Either $P'^{(1)}$ or $P'^{(2)}$ has a match in LG if and only if there exist vectors $x_i \in X$ and $y_j \in Y$ which are orthogonal.*

Proof. For ($\Rightarrow$) we assume that either $P'^{(1)}$ or $P'^{(2)}$ have a match in LG. By Lemma 8 this means that there exists a subpattern $P'^{(q)}_{x_i}$, $q \in \{1, 2\}$ which has a match in $LG^{(j)}_W$, for some j. Lemma 7 then ensures that $x_i \cdot y_j = 0$, thus x_i and y_j are orthogonal. For the other implication ($\Leftarrow$) we assume that there exists two orthogonal vectors $x_i \in X$ and $y_j \in Y$. Thanks to Lemma 7 we find a subpattern P'_{x_i} matching $LG^{(j)}_W$. By construction, P'_{x_i} has to be in even position either in $P'^{(1)}$ or in $P'^{(2)}$. By Lemma 8 this means that either $P'^{(1)}$ or $P'^{(2)}$ has a match in LG. ◀

Theorem 2 follows directly from the correctness of these constructions, except for the alphabet size reduction to binary, which will be covered in the extended version of this work.

Abstract

The complexity class CLS was proposed by Daskalakis and Papadimitriou in 2011 to understand the complexity of important NP search problems that admit both path following and potential optimizing algorithms. Here we identify a subclass of CLS – called UniqueEOPL – that applies a more specific combinatorial principle that guarantees unique solutions. We show that UniqueEOPL contains several important problems such as the P-matrix Linear Complementarity Problem, finding Fixed Point of Contraction Maps, and solving Unique Sink Orientations (USOs). UniqueEOPL seems to a proper subclass of CLS and looks more likely to be the right class for the problems of interest. We identify a problem – closely related to solving contraction maps and USOs – that is complete for UniqueEOPL. Our results also give the fastest randomised algorithm for P-matrix LCP.

2012 ACM Subject Classification Theory of computation → Problems, reductions and completeness

Keywords and phrases P-matrix linear complementarity problem, unique sink orientation, contraction map, TFNP, total search problems, continuous local search

1 Introduction

The complexity class TFNP contains search problems that are guaranteed to have a solution, and whose solutions can be verified in polynomial time [44]. While it is a semantically defined complexity class and thus unlikely to contain complete problems, a number of syntactically defined subclasses of TFNP have proven very successful at capturing the complexity of total search problems. In this paper, we focus on two in particular, PPAD and PLS. The class PPAD was introduced in [49] to capture the difficulty of problems that are guaranteed total by a parity argument. It has attracted intense attention in the past decade, culminating in a series of papers showing that the problem of computing a Nash-equilibrium in two-player games is PPAD-complete [10, 13], and more recently a conditional lower bound that rules out a PTAS for the problem [52]. No polynomial-time algorithms for PPAD-complete problems

are known, and recent work suggests that no such algorithms are likely to exist [4, 25]. PLS is the class of problems that can be solved by local search algorithms (in perhaps exponentially-many steps). It has also attracted much interest since it was introduced in [38], and looks similarly unlikely to have polynomial-time algorithms. Examples of PLS-complete problems include computing: a pure Nash equilibrium in a congestion game [19], a locally optimal max cut [53], or a stable outcome in a hedonic game [24].

If a problem lies in PPAD and PLS then it is unlikely to be complete for either class, since this would imply an extremely surprising containment of one class in the other. Daskalakis and Papadimitriou [14] observed that several prominent total function problems for which no polynomial-time algorithms are known lie in PPAD ∩ PLS. Motivated by this they introduced CLS, a syntactically defined subclass of PPAD ∩ PLS, that captures optimization problems over a continuous domain in which a continuous potential function is being minimized, with access to a polynomial-time continuous improvement function. They showed that many well-studied problems are in CLS, including the problem of solving a simple stochastic game, the more general problems of solving a P-matrix Linear Complementarity Problem, finding an approximate fixpoint to a contraction map, finding an approximate stationary point of a multivariate polynomial, and finding a mixed Nash equilibrium of a congestion game. In this paper we study an interesting subset of CLS consisting of problems with *unique* solutions.

Contraction. In this problem we are given a function $f : \mathbb{R}^d \to \mathbb{R}^d$ that is purported to be c-contracting, meaning that for all points $x, y \in [0, 1]^n$ we have $d(f(x), f(y)) \leq c \cdot d(x, y)$, where c is a constant satisfying $0 < c < 1$, and d is a distance metric. Banach's fixpoint theorem states that if f is contracting, then it has a unique *fixpoint* [3], meaning that there is a unique point $x \in \mathbb{R}^d$ such that $f(x) = x$.

P-LCP. The *P-matrix linear complementarity problem* (P-LCP) is a variant of the linear complementarity problem in which the input matrix is a P-matrix [12]. An interesting property of this problem is that, if the input matrix actually is a P-matrix, then the problem is guaranteed to have a unique solution [12]. Designing a polynomial-time algorithm for P-LCP has been open for decades, at least since the 1978 paper of Murty [47] that provided exponential-time examples for *Lemke's algorithm* [42] for P-LCPs.

USO. A *unique sink orientation* (USO) is an orientation of the edges of an n-dimensional hypercube such that every face of the cube has a unique sink. Since the entire cube is a face of itself, this means that there is a unique vertex of the cube that is a sink, meaning that all edges are oriented inwards. The USO problem is to find this *unique* sink.

All of these problems are most naturally stated as *promise* problems, since we have no way of efficiently verifying whether a function is contracting, whether a matrix is a P-matrix, or whether an orientation is a USO. Hence, it makes sense, for example, to study the contraction problem where it is promised that the function f is contracting, and likewise for the other two. However, each of these problems can be turned into non-promise problems that lie in TFNP. In the case of Contraction, if the function f is not contracting, then there exists a short certificate of this fact. Specifically, any pair of points $x, y \in \mathbb{R}^d$ such that $d(f(x), f(y)) > c \cdot d(x, y)$ give an explicit proof that the function f is not contracting. We call these *violations*, since they witness a violation of the promise inherent in the problem.

So, Contraction can be formulated as the non-promise problem of either finding a solution or finding a violation. This problem is in TFNP because in the case where there is not a unique solution, there must exist a violation of the promise. The P-LCP and USO problems also have violations that can be witnessed by short certificates, and so they can be turned into non-promise problems in the same way, and these problems also lie in TFNP. For Contraction and P-LCP we actually know that both are in CLS [14]. Prior to this work USO was not known to lie in any non-trivial subclass of TFNP, and placing USO into a non-trivial subclass of TFNP was identified as an interesting open problem by Kalai [39, Problem 6].

We remark that not every problem in CLS has the uniqueness properties that we identify above. For example, the KKT problem [14] lies in CLS, but has no apparent notion of having a unique solution. The problems that we study share the special property that there is a natural promise version of the problem, and that promise problem has a unique solution.

Our contributions. We define the complexity classes PromiseUEOPL and UniqueEOPL to capture problems in CLS that have unique solutions. We argue that UniqueEOPL is likely to be a strict subset of CLS. We introduce the notion of *promise-preserving reductions*, which allow us to simultaneously obtain results for the promise and non-promise versions of problems. We show that all of our motivating problems – USO, P-LCP, and finding a fixpoint of a Piecewise-Linear Contraction under an ℓ_p-norm – are contained in UniqueEOPL (PromiseUEOPL for the promise versions) via promise-preserving reductions. Thus, we resolve the open problem of Kalai mentioned above, by showing that USO is in UniqueEOPL and thus also CLS, PPAD and PLS. Our results also imply that parity, mean-payoff, discounted, and simple-stochastic games lie in UniqueEOPL. We also provide a complete problem for UniqueEOPL, called One-Permutation Discrete Contraction (OPDC). It is motivated by a discretized version of contraction, but it is also closely related to USO, and we consider its hardness to be a substantial step towards showing hardness for contraction and USO.

The new techniques used in our reductions also lead to new algorithmic results. We obtain direct polynomial-time algorithms for finding fixpoints of contraction maps in fixed dimension for any ℓ_p norm, where previously such algorithms relied on a reduction to the Tarski fixpoint problem [51]. Our reduction for P-LCP allows a technique of Aldous [2] to be applied, which in turn gives the fastest-known randomized algorithm for P-LCP.

A main message of our paper is that several important problems lie in UniqueEOPL *and* that UniqueEOPL is likely to be a proper subset of CLS.

Related work. Hubáček and Yogev [36] proved lower bounds for CLS. They introduced a problem known as EndOfMeteredLine which they showed was in CLS, and for which they proved a query complexity lower bound of $\Omega(2^{n/2}/\sqrt{n})$ and hardness under the assumption that there were one-way permutations and indistinguishability obfuscators for problems in $\mathsf{P}_{/\mathsf{poly}}$. Recently, two variants of ContractionMap have been shown to be CLS-complete. Whereas in the original definition of ContractionMap it is assumed that an ℓ_p or ℓ_∞ norm is fixed, and the contraction property is measured w.r.t. the induced metric, in these two complete variants, a metric [15] and meta-metric [20] are given as input to the problem.

Papadimitriou showed that P-LCP, the problem of solving the LCP or returning a violation of the P-matrix property, is in PPAD [49] using Lemke's algorithm. The relationship between Lemke's algorithm and PPAD has been studied by Adler and Verma [1]. Later, Daskalakis and Papadimitrou showed that P-LCP is in CLS [14], using the potential reduction method in [41]. Many algorithms for P-LCP have been studied, e.g., [47, 46, 40]. However, no polynomial-time algorithms are known for P-LCP. The best-known algorithms for P-LCP are based on a reduction to Unique Sink Orientations (USOs) of cubes [59]. For an P-matrix LCP of size n, the USO algorithms of [60] apply, and give a deterministic algorithm that runs in time $O(1.61^n)$ and a randomized algorithm with expected running time $O(1.43^n)$. The application of Aldous' algorithm [2] to the UniqueEOPL instance that we produce from a P-matrix LCP takes expected time $2^{n/2} \cdot \mathrm{poly}(n) = O(1.4143^n)$ in the worst case.

We study USOs of cubes, a problem that was first studied by Stickney and Watson [59] in the context of P-matrix LCPs. Motivated by Linear Programming, *acylic* USOs (AUSOs) have also been studied, both for cubes and general polytopes [33, 28]. Recently Gärtner

and Thomas studied the computational complexity of recognizing USOs and AUSOs [29]. A series of papers provide upper and lower bounds for approaches for solving (A)USOs, including [60, 31, 22, 43, 55, 23, 61, 26, 54]. To the best of our knowledge, we are first to study the general problem of solving a USO from a complexity-theoretic point of view.

The problem of computing a fixpoint of a continuous map $f : \mathcal{D} \to \mathcal{D}$ with Lipschitz constant c has been extensively studied, in both continuous and discrete variants [9, 8, 16]. For arbitrary maps with $c > 1$, exponential bounds on the query complexity are known [32, 7]. In [6, 35, 58], algorithms for computing fixpoints of weakly ($c = 1$) and strictly ($c < 1$) contracting maps are studied.

A number of algorithms are known for contractions w.r.t. the ℓ_2 norm [48, 34, 57]. There is an exponential lower bound for absolute approximation with $c = 1$ [57]. For relative approximation ($||x - f(x)|| \leq \epsilon$) in dimension d, an $O(d \cdot \log 1/\epsilon)$ time algorithm is known [34]. For absolute approximation ($||x - x^*|| \leq \epsilon$ where x^* is an exact fixpoint) with $c < 1$, an ellipsoid-based algorithm with time complexity $O(d \cdot [\log(1/\epsilon) + \log(1/(1-c))])$ is known [34]. For the ℓ_∞ norm, [56] gave an algorithm to find an ϵ-relative approximation in time $O(\log(1/\epsilon)^d)$ which is polynomial for constant d. A polynomial time algorithm for finding an approximate fixpoint of a contraction map in constant dimension can be obtained through a reduction to the Tarski fixpoint problem [51].

2 Unique End of Potential Line

We define two new complexity classes called EOPL and UniqueEOPL. EOPL combines EndOfLine and SinkOfDag, the canonical complete problems for PPAD and PLS [49].

▶ **Definition 1** (EndOfPotentialLine). *Given Boolean circuits $S, P : \{0,1\}^n \to \{0,1\}^n$ such that $P(0^n) = 0^n \neq S(0^n)$ and a Boolean circuit $V : \{0,1\}^n \to \{0,1,\ldots,2^m - 1\}$ such that $V(0^n) = 0$ find one of the following:*
(R1) *A point $x \in \{0,1\}^n$ such that $S(P(x)) \neq x \neq 0^n$ or $P(S(x)) \neq x$.*
(R2) *A point $x \in \{0,1\}^n$ such that $x \neq S(x)$, $P(S(x)) = x$, and $V(S(x)) - V(x) \leq 0$.*
This problem defines an exponentially large graph where each vertex has in-degree and out-degree at most one (as in EndOfLine) that is also a DAG (as in SinkOfDag). An edge exists from x to y if and only if $S(x) = y$, $P(y) = x$, and $V(x) < V(y)$. Only some bit-strings encode vertices. Specifically, if $S(x) = x$ for some bit-string x, then x does *not* encode a vertex. The problem consists of a single instance that is simultaneously an instance of EndOfLine and an instance of SinkOfDag. To solve the problem, it suffices to solve *either* of these problems. Solutions of type 1 are ends of lines, and solutions of type 2 are points where the potential does not increase along an edge.

We define the complexity class EOPL to consist of all problems that can be reduced in polynomial time to EndOfPotentialLine. We show the following containment.

▶ **Theorem 2.** EOPL $\subseteq$ CLS.

To prove this, we reduce EndOfPotentialLine to the EndOfMeteredLine, which was defined and shown to be in CLS by Hubáček and Yogev [36]. The difference between the two problems is that EndOfMeteredLine requires that the potential increases by *exactly* one along each edge. Our reduction inserts new vertices into the instance to satisfy this property.

2.1 Promise problems with unique solutions

Each of the problems that we study have a *promise*, and if the promise is satisfied the problem has a *unique* solution. For example, in the contraction problem, we are given a function as a circuit but cannot efficiently check whether the function is actually contracting.

If the function is contracting, then Banach's fixpoint theorem states that it has a unique fixpoint [3]. If it is not contracting, there exist *violations* that can be witnessed by short certificates. We can use violations to formulate the problem as a non-promise problem that lies in TFNP: we ask for either a fixpoint or a violation of contraction.

When we place this type of problem in EOPL, we obtain an instance with extra properties. Specifically, if the original problem has no violations, i.e., the promise is satisfied, then the EndOfPotentialLine instance will contain a *single* line that starts at 0^n, and ends at the unique solution. So, if we ever find two distinct lines, we immediately know that the instance fails to satisfy the promise. We define the following problem to capture these properties.

▶ **Definition 3** (UniqueEOPL). *Given Boolean circuits $S, P : \{0,1\}^n \to \{0,1\}^n$ such that $P(0^n) = 0^n \neq S(0^n)$ and a Boolean circuit $V : \{0,1\}^n \to \{0,1,\ldots,2^m-1\}$ such that $V(0^n) = 0$ find one of the following:*

(U1) *A point $x \in \{0,1\}^n$ such that $P(S(x)) \neq x$.*

(UV1) *A point $x \in \{0,1\}^n$ such that $x \neq S(x)$, $P(S(x)) = x$, and $V(S(x)) - V(x) \leq 0$.*

(UV2) *A point $x \in \{0,1\}^n$ such that $S(P(x)) \neq x \neq 0^n$.*

(UV3) *Two points $x, y \in \{0,1\}^n$, such that $x \neq y$, $x \neq S(x)$, $y \neq S(y)$, and either $V(x) = V(y)$ or $V(x) < V(y) < V(S(x))$.*

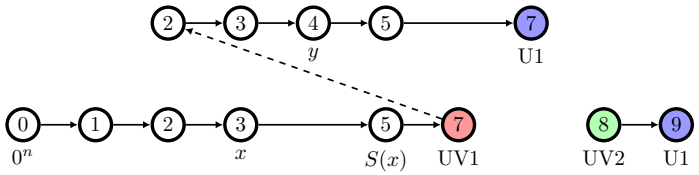

Figure 1 UniqueEOPL instance with 3 lines. The *main line* starts at 0^n and ends with a UV1 solution. There is a final line of length one to the bottom right, whose start vertex is a UV2 solution. The ranges of potential values for the main line and top line intersect, so they contribute many UV3 solutions. We highlight one on the diagram with x, $S(x)$, and y, such that $V(x) < V(y) < V(S(x))$.

We split solutions into two types: proper solutions and violations. Solutions of type 1 encode the end of a line, which are the proper solutions. 1 violations are vertices at which the potential fails to increase. 2 violations are the start of any line other than 0^n. 3 violations are a different witness that there are more than one line, namely a pair of vertices x and y, with either $V(x) = V(y)$, or such that $V(y)$ lies between $V(x)$ and $V(S(x))$, so x and y cannot lie on the same line. See Figure 1 for an illustration.

We remark that 1 and 2 violations already capture the property that "there is a unique line", since if we exclude them, then a second line cannot exist. However, with only these two violations, we may find two vertices on two different lines, but both may be exponentially many steps away from the start of their respective lines. 3 violations make any pair of vertices that are provably on two different lines a violation. All of the problems in UniqueEOPL have the property that if we ever find a 3 violation, the problem can be solved immediately.

We define UniqueEOPL to be the class of problems that can be reduced in polynomial time to UniqueEOPL[1]. For each of our problems, it is also interesting to consider the promise variant, in which it is guaranteed via a promise that no violations exist. We define

[1] We remark that Hubáček and Yogev [36] mention that their lower bound results for CLS may also apply to such problems, but they did not investigate a corresponding complexity class.

PromiseUniqueEOPL to be the promise version of UniqueEOPL in which it is promised that 0^n is the only start of a line, and PromiseUEOPL to be the class of promise problems that can be reduced in polynomial time to PromiseUniqueEOPL.

The problem UniqueEOPL has the interesting property that, if it is promised that there are no violation solutions, then there must be a unique solution. All of the problems that we study in this paper share this property, and indeed when we reduce them to UniqueEOPL, the resulting instance will have a unique line whenever the original problem has no violation solutions. We formalise this by defining the concept of a *promise-preserving* reduction. This is a reduction between two problems A and B, both of which have proper solutions and violation solutions. The reduction is promise-preserving if, when it is promised that A has no violations, then the resulting instance of B also has no violations. Hence, if we reduce a problem to UniqueEOPL via a chain of promise-preserving reductions, and we know that there are no violations in the original problem, then there is a unique line ending at the unique proper solution in the instance. So, if we show that a problem is in UniqueEOPL (or UniqueEOPL-complete) via a chain of promise-preserving reductions, then we automatically get that the promise version of that problem, where it is promised that there are no violations, lies in PromiseUEOPL (or PromiseUEOPL-complete).

3 One-Permutation Discrete Contraction (OPDC)

OPDC plays a crucial role in our results. We show that it lies in UniqueEOPL, and the we reduce both PL-Contraction and Unique-Sink-Orientation to it, thereby showing that those problems also lie in UniqueEOPL. We also show that UniqueEOPL can be reduced to OPDC, making it the first example of a non-trivial UniqueEOPL-complete problem.

Direction functions. OPDC can be seen as a discrete variant of the continuous contraction problem. A contraction map is a function $f : [0,1]^n \to [0,1]^d$ that is contracting under a metric d, i.e., $d(f(x), f(y)) \leq c \cdot f(x,y)$ for all $x, y \in [0,1]^d$ and some constant c satisfying $0 < c < 1$. We discretize this by overlaying a grid of points on the $[0,1]^d$ cube. Let $[k]$ denote the set $\{0, 1, \ldots, k\}$. Given a tuple of grid widths $(k_1, k_2, \ldots, k_d)$, we define the set $P(k_1, k_2, \ldots, k_d)$ as $[k_1] \times [k_2] \times \cdots \times [k_d]$. We sometimes refer to $P(k_1, k_2, \ldots, k_d)$ simply as P. Note that each point $p \in P$ is a tuple $(p_1, p_2, \ldots, p_d)$, where p_i is an integer between 0 and k_i, and this point maps onto the point $(p_1/k_1, p_2/k_2, \ldots, p_d/k_d) \in [0,1]^d$.

Instead of a single function f, in the discretized problem we use a family of *direction functions* over the grid P. For each dimension $i \leq d$, we have function $D_i : P \to \{\mathsf{up}, \mathsf{down}, \mathsf{zero}\}$. Intuitively, the natural reduction from a contraction map f to a family of direction functions would, for each point $p \in P$ and each dimension $i \leq d$ set: $D_i(p) = \mathsf{up}$ whenever $f(p)_i > p_i$, $D_i(p) = \mathsf{down}$ whenever $f(p)_i < p_i$, and $D_i(p) = \mathsf{zero}$ whenever $f(p)_i = p_i$. In other words, the function D_i simply outputs whether $f(p)$ moves up, down, or not at all in dimension i. So a point $p \in P$ with $D_i(p) = \mathsf{zero}$ for all i would correspond to the fixpoint of f.

A 2d example. To illustrate this definition, consider the 2d instance given in the two leftmost parts of Figure 2, which we use as a running example. These are two direction functions: the left one shows a direction function for the up-down dimension, which we will call dimension 1 and illustrate in blue. The right one shows the left-right dimension, which we will call dimension 2 and illustrate in red. Each square represents a point in the discretized space, and the value of the direction function is shown inside the box. Note that there is exactly one point p where $D_1(p) = D_2(p) = \mathsf{zero}$, which is the fixpoint that we seek.

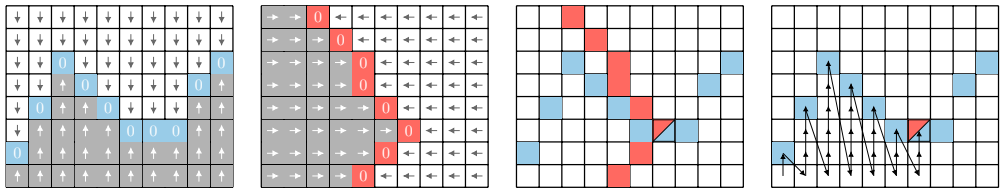

Figure 2 This figure should be viewed in color. From left to right: A direction function for the up/down dimension; a direction function for the left/right dimension; the red and blue surfaces; the path that we follow.

Slices. We will frequently refer to subsets of P in which some dimensions have been fixed. A *slice* is represented as a tuple $(s_1, s_2, \ldots, s_d)$, where each s_i is either: a number in $[k_i]$, which indicates that dimension i should be fixed to s_i; or the special symbol $*$, which indicates that dimension i is free to vary. We define Slice_d to be the set of all possible slices in dimension d. Given a slice $s \in \mathsf{Slice}_d$, we define $P_s \subseteq P$ to be the set of points in that slice, i.e., P_s contains every point $p \in P$ such that $p_i = s_i$ whenever $s_i \neq *$. We say that a slice $s' \in \mathsf{Slice}_d$ is a sub-slice of a slice $s \in \mathsf{Slice}_d$ if $s_j \neq * \implies s'_j = s_j$ for all $j \in [d]$. An *i-slice* is a slice s for which $s_j = *$ for all $j \leq i$, and $s_j \neq *$ for all $j > i$. In other words, all dimensions up to and including dimension i are allowed to vary, while all other dimensions are fixed.

In our 2d example, there are three types of i-slices. There is one 2-slice: the slice $(*, *)$ that contains every point. For each x, there is a 1-slice $(*, x)$, which restricts the left/right dimension to the value x. For each pair x, y there is a 0-slice (y, x), which contains only the exact point corresponding to x and y.

The OPDC problem. Let P be a grid of points in dimension d and $\mathcal{D} = (D_i)_{i=1,\ldots,d}$ a family of direction functions over P. We say that a point $p \in P_s$ in some slice s is a *fixpoint* of s if $D_i(p) = \mathsf{zero}$ for all dimensions i where $s_i = *$. The promise version of OPDC promises that for every i-slice s, the following conditions hold.

1. There is a unique fixpoint of s.
2. Let $s' \in \mathsf{Slice}_d$ be a sub-slice of s where some coordinate i for which $s_i = *$ has been fixed. If q is the unique fixpoint of s, and p is the unique fixpoint of s', then $p_i < q_i$ implies $D_i(p) = \mathsf{up}$, and $p_i > q_i$ implies $D_i(p) = \mathsf{down}$.

Since the slice $(*, *, \ldots, *)$ is an i-slice, the first condition implies that all i-slices including the full problem have a unique fixpoint. Intuitively, the second condition just ensures that the D_i behave as direction functions. It says that if we have found the unique fixpoint p of the $(i+1)$-slice s', and if it is not the unique fixpoint of the i-slice s, then $D_i(p)$ tells us which way to walk to find the fixpoint of s. This is a crucial property used in our reduction from OPDC to UniqueEOPL, and in our algorithms for contraction maps.

In our 2d example, the first condition requires that every slice $(*, x)$ has a unique fixpoint, i.e., in every column there is a unique blue zero. The second condition says that, if we are at some blue zero, then the red direction function at that point tells us the direction of the overall fixpoint. Our example satisfies both conditions. We next define a total variant of OPDC that uses violations to cover the cases where $\mathcal{D}$ fails to satisfy these two conditions.

▶ **Definition 4** (OPDC). *Given a tuple $(k_1, k_2, \ldots, k_d)$ and circuits $(D_i(p))_{i=1,\ldots,d}$, where each circuit $D_i : P(k_1, k_2, \ldots, k_d) \to \{\mathsf{up}, \mathsf{down}, \mathsf{zero}\}$, find one of the following*

(O1) *A point $p \in P$ such that $D_i(p) = \mathsf{zero}$ for all i.*

(OV1) *An i-slice s and points $p, q \in P_s$ with $p \neq q$ s.t. $D_j(p) = D_j(q) = \mathsf{zero}$ for all $j \leq i$.*

(OV2) *An i-slice s and points $p, q \in P_s$ s.t. $D_j(p) = D_j(q) = \mathsf{zero}$ for all $j < i$, $p_i = q_i + 1$, and $D_i(p) = \mathsf{down}$ and $D_i(q) = \mathsf{up}$.*

(OV3) *An i-slice s and a point $p \in P_s$ s.t. $D_j(p) = D_j(q) = \mathsf{zero}$ for all $j < i$, and either $p_i = 0$ and $D_i(p) = \mathsf{down}$, or $p_i = k_i$ and $D_i(p) = \mathsf{up}$.*

Solution type 1 encodes a fixpoint, which is the proper solution of OPDC. Solution type 1 witnesses a violation of the fact that each i-slice should have a unique fixpoint, by giving two different points p and q that are both fixpoints of the same i-slice. Solutions of type 2 witness violations of the first and second properties. In these solutions we have two points p and q that are both fixpoints of their respective $(i-1)$-slices and are directly adjacent in an i-slice s. If there is a fixpoint r of the slice s, then this witnesses a violation of the fact that $D_i(p)$ and $D_i(q)$ should both point towards r, since clearly one of them does not. On the other hand, if slice s has no fixpoint, then p and q also witness this fact, since the fixpoint should be in-between p and q, which is not possible. Solutions of type 3 consist of a point p that is a fixpoint of its $(i-1)$-slice but $D_i(p)$ points outside the boundary of the grid. These are violations because $D_i(p)$ should point towards the fixpoint of the i-slice containing p, but that fixpoint cannot be outside the grid.

It is perhaps not immediately obvious that OPDC is a total problem. Our promise-preserving reduction from OPDC to UniqueEOPL proves totality, and shows that if the OPDC instance has no violations then it has a unique solution. The prefix *One-Permutation* was chosen to emphasize that our solution conditions only consider i-slices. In the continuous contraction map problem with an ℓ_p metric, *every* slice has a unique fixpoint, and our reduction from contraction maps to OPDC works for any permutation of the dimensions.

3.1 One-Permutation Discrete Contraction is UniqueEOPL-complete

To show that OPDC lies in UniqueEOPL under promise-preserving reductions, we make use of an intermediate problem that we call UniqueForwardEOPL, which is a version of UniqueEOPL in which we only have a successor circuit S, meaning that no predecessor circuit P is given. Without this circuit, there is no way to tell if a vertex is the start of a line, so the only solutions to this problem are the end of a line, a vertex at which the potential fails to increase, or the analogue of 3. Although we no longer have a predecessor circuit, it is still the case that if the problem is promised to have no violations, then it must contain a single line ending at the unique proper solution. We reduce OPDC to UniqueForwardEOPL, and then reduce UniqueForwardEOPL to UniqueEOPL.

An illustration of the reduction. We illustrate using the 2d example shown in Figure 2. The reduction uses the notion of a *surface*. The surface of a direction function D_i is exactly the set of points $p \in P$ such that $D_i(p) = \mathsf{zero}$. In the third part of Figure 2, we have overlaid the surfaces of the two direction functions from Figure 2. The fixpoint p that we seek has $D_i(p) = \mathsf{zero}$ for all dimensions i, and so it lies at the intersection of these surfaces.

To reach the overall fixpoint, we walk along a path starting from the bottom-left corner, which is shown on the rightmost part of Figure 2. The path begins by walking upwards until it finds the blue surface. Once it has found the blue surface, it then there are two possibilities: either we have found the overall fixpoint, in which case the line ends, or we have not found the overall fixpoint, and the red direction function tells us that the direction of the overall fixpoint is to the right. If we have not found the overall fixpoint, then we move one step to the right, go back to the bottom of the diagram, and start walking upwards again. We keep repeating this until we find the overall fixpoint.

How do we define a potential? Observe that the dimension-two coordinates of the points on the line are weakly monotone, i.e., the line never moves to the left. Furthermore, for any dimension-two slice (any slice in which the left/right coordinate is fixed), the dimension-one coordinate is increasing. So, if $p = (p_1, p_2)$ denotes any point on the line, if k denotes the maximum coordinate in either dimension, then the function $V(p_1, p_2) = k \cdot p_2 + p_1$ is a function that monotonically increases along the line, which we can use as a potential function.

Uniqueness. For a promise-preserving reduction, the line must be unique whenever the OPDC instance has no violations. To do this we must be careful that only points that are to the left of the fixpoint are actually on the line, and that no "false" line exists to the right of the fixpoint. Here we rely on the following fact: if the line visits a point with coordinate x in dimension 2, then it must have visited the point p on the blue surface in the slice defined by $x - 1$. Moreover, for that point p we must have $D_2(p) = \mathsf{up}$, which means that it is to the left of the overall fixpoint. Using this fact, each vertex on our line will be a pair (p, q), where p is the current point that we are visiting, and q is either the symbol $-$, indicating that we are still in the first column of points, and we have never visited a point on the blue surface, or a point q that is on the blue surface that satisfies $q_2 = p_2 - 1$ and $D_2(q) = \mathsf{up}$. Hence q is always the last point that we visited on the blue surface, which provides a witness that we have not yet walked past the overall fixpoint. When we finish walking up a column, and find the point on the blue surface, we overwrite q with the new point. This step is not easily reversible, since to determine the predecessor of a vertex we would need to recover the value that was overwritten. So we create a UniqueForwardEOPL instance, and our onwards reduction to UniqueEOPL will produce a predecessor circuit.

Violations. Our 2d example does not contain any violations, but our reduction can still handle all possible violations in the OPDC instance. At a high level, there are two possible ways in which the reduction can go wrong if there are violations.

1. It is possible, that as we walk upwards in some column, we do not find a fixpoint, and our line will get stuck. In our 2d example, this case corresponds to a column of points in which there is no point on the blue surface. However, if there is no point on the blue surface, then we will either: find two adjacent points p and q in that column with $D_1(p) = \mathsf{up}$ and $D_2(p) = \mathsf{down}$, which is a solution of type 2, or find a point p at the top of the column with $D_1(p) = \mathsf{up}$, or a point q at the bottom of the column with $D_1(q) = \mathsf{down}$. Both of these are solutions of type 3. There is also the similar case where we walk all the way to the right without finding an overall fixpoint, in which case we will find a point p on the right-hand boundary that satisfies $D_1(p) = \mathsf{zero}$ and $D_2(p) = \mathsf{up}$, which is a solution of type 3.
2. The other possibility is that there may be more than one point on the blue surface in some columns. This inevitably leads to multiple lines, since if q and q' are both on the blue surface in some column, and p is in the column to the right of p and q, then (p, q) and (p, q') will both be valid vertices on two different lines. We map these violations back to solutions of type 1. Specifically, the points p and q, which are given as part of the two vertices, are both fixpoints of the same slice, which is exactly what 1 asks for.

Our reduction is promise-preserving because violations in the UFEOPL instance are never mapped back to proper solutions of the OPDC instance.

Generalizing to d dimensions. The full reduction from OPDC to UniqueForwardEOPL generalizes the approach given above to d dimensions. We say that a point $p \in P$ is on the *i-surface* if $D_j(p) = \mathsf{zero}$ for all $j \leq i$. In our 2d example we followed a line of points

on the 1-surface, in order to find a point on the 2-surface. In between any two points on the 1-surface, we followed a line of points on the 0-surface (every point is trivially on the 0-surface). Our line will visit a sequence of points on the $(d-1)$-surface in order to find the point on the d-surface, which is the fixpoint. Between any two points on the $(d-1)$-surface the line visits a sequence of points on the $(d-2)$-surface, between any two points on the $(d-2)$-surface the line visits a sequence of points on the $(d-3)$-surface, and so on. Every time we find a point on the i-surface, we remember it, increment our position in dimension i by 1, and reset our coordinates back to 0 for all dimensions $j < i$. Hence, a vertex will be a tuple $(p_0, p_1, \ldots, p_d)$, where each p_i is either the symbol $-$, indicating that we have not yet encountered the i-surface, or the most recent point on the i-surface that we have visited.

The potential is likewise generalized so that the potential of a point p is proportional to $\sum_{i=1}^{d} k^i p_i$, where k is some constant that is larger than the grid size. Thus progress in dimension i dominates progress in dimension j whenever $j < i$, and the potential monotonically increase along the line. We are also able to deal with all possible violations.

Completing the reduction to UniqueEOPL. The final step of the reduction uses SinkOfVerifiableLine, a problem introduced by Bitansky et al [4]. SinkOfVerifiableLine is intuitively similar to UniqueForwardEOPL. It was shown by Hubáček and Yogev [36] that SinkOfVerifiableLine can be reduced to an EndOfMeteredLine instance with a unique line, and hence to UniqueEOPL. However, [36] only deals with the promise problem. Our contribution is to deal with violations. In doing so, we complete our chain of promise-preserving reductions from OPDC to UniqueEOPL. It is worth pointing out that this step of the reduction implies that the cryptographic hardness results shown by Bitansky et al. for SinkOfVerifiableLine [5] also apply to UniqueEOPL.

Hardness of OPDC. We show that OPDC is UniqueEOPL-hard by giving a polynomial-time promise-preserving reduction from UniqueEOPL to OPDC. Our reduction produces an OPDC instances where the set of points P is the Boolean hypercube $\{0,1\}^n$. In the case where the UniqueEOPL instance has no violations, meaning that it contains a single line, the reduction embeds this line into the hypercube. To do this, it splits the line in half. The second half is embedded into a particular sub-cube, while the first half is embedded into all other sub-cubes. This process is recursive, so each half of the line is again split in half, and further embedded into sub-cubes. The reduction ensures that the only fixpoint of the instance corresponds to the end of the line. If the UniqueEOPL instance does have violations, this embedding may fail, but we are then able to produce a violation for the original UniqueEOPL instance. We remark that this reduction makes significant progress towards showing hardness for Contraction and USO, since OPDC is a discrete variant of Contraction, and when the set of points is a hypercube, the problem is also very similar to USO. The key difference is that OPDC insists that only i-slices have a unique fixpoint, whereas Contraction and USO insist that *all* slices have unique fixpoints.

▶ **Theorem 5.** OPDC *is* UniqueEOPL*-complete under promise-preserving reductions, even when the set of points P is a hypercube.*

4 UniqueEOPL containment results

We show that USO, P-LCP, and a variant of Contraction all lie in UniqueEOPL. For each of these three problems, we provide a reduction to OPDC, shown to be in UniqueEOPL in the previous section.

A USO instance naturally gives rise to an OPDC instance where the underlying grid of points is actually a cube, and there is an easy reduction that shows the following.

▶ **Theorem 6.** *USO is in* UniqueEOPL *under promise-preserving reductions.*

This result substantially advances our knowledge about USO, since prior to this work, it was only known to lie in TFNP, and Kalai [39, Problem 6] had posed the challenge to place it in some non-trivial subclass of TFNP. We place it in *all* of the standard subclasses of TFNP[2].

We provide two reductions from P-LCP to UniqueEOPL. One is via the known reduction from P-LCP to USO [59]. The other uses Lemke's algorithm and produces a UEOPL instance with size linear in that of the P-LCP, which we require for our algorithmic result in Section 5. Lemke's algorithm is a PPAD-style path-following algorithm. The potential comes from a parameter used in Lemke's algorithm that changes monotonically on an P-matrix LCP. The complication is to deal with violations when the input matrix is not a P-matrix.

The reason for two reductions is that each produces different types of violation. We emphasize that all violations used are well-known and natural, and perhaps one can convert between them in polynomial time. Moreover, for the promise problem the choice of violations is irrelevant: each reduction independently shows that promise P-LCP lies in PromiseUEOPL.

▶ **Theorem 7.** *P-LCP* $\in$ UniqueEOPL *under promise-preserving reductions.*

For contraction, we study maps specified by *piecewise linear* functions. This differs from [14], where the map is given by an arbitrary arithmetic circuit. Although every contraction map has a unique fixpoint, for an arbitrary arithmetic circuit, the unique *exact* fixpoint may be irrational, and finding it is not known to be in FNP. Prior work instead asked for an *approximate* fixpoint [14]. However, given our interest in uniqueness of solutions we need to consider exact fixpoints, and thus study the problem with LinearFIXP arithmetic circuits [18], where multiplication of two variables is disallowed, and when the function is contracting, there is a unique rational fixpoint. This is still an interesting class of contraction maps, since it is powerful enough to represent the well-studied simple-stochastic games [18, 11]. We place this problem in UniqueEOPL via a promise-preserving reduction to OPDC. When the promise is not satisfied, the reduction either produces the standard violation, a pair of points at which the function is not contracting, or a different, more technical, violation.

OPDC was inspired by the continuous contraction problem, and our reduction from contraction is to OPDC. The most complicated part of the reduction is picking a suitable set of points for the OPDC instance that is small enough, but also is guaranteed to contain the unique fixed point of the contraction instance. To do this, we formulate the fixpoint problem for a LinearFIXP circuit as an LCP and reason about the bit-length of solutions to this LCP.

▶ **Theorem 8.** *Finding the fixpoint of a piecewise linear contraction map in the* ℓ_p *norm is in* UniqueEOPL *under promise-preserving reductions for any* $p \in \mathbb{N} \cup \{\infty\}$.

Finally, we note that our results imply that several other problems lie in UniqueEOPL. The simple-stochastic game (SSG) problem is known to reduce to piecewise-linear Contraction [18] and P-LCP [30]. Discounted games are known to reduce to SSGs [62], mean-payoff games to discounted games [62], and parity games to mean-payoff games [50]. So all these problems lie in UniqueEOPL too. [27] noted that ARRIVAL [17] lies in EOPL; since their EndOfPotentialLine instance contains only one line, ARRIVAL also lies in UniqueEOPL. However, none of these are promise-problems. Each can be formulated so as to *unconditionally* have a unique solution. Hence, they seem to be easier than other problems captured by UniqueEOPL.

[2] However, we do not place the problem in the recently defined class PWPP [37]

▶ **Theorem 9.** *The following problems are in* UniqueEOPL*: Solving a parity game; mean-payoff game; discounted game; simple-stochastic game; the ARRIVAL problem.*

5 New algorithms

The insights provided by our containment results give two algorithmic results. Firstly, we obtain simple polynomial-time algorithms for finding the fixpoint of a contraction map in fixed dimension for any ℓ_p norm. This result was already known via a reduction to the problem of finding a Tarski fixpoint [51], but our algorithm utilises the structural properties of contraction that arise from our reduction to OPDC, and is arguably simpler.

Secondly, as noted in [27], one of our reductions for P-LCP allows a technique of Aldous [2] to be applied, giving the fastest known randomized algorithm for P-LCP.

6 Conjectures and conclusions

▶ **Conjecture 1.** *USO is hard for* UniqueEOPL.

Among our three motivating problems, USO seems the most likely to be UniqueEOPL-complete. Our hardness proof for OPDC already goes some way towards proving this, since it applies even on a hypercube. Going further, could we even show the stronger result of hardness for P-LCP, which would imply hardness of USO? The complexity of these two problems has been open for decades.

▶ **Conjecture 2.** *Piecewise-Linear Contraction in an ℓ_p norm is hard for* UniqueEOPL.

For this result, in addition to the i-slice vs. all slice issue, we would also need to convert the discrete OPDC problem to the continuous contraction problem. Converting discrete problems to continuous fixpoint problems has been well-studied in the context of PPAD-hardness reductions [13, 45], but here we must additionally maintain the contraction property.

Aside from hardness, we also think that the relationship between Contraction and USO should be explored further, since OPDC exposes significant, previously unrecognised, similarities between the two problems.

▶ **Conjecture 3.** UniqueEOPL $\subset$ EOPL $=$ CLS.

The question of EOPL vs CLS is unresolved, and we actually think it could go either way. One could show that EOPL $=$ CLS by placing either of the two known CLS-complete Contraction variants into EOPL [15, 20]. If the two classes are actually distinct, then it is interesting to ask which of the problems in CLS are also in EOPL.

On the other hand, we believe that UniqueEOPL is a strict subset of EOPL. The evidence for this is that the extra violation in UniqueEOPL that does not appear in EndOfPotentialLine changes the problem significantly. It introduces many new solutions whenever there are multiple lines in the instance, and so it is unlikely, in our view, that one could reduce EndOfPotentialLine to UniqueEOPL. We also believe it very unlikely that other problems in CLS, such as the KKT problem of finding an approximate stationary point of a multivariate polynomial, are in UniqueEOPL. Of course, there is little hope to unconditionally prove that UniqueEOPL $\subset$ EOPL, but we can ask for further evidence, such as oracle separations, to support the idea.

Abstract

In one of the most actively studied version of Constraint Satisfaction Problem, a CSP is defined by a relational structure called a template. In the decision version of the problem the goal is to determine whether a structure given on input admits a homomorphism into this template. Two recent independent results of Bulatov [FOCS'17] and Zhuk [FOCS'17] state that each finite template defines CSP which is tractable or NP-complete.

In a recent paper Brakensiek and Guruswami [SODA'18] proposed an extension of the CSP framework. This extension, called Promise Constraint Satisfaction Problem, includes many naturally occurring computational questions, e.g. approximate coloring, that cannot be cast as CSPs. A PCSP is a combination of two CSPs defined by two similar templates; the computational question is to distinguish a YES instance of the first one from a NO instance of the second.

The computational complexity of many PCSPs remains unknown. Even the case of Boolean templates (solved for CSP by Schaefer [STOC'78]) remains wide open. The main result of Brakensiek and Guruswami [SODA'18] shows that Boolean PCSPs exhibit a dichotomy (PTIME vs. NPC) when "all the clauses are symmetric and allow for negation of variables". In this paper we remove the "allow for negation of variables" assumption from the theorem. The "symmetric" assumption means that changing the order of variables in a constraint does not change its satisfiability. The "negation of variables" means that both of the templates share a relation which can be used to effectively negate Boolean variables.

The main result of this paper establishes dichotomy for all the symmetric boolean templates. The tractability case of our theorem and the theorem of Brakensiek and Guruswami are almost identical. The main difference, and the main contribution of this work, is the new reason for hardness and the reasoning proving the split.

1 Introduction

Constraint Satisfaction Problems have been studied in computer science in many forms. In the general approach an instance of the CSP consists of variables and constraints. In the decision version of the problem the objective is to verify whether there exists an evaluation of variables that meets all the constraints.

One particular type of CSPs received a lot of attention in the past years. In this approach constraints are relations taken from a fixed, finite relational structure called a template. The interest in this particular version was driven by a conjecture of Feder and Vardi [10] postulating that each finite template defines a CSP which is tractable or NP-complete.

A great variety of decision problems independently studied by computer scientists can be cast as CSPs. To name a few: 3-SAT, k-colorability, (generalized) unreachability in directed graphs or solving systems of linear equation over a finite field, are all CSPs defined by finite templates. The class of all the computational problems falling into the scope of the conjecture is very big and its verification was a gradual and lengthy process. Nevertheless, from the start, the claim was supported by strong evidence. In this context the classical result of Schaefer [15] showing that the dichotomy holds for templates over Boolean domain, is perhaps the most important.

The dichotomy for all the finite templates was recently confirmed by two, independent results of Bulatov [6] and Zhuk [16]. Both of them use the algebraic approach [13, 7], where the complexity of a template is studied via compatible operations called polymorphisms. The algebraic approach proved very successful not only in the decision version of the CSP: a number of important results in optimization [14], approximation [2] etc. of the CSP is based on some versions of polymorphisms.

A positive resolution of the dichotomy conjecture motivates the following question: is the class of CSPs unique, or maybe a part of a larger, natural class which also exhibits a dichotomy? Note that such a class should be amenable to some sort of the algebraic approach, as no other tools offer comparable power even in the case of the CSP. In the recent paper [5] Brakensiek and Guruswami proposed a candidate for such a class.

The Constraint Satisfaction Problem defined by a fixed language can be cast as a problem of finding homomorphism from a relational structure given on input to a fixed template. The class proposed by Brakensiek and Guruswami as an extension of CSP is called Promise Constraint Satisfaction Problems. A PCSP is based on two CSPs with similar templates and the question is to distinguish YES instances of the first CSP from NO instances of the second.

To provide a few examples: the CSP defined by an undirected clique (without loops) of size k as a template is just k-colorability. Defining PCSP by two cliques, say of sizes k and l satisfying $k < l$, we get the following problem: distinguish between the graphs with chromatic number $\leq k$ and those with chromatic number $> l$. These problems are studied independently [9, 12, 3, 8], but the characterization of complexities for all pairs (k, l) is either incomplete or done under additional assumptions.

Another example is a Boolean PCSP. A single ternary relation $\{(0,0,1),(0,1,0),(1,0,0)\}$ defines a CSP which is known as Monotone-1-in-3-SAT, and similarly the relation $\{0,1\}^3 \setminus \{(0,0,0),(1,1,1)\}$ gives rise to the CSP known as Monotone-NAE-SAT. Thus the question of distinguishing between instances which are satisfiable as Monotone-1-in-3-SAT instances and not satisfiable as Monotone-NAE-SAT instances is a PCSP. Surprisingly this problem is tractable even allowing for the negation of variables [1, 5].

Further examples of problems expressible as PCSPs can be found in [5]. Promise Constraint Satisfaction Problems generalize CSPs and include many additional, natural problems. The algebraic approach to the CSP can be adjusted to work in the case of

the PCSP. The first Galois correspondence between PCSPs and the polymorphisms was introduced in [5], and the more abstract algebraic approach was proposed in [8]. Despite all the interest, PCSPs lack a classification result that would play the role of Schaefer's theorem. This motivates a more systematic study of Boolean PCSPs.

The main result of Brakensiek and Guruswami, Theorem 2.1 in [5], establishes dichotomy for a certain class of Boolean PCSPs. A PCSP template falls into this class if all the relations in the templates are symmetric (i.e. invariant under permutations, or equivalently, determined by Hamming weights of the tuples) and additionally the template contains a relation which can be used to negate Boolean variables in both CSP templates. As the additional relation is binary and symmetric, the result concerns all the symmetric templates containing this particular relation. In this paper we remove the additional assumption and show that all symmetric Boolean templates exhibit a dichotomy.

Let us further compare the results. The algorithms required for the original and extended result are exactly the same: Gaussian elimination or linear programming relaxation depending on the polymorphisms of the template. The list of polymorphisms implying tractability differs slightly as we need to allow additional threshold functions (Boolean functions returning 0 if and only if the number of 1's is below a threshold). Unfortunately the condition which guarantees hardness in the original paper fails when the negating relation is absent. The new hardness condition and a more involved analysis of the minion of polymorphisms are required in the proof and constitute the main contribution of this paper.

The publication is organized as follows. The next section contains basic definitions commonly used in context of an algebraic approach to the CSP or the PCSP. Section 3 contains a list of polymorphisms that guarantee tractability, statement of the main theorem and a proof of the tractability case. In section 4 we introduce notation and nomenclature. Section 5 contains the algebraic condition implying hardness of PCSP and a proof of this implication. The main part of the reasoning behind the result is focused on showing that lack of polymorphisms from the tractability list implies, in our case, the condition for hardness. Section 6 contains an overview of this proof and a complete reasoning can be found in the full version of the paper.

2 Basic definitions

This section contains basic definitions and notions relevant to CSP and PCSP. A relation $R \subseteq A^n$ is an *n-ary relation* and the set A is its *universe*. A relation is *symmetric*, if for every permutation σ of $[n]$ (where $[n]$ is defined to be $\{1, \dots, n\}$) if $(a_1, \dots, a_n) \in R$ then also $(a_{\sigma(1)}, \dots, a_{\sigma(n)}) \in R$. A relation $R^m \subseteq (A^m)^n$ is a *Cartesian power* of $R \subseteq A^n$ if $(a^1, \dots, a^n) \in R^m$ if and only if $(a^1_i, \dots, a^n_i) \in R$ for every i (i.e. R^m is defined from R coordinate-wise).

A *relational structure* $\mathbf{A}$ is a tuple $(A; R_1, \dots R_n)$ where each R_i is a relation on A, and we call a relational structure *symmetric* if all its relations are. Two relational structures are *similar* if they have the same sequence of arities of their relations. E.g. a relational structure $(A; R_1, \dots R_n)$ and it's m-th power $(A^m; (R_1)^m, \dots (R_n)^m)$ are similar. For two similar structures say $\mathbf{A} = (A; R_1, \dots, R_n)$ and $\mathbf{B} = (B; S_1, \dots, S_n)$ a function $h : A \to B$ is *a homomorphism* if for every i and every tuple $(a_1, \dots, a_m) \in R_i$ the tuple $(h(a_1), \dots, h(a_m)) \in S_i$.

The Constraint Satisfaction Problem defined by a relational structure $\mathbf{B}$ (denoted by CSP($\mathbf{B}$)) is the following decision problem:

Input:	a relational structure $\mathbf{A}$ similar to $\mathbf{B}$
Question:	does there exists a homomorphism from $\mathbf{A}$ to $\mathbf{B}$?

The relational structure $\mathbf{B}$ is called a *template* of such a problem.

The Promise Constraint Satisfaction Problem is a promise problem defined by a pair of similar relational structures $(\mathbf{B}, \mathbf{C})$ such that there exists a homomorphism from $\mathbf{B}$ to $\mathbf{C}$. The PCSP$(\mathbf{B}, \mathbf{C})$ is:

Input:	a relational structure $\mathbf{A}$ similar to $\mathbf{B}$ and $\mathbf{C}$
Output YES:	if there exists a homomorphism from $\mathbf{A}$ to $\mathbf{B}$
Output NO:	if there is no homomorphism from $\mathbf{A}$ to $\mathbf{C}$.

Just like in the case of the CSP, the pair $(\mathbf{B}, \mathbf{C})$ is called a template. Clearly PCSP$(\mathbf{B}, \mathbf{B})$ is CSP$(\mathbf{B})$ and therefore the PCSP generalizes the CSP.

Both problems exhibit a Galois correspondence i.e. instead of studying the structure of the template one can choose to analyze the structure of template's polymorphisms [13, 7, 5, 8]. A *polymorphism* of a relational structure $\mathbf{B}$ is a homomorphism from a finite Cartesian power of $\mathbf{B}$ to $\mathbf{B}$. Similarly a polymorphism of a PCSP template $(\mathbf{B}, \mathbf{C})$ is a homomorphism from a finite Cartesian power of $\mathbf{B}$ to $\mathbf{C}$. We denote the set of all polymorphisms of $\mathbf{B}$ by Pol$(\mathbf{B})$, and the set of all polymorphisms of $(\mathbf{B}, \mathbf{C})$ by Pol$(\mathbf{B}, \mathbf{C})$.

For each relational structure $\mathbf{B}$ the set Pol$(\mathbf{B})$ is *clone* i.e. it contains projections and is closed under composition. Similarly for a pair $(\mathbf{B}, \mathbf{C})$ the set Pol$(\mathbf{B}, \mathbf{C})$ is a minion. *A minion* is a set of functions closed under taking *minors* i.e. creating functions by identifying variables, permuting variables and introducing dummy variables. If $f(x_1, \dots, x_n)$ is a function and $f'(x) = f(x, \dots, x)$ then $f'(x)$ is the unary minor of $f(x_1, \dots, x_n)$ and $f''(x, y) = f(x, y, \dots, y)$ is a binary minor of $f(x_1, \dots, x_n)$.

In some cases, instead of considering a PCSP template $((A; R_1, \dots, R_n), (B; S_1, \dots, S_n))$ we work with an equivalent concept of *a language* i.e. a sequence of pairs $[R_1, S_1], \dots, [R_n, S_n]$. We say that a pair $[S, T]$ is *compatible* with a minion $\mathcal{M}$, if every member of $\mathcal{M}$ maps an appropriate power of S to T (the exponent of the power is the arity of the operation).

A primitive positive formula (pp-formula) is a formula constructed using atomic formulas, conjunction and existential quantification. Such formulas play a special role in CSP and PCSP: if a relation R has a primitive positive definition in $\mathbf{B}$ then R is compatible with Pol$(\mathbf{B})$ and adding R to $\mathbf{B}$ does not change the computational complexity of the CSP$(\mathbf{B})$. Similarly, if a pair $[R, S]$ has a pp-definition in the language of $(\mathbf{A}, \mathbf{B})$ (pp-formula in $[R_i, S_i]$ defines such $[R, S]$ in the natural way) then $[R, S]$ is compatible with Pol$(\mathbf{A}, \mathbf{B})$ and adding it to the language/template does not change the complexity [5]. One more construction, called *strict relaxation*, plays an important role in the theory of PCSP: if $[R_i, S_i]$ is an element of the language $(\mathbf{B}, \mathbf{C})$ and $R \subseteq R_i$ while $S_i \subseteq S$ then $[R, S]$ is compatible with Pol$(\mathbf{A}, \mathbf{B})$ and adding it to the language/template does not change the complexity.

3 Main theorem and tractability

Focusing on the Boolean domain we present the main theorem of the paper and prove that the tractable cases are indeed solvable in P. In this part of the proof our paper does not deviate much from [5]; the polymorphisms which imply tractability are almost the same with an exception of the threshold case.

- A n-ary function is *a max* (*a min*) if it returns maximum (resp. minimum) of its arguments (in the natural order on $\{0, 1\}$).

- A function $f(x_1, \ldots, x_n)$ is *an alternating threshold* if $n = 2k + 1$ and

$$f(x_1, \ldots, x_k, x_{k+1}, \ldots, x_n) = \begin{cases} 0 & \text{if } \sum_{i=1}^{k} x_i \geq \sum_{i=k+1}^{n} x_i, \\ 1 & \text{if } \sum_{i=1}^{k} x_i < \sum_{i=k+1}^{n} x_i, \end{cases}$$

- A function $f(x_1, \ldots, x_n)$ is *an xor* if n is odd and $f(x_1, \ldots, x_n) = x_1 + \cdots + x_n \bmod 2$.
- A function $f(x_1, \ldots, x_n)$ is *a q-threshold* (where q is a rational between 0 and 1) if

$$f(x_1, \ldots, x_n) = \begin{cases} 0 & \text{if } \sum_{i=1}^{n} x_i < nq, \\ 1 & \text{if } \sum_{i=1}^{n} x_i > nq, \end{cases}$$

and nq is not an integer. Note that all the evaluations of the $f(x_1, \ldots, x_n)$ are determined. We denote the set of all max functions by MAX, all the min functions by MIN, all alternating thresholds by AT all xor by XOR and all q-thresholds by THR_q. For a set of functions F by $\overline{F}$ we denote $\{1 - f(x_1, \ldots, x_n) : f(x_1, \ldots, x_n) \in F\}$. We are ready to state the main result of the paper.

▶ **Theorem 1.** *Let $(\mathbf{A}, \mathbf{B})$ be a symmetric, Boolean PCSP language. If $Pol(\mathbf{A}, \mathbf{B})$ contains a constant or includes at least one of the sets MAX, MIN, AT, XOR , THR_q (for some q), $\overline{MAX}$, $\overline{MIN}$, $\overline{AT}$, $\overline{XOR}$ or $\overline{THR_q}$ (for some q) then $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is tractable. Otherwise it is NP-complete.*

Comparing the statement of Theorem 1 and Theorem 2.1 of [5] we find two differences: the earlier paper additionally assumes that negated variables can appear in instances and it allows the authors to substitute "THR_q for some q" with $\mathrm{THR}_{1/2}$ in the list of conditions that force tractability.

In the remaining part of this section we will show the tractability case of Theorem 1. The reasoning differs very little from the one found in [5] and therefore we cover it quickly: If $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ contains a constant function $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is clearly tractable; if it includes MAX, MIN and XOR tractability follows from Lemma 3.1 of [5]. If $\mathrm{AT} \subseteq \mathrm{Pol}(\mathbf{A}, \mathbf{B})$ then Claim 2 of Section 3.2 [5] implies tractability. Finally the case of THR_q is a minor generalization of the argument in Claim 1 of Section 3.2 in the same paper, or a special case of Theorem 5.2 in [4].

The remaining cases reduce, just like in [5], to the ones from the previous paragraph: let relational structure $\mathbf{B}'$ be obtained from $\mathbf{B}$ by exchanging the roles of 0 and 1 (that is, in every relation in $\mathbf{B}$, in every tuple of this relation and at every position in this tuple we change x to $1 - x$). The YES instances of $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}')$ and $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ are trivially the same and so are the NO instances. If $\overline{\mathrm{MIN}} \subseteq \mathrm{Pol}(\mathbf{A}, \mathbf{B})$ then $\mathrm{MIN} \subseteq \mathrm{Pol}(\mathbf{A}, \mathbf{B}')$ and, by the cases already established, $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}')$ is tractable. Clearly $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ is tractable as well and all the remaining tractable cases can be dealt with the same way.

4 The notation for symmetric Boolean PCSPs

In order to show NP-hardness in the remaining case of Theorem 1, we require a few definitions which allow us to work with symmetric Boolean relations and Boolean function concisely.

Every symmetric relation $R \subseteq \{0, 1\}^m$ is uniquely determined by the set $I \subseteq \{0, \ldots, m\}$ consisting of the Hamming weights of its elements. This fact allows us to use R and I interchangeably. Let $(\mathbf{B}, \mathbf{C})$ be a symmetric, Boolean PCSP template with language $[R_1, S_1], \ldots, [R_n, S_n]$ where the arities of the relations are $a_1, \ldots, a_n$. We will denote such a language by $[\, I_1 \mid J_1 \,]_{a_1}, \ldots, [\, I_n \mid J_n \,]_{a_n}$ where I_i (J_i) is a set of Hamming weights of elements

of R_i (S_i respectively). We will often use a flattened form of this notation: we will denote $[\,\{1\} \mid \{1,2\}\,]_2$ by $[\,1 \mid 1,2\,]_2$ and so on as well as $[n] = \{1,\dots,n\}$.

Focusing on compatibility; an operation $f(x_1,\dots,x_n)$ is compatible with $[\,0 \mid 0\,]_1$ if and only if $f(0,\dots,0) = 0$ and compatible with $[\,1 \mid 1\,]_1$ if and only if $f(1,\dots,1) = 1$. The pair $[\,1 \mid 1\,]_2$ defines negation in $\mathbf{A}$ and $\mathbf{B}$ and therefore the main result of [5] is a special case of Theorem 1; the additional assumption states that $[\,1 \mid 1\,]_2$ is in the language of PCSP.

We proceed to illustrate a number of pp-definitions and strict relaxations that appear repeatedly in the proofs. Using $[\,I \mid J\,]_n$ and $[\,0 \mid 0\,]_1$ one can define $[\,I \setminus \{n\} \mid J \setminus \{n\}\,]_{n-1}$ using the following pp-formula:

$$\exists x_1\ [\,0 \mid 0\,]_1(x_1) \wedge [\,I \mid J\,]_n(x_1,\dots,x_n).$$

Similarly

$$\exists x_1\ [\,1 \mid 1\,]_1(x_1) \wedge [\,I \mid J\,]_n(x_1,\dots,x_n)$$

defines $[\,I' \mid J'\,]_{n-1}$ where $I' = \{i-1 : i \in I \text{ and } i \neq 0\}$ and $J' = \{j-1 : j \in J \text{ and } j \neq 0\}$. The strict relaxations we use are straightforward: take $[\,I \mid J\,]_n$ with $i \in I$ while $j \notin J$ then, for example, $[\,i \mid \{0,\dots,n\} \setminus \{j\}\,]_n$ is a strict relaxation of $[\,I \mid J\,]_n$.

In the proof of tractability for $(\mathbf{B},\mathbf{C})$ (at the end of Section 3) we swapped the role of 0 and 1 in $\mathbf{C}$. In the new notation we change $[\,I_1 \mid J_1\,]_{a_1},\dots,[\,I_n \mid J_n\,]_{a_n}$ to $[\,I_1 \mid J_1'\,]_{a_1},\dots,[\,I_n \mid J_n'\,]_{a_n}$ where $J_k' = \{a_k - j : j \in J_k\}$. In some of the proofs we reuse this construction, although we usually swap for both $\mathbf{B}$ and $\mathbf{C}$ at the same time.

We define notation for Boolean functions next. A Boolean function $f(x_1,\dots,x_n)$ is *idempotent* if $f(0,\dots,0) = 0$ and $f(1,\dots,1) = 1$. By the discussion above a minion is idempotent (i.e. contains idempotent functions only) if it is compatible with $[\,0 \mid 0\,]_1$ and $[\,1 \mid 1\,]_1$. Moreover the idempotent part of $\mathrm{Pol}(\mathbf{B},\mathbf{C})$ can be obtained by adding these pairs to the language.

For a Boolean function $f(x_1,\dots,x_n)$ and a set $U \subseteq [n]$ the value $f(U)$ is defined as $f(x_1,\dots,x_n)$ where $\{i : x_i = 1\} = U$. When n is clear from the context we can write $\overline{U}$ instead of $[n] \setminus U$. Let $f(x_1,\dots,x_n)$ be a Boolean function $U \subseteq [n]$ then U is

- a 1-SET if $f(U) = 1$,
- a 0-SET if $f(\overline{U}) = 0$,
- a 1-FIXING-SET (0-FIXING-SET) if every $V \supseteq U$ is a 1-SET (resp. 0-SET).

Moreover we say that a minion has *small fixing sets*, if there exists a constant N such that every function from the minion has a 1-FIXING-SET smaller than N, or every function from the minion has a 0-FIXING-SET smaller than N. Finally we say that a minion has *bounded antichains*, if there exist a constant M such that no function in the minion has M pairwise disjoint 1-SETs, and no function in the minion has M pairwise disjoint 0-SETs.

5 The hardness proof

In order to satisfy the assumptions of Lemma 5.1, we need some structural properties of the minion $\mathrm{Pol}(\mathbf{A},\mathbf{B})$. The following theorem collects these properties and is a cornerstone of our classification.

▶ **Theorem 2.** *Let $\mathbf{A},\mathbf{B}$ be a symmetric PCSP language such that $Pol(\mathbf{A},\mathbf{B})$ is idempotent. If $Pol(\mathbf{A},\mathbf{B})$ does not include MAX, MIN, AT, XOR and THR_q (for any q), then $Pol(\mathbf{A},\mathbf{B})$ has small fixing sets and bounded antichains.*

The Brakensiek and Guruswami [5] version of Theorem 2 requires that $(\mathbf{A}, \mathbf{B})$ contains $[\,1 \mid 1\,]_2$ and concludes that there exists a constant M such that every member of $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ has a set of size at most M which is a 1-FIXING-SET and a 0-FIXING-SET at the same time. The following example illustrates that their condition fails in our case.

▶ **Example 3.** Consider PCSP defined by a language consisting of $[\,0 \mid 0\,]_1$, $[\,1 \mid 1\,]_1$, $[\,1 \mid 1,2\,]_3$ and $[\,1 \mid 1,2\,]_4$. It is easy to verify that it falls into the hardness case of Theorem 1. On the other hand for each odd n the function $f(x_1, \ldots, x_n)$ defined as maximum of x_1 and n-ary element of $\mathrm{THR}_{1/2}$ is compatible with all the relational pairs. These functions have no uniform bound on the size of minimal 0-FIXING-SETs.

In the reminder of this section we use Theorem 2 to finish the proof of Theorem 1. We begin by introducing the machinery developed in [8] (a direct proof is possible, but involves a bit more technical considerations). The paper [8] defines *minor identity* as a formal expression of the form

$$f(x_1, \ldots, x_n) \approx g(x_{\pi(1)}, \ldots, x_{\pi(m)})$$

where f and g are function symbols (of arity n and m, respectively), $x_1, \ldots, x_n$ are variables, and $\pi : [m] \to [n]$. A minor identity is satisfied in a minion $\mathcal{M}$ (of functions from A to B) if there exists an interpretation of the function symbols f and g in $\mathcal{M}$, say ζ, satisfying

$$\zeta(f)(a_1, \ldots, a_n) = \zeta(g)(a_{\pi(1)}, ..., a_{\pi(m)})$$

for all $a_1, \ldots, a_n \in A$.

A bipartite minor condition is a finite set of minor identities in which function symbols used on the right- and left-hand sides are disjoint. A minor condition is *satisfied in a minion*, if there exists an interpretation simultaneously satisfying all the identities. A minor condition is *trivial* if it is satisfied in every minion, in particular, in the minion consisting of all projections on a set A that contains at least two elements. Finally, still following [8], a bipartite minor condition Σ is ε-robust (for some $\varepsilon > 0$) if no ε-fraction of identities from Σ is trivial.

▶ **Lemma 5.1** (Corollary 5.8 from [8]). *If there exists an $\varepsilon > 0$ such that $Pol(\mathbf{A}, \mathbf{B})$ does not satisfy any ε-robust bipartite minor condition, then $PCSP(\mathbf{A}, \mathbf{B})$ is NP-hard.*

In order to apply Lemma 5.1 to $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ we need to ensure that $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ does not satisfy any ε-robust bipartite minor condition. Our first step is to prove it in the idempotent case.

▶ **Proposition 5.2.** *Let $\mathcal{M}$ be an idempotent minion with small fixing sets, and bounded antichains. Then $\mathcal{M}$ does not satisfy any ε-robust bipartite minor condition.*

Proof. The proof follows the same pattern as the proofs of Propositions 5.10 and 5.12 in [8] so we will use the notation from those Propositions in this proof. All we need to do is to find $\varepsilon > 0$ and a mapping assigning to each member of $\mathcal{M}$ a probability distribution on its variables. The probability distribution needs to satisfy the following condition: if $f, g \in \mathcal{M}$ and $f(x_1, \ldots, x_n) \approx g(x_{\pi(1)}, \ldots, x_{\pi(m)})$ then

- choosing a variable from the LHS according to the distribution for f and
- choosing a variable from the RHS according to the distribution for g,

with probability greater than ε we will choose the same variable.

In order to find such ε and the mapping for $\mathcal{M}$ we assume without loss of generality that small fixing sets in $\mathcal{M}$ are 1-FIXING-SETs and their size as well as a size of an antichain is bounded by constant M. We choose $\varepsilon < 1/M^4$ and define the probability distribution

as follows: fix $f \in \mathcal{M}$ and from the collection of 1-FIXING-SETs smaller than M choose a maximal subset of pairwise disjoint 1-FIXING-SETs. Let U_f be the set of numbers appearing in this subset and the probability distribution for f is the uniform distribution on U_f.

Take an identity as above; as $|U_f| \leq M^2$ and $|U_g| \leq M^2$ in order to prove the claim it suffices to show that $\pi(U_g) \cap U_f \neq \emptyset$. Let U be one of the 1-FIXING-SETs which defined U_g. The set $\pi(U)$ is a 1-FIXING-SET of f and its size is bounded by M. The maximality of the subset defining U_f implies that U_f and $\pi(U)$ intersect, which concludes the proof. ◀

We are now ready to finish the proof of Theorem 1 (modulo Theorem 2) following a reasoning similar to the one used in [5]. Let $(\mathbf{B}, \mathbf{C})$ be a PCSP language such that $\mathrm{Pol}(\mathbf{B}, \mathbf{C})$ doesn't contain constant functions and do not include any of MAX, MIN, AT, XOR, THR_q, $\overline{\mathrm{MAX}}$, $\overline{\mathrm{MIN}}$, $\overline{\mathrm{AT}}$, $\overline{\mathrm{XOR}}$, $\overline{\mathrm{THR}_q}$. Let $(\mathbf{B}_+, \mathbf{C}_+)$ be $(\mathbf{B}, \mathbf{C})$ with $[\,1 \mid 1\,]_1$ and $[\,0 \mid 0\,]_1$ added. By Theorem 2 and Proposition 5.2 $\mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)$ does not satisfy any ε-robust minor condition (for some fixed ε). Note that $\mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)$ consists of these elements of $\mathrm{Pol}(\mathbf{B}, \mathbf{C})$ which have identity as the unary minor. Thus $\mathrm{Pol}(\mathbf{B}, \mathbf{C}) \setminus \mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)$ consists of elements of $\mathrm{Pol}(\mathbf{B}, \mathbf{C})$ which have $x \mapsto 1 - x$ as the unary minor.

Consider the set $\overline{\mathrm{Pol}(\mathbf{B}, \mathbf{C}) \setminus \mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)}$. It is a minion and it is equal to $\mathrm{Pol}(\mathbf{B}_-, \mathbf{C}_-)$, where $(\mathbf{B}_-, \mathbf{C}_-)$ is obtained from $(\mathbf{B}, \mathbf{C})$ in two steps: first the roles of 0 and 1 are swapped in $\mathbf{C}$ (just like in the tractability proof) and then $[\,1 \mid 1\,]_1, [\,0 \mid 0\,]_1$ are added to the language. Applying Proposition 5.2 to $(\mathbf{B}_-, \mathbf{C}_-)$ we conclude that $\overline{\mathrm{Pol}(\mathbf{B}, \mathbf{C}) \setminus \mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)}$ does not satisfy any ε-robust minor condition (for some ε). The same holds for $\mathrm{Pol}(\mathbf{B}, \mathbf{C}) \setminus \mathrm{Pol}(\mathbf{B}_+, \mathbf{C}_+)$ and therefore $\mathrm{Pol}(\mathbf{B}, \mathbf{C})$ is a disjoint union of two minions which, for some ε, do not satisfy any ε-robust minor conditions. It follows that $\mathrm{Pol}(\mathbf{B}, \mathbf{C})$ does not satisfy any ε-robust minor condition and by Lemma 5.1 the $\mathrm{PCSP}(\mathbf{B}, \mathbf{C})$ is NP-hard.

6 Proof overview

Our proof of Theorem 2 consists of the following four propositions.

▶ **Proposition 6.1.** *Let $(\mathbf{A}, \mathbf{B})$ be a symmetric language such that $\mathcal{M} = Pol(\mathbf{A}, \mathbf{B})$ is idempotent. If $\mathcal{M}$ does not include neither MAX nor MIN, then it is compatible with some relational pair $[\,a \mid 1, \ldots, a+1\,]_{a+1}$ and some relational pair $[\,1 \mid 0, \ldots, c\,]_{c+1}$.*

For the next proposition we need to specialize the notion of bounded antichains. We say that a minion has *bounded antichains of 1-SETs (0-SETs)* if there exists a uniform bound on the number of pairwise disjoint 1-SETs (0-SETs respectively) an element of the minion can have.

▶ **Proposition 6.2.** *Let $\mathcal{M}$ be a minion compatible with $[\,a \mid 1, \ldots, a+1\,]_{a+1}$ and $[\,1 \mid 0, \ldots, c\,]_{c+1}$. Then $\mathcal{M}$ has bounded antichains of 1-SETs if and only if $\mathcal{M}$ has bounded antichains of 0-SETs.*

▶ **Proposition 6.3.** *Let $(\mathbf{A}, \mathbf{B})$ be a symmetric language such that $\mathcal{M} = Pol(\mathbf{A}, \mathbf{B})$ is idempotent. If $\mathcal{M}$ is compatible with some $[\,a \mid 1, \ldots, a+1\,]_{a+1}$, some $[\,1 \mid 0, \ldots, c\,]_{c+1}$ and does not have bounded antichains then $\mathcal{M}$ includes XOR or AT.*

▶ **Proposition 6.4.** *Let $(\mathbf{A}, \mathbf{B})$ be a symmetric language such that $\mathcal{M} = Pol(\mathbf{A}, \mathbf{B})$ is idempotent. If $\mathcal{M}$ has bounded antichains and does not include any of THR_q then it has small fixing sets.*

The structure of the proof is as follows: if $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ has MIN or MAX we are in a tractable case. Otherwise we split the reasoning in two cases: either $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ fails the bounded antichain condition and by Proposition 6.3 we are tractable due to AT or XOR, or

we have bounded antichains and by Proposition 6.4 we are either tractable due to THR_q or have small fixing sets which implies hardness (by Proposition 5.2). Proposition 6.2 allows us to "flip" the template if necessary.

In this section, we prove Propositions 6.1 and 6.2. We also provide proof sketches of Propositions 6.3 and 6.4. Detailed proofs can be found in the full version of the paper.

Proof of Proposition 6.1. The proof splits into two parts:

- $\mathcal{M}$ does not have MIN then $\mathcal{M}$ is compatible with $[\,a \mid 1,\dots,a+1\,]_{a+1}$
- $\mathcal{M}$ does not have MAX then $\mathcal{M}$ is compatible with $[\,1 \mid 0,\dots,c\,]_{c+1}$

Proof of both cases is analogous, so we will only prove the first part. Let us assume that $\mathcal{M} = \mathrm{Pol}(\mathbf{A},\mathbf{B})$ and $\mathcal{M}$ does not have MIN. So there must be $[\,I \mid J\,]_n$ in the language of $(\mathbf{A},\mathbf{B})$ such that MIN is not compatible with it. This implies that there exists $b < a < n$ such that $a \in I$ and $b \notin J$. Now, using pp-definitions and strict relaxations from Section 4, we will show that $\mathcal{M}$ is compatible with $[\,a-b \mid 1,\dots,a-b+1\,]_{a-b+1}$:

- use strict relaxation of $[\,I \mid J\,]_n$ to obtain $[\,a \mid 0,\dots,b-1,b+1,\dots,n\,]_n$;
- from the last pair pp-define, using $[\,0 \mid 0\,]_1$, the pair $[\,a \mid 0,\dots,b-1,b+1,\dots,a+1\,]_{a+1}$,
- finally from the previous pair pp-define, this time using $[\,1 \mid 1\,]_1$, the required pair $[\,a-b \mid 1,\dots,a-b+1\,]_{a-b+1}$. ◀

The following lemma is used in the proof of Proposition 6.2.

▶ **Lemma 6.5.** *Let $\mathcal{M}$ be a minion. Then:*

- *if $\mathcal{M}$ is compatible with some $[\,a \mid 1,\dots,a+1\,]_{a+1}$, then for each f in $\mathcal{M}$ a union of a-many pairwise disjoint 0-SETs is a 1-SET.*
- *if $\mathcal{M}$ is compatible with some $[\,1 \mid 0,\dots,c\,]_{c+1}$, then for each f in $\mathcal{M}$ a union of c-many pairwise disjoint 1-SETs is a 0-SET.*

Proof. The proofs of the two cases are analogous, so we will only prove the second one. Let $U_1,\dots,U_c$ be disjoint 1-SETs of the n-ary function $f \in \mathcal{M}$ and $U = \bigcup_{i=1}^{c} U_i$. Since every coordinate i occurs in exactly one set of $U_1,\dots,U_c,\overline{U}$ and f is compatible with $[\,1 \mid 0,\dots,c\,]_{c+1}$, the tuple $(f(U_1),\dots,f(U_c),f(\overline{U}))$ cannot evaluate to $(1,\dots,1)$. Therefore $f(\overline{U}) = 0$ and U is a 0-SET. See Figure 1 for example.

1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1
0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1
0	0	0	1	1	1	1	1	1	0	0	0	0	0	0	0	0	1
0	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1	0

Figure 1 Example of c disjoint 1-SETs creating a 0-SET with $c = 3$. The yellow column represents the result of an evaluation of function f on tuples represented by other columns. The columns are in $[\,1 \mid 0,1,2,3\,]_4$ and the grey cells are $U_1,\dots,U_c$ while the red cells are U. ◀

Proof of Proposition 6.2. By using Lemma 6.5 we conclude that:

- if f contains an antichain of 1-SETs of size n then it also contains an antichain of 0-SETs of size at least $\lfloor \frac{n}{c} \rfloor$
- if f contains an antichain of 0-SETs of size n then it also contains an antichain of 1-SETs of size at least $\lfloor \frac{n}{a} \rfloor$

so if one of the antichains of 0-SETs or 1-SETs is bounded then the other one has to be bounded as well. ◀

Proof sketch of Proposition 6.3. Since $\mathcal{M}$ has unbounded antichains, we can take a function from $\mathcal{M}$ with a arbitrarily large antichain of 1-SETs. By taking its minor, we obtain f satisfying

$$f(1,0,\dots,0) = f(0,1,0,\dots,0) = \cdots = f(0,\dots,0,1,0) = 1.$$

Notice that the last coordinate is exceptional, it does not have to form a 1-SET. By taking further minors of f we either get g, of arbitrarily large arity, that satisfies

$$g(1,0,\dots,0) = g(0,1,0,\dots,0) = \cdots = g(0,\dots,0,1) = 1,$$

or compatibility with AT (see the full version of the paper). We are left with the case when g's, of arbitrarily large arity, are in $\mathcal{M}$.

If $\mathcal{M}$ does not include AT, it is compatible (after possibly changing ones to zeros and zeros to ones) with $[\,1 \mid 0,\dots,n-2,n\,]_n$ or $[\,0,d \mid 0,\dots,n-1\,]_n$ for some $d < n$. We use these relational pairs for forcing further behavior of g, and finally obtain an xor of an arbitrarily large arity. This implies that XOR is a subset of $\mathcal{M}$. ◀

Proof sketch of Proposition 6.4. If a minion $\mathcal{M}$ has bounded antichains and does not have q-threshold for any q, we can find (skipping an easy case discussed in the full version of the paper) positive integers a, b, c, d such that $c/d < a/b < 1$ such that $\mathcal{M}$ is compatible with relational pairs

$$[\,a \mid 0,\dots,b-1\,]_b, \quad [\,c \mid 1,\dots,d\,]_d. \tag{1}$$

Notice that the converse, i.e. that these relational pairs prevent threshold, is clear since (1) disallows any q-threshold such that $q < a/b$ and any q-threshold such that $q > c/d$. It can be shown that these relational pairs are the general obstacle to a threshold polymorphism. We prove the proposition by induction on $a + b + c + d$.

For the reminder of the proof to work we are forced to work with weaker assumptions – instead of $\mathcal{M}$ being compatible with (1) we assume that $\mathcal{M}$ is "almost compatible" with the relational pairs. Nevertheless, the "almost compatibility" notion is rather technical, and we ignore it in this sketch. For a formal proof, see the full version of the paper. Here, let us simply assume that $\mathcal{M}$ is compatible with (1).

It turns out that the only interesting case is $c/d < a/b < 1/2$. All the other cases can be either resolved directly or reduced to this one. Now, consider a minimal (ordered by inclusion) 0-SET U and let f_U denote $|U|$-ary operation obtained from f by plugging zeros to every coordinate not contained in U. Since f is compatible with $[\,a \mid 0,\dots,b-1\,]_b$ and U is a 0-SET, f_U is compatible with $[\,c \mid 1,\dots,d-c\,]_{d-c}$. Every 1-SET in f_U is also a 1-SET in f, so f_U has bounded antichains of 1-SETs. (bounded across every $f \in \mathcal{M}$ and every U). Moreover, since U is minimal, the complement $\overline{U}$ of U is "almost" a 1-SET (every strict superset is). If $\overline{U}$ was a 1-SET, f_U would be compatible with $[\,a \mid 0,1,\dots,b-a-1\,]_{b-a}$ since f is compatible with $[\,a \mid 0,1,\dots,b-1\,]_b$. This is where the weaker notion of compatibility (the star-compatibility) is necessary in the full proof. However for the sake of simplicity, assume that f_U is compatible with $[\,a \mid 0,1,\dots,b-a-1\,]_{b-a}$. Since f_U has bounded antichains of 1-SETs and it is compatible with relational pairs

$$[\,a \mid 0,1,\dots,b-a-1\,]_{b-a}, \quad [\,c \mid 1,\dots,d-c\,]_{d-c}$$

where $c/(d-c) < a/(b-a)$, it has also bounded antichains of 0-SETs. Therefore, we can apply the induction hypothesis and obtain a small (bounded across every $f \in \mathcal{M}$ and every U) 1-FIXING-SET or 0-FIXING-SET V in f_U. For our purposes, we don't need to know

that the set is fixing, it suffices that it is a 0-SET or a 1-SET. Let $\mathcal{L}_f$ denote the set of all possible sets V above across all minimal 0-SETs U. From the induction hypothesis, we also get that either every $V \in \mathcal{L}_f$ is a 1-SET in the appropriate f_U, or every $V \in \mathcal{L}_f$ is a 0-SET in the appropriate f_U.

▷ Claim 4. The size of pairiwise disjoint subsystems of $\mathcal{L}_f$ is bounded by a number independent of the chosen $f \in \mathcal{M}$.

If every $V \in \mathcal{L}_f$ is a 1-SET in the appropriate f_U, then V is a 1-SET in f and the claim follows from $\mathcal{M}$ having bounded antichains. Let us prove the claim if every $V \in \mathcal{L}_f$ is a 0-SET in the appropriate f_U. Consider c disjoint elements $V_1, \ldots, V_c \in \mathcal{L}$, and let $U_1, \ldots, U_c$ be the appropriate minimal 0-SETs. Thus also every $\overline{U_i} \cup V_i$ is a 0-SET. Since

$$U_1, U_2, \ldots, U_c, \overline{U_1} \cup V_1, \overline{U_2} \cup V_2, \ldots, \overline{U_c} \cup V_c$$

are 0-SETs, $V_1 \cup \ldots \cup V_c$ is a 1-SET by compatibility with $[\, c \mid 1, 2, \ldots 2c+1 \,]_{2c+1}$. Let M be the bound on antichains of 1-SETs in $\mathcal{M}$, the size of antichains in $\mathcal{L}$ is bounded by cM.

Finally, we use the claim to find a small 1-FIXING-SET in f. Consider any maximal sequence $V_1, \ldots, V_n \in \mathcal{L}$ of disjoint sets and let

$$W = V_1 \cup V_2 \cup \ldots \cup V_n,$$

Every 0-SET contains a minimal 0-SET, every minimal 0-SET contains some $V \in \mathcal{L}$ and every $V \in \mathcal{L}$ intersects W. Therefore every 0-SET intersects W, so W is the desired 1-FIXING-SET. ◀

Abstract

The seminal result of Kahn, Kalai and Linial shows that a coalition of $O(\frac{n}{\log n})$ players can bias the outcome of *any* Boolean function $\{0,1\}^n \to \{0,1\}$ with respect to the uniform measure. We extend their result to arbitrary product measures on $\{0,1\}^n$, by combining their argument with a completely different argument that handles very biased input bits.

We view this result as a step towards proving a conjecture of Friedgut, which states that Boolean functions on the continuous cube $[0,1]^n$ (or, equivalently, on $\{1,\ldots,n\}^n$) can be biased using coalitions of $o(n)$ players. This is the first step taken in this direction since Friedgut proposed the conjecture in 2004.

Russell, Saks and Zuckerman extended the result of Kahn, Kalai and Linial to multi-round protocols, showing that when the number of rounds is $o(\log^* n)$, a coalition of $o(n)$ players can bias the outcome with respect to the uniform measure. We extend this result as well to arbitrary product measures on $\{0,1\}^n$.

The argument of Russell et al. relies on the fact that a coalition of $o(n)$ players can boost the expectation of any Boolean function from ϵ to $1-\epsilon$ with respect to the uniform measure. This fails for general product distributions, as the example of the AND function with respect to $\mu_{1-1/n}$ shows. Instead, we use a novel boosting argument alongside a generalization of our first result to arbitrary finite ranges.

1 Introduction

How can distributed processors collectively flip a somewhat fair coin if some processors may try to bias the outcome? In the *Collective Coin-Flipping Problem*, a classical problem in distributed computing, n processors wish to generate a single common random bit, even in the presence of faulty and possibly malicious processors. Collective coin-flipping protocols can be used to expedite *Byzantine Agreement* [6] and are closely related to *Leader Election Protocols* [7]. The problem has been considered in several scenarios, depending on the assumptions made on the type of the communication between the processors, the kind and number of faults, and the power of the adversary [6, 3, 7, 2].

A Boolean function $f\colon \{0,1\}^n \to \{0,1\}$, where $\{0,1\}^n$ is endowed with a product measure μ, naturally corresponds to a *single round collective coin-flipping protocol* in the *perfect information* model introduced by Ben-Or and Linial [2], where n players each broadcast a bit according to a private distribution, and at the end, the output of the protocol is the value of f on the broadcast string. An interesting and important concept in the design of collective coin-flipping protocols is *resilience* against coalitions of a significant number of players who attempt to influence the output of the protocol towards a particular value.

A *coalition* is a subset S of players that have a particular desired value $b \in \{0,1\}$ in mind, and if possible, broadcast bits that set the output of the protocol to b. We study the model where the coalition is allowed *rushing*: the corrupt players may wait until all the other players broadcast their bits before deciding on what bit to broadcast. In other words, they *succeed* on $x \sim \mu$ if it is possible to modify x only on the coordinates in S to obtain a string y with $f(y) = b$; they *fail* if the value of f is already determined to be *not* equal to b by the bits broadcast by the players outside the coalition. The success of such a coalition can be easily quantified as the probability that the coalition succeeds on a random $x \sim \mu$.

Fix a parameter $\epsilon > 0$. A protocol f is said to be *ϵ-resilient against coalitions of ℓ players* if no coalition of size at most ℓ succeeds with probability at least $1 - \epsilon$. How resilient can a function be against large coalitions? Over the uniform distribution, perhaps the most natural candidate for a highly resilient function is the majority function, which can be easily seen to be resilient against $\Omega(\sqrt{n})$ size coalitions. However, somewhat surprisingly, it turns out that plain democracy is not the most effective way to be immune against the influence of coalitions. Indeed, Ajtai and Linial [1] gave a *randomized* construction of a Boolean function that is resilient against coalitions of size $\Omega(n/\log^2 n)$, significantly better than the $\Omega(\sqrt{n})$ bound of the majority function. More recently, Chattopadhyay and Zuckerman [5] gave an *explicit* construction of a highly resilient function over the uniform measure. This was a key ingredient in their breakthrough work that introduced explicit two-source extractors

for polylogarithmic min-entropy. Subsequently, Meka [11] gave an explicit construction of a monotone depth three Boolean function that is as resilient as the randomized construction of Ajtai and Linial.

In this article, we are mainly interested in the limitations of resilience. The most classical theorem in this direction is due to Kahn, Kalai, and Linial [10], who proved that, for the uniform distribution, no Boolean function is resilient against coalitions of size $\omega(n/\log n)$. Closing the gap between this bound and the $\Omega(n/\log^2 n)$ construction of Ajtai and Linial remains a longstanding open problem.

Starting with the work of Ben-Or and Linial [2], researchers have studied two natural ways to generalize the discussed protocols: First, allow players to broadcast longer messages, and second, allow many rounds. In this paper, we mostly focus on the latter generalization. In the multi-round setting, the voting procedure that is described above is repeated r times: at every round, first the players who are not in the coalition broadcast their random messages, and then the players in the coalition decide and broadcast their messages in an adversarial manner. When the players are sending single-bit messages, the outcome is decided by a function $f\colon (\{0,1\}^n)^r \to \{0,1\}$.

The most efficient known protocols are due to Russell and Zuckerman [13] and to Feige [8]. In the case where players are allowed to send longer messages, they constructed $\log^\star n + O(1)$ round protocols resilient against coalitions of size βn for any $\beta < 1/2$. In the case when players are allowed to broadcast single bit messages, their protocols use $(1 - o(1))\log n$ rounds, and are still resilient against coalitions of size βn for any $\beta < 1/2$. For a discussion of various models and known upper and lower bounds, see a survey of Dodis [7].

In the multi-round setting, the players in the coalition have the disadvantage that they will not see the future-round votes of the other players before voting in the current round. Thus, it becomes significantly more difficult to prove limitations on resilience as r grows, and naturally the known bounds are weaker. Russell, Saks and Zuckerman [12], building upon the work of Kahn et al. [10], showed that over the uniform measure, no Boolean function $f\colon (\{0,1\}^n)^r \to \{0,1\}$ is ϵ-resilient against coalitions of size $\omega_\epsilon\left(\frac{r^2 n}{\log^{(2r-1)} n}\right)$, where $\log^{(2r-1)} n$ is an iterated logarithm. It follows as a simple corollary that $\Omega(\log^\star n)$ rounds are necessary in order for a protocol to be resilient against coalitions of size $\Omega(n)$.

The purpose of this paper is to generalize the above results from the uniform distribution to arbitrary product distributions on the Boolean cube.

A moment of reflection reveals that there are major differences between the uniform distribution and the general case, and indeed, prior to this work, it was not clear to us whether similar results were true for general product distributions. We will elaborate on this later, but for now, we only mention that the coordinates x_i that are not highly biased, i.e. $t \le \Pr[x_i = 1] \le 1 - t$ for some t that is not too small, can be handled using the same argument as in Kahn et al. [10]. Similarly, the argument of Russell et al. [12] can be used to analyze these coordinates in the multi-round setting. However, the highly biased coordinates behave very differently, and to handle those, we need to take an entirely new approach, and employ a new set of ideas. Indeed, our proofs for the highly biased case have almost no resemblance to those in previous works.

Our first theorem concerns single round protocols. By combining the argument of Kahn, Kalai and Linial with an argument geared towards biased coordinates, we are able to show that these protocols can always be influenced towards a single value, with coalitions which are only slightly worse than those guaranteed by the KKL theorem.

▶ **Theorem 1.** *Over any product distribution μ, there is no function $f\colon \{0,1\}^n \to \{0,1\}$ that is ϵ-resilient against coalitions of size $\omega_\epsilon(\frac{n \log\log n}{\log n})$.*

(In contrast, the KKL theorem shows the impossibility of ϵ-resilience against coalitions of size $\omega_\epsilon(\frac{n}{\log n})$.)

Next, we prove an impossibility result for resilience in the multi-round setting over arbitrary product distributions. This was posed as an open problem by Russell et al. [12]. Here we face several new challenges. Generalizing our argument for the biased coordinates to the multi-round setting is far from straightforward, and combining it with the argument of Russell et al. [12] for the unbiased coordinates also requires new ideas.

▶ **Theorem 2.** *Let n and $r < n$ be given. Over any product distribution μ over $(\{0,1\}^n)^r$, there is no r-round coin-flipping protocol $f\colon (\{0,1\}^n)^r \to \{0,1\}$ that is ϵ-resilient against coalitions of size $\omega_\epsilon\left(\frac{n(\log^\star n)^2}{\log^{(4r)} n}\right)$.*

As a result, over any product distribution μ, $\Omega(\log^\star n)$ rounds are necessary in order for a protocol to be resilient against coalitions of size $\Omega(n)$.

Influences. The notion of resilience of a Boolean function is related to the influences of variables and coalitions of variables. For a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ over a product probability measure μ, the *influence* of the k-th variable is defined as

$$I_k(f) := \Pr_{x\sim\mu}\left[f \text{ is not constant on } B_k(x)\right],$$

where $B_k(x) := \{y \in \{0,1\}^n \colon y_j = x_j \text{ for all } j \neq k\}$.

The influence of the k-th variable *towards a value* $b \in \{0,1\}$ is defined as

$$I_k^b(f) := \Pr_{x\sim\mu}\left[b \in f(B_k(x))\right].$$

Similarly, the *influence of a coalition* $S \subseteq [n]$ towards a value $b \in \{0,1\}$ is defined as

$$I_S^b(f) := \Pr_{x\sim\mu}\left[b \in f(B_S(x))\right],$$

where $B_S(x) := \{y \in \{0,1\}^n \colon y_j = x_j \text{ for all } j \notin S\}$.

Equivalently, $I_S^b(f)$ is the probability that a random $x \sim \mu$ can be modified on its S variables such that the output of f becomes b.

A function f is *not* ϵ-resilient against coalitions of size ℓ if and only if there exists a set S of size at most ℓ and a value b such that $I_S^b(f) \geq 1 - \epsilon$.

The seminal work of Kahn, Kalai and Linial introduced discrete Fourier-analytic techniques to the study of influences. Their main theorem, known as the KKL inequality, states that over the uniform measure, every unbiased Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ has an influential variable. Formally, there exists k such that $I_k(f) \geq \Omega(\frac{\alpha \log n}{n})$ when $\alpha \leq \mathbb{E}[f(x)] \leq 1 - \alpha$. Let $b \in \{0,1\}$ satisfy $\Pr[f(x) = b] \geq \epsilon$. Then repeated applications of the KKL inequality imply the existence of a set S with $|S| = O_\epsilon\left(\frac{n}{\log n}\right)$ such that $I_S^b(f) \geq 1 - \epsilon$. In particular, there are no $\omega_\epsilon(n/\log n)$-resilient functions over the uniform distribution.

The above argument shows that unless f is already very biased towards 0 or 1, one can pick any $b \in \{0,1\}$ and find a small coalition S that can bias f towards b. However, this is no longer true if we consider general product distributions.

▶ **Example 3.** Consider the p-biased distribution μ_p^n over $\{0,1\}^n$, i.e. each coordinate is 1 with probability p. Set $p = 1/n$ and let f be the OR function $\bigvee_{i=1}^n x_i$. Obviously, $\mathbb{E}[f] = 1-(1-p)^n \approx 1 - \frac{1}{e}$, and yet for every S with $|S| = o(n)$, we have $I_S^0(f) = 1-(1-p)^{n-|S|} \approx 1-\frac{1}{e}$. In other words, despite the fact that the expected value of the function is bounded away from both 0 and 1, no small coalition can influence the output of the function towards 0. However, this is not a counterexample to Theorem 1 because any set S with $|S| = 1$ satisfies $I_S^1(f) = 1$, and thus the function is not even 1-resilient.

As the above example illustrates, part of the difficulty of generalizing the coalition theorem of KKL is to figure out which $b \in \{0,1\}$ to bias towards.

Using the notation $I_S^b(f)$, Theorem 1 can be restated as follows.

▶ **Theorem 4** (Theorem 1 reformulated). *Let $f\colon \{0,1\}^n \to \{0,1\}$ be a function over a product distribution μ. There exists a set S of size $O_\epsilon(\frac{n \log\log n}{\log n})$ such that $I_S^b(f) \geq 1-\epsilon$ for some $b \in \{0,1\}$.*

▶ Remark 5. To simplify the statement, in Theorem 4, we did not explicitly state the dependence of $|S|$ on ϵ. Our proof yields the bound $|S| = O(\frac{\log(1/\epsilon)n}{\epsilon \log n} + \frac{n \log\log n}{\epsilon \log n})$.

Continuous cube and a conjecture of Friedgut. The Bernoulli distribution on $\{0,1\}$ with parameter p can be embedded in the continuous interval $[0,1]$ via the measure-preserving map $\sigma\colon [0,1] \to \{0,1\}$ defined as $\sigma(x) = 1$ if and only if $x \geq 1-p$. By taking the product of these maps, for every product probability measure μ on $\{0,1\}^n$, we obtain a measure-preserving map $\sigma_\mu\colon [0,1]^n \to \{0,1\}^n$. As a result, every function $f\colon (\{0,1\}^n, \mu) \to \{0,1\}$ naturally corresponds to a function $\overline{f}\colon [0,1]^n \to \{0,1\}$ defined by $\overline{f} = f \circ \sigma_\mu$. Note that $I_S^b[\overline{f}] = I_S^b[f]$, for every $S \subseteq [n]$ and $b \in \{0,1\}$. Thus, a more general setting for studying resilience is the set of measurable functions $f\colon [0,1]^n \to \{0,1\}$. Indeed, Bourgain et al [4] proved a generalization of the KKL inequality, but erroneously claimed that as a corollary, if $\epsilon \leq \mathbb{E}[f]$, then $I_S^1[f] \geq 1-\epsilon$ for a set S of size $|S| = o_\epsilon(n)$. Interestingly, Example 3, which was introduced in the same paper to demonstrate that the proof of the KKL inequality breaks down for the continuous cube, is also a counterexample to this false claim. Friedgut [9] pointed out this error, and suggested the following tantalizing conjecture to replace the false statement[1].

▶ **Conjecture 6** ([9]). *Let $f\colon [0,1]^n \to \{0,1\}$ be a measurable function. There exists a set S of size $o_\epsilon(n)$ such that $I_S^b(f) \geq 1-\epsilon$ for some $b \in \{0,1\}$.*

A standard compression argument shows that it suffices to prove this conjecture for increasing functions, and indeed the original form of the conjecture is stated for increasing functions. Furthermore, by discretization, the statement can be further reduced to functions $f\colon \{1,\dots,n^2\}^n \to \{0,1\}$, where the domain is endowed with the uniform measure. Note that this form of the conjecture corresponds to resilience of one-round collective coin-flipping protocols where each player is allowed to send $\log n$-bit messages.

The above discussion show that, qualitatively, Conjecture 6 is a generalization of Theorem 4, and thus our theorem can be considered as a step towards resolving Friedgut's conjecture. However, our techniques and ideas seem to fall short of proving the full conjecture.

[1] Nati Linial told the last author about this error and conjecture years earlier, but as far as we know this is the first published account.

Beyond the Boolean range. As we discussed above, the coalition theorem of KKL says that if $\mathbb{E}[f(x) = b] \geq \epsilon$ then there exists a small coalition S such that $I_S^b(f) \geq 1 - \epsilon$. Now consider a function $h\colon \{0,1\}^n \to \mathcal{R}$ over the uniform distribution, where $\mathcal{R}$ is a constant size set. Pick any $b \in \mathcal{R}$ with $\Pr[h(x) = b] \geq \epsilon$. We can apply the KKL theorem to the function $f\colon \{0,1\}^n \to \{0,1\}$ defined as $f(x) = 1$ if and only if $h(x) = b$, and conclude that there is a coalition of size $O_\epsilon(n/\log n)$ with $I_S^b(f) \geq 1 - \epsilon$. This shows that over the uniform distribution, the general range $\mathcal{R}$ easily reduces to the Boolean range.

Unfortunately, the above reduction cannot be carried for general product distributions, for in Theorem 4, the final outcome b is dictated to us by the function. To illustrate the problem, consider a function $h\colon \{0,1\}^n \to \{0,1,2\}$ and a general product distribution μ. By bundling $\{1,2\}$ into a single value and applying Theorem 4, we can conclude that there exists a small coalition S such that either it biases the outcome of the function towards 0, or it biases the outcome towards being in $\{1,2\}$. If it is the former case, then we are done, but in the latter case, it is not clear how to proceed.

We know that except for the x's that belong to a small-measure set $\mathcal{E}$, the coalition can modify x in such a way that the outcome is in $\{1,2\}$. Now at first glance, it might seem that by applying Theorem 4 again, we can find another coalition T that can modify x further to refine the outcome to a single value $b \in \{1,2\}$, and thus conclude that for most x's the alliance $S \cup T$ can influence the outcome of the function towards b. Unfortunately, this is actually not the case. One reason is that S and T might intersect, and suggest conflicting modifications to x. Even if S and T are disjoint, the proof doesn't work: denoting by x' the vector obtained from $x \sim \mu$ after modification by S, we no longer have $x' \sim \mu$, and so there is no guarantee that on most inputs T can be applied successfully. In other words, $\Pr[x' \in \mathcal{E}]$ need not be small.

The above discussion shows that one cannot deduce the general case via the simple reduction that was outlined above for the uniform measure, but surely, as cumbersome as it may be, one can go over the proof and generalize every step from $\{0,1\}$ to $\{0,1,2\}$ by making small notational adjustments. This turns out not to be the case either! The proof of Theorem 4, rather unexpectedly, relies on the assumption that the function takes only two values. Indeed, to generalize the result to larger ranges, we had to introduce new ideas, and in particular a strengthening of Theorem 4 (see Theorem 15 below) that provides stronger control over the set $\mathcal{E}$ described above.

▶ **Theorem 7** (Single round, general range)**.** *Let $\mathcal{R}$ be a constant size set, and $f\colon \{0,1\}^n \to \mathcal{R}$ be a function over a product distribution μ. There exists a set S of size $O_\epsilon(\frac{n \log\log n}{\log n})$ such that $I_S^b(f) \geq 1 - \epsilon$ for some $b \in \mathcal{R}$.*

▶ Remark 8. At the heart of the proof of Theorem 7 there is an intermediate result, Theorem 15, which states that if all coordinates are biased, say $\Pr[x_i = 1] < \alpha$, then a random coalition of size $O(\log^3 |\mathcal{R}| \log\log |\mathcal{R}| \cdot \alpha n)$ biases the outcome with high probability. This intermediate result is an essential ingredient in the proof of our result on the multi-round setting, Theorem 2. For this application, it was crucial to obtain a bound which depends only polylogarithmically in $|\mathcal{R}|$.

Even though Theorem 4 is a special case of Theorem 7, we prove them separately, as Theorem 4 can be proven using a shorter and simpler proof.

Paper organization. We prove Theorem 1, which shows that all single-round protocols can be biased using coalitions of size $o(n)$, in Section 2. We prove Theorem 7, which generalizes the preceding result to arbitrary finite domains, in Section 3. We prove our main result, Theorem 2, which shows the multi-round protocols can be biased, in Section 4.

Due to space constraints, some of the proofs are available only in the full version of the paper, which is attached as an appendix.

2 Single Round Case: Proof of Theorem 1

In this section we prove Theorem 1, showing that, under any product distribution, there exists a small coalition which can bias the output of the function towards one of the outputs.

Note that in order to prove Theorem 1, without loss of generality, we can assume that $\Pr_{x\sim\mu}[x_i = 1] \leq \frac{1}{2}$ for every $i \in [n]$, as otherwise we can simply change the role of 0 and 1 for the i-th coordinate. In light of this observation, the coordinates can be divided into two sets: the small bias coordinates, satisfying $\Pr_{x\sim\mu}[x_i = 1] \in (\alpha_0, \frac{1}{2}]$, and the highly biased coordinates, satisfying $\Pr_{x\sim\mu}[x_i = 1] \leq \alpha_0$, where α_0 is a threshold that is chosen to be $\alpha_0 = \frac{1}{\log n}$.

Indeed, we first consider the case where all the coordinates are of the same type:

- *Small bias case*: $\Pr_{x\sim\mu}[x_i = 1] \in (\alpha_0, \frac{1}{2}]$ for every $i \in [n]$.
- *Large bias case*: $\Pr_{x\sim\mu}[x_i = 1] \leq \alpha_0$ for every $i \in [n]$.

We handle the large bias case in Section 2.1, which is the novel part of the proof. The small bias case is handled in Section 2.2 via a reduction to the previous work of Russell et al. [12]. Finally, in Section 2.3 we show how to combine the two cases to handle any product distribution μ, thus completing the proof of Theorem 1.

2.1 Large Bias Case

We will sometimes identify the subsets of $[n]$ with elements of $\{0,1\}^n$. For example, $S \sim \mu$ would mean that $S = \mathrm{supp}(x)$, where x is sampled according to μ. We construct the coalitions from a certain boosted form of μ.

▶ **Definition 9** (Boosted distribution). *For a positive integer t, we denote by $\mu^{(t)}$ the distribution of $x^1 \vee \cdots \vee x^t$, where $x^1, \ldots, x^t$ are i.i.d. random variables distributed according to μ.*

The large bias case of Theorem 1 follows from the following general proposition, that holds for distributions that are not necessarily product distributions.

▶ **Proposition 10.** *Consider $f\colon (\{0,1\}^n, \mu) \to \{0,1\}$, where μ is an* arbitrary *probability measure, and let $S \sim \mu^{(k)}$, where $k \approx \frac{10 \log \frac{1}{\epsilon}}{\epsilon}$. For some $b \in \{0,1\}$, we have $\Pr_S[I^b_S[f] > 1-\epsilon] > 1-\epsilon$.*

Note that Proposition 10 implies (via a straightforward concentration bound) that in the large bias case, there exists a random coalition of expected size at most $k\alpha_0 n$ such that $\Pr_S[I^b_S[f] > 1-\epsilon] > 1-\epsilon$. As it will become apparent later, for the application to the multiround setting, it is important that in Proposition 10 the set S is chosen randomly from a distribution that does not depend on f.

Proposition 10 is a direct consequence of the following lemma, as for the Boolean range $\{0,1\}$, either Condition I holds for $b = 0$ or Condition II holds for $b = 1$. This, however, is not true for larger $\mathcal{R}$.

▶ **Lemma 11** (Key Lemma for Single Round). *Consider $f\colon (\{0,1\}^n, \mu) \to \mathcal{R}$, where μ is an* arbitrary *probability measure. Let $x, y \sim \mu$, $S \sim \mu^{(k)}$, where $k \approx \frac{10 \log \frac{1}{\epsilon}}{\epsilon}$. For $b \in \mathcal{R}$, either of*

- *Condition I:* $\Pr_x[\Pr_y[f(x \vee y) = b] \geq 1-\epsilon] > \epsilon/2$, *or*
- *Condition II:* $\Pr_x[\Pr_y[f(x \vee y) = b] \geq \epsilon] \geq 1 - \epsilon/2$,

implies $\Pr_S[I^b_S[f] > 1-\epsilon] > 1-\epsilon$.

Proof. Let $S = \mathrm{supp}(y^1 \vee \cdots \vee y^k)$, where $y^1, \ldots, y^k \sim \mu$ are drawn independently. Let the sets X^I and X^{II} denote the following subsets of the input space $\{0,1\}^n$:

$$X^I = \{x : \Pr_y[f(x \vee y) = b] \geq 1 - \epsilon\},$$
$$X^{II} = \{x : \Pr_y[f(x \vee y) = b] \geq \epsilon\}.$$

If we are in the Type I setting, then $\Pr\left[X^I\right] > \epsilon/2$, and so

$$\Pr_S[S \text{ contains some } x \in X^I] \geq 1 - \Pr\left[y^1, \ldots, y^k \notin X^I\right] \geq 1 - \left(1 - \frac{\epsilon}{2}\right)^k > 1 - \epsilon.$$

Note that if there exists $z \in X^I$ which is a subset of S then for every x, the two elements x and $x \vee z$ can only differ on a subset of S, and thus

$$I^b_S(f) \geq \Pr_x[f(x \vee z) = b] > 1 - \epsilon.$$

Now we turn our attention to Condition II. In this case, we shall prove that $\Pr_S[I^b_S[f] < 1 - \epsilon] \leq \epsilon$. Indeed,

$$\begin{aligned}\Pr_S[I^b_S[f] < 1 - \epsilon] &\leq \Pr_{y^1,\ldots,y^k}\left[\Pr_x[\exists i \in [k],\ f(x \vee y^i) = b] < 1 - \epsilon\right] \\ &= \Pr_{y^1,\ldots,y^k}\left[\Pr_x[\forall i \in [k],\ f(x \vee y^i) \neq b] \geq \epsilon\right]. \qquad (1)\end{aligned}$$

To bound the last probability, for $x \in \{0,1\}^n$ let E_x denote the event that for every $i \in [k]$, $f(x \vee y^i) \neq b$. Then

$$\Pr_x[E_x] \leq \Pr_x[x \notin X^{II}] + \Pr_x[E_x \ \wedge\ x \in X^{II}] \leq \frac{\epsilon}{2} + \Pr_x[E_x \mid x \in X^{II}].$$

Plugging this into (1), we get

$$\Pr_S[I^b_S[f] < 1 - \epsilon] \leq \Pr_{y^1,\ldots,y^k}[\Pr_x[E_x] \geq \epsilon] \leq \Pr_{y^1,\ldots,y^k}\left[\Pr_x[E_x \mid x \in X^{II}] \geq \frac{\epsilon}{2}\right] \leq \frac{1}{(\epsilon/2)} \Pr_{y^1,\ldots,y^k,x}[E_x \mid x \in X^{II}].$$

Since $k \approx \frac{10 \log \frac{1}{\epsilon}}{\epsilon}$,

$$\Pr_{x,y^1,\ldots,y^k}[E_x \mid x \in X^{II}] \leq (1 - \epsilon)^k \leq \frac{\epsilon^2}{2},$$

showing that

$$\Pr_S[I^b_S[f] < 1 - \epsilon] \leq \frac{1}{(\epsilon/2)} \cdot \frac{\epsilon^2}{2} \leq \epsilon.$$ ◀

2.2 Small Bias Case

To handle the small bias case for the sake of proving Theorem 1, one can simply repeat the argument of Kahn et al. [10], i.e. iteratively select influential variables and set them to the value that increases the probability of success. However, for the purposes of our results in the multi-round setting, we will need to prove a stronger result, which states that even if the coalition is selected *randomly*, there is a nontrivial chance of succeeding in influencing the outcome.

▶ **Lemma 12.** *Let $n \in \mathbb{N}$, $\gamma \in (0, 1/2)$ and $m \leq n$. Let $f\colon (\{0,1\}^n, \mu) \to \{0,1\}$, where μ is a product distribution such that for all i, $1/n < \alpha \leq \mathbb{E}[x_i] \leq 1/2$. Assume $m > \frac{n \log 1/\alpha}{2\gamma \log n}$. If $\mathbb{E}[f] \geq \gamma$ then*

$$\Pr_{S \subseteq [n]\colon |S|=m} \left[I_S^1[f] \geq 1 - \gamma\right] > \frac{1}{2} \left(\frac{m}{4n \log 1/\alpha}\right)^{2^{\frac{80n \log 1/\alpha}{m\gamma}}}.$$

Proof. The result is proved in [12] for constant α. The general case follows by representing a μ_p distributed variable as an AND of t variables that are distributed according μ_c, where $c \approx 1/2$ and $p = c^t$. The complete details appear in the full version of the paper. ◀

2.3 Finishing the Proof: Combining the Two Cases

We are ready to finish the proof of Theorem 1. Let $A := \{i : \Pr_{x \sim \mu}[x_i = 1] \in (\alpha_0, \frac{1}{2}]\}$, and recall that $\alpha_0 = \frac{1}{\log n}$. For every $y \in \{0,1\}^A$, define $f_y\colon \{0,1\}^{[n]\setminus A} \to \{0,1\}$ as $f_y(z) := f(y,z)$. By Proposition 10, for every $y \in \{0,1\}^A$, there exists $b := b_y \in \{0,1\}$ such that

$$\Pr_{S \sim \mu_{[n]\setminus A}^{(k)}} \left[I_S^b[f_y] > 1 - \frac{\epsilon}{2}\right] > 1 - \frac{\epsilon}{2},$$

where $k = O\left(\frac{\log(1/\epsilon)}{\epsilon}\right)$. Moreover, since every variable i in $[n]\setminus A$ satisfies $\mathbb{E}[x_i] \leq \alpha_0 = 1/\log n$, Chernoff's bound gives,

$$\Pr_{S \sim \mu_{[n]\setminus A}^{(k)}} \left[|S| \geq \frac{C \log(1/\epsilon) n}{\epsilon \log n}\right] \leq \exp\left(-\Omega\left(\frac{\log(1/\epsilon) n}{\epsilon \log n}\right)\right) \leq \frac{\epsilon}{2},$$

for some constant $C > 0$. Therefore,

$$\Pr_{S \sim \mu_{[n]\setminus A}^{(k)}} \left[I_S^b[f_y] > 1 - \frac{\epsilon}{2} \text{ and } |S| \leq \frac{C \log(1/\epsilon) n}{\epsilon \log n}\right] > 1 - \epsilon.$$

It follows that

$$\mathop{\mathbb{E}}_{S \sim \mu_{[n]\setminus A}^{(k)}} \left[\Pr_{y,b}\left[I_S^b[f_y] \geq 1 - \frac{\epsilon}{2}\right]\right] > \frac{1-\epsilon}{2} \geq \frac{1}{4},$$

assuming without loss of generality that $\epsilon \leq 1/2$. Hence, there exists a fixed $b_0 \in \{0,1\}$ and a set S, satisfying $|S| \leq \frac{C \log(1/\epsilon) n}{\epsilon \log n}$ and

$$\Pr_y \left[I_S^{b_0}[f_y] \geq 1 - \frac{\epsilon}{2}\right] \geq \frac{1}{4}.$$

Now, define $h\colon \{0,1\}^n \to \{0,1\}$ as $h(y) = 1$ if and only if $I_S^{b_0}[f_{y|_A}] \geq 1 - \epsilon/2$. Note that, h depends only on A variables. The above inequality asserts that $\mathbb{E}[h] \geq \frac{1}{4}$. Since, A contains only small bias variables, we may apply Lemma 12. Namely, there is $m = O(\frac{n \log\log n}{\epsilon \log n})$ such that

$$\Pr_{T \subseteq [n]\colon |T|=m} \left[I_T^1[h] \geq 1 - \frac{\epsilon}{2}\right] > 0.$$

Thus, there exists a coalition $T \subseteq A$ of size $O(\frac{n \log\log n}{\epsilon \log n})$ of players that can bias h towards 1. In other words, T can bias y towards cases where S is able to bias f_y towards b_0. As a result,

$$I_{S \cup T}^{b_0}[f] \geq \left(1 - \frac{\epsilon}{2}\right)\left(1 - \frac{\epsilon}{2}\right) > 1 - \epsilon.$$

Moreover, $|S \cup T| = O\left(\frac{n \log\log n}{\epsilon \log n} + \frac{\log(1/\epsilon) n}{\epsilon \log n}\right)$, as desired.

3 The Larger Range: Proof of Theorem 7

As outlined in the introduction, there are certain obstacles to generalizing Theorem 1 to larger ranges. In particular, the fact that the set $\mathcal{E}$ of all the points on which the coalition fails in Theorem 1 is of small measure does not seem to be a sufficiently strong condition for an induction to go through. We will need to prove a strengthening of Theorem 1 which shows that not only is $\mathcal{E}$ of small measure, but it is also small if it is measured via the boosted distributions introduced in Definition 9. This leads to a more general definition of influence.

▶ **Definition 13** (Boosted influence towards value)**.** *Let $\mathcal{R}$ be an arbitrary set. For a function $f\colon \{0,1\}^n \to \mathcal{R}$ and $b \in \mathcal{R}$, define $I_S^{b,t}(f) = \Pr_{x\sim\mu^{(t)}}[b \in f(B_S(x))]$.*

Note that $I_S^b(f) = I_S^{b,1}(f)$, as $\mu^{(1)} = \mu$.

The following lemma generalizes Lemma 11, as we spell out in its corollary.

▶ **Lemma 14.** *Consider $f\colon \{0,1\}^n \to \mathcal{R}$, let $t \in \mathbb{N}$, and let $S \sim \mu^{(k)}$, where $k = \frac{10t}{\delta}\log\frac{t}{\epsilon}$. Let $b \in \mathcal{R}$. We have $\Pr_S[\forall \ell \le t,\ I_S^{b,\ell}(f) \ge 1-\epsilon] \ge 1-\epsilon$, if any of the following two cases hold:*

- *Case I: For some $s \le t$, $\Pr_{u\sim\mu^{(s)}}[\Pr_{v\sim\mu^{(t)}}[f(u\vee v)=b] \ge 1-\epsilon/2] \ge \delta$.*
- *Case II: For every $s \le t$, $\Pr_{u\sim\mu^{(s)}}[\Pr_{v\sim\mu^{(t)}}[f(u\vee v)=b] \ge \delta] \ge 1-\frac{\epsilon}{2}$.*

Proof. The complete proof can be found in the full version of the paper. ◀

We can now state the main result of this section. The failure output † allows the inductive proof of Theorem 15, as well as our multi-round result, Theorem 17, to go through, as we explain in Section 4.

▶ **Theorem 15.** *Let $f\colon \{0,1\}^n \to \{0,1\}^m \cup \{\dagger\}$, and suppose that $\{0,1\}^n$ is endowed with a probability measure μ. Let t be a positive integer, and let $S \sim \mu^{(k)}$, where $k = k(m,t,\epsilon) = O(tm^3\epsilon^{-2}\log\frac{tm}{\epsilon})$. If $\Pr_{\mu^{(\ell)}}[\dagger] < \frac{\epsilon^4}{2^{16}}$ for every $\ell \le 2t$, then there exists a value $b \in \{0,1\}^m$ such that $\Pr_S\left[\forall \ell \le t,\ I_S^{b,\ell}(f) \ge 1-\epsilon\right] \ge 1-\epsilon$.*

Proof. The complete proof can be found in the full version of the paper. ◀

Theorem 7 follows from Theorem 15 using an argument very similar to that in Section 2.3, as we show in the full version of the paper.

4 Multi-Round Protocols: Proof of Theorem 2

In this section we will prove Theorem 2, showing that even in the multi-round setting, there are no protocols that are resilient against all coalitions of size $o(n)$. As described in the introduction, here at every round, first the players who are not in the coalition broadcast their random messages, and then the players in the coalition decide and broadcast their messages in an adversarial manner. The outcome is decided by a function $f\colon (\{0,1\}^n)^r \to \{0,1\}$.

To be more formal, let $\mu = \mu_1 \times \cdots \times \mu_r$ be a product distribution over $\{0,1\}^{rn} \equiv (\{0,1\}^n)^r$, where each μ_i is a product distribution over $\{0,1\}^n$. An (n,r) *coin-flipping protocol* is simply a map $f\colon (\{0,1\}^n)^r \to \{0,1\}$. Such a protocol is executed in r rounds. In the presence of a coalition $B \subseteq [n]$ of bad players, the protocol operates as follows. In round i, the players in $[n]\backslash B$ select $\alpha^i \in \{0,1\}^{[n]\backslash B}$ according to $\mu_i|_{[n]\backslash B}$. Then, the bad players B choose their values depending on $\alpha^1,\ldots,\alpha^i$. Formally, an (n,r)-strategy for a set $B \subseteq [n]$ is a sequence $\pi = (\pi_1,\ldots,\pi_r)$ of functions where $\pi_i\colon (\{0,1\}^{[n]\backslash B})^i \to \{0,1\}^B$. The function π_i describes the choice of bits the bad players make in the i-th round based on the broadcasted bits of the good players in the first i rounds.

▶ **Definition 16.** *Let $f\colon (\{0,1\}^n)^r \to \{0,1\}$ be an (n,r) coin-flipping protocol, and let μ be a product distribution on $(\{0,1\}^n)^r$. Given a Boolean value $b \in \{0,1\}$, a set $B \subseteq [n]$, and an (n,r)-strategy π for the bad players B,*

- *$I^b_{\pi,B}(f)$ is the probability that f outputs b given that the bad players B follow π.*
- *$I^b_B(f) := \sup_\pi\{I^b_{\pi,B}(f)\}$ is the influence of B on f towards b.*

Our goal is to show that there exists a coalition B of size $o(n)$ such that $I^b_B(f) \geq 1-\epsilon$ for some $b \in \{0,1\}$. For the moment, let us assume that we have only two rounds, and let $f(x,y)$ denote the protocol, where $x,y \in \{0,1\}^n$ correspond to the inputs in the first and the second round respectively. Let us also denote $f_x(y) \colon = f(x,y)$.

Russell et al. [12] proof of the uniform case. Pick $b \in \{0,1\}$ such that $\Pr[f(x,y)=b] \geq \frac{1}{2}$. Let $\mathcal{A}$ be the set of all $x \in \{0,1\}^n$ that satisfy $\Pr_y[f_x(y)=b] \geq \frac{1}{4}$, and note that $\Pr_x[x \in \mathcal{A}] \geq \frac{1}{4}$. By Lemma 12 of Russell et al. [12], for every $x \in \mathcal{A}$, a random coalition S can bias f_x towards b, with a probability δ that is not too small. Since S is chosen randomly and independently of x, it follows that there exists a fixed coalition S_0 that can bias f_x for at least a δ fraction of $x \in \mathcal{A}$, and thus for at least a $\frac{\delta}{4}$ fraction of $\{0,1\}^n$. Let $\mathcal{A}' \subseteq \mathcal{A} \subseteq \{0,1\}^n$ denote the set of such x. If $x \in \mathcal{A}'$, the coalition S_0 is able to bias the protocol by only interfering in the second round. The set $\mathcal{A}'$ is of measure at least $\frac{\delta}{4}$, which is not too small. Thus, applying Lemma 12 again, we can find another coalition $T_0 = o(n)$ which can modify most x's to fall in $\mathcal{A}'$. Now we can form the desired coalition $B = T_0 \cup S_0$: In the first round, the players in T_0 try to modify x into an element in $\mathcal{A}'$, and if they succeed, in the second round, the players in S_0 interfere to change the outcome of the protocol into b. This argument easily generalizes to more rounds.

We point out that it was crucial for the above argument, that the distribution of S in Proposition 10 is independent of f.

What fails for the general product distributions. Consider $f(x,y)$ over $\mu = \mu_1 \times \mu_2$, where μ_1 is *highly biased*, and μ_2 is the *uniform distribution*. Similar to the previous paragraph, we can find a set $\mathcal{A}' \subseteq \{0,1\}^n$, a value $b \in \{0,1\}$, and a small coalition S_0 such that $\Pr_{x\sim\mu_1}[x \in \mathcal{A}'] \geq \frac{\delta}{4}$, and moreover for every $x \in \mathcal{A}'$, the coalition S_0 is able to influence f towards b by interfering only in the second round. Now, if we are to follow the argument of Russell et al., we would like to find a set T_0 of players to add to the coalition such that, with high probability, T_0 is able to modify a random $x \sim \mu_1$ into an element in $\mathcal{A}'$. We could then conclude that $B = S_0 \cup T_0$ can bias f towards b.

Unfortunately, Proposition 10, the highly-biased counterpart of Lemma 12, only guarantees the existence of a small coalition T_0 which *either* modifies a random $x \sim \mu$ into being in $\mathcal{A}'$ *or* modifies a random $x \sim \mu$ into *not* being in $\mathcal{A}'$; in the latter case, the coalition T_0 is useless. As Example 3 shows, this is not just a caveat of the proof of the proposition. To be more concrete, suppose μ_1 is the $\frac{1}{n}$-biased distribution, and $\mathcal{A}'$ consists only of the single element $x = \vec{0}$. Even though $\Pr[x \sim \mathcal{A}] \geq \frac{1}{4}$, there is no coalition of size $o(n)$ which can, with high probability, modify a random $x \sim \mu_1$ into an element in $\mathcal{A}'$. On the other hand, even a single player can modify every x into an element outside $\mathcal{A}'$, but this is not helpful for our purposes, as the elements outside $\mathcal{A}'$ are the elements that S_0 cannot handle.

How to overcome the problem. Consider the same setting as in the previous paragraph. We know that for every x, a random coalition S of size $o(n)$ succeeds in influencing f_x towards one of the outputs, with probability at least δ, where δ is not too small. Instead of

picking one S_0, we select a collection of coalitions that cover almost all x's. More precisely, we find $S_1, \ldots, S_M$ and $b_1 \ldots, b_M$, where $M = O_\delta(1)$, such that apart from a small set of exceptions $\mathcal{E} \subseteq \{0,1\}^n$, every f_x can be biased towards some b_i using the coalition S_i.

Let $h\colon \{0,1\}^n \to \{1,\ldots,M\} \cup \{\dagger\}$ be defined as follows: If $x \in \mathcal{E}$, then $h(x) = \dagger$, and otherwise $h(x)$ is equal to some i such that S_i can bias f_x towards b_i. This brings us to the non-Boolean range case, which was analyzed in Section 3. We can apply Theorem 15 to find a coalition T that can influence h towards one of the values in $j \in \{1,\ldots,M\}$. Now $B = T \cup S_j$ will be our desired coalition. With high probability, in the first round the players in T can successfully modify a random element x into an element x' with $h(x') = j$, and then in the second round, the players in S_j can modify x' to bias the outcome towards b_j. This is the main new idea used below to resolve the multi-round setting over arbitrary distributions.

Theorem 2 is a consequence of the following more elaborate theorem which states that for sufficiently large n, and $r \leq \log^\star n/5$, no (n,r) protocol over an arbitrary product distribution is resilient against coalitions of $m = o(n)$ bad players.

▶ **Theorem 17.** *For every $\epsilon > 0$, and integers $n > 0$, and $r < \log^\star n/5$, there exists $\delta = \Omega(\frac{1}{\log(1/\epsilon)^r n})$, and $m = o(n)$ such that the following holds. For every $f\colon (\{0,1\}^n)^r \to \{0,1\}$ over a product distribution μ, there exists $b \in \{0,1\}$, such that the corresponding r-round protocol satisfies $\Pr_{S\sim\nu}[I^b_S(f) \geq 1-\epsilon] \geq \delta_r$, where ν is a distribution on $\binom{[n]}{m}$ that depends only μ but not on f. To be more precise, one can take $m = O_\epsilon\left(\frac{n\cdot r\cdot 4^r}{\log^{(4r)} n}\right) = O_\epsilon\left(\frac{n(\log^\star n)^2}{\log^{(4r)} n}\right)$.*

Proof. The complete proof can be found in the full version of the paper. ◀

5 Concluding Remarks and Open Problems

- Perhaps the most interesting next step is proving limitations for resilience of protocols where players may send longer messages. As was discussed below Conjecture 6, it is conjectured that even when the players are allowed to broadcast arbitrarily long messages, only resilience against coalitions of size $o(n)$ is possible. This question has also been studied in the multi-round setting [12, 13, 8]. In this case, if the players are allowed $\log n$-bit messages, we know of $(\log^\star n + O(1))$-round protocols resilient against coalitions of size $(1/2-\epsilon)n$ [13, 8]. On the other hand, Russell et al. [12] showed that $\Omega(\log^\star n)$ rounds are necessary if we have the added restriction that in the i-th round the players are allowed messages of length $(\log^{(2i-1)} n)^{1-o(1)}$. Strengthening this impossibility result to messages of length $\Omega(\log n)$ is another interesting problem that remains open.
- The key qualitative point of Theorems 1 and 2 is that there always exists a coalition of size $o(n)$ that can bias the outcome of the protocol towards a particular value. Interestingly, we are not aware of a simpler proof of this weaker qualitative statement even in the case of the uniform measure. The proof techniques introduced in this paper for the highly biased coordinates are more combinatorial and probabilistic in nature; however, the less biased coordinates are ultimately handled by the Fourier-analytic proof of [10]. These Fourier analytic arguments are *hard* in nature, in the sense that their purpose is to give effective bounds. It would be interesting to find more intuitive combinatorial proofs for these statements, potentially at the cost of obtaining less effective bounds, or by appealing to *soft analytic tools* such as compactness, at the cost of obtaining no quantitative bounds. We refer the reader to Terence Tao's blog post [14] for a discussion about hard and soft analysis.
- Over the uniform distribution, Kahn et al. [10] proved that there exists no Boolean function that is ϵ-resilient against coalitions of size $\omega_\epsilon\left(\frac{n}{\log n}\right)$. In this work we show that a similar bound of $\omega_\epsilon\left(\frac{n\log\log n}{\log n}\right)$ on resilience holds over arbitrary product distributions.

A natural question is whether the $\log \log n$ in our bound necessary. However, even in the uniform setting there is work left to be done. Here, the best known constructions guarantee resilience against coalitions of size $O(\frac{n}{\log^2 n})$ [11, 1], which is a factor of $\log n$ off from the impossibility result of Kahn, Kalai, and Linial.

Abstract

Perturbed graphic matroids are binary matroids that can be obtained from a graphic matroid by adding a noise of small rank. More precisely, an r-rank perturbed graphic matroid M is a binary matroid that can be represented in the form $I + P$, where I is the incidence matrix of some graph and P is a binary matrix of rank at most r. Such matroids naturally appear in a number of theoretical and applied settings. The main motivation behind our work is an attempt to understand which parameterized algorithms for various problems on graphs could be lifted to perturbed graphic matroids.

We study the parameterized complexity of a natural generalization (for matroids) of the following fundamental problems on graphs: Steiner Tree and Multiway Cut. In this generalization, called the Space Cover problem, we are given a binary matroid M with a ground set E, a set of *terminals* $T \subseteq E$, and a non-negative integer k. The task is to decide whether T can be spanned by a subset of $E \setminus T$ of size at most k.

We prove that on graphic matroid perturbations, for every fixed r, Space Cover is fixed-parameter tractable parameterized by k. On the other hand, the problem becomes W[1]-hard when parameterized by $r + k + |T|$ and it is NP-complete for $r \leq 2$ and $|T| \leq 2$.

On cographic matroids, that are the duals of graphic matroids, Space Cover generalizes another fundamental and well-studied problem, namely Multiway Cut. We show that on the duals of perturbed graphic matroids the Space Cover problem is fixed-parameter tractable parameterized by $r + k$.

1 Introduction

In this paper we develop parameterized algorithms on low-rank perturbations of graphic matroids and their duals. These matroids and their matrices naturally appear in various settings. For example, in the emerging Matroid Minors Project of Geelen, Gerards, and Whittle [15], perturbed matroids play a significant role in the characterization of proper minor-closed classes of binary matroids. More precisely, for each proper minor-closed class $\mathcal{M}$ of binary matroids, there exists a nonnegative integer r such that every sufficiently highly connected matroid $M \in \mathcal{M}$, is either a perturbation of graphic or cographic matroid. In other words, there exist matrices $I, P \in \mathrm{GF}(2)^{\ell \times n}$ such that I is the incidence matrix of a graph, the rank of P is at most r, and either M or its dual M^* is represented by $I + P$. Another example of closely related concept is the robust Principal Component Analysis (PCA), a popular approach to robust subspace learning and tracking by decomposing the data matrix into low-rank and sparse matrices. Here data matrix M is assumed to be a superposition of a low-rank perturbation component P and a sparse component I, that is, $M = I + P$. See Candès et al. [4], Wright et al. [24], and Chandrasekaran et al. [5] for further references on robust PCA. In particular, one of the well-studied, see e.g. [22, 26], of the variants of robust PCA is when the structure of the sparse matrix I is imposed from the structure of some graph. Perturbed matroids also come naturally in the settings when a structural input is corrupted by a noise. In graph algorithms, one of the questions studied in the literature about corrupted inputs is – what happens to special graph classes when they are perturbed adversarially? For example, Magen and Moharrami [19], and Bansal, Reichman, Umboh [2], studied approximation algorithms on noisy minor-free graphs, which are the graphs obtained from minor-free graphs by corrupting a fraction of edges and vertices.

Our results. We work with the following classes of binary matroids. A binary matroid M such that M can be represented in the form $I + P$, where I is the incidence matrix of some graph and P is a binary matrix of rank at most r, is called the *r-rank perturbed graphic matroid*. Similarly, when the dual matroid M^* can be represented as $I + P$ for some incidence matrix I and r-rank matrix P, we refer to M as to an *r-rank perturbed cographic matroid*.

In this paper we study parameterized complexity on binary perturbed matroids of the following generic problem. Let us remind that in a matroid M, a set F spans T, denoted by $T \subseteq \mathrm{span}(F)$, if the sets F and $T \cup F$ are of the same rank.

Space Cover
Input: A binary matroid M with a ground set E, a set of *terminals* $T \subseteq E$, and a non-negative integer k.
Question: Is there a set $F \subseteq E \setminus T$ with $|F| \leq k$ such that $T \subseteq \mathrm{span}(F)$?

In other words, Space Cover is the problem of covering a given set of vectors T over $\mathrm{GF}(2)$ by a minimum-dimension subspace of the space generated by vectors from $E \setminus T$. Space Cover encompasses various problems arising in different domains, such as coding theory, machine learning, and graph algorithms. For example, Space Cover is a natural generalization of Matroid Girth, the problem of finding a minimum set of dependent

elements in a matroid. Matroid Girth can be reduced to Space Cover by computing for each element t of M a minimum set of elements of the remaining part of the matroid that covers $T = \{t\}$.

On graphs (equivalently, special classes of binary matroids, namely graphic and cographic matroids), Space Cover generalizes well-studied optimization problems Steiner Tree and Multiway Cut. Various algorithmic techniques were developed for these problems, see e.g. [7], and it is very interesting to see which of these techniques, if any, can be lifted to matroids.

We obtain the following results about the complexity of Space Cover on r-rank perturbed matroids. (In all these results we assume that representation of r-rank perturbed matroid in the form $I + P$ is given.)

- Our first main algorithmic result (Theorem 1) states the following: On r-rank perturbed graphic matroids, for every fixed r, Space Cover is fixed-parameter tractable (FPT) when parameterized by k.
- We also show that a "weaker" parameterization makes the problem intractable. More precisely, we prove that on r-rank perturbed graphic matroids, Space Cover is W[1]-hard when parameterized by $r + k + |T|$ and the problem is NP-complete for $r \leq 2$ and $|T| \leq 2$ (see Theorems 3 and 4 respectively of [14]).
- Our second main algorithmic result (Theorem 2) concerns r-rank perturbed cographic matroids. This theorem states that Space Cover is FPT on r-rank perturbed cographic matroids when parameterized by $r + k$. We find it a bit surprising that the parameterized complexity of Space Cover is different on r-rank perturbed graphic and cographic matroids.

Previous work. Geelen and Kapadia [17] studied the problem of computing the girth of a binary r-rank perturbed matroid. (The girth of a matroid is the length of its shortest circuit.) Geelen and Kapadia have proved that the girth of an r-rank perturbed matroid is fixed-parameter tractable being parameterized by r. Let us note that while Space Cover generalizes Matroid Girth, our results are incomparable. In our FPT result for r-rank perturbed graphic matroids the parameter is k while the parameter r should be fixed. As our complexity lower bounds show, the requirement that r should be fixed and that k should be the parameter are, most likely, unavoidable. For binary matroids, Matroid Girth has several equivalent formulations. For example, it is equivalent to the Minimum Distance problem from coding theory, which asks for a minimum dependent set of columns in a matrix over GF(2). The complexity of this problem was open until 1997, when Vardy showed it to be NP-complete [23]. On the other hand, Geelen, Gerards and Whittle in [16] conjecture that for any proper minor-closed class $\mathcal{M}$ of binary matroids, there is a polynomial-time algorithm for computing the girth of matroids in $\mathcal{M}$. The parameterized version of the problem, namely Even Set, asks whether there is a dependent set $F \subseteq X$ of size at most k. The parameterized complexity of Even Set was a long-standing open question in the area, see e.g. [10], whose complexity was resolved only recently [3].

Space Cover on graphic and cographic matroids is a generalization of Steiner Tree and Multiway Cut, two very well-studied problems on graphs. By the classical result of Dreyfus and Wagner [12], Steiner Tree is fixed-parameter tractable (FPT) parameterized by the number of terminals T. Similar approach can be used to show that Space Cover is FPT on graphic matroids. On cographic matroids Space Cover is equivalent to the Restricted Edge-Subset Feedback Edge Set introduced by Xiao and Nagamochi [25] who also showed that the problem is FPT parameterized by k. Due to its connection to Multiway Cut, the NP-completeness result of Dahlhaus et al. [8] for Multiway Cut with three terminals implies that Space Cover is NP-hard even if $|T| = 3$ on cographic

matroids. Fomin et al. in [13] extended the results for Space Cover on graphic and cographic matroids to a more general class of binary matroids, namely, regular matroids, by providing an algorithm of running time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$. While the class of regular matroids is a proper minor-class of binary matroids, this class of matroids is incomparable to the class of perturbed matroids. It is also known that Space Cover is hard on general class of binary matroids: By the result of Downey et al. [11], Space Cover is W[1]-hard on binary matroids when parameterized by k even if restricted to the inputs with one terminal.

Organization of the paper. Due to space constraints, we only sketch the proofs of our main algorithmic results (Theorems 1 and 2) in Section 2. The detailed proofs of these theorems and our algorithmic lower bounds (Theorems 3 and 4) are given in the full version of the paper [14]. We conclude in Section 3 by stating some open problems.

2 Overview of Algorithmic Theorems

In this section, we give short descriptions of both of our algorithmic results. For standard graph and matroid-related terms, we refer to the books by Diestel [9] and Oxley [21]. We also give the formal definitions of graph and matroid-related terms in Section 3 of [14].

2.1 Perturbed Graphic Matroids

In this section, we give an overview of the proof of the first main result of the paper. The detailed proof is given in Section 4 of [14] version of the paper.

In this case, r-rank perturbed matroid M is represented by the perturbed incidence matrix $I(G)$ of a (multi) graph G. Formally we define the following problem.

Space Cover on Perturbed Graphic Matroid (Space Cover on PGM)
Input: A (multi) graph G with n vertices and m edges, an $(n \times m)$-matrix P over $GF(2)$ with $\text{rank}(P) \leq r$, a set of *terminals* $T \subseteq E$ where E is the set of columns of the matrix $A = I(G) + P$, and a non-negative integer k.
Question: Is there a set $F \subseteq E \setminus T$ with $|F| \leq k$ such that $T \subseteq \text{span}(F)$ in the binary matroid M represented by A?

▶ **Theorem 1.** *For any fixed constant r,* Space Cover on PGM *is solvable in time $k^{\mathcal{O}(k)} \cdot (n+m)^{\mathcal{O}(1)}$. In particular,* Space Cover on PGM *is* FPT *when parameterized by k whenever r is a constant.*

We underline that r is a constant here, that is, the constants hidden behind the big-O notation in the running time depend on r.

Before proceeding with the overview, it is useful to discuss how Space Cover on PGM is solvable when $r = 0$, i.e. on graphic matroids and what are the main challenges for solving the problem for $r > 0$. On graphic matroids Space Cover corresponds to the following problem. Given a set of terminal edges $T = \{e_1, e_2, \ldots, e_s\}$, we want to find a set of at most k edges $F \subseteq E \setminus T$ such that for every e_i, graph $G[F \cup e_i]$ has a cycle containing e_i. This can be seen as a variant of the Steiner Tree, and more generally, of the Steiner Forest problem. Here we are given a graph G, a collection of pairs of distinct non-adjacent terminal vertices $\{x_1, y_1\}, \ldots, \{x_s, y_s\}$ of G, and a non-negative integer k. The task is to decide whether there is a set $F \subseteq E(G)$ with $|F| \leq k$ such that for each $i \in \{1, \ldots, s\}$, graph $G[F]$ (which we can be assumed to be a forest) contains an (x_i, y_i)-path. The special case when $x_1 = x_2 = \cdots = x_s$, i.e. when edge set F is a tree spanning all demand vertices, is the Steiner Tree problem. To see that Steiner Forest is a special case of Space Cover,

we construct the following graph: For each $i \in \{1, \ldots, s\}$, we add a new edge $x_i y_i$ to G. Denote by G' the obtained graph and let T be the set of added edges and let $M(G')$ be the graphic matroid associated with G'. Then a set of edges $F \subseteq E(G)$ forms a graph containing all (x_i, y_i)-paths if and only if $T \subseteq \mathrm{span}(F)$ in $M(G')$.

Similar to Steiner Tree, Steiner Forest is fixed-parameter tractable parameterized by the number of terminals. This can be shown by applying a dynamic programming algorithm similar to the classical algorithm of Dreyfus and Wagner [12]. Notice that by [14, Theorem 4]), Space Cover on PGM is NP-complete when restricted to the instances with $r \leq 2$ and $|T| \leq 2$. This shows that for our problem the parameterization just by the number of terminals $|T|$ will not work; it also indicates that for matroids we should try a different approach. To show that Steiner Forest is FPT parameterized by the size k of the forest F, one can use the following idea. Since the size of F is at most k, there are $2^{\mathcal{O}(k)}$ non-isomorphic forests, so we can guess the structure of F. In other words, we can guess a forest H on at most k edges such that the solution F to Steiner Forest is isomorphic to H. Thus for each guess of H, the task is reduced to the following constraint variant of Subgraph Isomorphism: For given graph G and forest H, decide whether G contains a forest isomorphic to H and spanning all terminal vertices of G in the prescribed way. This problem can be solved by combining a color coding technique of Alon, Zwick, and Yuster [1] with dynamic programming.

This is exactly the approach we want to push forward for $r > 0$. However in this case reduction to constraint Subgraph Isomorphism is way more difficult. First, while perturbation matrix P is of bounded rank, adding it to $I(G)$ can change an unbounded number of its elements. On the other hand, since the rank of perturbation matrix P is bounded, we know that matrix P contains only a small number of different columns. Thus while adding P to $I(G)$ changes many elements of $I(G)$, the variety of these changes is bounded. We exploit this in order to guess the structure of a solution. Second, for graphic matroids, the way a forest H should be mapped into G is very clear – for every terminal element t, adding t to the solution should create a cycle containing t. This defines the constraints how the edges of the guessed solution should be connected to terminal edges and allows us to reduce the problem to a constraint variant of Subgraph Isomorphism. For $r > 0$, adding P to $I(G)$ completely destroys this nice property of the solution. Interestingly, the bounded rank of perturbation still allows us to establish the constraints expressed as parities of vertex degrees of a small number of vertices in G, coloring of edges of G, and some additional mappings. As a result, by a sequence of reductions, we succeed in reducing the original problem to a version of constraint Subgraph Isomorphism. Due to the nature of constraints, the solution to this problem also requires new ideas on top of color coding and dynamic programming.

We proceed with an overview of the proof of Theorem 1. The proof consists of two main parts. The first part is an FPT-Turing reduction from Space Cover to the following version of Subgraph Isomorphism, which we call Pattern Cover.

Pattern Cover
Input: A (multi) graph G with n vertices and m edges, a non-negative integer t that is a fixed constant, a function $\ell_G : E(G) \to \{1, 2, \ldots, t\}$, a non-negative integer k, a forest H with k vertices, a function $\ell_H : E(H) \to \{1, 2, \ldots, t\}$, a set $U \subseteq V(H)$ and an injective function $f : U \to V(G)$.
Question: Is there an injective homomorphism $g : V(H) \cup E(H) \to V(G) \cup E(G)$ such that (i) for all $e \in E(H)$, it holds that $\ell_H(e) = \ell_G(g(e))$, and (ii) for all $v \in U$, it holds that $g(v) = f(v)$?

In other words, we give a reduction that for an input (G, P, T, k) of Space Cover on PGM in time $k^{\mathcal{O}(k)} \cdot (n+m)^{\mathcal{O}(1)}$ constructs $k^{\mathcal{O}(k)} \cdot (n+m)^{\mathcal{O}(1)}$ instances of Pattern Cover such that (G, P, T, k) is a yes-instance if and only if at least one of the instances of Pattern Cover is.

The second part of the proof is an algorithm for solving Pattern Cover in time $k^{\mathcal{O}(k)} \cdot (n+m)^{\mathcal{O}(1)}$. The combination of the two parts provides the proof of the theorem.

In what follows, we provide a brief description of the FPT-Turing reduction. The reduction is done by a sequence of steps. For simplicity, here we explain how to construct a reduction in time $2^{\mathcal{O}(k^2)} \cdot (n+m)^{\mathcal{O}(1)}$; in Section 4 of [14] we provide more precise arguments that allow to reduce the running time.

We start by bounding $|T|$ by k. In case the columns in T are not linearly independent, we let T' denote a basis of T, and else we denote $T' = T$. We remove the columns in $T \setminus T'$ from $I(G)$ and P, and let (G', P', T', k) denote the resulting instance. Clearly, (G, P, T, k) is a yes-instance if and only if (G', P', T', k) is a yes-instance. Moreover, given a set X of size t of linearly independent vectors, for some $t \in \mathbb{N}$, there does not exist any set Y of vectors of size smaller than t such that $X \subseteq \text{span}(Y)$. Thus, in case $|T'| > k$, the input instance is a no-instance. Therefore, from now onwards we implicitly assume that $|T| \leq k$. We use the term *solution* to refer to any set $F \subseteq E \setminus T$ with $|F| \leq k$ such that $T \subseteq \text{span}(F)$ in the binary matroid M represented by A.

We define $\text{disc}(P) = \{C^1, \ldots, C^t\}$ to be the *set* of the distinct vectors that correspond to the columns in $\{P^e : e \in E(G)\}$ (we index the columns of A, $I(G)$ and P by the edges of G). Since the rank of P is r, it is easy to see that it has at most 2^r different columns, thus $t \leq 2^r$. We say that an edge $e \in E(G)$ is of *type* i, $1 \leq i \leq t$, if $P^e = C^i$ (as vectors). Given an edge $e \in E(G)$, we let $\text{type}(e)$ denote its type. Given a set of edges $E' \subseteq E(G)$, we denote $\text{type}(E', i) = |\{e \in E' : \text{type}(e) = i\}| \mod 2$. Towards to constructing the reduction to Pattern Cover, we define $\ell_G \colon E(G) \to \{1, \ldots, t\}$ by setting $\ell_G(e) = \text{type}(e)$.

We proceed by identifying a small graph that we can guess, and which will guide us how to find a solution. Let F be an inclusion-wise minimal solution; note that the minimality of F implies that F is an independent set. Consider the graph $H = G[\text{edges}(F)]$. The crucial structural lemma that we use states that H is "almost" a forest. More precisely, we show that H has at most 2^t cycles. To see it, assume that H has at least $2^t + 1$ cycles. There are at most t edge types in H. Hence by the pigeonhole principle, there are distinct sets of edges C_1 and C_2 of H that compose cycles and such that $\text{type}(C_1, i) = \text{type}(C_2, i)$ for all $i \in \{1, \ldots, t\}$. Then for the symmetric difference $C = C_1 \triangle C_2$, we obtain that $\text{type}(C, i) = 0$ for $i \in \{1, \ldots, t\}$. Thus the sum of the columns of P corresponding to edges of C is the zero-vector. Notice that since C is the union of cycles of H, the sum of the columns of matrix $I(G)$ corresponding to its edges is also the zero-vector. Hence, the sum of the corresponding vectors of A is also zero; and thus the corresponding set of columns of A, $\{A^e \mid e \in C\} \subseteq F$ is not independent. But this contradicts the minimality of F.

Let $\mathcal{H}$ denote the set of all non-isomorphic graphs with at most k edges, at most 2^t cycles, and no isolated vertices. Thus (G, P, T, k) is a yes-instance of Space Cover on PGM if and only if (G, P, T, k) has a solution isomorphic to some $H \in \mathcal{H}$. It is possible to show that all non-isomorphic graphs in $\mathcal{H}$ can be enumerated within time $2^{\mathcal{O}(k)}$. Therefore, we may explicitly examine each graph $H \in \mathcal{H}$ and check whether we have a solution F with subgraph of G, $G[\text{edges}(F)]$, isomorphic to H. In other words, we are looking for an injective

homomorphism $g : V(H) \cup E(H) \to V(G) \cup E(G)$[1] such that $F = \{A^e \mid e \in g(E(H))\}$ is a solution. This is an FPT-Turing reduction which reduces in time $2^{\mathcal{O}(k)}$ the solution of the original problem to the solution of $2^{\mathcal{O}(k)}$ new problems. We will use a less formal term *guess* to refer to such type of reductions. So we guess graph H.

Next, we observe that we can guess the types of edges of H. Since H has at most k edges, there are at most $t^k = 2^{\mathcal{O}(k)}$ distinct functions $\ell_H \colon E(H) \to \{1, \ldots, t\}$. Then for each guess of function ℓ_H, we want to decide whether there is an injective homomorphism g such that $\ell_G(g(e)) = \ell_H(e)$ for every $e \in E(H)$ and such that the set of columns F of A corresponding to the image of g, which is $F = \{A^e \mid e \in g(E(H))\}$, is a solution.

By definition, if $F = \{A^e \mid e \in g(E(H))\}$ is a solution, then for each $W \in T$, there is $F_W \subseteq F$ such that

$$W = \sum_{e \in F_W} A^e. \tag{1}$$

(The summations here are modulo 2.) We denote by $E_W = g^{-1}(\mathrm{edges}(F_W))$ the edge subset of H corresponding to F_W. Then by (1),

$$W = \sum_{e \in g(E_W)} (I^e(G) + P^e) = \sum_{e \in g(E_W)} I^e(G) + \sum_{e \in g(E_W)} P^e.$$

Each column P^e is equal to vector $C^{\ell_H(e)}$ from partition $\mathrm{disc}(P)$. Thus

$$W = \sum_{e \in g(E_W)} I^e(G) + \sum_{e \in E_W} C^{\ell_H(e)}. \tag{2}$$

Let $W' = W + \sum_{e \in E_W} C^{\ell_H(e)}$. The rows of matrix $I(G)$ and thus the elements of W' are indexed by the vertices of G. For $v \in V(G)$, we denote by w_v the element of W' indexed by v. Note that w_v is either 0 or 1. Let $V_W = \{v \in V(G) \mid w_v = 1\}$. Observe that V_W is uniquely defined by the choice of W and E_W. The crucial insight, whose proof is given in [14, Section 4], is that (2) and, therefore, (1) holds if and only if g acts as a bijection between V_W and vertices of $H[E_W]$ of odd degrees. This is the most important part of the reduction; it allows to reduce the algebraic requirement that every terminal vector should be in the span of the solution to constraints in the form of bijections, which can be guessed efficiently.

We exploit this property for the next set of guesses. For each $W \in T$, we guess a set $E_W \subseteq E(H)$ and construct V_W as described above. Since $|T| \leq k$ and $|E(H)| \leq k$, we have at most 2^{k^2} possible choices of the sets E_W. Then we find the set $U_W \subseteq V(H[E_W])$ of vertices that have odd degrees in $H[E_W]$. If $|V_W| \neq |U_W|$, we discard the choice. Otherwise, we set $U = \cup_{W \in T} U_W$. Notice that if our guesses correspond to a (potential) solution F, we have that corresponding injective homomorphism g should map U to $V' = \cup_{W \in T} V_W$ bijectively and, moreover, g should act as bijection between each U_W and V_W. We make all possible guesses of a bijection $f \colon U \to U'$. Since $|U| \leq 2k$, we have at most $(2k)^{2k}$ possible choices. Then for each U and f, we are searching for an injective homomorphism $g : V(H) \cup E(H) \to V(G) \cup E(G)$ such that (i) for all $e \in E(H)$, $\ell_H(e) = \ell_G(g(e))$, and (ii) for each $v \in U$, $g(v) = f(v)$.

Now we are ready for the final step of our reduction. Recall that H in the statement of Pattern Cover is required to be a forest. The graph H that was guessed so far does not have this property, but it is "almost" a forest, that is, it has at most 2^t cycles. To fix it, we

[1] Since we handle *multi* graphs, we define the domain and image of g to include edge-sets.

guess a set of edges $S \subseteq E(H)$ of size at most 2^t such that the graph obtained from H by the deletion of S is a forest and set $H = H - S$. Since $|S| \leq 2^t$, and t is a constant depending on r only, we can make a polynomial number of guesses how solution g could map S to $E(G)$; we have at most $|E(G)|^{2^t} = m^{\mathcal{O}(1)}$ possibilities for such partial mappings. For each guess of mapping $h : S \to V(G)$, we modify U and f respectively. Namely, we set $U = U \cup V(H[S])$ and define $f(v) = h(v)$ for $v \in V(H[S])$ as prescribed by our choice of the mapping h of S.

This concludes the description of the construction of an instance of Pattern Cover. It is possible to show that (G, P, T, k) is a yes-instance of Space Cover on PGM if and only if for at least one of the described guesses of a forest H, functions ℓ_H, ℓ_G, set $U \subseteq V(H)$ and function $f : U \to V(G)$, the instance of Pattern Cover with these parameters is a yes-instance. Since the total number of guesses we make is , $2^{\mathcal{O}(k^2)} \cdot (n+m)^{\mathcal{O}(1)}$, our construction is the required FPT-Turing reduction.

In order to solve Pattern Cover, and to complete the proof of Theorem 1, we still have to solve Pattern Cover. This is done by a non-trivial application of the color coding technique combined with dynamic programming. We give all the details in [14, Section 4].

2.2 Duals of Perturbed Graphic Matroids

In this section, we give an overview of the proof of our second main result. The detailed proof of the theorem is given in [14, Section 5].

Formally, we define the following problem.

> Space Cover on Dual of Perturbed Graphic Matroid (Space Cover on Dual-PGM)
> **Input:** A (multi) graph G with n vertices and m edges, an $(n \times m)$-matrix P over $GF(2)$ with $\mathrm{rank}(P) \leq r$, a set of *terminals* $T \subseteq E$ where E is the set of columns of the matrix $A = I(G) + P$, and a non-negative integer k.
> **Question:** Is there a set $F \subseteq E \setminus T$ with $|F| \leq k$ such that $T \subseteq \mathrm{span}(F)$ in the dual M^* of the binary matroid M represented by A?

▶ **Theorem 2.** Space Cover on Dual-PGM *is solvable in time* $2^{2^{\mathcal{O}((2^r+k^2)k)}} \cdot (n+m)^{\mathcal{O}(1)}$. *In particular,* Space Cover on Dual-PGM *is* FPT *when parameterized by* $r + k$.

As in the case with graphic matroids, it is useful to recall how Space Cover on Dual-PGM is solvable for $r = 0$, i.e. on cographic matroids. In a cographic matroid a circuit corresponds to a cut in the underlying graph G. In this case the solution set F should satisfy the following property: for every terminal element $e \in T$ there is a partition (or a cut) $(X_e, \overline{X}_e)$ of the vertex set of G such that this cut, i.e. the set of edges between X_e and $\overline{X}_e$, is of the form $\{e\} \cup F_e$, where $F_e \subseteq F$. Thus e is the only edge in the cut from T and all other edges are from F.

In graph theory this problem is known under name Edge Subset Feedback Edge Set. Xiao and Nagamochi [25] showed that this problem is FPT parameterized by $k = |F|$. The algorithm for solving Edge Subset Feedback Edge Set, as well as its special case Multiway Cut, uses the technique of Marx based on important separators [20]. The essence of this technique is that all required information about the cuts in a graph can be extracted from a carefully selected set of separators of size at most k. However, we do not see how this approach can be shifted to more general matroids, even when the rank of perturbation matrix is 1. The difficulty in this case is that solution F together with T cannot be represented as the union of the sets of edges of cuts in G anymore, and thus the sizes of important separators in G cannot be bounded by a function of k only. In order to overcome this challenge, we have to apply more powerful method of recursive understanding [6].

On a general level, the structure of the proof of Theorem 2 is similar to the structure of the proof of Theorem 1. It consists of two parts. In the first part we give FPT-Turing reduction to a cut problem on graphs and in the second part we use the method of recursive understanding to solve the problem. But here the similarities end. While on perturbation of graphic matroids Space Cover is about subgraph isomorphisms, on perturbation of cographic matroids it is about collections of cuts in graphs. This makes both parts of the proof of Theorem 2 much more challenging than in Theorem 1. In order to introduce the graph-cut problem we reduce to, we need several definitions.

Graph problem. Let G be a graph with n vertices and m edges given together with a set of terminal edges T and a partition of $V(G) = (V_1, V_2, \ldots, V_t)$. In addition, for every $e \in T$ graph G is provided with a function $f_e : E(G) \to \{0, 1\}$ and a binary vector $B^e = (b_1^e, b_2^e, \ldots, b_t^e)$.

For terminal edge $e \in T$ and a partition $(X, \bar{X})$ of $V(G)$, we say that an edge $e' \in E(G)$ *contributes to* $(e, (X, \bar{X}))$ (with respect to f_e) if one of the following conditions holds

1. Both endpoints of e' belong to X and $f_e(e') = 1$.
2. Both endpoints of e' belong to $\bar{X}$ and $f_e(e') = 1$.
3. Exactly one of the endpoints of e' belongs to X and $f_e(e') = 0$.

Accordingly, we define contribute(e, X) as the set of edges that contribute to $(e, (X, \bar{X}))$.

For partition $(X, \bar{X})$ of $V(G)$, and terminal edge $e \in T$, we say that $(X, \bar{X})$ *almost fits* e (with respect to f_e) if $T \cap$ contribute$(e, X) = \{e\}$. Moreover, if $(X, \bar{X})$ almost fits e and for all $1 \leq i \leq t$, it holds that $|X \cap V_i| = b_i^e \mod 2$, then we say that $(X, \bar{X})$ fits e (with respect to f_e and B^e).

We are now ready to define our graph problem.

Edge-Set Cover
Input: A (multi) graph G with n vertices and m edges, non-negative integers k and t, a partition $(V_1, V_2, \ldots, V_t)$ of $V(G)$, a set $T \subseteq E(G)$, a binary vector $B^e = (b_1^e, b_2^e, \ldots, b_t^e)$ for $e \in T$, and a function $f_e : E(G) \to \{0, 1\}$ for $e \in T$.
Question: Is there a set $F \subseteq E(G) \setminus T$ with $|F| \leq k$ such that for each $e \in T$, there exists a partition $(X_e, \bar{X}_e)$ of $V(G)$ that fits e and such that contribute$(e, X_e) \setminus \{e\} \subseteq F$?

In other words, we a looking for a set of edges F of size k, such that for every terminal edge e, there is a cut $(X_e, \bar{X}_e)$ such that (i) the parities of the intersections of X_e with sets V_i constitute vector B^e, (ii) e is the only terminal edge contributing to the cut and all other edges contributing to the cut are from F.

In the first part of the proof we give a reduction that for an input (G, P, T, k) of Space Cover on Dual-PGM in time $2^{\mathcal{O}(k2^r)} \cdot (n+m)^{\mathcal{O}(1)}$ constructs $2^{\mathcal{O}(k2^r)} \cdot (n+m)^{\mathcal{O}(1)}$ instances of Edge-Set Cover such that (G, P, T, k) is a yes-instance if and only if at least one of the instances of Edge-Set Cover is.

As in the case of perturbed graphic matroids, we can assume that $|T| \leq k$. Let $\mathrm{disr}(P) = \{R_1, \ldots, R_t\}$ be the set of the distinct vectors corresponding the rows of P. Since the rank of P is r, it has at most 2^r different rows, hence $t \leq 2^r$. Accordingly, we say that a vertex $v \in V(G)$ is of *type* i, $1 \leq i \leq t$, if $P_v = R_i$. Given a vertex $v \in V(G)$, we let type(v) denote its type. For $i \in \{1, \ldots, t\}$, we denote by V_i the set of vertices of type i.

Characterization of solutions. For Space Cover on Dual-PGM, we use the term *solution* to refer to a set $F \subseteq E \setminus T$ with $|F| \leq k$ such that $T \subseteq \mathrm{span}(F)$ in the dual M^* of the binary matroid M represented by A. Let I be a binary vector with m elements. Recall that given

$F \subseteq E$, edges(F) denotes the set of all edges $e \in E(G)$ such that $A^e \in F$. Now, given a set $F \subseteq E$, we say that I is the *characteristic vector* of F if the i^{th} entry of I is 1 if and only if F contains the i^{th} column of A. Moreover, a set $F \subseteq E$ is a *cocycle* in M if and only if it is a cycle in M^*. We need the following folklore result (see, e.g., [17]) characterizing cocycles of binary matroids.

▶ **Proposition 3.** *Let M be a binary matroid represented by an $(n \times m)$-matrix A, and let F be a subset of E, where E is the set of columns of A. Then, F is a cocycle in M if and only if the characteristic vector of F belongs to* span(V)*, where V is the set of rows of A.*

Note that a set $F \subseteq E \setminus T$ is a solution if and only if for each terminal $W \in T$, there exists a subset $F_W \subseteq F$ such that $F_W \cup \{W\}$ is a cocycle in M. Thus, in light of Proposition 3, we can think of a solution as follows:

▶ **Observation 4.** *A set $F \subseteq E \setminus T$ is a solution if and only if $|F| \leq k$ and for each terminal $W \in T$, there exists a subset $F_W \subseteq F$ such that the characteristic vector of $F_W \cup \{W\}$ belongs to* span(V)*, where V is the set of rows of A.*

Let F be a solution. For each $W \in T$, denote by $e(W)$ the edge of G corresponding to the terminal W. By Observation 4, for each $W \in T$, there is $F_W \subseteq F$ such that the characteristic vector I_W of $F'_W = F_W \cup \{W\}$ belongs to span(V). It means that there is a set of vertices $X_{e(W)} \subseteq V(G)$ such that $I_W = \sum_{v \in X_{e(W)}} A_v$. Hence, for each $W \in T$, we have the corresponding partition $(X_{e(W)}, \bar{X}_{e(W)})$ of $V(G)$, and the solution can be represented as a collection of cuts $\{(X_{e(W)}, \bar{X}_{e(W)}) \mid W \in T\}$ of G.

For each $W \in T$ and $i \in \{1, \ldots, t\}$, we guess the parity of $|X_{e(W)} \cap V_i|$ and define the vector $B^{e(W)} = (b_1^{e(W)}, \ldots, b_t^{e(W)})$ respectively by setting $b_i^{e(W)} = |X_{e(W)} \cap V_i| \mod 2$. Notice that we have at most 2^{tk} choices for $B^{e(W)}$, because $|T| \leq k$. For each guess, we are now looking for a solution represented by a collection of cuts $\{(X_{e(W)}, \bar{X}_{e(W)}) \mid W \in T\}$ of G such that $|X_{e(W)} \cap V_i| \mod 2 = b_i^{e(W)}$ for $W \in T$ and $i \in \{1, \ldots, t\}$.

Let $I_W = \sum_{v \in X_{e(W)}} A_v$ and let i_e^W for $e \in E(G)$ denote the elements of I_W. We have that

$$I_W = \sum_{v \in X_{e(W)}} (I_v(G) + P_v) = \sum_{v \in X_{e(W)}} I_v(G) + \sum_{v \in X_{e(W)}} P_v. \tag{3}$$

Let $P_W = \sum_{v \in X_{e(W)}} P_v$. Since $|X_{e(W)} \cap V_i| \mod 2 = b_i^{e(W)}$ for $W \in T$ and $i \in \{1, \ldots, t\}$, we obtain that $P_W = \sum_{i=1}^{t} b_i^{e(W)} R_i$. Notice that vector P_W is uniquely defined by the choice of $B^{e(W)}$. We define $f_{e(W)} \colon E(G) \to \{0, 1\}$, by setting $f_{e(W)}(e)$ to be equal to the element of P_W corresponding to e.

Recall that I_W is the characteristic vector of the cocycle F'_W. It means that $A^e \in F'_W$ if and only if $i_e^W = 1$. By making use of (3), we are able to show that for each edge $e \in E(G)$, $A^e \in F'_W$ if and only if one of the following holds:

- Both endpoints of e belong to $X_{e(W)}$ and $f_{e(W)}(e) = 1$.
- Both endpoints of e belong to $\bar{X}_{e(W)}$ and $f_{e(W)}(e) = 1$.
- Exactly one of the endpoints of e belongs to $X_{e(W)}$ and $f_{e(W)}(e) = 0$.

We have that $W \in F'_W$ and W is the unique element of T in this set. It means that for edge $e(W)$, cut $(X_{e(W)}, \bar{X}_{e(W)})$ almost fits $e(W)$ with respect to $f_{e(W)}$. Since $|X_{e(W)} \cap V_i| \mod 2 = b_i^{e(W)}$ for each $W \in T$ and $i \in \{1, \ldots, t\}$, we have that $(X_{e(W)}, \bar{X}_{e(W)})$ fits $e(W)$ with respect to $f_{e(W)}$ and $B^{e(W)}$. Moreover, we prove that for each $W \in T$ and $i \in \{1, \ldots, t\}$ the following are equivalent

- F'_W is a cocycle of M such that $|X_{e(W)} \cap V_i| \mod 2 = b_i^{e(W)}$ and such that its characteristic vector is expressible as $I_W = \sum_{v \in X_{e(W)}} A_v$;
- Cut $(X_{e(W)}, \bar{X}_{e(W)})$ fits $e(W)$ with respect to $f_{e(W)}$ and $B^{e(W)}$.

We also have that $F'_W = \text{contribute}(e(W), X_{e(W)})$.

Now we can complete the reduction to Edge-Set Cover. We consider the partition $(V_1, \ldots, V_t)$ of $V(G)$ and the set of terminal edges $T_G = \{e(W) \mid W \in T\}$. For each $W \in T$, we have a binary vector $B^{e(W)}$ and a function $f_{e(W)}$. Together, all these parameters compose an instance of Edge-Set Cover.

Solving Edge-Set Cover. The algorithm for Edge-Set Cover is the most technical part of the paper. Here we briefly highlight the approach. On a high-level, we use the method of recursive understanding [6], in which we incorporate various new, delicate subroutines. Informally, this means that at the basis, we are going to deal with a "highly-connected" or a small graph, and at each step where our graph is not highly-connected, we will break it using a very small number of edges into two graphs that are both neither too small nor too large.

Let G be a connected graph, and let p and q be positive integers. A partition (X, Y) of $V(G)$ is called (q, p)-*good edge separation* if $|X|, |Y| > q$, $|E(X, Y)| \leq p$, and $G[X]$ and $G[Y]$ are connected graphs.

Roughly speaking, a graph G is unbreakable if every partition of $V(G)$ with few edges going across must contain a large chunk of $V(G)$ in one of its two sets. Intuitively, this means that G is "highly-connected": any attempt to "break" it severely by using only few edges is futile. Formally, a graph G is (q, p)-*unbreakable* if it does not have a (q, p)-*good edge separation*.

If a graph G is not (q, p)-unbreakable, we say that it is (q, p)-breakable. Chitnis et al. [6] proved the following result.

▶ **Proposition 5** ([6]). *There exists a deterministic algorithm that given a connected graph G along with integers q and p, in time $\mathcal{O}(2^{\min\{q,p\}\cdot\log(q+p)} \cdot (n+m)^3 \log(n+m))$ either finds a (q, p)-good edge separation, or correctly concludes that G is (q, p)-unbreakable.*

In our case, we set $p = 2(k+1)$ and $q = 2^{2^{\lambda(t+k^2)|T|}}$ for some appropriate constant λ. To apply the method of recursive understanding, we introduce a special variant of Edge-Set Cover called Annotated Edge-Set Cover (see [14, Section 5] for the formal definition) that is tailored to apply recursion. We show that we can assume that the input graph G is connected. If G has bounded (by some function of r and k) size, we solve Annotated Edge-Set Cover directly. Otherwise, we use Proposition 5 to check whether G is (q, p)-unbreakable.

If G is not (q, p)-unbreakable, we find a (q, p)-good separation (X, Y) of G. Then we solve a special instance of Annotated Edge-Set Cover for one of the graphs $G[X]$ and $G[Y]$ recursively. We use the obtained solution to construct a new instance of the problem for a graph G' that has less vertices than G. Then we call our algorithm for this smaller instance.

If G is (q, p)-unbreakable, we obtain the crucial basic case that we briefly discuss here. For simplicity, we consider this case for Edge-Set Cover.

Recall that in the definition of Edge-Set Cover, we ask about a set $F \subseteq E(G) \setminus T$ with $|F| \leq k$ such that for each $e \in T$, there exists a partition $(X_e, \bar{X}_e)$ of $V(G)$ that fits e and such that $\text{contribute}(e, X_e) \setminus \{e\} \subseteq F$. We relax these conditions and look for a collection of partitions $\{(Y_e, \bar{Y}_e) \mid e \in T\}$ such that $(Y_e, \bar{Y}_e)$ almost fits e and $|\text{contribute}(e, Y_e) \setminus \{e\}| \leq k$ for $e \in T$. Then we can find such an auxiliary collection of partitions $\{(Y_e, \bar{Y}_e) \mid e \in T\}$ by

reducing the relaxed problem to at most k instances of the Edge Odd Cycle Transversal problem (also known as Edge Bipartization). The latter problem could be solved by the results of Guo et al. [18]. Finally we use auxiliary partitions $\{(Y_e, \bar{Y}_e) \mid e \in T\}$ to construct the required collection of partitions $\{(X_e, \bar{X}_e) \mid e \in T\}$ and a set F of size at most k. The final construction heavily exploit the high connectivity of G which allows to search only a "small neighborhood" of $(Y_e, \bar{Y}_e)$.

3 Conclusion

In this paper we established the fixed-parameter tractability of Space Cover on PGM and Space Cover on Dual-PGM. We also know that on the class of binary matroids Space Cover is not tractable. So where lies the tractability border for Space Cover? Our positive results on perturbed matroids, combined with the structure theorem of Geelen, Gerards, and Whittle [16], rise a natural question: could the tractability of Space Cover be extended to any proper minor-closed class $\mathcal{M}$ of binary matroids? Let us note that while we formulate Space Cover only on binary matroids, it can be naturally defined on any class of matroids. In particular, the parameterized complexity of Space Cover on proper minor-closed classes of matroids representable over a finite field is open.

Finally, two concrete open questions. First, what is the parameterized complexity of Space Cover on PGM when $|T|$ is a constant and the parameter is $r + k$? Second, we know that Space Cover on PGM is NP-complete even when $|T| = 2$ and $r \leq 2$ (see [14, Theorem 4]). On the other hand, for $r = 0$ the problem is in P for any fixed number of terminals (it is actually FPT parameterized by $|T|$). What about the case $|T| = 2$ and $r = 1$?

Abstract

Bidimensionality is the most common technique to design subexponential-time parameterized algorithms on special classes of graphs, particularly planar graphs. The core engine behind it is a combinatorial lemma of Robertson, Seymour and Thomas that states that every planar graph either has a $\sqrt{k} \times \sqrt{k}$-grid as a minor, or its treewidth is $\mathcal{O}(\sqrt{k})$. However, bidimensionality theory cannot be extended directly to several well-known classes of geometric graphs like unit disk or map graphs. This is mainly due to the presence of large cliques in these classes of graphs. Nevertheless, a relaxation of this lemma has been proven useful for unit disk graphs. Inspired by this, we prove a new decomposition lemma for map graphs, the intersection graphs of finitely many simply-connected and interior-disjoint regions of the Euclidean plane. Informally, our lemma states the following. For any map graph G, there exists a collection $(U_1, \ldots, U_t)$ of cliques of G with the following property: *G either contains a $\sqrt{k} \times \sqrt{k}$-grid as a minor, or it admits a tree decomposition where every bag is the union of $\mathcal{O}(\sqrt{k})$ cliques in the above collection.*

The new lemma appears to be a handy tool in the design of subexponential parameterized algorithms on map graphs. We demonstrate its usability by designing algorithms on map graphs with running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ for Connected Planar $\mathcal{F}$-Deletion (that encompasses problems such as Feedback Vertex Set and Vertex Cover). Obtaining subexponential algorithms for Longest Cycle/Path and Cycle Packing is more challenging. We have to construct tree decompositions with more powerful properties and to prove sublinear bounds on the number of ways an optimum solution could "cross" bags in these decompositions.

For Longest Cycle/Path, these are the first subexponential-time parameterized algorithm on map graphs. For Feedback Vertex Set and Cycle Packing, we improve upon known $2^{\mathcal{O}(k^{0.75}\log k)} \cdot n^{\mathcal{O}(1)}$-time algorithms on map graphs.

1 Introduction

In this paper, we develop new proof techniques to design parameterized subexponential-time algorithms for problems on map graphs, particularly problems that involve hitting or connectivity constraints. The class of map graphs was introduced by Chen, Grigni, and Papadimitriou [7, 8] as a modification of the class of planar graphs. Roughly speaking, map graphs are graphs whose vertices represent countries in a map, where two countries are considered adjacent if and only if their boundaries have at least one point in common; this common point can be a single common point rather than necessarily an edge as standard planarity requires. Formally, a *map* $\mathcal{M}$ is a pair $(\mathscr{E}, \omega)$ defined as follows : $\mathscr{E}$ is a plane graph (i.e., a planar graph with an embedding) where each connected component of $\mathscr{E}$ is biconnected, and ω is a function that maps each face f of $\mathscr{E}$ to 0 or 1. A face f of $\mathscr{E}$ is called *nation* if $\omega(f) = 1$ and *lake* otherwise. The graph associated with $\mathcal{M}$ is the simple graph G where $V(G)$ consists of the nations of $\mathcal{M}$, and $E(G)$ contains $\{f_1, f_2\}$ for every pair of faces f_1 and f_2 that are adjacent (that is, share at least one vertex). Accordingly, a graph G is called a map graph if there exists a map $\mathcal{M}$ such that G is the graph associated with $\mathcal{M}$.

Every planar graph is a map graph [7, 8], but the converse does not hold true. Moreover, map graphs can have cliques of any size and thus they can be "highly non-planar". These two properties of map graphs can be contrasted with those of H-minor free graphs and unit disk graphs: the class of H-minor free graphs generalizes the class of planar graphs, but can only have cliques of constant size (where the constant depends on H), while the class of unit disk graphs does not generalize the class of planar graphs, but can have cliques of any size. At least in this sense, map graphs offer the best of both worlds. Nevertheless, this comes at the cost of substantial difficulties in the design of efficient algorithms on them.

Arguably, the two most natural and central algorithmic questions concerning map graphs are as follows. First, we would like to efficiently recognize map graphs, that is, determine whether a given graph is a map graph. In 1998, Thorup [29] announced the existence of a polynomial-time algorithm for map graph recognition. Although this algorithm is complicated and its running time is about $\mathcal{O}(n^{120})$, where n is the number of vertices of the input graph, no improvement has yet been found; the existence of a simpler or faster algorithm for map graph recognition has so far remained an important open question in the area (see, e.g., [9]).

The second algorithmic question – or rather family of algorithmic questions – concerns the design of efficient algorithms for various optimization problems on map graphs. Most well-known problems that are NP-complete on general graphs remain NP-complete when restricted to planar (and hence on map) graphs. Nevertheless, a large number of these problems can be solved faster or "better" when restricted to planar graphs. For example, nowadays we know of many problems that are APX-hard on general graphs, but which admit polynomial time approximation schemes (PTASes) or even efficient PTASes (EPTASes) on planar graphs (see, e.g., [4, 14, 15, 22]). Similarly, many parameterized problems that on general graphs cannot be solved in time $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ unless the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi and Zane [24] fails, admit parameterized subexponential-time algorithms on planar graphs (see, e.g., [1, 2, 14, 27]). It is compelling to ask whether the algorithmic results and techniques for planar graphs can be extended to map graphs.

For approximation algorithms, Chen [6] and Demaine et al. [12] developed PTASes for the Maximum Independent Set and Minimum r-Dominating Set problems on map graphs. Moreover, Fomin et al. [21, 22] developed an EPTAS for Treewidth-η Modulator for any fixed constant $\eta \geq 0$, which encompasses Feedback Vertex Set (FVS) and Vertex Cover (VC). For parameterized subexponential-time algorithms on map graphs,

the situation is less explored. While on planar graphs there are general algorithmic methods – in particular, the powerful theory of bidimensionality [15, 13] – to design parameterized subexponential-time algorithms, we are not aware of any general algorithmic method that can be easily adapted to map graphs. Demaine et al. [12] gave a parameterized algorithm for Dominating Set, and more generally for (k,r)-Center, with running time $2^{\mathcal{O}(r\log r\sqrt{k})}n^{\mathcal{O}(1)}$ on map graphs. Moreover, Fomin et al. [21, 22] gave $2^{\mathcal{O}(k^{0.75}\log k)}n^{\mathcal{O}(1)}$-time parameterized algorithms for FVS and Cycle Packing on map graphs. Additionally, Fomin et al. [21, 22] noted that the same approach yields $2^{\mathcal{O}(k^{0.75}\log k)}n^{\mathcal{O}(1)}$-time parameterized algorithms for Vertex Cover and Connected Vertex Cover (CVC) on map graphs. However, the existence of a parameterized subexponential-time algorithm for Longest Path/Cycle on map graphs was left open. (In these problems we are asked whether an n-vertex graph contains a path/cycle of length at least k.) Furthermore, time complexities of $2^{\mathcal{O}(k^{0.75}\log k)}n^{\mathcal{O}(1)}$, although having subexponential dependency on k, remain far from time complexities of $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ and $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ that commonly arise for planar graphs [27]. We remark that time complexities of $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ and $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ are particularly important since they are often known to be essentially optimal under the aforementioned ETH [27].

In the field of Parameterized Complexity, Longest Path/Cycle , FVS and Cycle Packing serve as testbeds for development of fundamental algorithmic techniques such as color-coding [3], methods based on polynomial identity testing [25, 26, 30, 5], cut-and-count [11], and methods based on matroids [19]. By combining the bidimensionality theory of Demaine et al. [13] with efficient algorithms on graphs of bounded treewidth [17, 10], Longest Path/Cycle, Cycle Packing and FVS are solvable in time $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ on planar graphs. Furthermore, the parameterized subexponential-time "tractability" of these problems can be extended to graphs excluding some fixed graph as a minor [15].

Our results. We design parameterized subexponential-time algorithms with running time $2^{\mathcal{O}(\sqrt{k}\log k)}\cdot n^{\mathcal{O}(1)}$ for a number of natural and well-studied problems on map graphs.

Let $\mathcal{F}$ be a family of connected graphs that contains at least one planar graph. Then Connected Planar $\mathcal{F}$-Deletion (or just $\mathcal{F}$-Deletion) is defined as follows. The input is a graph G and a non-negative integer k, and our objective is to test whether there exists a set S of at most k vertices such that $G-S$ does not contain any of the graphs in $\mathcal{F}$ as a minor. $\mathcal{F}$-Deletion is a general problem and several problems such as VC, FVS, Treewidth-η Vertex Deletion, Pathwidth-η Vertex Deletion, Treedepth-η Vertex Deletion, Diamond Hitting Set and Outerplanar Vertex Deletion are its special cases. We give the first parameterized subexponential algorithm for this problem on map graphs, which runs in time $2^{\mathcal{O}(\sqrt{k}\log k)}\cdot n^{\mathcal{O}(1)}$. Our approach for $\mathcal{F}$-Deletion also directly extends to yield $2^{\mathcal{O}(\sqrt{k}\log k)}\cdot n^{\mathcal{O}(1)}$-time parameterized algorithms for CVC and Connected Feedback Vertex Set (CFVS) on map graphs. (In this versions we are asked if there is a *connected* vertex cover or a feedback vertex set of size at most k.)

With additional ideas, we derive the first subexponential-time parameterized algorithm on map graphs for Longest Path/Cycle. Our technique also allows to improve the running time for Cycle Packing (does a map graph contains at least k vertex-disjoint cycles) from $2^{\mathcal{O}(k^{0.75}\log k)}\cdot n^{\mathcal{O}(1)}$ to $2^{\mathcal{O}(\sqrt{k}\log k)}\cdot n^{\mathcal{O}(1)}$. Our results are summarized in Table 1.

Our methods. The starting point of our study is the technique of bidimensionality [15, 13]. The core engine behind this technique is a combinatorial lemma of Robertson, Seymour and Thomas [28] that states that every planar graph either has a $\sqrt{k}\times\sqrt{k}$-grid as a minor, or its treewidth is $\mathcal{O}(\sqrt{k})$. Unfortunately, a clique on $k-1$ vertices has no $\sqrt{k}\times\sqrt{k}$-grid as a minor

Table 1 Parameterized complexity of problems on map graphs. For $\mathcal{F}$-Deletion, Longest Cycle, and Longest Path no faster (than on general graphs) algorithms were known.

$\mathcal{F}$-Deletion	$2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$	$2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ [18]
Longest Cycle/Path	$2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$	$2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ [10]
Cycle Packing	$2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$	$2^{\mathcal{O}(k^{0.75}\log k)} \cdot n^{\mathcal{O}(1)}$ [22]

and its treewidth is $k-2$. Because classes of geometric graphs such as unit disk graphs and map graphs can have arbitrarily large cliques, the combinatorial lemma is inapplicable to them. Nevertheless, a relaxation of this lemma has been proven useful for unit disk graphs. Specifically, every unit disk graph G has a natural partition $(U_1, \ldots, U_t)$ of $V(G)$ such that each part induces a clique with "nice" properties – in particular, it has neighbors only in a *constant number* (to be precise, this constant is at most 24) of other parts; it was shown that G either has a $\sqrt{k} \times \sqrt{k}$-grid as a minor, or it has a tree decomposition where every bag is the union of $\mathcal{O}(\sqrt{k})$ of these cliques [20]. In particular, given a parameterized problem where any two cliques have constant-sized "interaction" in a solution, it is implied that any bag has $\mathcal{O}(\sqrt{k})$-sized "interaction" with all other bags in a solution. For any map graph G, there also exists a natural collection of subsets of $V(G)$ that induce cliques with "nice" properties. However, not only are these cliques not vertex disjoint, but each of these cliques can have neighbors in *arbitrarily many* other cliques.

In this paper, we first prove that every map graph either has a $\sqrt{k} \times \sqrt{k}$-grid as a minor, or it has a tree decomposition where every bag is the union of $\mathcal{O}(\sqrt{k})$ of the cliques in the above collection. For $\mathcal{F}$-Deletion, CVC, and CFVS, this combinatorial lemma alone already suffices to design $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$-time algorithms on map graphs. Indeed, we can choose a fixed constant $c > 0$ so that in case we have a $c\sqrt{k} \times c\sqrt{k}$-grid as a minor, there does not exist a solution, and otherwise we can solve the problem by using dynamic programming over the given tree decomposition. Specifically, since every bag is the union of $\mathcal{O}(\sqrt{k})$ cliques, and the size of each clique is upper bounded by $\mathcal{O}(k)$ (once we know that no $c\sqrt{k} \times c\sqrt{k}$-grid exists), only $\mathcal{O}(\sqrt{k})$ vertices in the bag are not to be taken into a solution – there are only $2^{\mathcal{O}(\sqrt{k}\log k)}$ choices to select these vertices, and once they are selected, the information stored about the remaining vertices is the same as in normal dynamic programming over a tree decomposition of $\mathcal{O}(\sqrt{k})$ width.

This approach already substantially improves upon the previously best known algorithms for FVS, VC and CVC of Fomin et al. [21, 22]. However, $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$-time algorithms for Longest Path/Cycle and Cycle Packing on map graphs require more efforts. The main reason why we cannot apply the same arguments as for unit disk graphs is the following. Recall that for unit disk graphs, given a parameterized problem where any two cliques have constant-sized "interaction" in a *solution* (in our case, this means a path/cycle on at least k vertices, or a cycle packing of k cycles), it is implied that any bag has $\mathcal{O}(\sqrt{k})$-sized "interaction" with all other bags in a solution. Here, interaction between two cliques refers to the number of edges in a solution "passing" between these two cliques; similarly, interaction between a bag B and a collection of other bags refers to the number of edges in a solution that have one endpoint in B and the other endpoint in some bag in the collection. In this context, dealing with map graphs is substantially more difficult than dealing with unit disk

graphs. In map graphs vertices in a clique can have neighbors in arbitrarily many other cliques in the collection rather than only in a constant number as in unit disk graphs. This is why it is difficult to obtain an $\mathcal{O}(\sqrt{k})$-sized "interaction" as for unit disk graphs.

Hence, we are forced to take a different approach for map graphs by bounding "the interaction within a clique across all the bags of a decomposition". Towards this, we first need to strengthen our tree decomposition. To explain the new properties required, we note that every clique in the aforementioned collection of cliques, say $\mathcal{K}$, is either a single vertex or the neighborhood of some "special vertex" in an exterior bipartite graph (see Section 2). Further, every vertex of G occurs as a singleton in $\mathcal{K}$. We construct our decomposition in a way such that every bag is not necessarily a union of $\mathcal{O}(\sqrt{k})$ cliques in $\mathcal{K}$, but a union of carefully chosen subcliques of $\mathcal{O}(\sqrt{k})$ cliques in $\mathcal{K}$ (with one subclique for each of these $\mathcal{O}(\sqrt{k})$ cliques); subcliques of the same clique chosen in different bags may be different. We then prove properties that roughly state that, if we look at the collection of bags that include some vertex v of G, then this collection induces a subtree and a path as follows: (♣) *the subtree consists of the bags that correspond to the singleton clique v, and the path goes "upwards" (in the tree decomposition) from the root of this subtree.* We thereby implicitly derive that in every bag B, every subclique of size larger than 1 can only have as neighbors vertices that are *(i)* in the bag B itself or in one of its descendants, or *(ii)* in cliques that have a subclique in the bag B. In particular, this means that if we prove that there exists a solution such that for any clique K in $\mathcal{K}$, the number of edges in $E(K)$ that "cross any bag B" (i.e., the edges in $E(K)$ with one endpoint in B and the other in the collection of all bags that are not descendants of B) is a constant, then we obtain a bound of $\mathcal{O}(\sqrt{k})$ on the interaction between any bag B and the collection of all bags that are not descendants of B. We prove the mentioned statement using property (♣). The proof that such a property simultaneously holds for all cliques and all bags is the most challenging part of the proof.

In Section 3 we give our special tree decomposition of map graphs and in Section 4 we explain its application in the algorithm for Longest Cycle on map graphs. For the proofs of results marked with $\star$ and all other results we refer to the full version of the paper.

2 Preliminaries

For any $t \in \mathbb{N}$, we use $[t]$ and $[t]_0$ as shorthands for $\{1, 2, \ldots, t\}$ and $\{0, 1, \ldots, t\}$, respectively. For a set U, we use 2^U to denote the power set of U. For a sequence $\sigma = x_1 x_2 \ldots x_n$ and any $1 \leq i \leq j \leq n$, the sequence $\sigma' = x_i \ldots x_j$ is called a *segment* of σ. For a sequence $\sigma = x_1 x_2 \ldots x_n$ and a subset $Z \subseteq \{x_1, \ldots, x_n\}$, the restriction of σ on Z, denoted by $\sigma|_Z$, is the sequence obtained from σ by deleting the elements of $\{x_1, \ldots, x_n\} \setminus Z$.

Graphs. We use standard notation and terminology from the book of Diestel [16] for graph-related terms. Given a graph G, let $V(G)$ and $E(G)$ denote its vertex-set and edge-set, respectively. For a set $\mathcal{Q}$ of graphs we slightly abuse terminology and let $V(\mathcal{Q})$ and $E(\mathcal{Q})$ denote the union of the sets of vertices and edges of the graphs in $\mathcal{Q}$, respectively. For a vertex subset $X \subseteq V(G)$ in a graph G, $E(X)$ denotes the set $\{\{u, v\} \in E(G) \colon u, v \in X\}$. For a graph G and a degree-2 vertex $v \in V(G)$, by *contracting* v, we mean deleting v from G and adding an edge between the two neighbors of v in G.

A binary tree is a rooted tree where each node has at most two children. In a labelled binary tree, for each node with two children one of the children is labelled as "left child" and the other child is labelled as "right child". A *postorder transversal* of a labelled binary tree T is the sequence σ of $V(T)$ where for each node $t \in V(T)$, t appears after all its descendants,

and if t has two children, then the nodes in the subtree rooted at the left child appear before the nodes in the subtree rooted at the right child. For a binary tree T, we say that a sequence σ of $V(T)$ is a postorder transversal if there is a labelling of T such that σ is its postorder transversal.

▶ **Definition 2.1** (Treewidth). *A* tree decomposition *of a graph G is a pair $\mathcal{T} = (T_\tau, \beta_\tau)$, where T is a rooted tree and β_τ is a function from $V(T_\tau)$ to $2^{V(G)}$, that satisfies the following three conditions. (We use the term* nodes *to refer to the vertices of T_τ.)*

(a) $\bigcup_{x \in V(T_\tau)} \beta_\tau(x) = V(G)$.

(b) *For every edge $\{u, v\} \in E(G)$, there exists $x \in V(T_\tau)$ such that $\{u, v\} \subseteq \beta_\tau(x)$.*

(c) *For every vertex $v \in V(G)$, the set of nodes $\{t \in V(T_\tau) : v \in \beta_\tau(t)\}$ induces a (connected) subtree of T_τ.*

The width *of $\mathcal{T}$ is $\max_{x \in V(T_\tau)} |\beta_\tau(x)| - 1$. Each set $\beta_\tau(x)$ is called a* bag. *Moreover, $\gamma_\tau(x)$ denotes the union of the bags of x and its descendants. The* treewidth *of G is the minimum width among all possible tree decompositions of G, and it is denoted by $\mathsf{tw}(G)$.*

▶ **Definition 2.2.** *A tree decomposition $\mathcal{T} = (T_\tau, \beta_\tau)$ of a graph G is* nice *if for the root r of T_τ, it holds that $\beta_\tau(r) = \emptyset$, and each node $v \in V(T_\tau)$ is of one of the following types.*

- ***Leaf**: v is a leaf in T_τ and $\beta_\tau(v) = \emptyset$. This bag is labelled with **leaf**.*
- ***Forget vertex**: v has exactly one child u, and there exists a vertex $w \in \beta_\tau(u)$ such that $\beta_\tau(v) = \beta_\tau(u) \setminus \{w\}$. This bag is labelled with **forget** (w).*
- ***Introduce vertex**: v has exactly one child u, and there exists a vertex $w \in \beta_\tau(v)$ such that $\beta_\tau(v) \setminus \{w\} = \beta_\tau(u)$. This bag is labelled with **introduce**(w).*
- ***Join**: v has exactly two children, u and w, and $\beta_\tau(v) = \beta_\tau(u) = \beta_\tau(w)$. This bag is labelled with **join**.*

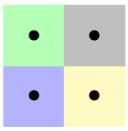
We will use the following folklore observation and proposition in the later sections.

▶ **Observation 2.3.** *Let $\mathcal{T}$ be a nice tree decomposition of a graph G. For any $v \in V(G)$, there is exactly one node $t \in V(T_\tau)$ such that t is labelled with **forget**(v).*

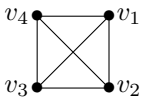
▶ **Proposition 2.4** (Theorem 7.23 in [10], [23, 28]). *There exists an $\mathcal{O}(n^2)$ time algorithm that given an n-vertex planar graph G and $t \in \mathbb{N}$, either outputs a (nice) tree decomposition of G of width less than $5t$, or constructs a $t \times t$ grid minor in G.*

Map graphs. Map graphs are the intersection graphs of finitely many connected and interior-disjoint regions of the Euclidean plane. Map graphs can be represented as the *half-squares of planar bipartite graphs*. For a bipartite graph B with bipartition $V(B) = W \uplus U$, the half-square of B is the graph G with vertex set W and edge set is defined as follows: two vertices in W are adjacent in G if they are at distance 2 in B. It is known that the half-square of a planar bipartite graph is a map graph [7, 8]. Moreover, for any map graph G, there exists a planar bipartite graph B such that G is a half-square of B [7, 8]; we refer to such B as a planar bipartite graph *corresponding* to the map graph G (see Figure 1).

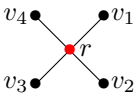
Throughout this paper, we assume that any input map graph G is given with a corresponding planar bipartite graph B. This assumption is made without loss of generality in the sense that if G is given with an embedding instead to witness that it is a map graph, then B is easily computable in linear time [7, 8]. We remark that we consider map graphs as simple graphs, that is, there are no multiple edges between two vertices u and v, even if there are two or more internally vertex-disjoint paths of length 2 between u and v in B. For a map graph G with a corresponding planar bipartite graph B having bipartition $V(B) = W \uplus U$, we refer to the vertices in $W = V(G)$ simply as *vertices* and the vertices in U as *special vertices*.



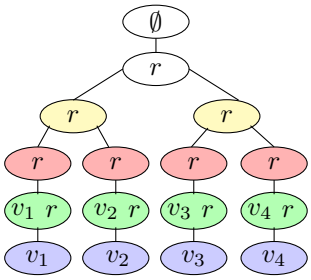
(a) A map $\mathcal{M}$.



(b) A map graph G associated with $\mathcal{M}$.



(c) A corresponding planar bipartite graph B of the map graph G. Here, red colored vertices are special vertices.



(d) A tree decomposition $\mathcal{D} = (T_\mathcal{D}, \beta_\mathcal{D})$ of B of width < 2. The nodes colored blue, green, red, and yellow are labelled with **introduce**(v_i), **introduce**(r), **forget**(v_i) and **join**, resp.

Figure 1 Example of a map graph G, and a corresponding planar bipartite graph B. Figure 1d represents a tree decomposition of B (obtained after deleting the leaves of a nice tree decomposition).

Moreover, we denote the special vertices by $S(G)$. Notice that for any $s \in S(G)$, $N_B(s)$ forms a clique in G; we refer to these cliques as *special cliques* of G. We remark that the collection $\mathcal{K}$ of cliques mentioned in Section 1 refers to $\{N_B(s) \colon s \in S(G)\} \cup \{\{v\} \colon v \in V(G)\}$.

3 Few Cliques Tree Decomposition of Map Graphs

In this section, we define a special tree decomposition for map graphs. This decomposition will be derived from a tree decomposition of the bipartite planar graph corresponding to the given map graph. Once we have defined our new decomposition, we will gather a few of its structural properties that will be useful in designing fast subexponential time algorithms.

▶ **Definition 3.1.** *Let G be a map graph with a corresponding planar bipartite graph B. Let $\mathcal{D} = (T_\mathcal{D}, \beta_\mathcal{D})$ be a tree decomposition of B of width less than ℓ. A pair $\mathcal{D}' = (T_{\mathcal{D}'}, \beta_{\mathcal{D}'})$ is called the* ℓ-few cliques tree decomposition derived from $\mathcal{D}$, *or simply an* $(\ell, \mathcal{D})$-FewCliTD, *if it is constructed as follows (see Figure 2).*

1. *The tree $T_{\mathcal{D}'}$ is equal to $T_\mathcal{D}$. Whenever $\mathcal{D}'$ and $\mathcal{D}$ are clear from context, we denote both $T_{\mathcal{D}'}$ and $T_\mathcal{D}$ by T.*
2. *For each node $t \in V(T)$, $\beta_{\mathcal{D}'}(t) = (\beta_\mathcal{D}(t) \cap V(G)) \cup (\bigcup_{s \in \beta_\mathcal{D}(t) \cap S(G)} N_B(s) \cap \gamma_\mathcal{D}(t))$. That is, for each node $t \in V(T)$, we derive $\beta_{\mathcal{D}'}(t)$ from $\beta_\mathcal{D}(t)$ by replacing every special vertex $s \in \beta_\mathcal{D}(t) \cap S(G)$ by $N_B(s) \cap \gamma_\mathcal{D}(t)$.*

In words, the second item states that for every vertex $v \in V(G)$ and node $t \in V(T)$, we have that $v \in \beta_{\mathcal{D}'}(t)$ if and only if either (i) $v \in \beta_\mathcal{D}(t) \cap V(G)$ or (ii) $v \in N_B(s)$ for some $s \in S(G) \cap \beta_\mathcal{D}(t)$ and $v \in \beta_\mathcal{D}(t')$ for some node t' in the subtree of T rooted at t.

We can prove that the $(\ell, \mathcal{D})$-FewCliTD $(T, \beta_{\mathcal{D}'})$ in Definition 3.1 is a tree decomposition of G (see the full version of the paper for a proof). We remark that if we replace the term $N_B(s) \cap \gamma_\mathcal{D}(t)$ by the term $N_B(s)$ in the second item of Definition 3.1, then we still derive a tree decomposition, but then some of the properties proved later do not hold true.

To simplify statements ahead, from now on, we have the following notation.

> Throughout the section, we fix a map graph G, a corresponding planar bipartite graph B of G, an integer $\ell \in \mathbb{N}$, a nice tree decomposition $\mathcal{D}$ of B of width less than ℓ and an *ℓ-few cliques tree decomposition* $\mathcal{D}'$ of G derived from $\mathcal{D}$ using Definition 3.1

Recall that $T = T_\mathcal{D} = T_{\mathcal{D}'}$ and that for each node $t \in V(T)$, $\beta_{\mathcal{D}'}(t)$ was obtained from $\beta_\mathcal{D}(t)$ by replacing every special vertex $s \in S(G)$ with $N_B(s) \cap \gamma_\mathcal{D}(s)$.

▶ **Definition 3.2.** *For a node $t \in V(T)$, we use* Original(t) *to denote the set $\beta_{\mathcal{D}}(t) \cap \beta_{\mathcal{D}'}(t)$,* Fake$(t)$ *to denote the set $\beta_{\mathcal{D}'}(t) \setminus \beta_{\mathcal{D}}(t)$, and* Cliques$(t)$ *to denote the set $\{N_B(s) \colon s \in S(G) \cap \beta_{\mathcal{D}}(t)\}$ of special cliques of G.*

Informally, for a node $t \in V(T)$, $\mathsf{Original}(t)$ denotes the set of vertices of $V(G)$ present in the bag $\beta_{\mathcal{D}}(t)$, $\mathsf{Fake}(t)$ denotes the set of "new" vertices added to $\beta_{\mathcal{D}'}(t)$ while replacing special vertices in $\beta_{\mathcal{D}}(t)$, and $\mathsf{Cliques}(t)$ is the set of special cliques in G that consist of one for each special vertex $s \in \beta_{\mathcal{D}}(t)$. For example, let t be the node in Figure 1d that is labelled with $\mathbf{forget}(v_1)$ by $\mathcal{D}$. Then, $\mathsf{Original}(t) = \emptyset$, $\mathsf{Fake}(t) = \{v_1\}$ and $\mathsf{Cliques}(t) = \{\{v_1, \ldots, v_4\}\}$.

In the remainder of this section we prove properties related to $\mathcal{D}$ and $\mathcal{D}'$, which we use later in the paper. Towards the formulation of the first property, consider the tree decomposition $\mathcal{D}'$ in Figure 2 and the set of its nodes whose bags contain the vertex v_1 as a "fake" vertex. This set of nodes forms a path with one end-vertex being the unique node t_{v_1} of T labelled with $\mathbf{forget}(v_1)$ by $\mathcal{D}$ and the other end-vertex being an ancestor of t_{v_1}. In fact, the set of nodes $Q = \{t \in V(T) \colon v_1 \in \mathsf{Fake}(t) \text{ and } r \in \beta_{\mathcal{D}}(t)\}$ forms the unique path in T from t_{v_1} to t_r where t_r is the unique child of the node labelled with $\mathbf{forget}(r)$ by $\mathcal{D}$. This observation is abstracted and formalized in the following lemma.

▶ **Lemma 3.3.** *Let $v \in V(G)$ and $s \in S(G)$ such that $v \in N_B(s)$ and $Q = \{t \in V(T) \colon v \in$ Fake(t) and $s \in \beta_{\mathcal{D}}(t)\} \neq \emptyset$. Let x be the node in T labelled with $\mathbf{forget}(v)$ by $\mathcal{D}$, and y be the unique child of the node labelled with $\mathbf{forget}(s)$ by $\mathcal{D}$. Then, y is an ancestor of x, and Q induces a path in T which is the unique path between x and y in T.*

Proof. First, we prove that Q induces a (connected) subtree of T. Suppose not. Then, there exist two connected components C_1 and C_2 of $T[Q]$ such that there exists a path P in T from a vertex in C_1 to a vertex in C_2 whose internal vertices all belong to $V(T) \setminus Q$. By Property (c) of the tree decomposition $\mathcal{D}$, we have that $s \in \beta_{\mathcal{D}}(t)$ for any $t \in V(P)$. Moreover, there is an internal vertex w of P such that w is an ancestor of one of the end-vertices of P. This implies that $v \in \gamma_{\mathcal{D}}(w)$, because v belong to the bags of the endpoints of P (by the definition of Q and Fake). As we have also shown that $s \in \beta_{\mathcal{D}}(t)$ for all $t \in V(P)$, this implies that $w \in Q$, which is a contradiction. Hence, we have proved that $T[Q]$ is connected.

Next, we prove that $T[Q]$ is a path such that one of its endpoints is a descendant of the other. Towards this, it is enough to prove that (i) for any distinct $t, t' \in Q$, either t is a descendant of t' or t' is a descendant of t. For the sake of contradiction, assume that there exist $t, t' \in Q$ such that neither t is a descendent of t' nor t' is a descendent of t. By the definition of Q and because $t, t' \in Q$, we have that $v \in \gamma_{\mathcal{D}}(t)$ and $v \in \gamma_{\mathcal{D}}(t')$. Thus by Property (c) of the tree decomposition $\mathcal{D}$, we have that $v \in \beta_{\mathcal{D}}(t)$ and $v \in \beta_{\mathcal{D}}(t')$. Because $v \in \mathsf{Fake}(t)$ and $v \in \mathsf{Fake}(t')$, this is a contradiction to the definition of Fake.

It remains to prove that y is an ancestor of x and that x and y are endpoints of $T[Q]$. First, we prove that x is an end-vertex of the path $T[Q]$. Let x' be the only child of x. To prove x is an end-vertex of the path $T[Q]$, it is enough to show that $x \in Q$ and $x' \notin Q$. Since x is labelled with $\mathbf{forget}(v)$ by $\mathcal{D}$, we have that $v \notin \beta_{\mathcal{D}}(x)$, $v \in \beta_{\mathcal{D}}(x')$, and $v \in \gamma_{\mathcal{D}}(x)$. This implies that $v \in \mathsf{Original}(x')$ and hence $x' \notin Q$. Now, we prove that $x \in Q$. For this purpose, let $R = \{t \in V(T) \colon s \in \beta_{\mathcal{D}}(t)\}$. Clearly, $Q \subseteq R$. By Property (c) of the tree decomposition $\mathcal{D}$, we have that $T[R]$ is connected. We have already proved that $T[Q]$ is a path and since $Q \subseteq R$, $T[Q]$ is a path in $T[R]$. Since x is labelled with $\mathbf{forget}(v)$ by $\mathcal{D}$, for any node x'' in the subtree rooted at x and $x'' \neq x$, either $v \in \beta_{\mathcal{D}}(x'')$ or $v \notin \gamma_{\mathcal{D}}(x'')$ (this fact follows from Property (c) of $\mathcal{D}$). This implies that Q contains no node in the subtree of T rooted at x and not equal to x. Moreover, observe that there exists a node $x^\star$ in the subtree of T rooted

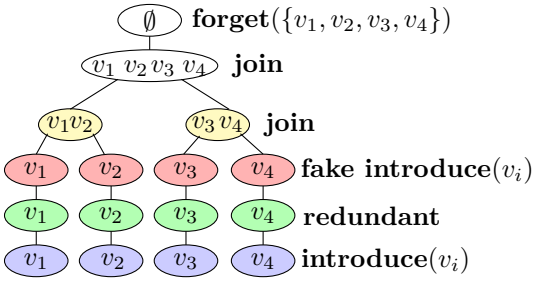


Figure 2 An $(\ell, \mathcal{D})$-*FewCliTD* $\mathcal{D}'$ derived from the nice tree decomposition $\mathcal{D}$ in Figure 1d using Definition 3.1. The labels of the nodes in $\mathcal{D}'$ are mentioned on the right.

at x such that $\{s, v\} \subseteq \beta_{\mathcal{D}}(x^\star)$ and hence $x^\star \in R$. Now, since Q is non-empty and $T[Q]$ is connected, we have that $s \in \beta_{\mathcal{D}}(x)$. Since $v \notin \beta_{\mathcal{D}}(x)$, $v \in \gamma_{\mathcal{D}}(x)$ and $s \in \beta_{\mathcal{D}}(x)$, we conclude that $x \in Q$. Thus, we have proved that x is an end-vertex of the the path $T[Q]$.

Next we prove that y is the other end-vertex of the path $T[Q]$ and y is an ancestor of x. Since y is the only child of the node y' labelled with **forget**(s), we have that $s \in \beta_{\mathcal{D}}(y)$ and $s \notin \beta_{\mathcal{D}}(y')$. This implies that $y' \notin Q$. Thus to prove that y is an end-vertex of the path $T[Q]$, it is enough to prove that $y \in Q$. Since $s \in \beta_{\mathcal{D}}(x)$, $s \in \beta_{\mathcal{D}}(y)$, $s \notin \beta_{\mathcal{D}}(y')$ and y' is the parent of y, by Property (c) of $\mathcal{D}$, we have that y is an ancestor of x. This also implies that $v \in \gamma_{\mathcal{D}}(y)$ and $v \notin \beta_{\mathcal{D}}(y)$. Hence, $y \in Q$. This completes the proof of the lemma. ◀

In the next lemma we show that for any special vertex $s \in S(G)$ and any node t in T labelled with **introduce**(s) by $\mathcal{D}$, it holds that t and its child carry the "same information".

▶ **Lemma 3.4** $(\star)$**.** *Let $s \in S(G)$ and t be a node in T labelled with **introduce**(s) by $\mathcal{D}$. Let t' be the only child of t. Then, $\mathsf{Original}(t) = \mathsf{Original}(t')$ and $\mathsf{Fake}(t) = \mathsf{Fake}(t')$.*

Next, we see a property of nodes $t \in V(T)$ labelled with **join**.

▶ **Lemma 3.5** $(\star)$**.** *Let t be a node in T labelled with **join** by D, and t_1 and t_2 are its children. Then, $\mathsf{Original}(t) = \mathsf{Original}(t_1) = \mathsf{Original}(t_2)$, $\mathsf{Cliques}(t) = \mathsf{Cliques}(t_1) = \mathsf{Cliques}(t_2)$, $\mathsf{Fake}(t_1) \cap \mathsf{Fake}(t_2) = \emptyset$, and $\mathsf{Fake}(t) = \mathsf{Fake}(t_1) \cup \mathsf{Fake}(t_2)$.*

Now, we define a notion of *nice ℓ-few cliques tree decomposition* of G as the tree decomposition of G derived from a nice tree decomposition $\mathcal{D}$ of B of width $< \ell$ (see Definition 3.1) with additional labeling of nodes. In what follows, we describe this additional labeling of nodes. Towards this, observe that because of Lemma 3.4, for any special vertex $s \in S(G)$ and any node $t \in V(T)$ labelled with **introduce**(s) by $\mathcal{D}$, the bags $\beta_{D'}(t)$ and $\beta_{D'}(t')$ carry the "same information" where t' is the only child of t. Informally, one may choose to handle these nodes by contracting them. However, to avoid redundant proofs ahead, instead of getting rid of such nodes, we label them with **redundant** in $\mathcal{D}'$. Next, we explain how to label other nodes of T in the decomposition $\mathcal{D}'$ (see Figure 2). To this end, let $t \in V(T)$.

- If t is labelled with **leaf** by $\mathcal{D}$, then we label t with **leaf**. Here, $\beta_{\mathcal{D}'}(t) = \emptyset$.
- If t is labelled with **introduce**(v) by $\mathcal{D}$ for some $v \in V(G)$, then we label t with **introduce**(v). In this case, t has only one child t' in T and $\beta_{\mathcal{D}'}(t) \setminus \{v\} = \beta_{\mathcal{D}'}(t')$.
- If t is labelled with **forget**(v) by $\mathcal{D}$ for some $v \in V(G)$ and $v \in \mathsf{Fake}(t)$, then we label t with **fake introduce**(v). In this case, t has only one child t' and $\beta_{\mathcal{D}'}(t) = \beta_{\mathcal{D}'}(t')$, but $\mathsf{Original}(t) = \mathsf{Original}(t') \setminus \{v\}$ and $\mathsf{Fake}(t) = \mathsf{Fake}(t') \cup \{v\}$.

- If t is labelled with **forget**(v) by $\mathcal{D}$ for some $v \in V(G)$ and $v \notin \mathsf{Fake}(t)$, then we label t with **forget**(v). In this case, t has only one child t', $\beta_{\mathcal{D}'}(t) = \beta_{\mathcal{D}'}(t') \setminus \{v\}$, $\mathsf{Original}(t) = \mathsf{Original}(t') \setminus \{v\}$ and $\mathsf{Fake}(t) = \mathsf{Fake}(t')$.
- Suppose t is labelled with **forget**(s) by $\mathcal{D}$ for some $s \in S(G)$. Then, t has only one child t'. Here, we label t with **forget**$(\beta_{\mathcal{D}'}(t') \setminus \beta_{\mathcal{D}'}(t))$. In this case, $\mathsf{Fake}(t) \subseteq \mathsf{Fake}(t')$ and $\mathsf{Original}(t) = \mathsf{Original}(t')$.
- If t is labelled with **join** by $\mathcal{D}$, then we label t with **join**. Let t_1 and t_2 be the children of t. Then, $\mathsf{Original}(t) = \mathsf{Original}(t_1) = \mathsf{Original}(t_2)$, $\mathsf{Cliques}(t) = \mathsf{Cliques}(t_1) = \mathsf{Cliques}(t_2)$, $\mathsf{Fake}(t_1) \cap \mathsf{Fake}(t_2) = \emptyset$, and $\mathsf{Fake}(t) = \mathsf{Fake}(t_1) \cup \mathsf{Fake}(t_2)$. (See Lemma 3.5).
- If t is labelled with **introduce**(s) for some $s \in S(G)$, then we label t with **redundant**.

This completes the definition of the nice ℓ-few cliques tree decomposition of G derived from $\mathcal{D}$, to which we simply call an $(\ell, \mathcal{D})$-NFewCliTD. Notice that for each node t in T, $|\mathsf{Original}(t)| + |\mathsf{Cliques}(t)| \leq \ell$. That is, for any node $t \in V(T)$, there exist $i, j \in \mathbb{N}$ such that $i + j \leq \ell$, the cardinality of $\mathsf{Original}(t)$ is at most i, and the vertices in $\beta_{\mathcal{D}'}(t) \setminus \mathsf{Original}(t)$ were obtained from at most j special cliques. From now on, we assume that $\mathcal{D}'$ is an $(\ell, \mathcal{D})$-NFewCliTD of a map graph G.

Since the number of nodes with label **forget**(v) in the tree decomposition $\mathcal{D}$ is exactly one for any $v \in V(B)$ (see Observation 2.3), *at most one* node in T is labelled with **fake introduce**(v) in $\mathcal{D}'$. This is formally stated in the following observation.

▶ **Observation 3.6.** *Let $t \in V(T)$ and $v \in \mathsf{Fake}(t)$. Then,*

(i) *there is a unique node $t' \in V(T)$ such that t' is labelled with **fake introduce**(v) in $\mathcal{D}'$,*

(ii) *t is an ancestor of t' or $t = t'$, and*

(iii) *for any node t'' in the unique path between t and t', we have that $v \in \mathsf{Fake}(t'')$.*

The correctness of Observation 3.6 follows from Observation 2.3 and Lemma 3.3. The discussion above, along with Proposition 2.4, implies the following lemma.

▶ **Lemma 3.7 ($\star$).** *Given a map graph G, a corresponding planar bipartite graph B, and an integer $\ell \in \mathbb{N}$, in time $\mathcal{O}(n^2)$, one can either correctly conclude that B contains an $\ell \times \ell$ grid as a minor, or compute a nice tree decomposition $\mathcal{D}$ of B of width less than 5ℓ and a $(5\ell, \mathcal{D})$-NFewCliTD of G.*

Lastly, we prove an important property of $\mathcal{D}'$. In particular, the edges considered in the following lemma are precisely those that connect the vertices "already seen" (when we use dynamic programming (DP)) with vertices to "see in the future".

▶ **Lemma 3.8.** *For any node $t \in V(T)$, the edges with one endpoint in $\gamma_{\mathcal{D}'}(t)$ and other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ are of two kinds: (i) edges incident with vertices in $\mathsf{Original}(t)$, and (ii) edges belonging to some special clique in $\mathsf{Cliques}(t)$ (these edges are incident to vertices in $\mathsf{Fake}(t)$).*

Proof. Fix $t \in V(T)$. Since $\mathcal{D}'$ is a tree decomposition of G, for any edge $e \in E(G)$ with one endpoint in $\gamma_{\mathcal{D}'}(t)$ and other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$, the endpoint of e in $\gamma_{\mathcal{D}'}(t)$ should belong to $\beta_{\mathcal{D}'}(t)$. Let u be the endpoint of e that belongs to $\beta_{\mathcal{D}'}(t)$, and v be the other endpoint of e. Notice that the set $\beta_{\mathcal{D}'}(t)$ is partitioned into $\mathsf{Original}(t)$ and $\mathsf{Fake}(t)$, so u belongs to either $\mathsf{Original}(t)$ or $\mathsf{Fake}(t)$, and in the former case we are done. We now assume that $u \in \mathsf{Fake}(t)$.

Since $\{u, v\} = e \in E(G)$, there is a special vertex $s \in S(G)$ such that $\{u, s\}, \{v, s\} \in E(B)$. If $s \in \beta_{\mathcal{D}}(t)$, then the edge $\{u, v\}$ belongs to the special clique $K = N_B(s)$ in G and $K \in \mathsf{Cliques}(t)$. We claim that indeed $s \in \beta_{\mathcal{D}}(t)$. Towards this, notice that $u \in \mathsf{Fake}(t)$. This implies that $u \notin \beta_{\mathcal{D}}(t)$, but u is present in a bag $\beta_{\mathcal{D}}(t')$ of some descendant t' of t. Moreover, since $\{u, s\} \in E(B)$, we further know that $\{u, s\} \subseteq \beta_{\mathcal{D}}(t_1)$ for some descendent t_1 of t. Since

$\{v, s\} \in E(B)$ and $v \notin \gamma_{\mathcal{D}'}(t)$, there is a bag $\beta_{\mathcal{D}}(t_2)$ such that $\{v, s\} \subseteq \beta_{\mathcal{D}}(t_2)$ and t_2 is not a descendent of t. Thus, since $s \in \beta_{\mathcal{D}}(t_1) \cap \beta_{\mathcal{D}}(t_2)$, by Property (c) of the tree decomposition $\mathcal{D}$, we have that $s \in \beta_{\mathcal{D}}(t)$. This completes the proof of the lemma. ◀

4 Longest Cycle

In this section we prove the following theorem.

▶ **Theorem 4.1.** Longest Cycle *on map graphs can be solved in* $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ *time.*

Notice that if there is a special vertex $s \in S(G)$ such that $|N_B(s)| \geq k$, then G has a cycle of length at least k, because $N_B(s)$ forms a clique in G. Moreover, observe that if there is a "large enough" grid in B, then we can answer Yes. These observations along with Lemma 3.7 lead to the following lemma.

▶ **Lemma 4.2** (⋆). *There is an algorithm that given an instance* (G, B, k) *of* Longest Cycle*, runs in time* $\mathcal{O}(n^2)$*, and either correctly concludes that* G *has a cycle of length at least* k*, or outputs a nice tree decomposition* $\mathcal{D}$ *of* B *of width* $< 5\sqrt{2k}$ *and a* $(5\sqrt{2k}, \mathcal{D})$*-NFewCliTD* $\mathcal{D}'$ *of* G *such that for each node* $t \in V(T)$*,* $|\beta_{\mathcal{D}'}(t)| \leq 5\sqrt{2} \cdot k^{1.5}$*.*

Because of Lemma 4.2, to prove Theorem 4.1, we may assume that the input contains a $(5\sqrt{2k}, \mathcal{D})$-NFewCliTD $\mathcal{D}'$ of G (derived from a nice tree decomposition $\mathcal{D}$ of B) such that for each node $t \in V(T)$, $|\beta_{\mathcal{D}'}(t)| \leq 5\sqrt{2} \cdot k^{1.5}$. That is, from now on, we fix our input to be an instance (G, B, k) of Longest Cycle, a nice tree decomposition $\mathcal{D}$ of B and a $(5\sqrt{2k}, \mathcal{D})$-NFewCliTD $\mathcal{D}'$ of G such that for each node $t \in V(T)$, $|\beta_{\mathcal{D}'}(t)| \leq 5\sqrt{2} \cdot k^{1.5}$. Towards the proof of Theorem 4.1, the main ingredient is to prove the following claim: if G has a cycle of length ℓ, then there is a cycle C of length ℓ, with the following property.

For each node $t \in V(T)$, the number of edges of $E(C)$ with one endpoint in $\beta_{\mathcal{D}'}(t)$ and the other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ is upper bounded by $\mathcal{O}(\sqrt{k})$.

The above mentioned property is encapsulated in the following sublinear crossing lemma.

▶ **Lemma 4.3** (Sublinear Crossing Lemma (⋆))**.** *Let* C *be a cycle in* G*. Then there is a cycle* C' *of the same length as* C *such that for any node* $t \in V(T)$*, the number of edges in* $E(C')$ *with one endpoint in* $\beta_{\mathcal{D}'}(t)$ *and the other in* $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ *is at most* $20\sqrt{2k}$*.*

Lemma 4.3 lies at the heart of the proof of Theorem 4.1 and is one of the main technical contributions of the paper. Assuming Lemma 4.3, the proof of Theorem 4.1 is by designing a DP algorithm on a $(5\sqrt{2k}, \mathcal{D})$-NFewCliTD of G. This part is similar to the algorithm for Longest Cycle in [20] on a so called *special path decomposition*. The main ingredient of Lemma 4.3 is the following lemma (Lemma 4.4). The proof of Lemma 4.3 is by an inductive argument assuming Lemma 4.4. The rest of the section is devoted to the proof of Lemma 4.4.

▶ **Lemma 4.4.** *Let* C *be a cycle in* G *and* K *be a special clique in* G*. Then, there is a cycle* C' *of the same length as* C *such that* $E(C') \setminus E(K) = E(C) \setminus E(K)$ *and for any node* $t \in V(T)$*, the number of edges of* $E(C') \cap E(K)$ *with one endpoint in* $\mathsf{Fake}(t) \cap K$ *and the other in* $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ *is at most* 4*.*

Before formally proving Lemma 4.4, we give a high level overview of the proof and an auxiliary lemma which we use in the proof of Lemma 4.4. The proof idea is to change the edges of $E(K) \cap E(C)$ in C (because in Lemma 4.4 our objective is to bound the "crossing edges" from a subset of $E(K)$ for each node $t \in V(T)$) to obtain a new cycle C' of the same

length as C that satisfies the following property: (i) for any node $t \in V(T)$, the number of edges of $E(C') \cap E(K)$ with one endpoint in $\mathsf{Fake}(t) \cap K$ and the other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ is at most 4. For the ease of presentation, assume that $K \subseteq V(C)$. Now, consider the graph $\mathcal{P}$ obtained from the cycle C after deleting edges in $E(K)$. Without loss of generality assume that $E(C) \cap E(K) \neq \emptyset$. Otherwise, Lemma 4.4 is true where $C' = C$. We consider $\mathcal{P}$ as a collection of vertex-disjoint paths where the end-vertices of the paths are in K. Some paths in $\mathcal{P}$ may be of length 0. Let Z be the set of end-vertices of the paths in $\mathcal{P}$. Clearly, $Z \subseteq K$. We will "complete" the collection of paths $\mathcal{P}$ to a cycle by adding edges from $E(Z)$ satisfying Statement (i). Any cycle C' with $V(C') = V(\mathcal{P})$ has the same length as C. So, all the work that is required for us is to complete the collection of paths $\mathcal{P}$ to a cycle by adding edges from $E(Z)$ satisfying Statement (i). Towards that, let $\widehat{\sigma} = v_1, \ldots, v_{k'}$ be an arbitrary sequence of vertices in Z. We show (in Claim 4.7) that (ii) there is a subset of edges $F \subseteq E(Z)$ such that $E(\mathcal{P}) \cup F$ forms a cycle C' with vertex set $V(\mathcal{P})$ and for any $j \in [k']$, the number of edges in F with one endpoint in $\{v_1, \ldots, v_j\}$ and the other in $\{v_{j+1}, \ldots, v_{k'}\}$ is at most 2. This implies that for any $1 \leq i \leq j \leq k'$, the number of edges in F with one endpoint in $\{v_i, \ldots, v_j\}$ and the other in $Z \setminus \{v_i, \ldots, v_j\}$ is at most 4. In the light of Statement (ii), our aim will be to prove that (iii) for any node $t \in V(T)$, there exist $1 \leq i \leq j \leq k'$ such that $\mathsf{Fake}(t) \cap Z \subseteq \{v_i, \ldots, v_j\}$ and no vertex in $Z \setminus \gamma_{\mathcal{D}'}(t)$ belongs to $\{v_i, \ldots, v_j\}$. Then, Statement (i) will follow (because edges of C' incident with vertices in $K \setminus Z$ are from $E(G) \setminus E(K)$ and will not be counted in Statement (i)). In fact, we will prove that there is a sequence σ on Z (derived from a postorder transversal of T) such that Statement (iii) is true (see Claim 4.8). The proof of Statement (ii) is encapsulated in the following lemma.

▶ **Lemma 4.5** $(\star)$**.** *Let $\ell \geq 3$ be an integer. Let $u_1, \ldots, u_\ell$ be a sequence of vertices in a graph H where $X = \{u_1, \ldots, u_\ell\}$ is a clique in H. Let $\mathcal{Q}$ be a family of vertex-disjoint paths in H (which possibly contains paths of length 0) such that each $v \in X$ is an end-vertex of a path in $\mathcal{Q}$ and $E(\mathcal{Q}) \cap E(X) = \emptyset$. Then, there is a set $F \subseteq E(X)$ with the following conditions.*

(a) *$E(\mathcal{Q}) \cup F$ forms a cycle containing all the vertices of $V(\mathcal{Q})$,*

(b) *For any $j \in [\ell]$, the number of edges in F with one endpoint in $\{u_1, \ldots, u_j\}$ and the other in $\{u_{j+1}, \ldots, u_\ell\}$ is at most 2.*

Next, we move to a formal proof of Lemma 4.4.

Proof of Lemma 4.4. Without loss of generality, assume that $K \subseteq V(C)$. Otherwise, we can consider the statement of the lemma for cycle C in the graph $G' = G - (K \setminus V(C))$ and special clique $K \cap V(C)$ of G'. We also assume that $E(C) \cap E(K) \neq \emptyset$, else the correctness is trivial because we can take C' as C.

Let π' be a postorder transversal of the nodes in the rooted binary tree T, and let π be the restriction of π' where we only keep the nodes that are labeled with **fake introduce**(v) for some $v \in K$. Denote $\pi = t_1, \ldots, t_{k''}$ such that each t_i, $i \in [k'']$, is labelled with **fake introduce**(x_i) where $x_i \in K$. Notice that $\bigcup_{t \in V(T)} \mathsf{Fake}(t) \cap K = \{x_1, \ldots, x_{k''}\}$ (by Observation 3.6). Let σ_1 be the sequence $x_1, \ldots, x_{k''}$ and $U = \{x_1, \ldots, x_{k''}\}$. Let σ_2 be a fixed arbitrary sequence of $K \setminus U$, i.e., all the vertices of K that are never "fakely introduced". Let σ be the sequence which is a concatenation of σ_1 and σ_2.

Let $\mathcal{P} = (V(C), E(C) \setminus E(K))$. That is, $\mathcal{P}$ is the graph obtained by deleting edges of $E(K)$ from the cycle C. Notice that each connected component of $\mathcal{P}$ is a path (may be of length 0) with end-vertices in K. Let Z be the set of end-vertices of the paths in $\mathcal{P}$. Notice that for any vertex $u \in K \setminus Z$, both edges of C incident with u are from $E(C) \setminus E(K)$ (see the left part of Figure 3). That is, $E(C) \setminus E(K) = E(C) \setminus E(Z) = E(\mathcal{P})$. Since we seek a cycle C' in which $E(C') \setminus E(K) = E(C) \setminus E(K)$, no edge of C' incident with u for any vertex $u \in K \setminus Z$, is in $E(K)$. That is, all the edges of $E(C') \cap E(K)$ will belong to $E(Z)$.

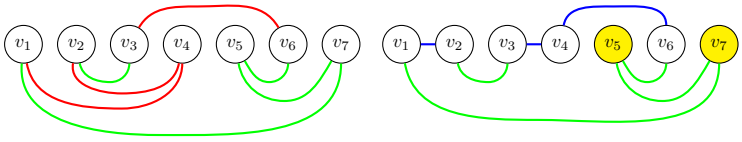

Figure 3 Left part illustrates a cycle C interacting with a special clique $K = \{v_1, \ldots, v_7\}$. The red curves represent edges in $E(C) \cap E(K)$ and green curves represent paths in C with endpoints in K and (at least one) internal vertices in $V(G) \setminus K$. Thus, $\mathcal{P}$ is the collection of paths that is a union of the set of two "green" paths $((v_2 - v_3)$ and $(v_1 - v_7 - v_5 - v_6))$ and $\{[v_4]\}$. Here $Z = \{v_1, v_2, v_3, v_4, v_6\}$. Any edge of $E(C)$ incident with v_5 and v_7 (i.e., vertices in $K \setminus Z$) are from $E(C) \setminus E(K)$. The right part illustrates the proof of Claim 4.7. The edges of $E(C') \setminus E(C)$ mentioned in the proof of Claim 4.7 are colored blue.

▶ **Observation 4.6.** *Let C' be a cycle in G such that $E(C') \setminus E(K) = E(C) \setminus E(K)$ and $t \in V(T)$. The number of edges of $E(C') \cap E(K)$ with one endpoint in $\mathsf{Fake}(t) \cap K$ and the other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ is equal to the number of edges of $E(C') \cap E(Z)$ with one endpoint in $\mathsf{Fake}(t) \cap Z$ and the other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$.*

Let $Z = \{v_1, \ldots, v_{k'}\}$ and $\sigma' = \sigma|_Z = v_1, \ldots, v_{k'}$. The main ingredients of the proof are the following two claims.

▷ Claim 4.7. There is a cycle C' of the same length as C such that (i) $E(C') \setminus E(Z) = E(C) \setminus E(Z)$, and (ii) for any $j \in [k']$, the number of edges of $E(C') \cap E(Z)$ with one endpoint in $\{v_1, \ldots, v_j\}$ and the other in $\{v_{j+1}, \ldots, v_{k'}\}$ is at most 2.

The proof of Claim 4.7 follows from Lemma 4.5.

▷ Claim 4.8. For any node $t \in V(T)$, there is a segment σ'' of σ' such that each vertex in $\mathsf{Fake}(t) \cap Z$ appears in σ'', and each vertex in $Z \setminus \gamma_{\mathcal{D}'}(t)$ does not appear in σ''.

Proof. Fix a node $t \in V(T)$. Recall that $\sigma = \sigma_1\sigma_2$ and $\sigma' = \sigma|_Z$. Here, the set of vertices present in σ_1 is $U = (\bigcup_{t \in V(T)} \mathsf{Fake}(t) \cap K) \supseteq (\bigcup_{t \in V(T)} \mathsf{Fake}(t) \cap Z)$ (because $Z \subseteq K$), and no vertex in σ_2 is from U. This implies that all the vertices of $\mathsf{Fake}(t) \cap Z$ are in the sequence σ_1. That is, the sequence σ'' we seek is also a sequence of $\sigma_1|_Z$ and this is the reason we defined σ to be $\sigma_1\sigma_2$. Thus, to prove the claim it is enough to prove that there is a segment σ_1' of $\sigma_1|_Z$ such that each vertex in $\mathsf{Fake}(t) \cap Z$ appears in σ_1' and each vertex in $Z \setminus \gamma_{\mathcal{D}'}(t)$ does not appear in σ_1'.

Recall that $\sigma_1 = x_1 \ldots x_{k''}$ is obtained from the sequence $\pi = t_1, \ldots, t_{k''}$. In turn, recall that π is the restriction of the postorder transversal π' of T, where for each $i \in [k'']$, t_i is labelled with **fake introduce**(x_i) for $x_i \in K$. Let W_t be the nodes of the subtree of T rooted at t, and $V_t = \{v \in K$: there is $t' \in W_t$ such that t' is labelled with **fake introduce**$(v)\}$.

The vertices in W_t appear consecutively in π. Thus, we can let π_t be the minimal segment of π that contains all the nodes in V_t. Let $i, j \in [k'']$ be such that $\pi_t = t_i, \ldots, t_j$. Now, we define σ_t be the segment $x_i, \ldots, x_j$ of σ_1. Now we prove the claim. By conditions (i) and (ii) in Observation 3.6, $\mathsf{Fake}(t) \cap Z \subseteq V_t$. Clearly, no vertex in $Z \setminus \gamma_{\mathcal{D}'}(t)$ is in V_t. This implies that each vertex in $\mathsf{Fake}(t) \cap Z$ appears in σ_t and no vertex from $Z \setminus \gamma_{\mathcal{D}'}(t)$ appears in σ_t. In turn, this implies that $\sigma_t|_Z$ is the required segment σ'' of $\sigma' = \sigma|_Z$. ◁

Now, having the above two claims, we are ready to prove the lemma. By Claim 4.7, we have that there is a cycle C' such that (i) $E(C') \setminus E(Z) = E(C) \setminus E(Z)$, and (ii) for any $j \in [k']$, the number of edges of $E(C) \cap E(Z)$ with one endpoint in $\{v_1, \ldots, v_j\}$ and other in $\{v_{j+1}, \ldots, v_{k'}\}$ is at most 2. By Claim 4.8, we know that for any $t \in V(T)$, there is a segment

σ'' of σ' such that all vertices in $\mathsf{Fake}(t) \cap Z$ appear in a segment σ'' and no vertex from $Z \setminus \gamma_{\mathcal{D}'}(t)$ appears in σ''. That is, there exist $i, j \in [k']$ such that $\mathsf{Fake}(t) \cap Z \subseteq \{v_i, \ldots, v_j\}$ and $(Z \setminus \gamma_{\mathcal{D}'}(t)) \cap \{v_i, \ldots, v_j\} = \emptyset$. Therefore, by (ii), the number of edges of $E(C') \cap E(Z)$ with one endpoint in $\mathsf{Fake}(t) \cap Z$ and the other in $V(G) \setminus \gamma_{\mathcal{D}'}(t)$ is at most 4. Then, by Observation 4.6, the proof of the lemma is complete. ◀

Abstract

Propositional satisfiability (SAT) is one of the most fundamental problems in computer science. Its worst-case hardness lies at the core of computational complexity theory, for example in the form of NP-hardness and the (Strong) Exponential Time Hypothesis. In practice however, SAT instances can often be solved efficiently. This contradicting behavior has spawned interest in the average-case analysis of SAT and has triggered the development of sophisticated rigorous and non-rigorous techniques for analyzing random structures.

Despite a long line of research and substantial progress, most theoretical work on random SAT assumes a *uniform* distribution on the variables. In contrast, real-world instances often exhibit large fluctuations in variable occurrence. This can be modeled by a *non-uniform* distribution of the variables, which can result in distributions closer to industrial SAT instances.

We study satisfiability thresholds of non-uniform random 2-SAT with n variables and m clauses and with an arbitrary probability distribution $(p_i)_{i\in[n]}$ with $p_1 \geqslant p_2 \geqslant \ldots \geqslant p_n > 0$ over the n variables. We show for $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ that the asymptotic satisfiability threshold is at $m = \Theta\left(\left(1 - \sum_{i=1}^n p_i^2\right) / \left(p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)\right)$ and that it is coarse. For $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$ we show that there is a sharp satisfiability threshold at $m = \left(\sum_{i=1}^n p_i^2\right)^{-1}$. This result generalizes the seminal works by Chvatal and Reed [FOCS 1992] and by Goerdt [JCSS 1996].

1 Introduction

Satisfiability of Propositional Formulas (SAT) is one of the most thoroughly researched topics in theoretical computer science. It was one of the first problems shown to be NP-complete by Cook [15] and, independently, by Levin [30]. Today SAT stands at the core of many techniques in modern complexity theory, for example NP-completeness proofs [29] or running time lower bounds assuming the (Strong) Exponential Time Hypothesis [10, 17, 26, 27].

In addition to its importance for theoretical research, Propositional Satisfiability is also famously applied in practice. Despite the theoretical hardness of SAT, many problems arising in practice can be transformed to SAT instances and then solved efficiently with

state-of-the-art solvers. Problems like hard- and software verification, automated planning, and circuit design are often transformed into SAT instances. Such formulas arising from practical and industrial problems are therefore referred to as *industrial SAT instances*. The efficiency of SAT solvers on these instances suggests that they have a structure that makes them easier to solve than the theoretical worst-case.

1.1 Uniform Random k-SAT and the satisfiability threshold conjecture:

Random k-SAT is used to study the average-case complexity of Boolean Satisfiability. In the model, a random formula Φ with n variables, m clauses, and k literals per clause is generated in conjunctive normal form. Each of these formulas has the same uniform probability to be generated. Therefore, we also refer to this model as *uniform random k-SAT*.

One of the most prominent questions related to studying uniform random k-SAT is trying to prove the *satisfiability threshold conjecture*. The conjecture states that for a uniform random k-SAT formula Φ with n variables and m clauses there is a real number r_k such that

$$\lim_{n\to\infty} \Pr\left(\Phi \text{ is satisfiable}\right) = \begin{cases} 1 & m/n < r_k; \\ 0 & m/n > r_k. \end{cases}$$

Chvatal and Reed [11] and, independently, Goerdt [24] proved the conjecture for $k = 2$ and showed that $r_2 = 1$. For larger values of k upper and lower bounds have been established, e. g., $3.52 \leqslant r_3 \leqslant 4.4898$ [18, 25, 28]. Methods from statistical mechanics [32] were used to derive a numerical estimate of $r_3 \approx 4.26$. Coja-Oghlan and Panagiotou [12, 13] showed a bound (up to lower order terms) for $k \geqslant 3$ with $r_k = 2^k \log 2 - \frac{1}{2}(1 + \log 2) \pm o_k(1)$. Finally, Ding, Sly, and Sun [19] proved the exact position of the threshold for sufficiently large values of k. Still, for k between 3 and the values determined by Ding, Sly, and Sun the conjecture remains open.

The satisfiability threshold is also connected to the average hardness of solving instances. For uniform random k-SAT for example, the on average hardest instances are concentrated around the threshold [33].

1.2 Non-Uniform Random SAT

There is a large body of work which considers other random SAT models, e. g. regular random k-SAT [7, 8, 14, 38], random geometric k-SAT [9] and $2 + p$-SAT [1, 35, 34, 36]. However, most of these are not motivated by modeling the properties of industrial instances. One such property is community structure [6], i. e. some variables have a bias towards appearing together in clauses. It is clear by definition that such a bias does not exist in uniform random k-SAT. Therefore, Giráldez-Cru and Levy [23] proposed the Community Attachment Model, which creates random formulas with clear community structure. However, the work of Mull et al. [37] shows that instances generated by this model have exponentially long resolution proofs with high probability, making them hard on average for solvers based on conflict-driven clause learning.

Another important property of industrial instances is their degree distribution. The degree distribution of a formula Φ is a function $f\colon \mathbb{N} \to \mathbb{N}$, where $f(x)$ denotes the fraction of different Boolean variables that appear x times in Φ (negated or unnegated). Instances created with the uniform random k-SAT model have a binomial distribution, while some families of industrial instances appear to follow a power-law distribution [4], i. e. $f(x) \sim x^{-\beta}$, where β is a constant intrinsic to the instance. Therefore, Ansótegui et al. [5] proposed a random k-SAT model with a power-law degree distribution. Empirical studies by the

same authors [2, 3, 4, 5] found that this distribution is beneficial for the runtime of SAT solvers specialized in industrial instances. However, it looks like instances generated with their model can be solved faster than uniform instances, but not as fast as industrial ones: median runtimes around the threshold still seem to scale exponentially for several state-of-the-art solvers [21].

Therefore, we want to consider a generalization of the model by Ansótegui et al. [4]. Our model allows instances with *any* given ensemble of variable distributions instead of only power laws: We draw m clauses of length k at random. For each clause the k variables are drawn with a probability proportional to the n-th distribution in the ensemble, then they are negated independently with a probability of $1/2$ each. This means, the probability ensemble is part of the model, but the number of variables n determines which distribution from the ensemble we actually use. We call this model *non-uniform random k-SAT* and denote it by $\mathcal{D}(n, k, (\vec{p}_x)_{x\in\mathbb{N}}, m)$. Although $\mathcal{D}(n, k, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ cannot capture all properties of industrial instances, e.g. community structure, it can help us to investigate the influence of the degree distribution on the structure and on the computational complexity of such instances in an average-case scenario.

As one of the steps in analyzing this connection, we would like to find out for which ensembles of variable probability distributions an equivalent of the satisfiability threshold conjecture holds in non-uniform random k-SAT. In previous works we already proved upper and lower bounds on the threshold position [20] and showed sufficient conditions on sharpness [22]. In this work we are interested in actually determining the satisfiability threshold for $k = 2$. This is helpful in determining bounds on the satisfiability threshold for higher values of k, since 2-SAT instances appear as parts of k-SAT instances. We already successfully used this approach in [20] to derive lower bounds on the satisfiability threshold for non-uniform random k-SAT with a power-law distribution on the variables.

It has to be noted that Cooper et al. [16] and Levy [31] already studied thresholds in a similar random 2-SAT model. The difference is that in their models the degrees are fixed and the random instances determined in a configuration-model-like fashion, while in our model we only have a sequence of expected degrees from which the actual degrees might deviate. Note that it is not clear if the satisfiability thresholds in these two models coincide if they use the same sequence of (expected) degrees. Cooper et al. derive the position of the satisfiability threshold in their model if the maximum degree is sufficiently bounded. Levy only shows necessary conditions on unsatisfiability in the model of Cooper et al. This is not enough to derive the actual threshold position. In contrast, our result allows us to determine the position of the satisfiability threshold for *any* probability ensemble in the model we consider.

1.3 Our Results

We investigate the position and behavior of the satisfiability threshold for non-uniform random 2-SAT. That is, we fix the number of variables n and the variable distribution $\vec{p}_n$ from the ensemble and vary the number of clauses $m(n)$. To this end, we use the following definition and say that a function $m^*(n)$ is an *asymptotic satisfiability threshold* if

$$\Pr_{\Phi\sim\mathcal{D}(n,k,(\vec{p}_x)_{x\in\mathbb{N}},m)}(\Phi \text{ satisfiable}) = \begin{cases} 1-o(1) & \text{if } m(n) = o(m^*(n)) \\ o(1) & \text{if } m(n) = \omega(m^*(n)). \end{cases}$$

We also say that an asymptotic satisfiability threshold $m^*(n)$ is *sharp* if for all $\varepsilon > 0$

$$\Pr_{\Phi\sim\mathcal{D}(n,k,(\vec{p}_x)_{x\in\mathbb{N}},m)}(\Phi \text{ satisfiable}) = \begin{cases} 1-o(1) & \text{if } m(n) \leqslant (1-\varepsilon)\cdot m^*(n) \\ o(1) & \text{if } m(n) \geqslant (1+\varepsilon)\cdot m^*(n). \end{cases}$$

If an asymptotic threshold is not sharp, we call it *coarse*.

Let $\vec{p}_n = (p_1, p_2, \ldots, p_n)$ be the variable probability distribution we use. W. l. o. g. we assume $p_1 \geqslant p_2 \geqslant \ldots \geqslant p_n$. We are going to show that there are three cases depending on $\vec{p}_n$:

1. If $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$, then we can show that the asymptotic satisfiability threshold is at $m = \Theta\left(q_{\max}^{-1}\right)$, where $q_{\max} = \Theta\left((p_1 \cdot p_2) \,/\, \left(1 - \sum_{i=1}^n p_i^2\right)\right)$ is the maximum clause probability. We can also show that this threshold is coarse. The coarseness stems from the emergence of an unsatisfiable sub-formula of size 4, which contains only the two most probable variables.
2. If $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = o\left(\sum_{i=2}^n p_i^2\right)$, then the asymptotic threshold is at $m = \Theta\left(\left(1 - \sum_{i=1}^n p_i^2\right) \,/\, \left(p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)\right)$ and it is again coarse. This time the coarseness stems from the emergence of an unsatisfiable sub-formula with 3 variables and 4 clauses.
3. If $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$, then there is a sharp threshold at exactly $m = 1/\left(\sum_{i=1}^n p_i^2\right)$.

Note that these three cases give us a complete dichotomy of coarseness and sharpness for the satisfiability threshold of non-uniform random 2-SAT. This result generalizes the seminal works by Chvatal and Reed [11] and by Goerdt [24] to arbitrary variable probability distributions and includes their findings as a special case (c. f. Section 6). We summarize our findings in the following theorem.

▶ **Theorem 1.1.** *Let $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ be the non-uniform random 2-SAT model with n variables, m clauses, and an ensemble of probability distributions $(\vec{p}_x)_{x\in\mathbb{N}}$. Let $\vec{p}_n = (p_1, p_2, \ldots, p_n)$ be the n-th distribution from the ensemble. W. l. o. g. let $p_1 \geqslant p_2 \geqslant \ldots \geqslant p_n$. If $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$, then $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ has a sharp satisfiability threshold at $m = \left(\sum_{i=1}^n p_i^2\right)^{-1}$. Otherwise, $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ has a coarse satisfiability threshold at $m = \Theta\left(\left(1 - \sum_{i=1}^n p_i^2\right) \,/\, \left(p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)\right)$.*

1.4 Techniques

For the sharp threshold result, we only show the conditions on sharpness. These also imply the existence of an asymptotic threshold. For the coarse threshold results, however, we first have to show the existence of an asymptotic threshold at some number of clauses $m^*(n)$. Then, we have to show that for some range of constants $\varepsilon \in [\varepsilon_1, \varepsilon_2]$ the probability to generate a satisfiable instance at $\varepsilon \cdot m^*(n)$ is a constant bounded away from zero and one.

We extend and generalize the proof ideas of Chvatal and Reed [11]. In order to show a lower bound on the threshold, we investigate the existence of bicycles. Bicycles were introduced by Chvatal and Reed. They are sub-formulas which appear in every unsatisfiable formula. We can show with a first moment argument, that these do not appear below a certain number of clauses, thus making formulas satisfiable.

In order to show an upper bound on the threshold, we investigate the existence of snakes. Snakes are unsatisfiable sub-formulas and have also been introduced by Chvatal and Reed. We can show with a second-moment argument that snakes of certain sizes do appear above a certain number of clauses, thus making formulas unsatisfiable. However, we need to be careful and distinguish more possibilities of partially mapping snakes onto each other than in the uniform case. Unfortunately, this method does not work if $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$. In that case we lower-bound the probability that an unsatisfiable sub-formula containing only the two most-probable variables exists. This can be done with a simple inclusion-exclusion argument and the resulting lemma also work for $k \geqslant 3$.

2 Preliminaries

We analyze non-uniform random k-SAT on n variables and m clauses. We denote by $X_1, \dots, X_n$ the Boolean variables. A clause is a disjunction of k literals $\ell_1 \vee \dots \vee \ell_k$, where each literal assumes a (possibly negated) variable. For a literal ℓ_i let $|\ell_i|$ denote the variable of the literal. A formula Φ in conjunctive normal form is a conjunction of clauses $c_1 \wedge \dots \wedge c_m$. We conveniently interpret a clause c both as a Boolean formula and as a set of literals. We say that Φ is satisfiable if there exists an assignment of variables $X_1, \dots, X_n$ such that the formula evaluates to 1. Now let $(\vec{p}_n)_{n\in\mathbb{N}}$ be an ensemble of probability distributions, where $\vec{p}_n = (p_{n,1}, p_{n,2}, \dots, p_{n,n})$ is a probability distribution over n variables with $\Pr(X = X_i) = p_{n,i} =: p_n(X_i)$.

▶ **Definition 2.1** (Clause-Drawing Non-Uniform Random k-SAT). *Let m, n, k be given, and consider any ensemble of probability distributions $(\vec{p}_n)_{n\in\mathbb{N}}$, where $\vec{p}_n = (p_{n,1}, p_{n,2}, \dots, p_{n,n})$ is a probability distribution over n variables with $\sum_{i=1}^n p_{n,i} = 1$. The* clause-drawing non-uniform random k-SAT (non-uniform random k-SAT) *model $\mathcal{D}(n, k, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ constructs a random SAT formula Φ by sampling m clauses independently at random. Each clause is sampled as follows:*

1. *Select k variables independently at random from the distribution $\vec{p}_n$. Repeat until no variables coincide.*
2. *Negate each of the k variables independently at random with probability $1/2$.*

For the sake of simplicity and since we will always only consider one distribution from the ensemble, we will omit the index n throughout the paper, e. g. the probability distribution $\vec{p}_n$ will be denoted as $(p_1, p_2, \dots, p_n)$. W. l. o. g. we will assume $p_1 \geqslant p_2 \geqslant \dots p_n$.

The clause-drawing non-uniform random k-SAT model is equivalent to drawing each clause independently at random from the set of all k-clauses which contain no variable more than once. The probability to draw a clause c over n variables is then

$$q_c := \frac{\prod_{\ell\in c} p(|\ell|)}{2^k \sum_{J\in\mathcal{P}_k(\{1,2,\dots,n\})} \prod_{j\in J} p_j}, \tag{2.1}$$

where $\mathcal{P}_k(\cdot)$ denotes the set of cardinality-k elements of the power set. The factor 2^k in the denominator comes from the different possibilities to negate variables. Note that $k! \sum_{J\in\mathcal{P}_k(\{1,2,\dots,n\})} \prod_{j\in J} p_{n,j}$ is the probability of choosing a k-clause that contains no variable more than once. We can now write

$$q_c = C \frac{k!}{2^k} \prod_{X\in S} p_n(X), \tag{2.2}$$

where we define $C := 1/\left(k! \cdot \sum_{J\in\mathcal{P}_k(\{1,2,\dots,n\})} \prod_{j\in J} p_{n,j}\right)$. For $k = 2$ it holds that $C = 1/\left(1 - \left(\sum_{i=1}^n p_i^2\right)\right)$. Hiding this factor in C makes clause probabilities easier to handle. Throughout the paper we let $q_{\max}$ denote the maximum clause probability as defined in equation (2.2). In Section 3 and Section 4 we will assume $q_{\max} = o(1)$. The case $q_{\max} = \Theta(1)$ will be handled in Section 5. Note that this case can only happen for $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$.

3 Bi-Cycles and a Lower Bound on the Satisfiability Threshold

Chvatal and Reed [11] define the following sub-structure of 2-SAT formulas and show that every unsatisfiable 2-CNF contains this substructure.

▶ **Definition 3.1** (bi-cycle). *We define a bicycle of length t to be a sequence of $t+1$ clauses of the form*

$$(u, w_1), (\overline{w}_1, w_2), \ldots, (\overline{w}_{t-1}, w_t), (\overline{w}_t, v),$$

where $w_1, \ldots, w_t$ are literals of distinct variables and $u, v \in \{w_1, \ldots, w_t, \overline{w}_1, \ldots, \overline{w}_t\}$.

To lower-bound the probability for a random 2-CNF to be satisfiable it is therefore sufficient to upper-bound the probability that such a formula contains a bicycle. This is done in the following two lemmas. Their proofs are oriented along the lines of the proof of Theorem 3 from [11].

▶ **Lemma 3.1.** *Consider a non-uniform random 2-SAT formula Φ with $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$. Then, Φ is satisfiable with probability at least $1 - o(1)$ for a number of clauses $m < (1-\varepsilon)\left(\sum_{i=1}^n p_i^2\right)^{-1}$, where $\varepsilon > 0$ is a constant.*

Proof. To show this result, we show that the expected number of bicycles is $o(1)$ for the setting we consider. The result then follows by Markov's inequality.

First, we fix a set $S \subseteq [n]$ of variables to appear in a bicycle with $|S| = t \geqslant 2$. The probability that a *specific* bicycle B with these variables appears in Φ is

$$\Pr(B \text{ in } \Phi) = \underbrace{\binom{m}{t+1}(t+1)!}_{\text{positions of } B \text{ in } \Phi} \cdot \Pr(u \vee w_1) \cdot \Pr(\overline{w}_t \vee v) \prod_{h=1}^{t-1} \Pr(\overline{w}_h \vee w_{h+1}).$$

For literals w_i over variables x_i it holds that

$$\Pr(w_j \vee w_i) = \frac{C}{2} p_i \cdot p_j,$$

where $1 \leqslant C = \left(1 - \sum_{i=1}^n p_i^2\right)^{-1} = 1 + o(1)$, since $\sum_{i=1}^n p_i^2 = o(1)$ due to the requirement $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$. There are at most $t!$ possibilities to arrange the t variables in a bicycle and 2^t possibilities to choose literals from the t variables. For the probability that *any* bicycle with the variables from S appears in Φ it now holds that

$$\Pr(S\text{-bicycle in } \Phi) \leqslant m^{t+1} \cdot t! \cdot 2^t \cdot \left(\frac{C}{2}\right)^{t+1} \cdot \prod_{i \in S} p_i^2 \left(2 \cdot \sum_{i \in S} p_i\right)^2$$

where the last factor accounts for the possibilities to choose u and v. It now holds that

$$\begin{aligned}
\Pr(\Phi \text{ contains a bicycle}) &\leqslant \sum_{t=2}^{n} \sum_{S \subseteq \mathcal{P}_t(V)} m^{t+1} \cdot t! \cdot 2^t \cdot \left(\frac{C}{2}\right)^{t+1} 2^2 \cdot \prod_{i \in S} p_i^2 \left(\sum_{i \in S} p_i\right)^2 \\
&\leqslant 2 \cdot \sum_{t=2}^{n} (C \cdot m)^{t+1} \cdot t! \cdot t^2 \cdot p_1^2 \cdot \sum_{S \subseteq \mathcal{P}_t(V)} \prod_{i \in S} p_i^2 \\
&\leqslant 2 \cdot \sum_{t=2}^{n} (C \cdot m)^{t+1} \cdot t^2 \cdot p_1^2 \cdot \left(\sum_{i \in S} p_i^2\right)^t \\
&= o\left(2 \cdot \sum_{t=2}^{n} \left(C \cdot m \left(\sum_{i \in S} p_i^2\right)\right)^{t+1} \cdot t^2\right),
\end{aligned}$$

where we used $\sum_{i\in S} p_i \leqslant t \cdot p_1$ in the second, $\sum_{S\subseteq\mathcal{P}_t(V)} \prod_{i\in S} p_i^2 \leqslant \frac{1}{t!} \cdot \left(\sum_{i\in S} p_i^2\right)^t$ in the third line, and the requirement $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$ in the fourth line. It is obvious that this probability is o(1) as soon as the sum becomes a constant. This holds for $m < (1-\varepsilon)\left(\sum_{i=1}^n p_i^2\right)^{-1} < \left(C \cdot \sum_{i=1}^n p_i^2\right)^{-1}$, where $\varepsilon > 0$ is a constant. ◀

It has to be noted that in the former lemma we ignored the factor C in our bound. We can do this, since for $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$ it always is $1+o(1)$ and does not make a difference for sharpness due to our definition. In the case of $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$, we can show the following result with a similar proof, but now we have to take C into account, since it might become super-constant. Also we have to do a case distinction between the terms with $p_1 \in S$ and $p_1 \notin S$ to get $\sum_{S\subseteq\mathcal{P}_t(V)} \left(\prod_{i\in S} p_i^2\right) \cdot \left(\sum_{i\in S} p_i\right)^2 = \mathcal{O}\left(t^3 \cdot p_1^4 \cdot \frac{1}{t!} \cdot \left(\sum_{i=2}^n p_i^2\right)^{t-1}\right)$. See the full version of the paper for the whole proof.

▶ **Lemma 3.2.** *Consider a non-uniform random 2-SAT formula Φ with $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $q_{\max} = o(1)$. Then, Φ is satisfiable with probability at least $1 - o(1)$ for a number of clauses $m = o\left(\left(C \cdot p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right)$. Also, there is a constant $\varepsilon \in (0,1)$ such that Φ is satisfiable with a positive constant probability for a number of clauses $m \leqslant (1-\varepsilon)\left(C \cdot p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}$.*

Note that this lemma captures both cases for $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$. If also $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$, then $\left(C \cdot p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1} = \Theta\left(q_{\max}^{-1}\right)$ is the asymptotic threshold as we stated in the introduction. The case $q_{\max} = \Theta(1)$ has to be excluded, since for that case the asymptotic threshold is a constant. The above lemma might then give us a value so small that the ranges where we can lower- and upper-bound satisfiability to constants away from zero resp. one do not overlap. Thus, this case is handled separately in Section 5.

4 Snakes and an Upper Bound on the Satisfiability Threshold

The two lemmas from the previous section provided a lower bound on the satisfiability threshold for non-uniform random 2-SAT. By using the second moment method, we can also derive an upper bound on the threshold. Again, this proof is inspired by Chvatal and Reed [11, Theorem 4], who provide us with the following definition.

▶ **Definition 4.1** (snake). *A* snake *of size t is a sequence of literals $w_1, w_2, \dots, w_{2t-1}$ over distinct variables. Each snake A is associated with a set F_A of $2t$ clauses $(\overline{w}_i, w_{i+1})$, $0 \leqslant i \leqslant 2t-1$, such that $w_0 = w_{2t} = \overline{w}_t$.*

We will also call the variable $|w_t|$ of a snake its *central* variable. Note that the set of clauses F_A defined by a snake A is unsatisfiable. Also, the snakes $(w_1, \dots, w_{t-1}, w_t, w_{t+1}, \dots, w_s)$, $(\overline{w_{t-1}}, \overline{w_{t-2}} \dots, \overline{w_1}, w_t, w_{t+1}, \dots, w_s)$, $(w_1, \dots, w_{t-1}, w_t, \overline{w_s}, \overline{w_{s-1}} \dots, \overline{w_{t+1}})$ and $(\overline{w_{t-1}}, \overline{w_{t-2}} \dots, \overline{w_1}, w_t \overline{w_s}, \overline{w_{s-1}} \dots, \overline{w_{t+1}})$ create the same set of formulas.

The *variable-variable incidence graph (VIG)* for a formula Φ is a simple graph $G_\Phi = (V_\Phi, E_\Phi)$ with V_Φ consisting of all variables appearing in Φ and two variables being connected by an edge if they appear together in at least one clause of Φ. An example for a snake's VIG can be seen in Figure 1. This representation will come in handy later in the proofs of Lemmas 4.4 and 4.6.

In order to show our upper bounds, we will prove that snakes of a certain length t appear with sufficiently high probability in a random formula $\Phi \sim \mathcal{D}\left(n, k, (\vec{p}_x)_{x\in\mathbb{N}}, m\right)$ To this end we utilize the second moment method: If $X \geqslant 0$ is a random variable with finite variance, then

$$\Pr(X > 0) \geqslant \frac{\mathbb{E}[X]^2}{\mathbb{E}[X^2]}.$$

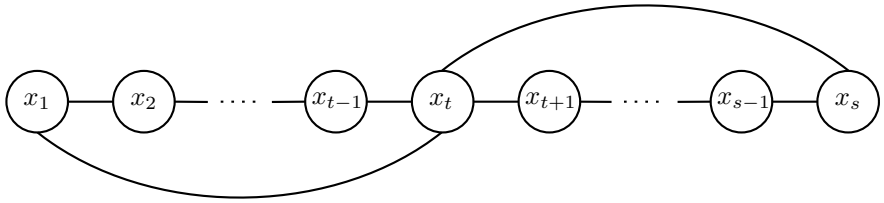

Figure 1 Variable-variable-incidence graph of a snake $w_1, w_2, \ldots, w_s$ where $|w_i| = x_i$ (the variable of the literal w_i) for $1 \leqslant i \leqslant s = 2t - 1$.

We define the following indicator variables for each snake A of size t

$$X_A = \begin{cases} 1 & \text{if } F_A \text{ appears exactly once in } \Phi \\ 0 & \text{otherwise} \end{cases}$$

and their sum $X_t = \sum_A X_A$. For carefully chosen t we will show $\mathbb{E}\left[X_t^2\right] = \mathcal{O}(\mathbb{E}[X_t]^2)$ to show a coarse and $\mathbb{E}\left[X_t^2\right] = (1 + o(1)) \cdot (\mathbb{E}[X_t]^2)$ to show a sharp threshold. This implies a constant resp. $1 - o(1)$ probability to be unsatisfiable due to the second moment method. In the case of $p_1^2 = o(\sum_{i=1}^n p_i^2)$, we will chose $t = \Theta\left(\log^2 f(n)\right)$, where we define $f(n) = \left(\sum_{i=1}^n p_i^2\right)/p_1^2$. For $p_1^2 = \Theta(\sum_{i=1}^n p_i^2)$ and $p_2^2 = o(\sum_{i=2}^n p_i^2)$ we choose $t = 2$. We only want to use the method for these two cases. The third case with $p_1 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$ will be handled with the more general Lemma 4.7.

Now, if we want to use the second moment method, we first have to ensure that the expected number of snakes of a certain size is large enough. The following lemma provides a lower bound on this expected number. Due to space limitations, its proof can be found in the full version.

▶ **Lemma 4.1.** *Let X_t be the number of snakes of size $s + 1 = 2t$ whose associated formulas appear exactly once in a non-uniform random 2-SAT formula. Then it holds that*

$$\mathbb{E}[X_t] \geqslant \frac{1}{2}(m - 2t)^{2t} \cdot C^{2t} \cdot e^{-(m-2t)\frac{2t \cdot q_{\max}}{1-2t \cdot q_{\max}}} \cdot \left(\sum_{i=1}^n p_i^4\right) \cdot \left(\sum_{i=2}^n p_i^2 - (2t-2) \cdot p_2^2\right)^{2t-2}.$$

In order to use the second moment method we have to show that this expected value is at least a constant if we want to show a coarse threshold and asymptotically bigger than a constant if we want to show a sharp threshold. Hence, the following lemmas give lower bounds on $\mathbb{E}[X_t]$ for the first two cases and the respective ranges of t we consider. Again, their proofs can be found in the full version of this paper.

▶ **Lemma 4.2.** *Let X_t be the number of snakes of size t that appear exactly once in a non-uniform random 2-SAT formula with $p_1^2 = o(\sum_{i=1}^n p_i^2)$ and $m = (1 + \varepsilon)\left(\sum_{i=1}^n p_i^2\right)^{-1}$ for some $\varepsilon > 0$. Then it holds that*

$$\mathbb{E}[X_t] \geqslant (1 - o(1)) \cdot m^{2t} \left(\sum_{i=1}^n p_i^4\right) \cdot \left(\sum_{i=1}^n p_i^2\right)^{2t-2} = \omega(1)$$

if $t = o\left(\sqrt{f(n)}\right) \cap \omega(\log f(n))$, where $f(n) = \left(\sum_{i=1}^n p_i^2\right)/p_1^2$.

▶ **Lemma 4.3.** *Let X_t be the number of snakes of size t that appear exactly once in a non-uniform random 2-SAT formula with $p_1^2 = \Theta(\sum_{i=1}^n p_i^2)$ and $p_2^2 = o(\sum_{i=2}^n p_i^2)$. For $t = 2$ and $m = \Omega\left(\left(C \cdot p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right) \cap o\left(q_{\max}^{-1}\right)$ it holds that*

$$\mathbb{E}[X_2] \geqslant (1 - o(1)) \cdot m^4 \cdot C^4 \cdot p_1^4 \cdot \left(\sum_{i=1}^n p_i^2\right)^2.$$

Furthermore,

$$\mathbb{E}[X_2] = \begin{cases} \Omega(1) & , m = \Theta\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right) \text{ and} \\ \omega(1) & , m = \omega\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right) \cap o\left((q_{\max})^{-1}\right). \end{cases}$$

Now we are ready to prove an upper bound on the non-uniform random 2-SAT threshold. To get to know the proof technique, we start with the much simpler case $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = o\left(\sum_{i=2}^n p_i^2\right)$. The proof contains a small case distinction depending on how the shared clauses of two snakes A and B influence $\Pr(X_A \wedge X_B)$. The next lemma establishes that there is a regime of m where random formulas are unsatisfiable with a positive constant probability. Its proof is in the full version.

▶ **Lemma 4.4.** *Consider a non-uniform random 2-SAT formula Φ with $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = o\left(\sum_{i=2}^n p_i^2\right)$. Then Φ is unsatisfiable with positive constant probability for $m = \Theta\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right)$.*

The following lemma complements the former one, showing that above that regime of m random formulas are unsatisfiable with probability $1 - o(1)$. Its proof is very similar and is therefore omitted. It can be found in the full version of this work.

▶ **Lemma 4.5.** *Consider a non-uniform random 2-SAT formula Φ with $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = o\left(\sum_{i=2}^n p_i^2\right)$. Then Φ is unsatisfiable with probability $1 - o(1)$ for $m = \omega\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right)$.*

The former two lemmas together with Lemma 3.2 establish that in the case of $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = o\left(\sum_{i=2}^n p_i^2\right)$ the asymptotic threshold is at $m = \Theta\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right)$ and that it is coarse.

We now turn to the case $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$. Again, we have to consider different possibilities for the shared clauses of snakes A and B to influence $\Pr(X_A \wedge X_B)$. In the proofs of the former case this was rather easy, since we only considered the smallest possible snakes of size 3. Now the distinction becomes a bit more difficult. We will distinguish several cases: If the number of shared clauses is at least $t - 1$ then $\Pr(X_A \wedge X_B)$ is by roughly a factor of $(1 + \varepsilon)^t$ smaller than $\mathbb{E}[X_t]^2$. If the shared clauses form at least two connected sub-formulas, then there are enough variable appearances pre-defined for B to make $\Pr(X_A \wedge X_B)$ sufficiently small. The last case is that there is only one connected sub-formula, which is a lot smaller than $t - 1$. In that case we have to carefully consider what happens to the central variable from B, since this variable appears most times in B and the many appearances take degrees of freedom away from other variables, therefore making $\Pr(X_A \wedge X_B)$ small. The whole proof of the lemma can be found in the full version.

▶ **Lemma 4.6.** *Consider a non-uniform random 2-SAT formula Φ with $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$. Then Φ is unsatisfiable with probability $1 - o(1)$ for $m > (1+\varepsilon) \cdot \left(\sum_{i=1}^n p_i^2\right)^{-1}$, where $\varepsilon > 0$ is a constant.*

Lemma 4.6 and Lemma 3.1 now establish the existence of a sharp threshold at $m = \left(\sum_{i=1}^n p_i^2\right)^{-1}$.

Now we still have to consider the case $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$ and $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$. In the following lemma, we give a lower bound on the probability to be unsatisfiable by showing the existence of an unsatisfiable sub-formula consisting only of the two most-probable variables. The lemma generally holds for $k \geqslant 2$, but it especially serves our purpose of considering the remaining case. The proof uses a simple inlcusion-exclusion argument and can be found in the full version.

▶ **Lemma 4.7.** *Consider a non-uniform random k-SAT formula Φ with $q_{\max} = o(1)$. Then Φ is unsatisfiable with probability at least*

$$\sum_{l=0}^{2^k} \left(\binom{2^k}{l} (-1)^l \left(1 - l \cdot q_{\max}\right)^m \right) \geqslant \left(1 - \exp\left(-q_{\max} \cdot m\right)\right)^{2^k} - q_{\max}^2 \cdot 2^{2k} \cdot m \cdot \left(1 + \exp\left(-q_{\max} \cdot m\right)\right)^{2^k}.$$

The former lemma now yields the following corollary.

▶ **Corollary 4.1.** *Consider a non-uniform random k-SAT formula Φ with $q_{\max} = o(1)$. Then*

1. $\Pr(\Phi$ *unsatisfiable*$) = \Omega(1)$ *for* $m = \Theta\left(q_{\max}^{-1}\right)$ *and*
2. $\Pr(\Phi$ *unsatisfiable*$) = 1 - o(1)$ *for* $m = \omega(q_{\max}^{-1})$.

In the second case the result follows from Lemma 4.7 for $m = \omega(q_{\max}^{-1}) \cap o(q_{\max}^{-2})$ and by monotonicity of the satisfiability probability in m. This corollary together with Lemma 3.2 establishes the existence of a coarse threshold at $m = \Theta\left(\left(C \cdot p_1 \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)^{-1}\right) = \Theta\left(q_{\max}^{-1}\right)$ for non-uniform random 2-SAT with $p_1^2 = \Theta\left(\sum_{i=1}^n p_i^2\right)$, $p_2^2 = \Theta\left(\sum_{i=2}^n p_i^2\right)$.

5 Constant Clause Probabilities

We assumed $q_{\max} = o(1)$ throughout the paper. For the sake of completeness we still have to take care of the case $q_{\max} = \Theta(1)$. It is easy to see that for $\Phi \sim \mathcal{D}\left(n, 2, (\vec{p}_x)_{x \in \mathbb{N}}, m\right)$ and a constant $m \geqslant 4$ it holds that $\Pr(\Phi \text{ unsatisfiable}) \geqslant q_{\max}^m$, since this is the probability of an unsatisfiable instance, where the most probable clause appears with all four combinations of signs and then one of these clauses appears an additional $m - 4$ times. Similarly, $\Pr(\Phi \text{ satisfiable}) \geqslant q_{\max}^m$, as this is the probability of a satisfiable instance, where the same most probable clause appears m times with the same sign. Since $0 < q_{\max} \leqslant 1/4$ is a constant, the probability is a constant bounded away from zero and one. It remains to show that Φ is unsatisfiable with probability $1 - o(1)$ for $m = \omega(1)$. The following lemma establishes this. Again, this lemma also holds for $k \geqslant 2$ in general.

▶ **Lemma 5.1.** *Consider a non-uniform random k-SAT formula Φ. Then Φ is unsatisfiable with probability at least*

$$2 - \left(1 + \exp\left(-q_{\max} \cdot m\right)\right)^{2^k}.$$

Proof. As in Lemma 4.7, it holds that

$$\Pr(\Phi \text{ unsat}) \geqslant \sum_{l=0}^{2^k} \left(\binom{2^k}{l} (-1)^l (1 - l \cdot q_{\max})^m \right).$$

We can now estimate

$$\begin{aligned}
\sum_{l=0}^{2^k} \left(\binom{2^k}{l} (-1)^l (1 - l \cdot q_{\max})^m \right) &\geqslant 1 - \sum_{l=1}^{2^k} \left(\binom{2^k}{l} (1 - l \cdot q_{\max})^m \right) \\
&\geqslant 1 - \sum_{l=1}^{2^k} \left(\binom{2^k}{l} \exp\left(-m \cdot \frac{l \cdot q_{\max}}{1 - l \cdot q_{\max}} \right)^m \right) \\
&\geqslant 1 - \sum_{l=1}^{2^k} \left(\binom{2^k}{l} \exp\left(-m \cdot l \cdot q_{\max} \right) \right) \\
&= 2 - \left(1 + \exp\left(-m \cdot q_{\max}\right)\right)^{2^k}
\end{aligned}$$

◀

For $q_{\max} = \Theta(1)$ and $m = \omega\left(q_{\max}^{-1}\right)$ this lemma implies $\Pr(\Phi \text{ unsatisfiable}) \geqslant 1 - o(1)$. All lemmas together now imply our main theorem.

▶ **Theorem 1.1.** *Let $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ be the non-uniform random 2-SAT model with n variables, m clauses, and an ensemble of probability distributions $(\vec{p}_x)_{x\in\mathbb{N}}$. Let $\vec{p}_n = (p_1, p_2, \dots, p_n)$ be the n-th distribution from the ensemble. W. l. o. g. let $p_1 \geqslant p_2 \geqslant \dots \geqslant p_n$. If $p_1^2 = o\left(\sum_{i=1}^n p_i^2\right)$, then $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ has a sharp satisfiability threshold at $m = \left(\sum_{i=1}^n p_i^2\right)^{-1}$. Otherwise, $\mathcal{D}(n, 2, (\vec{p}_x)_{x\in\mathbb{N}}, m)$ has a coarse satisfiability threshold at $m = \Theta\left(\left(1 - \sum_{i=1}^n p_i^2\right) / \left(p_1 \cdot \left(\sum_{i=2}^n p_i^2\right)^{1/2}\right)\right)$.*

6 Example Applications of our Theorem

We will now show on some examples how our main theorem can be applied.

6.1 Uniform Distribution

The simplest distribution we can apply our theorem to is the uniform distribution, i. e. $\vec{p}_n = \left(\frac{1}{n}, \frac{1}{n}, \dots, \frac{1}{n}\right)$ for all $n \in \mathbb{N}$. It holds that $p_1^2 = \frac{1}{n^2}$ and $\sum_{i=1}^n p_i^2 = \frac{1}{n}$. Thus, Theorem 1.1 implies a sharp threshold at $m^*(n) = n$ for all $n \in \mathbb{N}$. This reproves [11, 24] the satisfiability threshold conjecture for $k = 2$, since these sharp threshold are all at $m^*(n) = n$.

6.2 Power Law Distribution

Another ensemble of distributions we can choose are power-law distributions, i.e. we consider the power law random 2-SAT model introduced by Ansótegui et al. [5]. Thus, for a constant $\beta > 2$ we choose $\vec{p}_n = (p_1, p_2, \dots, p_n)$ with

$$p_i = \frac{(n/i)^{\frac{1}{\beta-1}}}{\left(\sum_{j=1}^n (n/j)^{\frac{1}{\beta-1}}\right)}.$$

It already holds that $p_1 \geqslant p_2 \geqslant \dots \geqslant p_n$. Now it is an easy exercise to show that

$$\left(\sum_{j=1}^n (n/j)^{\frac{1}{\beta-1}}\right) = (1 - o(1)) \cdot \frac{\beta - 1}{\beta - 2}.$$

Furthermore

$$p_1^2 = (1 \pm o(1)) \cdot \left(\frac{\beta - 1}{\beta - 2}\right)^2 \cdot n^{-2\frac{\beta-2}{\beta-1}}.$$

Finally, one can show that

$$\sum_{i=1}^{n} p_i^2 = \begin{cases} (1 \pm o(1)) \cdot \frac{(\beta-2)^2}{(\beta-3)\cdot(\beta-1)} \cdot n^{-2\frac{\beta-2}{\beta-1}} & \text{for } \beta < 3 \\ (1 \pm o(1)) \cdot \frac{1}{4} \cdot \frac{\ln n}{n} & \text{for } \beta = 3 \\ (1 \pm o(1)) \cdot \frac{(\beta-2)^2}{(\beta-3)\cdot(\beta-1)} \cdot n^{-1} & \text{for } \beta > 3. \end{cases}$$

Thus, applying our theorem we can see that for $\beta < 3$ there is a coarse threshold at $m = \Theta\left(n^{-2\frac{\beta-2}{\beta-1}}\right)$, since $p_1^2 = \Theta\left(\sum_{i=1}^{n} p_i^2\right) = \Theta\left(n^{2\frac{\beta-2}{\beta-1}}\right)$ and $C = 1 + o(1)$. For $\beta = 3$ there is a sharp threshold at $4 \cdot \frac{n}{\ln n}$, since $p_1^2 = \Theta\left(n^{-1}\right) = o\left(\frac{\ln n}{n}\right)$. Also, there is a sharp threshold at $\frac{(\beta-3)\cdot(\beta-1)}{(\beta-2)^2} \cdot n$ for $\beta > 3$, since $p_1^2 = \Theta\left(n^{-2\frac{\beta-2}{\beta-1}}\right) = o(n)$. We already observed the behavior for the latter case experimentally in previous works [21, 20]. Thus, we can say that for power-law random 2-SAT with a fixed power-law exponent $\beta \geqslant 3$ an equivalent of the satisfiability threshold conjecture holds, since the sharp thresholds converge to a function with the same leading constant factor.

6.3 Geometric Distribution

Ansótegui et al. [5] also considered an ensemble of geometric distributions with

$$p_i = \frac{b \cdot (1 - b^{-1/n})}{b - 1} \cdot b^{-(i-1)/n}$$

for $i = 1, \ldots, n$ and for some constant $b > 1$. Again, it already holds that $p_1 \geqslant p_2 \geqslant \ldots \geqslant p_n$. It holds that

$$p_1^2 = \frac{b^2 \cdot (1 - b^{-1/n})^2}{(b-1)^2}$$

and

$$\sum_{i=1}^{n} p_i^2 = \frac{b+1}{b-1} \cdot \frac{1 - b^{-1/n}}{1 + b^{-1/n}}.$$

One can show that $p_1^2 = o(\sum_{i=1}^{n} p_i^2)$. Theorem 1.1 now tells us that there is a sharp threshold at $\frac{b-1}{b+1} \cdot \frac{1+b^{-1/n}}{1-b^{-1/n}}$. This function grows as fast as $\frac{2\cdot(b-1)}{(b+1)\cdot\ln b} \cdot n$ in the limit. Again, we can say that an equivalent of the satisfiability threshold conjecture holds for geometric random 2-SAT with some fixed $b > 1$, since the sharp thresholds $m^*(n)$ converge to $\frac{2\cdot(b-1)}{(b+1)\cdot\ln b} \cdot n$.

7 Discussion and Future Work

We showed a dichotomy of coarse and sharp thresholds for the non-uniform random 2-SAT model depending on the variable probability distribution. In the case of a coarse threshold, the coarseness either stems from two variables being present in too many clauses and forming an unsatisfiable sub-formula of size 4 with constant probability or from a snake with three variables which emerges with constant probability. Furthermore we determined the exact position of the satisfiability threshold in the case of a sharp threshold. Hence, our result generalizes the seminal works by Chvatal and Reed [11] and by Goerdt [24] to arbitrary variable probability distributions. It allows us to prove or disprove an equivalent of the

satisfiability threshold conjecture for non-uniform random 2-SAT. For example for power-law random 2-SAT, an equivalent of the conjecture holds for power law exponents $\beta \geqslant 3$ and the satisfiability threshold is at exactly $\frac{(\beta-3)\cdot(\beta-1)}{(\beta-2)^2} \cdot n$ for $\beta > 3$ and exactly at $4 \cdot \frac{n}{\ln n}$ for $\beta = 3$.

The grand goal of our works is to show similar results for higher values of k, where we already made a first step by showing sharpness for certain variable probability distributions [22]. Another direction we are interested in for $k \geqslant 3$ is proving bounds on the average computational hardness of formulas around the threshold, for example by showing resolution lower bounds like Mull et al. [37].

Abstract

The determinant polynomial $\mathsf{Det}_n(\mathbf{x})$ of degree n is the determinant of a $n \times n$ matrix of formal variables. A polynomial f is equivalent to $\mathsf{Det}_n(\mathbf{x})$ over a field $\mathbb{F}$ if there exists a $A \in GL(n^2, \mathbb{F})$ such that $f = \mathsf{Det}_n(A \cdot \mathbf{x})$. *Determinant equivalence test over* $\mathbb{F}$ is the following algorithmic task: Given black-box access to a $f \in \mathbb{F}[\mathbf{x}]$, check if f is equivalent to $\mathsf{Det}_n(\mathbf{x})$ over $\mathbb{F}$, and if so then output a transformation matrix $A \in GL(n^2, \mathbb{F})$. In (Kayal, STOC 2012), a randomized polynomial time determinant equivalence test was given over $\mathbb{F} = \mathbb{C}$. But, to our knowledge, the complexity of the problem over finite fields and over $\mathbb{Q}$ was not well understood.

In this work, we give a randomized $\mathrm{poly}(n, \log |\mathbb{F}|)$ time determinant equivalence test over finite fields $\mathbb{F}$ (under mild restrictions on the characteristic and size of $\mathbb{F}$). Over $\mathbb{Q}$, we give an efficient randomized reduction from factoring square-free integers to determinant equivalence test for quadratic forms (i.e. the $n = 2$ case), assuming GRH. This shows that designing a polynomial-time determinant equivalence test over $\mathbb{Q}$ is a challenging task. Nevertheless, we show that determinant equivalence test over $\mathbb{Q}$ is decidable: For bounded n, there is a randomized polynomial-time determinant equivalence test over $\mathbb{Q}$ with access to an oracle for integer factoring. Moreover, for *any* n, there is a randomized polynomial-time algorithm that takes input black-box access to a $f \in \mathbb{Q}[\mathbf{x}]$ and if f is equivalent to Det_n over $\mathbb{Q}$ then it returns a $A \in GL(n^2, Ł)$ such that $f = \mathsf{Det}_n(A \cdot \mathbf{x})$, where Ł is an extension field of $\mathbb{Q}$ and $[Ł : \mathbb{Q}] \leq n$.

The above algorithms over finite fields and over $\mathbb{Q}$ are obtained by giving a polynomial-time randomized reduction from determinant equivalence test to another problem, namely the *full matrix algebra isomorphism* problem. We also show a reduction in the converse direction which is efficient if n is bounded. These reductions, which hold over any $\mathbb{F}$ (under mild restrictions on the characteristic and size of $\mathbb{F}$), establish a close connection between the complexity of the two problems. This then leads to our results via applications of known results on the full algebra isomorphism problem over finite fields (Rónyai, STOC 1987 and Rónyai, J. Symb. Comput. 1990) and over $\mathbb{Q}$ (Ivanyos et al., Journal of Algebra 2012 and Babai et al., Mathematics of Computation 1990).

Acknowledgements We would like to thank Youming Qiao for pointing us to the module decomposition algorithm in [4]. NG would like to thank Vineet Nair for discussions on the structure of the Lie algebra of Det. We thank him for sharing his proof of Theorem 10. We also thank anonymous reviewers for their comments.

1 Introduction

Two m-variate polynomials $f(\mathbf{x})$ and $g(\mathbf{x})$ with coefficients from a field $\mathbb{F}$ are said to be *equivalent over* $\mathbb{F}$ if there exists a $A \in GL(m, \mathbb{F})$ such that $f = g(A \cdot \mathbf{x})$. The algorithmic task of determining if f is equivalent to g, and if so then finding a linear transformation A such that $f = g(A \cdot \mathbf{x})$, is known as the polynomial *equivalence test* problem. It is a natural problem arising in algebraic complexity theory, becoming more important with the advent of Geometric Complexity Theory (GCT) [22] – which proposes the uses of deep tools and insights from group theory, representation theory and algebraic geometry towards the study of the VP vs VNP question.

A naïve approach for equivalence test is to reduce it to solving a system of polynomial equations over $\mathbb{F}$. But, unfortunately, polynomial solvability problem is NP-hard over $\mathbb{C}$ and finite fields and not known to be decidable over $\mathbb{Q}$. Nevertheless, it does appear that the complexity of equivalence test is much lower than the complexity of solving polynomial systems. It is known that over finite fields, the polynomial equivalence problem can not be NP-hard unless PH collapses (when the polynomials are given as lists of coefficients) [29, 28].

Can we hope to solve equivalence test over $\mathbb{C}$ and over finite fields [1] in (randomized) polynomial time? Finding such an algorithm is indeed quite demanding as it was shown in [1, 2] that the graph isomorphism problem reduces in polynomial time to equivalence test for cubic forms (i.e. homogeneous degree three polynomials) over *any* field. Over $\mathbb{Q}$, it is not even known if cubic form equivalence is decidable. On the other hand, we have a fairly good understanding of the complexity of quadratic form equivalence test: Over $\mathbb{C}$ and finite fields, equivalence of two quadratic forms can be tested in polynomial time due to well-known results on classification of quadratic forms. Quadratic form equivalence over $\mathbb{Q}$ can be done in polynomial-time with access to an oracle for integer factoring (IntFact). Moreover, IntFact reduces in randomized polynomial time to quadratic form equivalence over $\mathbb{Q}$ (see [31]). Given this state of affairs, designing efficient equivalence tests for even bounded degree polynomials seems like a difficult proposition. Indeed, there is a cryptographic authentication scheme based on the presumed average-case hardness of equivalence test for constant degree polynomials (see [23]).

The work in [15] initiated the study of a kind of equivalence test in which one polynomial f is given as input and the other polynomial g belongs to a well-defined polynomial family. Some of the polynomial families that are well-studied in algebraic complexity theory, particularly in the context of arithmetic circuit lower bounds, are those defined by the power symmetric polynomial, the elementary symmetric polynomial, the permanent, the determinant and the iterated matrix multiplication polynomial. In [15], randomized polynomial time equivalence tests over $\mathbb{C}$ were given for the power symmetric polynomial and the elementary symmetric polynomial families. These equivalence tests, which also hold over finite fields and $\mathbb{Q}$, work

[1] Typically, a computation model over $\mathbb{C}$ assumes that basic arithmetic operations with complex numbers and root finding of univariate polynomials over $\mathbb{C}$ can be done efficiently. Also, we will work with finite fields that have sufficiently large size and characteristic.

even if f is given as a black-box[2]. Henceforth, let us assume that the input polynomial f is given as a black-box. Subsequently, in [16], randomized polynomial time equivalence tests over $\mathbb{C}$ were given for the permanent and the determinant polynomial families. The test for the permanent holds over finite fields and $\mathbb{Q}$, but the same is *not true* for the determinant equivalence test in [16]. In [18], an equivalence test for the iterated matrix multiplication (IMM) was given which holds over $\mathbb{C}$, finite fields and $\mathbb{Q}$ (see also [13]). The iterated matrix multiplication and the determinant families have very similar circuit complexity: Both the families are complete under p-projections for class of algebraic branching programs (ABP) (see [20, 21]). But, it was unclear if determinant admits an efficient equivalence test over finite fields and $\mathbb{Q}$, just like the iterated matrix multiplication polynomial. In this paper, we fill in this gap in our understanding.

It is worth noting that determinant equivalence test is interesting in the context of the permanent versus determinant problem [30], which conjectures that the permanent is not an affine projection of a polynomial-size determinant. Geometric Complexity Theory [22], an approach to resolving this conjecture, suggests (among other things) to look for an algorithm to determine if the (padded) permanent is in the orbit closure of a polynomial-size determinant. In this language, determinant equivalence testing is the related problem of checking if a given polynomial is in the orbit of the determinant polynomial.

1.1 Our results

Let $n \in \mathbb{N}^{\times}$, $X = (x_{ij})_{i,j\in[n]}$ be a $n \times n$ matrix of formal variables, and $\mathbf{x} = (x_{11}\ x_{12}\ \ldots\ x_{n\,n-1}\ x_{nn})^T$ a column vector consisting of the variables in X arranged in a row-major fashion. The polynomial $\mathsf{Det}_n(\mathbf{x}) := \det(X)$; we will drop the subscript n whenever it is clear from the context. Hereafter, we will use the acronym DET for Determinant Equivalence Test.

▶ **Theorem 1** (DET over finite fields). *Let $\mathbb{F}$ be a finite field such that $|\mathbb{F}| \geq 10n^4$ and $char(\mathbb{F}) \nmid n(n-1)$. There is a randomized $\mathsf{poly}(n, \log|\mathbb{F}|)$ time algorithm that takes input black-box access to a $f \in \mathbb{F}[\mathbf{x}]$ of degree n and does the following with high probability: If f is equivalent to $\mathsf{Det}(\mathbf{x})$ over $\mathbb{F}$ then it outputs a $A \in GL(n^2, \mathbb{F})$ such that $f = \mathsf{Det}(A \cdot \mathbf{x})$; otherwise, it outputs "Fail".*

In [17], a DET over a finite field $\mathbb{F}_q$ was given that is similar to the equivalence test for the permanent in [16], but the test outputs a $A \in GL(n^2, \mathbb{F}_{q^n})$. Whereas, our algorithm (which is different and relatively more involved) outputs a $A \in GL(n^2, \mathbb{F}_q)$. One consequence of this is that the average-case ABP reconstruction algorithm in [17] holds over the base field $\mathbb{F}_q$.

▶ **Theorem 2** (DET over $\mathbb{Q}$).

(a) *There is a randomized algorithm, with oracle access to $\mathsf{IntFact}$, that takes input black-box access to a $f \in \mathbb{Q}[\mathbf{x}]$ of degree n and does the following with high probability: If f is equivalent to $\mathsf{Det}(\mathbf{x})$ over $\mathbb{Q}$ then it outputs a $A \in GL(n^2, \mathbb{Q})$ such that $f = \mathsf{Det}(A \cdot \mathbf{x})$; otherwise, it outputs "Fail". If n is bounded then the algorithm runs in time polynomial in the bit length of the coefficients of f.*

[2] An algorithm with black-box access to a m-variate polynomial f is only allowed to query the black-box for evaluations of f at points in $\mathbb{F}^m$.

(b) *There is a randomized algorithm that takes input black-box access to a $f \in \mathbb{Q}[\mathbf{x}]$ of degree n and does the following with high probability: If f is equivalent to $\mathsf{Det}(\mathbf{x})$ over $\mathbb{Q}$ then it outputs a $A \in GL(n^2, Ł)$ such that $f = \mathsf{Det}(A \cdot \mathbf{x})$, where Ł is an extension field of $\mathbb{Q}$ and $[Ł : \mathbb{Q}] \leq n$. The algorithm runs in time polynomial in n and the bit length of the coefficients of f.*

To our knowledge, it was not known if DET over $\mathbb{Q}$ is decidable prior to this work. It is natural to wonder if we can get rid of the IntFact oracle from part (a) of the above theorem. In this regard, we show the following.

▶ **Theorem 3** (IntFact reduces to DET for quadratic forms)**.** *Assuming GRH, we give a randomized polynomial-time reduction from factoring square-free integers to finding a $A \in M_2(\mathbb{Q})$ such that a given quadratic form $f \in \mathbb{Q}[\mathbf{x}]$ equals $\mathsf{Det}_2(A \cdot \mathbf{x})$, if f is equivalent to Det_2.*

The complexity of IntFact is the same as that of DET over $\mathbb{Q}$ for quadratic forms (modulo GRH and the use of randomization). Theorem 3 is a reduction from a result in [24].

Theorem 1 and 2 are proved by reducing DET to the *full matrix algebra isomorphism* problem. An $\mathbb{F}$-algebra $\mathcal{A}$ has two binary operations $+$ and $\cdot$ defined on its elements such that $(\mathcal{A}, +)$ is a $\mathbb{F}$-vector space, $(\mathcal{A}, +, \cdot)$ is an associative ring, and for every $a, b \in \mathbb{F}$ and $B, C \in \mathcal{A}$ it holds that $(aB)C = B(aC) = a(BC)$. For example, the set $M_n(\mathbb{F})$ of all $n \times n$ matrices over $\mathbb{F}$ is a $\mathbb{F}$-algebra with respect to the usual matrix addition and multiplication operations; it is called the full matrix algebra. Two $\mathbb{F}$-algebra $\mathcal{A}_1$ and $\mathcal{A}_2$ are isomorphic, denoted by $\mathcal{A}_1 \cong \mathcal{A}_2$, if there is a bijection ϕ from $\mathcal{A}_1$ to $\mathcal{A}_2$ such that for every $a, b \in \mathbb{F}$ and $B, C \in \mathcal{A}_1$ it holds that $\phi(aB + bC) = a\phi(B) + b\phi(C)$ and $\phi(BC) = \phi(B)\phi(C)$. Any finite dimensional $\mathbb{F}$-algebra is isomorphic to a $\mathbb{F}$-algebra $\mathcal{A}' \subseteq M_m(\mathbb{F})$, where $m = \dim_{\mathbb{F}}(\mathcal{A})$. A $\mathbb{F}$-algebra $\mathcal{A} \subseteq M_m(\mathbb{F})$ can be specified by a $\mathbb{F}$-basis $B_1, \ldots, B_r \in M_m(\mathbb{F})$.

▶ **Definition 4.** *The full matrix algebra isomorphism (FMAI) problem over $\mathbb{F}$ is the following: Given a basis of a $\mathbb{F}$-algebra $\mathcal{A} \subseteq M_m(\mathbb{F})$, check if $\mathcal{A} \cong M_n(\mathbb{F})$, where $n^2 = \dim_{\mathbb{F}}(\mathcal{A})$. If $\mathcal{A} \cong M_n(\mathbb{F})$ then output an isomorphism from $\mathcal{A}$ to $M_n(\mathbb{F})$.*

In [24, 25], a $\mathsf{poly}(m, \log|\mathbb{F}|)$ time randomized algorithm was given to solve FMAI over a finite field $\mathbb{F}$. Over $\mathbb{Q}$, the FMAI problem is more difficult. In [14, 6], a randomized algorithm (with access to a IntFact oracle) was given to solve FMAI over $\mathbb{Q}$. The algorithm runs in polynomial-time if $\dim_{\mathbb{Q}}(\mathcal{A})$ is bounded. In [3, 10], randomized polynomial time algorithms were given to compute an isomorphism from $\mathcal{A} \otimes_{\mathbb{Q}} Ł$ to $M_n(Ł)$ for some extension field $Ł \supseteq \mathbb{Q}$ satisfying $[Ł : \mathbb{Q}] \leq n$, if $\mathcal{A} \cong M_n(\mathbb{Q})$ to begin with. We give a randomized polynomial-time reduction from DET to FMAI over any sufficiently large $\mathbb{F}$ in Section 4, thereby proving Theorem 1 and 2. The reduction is obtained by giving an algorithm to decompose the Lie algebra of f into its two simple Lie subalgebras over any sufficiently large $\mathbb{F}$ (see Section 3). The same reduction also gives DET over $\mathbb{R}$ and $\mathbb{C}$ via the FMAI algorithms in [9, 26] (thereby giving alternative algorithms to the one presented in [16]). We also show a reduction from FMAI to DET (in Section 7) which is efficient if the dimension n is bounded.

The above results underscore the close connection between the DET and the FMAI problems. In order to get efficient DET over $\mathbb{Q}$ for even bounded degree polynomials, we *need to* solve FMAI efficiently for $\mathbb{Q}$-algebras of bounded dimensions. Currently, the best known algorithm for FMAI over $\mathbb{Q}$ uses an IntFact oracle [14]. This situation of the determinant is somewhat surprising as it contrasts that of IMM (the close cousin of the determinant) – IMM equivalence test over $\mathbb{Q}$ can be solved efficiently for polynomials of degree greater than four [18].

2 Preliminaries

2.1 Notations

The set of trace zero or traceless matrices in $M_n(\mathbb{F})$ is denoted by $\mathcal{Z}_n(\mathbb{F})$; we will drop $\mathbb{F}$ from $M_n(\mathbb{F})$ and $\mathcal{Z}_n(\mathbb{F})$ when it is clear from the context. Let I_n be the $n \times n$ identity matrix. $\otimes$ denotes tensor product of two matrices. Define,

$$\mathcal{M}_{\text{col}} := I_n \otimes M_n, \quad \mathcal{M}_{\text{row}} := M_n \otimes I_n \qquad \text{and} \qquad \mathcal{L}_{\text{col}} := I_n \otimes \mathcal{Z}_n, \quad \mathcal{L}_{\text{row}} := \mathcal{Z}_n \otimes I_n.$$

Observe $\mathcal{M}_{\text{col}}$, $\mathcal{M}_{\text{row}} \subseteq M_{n^2}$ are $\mathbb{F}$-algebras isomorphic to M_n, and $\mathcal{L}_{\text{col}}$, $\mathcal{L}_{\text{row}}$ are their subspaces , respectively, of dimension n^2-1 each. Henceforth, we set $m = n^2$ and $r = n^2 - 1$.

2.2 Definitions

▶ **Definition 5** (Lie bracket). *For $A, B \in M_n$, the Lie bracket operation $[A, B] := AB - BA$.*

▶ **Definition 6** (Lie algebra of a polynomial). *The Lie algebra $\mathfrak{g}_f$ of a m-variate polynomial $f \in \mathbb{F}[\mathbf{x}]$ is the set of matrices $B = (b_{i,j})_{i,j\in[m]}$ satisfying,*

$$\sum_{i,j\in[m]} b_{i,j} \cdot x_j \cdot \frac{\partial f}{\partial x_i} = 0.$$

It is easy to verify that $[\cdot,\cdot]$ is a $\mathbb{F}$-bilinear map on M_n, and $\mathfrak{g}_f$ is an $\mathbb{F}$-vector space.[3] Let $\mathcal{V}$ be a $\mathbb{F}$-vector space, $\text{End}_{\mathbb{F}}(\mathcal{V}) := \{\varphi : \varphi \text{ is a } \mathbb{F}\text{-linear map from } \mathcal{V} \text{ to } \mathcal{V}\}$ and $\mathcal{T} \subseteq \text{End}_{\mathbb{F}}(\mathcal{V})$.

▶ **Definition 7.** *A subspace $\mathcal{U}$ of $\mathcal{V}$ is called $\mathcal{T}$-invariant if for every $\varphi \in \mathcal{T}$, $\varphi(\mathcal{U}) \subseteq \mathcal{U}$.*

If $\mathcal{T} \subseteq M_{2r}$, the terminology "invariant subspace of $\mathcal{T}$" means $\mathcal{T}$-invariant subspace of $\mathbb{F}^{2r}$.

▶ **Definition 8** (Irreducible invariant subspace). *A $\mathcal{T}$-invariant subspace $\mathcal{U}$ of $\mathcal{V}$ is irreducible if there do not exist proper $\mathcal{T}$-invariant subspaces $\mathcal{U}_1, \mathcal{U}_2$ of $\mathcal{U}$, such that $\mathcal{U} = \mathcal{U}_1 \oplus \mathcal{U}_2$.*

▶ **Definition 9** (Closure of a vector). *Let $\mathbf{w} \in \mathcal{V}$. Then, the closure of $\mathbf{w}$ with respect to $\mathcal{T}$, denoted $\text{closure}_{\mathcal{T}}(\mathbf{w})$, is the smallest $\mathcal{T}$-invariant subspace of $\mathcal{V}$ containing $\mathbf{w}$.*

2.3 Some basic results

▶ **Observation 2.1.** *For $i, j \in [n], i \neq j$, let $E_{ij} \in M_n$ be such that the (i,j)-th entry is 1 and other entries are 0, and for $\ell \in [2, n]$, let $E_\ell \in M_n$ be a diagonal matrix with the $(1,1)$-th and (ℓ,ℓ)-th entries as 1 and -1 respectively and other entries as 0. Then,*

1. *$\{I_n \otimes E_{ij},\ I_n \otimes E_\ell \ :\ i, j \in [n], i \neq j,\ \text{and } \ell \in [2, n]\}$ is a basis of $\mathcal{L}_{col}$. Denote the elements of this standard basis as $S_1, \ldots, S_r$.*
2. *$\{E_{ij} \otimes I_n,\ E_\ell \otimes I_n \ :\ i, j \in [n], i \neq j,\ \text{and } \ell \in [2, n]\}$ is a basis of $\mathcal{L}_{row}$. Denote the elements of this standard basis as $S_{r+1}, \ldots, S_{2r}$.*

▶ **Observation 2.2.** *For every $F \in \mathcal{M}_{row}$ and $L \in \mathcal{M}_{col}$, $[F, L] = FL - LF = 0$.*

▶ **Observation 2.3.** *For every $L_1, L_2 \in \mathcal{L}_{col}$ (or $\mathcal{L}_{row}$), $[L_1, L_2] \in \mathcal{L}_{col}$ (respectively. $\mathcal{L}_{row}$).*

[3] Over $\mathbb{C}$, $\mathfrak{g}_f$ also turns out to be a Lie algebra i.e. closed under the Lie bracket operation. However, over finite fields, it is not clear if it is closed under the bracket operation. We still stick with the terminology Lie algebra of a polynomial since in many cases, it does turn out to be closed under the bracket operation.

A proof of the following standard fact is given in Section A.1 of the Appendix of the full version [11].

▶ **Fact 1.** *Let $B \in M_n$. Then, the dimension of the space of matrices in M_n that commute with B is at least n, and the dimension of the space of matrices in $\mathcal{Z}_n$ that commute with B is at least $n-1$.*

We would also need the following facts (see [16, 18] for their proofs).

▶ **Fact 2.** *If $g \in \mathbb{F}[\mathbf{x}]$ and $f(\mathbf{x}) = g(A \cdot \mathbf{x})$ for some $A \in GL(m, \mathbb{F})$ then $\mathfrak{g}_f = A^{-1} \cdot \mathfrak{g}_g \cdot A$.*

▶ **Fact 3.** *Suppose we have black box access to a m-variate polynomial $f \in \mathbb{F}[\mathbf{x}]$, where $|\mathbb{F}| \geq 2n^3$. Then, a basis of $\mathfrak{g}_f$ can be computed in randomized polynomial time.*

▶ **Fact 4.** *Given a basis $\{T_1, \ldots, T_s\}$ of $\mathcal{T} \subseteq M_{2r}$ and a $\mathbf{w} \in \mathbb{F}^{2r}$, a basis of $\text{closure}_{\mathcal{T}}(\mathbf{w})$ can be computed in time polynomial in r and the bit length of the entries in $\mathbf{w}$ and $T_1, \ldots, T_s$.*

The following theorem on the Lie algebra of Det is well-known over $\mathbb{C}$. We give a proof over any field (with a mild condition on the characteristic) in Section A.2 of the Appendix of [11].

▶ **Theorem 10** (Lie algebra of Det)**.** *Let $n \geq 2$ and $\mathbb{F}$ be a field such that $char(\mathbb{F}) \nmid n$. Then, the Lie algebra of Det_n equals the direct sum of the spaces $\mathcal{L}_{row}$ and $\mathcal{L}_{col}$, i.e., $\mathfrak{g}_{\mathsf{Det}} = \mathcal{L}_{row} \oplus \mathcal{L}_{col}$.*

The theorem implies that $\{S_1, \ldots, S_{2r}\}$, in Observation 2.1, forms a basis of $\mathfrak{g}_{\mathsf{Det}}$. The rows and columns of every element in $\mathfrak{g}_{\mathsf{Det}}$ are indexed by the $\mathbf{x}$ variables, in order. Let $f = \mathsf{Det}(A \cdot \mathbf{x})$ for some $A \in GL(m, \mathbb{F})$. Then, Theorem 10 and Fact 2 imply that $\mathfrak{g}_f = A^{-1} \cdot \mathcal{L}_{\text{row}} \cdot A \oplus A^{-1} \cdot \mathcal{L}_{\text{col}} \cdot A$. We denote $A^{-1} \cdot \mathcal{L}_{\text{row}} \cdot A$ and $A^{-1} \cdot \mathcal{L}_{\text{col}} \cdot A$ by $\mathcal{F}_{\text{row}}$ and $\mathcal{F}_{\text{col}}$ respectively, and refer to $\mathcal{F}_{\text{row}}$ and $\mathcal{F}_{\text{col}}$ (similarly, $\mathcal{L}_{\text{row}}$ and $\mathcal{L}_{\text{col}}$) as the Lie subalgebras of $\mathfrak{g}_f$ (respectively, $\mathfrak{g}_{\mathsf{Det}}$) [4]. From Theorem 10, Observation 2.2 and 2.3, we get the following.

▶ **Observation 2.4.** *For every $E, F \in \mathfrak{g}_f$, $[E, F] \in \mathfrak{g}_f$.*

▶ **Observation 2.5.** *Let $\mathcal{A} \subseteq M_m$ be the $\mathbb{F}$-algebra generated by a basis of $\mathcal{F}_{col}$. Then,*

$$\mathcal{A} = A^{-1} \cdot (I_n \otimes M_n) \cdot A.$$

This can be proved easily. Finally, we record a special case of the Skolem-Noether theorem which will be used in Section 4. Its general statement can be found in [19] (page 173).

▶ **Theorem 11** (Skolem-Noether)**.** *Let $n, s \in \mathbb{N}^{\times}$ such that $n \mid s$, and $\mathcal{A} \subseteq M_s$ be a $\mathbb{F}$-algebra (containing I_s) that is isomorphic to M_n via $\phi : M_n \to \mathcal{A}$. Then there exists a $K \in GL(s, \mathbb{F})$ s.t.,*

$$\phi(C) = K^{-1} \cdot (I_{s/n} \otimes C) \cdot K, \quad \text{for every } C \in M_n.$$

3 Decomposition of $\mathfrak{g}_f$ into its Lie subalgebras

We show how to compute bases of $\mathcal{F}_{\text{row}}$ and $\mathcal{F}_{\text{col}}$ from black box access to $f = \mathsf{Det}(A \cdot \mathbf{x})$.

▶ **Theorem 12** (Decomposition of $\mathfrak{g}_f$)**.** *Let $n \geq 2$, $|\mathbb{F}| \geq 10n^4$ and $\text{char}(\mathbb{F}) \nmid n(n-1)$. There is a randomized algorithm, which takes input black box access to f and outputs bases of $\mathcal{F}_{row}$ and $\mathcal{F}_{col}$ with high probability. The running time is $\text{poly}(n, \gamma)$, where γ is the bit length of coefficients of f.*

We first present the proof idea, and then the algorithm and its proof of correctness. The missing proofs are given in Sections B,C and D of the Appendix of [11].

[4] Observation 2.3 implies that $\mathcal{F}_{\text{row}}$ and $\mathcal{F}_{\text{col}}$ are closed under the Lie bracket operation and hence they are matrix Lie algebras.

3.1 Proof of Theorem 12: The idea

The algorithm relies on finding the irreducible invariant subspaces of a set of $\mathbb{F}$-linear maps on $\mathfrak{g}_f$. These linear maps (a.k.a adjoint homomorphisms of $\mathfrak{g}_f$) are defined for every $F \in \mathfrak{g}_f$,

$$\rho_F : \mathfrak{g}_f \to \mathfrak{g}_f \ ; \ E \mapsto [E, F].$$

It is easy to see that ρ_F is linear. Let $\{B_1, \ldots, B_{2r}\}$ be a basis of $\mathfrak{g}_f$ which can be computed in randomized polynomial time (by Fact 3). As ρ_F is $\mathbb{F}$-linear, we can associate a matrix $P_F \in M_{2r}$ with ρ_F, after fixing an ordering of the basis $(B_1, \ldots, B_{2r})$. Let $\mathcal{P} := \{P_F : F \in \mathfrak{g}_f\}$.

▷ Claim 13. $\mathfrak{g}_f$ and $\mathcal{P}$ are isomorphic as vector spaces via the map $F \mapsto P_F$ for every $F \in \mathfrak{g}_f$.

Its proof is given in Section B.1 of the Appendix of [11]. This implies the following.

▶ **Observation 3.1.** *The matrices $\{P_{B_1}, \ldots, P_{B_{2r}}\}$ is a basis of $\mathcal{P}$, which can be efficiently computed from $\{B_1, \ldots, B_{2r}\}$ (by considering the elements $[B_i, B_j]$, for $i, j \in [2r]$).*

We intend to study the irreducible invariant subspaces of $\mathcal{P}$ in order to compute bases of $\mathcal{F}_{\text{row}}$ and $\mathcal{F}_{\text{col}}$. The following Claim 14 would be useful in this regard.

It follows from Fact 2 that $J_i := A \cdot B_i \cdot A^{-1}$, for $i \in [2r]$, is a basis of $\mathfrak{g}_{\mathsf{Det}}$. Like ρ_F, we can associate a $\mathbb{F}$-linear map (i.e. adjoint homomorphism) χ_L with every $L \in \mathfrak{g}_{\mathsf{Det}}$ as follows:

$$\chi_L : \mathfrak{g}_{\mathsf{Det}} \to \mathfrak{g}_{\mathsf{Det}} \ ; \ K \mapsto [K, L].$$

Let $Q_L \in M_{2r}$ be the matrix corresponding to the linear map χ_L, with respect to the (ordered) basis $(J_1, \ldots, J_{2r})$. The following claim implies that $\mathcal{P}$ does not depend on the transformation matrix A. Thus, it is sufficient to focus on $\mathfrak{g}_{\mathsf{Det}}$ to study the invariant subspaces of $\mathcal{P}$. The proof of the claim is given in Section B.2 of the Appendix of [11].

▷ Claim 14. For every $i \in [2r]$, $Q_{J_i} = P_{B_i}$ and so the space $\mathcal{P} = \{Q_L : L \in \mathfrak{g}_{\mathsf{Det}}\}$.

Like Claim 13, $\mathfrak{g}_{\mathsf{Det}}$ and $\mathcal{P}$ are isomorphic as vector spaces via the map $L \mapsto Q_L$, for $L \in \mathfrak{g}_{\mathsf{Det}}$. The algorithm computes two invariant subspaces $\mathcal{V}_1$ and $\mathcal{V}_2$ of $\mathcal{P}$ that are defined as follows

$$\mathcal{V}_1 = \left\{ \mathbf{v} = (a_1, \ldots, a_{2r})^T \in \mathbb{F}^{2r} : \sum_{i \in [2r]} a_i \cdot J_i \in \mathcal{L}_{\text{col}} \right\},$$

$$\mathcal{V}_2 = \left\{ \mathbf{v} = (b_1, \ldots, b_{2r})^T \in \mathbb{F}^{2r} : \sum_{i \in [2r]} b_i \cdot J_i \in \mathcal{L}_{\text{row}} \right\}. \tag{1}$$

Clearly, $\dim(\mathcal{V}_1) = \dim(\mathcal{V}_2) = r$. As $B_i = A^{-1} \cdot J_i \cdot A$, for $i \in [2r]$, we get

$$\mathcal{V}_1 = \left\{ \mathbf{v} = (a_1, \ldots, a_{2r})^T \in \mathbb{F}^{2r} : \sum_{i \in [2r]} a_i \cdot B_i \in \mathcal{F}_{\text{col}} \right\},$$

$$\mathcal{V}_2 = \left\{ \mathbf{v} = (b, \ldots, b_{2r})^T \in \mathbb{F}^{2r} : \sum_{i \in [2r]} b_i \cdot B_i \in \mathcal{F}_{\text{row}} \right\}. \tag{2}$$

From bases of $\mathcal{V}_1$ and $\mathcal{V}_2$, and $(B_1, \ldots, B_{2r})$, we get bases of $\mathcal{F}_{\text{col}}$ and $\mathcal{F}_{\text{row}}$ readily. The aspects of the space $\mathcal{P}$ that help in computing $\mathcal{V}_1$ and $\mathcal{V}_2$ are the facts that these are the only two irreducible invariant subspaces of $\mathcal{P}$ and bases of these can be computed from a random element of $\mathcal{P}$. These facts are proved in the proof of correctness of Algorithm 1.

3.2 The decomposition algorithm

Algorithm 1 Computation of bases of $\mathcal{F}_{row}$ and $\mathcal{F}_{col}$.

Input: Black box access to f.
Output: Bases of spaces $\mathcal{V}_1$ and $\mathcal{V}_2$ (as in Equation (2)).

1: Compute a basis $B_1, \ldots, B_{2r}$ of $\mathfrak{g}_f$ (see Fact 3), and form the basis $P_{B_1}, \ldots, P_{B_{2r}}$ of $\mathcal{P}$.
2: Pick a random element $Q = r_1 P_{B_1} + \cdots + r_{2r} P_{B_{2r}}$ from $\mathcal{P}$, where every r_i is chosen uniformly and independently at random from a fixed subset of $\mathbb{F}$ of size $10n^4$.
3: Compute the characteristic polynomial $h(z)$ of Q.
4: Factor $h(z)$ into irreducible factors over $\mathbb{F}$. Let $h(z) = z^{2(n-1)} \cdot h_1(z) \cdots h_k(z)$, where $z, h_1, \ldots, h_k$ are mutually coprime and irreducible. If this is not the split, output "Fail".
5: For every $i \in [k]$, compute a basis of the null space $\mathcal{N}_i$ of $h_i(Q)$, pick a vector $\mathbf{v}$ from the basis of $\mathcal{N}_i$ and compute a basis of $\mathcal{C}_i := \text{closure}_{\mathcal{P}}(\mathbf{v})$ (using Fact 4).
6: Remove repetitive spaces from the set $\{\mathcal{C}_1, \ldots, \mathcal{C}_k\}$. After this, if we are *not* left with exactly two spaces $\mathcal{U}_1$ and $\mathcal{U}_2$ then output "Fail". Else, output bases of $\mathcal{U}_1$ and $\mathcal{U}_2$.

3.3 Analysis of the algorithm

Let us view the space $\mathcal{P}$ through the lens of a convenient basis of $\mathfrak{g}_{\mathsf{Det}}$, namely the standard basis $\{S_1, \ldots, S_{2r}\}$ (given in Observation 2.1). For $K \in \mathfrak{g}_{\mathsf{Det}}$, let $\mathbf{w}_K, \mathbf{v}_K \in \mathbb{F}^{2r}$ be the coordinate vectors of K with respect to the ordered bases $(S_1, \ldots, S_{2r})$ and $(J_1, \ldots, J_{2r})$ respectively. There is a basis change matrix $H \in \mathrm{GL}(2r, \mathbb{F})$, such that for every $K \in \mathfrak{g}_{\mathsf{Det}}$,

$$\mathbf{v}_K = H \cdot \mathbf{w}_K. \tag{3}$$

Recall Q_L from Claim 14. Let $R_L := H^{-1} \cdot Q_L \cdot H$, for every $L \in \mathfrak{g}_{\mathsf{Det}}$, and

$$\mathcal{R} := \{R_L \ : \ L \in \mathfrak{g}_{\mathsf{Det}}\} = H^{-1} \cdot \mathcal{P} \cdot H. \tag{4}$$

Observe that $\{R_{S_1}, \ldots, R_{S_{2r}}\}$ is a basis of $\mathcal{R}$. Also, for every $L, K \in \mathfrak{g}_{\mathsf{Det}}$.

$$R_L \cdot \mathbf{w}_K = \mathbf{w}_{[K,L]}, \tag{5}$$

▶ **Observation 3.2.** *Every $R \in \mathcal{R} \subseteq M_{2r}$ is a block diagonal matrix having two blocks of size $r \times r$ each, i.e, the non-zero entries of R are confined to the entries $\{(S_i, S_j) \ : \ i, j \in [r]\}$ and $\{(S_i, S_j) \ : \ i, j \in [r+1, 2r]\}$.*

The proof of Observation 3.2 is given in Section C.1 of the Appendix of [11]. We refer to the two blocks of R as $R^{(1)}$ and $R^{(2)}$, corresponding to $\{S_1, \ldots, S_r\}$ and $\{S_{r+1}, \ldots, S_{2r}\}$, respectively. Observation 3.3 follows directly from definition of $\mathcal{R}$.

▶ **Observation 3.3.** *$\mathcal{W}$ is an invariant subspace of $\mathcal{R}$ iff $H \cdot \mathcal{W}$ is an invariant subspace of $\mathcal{P}$.*

It allows us to switch from $\mathcal{P}$ to $\mathcal{R}$ while studying the invariant subspaces of $\mathcal{P}$. The following lemmas on the invariant subspaces of $\mathcal{R}$ are crucial in arguing the correctness of Algorithm 1. Their proofs are given in Sections C.2 and C.3 of the Appendix of [11].

▶ **Lemma 15** (Irreducible invariant subspaces). *Let $\mathbf{w}_K \in \mathbb{F}^{2r}$ for a nonzero K in $\mathcal{L}_{col}$ or in $\mathcal{L}_{row}$.*

$$\begin{aligned} \textit{Then,}\ \ \text{closure}_{\mathcal{R}}(\mathbf{w}_K) &= \{\mathbf{w}_L \ : \ L \in \mathcal{L}_{col}\} =: \mathcal{W}_1, \quad \text{if } K \in \mathcal{L}_{\text{col}}, \\ \text{closure}_{\mathcal{R}}(\mathbf{w}_K) &= \{\mathbf{w}_L \ : \ L \in \mathcal{L}_{row}\} =: \mathcal{W}_2, \quad \text{if } K \in \mathcal{L}_{\text{row}}. \end{aligned}$$

Moreover, $\mathcal{W}_1$ and $\mathcal{W}_2$ are the only two irreducible invariant subspaces of $\mathcal{R}$, and $\mathbb{F}^{2r} = \mathcal{W}_1 \oplus \mathcal{W}_2$.

▶ **Lemma 16** (Characteristic polynomial). *Let $R = \sum_{i\in[2r]} \ell_i(r_1,\ldots,r_{2r})\cdot R_{S_i}$, where $\ell_1,\ldots,\ell_{2r}$ are $\mathbb{F}$-linearly independent linear forms and $r_1,\ldots,r_{2r}$ are picked uniformly and independently at random from a fixed subset of $\mathbb{F}$ of size $10n^4$. Then, with high probability, the characteristic polynomial $h_R(z)$ of R factors as $z^{2(n-1)}\cdot h_1(z)\cdots h_k(z)$, where $z, h_1(z),\ldots,h_k(z)$ are mutually coprime irreducible polynomials over $\mathbb{F}$.*

3.3.1 Proof of correctness of Algorithm 1

In Step 2, we choose a random Q from $\mathcal{P}$. By Equation (4), there is a $R\in\mathcal{R}$, such that,

$$R = H^{-1}\cdot Q\cdot H \;=\; r_1R_{J_1}+\cdots+r_{2r}R_{J_{2r}} \;=\; \ell_1(r_1,\ldots,r_{2r})\cdot R_{S_1}+\cdots+\ell_{2r}(r_1,\ldots,r_{2r})\cdot R_{S_{2r}},$$

where $\ell_1,\ldots,\ell_{2r}$ are $\mathbb{F}$-linearly independent linear forms in $r_1,\ldots,r_{2r}$. By Lemma 16, Step 4 holds with high probability. From Observation 3.2, R is a block diagonal matrix with blocks $R^{(1)}$ and $R^{(2)}$. Let $h(z) = g_1(z)\cdot g_2(z)$, where $g_1(z)$ and $g_2(z)$ are the characteristic polynomials of $R^{(1)}$ and $R^{(2)}$, respectively. There are a couple of factors of h, say h_1 and h_2, that divide g_1 and g_2, respectively. In Step 5, we compute the null spaces $\mathcal{N}_1$ and $\mathcal{N}_2$ of $h_1(Q)$ and $h_2(Q)$ respectively. As $h_1(R) = H^{-1}\cdot h_1(Q)\cdot H$ and $h_2(R) = H^{-1}\cdot h_2(Q)\cdot H$, the null spaces of $h_1(R)$ and $h_2(R)$, denoted by $\mathcal{O}_1$ and $\mathcal{O}_2$ respectively, satisfy $\mathcal{O}_1 = H^{-1}\cdot\mathcal{N}_1$ and $\mathcal{O}_2 = H^{-1}\cdot\mathcal{N}_2$ (due to Equation (3)).

▷ Claim 17. If $\mathbf{w}_K\in\mathcal{O}_1$ (similarly, $\mathbf{w}_K\in\mathcal{O}_2$) then $K\in\mathcal{L}_{\text{col}}$ (respectively, $K\in\mathcal{L}_{\text{row}}$).

Its proof is given in Section D.1 of the Appendix of [11]. In Step 5, we also pick a vector $\mathbf{v}$ from a null space, say $\mathcal{N}_1$, and compute $\text{closure}_{\mathcal{P}}(\mathbf{v})$. Clearly, $\mathbf{v} = \mathbf{v}_K$ for some $K\in\mathfrak{g}_{\mathsf{Det}}$. So, $\mathbf{v}_K\in\mathcal{N}_1$ if and only if $\mathbf{w}_K = H^{-1}\cdot\mathbf{v}_K\in\mathcal{O}_1$. As $\mathcal{R} = H^{-1}\cdot\mathcal{P}\cdot H$, Observation 3.3 implies

$$\begin{aligned}\text{closure}_{\mathcal{P}}(\mathbf{v}_K) &= H\cdot\text{closure}_{\mathcal{R}}(\mathbf{w}_K)\\ &= H\cdot\mathcal{W}_1 \quad (\text{ by Claim 17 and Lemma 15})\\ &= \mathcal{V}_1 \qquad (\text{ by Equations (1) and (3), as } \mathcal{V}_1 = \{\mathbf{v}_L \;:\; L\in\mathcal{L}_{\text{col}}\}).\end{aligned}$$

Similarly, if we pick a $\mathbf{v}\in\mathcal{N}_2$ then $\text{closure}_{\mathcal{P}}(\mathbf{v}) = \mathcal{V}_2$. Thus, in Step 6, one of $\mathcal{U}_1$ and $\mathcal{U}_2$ is $\mathcal{V}_1$ and the other is $\mathcal{V}_2$. Finally, we can take $\mathcal{U}_1 = \mathcal{V}_1$ and $\mathcal{U}_2 = \mathcal{V}_2$ without loss of generality: Let $P\in M_m$ be the permutation matrix, such that when multiplied to $\mathbf{x}$, P maps x_{ij} to x_{ji}. Clearly, $P^{-1} = P$. The following equation holds because P is a symmetry of Det.

$$\mathsf{Det}(\mathbf{x}) = \mathsf{Det}(P\cdot\mathbf{x}) \quad\text{and hence}\quad f(\mathbf{x}) = \mathsf{Det}(A\cdot\mathbf{x}) = \mathsf{Det}(PA\cdot\mathbf{x}).$$

Observe that $\mathcal{L}_{\text{col}} = P^{-1}\cdot\mathcal{L}_{\text{row}}\cdot P$. Hence,

$$\mathcal{F}_{\text{col}} = A^{-1}P^{-1}\cdot\mathcal{L}_{\text{row}}\cdot PA \quad\text{and}\quad \mathcal{F}_{\text{row}} = A^{-1}P^{-1}\cdot\mathcal{L}_{\text{col}}\cdot PA.$$

As the transformation matrix is unknown to the algorithm, we can take it to be either A or PA.

A comparison with [8], [4]: In [8, 7], a polynomial time algorithm was given to decompose a semisimple Lie algebra over $\mathbb{Q}$ (more generally, a characteristic 0 field) into a direct sum of simple Lie subalgebras. The Lie algebra $\mathfrak{g}_{\mathsf{Det}}$ is semisimple and $\mathcal{L}_{\text{col}}$ and $\mathcal{L}_{\text{row}}$ are its two simple Lie subalgebras. So, our decomposition problem is a special case of the problem studied in [8]. However, our algorithm works over any sufficiently large field $\mathbb{F}$ (in particular, finite fields), if $\text{char}(F)\nmid n(n-1)$. It is not quite clear to us if the algorithm in [8] (which is somewhat different from our algorithm) can be easily adapted to achieve

the same result in this special case. Lemma 15 shows that the decomposition of $\mathbb{F}^{2r}$ into irreducible invariant subspaces of $\mathcal{R}$ is unique. Using this information, it is possible to use the module decomposition algorithm in [4] to compute bases of $\mathcal{F}_{\text{col}}$ and $\mathcal{F}_{\text{row}}$ in randomized polynomial time over finite fields. However, the module decomposition algorithm in [4] does not work in general over $\mathbb{Q}$ without moving to an extension field.

A comparison with [12, 13]: In [12] and Section 4.9 of [13], a DET over $\mathbb{C}$ was given by reducing it to the Lie algebra conjugacy problem. It was also suggested there that the approach can be made to work over finite field by reduction to the problem of finding and diagonalizing split Cartan subalgebra and then applying Ryba's algorithm [27]. However, it is not quite clear to us how to carry out this approach in full details. Despite the similarities between these two approaches originating from the use of Lie algebra, our approach of reducing DET to FMAI does appear somewhat different from the approach suggested in [12, 13].

4 Reduction of DET to FMAI

We give a randomized polynomial time reduction from DET to the FMAI problem. Recall the FMAI problem from Definition 4: An algorithm for FMAI takes input an ordered basis $(L_1, \ldots, L_m)$ of a $\mathbb{F}$-algebra $\mathcal{A} \subseteq M_s$ such that $\mathcal{A} \cong M_n$, and outputs a $\mathbb{F}$-algebra isomorphism $\phi : \mathcal{A} \to M_n$ in the form of an ordered basis $(C_1, \ldots, C_m)$ of M_n, where $C_i = \phi(L_i)$ for $i \in [m]$.

▶ **Lemma 18** (Reduction of DET to FMAI). *Let $n \geq 2$, $|\mathbb{F}| > 10n^4$ and $\text{char}(\mathbb{F}) \nmid n(n-1)$. Then, there exists a randomized algorithm, with oracle access to FMAI, that takes input black-box access to a $f \in \mathbb{F}[\mathbf{x}]$ of degree n and solves DET for f over $\mathbb{F}$ with high probability. The running time of the algorithm is polynomial in n and the bit length of the coefficients of f.*

The proof of this lemma follows from the proof of correctness of the following algorithm.

4.1 The algorithm

Algorithm 2 Reduction of DET to FMAI.

Input: Black-box access to $f \in \mathbb{F}[\mathbf{x}]$ of degree n, and oracle access to an algo for FMAI.
Output: $B \in \text{GL}(m, \mathbb{F})$ such that $f = \mathsf{Det}(B \cdot \mathbf{x})$, if such a B exists. Else, output "Fail".

1: Invoke Algorithm 1. Let $\{U_1, \ldots, U_r\}$ be the basis of the space $\mathcal{U}_1$ returned by Algorithm 1, where $\mathcal{U}_1 = \mathcal{F}_{\text{col}}$.
2: Generate a basis $\{L_1, \ldots, L_k\}$ of the algebra $\mathcal{A} := \mathbb{F}[U_1, \ldots, U_r]$. If $k \neq m$, output "Fail".

3: Invoke the FMAI oracle on $(L_1, \ldots, L_m)$ which returns a basis $(C_1, \ldots, C_m)$ of M_n.
4: Pick a *random* $M \in M_m$ satisfying $L_i \cdot M = M \cdot (I_n \otimes C_i)$ for every $i \in [m]$.
5: Let b be the evaluation of $f(M \cdot \mathbf{x})$ at $x_{11} = \ldots = x_{nn} = 1$ and remaining x_{ij} set to 0.
6: If $M \notin \text{GL}(m, \mathbb{F})$ or $b = 0$, output "Fail". Else, set $D = \text{diag}(b, 1, \ldots, 1) \in M_n$. Output $(I_n \otimes D) \cdot M^{-1}$.

4.2 Proof of correctness of Algorithm 2

If f is not equivalent to Det then it can be detected with high probability by checking if $f(\mathbf{a}) = b \cdot \mathsf{Det}(M^{-1}\mathbf{a})$ at a random point $\mathbf{a} \in_r S^m$, where $S \subseteq \mathbb{F}$ is sufficiently large. So, assume that $f = \mathsf{Det}(A \cdot \mathbf{x})$ for some $A \in \mathrm{GL}(m, \mathbb{F})$. The correctness of Algorithm 1 ensure that $\mathcal{U}_1 = \mathcal{F}_{\mathrm{col}}$ without loss of generality. Step 2 can be executed efficiently by checking if $U_iU_j \in \mathrm{span}_{\mathbb{F}}\{U_1, \ldots, U_r\}$ for $i, j \in [r]$. Observation 2.5 implies that $\mathcal{A} \cong M_n$, i.e., $L_i = A^{-1} \cdot (I_n \otimes B_i) \cdot A$ for every $i \in [m]$, where $\{B_1, \ldots, B_m\}$ is a basis of M_n. In Step 3, the FMAI oracle returns a $\mathbb{F}$-algebra isomorphism $\phi : \mathcal{A} \to M_n$ such that $\{C_i = \phi(L_i) : i \in [m]\}$ is a basis of M_n. The following claim ensures the existence of a matrix M, computed in Step 4. Its proof is given in Section E.1 of the Appendix of [11].

▷ Claim 19. There exists a $S \in \mathrm{GL}(n, \mathbb{F})$ such that $B_i = S^{-1} \cdot C_i \cdot S$ for every $i \in [m]$.

Consider the linear system defined by the equation $L_i \cdot M = M \cdot (I_n \otimes C_i)$, where the entries of M are taken as variables. Step 4 is executed by picking the free variables of the solution space of the system from a sufficiently large subset of $\mathbb{F}$. Finally, the correctness of Step 6 is argued in the proof of the following claim which is given in Section E.2 of the Appendix of [11].

▷ Claim 20. Suppose $f = \mathsf{Det}(A \cdot \mathbf{x})$, where $A \in \mathrm{GL}(m, \mathbb{F})$. Then, $f = \mathsf{Det}((I_n \otimes D) \cdot M^{-1} \cdot \mathbf{x})$ with high probability.

5 DET over finite fields and over $\mathbb{Q}$

The proofs of Theorem 1 and 2 are completed by replacing the FMAI oracle in Step 3 of Algorithm 2 by the following known algorithms for FMAI over finite fields and $\mathbb{Q}$.

▶ **Theorem 21** (Theorem 5.1 of [25]). *Let $\mathbb{F}$ be a finite field. Given a basis of a $\mathbb{F}$-algebra $\mathcal{A} \subseteq M_m$ such that $\mathcal{A} \cong M_n$, an isomorphism $\phi : \mathcal{A} \to M_n$ can be constructed in randomized $(m, \log |\mathbb{F}|)$ time.*

▶ **Theorem 22** (Theorem 1 of [14]). *There is a randomized algorithm with oracle access to* IntFact *that takes input a basis of a $\mathbb{Q}$-algebra $\mathcal{A} \subseteq M_m$ such that $\mathcal{A} \cong M_n$, and outputs an isomorphism $\phi : \mathcal{A} \to M_n$ with high probability. The algorithm runs in time polynomial in the bit length of the input, if n is bounded.*

▶ **Theorem 23** (Lemma 2.5 of [3]). *There is a randomized algorithm that takes input a basis of a $\mathbb{Q}$-algebra $\mathcal{A} \subseteq M_m$ such that $\mathcal{A} \cong M_n$, and outputs an isomorphism $\phi : \mathcal{A} \otimes_{\mathbb{Q}} Ł \to M_n(Ł)$ with high probability, where Ł is an extension field of $\mathbb{Q}$ satisfying $[Ł : \mathbb{Q}] \leq n$. The algorithm runs in time polynomial in the bit length of the input.*

6 Factoring hardness of DET over $\mathbb{Q}$

This section is devoted to proving Theorem 3. We show that DET in the 2×2 setting over $\mathbb{Q}$ is at least as hard as factoring square-free integers. We will need the following theorem.

▶ **Theorem 24** ([24]). *Assuming GRH, there is a randomized polynomial time reduction from the problem of factoring square-free integers to the following problem: Given non-zero $a, b \in \mathbb{Q}$, find rational numbers x, y, z (not all zero) such that $x^2 - ay^2 - bz^2 = 0$, if there exists such a solution.*

We will also need the following proposition, cited in [24], to prove the next theorem. We give a proof from [5] in Section F.1 of [11], for completeness.

▶ **Proposition 25.** *Let $a, b \in \mathbb{Q}^\times$. Then the equation $x^2 - ay^2 - bz^2 = 0$ has a non-zero rational solution if and only if the equation $x^2 - ay^2 - bz^2 + abw^2 = 0$ has a non-zero rational solution.*

We are now ready to prove integer factoring hardness of DET in the next theorem.

▶ **Theorem 26.** *Consider the polynomial $f_{a,b}(\mathbf{x}) = x_{1,1}^2 - ax_{1,2}^2 - bx_{2,1}^2 + abx_{2,2}^2$, where $a, b \in \mathbb{Q}$ are non-zero. Then $f_{a,b}(\mathbf{x}) = \mathsf{Det}_2(A \cdot \mathbf{x})$ for some $A \in \mathrm{GL}(4, \mathbb{Q})$ if and only if the equation $x^2 - ay^2 - bz^2 = 0$ has a non-zero rational solution (moreover, such a rational solution can be efficiently computed from A).*

Its proof is given in Section F.2 of [11]. Combining Theorems 24 and 26, we obtain Theorem 3.

▶ Remark 27. We want to explain how we got to the above reduction. Ronyai [24] proved that the FMAI problem over $\mathbb{Q}$ is factoring hard even for $n = 2$ via quaternion algebras. If one takes a specific quaternion algebra and tries to constructs a polynomial f whose Lie algebra is the traceless part of the quaternion algebra, then it turns out the polynomial $f_{a,b}(\mathbf{x})$ is the unique homogeneous degree 2 polynomial that comes out. But in any case, in hindsight, the polynomial $f_{a,b}(\mathbf{x})$ seems like a natural candidate to use.

7 Characterization of the determinant by its Lie algebra

In this section, we reduce FMAI to DET under mild restrictions on $\mathbb{F}$. We start with the claim that the Lie algebra of the determinant characterizes the determinant. This is well known over $\mathbb{C}$, but we give a proof in Section G.1 of [11] that works under mild restrictions on $\mathbb{F}$.

▶ **Lemma 28.** *Let $f \in \mathbb{F}[\mathbf{x}]$ be any homogeneous polynomial of degree n such that $\mathcal{L}_{col} \subseteq \mathfrak{g}_f$ (recall $\mathcal{L}_{col}$ from Section 2). Also suppose $\mathrm{char}(\mathbb{F}) \nmid n$. Then $f(\mathbf{x}) = \alpha \cdot \mathsf{Det}_n(\mathbf{x})$ for some $\alpha \in \mathbb{F}$.*

▶ Remark 29. Note that without the $\mathrm{char}(\mathbb{F}) \nmid n$ condition, Lemma 28 is not true. For example, $f(\mathbf{x}) = x_{1,1}^n + \mathsf{Det}_n(\mathbf{x})$ will have the same Lie algebra as $\mathsf{Det}_n(\mathbf{x})$ if $\mathrm{char}(\mathbb{F}) \mid n$.

▶ **Corollary 30.** *Let $f \in \mathbb{F}[\mathbf{x}]$ be a degree n homogeneous polynomial. Suppose that $A^{-1} \cdot \mathcal{L}_{col} \cdot A \subseteq \mathfrak{g}_f$ for some $A \in \mathrm{GL}(n^2, \mathbb{F})$ and $\mathrm{char}(\mathbb{F}) \nmid n$. Then $f(\mathbf{x}) = \alpha \cdot \mathsf{Det}_n(A \cdot \mathbf{x})$ for some $\alpha \in \mathbb{F}$.*

Proof. Consider $f'(\mathbf{x}) = f(A^{-1} \cdot \mathbf{x})$. By Fact 2, $\mathfrak{g}_{f'} = A \cdot \mathfrak{g}_f \cdot A^{-1}$, so $\mathcal{L}_{\mathrm{col}} \subseteq \mathfrak{g}_{f'}$. By Lemma 28, we get that $f'(\mathbf{x}) = \alpha \cdot \mathsf{Det}_n(\mathbf{x})$ for some $\alpha \in \mathbb{F}$ and hence $f(\mathbf{x}) = \alpha \cdot \mathsf{Det}_n(A \cdot \mathbf{x})$. ◀

Corollary 30 allows us to reduce FMAI to DET when n is constant (see Algorithm 3).

7.1 Proof of correctness of Algorithm 3 when $\mathrm{char}(\mathbb{F}) \nmid n$

The proof of correctness will follow from the following proposition, proved in Section G.2 of [11]. The matrices $B_{i,j}$ and $L_{i,j}$ are as defined in Step 2 of the algorithm.

▶ **Proposition 31.** *Suppose the algebra $\mathcal{A}$ spanned by $B_{1,1}, \ldots, B_{n,n}$ is isomorphic to M_n. Then there exist $K \in \mathrm{GL}(n^2, \mathbb{F})$ and $C_{1,1}, \ldots, C_{n,n} \in M_n$, s.t. $L_{i,j} = K^{-1}(I_n \otimes C_{i,j})K$ for all $i, j \in [n]$.*

Now let us proceed to the proof of correctness of Algorithm 3. First of all, it is easy to ensure that whenever the algorithm outputs an isomorphism, it is actually an isomorphism. So what we need to prove is the converse. Suppose the algebra $\mathcal{A}$ is isomorphic to M_n. Then by Proposition 31, the space spanned by $\tilde{L}_1, \ldots, \tilde{L}_{n^2-1}$ is $K^{-1} \cdot \mathcal{L}_{\text{col}} \cdot K$. Then by Corollary 30, there is a unique solution to the equations in Step 4 given by $f(\mathbf{x}) = \alpha \cdot \mathsf{Det}_n(K \cdot \mathbf{x})$, for some $\alpha \in \mathbb{F}$, and so f is equivalent to the determinant. Hence, in Step 5, we will get an $A \in \mathrm{GL}(n^2, \mathbb{F})$ s.t. $f(\mathbf{x}) = \mathsf{Det}_n(A \cdot \mathbf{x})$. Since $\tilde{L}_1, \ldots, \tilde{L}_{n^2-1}$ span a Lie algebra of dimension n^2-1 and since they lie inside the Lie algebra of $\mathsf{Det}_n(A \cdot \mathbf{x})$, we must have that $\tilde{L}_1, \ldots, \tilde{L}_{n^2-1}$ span either $A^{-1} \cdot \mathcal{L}_{\text{col}} \cdot A$ or $A^{-1} \cdot \mathcal{L}_{\text{row}} \cdot A$. From this, we get that one of the following conditions should be true:

- There exist matrices $F_{1,1}, \ldots, F_{n,n} \in M_n$ such that $A \cdot L_{i,j} \cdot A^{-1} = I_n \otimes F_{i,j}$ for all $i, j \in [n]$.
- There exist matrices $F_{1,1}, \ldots, F_{n,n} \in M_n$ such that $A \cdot L_{i,j} \cdot A^{-1} = F_{i,j} \otimes I_n$ for all $i, j \in [n]$.

The implies that the algorithm will output 1 and an isomorphism into M_n. The complexity of the reduction is dominated by Step 4 which takes $n^{O(n)}$ field operations.

Algorithm 3 Reduction of FMAI to DET.

Input: Basis $\{B_1, \ldots, B_r\}$ of a $\mathbb{F}$-algebra $\mathcal{A} \subseteq M_m$, and access to an algorithm for DET.
Output: if $\mathcal{A} \cong M_n$ for some $n \in \mathbb{N}$, then output an isomorphism, 0 otherwise.

1: If $r = \dim_{\mathbb{F}} \mathcal{A} \neq n^2$ for any $n \in \mathbb{N}$, output 0 and halt.
2: Index the basis elements by $[n] \times [n]$, i.e., rename them as $B_{1,1}, \ldots, B_{n,n}$. Compute $n^2 \times n^2$ matrices $L_{1,1}, \ldots, L_{n,n}$ as follows: $L_{i,j}$ is the matrix corresponding to the left-multiplication action of $B_{i,j}$ on $B_{1,1}, \ldots, B_{n,n}$. That is $B_{i,j} \cdot B_{i_2,j_2} = \sum_{i_1,j_1} L_{i,j}((i_1,j_1),(i_2,j_2)) \cdot B_{i_1,j_1}$.
3: Compute a basis for the traceless parts of the matrices $L_{i,j}$. That is, compute a basis $\tilde{L}_1, \ldots, \tilde{L}_s$ of the space spanned by $L_{1,1} - \frac{\mathrm{tr}(L_{1,1})}{n^2} I_{n^2}, \ldots, L_{n,n} - \frac{\mathrm{tr}(L_{n,n})}{n^2} I_{n^2}$. If $s \neq n^2 - 1$, output 0 and halt.
4: Find a non-zero homogeneous polynomial of degree n, $f(\mathbf{x})$, satisfying the equations

$$\sum_{i_1,j_1,i_2,j_2} M((i_1,j_1),(i_2,j_2)) \cdot x_{i_2,j_2} \cdot \frac{\partial f}{\partial x_{i_1,j_1}} = 0$$

for every $M \in \{\tilde{L}_1, \ldots, \tilde{L}_{n^2-1}\}$ (these give linear equations in the coefficients of f). If no such non-zero polynomial exists then output 0 and halt.
5: Run DET on f. If the output is "Fail" then output 0 and halt. If $f(\mathbf{x}) = \mathsf{Det}_n(A \cdot \mathbf{x})$ then check if there exist matrices $F_{1,1}, \ldots, F_{n,n} \in M_n$ such $A \cdot L_{i,j} \cdot A^{-1} = I_n \otimes F_{i,j}$ for all i, j. If yes, output 1 and the isomorphism $\phi(B_{i,j}) = F_{i,j}$ (extended linearly to whole of $\mathcal{A}$). If no, check if there exist matrices $F_{1,1}, \ldots, F_{n,n} \in M_n$ such that $A \cdot L_{i,j} \cdot A^{-1} = F_{i,j} \otimes I_n$ for all i, j. If yes, output 1 and the isomorphism $\phi(B_{i,j}) = F_{i,j}$ (extended linearly to whole of $\mathcal{A}$). If no, output 0.

Abstract

We consider the online problem of scheduling jobs on identical machines, where jobs have precedence constraints. We are interested in the demanding setting where the jobs sizes are not known up-front, but are revealed only upon completion (the *non-clairvoyant* setting). Such precedence-constrained scheduling problems routinely arise in map-reduce and large-scale optimization. For minimizing the total weighted completion time, we give a constant-competitive algorithm. And for total weighted flow-time, we give an $O(1/\varepsilon^2)$-competitive algorithm under $(1+\varepsilon)$-speed augmentation and a natural "no-surprises" assumption on release dates of jobs (which we show is necessary in this context).

Our algorithm proceeds by assigning *virtual rates* to all waiting jobs, including the ones which are dependent on other uncompleted jobs. We then use these virtual rates to decide on the actual rates of minimal jobs (i.e., jobs which do not have dependencies and hence are eligible to run). Interestingly, the virtual rates are obtained by allocating time in a fair manner, using a Eisenberg-Gale-type convex program (which we can solve optimally using a primal-dual scheme). The optimality condition of this convex program allows us to show dual-fitting proofs more easily, without having to guess and hand-craft the duals. This idea of using fair virtual rates may have broader applicability in scheduling problems.

1 Introduction

We consider the problem of online scheduling of jobs under precedence constraints. We seek to minimize the average weighted flow time of the jobs on multiple parallel machines, in the online *non-clairvoyant* setting. Formally, there are m identical machines, each capable

of one unit of processing per unit of time. A set of $[n]$ jobs arrive online. Each job has a processing requirement p_j and a weight w_j, and is released at some time r_j. If the job finishes at time C_j, its flow or response time is defined to be $C_j - r_j$. The goal is to give a preemptive schedule that minimizes the total (or, equivalently, the average) weighted flow-time $\sum_{j\in[n]} w_j \cdot (C_j - r_j)$. The main constraints of our model are the following: (i) the scheduling is done *online*, so the scheduler does not know of the jobs before they are released; (ii) the scheduler is *non-clairvoyant* – when a job arrives, the scheduler knows its weight but *not its processing time* p_j. (It is only when the job finishes its processing that the scheduler knows the job is done, and hence knows p_j.); And (iii) there are *precedence constraints* between jobs given by a partial order $([n], \prec)$: $j \prec j'$ means job j' cannot be started until j is finished. Naturally, the partial order should respect release dates: if $j \prec j'$ then $r_j \le r'_j$. (We will require a stronger assumption for some of our results.)

This model for constrained parallelism is a natural one, both in theory and in practice. In theory, this precedence-constrained (and non-clairvoyant!) scheduling model (with other objective functions) goes back to Graham's work on list scheduling [8]. In practice, most languages and libraries produce parallel code that can be modeled using precedence DAGs [20, 1, 9]. Often these jobs (i.e., units of processing) are distributed among some m workstations or servers, either in server farms or on the cloud, i.e., they use identical parallel machines.

1.1 Our Results and Techniques

Weighted Completion Time. We develop our techniques on the problem of minimizing the *average weighted completion time* $\sum_j w_j C_j$. Our convex-programming approach gives us:

▶ **Theorem 1.1.** *There is a* 10*-competitive deterministic online algorithm for minimizing the average weighted completion time on parallel machines with both release dates and precedences, in the online non-clairvoyant setting.*

For this result, at each time t, the algorithm has to know only the partial order restricted to $\{j \in [n] \mid r_j \le t\}$, i.e., the jobs released by time t. The algorithmic idea is simple in hindsight: the algorithm looks at the *minimal* unfinished jobs (i.e., they do not depend on any other unfinished jobs): call them I_t. If J_t is the set of (already released and) unfinished jobs at time t, then $I_t \subseteq J_t$. To figure out how to divide our processing among the jobs in I_t, we write a convex program that fairly divides the time among all jobs in the larger set J_t, such that (a) these jobs can "donate" their allocated time to some preceding jobs in I_t, and that (b) the jobs in I_t do not get more than 1 unit of processing per time-step.

For this fair allocation, we maximize the (weighted) Nash Welfare $\sum_{j\in J_t} w_j \log R_j$, where R_j is the *virtual rate* of processing given to job $j \in J_t$, regardless of whether it can currently be run (i.e., is in I_t). This tries to fairly distribute the virtual rates among the jobs [19], and can be solved using an Eisenberg-Gale-type convex program. (We can solve this convex program in our setting using a simple primal-dual algorithm, see the full version.) The proof of Theorem 1.1 is via writing a linear-programming relaxation for the weighted completion time problem, and fitting a dual to it. Conveniently, the dual variables for the completion time LP naturally fall out of the dual (KKT) multipliers for the convex program!

Weighted Flow Time. We then turn to the *weighted flow-time minimization* problem. We first observe that the problem has no competitive algorithm if there are jobs j that depend on jobs released before r_j. Indeed, if OPT ever has an empty queue while the algorithm is processing jobs, the adversary could give a stream of tiny new jobs, and we would be sunk. Hence we make an additional *no-surprises* assumption about our instance: when a job j is

released, all the jobs having a precedence relationship to j are also released at the same time. In other words, the partial order is a collection of disjoint connected DAGs, where all jobs in each connected component have the same release date. A special case of this model has been studied in [20, 1] where each DAG is viewed as a "hyper-job" and there are no precedence constraints between different hyper-jobs. In this model, we show:

▶ **Theorem 1.2.** *There is an $O(1/\varepsilon^2)$-competitive deterministic non-clairvoyant online algorithm for the problem of minimizing the average weighted flow time on parallel machines with release dates and precedences, under the no-surprises and $(1+\varepsilon)$-speedup assumptions.*

Interestingly, the algorithm for weighted flow-time is almost the same as for weighted completion time. In fact, *exactly* the same algorithm works for both the completion time and flow time cases, if we allow a speedup of $(2+\varepsilon)$ for the latter. To get the $(1+\varepsilon)$-speedup algorithm, we give preference to the recently-arrived jobs, since they have a smaller current time-in-system and each unit of waiting proportionally hurts them more. This is along the lines of strategies like LAPS and WLAPS [7].

1.2 The Intuition

Consider the case of unit weight jobs on a single machine. Without precedence constraints, the round-robin algorithm, which runs all jobs at the same rate, is $O(1)$-competitive for the flow-time objective with a 2-speed augmentation. Now consider precedences, and let the partial order be a collection of disjoint chains: only the first remaining job from each chain can be run at each time. We generalize round-robin to this setting by running all minimal jobs simultaneously, but at rates proportional to length of the corresponding chains. We can show this algorithm is also $O(1)$-competitive with a 2-speed augmentation. While this is easy for chains and trees, let us now consider the case when the partial order is the union of general DAGs, where each DAG may have several minimal jobs. Even though the sum of the rates over all the minimal jobs in any particular DAG should be proportional to the number of jobs in this DAG, running all minimal jobs at equal rates does not work. (Indeed, if many jobs depend on one of these minimal jobs, and many fewer depend on the other minimal jobs in this DAG, we want to prioritize the former.)

Instead, we use a convex program to find rates. Our approach assigns a "virtual rate" R_j to each job in the DAG (regardless of whether it is minimal or not). This virtual rate allows us to ensure that even though this job may not run, it can help some minimal jobs to run at higher rates. This is done by an assignment problem where these virtual rates get translated into actual rates for the minimal jobs. The virtual rates are then calculated using Nash fairness, which gives us max-min properties that are crucial for our analysis.

Analysis Challenges: In typical applications of the dual-fitting technique, the dual variables for each job encode the *increase in total flow-time* caused by arrival of this job. Using this notion turns out to create problems. Indeed, consider a minimal job of low weight which is running at a high rate (because a large number of jobs depend on it). The increase in overall flow-time because of its arrival is very large. However the dual LP constraints require these dual variables to be bounded by the weights of their jobs, which now becomes difficult to ensure. To avoid this, we define the dual variables directly in terms of the virtual rates of the jobs, given by the convex program.

Having multiple machines instead of a single machine creates new problems. The *actual rates* assigned to any minimal job cannot exceed 1, and hence we have to throttle certain actual rates. Again the versatility of the convex program helps us, since we can add this as a

constraint. Arguing about the optimal solution to such a convex program requires dealing with the suitable KKT conditions, from which we can infer many useful properties. We also show in the full version that the optimal solution corresponds to a natural "water-filling" based algorithm.

Finally, we obtain matching results for the case of $(1+\varepsilon)$-speed augmentation. Im et al. [12] gave a general-purpose technique to translate a round-robin based algorithm to a LAPS-like algorithm. In our setting, it turns out that the LAPS-like policy needs to be run on the virtual rates of jobs. Analyzing this algorithm does not follow in a black-box manner (as prescribed by [12]), and we need to adapt our dual-fitting analysis suitably.

1.3 Related Work and Organization

Completion Time. Minimizing $\sum_j w_j C_j$ on parallel machines with precedence constraints has $O(1)$-approximations in the *offline* setting: Li [16] improves on [11, 18] to give a $3.387+\varepsilon$-approximation. For *related* machines, the precedence constraints make the problem much harder: there is a $O(\log m/\log\log m)$-approximation [16] improving on a prior $O(\log m)$ result [4], and a hardness of $\omega(1)$ under certain complexity assumptions [3]. In the *online* setting, any offline algorithm for (a dual problem to) $\sum_j w_j C_j$ gives an *clairvoyant* online algorithm, losing $O(1)$ factors [11]. Two caveats: it is unclear (a) how to make this algorithm non-clairvoyant, and (b) how to solve the (dual of the) weighted completion time problem with precedences in poly-time.

Flow Time without Precedence. To minimize $\sum_j w_j(C_j - r_j)$, strong lower bounds are known for the competitive ratio of any online algorithm even on a single machine [17]. Hence we use speed augmentation [14]. For the general setting of non-clairvoyant weighted flow-time on unrelated machines, Im et al. [13] showed that weighted round-robin with a suitable migration policy yields a $(2+\varepsilon)$-competitive algorithm using $(1+\varepsilon)$-speed augmentation. They gave a general purpose technique, based on the LAPS scheduling policy, to convert any such round-robin based algorithm to a $(1+\varepsilon)$-competitive algorithm while losing an extra $1/\varepsilon$ factor in the competitive ratio. Their analysis also uses a dual-fitting technique [2, 10]. However, they do not consider precedence constraints.

Flow Time with Precedence. Much less is known for flow-time problems with precedence constraints. For the offline setting on identical machines, [15] give $O(1)$-approximations with $O(1)$-speedup, even for general delay functions. In the current paper, we achieve a $\mathrm{poly}(1/\varepsilon)$-approximation with $(1+\varepsilon)$-speedup for flow-time. Interestingly, [15] show that beating a n^{1-c}-approximation for any constant $c \in [0,1)$ requires a speedup of at least the optimal approximation factor of makespan minimization in the same machine environment. However, this lower bound requires different jobs with a precedence relationship to have different release dates, which is something our model disallows. (The full version gives another lower bound showing why we disallow such precedences in the online setting.)

In the *online* setting, [20] introduced the DAG model where each *job* is a directed acyclic graph (of *tasks*) released at some time, and a job/DAG completes when all the tasks in it are finished, and we want to minimize the total *unweighted* flow-time. They gave a $(2+\varepsilon)$-speed $O(\kappa/\varepsilon)$-competitive algorithm, where κ is the largest antichain within any job/DAG. [1] show $\mathrm{poly}(1/\varepsilon)$-competitiveness with $(1+\varepsilon)$-speedup, again in the non-clairvoyant setting. The case where jobs are entire DAGs, and not individual nodes within DAGs, is captured in our weighted model by putting zero weights for all original jobs, and adding a unit-weight zero-sized job for each DAG which now depends on all jobs in the DAG. Assigning arbitrary

weights to individual nodes within DAGs makes our problem quite non-trivial – we need to take into account the structure of the DAG to assign rates to jobs. Another model to capture parallelism and precedences uses *speedup functions* [6, 5, 7]: relating our model to this setting remains an open question.

Our work is closely related to Im et al. [12] who use a Nash fairness approach for completion-time and flow-time problems with multiple resources. While our approaches are similar, to the best of our understanding their approach does not immediately extend to the setting with precedences. Hence we have to introduce new ideas of using virtual rates (and being fair with respect to them), and throttling the induced actual rates at 1. The analyses of [12] and our work are both based on dual-fitting; however, we need some new ideas for the setting with precedences.

Organization. The weighted completion time case is solved in §2. A $(2+\varepsilon)$-speedup result for weighted flow-time is in §3. In the full version we improve this to a $(1+\varepsilon)$-speedup. There we also show the need for the "no-surprises" assumption on release dates, how to solve the convex program using a "water-filling" based algorithm, and the missing proofs.

2 Minimizing Weighted Completion Time

In this section, we describe and analyze the scheduling algorithm for the problem of minimizing weighted completion time on parallel machines. Recall that the precedence constraints are given by a DAG G, and each job j has a release date r_j, processing size p_j and weight w_j.

2.1 The Scheduling Algorithm

We first assume that each of the m machines run at rate 2 (i.e., they can perform 2 units of processing in a unit time). We will show later how to remove this assumption (at a constant loss of competitive ratio). We begin with some notation. We say that a job j is *waiting* at time t (with respect to a schedule) if $r_j \le t$, but j has not been processed to completion by time t. We use J_t to denote the set of waiting jobs at time t. Note that at time t, the algorithm gets to see the subgraph G_t of G which is induced by the jobs in J_t. We say that a job j is *unfinished* at time t if it is either waiting at time t, or its release date is at least t (and hence the algorithm does not even know about this job). Let U_t denote the set of unfinished jobs at time t. Clearly, $J_t \subseteq U_t$. At time t, the algorithm can only process those jobs in J_t which do not have a predecessor in G_t – denote these *minimal* jobs by I_t: they are independent of all other current jobs. For every time t, the scheduling algorithm needs to assign a rate to each job $j \in I_t$. We now describe how it decides on these rates.

Consider a time t. The algorithm considers a bipartite graph $H_t = (I_t, J_t, E_t)$ with vertex set consisting of the minimal jobs I_t on left and the waiting jobs J_t on right. Since $I_t \subseteq J_t$, a job in I_t appears as a vertex on both sides of this bipartite graph. When there is no confusion, we slightly overload terminology by referring to a job as a vertex in H_t. The set of edges E_t are as follows: let $j_l \in I_t, j_r \in J_t$ be vertices on the left and the right side respectively. Then (j_l, j_r) is an edge in E_t if and only if there is a directed path from j_l to j_r in the DAG G_t.

The following convex program now computes the rate for each vertex in I_t. It has variables z_e^t for each edge $e \in E_t$. For each job j on the left side, i.e., for $j \in I_t$, define $L_j^t := \sum_{e \in \partial j} z_e^t$ as the sum of z_e values of edges incident to j. Similarly, define $R_j^t := \sum_{e \in \partial j} z_e^t$ for a job $j \in J_t$, i.e., on the right side. The objective function is the Nash bargaining objective function on the R_j^t values, which ensures that each waiting job gets some attention. In the full version

we give a combinatorial algorithm to efficiently solve this convex program.

$$\max \sum_{j \in J_t} w_j \ln R_j^t \tag{CP}$$

$$L_j^t = \sum_{j' \in J_t : (j,j') \in E_t} z_{jj'}^t \qquad \forall j \in I_t \tag{1}$$

$$R_j^t = \sum_{j' \in I_t : (j',j) \in E_t} z_{j'j}^t \qquad \forall j \in J_t \tag{2}$$

$$L_j^t \le 1 \qquad \forall j \in I_t \tag{3}$$

$$\sum_{j \in I_t} L_j^t \le m \tag{4}$$

$$z_e^t \ge 0 \qquad \forall e \in E_t \tag{5}$$

Let $(\bar{z}^t, \bar{L}^t, \bar{R}^t)$ be an optimal solution to the above convex program. We define the *rate of a job* $j \in I_t$ as being $\bar{L}_j^t$.

Although we have defined this as a continuous time process, it is easy to check that the rates only change if a new job arrives, or if a job completes processing. Also observe that we have effectively combined the m machines into one in this convex program. But assuming that all events happen at integer times, we can translate the rate assignment to an actual schedule as follows. For a time slot $[t, t+1]$, the total rate is at most m (using (4)), so we create m time slots $[t, t+1]_i$, one for each machine i, and iteratively assign each job j an interval of length $\bar{L}_j^t$ within these time slots. It is possible that a job may get assigned intervals in two different time slots, but the fact that $\bar{L}_j^t \le 1$ means it will not be assigned the same time in two different time slots. Further, we will never exceed the slots because of (4). Thus, we can process these jobs in the m time slots on the m parallel machines such that each job j gets processed for $\bar{L}_j^t$ amount of time and no job is processed concurrently on multiple machines. This completes the description of the algorithm; in this, we assume that we run the machines at twice the speed. Call this algorithm $\mathcal{A}$.

The final algorithm $\mathcal{B}$, which is only allowed to run the machines at speed 1, is obtained by running $\mathcal{A}$ in the background, and setting $\mathcal{B}$ to be a slowed-down version of $\mathcal{A}$. Formally, if $\mathcal{A}$ processes a job j on machine i at time $t \in \mathbb{R}_{\ge 0}$, then $\mathcal{B}$ processes this at time $2t$. This completes the description of the algorithm.

2.2 A Time-Indexed LP formulation

We use the dual-fitting approach to analyze the above algorithm. We write a time-indexed linear programming relaxation (LP) for the weighted completion time problem, and use the solutions to the convex program (CP) to obtain feasible primal and dual solutions for (LP) which differ by only a constant factor.

We divide time into integral time slots (assuming all quantities are integers). Therefore, the variable t will refer to integer times only. For every job j and time t, we have a variable $x_{j,t}$ which denotes the volume of j processed during $[t, t+1]$. Note that this is defined only for $t \ge r_j$. The LP relaxation is as follows:

$$\min \quad \textstyle\sum_{j,t} w_j \cdot \frac{t \cdot x_{j,t}}{p_j} \tag{LP}$$

$$\textstyle\sum_{t \ge r_j} \frac{x_{j,t}}{p_j} \ge 1 \quad \forall j \tag{6}$$

$$\textstyle\sum_j x_{j,t} \le m \quad \forall t \tag{7}$$

$$\textstyle\sum_{s \le t} \frac{x_{j,s}}{p_j} \ge \sum_{s \le t} \frac{x_{j',s}}{p_{j'}} \quad \forall t, j \prec j' \tag{8}$$

The following claim, whose proof is deferred to the full version, shows that it is a valid relaxation.

▷ Claim 2.1. Let *opt* denote the weighted completion time of an optimal off-line policy (which knows the processing time of all the jobs). Then the optimal value of the LP relaxation is at most *opt*.

The (LP) has a large integrality gap. Observe that the LP just imagines the m machines to be a single machine with speed m. Therefore, (LP) has a large integrality gap for two reasons: (i) a job j can be processed concurrently on multiple machines, and (ii) suppose we have a long chain of jobs of equal size in the DAG G. Then the LP allows us to process all these jobs at the same rate in parallel on multiple machines. We augment the LP lower bound with another quantity and show that the sum of these two lower bounds suffice.

A *chain* C in G is a sequence of jobs $j_1, \ldots, j_k$ such that $j_1 \prec j_2 \prec \ldots \prec j_k$. Define the processing time of C, $p(C)$, as the sum of the processing time of jobs in C. For a job j, define chain_j as the maximum over all chains C ending in j of $p(C)$. It is easy to see that $\sum_j w_j \cdot (r_j + \mathsf{chain}_j)$ is a lower bound (up to a factor 2) on the objective of an optimal schedule.

We now write down the dual of the LP relaxation above. We have dual variables α_j for every job j, and β_t for every time t, and $\gamma_{s,j\to j'}$

$$\max \quad \sum_j \alpha_j - m \sum_t \beta_t \tag{DLP}$$

$$\alpha_j - w_j \cdot t + \sum_{s \geq t} \Big(\sum_{j \prec j'} \gamma_{s,j\to j'} - \sum_{j' \prec j} \gamma_{s,j'\to j} \Big) \leq p_j \cdot \beta_t \quad \forall j, t \geq r_j \tag{9}$$

$$\alpha_j, \beta_t \geq 0$$

We write the dual constraint (9) in a more readable manner. For a job j and time s, let $\gamma^{\text{in}}_{s,j}$ denote $\sum_{j' \prec j} \gamma_{s,j'\to j}$, and define $\gamma^{\text{out}}_{s,j}$ similarly. We now write the dual constraint (9) as

$$\alpha_j - w_j \cdot t + \sum_{s \geq t} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \right) \leq p_j \cdot \beta_t \quad \forall j, t \geq r_j \tag{10}$$

2.3 Properties of the Convex Program

We now prove certain properties of an optimal solution $(\bar{z}^t, \bar{L}^t, \bar{R}^t)$ to the convex program (CP). The first property, whose proof is deferred to the full version, is easy to see:

▷ Claim 2.2. If $\sum_{j \in I_t} \bar{L}^t_j < m$, then $\bar{L}^t_j = 1$ for all $j \in I_t$.

We now write down the KKT conditions for the convex program. (In fact, we can use (1) and (2) to replace $\bar{L}^t_j$ and $\bar{R}^t_j$ in the objective and the other constraints.) Then letting $\theta^t_j \geq 0, \eta^t \geq 0, \nu^t_e \geq 0$ be the Lagrange multipliers corresponding to constraints (3), (4) and (5), we get

$$\frac{w_j}{\bar{R}^t_j} = \theta^t_{j'} + \eta^t - \nu^t_e \qquad \forall e = (j', j), j' \in I_t, j \in J_t \tag{11}$$

$$\theta^t_j \, (\bar{L}^t_j - 1) = 0 \qquad \forall j \in I_t \tag{12}$$

$$\eta^t \, (\textstyle\sum_{j \in I_t} \bar{L}^t_j - m) = 0 \tag{13}$$

$$\nu^t_e \cdot \bar{z}^t_e = 0 \qquad \forall e \in E_t \tag{14}$$

We derive a few consequences of these conditions, the proofs are deferred to the full version.

▷ Claim 2.3. Consider a job $j \in J_t$ on the right side of H_t. Then $w_j \geq \bar{R}^t_j \cdot \eta^t$.

▷ Claim 2.4. Consider a job $j \in J_t$ on the right side of H_t. Suppose j has a neighbor $j' \in I_t$ such that $\bar{L}^t_{j'} < 1$ and $\bar{z}^t_{j'j} > 0$. Then $w_j = \bar{R}^t_j \cdot \eta^t$.

A crucial notion is that of an *active* job:

▶ **Definition 2.5** (Active Jobs). *A job $j \in J_t$ is* active *at time t if it has at least one neighbor in I_t (in the graph H_t) running at rate strictly less than 1.*

Let J^{act}_t denote the set of active jobs at time t. We can strengthen the above claim as follows.

▶ **Corollary 2.6.** *Consider an active job j at time t. Then $w_j = \bar{R}^t_j \cdot \eta^t$.*

▷ Claim 2.7. $w(J^{\text{act}}_t)/m \leq \eta^t \leq w(J_t)/m$.

2.4 Analysis via Dual Fitting

We analyze the algorithm $\mathcal{A}$ first. We define feasible dual variables for (DLP) such that the value of the dual objective function (along with the chain_j values that capture the maximum processing time over all chains ending in j) forms a lower bound on the weighted completion time of our algorithm. Intuitively, α_j would be the weighted completion time of j, and β_t would be $1/2m$ times the total weight of unfinished jobs at time t. Thus, $\sum_j \alpha_j - m \sum_t \beta_t$ would be at $1/2$ times the total weighted completion time. This idea works as long as all the machines are busy at any point of time, the reason being that the primal LP essentially views the m machines as a single speed-m machine. Therefore, we can generate enough dual lower bound if the rate of processing in each time slot is m. If all machines are not busy, we need to appeal to the lower bound given by the chain_j values.

We use the notation used in the description of the algorithm. In the graph H_t, we had assigned rates $\bar{L}^t_j$ to all the nodes j in I_t. Recall that a vertex $j \in J_t$ on the right side of H_t is said to be *active* at time t if it has a neighbor $j' \in I_t$ for which $\bar{L}^t_{j'} < 1$. Otherwise, we say that j is inactive at time t. We say that an edge $e = (j_l, j_r) \in E_t$, where $j_l \in I_t, j_r \in J_t$ is *active* at time t if the vertex j_r is active. Let A_t denote the set of active edges in E_t. Let $e = (j_l, j_r)$ be an edge in E_t. By definition, there is a path from j_l to j_r in G_t – we fix such a path P_e. As before, let C_j denote the completion time of job j. The dual variables are defined as follows:

- For each job j and time t, we define quantities $\alpha_{j,t}$. The dual variable α_j would be equal to $\sum_{t \geq 0} \alpha_{j,t}$. Fix a job j. If $t \notin [r_j, C_j]$ we set $\alpha_{j,t}$ to 0. Now, suppose $j \in J_t$. Consider the job j as a vertex in J_t (i.e., right side) in the bipartite graph H_t. We set $\alpha_{j,t}$ to w_j if j is active at time t, otherwise it is inactive.
- For each time t, we set β to $1/2m \cdot w(U_t)$ (Recall that U_t is the set of unfinished jobs at time t).
- We now need to define $\gamma_{t,j' \to j}$, where $j' \prec j$. If j or j' does not belong to J_t, we set this variable to 0. So assume that $j, j' \in J_t$ (and so the edge (j', j) lies in G_t). We define

$$\gamma_{t,j' \to j} := \eta^t \cdot \sum_{e : e \in A_t, (j' \to j) \in P_e} \bar{z}^t_e.$$

  In other words, we consider all the active edges e in the graph H_t for which the corresponding path P_e contains (j', j). We add up the fractional assignment $\bar{z}^t_e$ for all such edges.

This completes the description of the dual variables.

We first show that the objective function for (DLP) is close to the weighted completion time incurred by the algorithm. The proof is deferred to the full version.

▷ Claim 2.8. The total weighted completion time of the jobs in $\mathcal{A}$ is at most $2(\sum_j \alpha_j - m \cdot \sum_t \beta_t) + \sum_j w_j \cdot (\mathsf{chain}_j + 2r_j)$.

We now argue about feasibility of the dual constraint (9). Consider a job j and time $t \geq r_j$. Since $\alpha_{j,s} \leq w_j$ for all time s, $\sum_{s \leq t} \alpha_{j,s} \leq w_j \cdot t$. Therefore, it suffices to show:

$$\sum_{s \geq t} \alpha_{j,s} + \sum_{s \geq t} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \right) \leq p_j \cdot \beta_t \tag{15}$$

Let $t^\star_j$ be the first time t when the job j appears in the set I_t. This would also be the first time when the algorithm starts processing j because a job that enters I_t does not leave I_t before completion.

▷ Claim 2.9. For any time s lying in the range $[r_j, t^\star_j)$, $\alpha_{j,s} + \gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} = 0$.

Proof. Fix such a time s. Note that $j \notin I_s$. Thus j appears as a vertex on the right side in the bipartite graph H_s, but does not appear on the left side. Let e be in active edge in H_s such that the corresponding path P_e contains j as an internal vertex. Then $\bar{z}^s_e$ gets counted in both $\gamma^{\text{out}}_{s,j}$ and $\gamma^{\text{in}}_{s,j}$. There cannot be such a path P_e which starts with j, because then j will need to be on the left side of the bipartite graph. There could be paths P_e which end with j – these will correspond to active edges e incident with j in the graph H_t (this happens only if j itself is active). Let $\Gamma(j)$ denote the edges incident with j. We have shown that

$$\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} = -\eta^t \cdot \sum_{e \in \Gamma(j) \cap A_s} \tilde{z}^s_e. \tag{16}$$

If j is not active, the RHS is 0, and so is $\alpha_{j,s}$. So we are done. Therefore, assume that j is active. Now, $A(s)$ contains all the edges incident with j, and so, the RHS is same as $-\eta^t \cdot \bar{R}^t_j$. But then, Corollary 2.6 implies that $-\eta^t \cdot \bar{R}^t_j = -w_j$. Since $\alpha_{j,s} = w_j$, we are done again. ◁

Coming back to inequality (15), we can assume that $t \geq t^\star_j$. To see this, suppose $t < t^\star_j$. Then by Claim 2.9 the LHS of this constraint is same as

$$\sum_{s \geq t^\star_j} \alpha_{j,s} + \sum_{s \geq t^\star_j} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \right).$$

Since $\beta_t \geq \beta_{t^\star_j}$ (the set of unfinished jobs can only diminish as time goes on), (15) for time t follows from the corresponding statement for time $t^\star_j$. Therefore, we assume that $t \geq t^\star_j$. We can also assume that $t \leq C_j$, otherwise the LHS of this constraint is 0.

▷ Claim 2.10. Let $s \in [t^\star_j, C_j]$ be such that j is inactive at time s. Then $\alpha_{j,s} + \gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \leq \eta^s \cdot \bar{L}^s_j$.

Proof. We know that $\alpha_{j,s} = 0$. As in the proof of Claim 2.9, we only need to worry about those active edges e in H_s for which P_e either ends at j or begins with j. Since any edge incident with j as a vertex on the right side is inactive, we get (let $\Gamma(j)$ denote the edges incident with j, where we consider j on the left side)

$$\alpha_{j,s} + \gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} = \eta^s \cdot \sum_{e \in \Gamma(j) \cap A(s)} \bar{z}^s_e \leq \eta^s \cdot \bar{L}^s_j,$$

because $\eta^s \geq 0$ and $\bar{L}^s_j = \sum_{e \in \Gamma(j)} \bar{z}^s_e$. ◁

▷ Claim 2.11. Let $s \in [t^\star_j, C_j]$ be such that j is active at time s. Then $\alpha_{j,s} + \gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \leq \eta^s \cdot \bar{L}^s_j$.

Proof. The argument is very similar to the one in the previous claim. Since j is active, $\alpha_{j,s} = w_j$. As before we only need to worry about the active edges e for which P_e either ends or begins with j. Any edge which is incident with j on the right side (note that there will only one such edge – one the one joining j to its copy on the left side of H_t) is active. The following inequality now follows as in the proof of Claim 2.10:

$$\alpha_{j,s} + \gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j} \leq w_j + \eta^s \cdot \bar{L}^s_j - \eta^s \cdot \bar{R}^s_j.$$

The result now follows from Corollary 2.6. ◁

We are now ready to show that (15) holds. The above two claims show that the LHS of (15) is at most $\sum_{s=t}^{C_j} \eta^s \cdot \bar{L}^s_j$. Note that for any such time s, the rate assigned to j is $\bar{L}^j_s$, and so, we perform $2 \cdot \bar{L}^j_s$ amount of processing on j during this time slot. It follows that $\sum_{s=t}^{C_j} \bar{L}^s_j \leq p_j/2$. Now Claim 2.7 shows that $\eta^s \leq w(U_s)/m \leq w(U_t)/m$, and so we get

$$\sum_{s=t}^{C_j} \eta^s \cdot \bar{L}^s_j \leq \frac{p_j \cdot w(U_t)}{2m} = p_j \cdot \beta_t.$$

This shows that (15) is satisfied. We can now prove our algorithm is constant competitive.

▶ **Theorem 2.12.** *The algorithm $\mathcal{B}$ is 10-competitive.*

Proof. We first argue about $\mathcal{A}$. We have shown that the dual variables are feasible to (DLP), and so, Claim 2.8 shows that the total completion time of $\mathcal{A}$ is at most $2opt + \sum_j w_j(\mathsf{chain}_j + 2r_j)$, where opt denotes the optimal off-line objective value. Clearly, $opt \geq \sum_j w_j \cdot r_j$ and $opt \geq \sum_j w_j \cdot \mathsf{chain}_j$. This implies that $\mathcal{A}$ is 5-competitive. While going from $\mathcal{A}$ to $\mathcal{B}$ the completion time of each job doubles. ◀

3 Minimizing Weighted Flow Time

We now consider the setting of minimizing the total weighted flow time, again in the non-clairvoyant setting. The setting is almost the same as in the completion-time case: the major change is that all jobs which depend on each other (i.e., belong to the same DAG in the "collection of DAGs view" have the same release date). In the full version we show that if related jobs can be released over time then no competitive online algorithms are possible.

As before, let J_t denote the jobs which are *waiting* at time t, i.e., which have been released but not yet finished, and let G_t be the union of all the DAGs induced by the jobs in J_t. Again, let I_t denote the *minimal* set of jobs in J_t, i.e., which do not have a predecessor in G_t and hence can be scheduled.

▶ **Theorem 3.1.** *There exists an $O(1/\varepsilon)$-approximation algorithm for non-clairvoyant DAG scheduling to minimize the weighted flow time on m parallel machines, when there is a speedup of $2 + \varepsilon$.*

The rest of this section gives the proof of Theorem 3.1. The algorithm remains unchanged from §2 (we do not need the algorithm $\mathcal{B}$ now): we write the convex program (CP) as before, which assign rates $\bar{L}^t_j$ to each job $j \in I_t$. The analysis again proceeds by writing a linear

programming relaxation, and showing a feasible dual solution. The LP is almost the same as (LP), just the objective is now (with changes in dashed box):

$$\sum_{j,t} w_j \cdot \frac{\boxed{(t - r_j)} \cdot x_{j,t}}{p_j}.$$

Hence, the dual is also almost the same as (DLP): the new dual constraint requires that for every job j and time $t \geq r_j$:

$$\alpha_j + \sum_{s \geq t} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j}\right) \leq \beta_t \cdot p_j + w_j \boxed{(t - r_j)}. \tag{17}$$

3.1 Defining the Dual Variables

In order to set the dual variables, define a total order $\prec$ on the jobs as follows: First arrange the DAGs in order of release dates, breaking ties arbitrarily. Let this order be $D_1, D_2, \ldots, D_\ell$. All jobs in D_i appear before those in D_{i+1} in the order $\prec$. Now for each dag D_i, arrange its jobs in the order they complete processing by our algorithm. Note that this order is consistent with the partial order given by the DAG. This also ensures that at any time t, the set of waiting jobs in any DAG D_i form a suffix in this total order (restricted to D_i).

For a time t and $j \in J_t$, let $\mathbf{I}[j \in J^{\text{act}}_t]$ denote the indicator variable which is 1 exactly if j is active at time t. The dual variables are defined as follows:

- For a job $j \in J_t$, we set $\alpha_j := \sum_{t=r_j}^{C_j} \alpha_{j,t}$, where the quantity $\alpha_{j,t}$ as defined as:

$$\alpha_{j,t} := \frac{1}{m}\Big[w_j \cdot \mathbf{I}[j \in J^{\text{act}}_t] \cdot \Big(\sum_{j' \in J_t : j' \preceq j} \bar{R}^t_{j'}\Big) + \bar{R}^t_j \cdot \Big(\sum_{j' \in J^{\text{act}}_t : j' \prec j} w_{j'}\Big)\Big].$$

- The variable $\beta_t := \frac{w(J_t)}{(1+\varepsilon)m}$. Recall that the machines are allowed $2(1+\varepsilon)$-speedup.
- The definition of the γ variables changes as follows. Let $(j' \to j)$ be an edge in the DAG G_t. Earlier we had considered paths P_e containing $(j' \to j)$ only for the active edges e. But now we include *all* edges. Moreover, we replace the multiplier η^t by η^t_j, where $\eta^t_j := \frac{1}{m} \cdot \Big(\sum_{j' \in J_t : j' \preceq j} w_{j'}\Big)$. In other words, we define

$$\gamma_{t,j' \to j} := \eta^t_j \cdot \sum_{e : e \in H_t, (j' \to j) \in P_e} \bar{z}^t_e.$$

In the following sections, we show that these dual settings are enough to "pay for" the flow time of our solution (i.e., have large objective function value), and also give a feasible lower bound (i.e., are feasible for the dual linear program).

3.2 The Dual Objective Function

We first show that $\sum_j \alpha_j - m \sum_t \beta_t$ is close to the total weighted flow-time of the jobs. The quantity chain_j is defined as before. Notice that chain_j is still a lower bound on the flow-time of job j in the optimal schedule because all jobs of a DAG are simultaneously released. The following claim, whose result is deferred to the full version, shows that the dual objective value is close to the weighted flow time of the algorithm.

▷ Claim 3.2. The total weighted flow-time is at most $\frac{2}{\varepsilon}\Big(\sum_j \alpha_j - m \sum_t \beta_t + \sum_j w_j \cdot \mathsf{chain}_j\Big)$.

3.3 Checking Dual Feasibility

Now we need to check the feasibility of the dual constraint (17). In fact, we will show the following weaker version of that constraint:

$$\alpha_j + \left\lceil \frac{2}{} \right\rceil \sum_{s \geq t} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j}\right) \leq \beta_t \cdot p_j + \left\lceil \frac{2}{} \right\rceil w_j(t - r_j). \tag{18}$$

This suffices to within another factor of 2: indeed, scaling down the α and β variables by another factor of 2 then gives dual feasibility, and loses only another factor of 2 in the objective function. We begin by bounding $\alpha_{j,s}$ in two different ways.

▶ **Lemma 3.3.** *For any time $s \geq r_j$, we have $\alpha_{j,s} \leq 2w_j$.*

Proof. Consider the second term in the definition of $\alpha_{j,s}$. This term contains $\sum_{j' \in J^{\text{act}}_s : j' \prec j} w_{j'}$. By Corollary 2.6, for any $j' \in J^{\text{act}}_s$ we have $w_{j'} = \bar{R}^s_{j'} \cdot \eta^s$. Therefore,

$$\sum_{j' \in J^{\text{act}}_s : j' \prec j} w_{j'} \quad \leq \quad \eta^s \cdot \sum_{j' \in J^{\text{act}}_s : j' \prec j} \bar{R}^s_{j'} \quad \leq \quad \eta^s \cdot \sum_{j' \in J_s} \bar{R}^s_{j'}.$$

Now we can bound $\alpha_{j,s}$ by dropping the indicator on the first term to get

$$\frac{1}{m} \cdot \Big[\Big(w_j \cdot \sum_{j' \in J_s : j' \preceq j} \bar{R}^s_{j'} \Big) + \bar{R}^s_j \cdot \Big(\eta^s \cdot \sum_{j' \in J^{\text{act}}_s : j' \prec j} \bar{R}^s_{j'} \Big) \Big] \;\leq\; \frac{1}{m} w_j \Big[\sum_{j' \in J_s} \bar{R}^s_{j'} + \sum_{j' \in J_s} \bar{R}^s_{j'} \Big],$$

the last inequality using Claim 2.3. Simplifying, $\alpha_{j,s} \leq \frac{2}{m} \cdot w_j \cdot \sum_{j'' \in I_s} \bar{L}^s_{j''} = 2w_j$. ◀

Here is a slightly different upper bound on $\alpha_{j,s}$.

▶ **Lemma 3.4.** *For any time $s \geq r_j$, we have $\alpha_{j,s} \leq 2\eta^s_j \cdot \bar{R}^s_j$.*

Proof. The second term in the definition of $\alpha_{j,s}$ is at most $\eta^s_j \cdot \bar{R}^s_j$, directly using the definition of η^s_j. For the first term, assume j is active at time s, otherwise this term is 0. Now Corollary 2.6 shows that $w_j = \eta^s \cdot \bar{R}^s_j$, so the first term can be bounded as follows:

$$\frac{w_j}{m} \cdot \sum_{j' \in J_s : j' \preceq j} \bar{R}^s_{j'} \quad = \quad \frac{\bar{R}^s_j \cdot \eta^s}{m} \cdot \sum_{j' \in J_s : j' \preceq j} \bar{R}^s_{j'} \quad \overset{\text{(Claim 2.3)}}{\leq} \quad \frac{\bar{R}^s_j}{m} \cdot \sum_{j' \in J_s : j' \preceq j} w_{j'} \quad = \quad \bar{R}^s_j \cdot \eta^s_j,$$

which completes the proof. ◀

To prove (18), we write $\alpha_j = \sum_{s=r_j}^{t-1} \alpha_{j,s} + \sum_{s \geq t} \alpha_{j,s}$, and use Lemma 3.3 to cancel the first summation with the term $2w_j(t - r_j)$. Hence, it remains to prove

$$\sum_{s \geq t} \alpha_{j,s} + 2 \sum_{s \geq t} \left(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j}\right) \leq \beta_t \cdot p_j. \tag{19}$$

Let $t^\star_j$ be the time at which the algorithm starts processing j. We first argue why we can ignore times $s < t^\star_j$ on the LHS of (19).

▷ Claim 3.5. Let s be a time satisfying $r_j \leq s < t^\star_j$. Then $\alpha_{j,s} + 2(\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j}) \leq 0$.

Proof. While computing $\gamma^{\text{out}}_{s,j} - \gamma^{\text{in}}_{s,j}$, we only need to consider paths P_e for edges e in H_s which have j as end-point. Since j does not appear on the left side of H_s, this quantity is equal to $-\eta^s_j \cdot \bar{R}^s_j$. The result now follows from Lemma 3.4. ◁

So using Claim 3.5 in (19), it suffices to show

$$\sum_{s \geq \max\{t, t_j^\star\}} \alpha_{j,s} + 2 \sum_{s \geq \max\{t, t_j^\star\}} \left(\gamma_{s,j}^{\text{out}} - \gamma_{s,j}^{\text{in}}\right) \leq \beta_t \cdot p_j. \tag{20}$$

Note that we still have β_t on the right hand side, even though the summation on the left is over times $s \geq \max\{t, t_j^\star\}$. The proof of the following claim is deferred to the full version.

▷ Claim 3.6. Let s be a time satisfying $s \geq \max\{t, t_j^\star\}$. Then $\alpha_{j,s} + 2(\gamma_{s,j}^{\text{out}} - \gamma_{s,j}^{\text{in}}) \leq 2(1+\varepsilon)\beta_t \cdot \bar{L}_j^s$.

Hence, the left-hand side of (20) is at most $2(1+\varepsilon)\beta_t \cdot \sum_{s \geq \max\{t, t_j^\star\}} \bar{L}_j^s$. However, since job j is assigned a rate of $\bar{L}_j^s$ and the machines run at speed $2(1+\varepsilon)$, we get that this expression is at most $p_j \cdot \beta_t$, which is the right-hand side of (20). This proves the feasibility of the dual constraint (18).

Proof of Theorem 3.1. In the preceding §3.3 we proved that the variables $\alpha_j/2$, $\beta_t/2$ and $\gamma_{t,j' \to j}$ satisfy the dual constraint for the flow-time relaxation. Since $\sum_j (\alpha_j/2) - m \sum_t (\beta_t/2)$ is a feasible dual, it gives a lower bound on the cost of the optimal solution. Moreover, $\sum_j w_j \cdot \mathsf{chain}_j$ is another lower bound on the cost of the optimal schedule. Now using the bound on the weighted flow-time of our schedule given by Claim 3.2, this shows that we have an $O(1/\varepsilon)$-approximation with $2(1+\varepsilon)$-speedup. ◀

In the full version we show how to use a slightly different scheduling policy that prioritizes the last arriving jobs to reduce the speedup to $(1+\varepsilon)$.

Abstract

For any relation $f \subseteq \{0,1\}^n \times S$ and any partial Boolean function $g : \{0,1\}^m \to \{0,1,*\}$, we show that

$$\mathsf{R}_{1/3}(f \circ g^n) \in \Omega(\mathsf{R}_{4/9}(f) \cdot \sqrt{\mathsf{R}_{1/3}(g)}),$$

where $\mathsf{R}_\epsilon(\cdot)$ stands for the *bounded-error randomized query complexity* with error at most ϵ, and $f \circ g^n \subseteq (\{0,1\}^m)^n \times S$ denotes the composition of f with n instances of g.

The new composition theorem is *optimal*, at least, for the general case of relational problems: A relation f_0 and a partial Boolean function g_0 are constructed, such that $\mathsf{R}_{4/9}(f_0) \in \Theta\left(\sqrt{n}\right)$, $\mathsf{R}_{1/3}(g_0) \in \Theta(n)$ and $\mathsf{R}_{1/3}(f_0 \circ g_0^n) \in \Theta(n)$.

The theorem is proved via introducing a new complexity measure, *max-conflict complexity*, denoted by $\bar{\chi}(\cdot)$. Its investigation shows that $\bar{\chi}(g) \in \Omega(\sqrt{\mathsf{R}_{1/3}(g)})$ for any partial Boolean function g and $\mathsf{R}_{1/3}(f \circ g^n) \in \Omega(\mathsf{R}_{4/9}(f) \cdot \bar{\chi}(g))$ for any relation f, which readily implies the composition statement. It is further shown that $\bar{\chi}(g)$ is always at least as large as the *sabotage complexity* of g.

We thank the anonymous reviewers for their helpful comments.

1 Introduction

For a relational problem $f \subseteq \{0,1\}^n \times S$ and a partial Boolean function $g : \{0,1\}^m \to \{0,1,*\}$, their *composition* $f \circ g^n \subseteq (\{0,1\}^m)^n \times S$ is defined as

$$f \circ g^n(x) = \begin{cases} S & \text{if } * \in \{g(x_i) | i \in [n]\}; \\ f(g(x_1), \ldots, g(x_n)) & \text{otherwise.} \end{cases}$$

Relating the complexity of $f \circ g^n$ to the complexities of f and g is a natural research problem.

A *query algorithm* for computing h is allowed to query *individual bits* of the input x, with the goal of outputting $h(x)$ (or an element of $h(x)$ if the problem is a relational one). The *query complexity of an algorithm* is the maximum possible number of queries that it makes.

Query algorithms can be *deterministic*, *randomized* or *quantum*, where the latter two classes allow for (bounded) errors. The corresponding *query complexity of a function* – denoted, respectively, by $\mathsf{D}(h)$, $\mathsf{R}(h)$ or $\mathsf{Q}(h)$ – is the minimal query complexity of an algorithm that belongs to the corresponding class and computes h with error $1/3$[1]. Section 2 contains formal definitions of various query complexity measures.

It is easy to see that $\mathsf{D}(f \circ g^n) \leq \mathsf{D}(f) \cdot \mathsf{D}(g)$. [2] For the cases of randomized and quantum query complexity the argument is slightly more subtle, though very similar conceptually; in particular, both $\mathsf{R}(f \circ g^n) \in O(\mathsf{R}(f) \cdot \mathsf{R}(g) \cdot \log n)$ and $\mathsf{Q}(f \circ g^n) \in O(\mathsf{Q}(f) \cdot \mathsf{Q}(g))$ hold. [3]

Showing a strong *lower bounds* on the query complexity of $f \circ g^n$ (preferably, matching the trivial upper bound) is often more interesting, the corresponding statements are sometimes called *composition theorems*. Such results can lead to further theoretical developments (e.g., separating complexity measures, as well as different classes in structural complexity).

For deterministic query complexity it has been shown [10, 13] that

$$\mathsf{D}(f \circ g^n) = \mathsf{D}(f) \cdot \mathsf{D}(g),$$

which means that *the trivial query algorithm for $f \circ g^n$ described above is optimal*. Similarly, for bounded-error quantum query complexity it has been shown [8, 11] that

$$\mathsf{Q}(f \circ g^n) \in \Theta(\mathsf{Q}(f) \cdot \mathsf{Q}(g)).$$

Prior to this work, the randomized query complexity of composition has remained an open problem. We partially solve it for the most general case of composition: namely, letting f be a *relational problem* and g be a *partial Boolean function*. [4]

---

[1] In general, $\mathsf{R}_\epsilon(h)$ (resp. $\mathsf{Q}_\epsilon(h)$) stands for the randomized (resp. quantum) query complexity with respect to error ϵ.

[2] To compute $f \circ g^n$, one can simulate an optimal query algorithm for f, serving every query of this algorithm by running an optimal query algorithm for g.

[3] The multiplicative factor of $\log n$ in the case of $\mathsf{R}(h)$ is due to the need to reduce the error in computing each instance of g to $O(1/n)$; in the quantum case this can be handled in a more elegant, "lossless" way.

[4] Letting g be a relation seems to result in a rather awkward definition of $f \circ g^n$. Letting g be a non-Boolean promise function doesn't seem to lead to any interesting development (the original version of this work [5] has demonstrated the same composition result for an arbitrary partial g; switching to the Boolean case in the current version has allowed somewhat clearer presentation).

▶ **Theorem 1.** *For any relation* $f \subseteq \{0,1\}^n \times S$ *and any partial Boolean function* $g : \{0,1\}^m \to \{0,1,*\}$,

$$\mathsf{R}_{1/3}(f \circ g^n) \in \Omega\Big(\mathsf{R}_{4/9}(f) \cdot \sqrt{\mathsf{R}_{1/3}(g)}\Big).$$

Note that the above lower bound *does not match the trivial upper bound*, so its optimality has to be addressed separately. That is done via constructing an example where the above bound is tight: in other words, while some *incomparable* lower bounds on $\mathsf{R}_{1/3}(f \circ g^n)$ are conceivable, the statement of Theorem 1 is *a strongest possible in general*. [5]

▶ **Theorem 2.** *There exists a relation* $f_0 \subseteq \{0,1\}^n \times \{0,1\}^n$ *and a partial Boolean function* $g_0 : \{0,1\}^n \to \{0,1,*\}$, *such that*

$$\mathsf{R}_{4/9}(f_0) \in \Theta\big(\sqrt{n}\big),\ \mathsf{R}_{1/3}(g_0) \in \Theta(n) \text{ and } \mathsf{R}_{1/3}(f_0 \circ g_0^n) \in \Theta(n).$$

Our approach

We introduce a new complexity measure of Boolean functions, the *max-conflict complexity*, denoted by $\bar{\chi}(g)$. We show that $\bar{\chi}(g)$ is a quadratically tight lower bound on randomized query complexity of a (partial) function g.

▶ **Theorem 3.** *For any partial Boolean function* $g : \{0,1\}^m \to \{0,1,*\}$,

$$\bar{\chi}(g) \in \Omega\Big(\sqrt{\mathsf{R}_{1/3}(g)}\Big).$$

The main technical ingredient of this work is the following composition statement for the max-conflict complexity.

▶ **Theorem 4.** *For any relation* $f \subseteq \{0,1\}^n \times S$ *and any partial Boolean function* $g : \{0,1\}^m \to \{0,1,*\}$,

$$\mathsf{R}_{1/3}(f \circ g^n) \in \Omega\big(\mathsf{R}_{4/9}(f) \cdot \bar{\chi}(g)\big).$$

Combining Theorem 3 with Theorem 4 implies Theorem 1.

Previous work

In the special case of f being a partial function and g being a total one, a significant progress has been made by Ben-David and Kothari [4], who showed recently that

$$R_{1/3}(f \circ g^n) \in \Omega\left(R_{1/3}(f) \cdot \sqrt{\frac{R_0(g)}{\log R_0(g)}}\right). \tag{1}$$

To prove the above statement, the authors have introduced and investigated a new complexity measure of Boolean functions, *sabotage complexity*, denoted by $\mathrm{RS}(g)$. This notion has a very natural definition and is of independent interest. In this work we show that max-conflict complexity is always lower-bounded by the sabotage complexity of the same function.

▶ **Theorem 5.** *For any partial Boolean function* $g : \{0,1\}^m \to \{0,1,*\}$,

$$\bar{\chi}(g) \geq \mathrm{RS}(g).$$

Theorem 5 along with Theorem 4 imply (1).

[5] The following construction also witnesses the possibility of $\mathsf{R}(f \circ g^n) \in O(\mathsf{R}(g))$ when $\mathsf{R}(f) \in \Omega\big(\sqrt{n}\big)$ – in other words, *it is not, in general, true, that composition with a "hard" relation makes a Boolean function harder for randomized query algorithms.*

1.1 Proof Technique

At a high level, the proof of Theorem 4 follows the structure of the proof by Anshu et al. [2] and Ben-David and Kothari [4]. We show that for every probability distribution η over the input space $\{0,1\}^n$ of f, there exists a deterministic query algorithm $\mathcal{A}$ that makes $O(\mathsf{R}_{1/3}(f \circ g^n)/\sqrt{\mathsf{R}_{1/3}(g)})$ queries in the worst case, and computes f with high probability, $\Pr_{z\sim\eta}[(z, \mathcal{A}(z)) \in f] \geq 5/9$. By the minimax principle (Fact 4) this implies Theorem 4.

We do this by using a query algorithm for $f \circ g^n$ to construct a query algorithm for f. We define a sampling procedure that for any $z \in \{0,1\}^n$ samples $x = (x_1, \ldots, x_n)$ such that $(z, s) \in f$ if and only if $(x, s) \in f \circ g^n$. This procedure is defined in terms of $\mathcal{Q}$, which is a probability distribution over pairs of distributions (μ_0, μ_1), where μ_0 is supported on $g^{-1}(0)$ and μ_1 is supported on $g^{-1}(1)$. We define a distribution γ_η over $(\{0,1\}^m)^n$ in terms of this sampling process as follows:

1. Sample $z = (z_1, \ldots, z_n)$ from $\{0,1\}^n$ according to η.
2. Independently sample $(\mu_0^{(i)}, \mu_1^{(i)})$ from $\mathcal{Q}$ for $i = 1, \ldots, n$.
3. Sample $x_i = (x_i^{(1)}, \ldots, x_i^{(m)})$ according to $\mu_{z_i}^{(i)}$ for $i = 1, \ldots, n$. Return $x = (x_1, \ldots, x_n)$.

Notice that steps (1) and (2) are independent and the order in which they are performed does not matter. For future reference, for a fixed z let $\gamma_z(\mathcal{Q})$ be the probability distribution defined by the last two steps.

Now γ_η is simply a probability distribution over $(\{0,1\}^m)^n$. Thus by the minimax principle (Fact 4 below), there is a deterministic query algorithm $\mathcal{A}'$ of worst-case complexity at most $\mathsf{R}_{1/3}(f \circ g^n)$ such that $\Pr_{x\sim\gamma_\eta}[(x, \mathcal{A}'(x)) \in f \circ g^n] \geq 2/3$. We first use $\mathcal{A}'$ to construct a randomized query algorithm T for f with bounded *expected* query complexity and error at most $1/3$. The final algorithm $\mathcal{A}$ will be a truncation of T which has bounded worst-case complexity and error at most $4/9$.

On input z, the algorithm T seeks to sample a string x from $\gamma_z(\mathcal{Q})$, and run $\mathcal{A}'$ on x. Put another way, $\gamma_z(\mathcal{Q})$ induces a probability distribution over the leaves of $\mathcal{A}'$, and the goal of T is to sample a leaf of $\mathcal{A}'$ according to this distribution. Since for each $s \in S$, $(x, s) \in f \circ g^n$ if and only if $(z, s) \in f$, and $\Pr_{x\sim\gamma_\eta}[(x, \mathcal{A}'(x)) \in f \circ g^n] \geq 2/3$, we have that $\Pr_{z\sim\eta}[(z, T(z)) \in f] \geq 2/3$. Thus T meets the accuracy requirement.

The catch, of course, is to specify how T samples from $\gamma_z(\mathcal{Q})$ *without making too many queries to* z. To sample x_i from $\mu_{z_i}^{(i)}$ seems to require knowledge of z_i, and thus T would have to query all of z.

To bypass this problem, we remember that $\mathcal{A}'$, being an efficient algorithm, will query only a few bits of x. This allows us to sample x bit by bit as and when they are queried by $\mathcal{A}'$. To see this more clearly, consider a run of T where the pairs of distributions $(\mu_0^{(1)}, \mu_1^{(1)}), \ldots, (\mu_0^{(n)}, \mu_1^{(n)})$ were chosen in step (2) of the sampling procedure. Suppose that T is trying to simulate $\mathcal{A}'$ at a vertex v where $x_i^{(j)}$ is queried. To respond to this query, T will sample $x_i^{(j)}$ from its marginal distribution according to $\mu_{z_i}^{(i)}$ conditioned on the event $x \in v$. Let the following be the marginal distributions of $x_i^{(j)}$ for the two possible values of z_i.

	$\Pr_{x_i\sim\mu_{z_i}^{(i)}}[x_i^{(j)} = 0 \mid x \in v]$	$\Pr_{x_i\sim\mu_{z_i}^{(i)}}[x_i^{(j)} = 1 \mid x \in v]$
$z_i = 0$	p_0	$1 - p_0$
$z_i = 1$	p_1	$1 - p_1$

Without loss of generality, assume that $p_0 \leq p_1$. T answers the query by the procedure BITSAMPLER given in Algorithm 1. Note that the bit returned by BITSAMPLER has the desired distribution. The step in which BITSAMPLER returns the bit depends on the value

Algorithm 1: BITSAMPLER (suppose $p_0 \leq p_1$).

```
1  Sample r ∼ [0,1] uniformly at random.
2  if r < p_0 then
3      return 0.
4
5  else if r > p_1 then
6      return 1.
7
8  else
9      query z_i.
10     if r ≤ p_{z_i} then
11         return 0.
12     else
13         return 1.
```

of r sampled in step 1. In particular, z_i is queried if and only if $r \in [p_0, p_1]$, and the bit is returned in step 11 or 13. Such a query to z_i contributes to the query complexity of T. Thus the probability that T makes a query when the underlying simulation of $\mathcal{A}'$ is at vertex v is $(p_1 - p_0)$. We refer to this quantity as $\Delta(v)$. It plays an important role in our analysis (in particular, in the proof of Theorem 6 that can be found in [6]).

Our sampling procedure and the tools we use to bound its cost is reminiscent of work of Barak et al. [3] in communication complexity. They look at a communication analog of our setting where two players are trying to sample a leaf in a communication protocol while communicating as little as possible.

1.1.1 Conflict complexity and max-conflict complexity

Bounding the query complexity of T naturally suggests the quantities that we define in this work: the conflict complexity $\chi(g)$ and the max-conflict complexity $\bar{\chi}(g)$ of a partial Boolean function g. A formal definition can be found in Section 4; here we give the high-level idea and motivation behind these quantities.

Forget about T for a moment and just consider a deterministic query algorithm $\mathcal{B}$ computing the partial function $g \subseteq \{0,1\}^m \times \{0,1\}$. Let μ_0, μ_1 be distributions with support on $g^{-1}(0), g^{-1}(1)$, respectively. For each vertex $v \in \mathcal{B}$ let $p_0(v)$ (respectively $p_1(v)$) be the probability that the answer to the query at v is 0 on input $x \sim \mu_0$ (respectively $x \sim \mu_1$), conditioned on x reaching v. Now we can imagine a process $\mathcal{P}(\mathcal{B}, \mu_0, \mu_1)$ that runs BITSAMPLER on the tree $\mathcal{B}$: $\mathcal{P}(\mathcal{B}, \mu_0, \mu_1)$ begins at the root, and at a vertex v in $\mathcal{B}$ it uniformly chooses a random real number $r \in [0,1]$. If $r < \min\{p_0(v), p_1(v)\}$ then the query is "answered" 0 and it moves to the left child. If $r > \max\{p_0(v), p_1(v)\}$ then the query is "answered" 1 and it moves to the right child. If $r \in [\min\{p_0(v), p_1(v)\}, \max\{p_0(v), p_1(v)\}]$ then the process halts. The conflict complexity $\chi(\mathcal{B}, (\mu_0, \mu_1))$ is the expected number of vertices this process visits before halting. The conflict complexity of g is defined to be

$$\chi(g) = \max_{(\mu_0,\mu_1)} \min_{T} \chi(T, (\mu_0, \mu_1)) \ ,$$

where the minimum is taken over trees T that compute g. For *max-conflict complexity* we enlarge the set over which we maximize. Let $\mathcal{Q}$ be a distribution over pairs of distributions (μ_0, μ_1), where $\mathrm{supp}(\mu_0) \subseteq g^{-1}(0), \mathrm{supp}(\mu_1) \subseteq g^{-1}(1)$ for each pair (μ_0, μ_1) in the support of $\mathcal{Q}$. Let $\chi(\mathcal{B}, \mathcal{Q}) = \mathsf{E}_{(\mu_0,\mu_1)\sim\mathcal{Q}}\,[\chi(\mathcal{B}, (\mu_0, \mu_1))]$. The max-conflict complexity $\bar{\chi}(g)$ is defined as

$$\bar{\chi}(g) = \max_{\mathcal{Q}} \min_{T} \chi(T, \mathcal{Q}) \ ,$$

where the minimum is taken over trees T that compute g. Clearly, the max-conflict complexity is at least as large as the conflict complexity.

To motivate the max-conflict complexity, note that the query complexity of T is the number of times step 9 in BITSAMPLER is executed, i.e. when the random number $r \in [p_0, p_1]$. In the definition of T we will choose $\mathcal{Q}$ to achieve the optimal value in the definition of $\bar{\chi}(g)$. Then intuitively one expects that for each i, T queries z_i only after $\mathcal{A}'$ makes about $\bar{\chi}(g)$ queries into x_i. By means of a direct sum theorem for max-conflict complexity we make this intuition rigorous and prove that the expected query complexity of T is at most $\mathsf{R}_{1/3}(f \circ g^n)/\bar{\chi}(g)$. We refer the reader to [6] for a formal proof.

1.1.2 $\bar{\chi}(g)$ and $\mathsf{R}(g)$

Note that applying Theorem 4 with the outer function $f(z) = z_1$ shows that $\mathsf{R}_{1/3}(g) \in \Omega(\bar{\chi}(g))$. We complete the proof of Theorem 1 by showing that max-conflict complexity is a quadratically tight lower bound on randomized query complexity, even for partial functions g. In fact, we show the stronger result that this is true even for the conflict complexity.

▶ **Theorem 6.** *For any partial Boolean function $g \subseteq \{0,1\}^m \times \{0,1\}$,*

$$\chi(g) \in \Omega\Big(\sqrt{\mathsf{R}_{1/3}(g)}\Big).$$

A proof of Theorem 6 can be found in [6]. At a high level, our proof is reminiscent of the result of [3] on compressing communication protocols in that both look at a random sampling process to navigate a tree, and relate the probability of this process needing to query or communicate at a node to the amount of information that is learned at the node.

To prove $\mathsf{R}(g) \in O(\chi(g)^2)$, we again resort to the minimax principle; we show that for each probability distribution μ over the valid inputs to g, there is an accurate and efficient distributional query algorithm for g. For $b \in \{0,1\}$, let μ_b be the distribution obtained by conditioning μ on the event $g(x) = b$. By the definition of $\chi(g)$, there is a query algorithm $\mathcal{B}$ such that the following is true: if its queries are served by BITSAMPLER, step 9 is executed within expected $\chi(\mathcal{B}, \mu_0, \mu_1) \leq \chi(g)$ queries. Note that at a vertex v which queries i, the probability that step 9 is executed is $\Delta(v) = |\Pr_{\mu_0}[x_i = 0 \mid x \text{ at } v] - \Pr_{\mu_1}[x_i = 0 \mid x \text{ at } v]|$. This roughly implies that for a typical vertex v of $\mathcal{B}$, $\Delta(v)$ is at least about $\frac{1}{\chi(g)}$. By a technical claim this implies that the query outcome at v carries about $\frac{1}{\chi(g)^2}$ bits of information about $g(x)$. Using the *chain rule of mutual information*, we can show that the mutual information between $g(x)$ and the outcomes of first $O(\chi(g))^2$ queries by $\mathcal{B}$ is $\Omega(1)$. This enables us to conclude that we can infer the value of $g(x)$ with success probability $1/2 + \Omega(1)$ from the transcript of $\mathcal{B}$ restricted to the first $O(\chi(g)^2)$ queries. The distributional algorithm of g for μ is simply the algorithm $\mathcal{B}$ terminated after $O(\chi(g)^2)$ queries.

1.1.3 $\bar{\chi}(g)$ and $\mathrm{RS}(g)$

To see why $\bar{\chi}(g) \geq \mathrm{RS}(g)$, we first give an alternative characterization of $\mathrm{RS}(g)$. For a deterministic tree T computing g and strings x, y such that $g(x) \neq g(y)$, let $\mathrm{sep}_T(x, y)$ be the depth of the node v in T such that x and y both reach v yet $x_{q(v)} \neq y_{q(v)}$, where $q(v)$

is the index queried at v. Let $\mathcal{T}$ be a zero-error randomized protocol for g, i.e. $\mathcal{T}$ is a probability distribution supported on deterministic trees that compute g. Then we have (for a proof see [6])

$$\mathrm{RS}(g) = \min_{\mathcal{T}} \max_{\substack{x,y \\ g(x)\neq g(y)}} \mathsf{E}_{T\sim\mathcal{T}}[\mathrm{sep}_T(x,y)] \ .$$

By von Neumann's minimax theorem [14], this is equal to

$$\mathrm{RS}(g) = \max_{p} \min_{T} \mathsf{E}_{(x,y)\sim p}[\mathrm{sep}_T(x,y)] \ .$$

Here, the max is taken over distributions p on pairs (x,y) where $g(x)\neq g(y)$, and the min is taken over deterministic trees T computing g.

We have seen that the definition of $\bar{\chi}(g)$ is

$$\bar{\chi}(g) = \max_{\mathcal{Q}} \min_{T} \mathsf{E}_{(\mu_0,\mu_1)\sim\mathcal{Q}} \ [\chi(T,(\mu_0,\mu_1))] \ ,$$

where $\mathcal{Q}$ is a distribution over pairs (μ_0,μ_1) and T is a deterministic tree computing g. When (μ_0,μ_1) are taken to be singleton distributions, i.e. μ_0 puts all its weight on a single x with $g(x)=0$, and μ_1 puts all its weight on a single y with $g(y)=1$, it can be shown that $\chi(T,(\mu_0,\mu_1)) = \mathrm{sep}_T(x,y)$ (see [6] for details). Thus $\bar{\chi}(g)$ is at least as large as the sabotage complexity of g as $\mathcal{Q}$ is allowed to be a distribution over general (μ_0,μ_1), not just singleton distributions.

2 Preliminaries

Let $g \subseteq \{0,1\}^m \times \{0,1\}$ be a partial Boolean function. For $b\in\{0,1\}$, $g^{-1}(b)$ is defined to be the set of strings x in $\{0,1\}^m$ for which $(x,b)\in g$ and $(x,\bar{b})\notin g$. We refer to $g^{-1}(0)\cup g^{-1}(1)$ as the set of valid inputs to g. We assume that for all strings $y\notin g^{-1}(0)\cup g^{-1}(1)$, both $(y,0)$ and $(y,1)$ are in g. For a string $x\in g^{-1}(0)\cup g^{-1}(1)$, $g(x)$ refers to the unique bit b such that $(x,b)\in g$. All the probability distributions μ over the domain of a partial Boolean function g in this paper are assumed to have support on $g^{-1}(0)\cup g^{-1}(1)$. Thus $g(x)$ is well-defined for any x in the support of μ.

Let S be any set. Let $h\subseteq\{0,1\}^k\times S$ be any relation. Consider query algorithms $\mathcal{A}$ that accept a string $x\in\{0,1\}^k$ as input, query various bits of x, and produce an element of S as output. We denote the output by $\mathcal{A}(x)$.

▶ **Definition 1** (Deterministic query complexity). *A deterministic query algorithm $\mathcal{A}$ is said to compute h if $(x,\mathcal{A}(x))\in h$ for all $x\in\{0,1\}^k$. The deterministic query complexity $\mathsf{D}(h)$ of h is the minimum over all deterministic query algorithms $\mathcal{A}$ computing h of the maximum number of queries made by $\mathcal{A}$ over $x\in\{0,1\}^k$.*

▶ **Definition 2** (Bounded-error randomized query complexity). *Let $\epsilon\in[0,1/2)$. We say that a randomized query algorithm $\mathcal{A}$ computes h with error ϵ if $\Pr[(x,\mathcal{A}(x))\in h]\geq 1-\epsilon$ for all $x\in\{0,1\}^k$. The bounded-error randomized query complexity $\mathsf{R}_\epsilon(h)$ of h is the minimum over all randomized query algorithms $\mathcal{A}$ computing h with error ϵ of the maximum number of queries made by $\mathcal{A}$ over all $x\in\{0,1\}^k$ and the internal randomness of $\mathcal{A}$.*

▶ **Definition 3** (Distributional query complexity). *Let μ a distribution on the input space $\{0,1\}^k$ of h, and $\epsilon\in[0,1/2)$. We say that a deterministic query algorithm $\mathcal{A}$ computes h with distributional error ϵ on μ if $\Pr_{x\sim\mu}[(x,\mathcal{A}(x))\in h]\geq 1-\epsilon$. The distributional query complexity $\mathsf{D}^\mu_\epsilon(h)$ of h is the minimum over deterministic algorithms $\mathcal{A}$ computing h with distributional error ϵ on μ of the maximum over $x\in\{0,1\}^k$ of the number of queries made by $\mathcal{A}$ on x.*

We will use the minimax principle in our proofs to go between distributional and randomized query complexity.

▶ **Fact 4** (Minimax principle). *For any integer $k > 0$, set S, and relation $h \subseteq \{0,1\}^k \times \mathcal{S}$,*

$$\mathsf{R}_\epsilon(h) = \max_\mu \mathsf{D}^\mu_\epsilon(h).$$

A proof of Fact 4 can be found in [6].

Let μ be a probability distribution over $\{0,1\}^k$. We use $\mathrm{supp}(\mu)$ to denote the support of μ. By $x \sim \mu$ we mean that x is a random string drawn from μ. Let $C \subseteq \{0,1\}^k$ be an arbitrary set such that $\Pr_{x\sim\mu}[x \in C] = \sum_{y\in C} \mu(y) > 0$. Then $\mu \mid C$ is defined to be the probability distribution obtained by conditioning μ on the event that the sampled string belongs to C, i.e.,

$$(\mu \mid C)(x) = \begin{cases} 0 & \text{if } x \notin C \\ \frac{\mu(x)}{\sum_{y\in C}\mu(y)} & \text{if } x \in C \end{cases}$$

For a distribution $\mathcal{Q}$ over pairs of distributions (μ_0, μ_1), let $\mathrm{supp}_0(\mathcal{Q}) = \cup\{\mathrm{supp}(\mu_0) : \exists \mu_1, (\mu_0,\mu_1) \in \mathrm{supp}(\mathcal{Q})\}$. Similarly let $\mathrm{supp}_1(\mathcal{Q}) = \cup\{\mathrm{supp}(\mu_1) : \exists \mu_0, (\mu_0,\mu_1) \in \mathrm{supp}(\mathcal{Q})\}$. We say that $\mathcal{Q}$ is *consistent* if $\mathrm{supp}_0(\mathcal{Q})$ and $\mathrm{supp}_1(\mathcal{Q})$ are disjoint sets. We say that $\mathcal{Q}$ is consistent with a (partial) function g if $\mathrm{supp}_0(\mathcal{Q}) \subseteq g^{-1}(0)$ and $\mathrm{supp}_1(\mathcal{Q}) \subseteq g^{-1}(1)$.

▶ **Definition 5** (Subcube, co-dimension). *A subset $\mathsf{C} \subseteq \{0,1\}^m$ is called a subcube if there exists a set $S \subseteq \{1,\ldots,m\}$ of indices and an* assignment function *$\sigma : S \to \{0,1\}$ such that $\mathsf{C} = \{x \in \{0,1\}^m : \forall i \in S, x_i = \sigma(i)\}$. The co-dimension $\mathsf{codim}(C)$ of C is defined to be $|S|$.*

Now we define the composition of a relation and a partial Boolean function.

▶ **Definition 6** (Composition of a relation and a partial Boolean function). *Let $f \subseteq \{0,1\}^n \times S$ and $g \subseteq \{0,1\}^m \times \{0,1\}$ be a relation and a partial Boolean function respectively. The composed relation $f \circ g^n \subseteq (\{0,1\}^m)^n \times S$ is defined as follows: For $x = (x^{(1)},\ldots,x^{(n)}) \in (\{0,1\}^m)^n$ and $s \in S$, $(x,s) \in f \circ g^n$ if and only if one of the following holds:*

- *$x_i \notin g^{-1}(0) \cup g^{-1}(1)$ for some $i \in \{1,\ldots,n\}$.*
- *$x_i \in g^{-1}(0) \cup g^{-1}(1)$ for each $i \in \{1,\ldots,n\}$ and $((g(x_1),\ldots,g(x_n)), s) \in f$.*

We will often view a deterministic query algorithm as a binary decision tree. In each vertex v of the tree, an input variable is queried. Depending on the outcome of the query, the computation goes to a child of v. The child of v corresponding to outcome b of the query is denoted by v_b.

The set of inputs that lead the computation of a decision tree to a certain vertex is a subcube. We will use the same symbol (e.g. v) to refer to a vertex as well as the subcube associated with it.

The execution of a decision tree terminates at some leaf. If the tree computes some relation $h \subseteq \{0,1\}^k \times S$, the leaves are labelled by elements of S, and the tree outputs the label of the leaf at which it terminates. We will also consider decision tree with unlabelled leaves (see Section 4).

3 Conflict Complexity

In this section, we define the conflict complexity and max-conflict complexity of a partial Boolean function g on m bits. For this, we will need to introduce some notation related to a deterministic decision tree T. For a node $v \in T$, let $\pi(v) = \perp$ if v is the root and $\pi(v)$ be the parent of v otherwise. Let $q(v)$ be the index that is queried at v in T, and let $d_T(v)$ be the number of vertices on the unique path in T from the root to v. The depth of the root is 1.

Now fix a partial function $g \subseteq \{0,1\}^m \times \{0,1\}$ and probability distributions μ_0, μ_1 over $g^{-1}(0), g^{-1}(1)$, respectively. Let T be a tree that computes g. For a node $v \in T$ let $p_0(v) = \Pr_{\mu_0}[x_{q(v)} = 0 | x \text{ at } v]$ and $p_1(v) = \Pr_{\mu_1}[x_{q(v)} = 0 | x \text{ at } v]$, and

$$R(v) = \begin{cases} 1 & \text{if } v \text{ is the root} \\ R(\pi(v)) \cdot \min\{\Pr_{\mu_0}[x \to v | x \text{ at } \pi(v)], \Pr_{\mu_1}[x \to v | x \text{ at } \pi(v)]\} & \text{otherwise .} \end{cases}$$

Also define

$$\Delta(v) = |p_0(v) - p_1(v)| \ .$$

To gather intuition about these quantities, imagine a random walk on T that begins at the root. At a node v, this walk moves to the left child with probability $\min\{p_0(v), p_1(v)\}$, and it moves to the right child with probability $1 - \max\{p_0(v), p_1(v)\}$. With the remaining probability, $\Delta(v)$, it terminates at v. Note that for any tree T computing g we have $\sum_{v \in T} \Delta(v) R(v) = 1$. This is because the walk always terminates before it reaches a leaf of T. In particular, this means that $\sum_{v \in T} d_T(v) \Delta(v) R(v)$ – the expected number of steps the walk takes before it terminates – is always at most the depth of the tree T.

▶ **Definition 7** (Conflict complexity and max-conflict complexity)**.** *Let g be a partial function. For distributions μ_0, μ_1 with $\mathrm{supp}(\mu_b) \subseteq g^{-1}(b)$ for $b \in \{0,1\}$, and a deterministic decision tree T computing g, define*

$$\chi(T, (\mu_0, \mu_1)) = \sum_{v \in T} d_T(v) \Delta(v) R(v) \ .$$

The conflict complexity of g is

$$\chi(g) = \max_{\mu_0, \mu_1} \min_T \chi(T, (\mu_0, \mu_1)) \ ,$$

where the maximum is over all pairs of distributions (μ_0, μ_1) supported on $g^{-1}(0)$ and $g^{-1}(1)$ respectively, and the minimum is taken over all deterministic trees T computing g. For $\mathcal{Q}$ a distribution over pairs satisfying $\mathrm{supp}_b(\mathcal{Q}) \subseteq g^{-1}(b)$ for $b \in \{0,1\}$, and T a deterministic tree computing g, let $\chi(T, \mathcal{Q}) = \mathsf{E}_{(\mu_0,\mu_1)\sim\mathcal{Q}}[\chi(T, (\mu_0, \mu_1))]$. Finally, the max-conflict complexity of g is

$$\bar{\chi}(g) = \max_{\mathcal{Q}} \min_T \chi(T, \mathcal{Q}) \ ,$$

where the maximum is taken over $\mathcal{Q}$ with $\mathrm{supp}_b(\mathcal{Q}) \subseteq g^{-1}(b)$ for $b \in \{0,1\}$, and the minimum is taken over deterministic trees T computing g.

We can extend the definition of conflict complexity and max-conflict complexity to more general query processes that do not necessarily compute a function. We first need the notion of FULL.

▶ **Definition 8.** *For a deterministic tree T and pair of distributions (μ_0, μ_1) with disjoint support, we say that $(T, (\mu_0, \mu_1))$ is* FULL *if $\sum_{v \in T} \Delta(v) R(v) = 1$, i.e. if the random walk described above terminates with probability 1. We say that $(T, \mathcal{Q})$ is* FULL *if $(T, (\mu_0, \mu_1))$ is* FULL *for each $(\mu_0, \mu_1) \in \mathrm{supp}(\mathcal{Q})$.*

▶ **Definition 9.** *For a deterministic tree T and pair of distributions (μ_0, μ_1) such that $(T, (\mu_0, \mu_1))$ is* FULL*, define $\chi(T, (\mu_0, \mu_1)) = \sum_{v \in T} d_T(v) \Delta(v) R(v)$. For a distribution $\mathcal{Q}$ such that $(T, \mathcal{Q})$ is* FULL*, define $\chi(T, \mathcal{Q}) = \mathsf{E}_{(\mu_0,\mu_1)\sim\mathcal{Q}}[\chi(T, (\mu_0, \mu_1))]$.*

3.1 Comparison with other query measures

Li [9] shows that the conflict complexity of a total Boolean function g is at least the block sensitivity of g. As mentioned in Section 1.1.3, in this work we show that the max-conflict complexity of a (partial) function g is at least as large as the sabotage complexity of g. For a total Boolean function g, Ben-David and Kothari [4] show that the sabotage complexity of g is at least as large as the fractional block sensitivity of g [1, 13, 7], which in turn is at least as large as the block sensitivity. They also show examples where the sabotage complexity is much larger than the partition bound, quantum query complexity and approximate polynomial degree, thus the same holds for max-conflict complexity as well.

▶ **Theorem 7.** *Let $g \subseteq \{0,1\}^m \times \{0,1\}$ be a partial function. Then $\bar{\chi}(g) \geq \mathrm{RS}(g)$.*

A proof of Theorem 7 can be found in [6].

4 Query Process

We now come to the most important definition of the paper, that of the query process $\mathcal{P}(\mathcal{B}, \mathcal{Q})$. Let $t > 0$ be any integer and $\mathcal{B}$ be any deterministic query algorithm that runs on inputs in $(\{0,1\}^m)^t$. Let $x = (x_i^{(j)})_{\substack{i=1,\ldots,t \\ j=1,\ldots,m}}$ be a generic input to $\mathcal{B}$, and let x_i stand for $(x_i^{(j)})_{j=1,\ldots,m}$. For a vertex v of $\mathcal{B}$, let $v^{(i)}$ denote the subcube in v corresponding to x_i, i.e., $v = v^{(1)} \times \ldots \times v^{(t)}$. Recall from Section 2 that v_b stands for the child of v corresponding to the query outcome being b, for $b \in \{0,1\}$.

The query process $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ runs on an input $z \in \{0,1\}^t$ and uses the BITSAMPLER (Algorithm 1) routine to simulate the queries of $\mathcal{B}$ to x when it can. This process is the heart of how we will transform an algorithm for $f \circ g^n$ into a query efficient algorithm for f.

▶ **Definition 10** (Query process $\mathcal{P}(\mathcal{B}, \mathcal{Q})$)**.** *Let $\mathcal{B}$ be a decision tree that runs on inputs $(\{0,1\}^m)^t$. Let $\mathcal{Q}$ be a consistent probability distribution over pairs of distributions (μ_0, μ_1). The query process $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ is run on an input $z \in \{0,1\}^t$ and is defined by Algorithm 2.*

A few comments about Definition 10. First, we think of $\mathcal{B}$ and $\mathcal{P}$ as query procedures that query input variables and terminate. In particular, they do not have to produce outputs, i.e. their leaves do not have to be labeled. Also note that in Algorithm 2 the segment from line 9 to line 19 corresponds to the BITSAMPLER procedure in Algorithm 1. Queries to the input bits z_i are made in line 15, which corresponds to step 9 of BITSAMPLER.

We now present an important structural result about $\mathcal{P}(\mathcal{B}, \mathcal{Q})$. In particular, this formally proves that the procedure BITSAMPLER given in Algorithm 1 samples the bits from the right distribution.

▶ **Theorem 8.** *Let $\mathcal{B}$ be a deterministic decision tree running on inputs from $(\{0,1\}^m)^t$, and let v be a vertex in $\mathcal{B}$. Let $A_z(v, \mathcal{Q})$ be the event that $\mathcal{P}(\mathcal{B}, \mathcal{Q})$, when run on z, reaches node v. Let $B_z(v, \mathcal{Q})$ be the event that for a random input x sampled from $\gamma_z(\mathcal{Q})$, the computation of $\mathcal{B}$ reaches v. Then for every $z \in \{0,1\}^t$ and each vertex v of $\mathcal{B}$,*

$$\Pr[A_z(v, \mathcal{Q})] = \Pr[B_z(v, \mathcal{Q})] \ .$$

A proof of Theorem 8 is given in [6].

We will be interested in the number of queries $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ is able to simulate before making a query to z_i. To this end, let the random variable $\mathcal{N}_i(\mathcal{B}, z, \mathcal{Q})$ stand for the value of the variable N_i in Algorithm 2 after the termination of $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ on input z. Note that $\mathcal{N}_i$ depends on the randomness in the choices of r (step 9) and also on the randomness in $\mathcal{Q}$ in the choice of distributions $(\mu_0^{(k)}, \mu_1^{(k)})$ (step 4).

Algorithm 2: $\mathcal{P}(\mathcal{B}, \mathcal{Q})$.

Input: $z = (z_1, \ldots, z_t) \in \{0,1\}^t$.

for $1 \le k \le t$ **do**
  $\mathsf{QUERY}_k \leftarrow 0$.
  $\mathsf{N}_k \leftarrow 0$.
  Sample $(\mu_0^{(k)}, \mu_1^{(k)})$ from $\mathcal{Q}$.
$v \leftarrow$Root of $\mathcal{B}$
while *v is not a leaf of* $\mathcal{B}$ **do**
  Let $q(v) = (i, j)$, the j^{th} coordinate of x_i
  if $\mathsf{QUERY}_i = 0$ **then**
    Sample a fresh real number $r \sim [0,1]$ uniformly at random.
    if $r < \min_b \Pr_{x_i \sim \mu_b^{(i)}}[x_i^{(j)} = 0 \mid x_i \in v^{(i)}]$ **then**
      $v \leftarrow v_0$.
    else if $r > \max_b \Pr_{x_i \sim \mu_b^{(i)}}[x_i^{(j)} = 0 \mid x_i \in v^{(i)}]$ **then**
      $v \leftarrow v_1$.
    else
      Query z_i. $\mathsf{QUERY}_i \leftarrow 1$.
      if $r \le \Pr_{x_i \sim \mu_{z_i}^{(i)}}[x_i^{(j)} = 0 \mid x_i \in v^{(i)}]$ **then**
        $v \leftarrow v_0$.
      else
        $v \leftarrow v_1$.
    $\mathsf{N}_i \leftarrow \mathsf{N}_i + 1$.
  else
    $b \leftarrow \begin{cases} 1 & \text{with probability } \Pr_{x_i \sim \mu_{z_i}^{(i)}}[x_i^{(j)} = 1 \mid x_i \in v^{(i)}] \\ 0 & \text{with probability } \Pr_{x_i \sim \mu_{z_i}^{(i)}}[x_i^{(j)} = 0 \mid x_i \in v^{(i)}] \end{cases}$
    $v \leftarrow v_b$

4.1 Relating $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ to max-conflict complexity

A key to our composition theorem will be relating the number of simulated queries made by $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ to max-conflict complexity, which we do in this section. Let $\mathcal{B}$ be a query algorithm taking inputs from $\{0,1\}^m$. In this case, $\mathcal{N}_1(\mathcal{B}, 1, \mathcal{Q}) = \mathcal{N}_1(\mathcal{B}, 0, \mathcal{Q})$. This is because the behavior of $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ on input 0 is exactly the same as the behavior on input 1 before a query to z is made, and after z is queried the value of N_i does not change.

▷ Claim 11. Let $\mathcal{B}$ be an algorithm taking inputs from $\{0,1\}^m$. Then $(\mathcal{B}, \mathcal{Q})$ is FULL if and only if $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ queries z with probability 1. If $(\mathcal{B}, \mathcal{Q})$ is FULL then

$$\chi(\mathcal{B}, \mathcal{Q}) = \mathsf{E}[\mathcal{N}_1(T, 1, \mathcal{Q})]$$

Proof. Note that until z is queried, $\mathcal{P}(\mathcal{B}, (\mu_0, \mu_1))$ exactly executes the random walk described in Section 3, and querying z in $\mathcal{P}(\mathcal{B}, (\mu_0, \mu_1))$ corresponds to this random walk terminating. The first part of the claim then follows as $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ queries z with probability 1 if and only if $\mathcal{P}(\mathcal{B}, (\mu_0, \mu_1))$ queries z with probability 1 for every $(\mu_0, \mu_1) \in \mathrm{supp}(\mathcal{Q})$.

Also because $\mathcal{P}(\mathcal{B}, (\mu_0, \mu_1))$ exactly executes the random walk described in Section 3 we see that $\chi(\mathcal{B}, (\mu_0, \mu_1)) = \mathsf{E}[\mathcal{N}_1(T, 1, (\mu_0, \mu_1))]$. The second part of the claim follows by taking the expectation of this equality over $(\mu_0, \mu_1) \sim \mathcal{Q}$. ◁

The correspondence of claim 11 prompts us to define FULL in a more general setting.

▶ **Definition 12** (FULL). *Let $\mathcal{B}$ be a query algorithm taking inputs from $(\{0,1\}^m)^t$. The pair $(\mathcal{B}, \mathcal{Q})$ is said to be* FULL *if for every $z \in \{0,1\}^t$ it holds that $\mathcal{P}(\mathcal{B}, \mathcal{Q})$ queries z_i with probability 1, for every $i = 1, \ldots, t$.*

5 The Composition Theorem

A proof of Theorem 4 is given in [6].

6 Tightness: $\mathsf{R}_{1/3}(f \circ g^n) \in O\left(\mathsf{R}_{4/9}(f) \cdot \sqrt{\mathsf{R}_{1/3}(g)}\right)$ is possible

In this section we prove Theorem 2. We construct a relation $f_0 \subseteq \{0,1\}^n \times \{0,1\}^n$ (i.e., $\mathcal{S} = \{0,1\}^n$) and a promise function $g_0 \subseteq \{0,1\}^n \times \{0,1\}$ (i.e., $m = n$), such that $\mathsf{R}_{4/9}(f_0) \in \Theta(\sqrt{n})$, $\mathsf{R}_{1/3}(g_0) \in \Theta(n)$ and $\mathsf{R}_{1/3}(f_0 \circ g_0^n) \in \Theta(n)$.

For strings $x = (x_1, \ldots, x_n), z = (z_1, \ldots, x_n)$ in $\{0,1\}^n$, let $x \oplus z$ be the string $(x_1 \oplus z_1, \ldots, x_n \oplus z_n)$ obtained by taking their bitwise XOR. Let $|x|$ stand for the *Hamming weight* $|\{i \in [n] : x_i = 1\}|$ of x. We define f_0 as follows:

$$f_0(z) \stackrel{\text{def}}{=} \left\{(a, z) \in \{0,1\}^n \times \{0,1\}^n \middle| |a \oplus z| \leq \frac{n}{2} - \sqrt{n}\right\}$$

Now we define g_0 by specifying $g_0^{-1}(0)$ and $g_0^{-1}(1)$.

$$g_0^{-1}(0) \stackrel{\text{def}}{=} \left\{(x, 0) \middle| x \in \{0,1\}^n, |x| \leq n/2 - \sqrt{n}\right\},$$
$$g_0^{-1}(1) \stackrel{\text{def}}{=} \left\{(x, 1) \middle| x \in \{0,1\}^n, |x| \geq n/2 + \sqrt{n}\right\}.$$

We now determine the randomized query complexities of f_0, g_0 and $f_0 \circ g_0^n$.

▷ Claim 13.

(i) $\mathsf{R}_{4/9}(f_0) \in \Omega(\sqrt{n})$.

(ii) $\mathsf{R}_{1/3}(g_0) \in \Omega(n)$.

(iii) $\mathsf{R}_{\varepsilon}(f_0 \circ g_0^n) \in O\left(n \cdot \sqrt{\log(1/\varepsilon)}\right)$.

A proof of Claim 13 can be found in [6]. Theorem 2 follows from Theorem 4 and Claim 13 with ε set to $1/3$.

Abstract

The Hairy Ball Theorem states that every continuous tangent vector field on an even-dimensional sphere must have a zero. We prove that the associated computational problem of computing an approximate zero is PPAD-complete. We also give a FIXP-hardness result for the general exact computation problem.

In order to show that this problem lies in PPAD, we provide new results on multiple-source variants of End-of-Line, the canonical PPAD-complete problem. In particular, finding an approximate zero of a Hairy Ball vector field on an even-dimensional sphere reduces to a 2-source End-of-Line problem. If the domain is changed to be the torus of genus $g \geq 2$ instead (where the Hairy Ball Theorem also holds), then the problem reduces to a $2(g-1)$-source End-of-Line problem.

These multiple-source End-of-Line results are of independent interest and provide new tools for showing membership in PPAD. In particular, we use them to provide the first full proof of PPAD-completeness for the Imbalance problem defined by Beame et al. in 1998.

1 Introduction

The Hairy Ball Theorem (HBT) is a well-known topological theorem stating that there is no non-vanishing continuous tangent vector field on an even-dimensional k-sphere. It has various informal statements such as "you can't comb a hairy ball flat without creating a cowlick"[1], or "there is a point on the surface of the earth with zero horizontal wind velocity". The HBT is superficially reminiscent of the Borsuk-Ulam Theorem, stating that given any continuous mapping from the 2-sphere to the plane, there are two antipodal points that map to the same value. (Informally, "there are two antipodal points on the surface of the earth where the temperature and pressure are the same"). As we shall see, the present paper highlights a fundamental difference between the two, in terms of the complexity class naturally associated with each of them.

The HBT was first proved in 1885 by Poincaré [29] for the case $k = 2$. The theorem as stated for all even k was proved in 1912 by Brouwer [5]. Accordingly, this result is sometimes also called the Poincaré-Brouwer theorem. In fact, the result proved by Poincaré [29] is

[1] `https://en.wikipedia.org/wiki/Hairy_ball_theorem`

stronger than stated above. It follows from it that for any (sufficiently well-behaved) 2-dimensional manifold with genus $g \neq 1$, any continuous tangent vector field must have a zero. In particular, this means that the HBT also holds for the torus of genus g for $g \geq 2$, i.e. the 2-dimensional torus with g holes. It is easy to see that it does not hold for the standard single-hole torus.

Over the years, various papers in the *American Mathematical Monthly* have presented alternative proofs of the Hairy Ball Theorem and variants, for example [22, 26, 4, 14, 24, 9].

Topological existence results (such as the HBT, Borsuk-Ulam, and the Brouwer and Banach fixpoint theorems) have a very interesting relationship with complexity classes of search problems in which any instance has a guaranteed solution. Any such theorem has a corresponding computational challenge, of searching for such a solution, given a circuit that computes an appropriate function. The assumption that these complexity classes are distinct from each other (the ones of main interest here being PPAD and PPA, discussed below in more detail) provides a taxonomy of these theorems. Our results highlight a fundamental distinction between the HBT and Borsuk-Ulam, by showing that the corresponding search problem for the HBT is characterised by the complexity class PPAD, in contrast to Borsuk-Ulam, which is characterised by PPA [1]. The complexity-theoretic analysis of topological search problems provides a well-defined sense in which the HBT is "Brouwer-like" rather than "Borsuk-Ulam-like". It has previously been noted that the HBT may be used to prove Brouwer's fixed point theorem [26], but not the other way around.

1.1 Background on NP total search and PPAD

The complexity class TFNP is the set of all *total* function computation problems in NP: functions where *every* input has an efficiently-checkable solution (in Section 2.2 we give a precise definition). Many problems in TFNP appear to be computationally difficult, notably Factoring, the problem of computing a prime factorisation of a given number, also Nash, the problem of computing a Nash equilibrium of a game. However, such problems are unlikely to be NP-hard, due to the 1991 result of Megiddo and Papadimitriou [25] showing that TFNP problems cannot be NP-hard unless NP is equal to co-NP. This basic fact, that hard TFNP problems are in a very strong sense "NP-intermediate", provides TFNP's strong theoretical appeal. This has led to the classification of these problems in terms of certain syntactic subclasses of TFNP, whose problems are shown to be total due to some basic combinatorial principle. The best-known of these classes are PLS, PPP, PPAD, and PPA, identified by Papadimitriou in 1994 [28].

- PPAD consists of problems whose totality is based on the principle that given a source in a directed graph whose vertices have in-degree and out-degree at most 1, there exists another degree-1 vertex. Its canonical problem End-of-Line consists of an exponentially-large graph of this kind, presented concisely via a circuit.
- PPA differs from PPAD in that the graph need not be directed; being a more general principle, PPA is thus a superset of PPAD. Its canonical problem Leaf is similar, only the graph is undirected.

Subsequently, many TFNP problems of interest were shown PPAD-complete [10, 7, 23, 13], while more recently others were shown PPA-complete [17, 18]. Despite their similar definitions, PPAD and PPA are usually conjectured to be different, and (along with other syntactic TFNP subclasses) are separated by oracles [3].

1.2 Our results and their significance

Given the long-standing interest in the Hairy Ball Theorem, it is natural to study the corresponding computational search problem. In this paper, we prove that computing an approximate zero of a Hairy Ball vector field is PPAD-complete. While many PPAD-completeness results already exist, a noteworthy novelty of our results is that we find that computing HBT solutions corresponds with *multiple-source* variants of the End-of-Line problem: given a large directed graph implicitly represented by a circuit, suppose you are shown several sources and told to find another degree-1 vertex. This is in contrast with previous PPAD-complete problems that naturally reduce to standard single-source End-of-Line.

In Section 6 we prove that these multiple-source End-of-Line variants are PPAD-complete (membership of PPAD being the tricky aspect). Our results make progress on the general question (studied in [19]) of whether there exist combinatorial principles indicating totality of search problems, that are fundamentally different from the known ones that give rise to complexity classes such as PPAD. In particular, in Section 6.3, we note that a proof of PPAD-completeness for the Imbalance problem by Beame et al. [3] is incomplete and provide a full proof using our results.

The generalisation of Poincaré's result to higher dimensions is called the Poincaré-Hopf theorem (see e.g. [20]). This theorem relates the number and types of zeros of a vector field on a manifold with its Euler characteristic, a topological invariant. In particular, if the Euler characteristic of a manifold is not 0, then any continuous tangent vector field on the surface must have a zero. The Euler characteristic of even-dimensional spheres is 2, while it is $2(1-g)$ for 2-dimensional toruses of genus $g \geq 2$. For odd-dimensional spheres it is 0.

We believe that the reduction to multiple-source End-of-Line is not an artefact of our techniques, but instead intrinsically related to the Euler characteristic of the domain. Indeed, the reduction from the HBT problem on even-dimensional spheres to End-of-Line yields 2 sources (Section 4). On the other hand, if we consider the HBT problem on the 2-dimensional torus of genus $g \geq 2$, then we obtain $2(g-1)$ sources (Section 7 of the full version). The connection between HBT and directed graph problems has previously only appeared in a proof for the 2-dimensional sphere case [22].

Finally, we note that PPAD-hardness is obtained by constructing a HBT vector field from multiple copies of a discrete Brouwer fixpoint problem. The usage of multiple copies is a new conceptual feature, closely related to the multi-source aspect. Using the same high-level idea, we also provide a FIXP-hardness result for the problem of computing an *exact* solution (Section 5.2).

1.3 Other related work

Banach's Fixed Point Theorem [2] says that a *contraction map* has a unique fixpoint. Its corresponding computational problem Contraction, is to find a fixed point of a given contraction map. Some versions of Contraction have been shown complete for CLS, a subclass of PPAD [11, 12, 16]. The search for Brouwer fixpoints (including discretised versions of Brouwer functions) is PPAD-complete for most variants of the problem [28, 7], which is why we say the HBT is "Brouwer-like". Finally – in contrast – the computational problem of searching for a Borsuk-Ulam solution is PPA-complete [1]. Other topological existence results that have PPA-complete search problems include the Hobby-Rice theorem [17] and the Ham Sandwich Theorem [18].

2 Preliminaries

Let k be a positive integer. For $x \in \mathbb{R}^k$, $\|x\|_2$, $\|x\|_1$ and $\|x\|_\infty$ denote the standard ℓ_2-norm, ℓ_1-norm and ℓ_∞-norm respectively. For $x, y \in \mathbb{R}^k$, $\langle x, y\rangle := \sum_{i=1}^m x_i y_i$ denotes the inner product.

The k-dimensional unit sphere in $\mathbb{R}^{k+1}$ (or k-sphere) is denoted $S^k = \{x \in \mathbb{R}^{k+1} : \|x\|_2 = 1\}$. A continuous tangent vector field on S^k is a continuous function $f : S^k \to \mathbb{R}^{k+1}$ such that for all $x \in S^k$ we have $\langle f(x), x\rangle = 0$. The Hairy Ball Theorem can be stated as follows:

▶ **Theorem 1** (Poincaré [29]–Brouwer [5]). *If $k \geq 2$ is even, then for any continuous tangent vector field $f : S^k \to \mathbb{R}^{k+1}$, there exists $x \in S^k$ such that $f(x) = 0$.*

2.1 Model of Computation

We work in the standard Turing machine model. All numbers appearing in computations are rational numbers where the numerator and denominator are integers represented in binary. For a rational number x, size(x) denotes the size of the representation of x, i.e. the sum of the representation length of its numerator and denominator in binary. For an arithmetic circuit F, size(F) denotes the number of gates in the circuit added to the representation length of any rational constants used by the circuit.

2.2 Formal definition of TFNP

A computational search problem is given by a binary relation $R \subseteq \{0,1\}^* \times \{0,1\}^*$, interpreted as follows: $y \in \{0,1\}^*$ is a solution to instance $x \in \{0,1\}^*$, if and only if $(x, y) \in R$. The search problem R is in FNP (*Functions in NP*), if R is polynomial-time computable (i.e. $(x, y) \in R$ can be decided in polynomial time in $|x| + |y|$) and there exists some polynomial p such that $(x, y) \in R \implies |y| \leq p(|x|)$. Here $\{0,1\}^*$ denotes all finite length bit-strings and $|x|$ is the length of bit-string x.

The class TFNP (*Total Functions in NP* [25]) contains all search problems R that are in FNP and are *total*, i.e. every instance has at least one solution. Formally, this corresponds to requiring that for every $x \in \{0,1\}^*$ there exists $y \in \{0,1\}^*$ such that $(x, y) \in R$.

Let R and S be total search problems in TFNP. We say that R (many-one) reduces to S, if there exist polynomial-time computable functions f, g such that

$$(f(x), y) \in S \implies (x, g(x, y)) \in R.$$

Note that if S is polynomial-time solvable, then so is R. We say that two problems R and S are (polynomial-time) equivalent, if R reduces to S and S reduces to R.

To be PPAD-complete, a problem must be equivalent to End-of-Line (Definition 12); in Section 6 we show that the multiple-source version MS-EoL (Definition 13) is equivalent.

3 The Hairy-Ball Problem

3.1 The kD-Hairy-Ball problem

The Hairy Ball Theorem naturally yields a corresponding computational problem. We are given a continuous tangent vector field f on the unit sphere and have to find a point where it is zero. In trying to formalise this, some issues need to be addressed. First, one has to decide how the vector field should be represented in the input. Here we take the usual approach of assuming that it is represented as an arithmetic circuit.

Before we discuss the types of gates that we want to allow in the circuit, let us briefly handle the second issue: the vector field might not have a rational zero. Indeed, consider the following example: at $x \in S^2$ the vector field is simply the vector $(1, 1, 1)$ projected onto the tangent space of S^2 at x. In this case, the only solutions are $\pm(1/\sqrt{3}, 1/\sqrt{3}, 1/\sqrt{3})$. Thus, we cannot hope to always output an exact solution. We bypass this problem by asking for an *approximate* solution instead, i.e. a point $x \in S^2$ such that $\|f(x)\|_\infty \leq \varepsilon$ for some $\varepsilon > 0$ provided in the input. This notion of approximate solution is the standard one used when studying topological existence theorems in the context of TFNP (e.g. Brouwer's fixed point theorem or the Borsuk-Ulam theorem).

As mentioned above, the vector field will be represented as an arithmetic circuit. In the case of S^2, the circuit will have three input gates and three output gates. The arithmetic circuit will be allowed to use gates $\{+, -, \times\zeta, \max, \min\}$ and rational constants. All the gates have fan-in 2, except $\times\zeta$ which has fan-in 1 and corresponds to multiplication by a rational constant ζ. Note that such a circuit is polynomially equivalent to a circuit only using gates $\{+, \times\zeta, \max\}$ and rational constants, since the other gates can be efficiently simulated using these. These circuits correspond to LINEAR-FIXP-type circuits that are known to be sufficient to obtain PPAD-hardness of Brouwer [15]. A discussion about why we don't use more powerful gates in our definition can be found in Section 3.2 of the full version.

This type of circuit yields piece-wise affine functions that are continuous. Furthermore, it has the following nice property: for any such arithmetic circuit F, and any rational x, we can compute $F(x)$ exactly in polynomial time in size(F) and size(x). One potential issue is that F might not be *tangent* to the sphere, but this is easy to fix by simply considering the vector field given by the projection of F onto the corresponding tangent space to the sphere. Thus, we define the computational problem as follows:

▶ **Definition 2** (kD-Hairy-Ball)**.** *Let $k \geq 2$ be even. The* kD-Hairy-Ball *problem is defined as: given $\varepsilon > 0$ and an arithmetic circuit F with $k + 1$ inputs and outputs, using gates $\{+, \times\zeta, \max\}$ and rational constants, find $x \in S^k$ such that $\|P_x[F(x)]\|_\infty \leq \varepsilon$.*

Here $P_x[\cdot]$ denotes the projection onto the tangent space to the sphere S^k at $x \in S^k$. Note that for any $v \in \mathbb{R}^{k+1}$, we have $P_x[v] = v - \langle v, x\rangle x$, because $\|x\|_2 = 1$. Thus, the projection of any rational vector v onto the tangent space at rational $x \in S^k$ can be computed exactly in polynomial time in size(v) and size(x). Note that we are looking for a solution with respect to the ℓ_∞-norm, but we could also have used the ℓ_2- or ℓ_1-norm, since all these versions are computationally equivalent.

kD-Hairy-Ball lies in TFNP. Clearly, any solution can be checked in polynomial time. Totality of kD-Hairy-Ball will immediately follow when we prove that it lies in PPAD (Corollary 8). The following Lemma is proved in Section 3.1 of the full version.

▶ **Lemma 3.** *Let $k \geq 2$ be even. Let F be an arithmetic circuit with $k + 1$ inputs and outputs, using gates $\{+, \times\zeta, \max\}$ and rational constants. Then, the function $S^k \to \mathbb{R}^{k+1}$, $x \mapsto P_x[F(x)]$ is Lipschitz-continuous with Lipschitz constant $L = k \cdot 2^{\text{size}(F)^2+3}$ (w.r.t. ℓ_∞-norm).*

Our main result is Theorem 4. Containment in PPAD, which turns out to be the most challenging part of this result, is presented in Section 4 (using the multiple-source End-of-Line results of Section 6). PPAD-hardness is presented in Section 5.

▶ **Theorem 4.** *For all even $k \geq 2$, kD-Hairy-Ball is* PPAD*-complete.*

4 The Hairy-Ball Problem is in PPAD

In this section we present our main result: the problem of computing an approximate Hairy Ball solution reduces to End-of-Line, the canonical PPAD-complete problem.

From a purely mathematical standpoint, our proof can be used to provide a (fairly cumbersome) proof of the Hairy Ball theorem by using Brouwer's fixed point theorem. Indeed, it is known [28] that End-of-Line reduces to Brouwer (in fact, even 2D-Brouwer [7]). Thus, given a Hairy Ball function f, using our reduction and Brouwer's fixed point theorem, one can prove the existence of a point x_k such that $\|f(x_k)\| \leq 1/2^k$ for any k (using the fact that f must be uniformly continuous since the sphere is compact). Then, since any sequence in a compact set must have a converging subsequence it follows that there must exist x such that $f(x) = 0$. Finding a more direct way to deduce the Hairy Ball theorem from Brouwer's fixed point theorem is an interesting open question.

Our goal is to prove that the Hairy Ball problem lies in PPAD in a setting that is as general and encompassing as possible. The way the function is represented, as a circuit or otherwise, should not play a role. Thus, we are only going to make two assumptions about the tangent vector field: that it can be evaluated in polynomial time and that it is polynomially continuous in some well-defined sense. The first assumption is very natural: if we are given a Hairy Ball function, we expect to be able to evaluate it efficiently. The motivation for the second assumption is that if we omit it, then there is no guarantee that there will exist an approximate solution with representation size that is polynomial in the input size.

We now define these assumptions formally, following the analogous definitions by Etessami and Yannakakis [15] for Brouwer fixed point problems. Let $\mathcal{F}$ be a class of Hairy Ball functions $f : S^k \to \mathbb{R}^{k+1}$ (i.e. continuous tangent vector fields) with $k \geq 2$ even. Note that here k is not fixed for all $f \in \mathcal{F}$, but we assume that $k \leq \text{size}(f)$. For any $f \in \mathcal{F}$, $\text{size}(f)$ denotes the length of the representation of f in $\mathcal{F}$. In the case of kD-Hairy-Ball, k is fixed and $\mathcal{F}$ is the class of all such functions represented using arithmetic circuits with gates $\{+, \times\zeta, \max\}$ (with the projection onto the tangent space at the end). In that case, $\text{size}(f)$ is the size of the circuit representing f. Recall that for rational vector x, $\text{size}(x)$ is the length of the representation of x.

▶ **Definition 5** ([15]). *Let $\mathcal{F}$ be a class of Hairy Ball functions.*

- *$\mathcal{F}$ is* polynomially computable*, if there exists some polynomial p such that for any $f \in \mathcal{F}$ and any rational input $x \in S^k$, $f(x)$ can be computed in time $p(\text{size}(f) + \text{size}(x))$.*
- *$\mathcal{F}$ is* polynomially continuous*, if there exists some polynomial q such that for any $f \in \mathcal{F}$ and any rational $\varepsilon > 0$, there exists a rational $\delta > 0$ with $\text{size}(\delta) \leq q(\text{size}(f) + \text{size}(\varepsilon))$ such that for all $x, y \in S^k$ we have $\|x - y\|_\infty \leq \delta \implies \|f(x) - f(y)\|_\infty \leq \varepsilon$.*

Note that kD-Hairy-Ball yields a class $\mathcal{F}$ that is both polynomially computable and polynomially continuous (by Lemma 3).

▶ **Definition 6.** *Let $\mathcal{F}$ be a class of Hairy Ball functions. The problem* Hairy-Ball($\mathcal{F}$) *is defined as: given $f \in \mathcal{F}$ and $\varepsilon > 0$, find $x \in S^k$ such that $\|f(x)\|_\infty \leq \varepsilon$.*

For simplicity we assume that we can recognise whether some string in $\{0,1\}^*$ represents an element $f \in \mathcal{F}$ in polynomial time. If this does not hold, then Hairy-Ball($\mathcal{F}$) has to be studied as a *promise* problem. The reduction to End-of-Line given in the proof below still holds. However, this does not imply that the problem lies in PPAD, because TFNP requires the problem to be total without any promise.

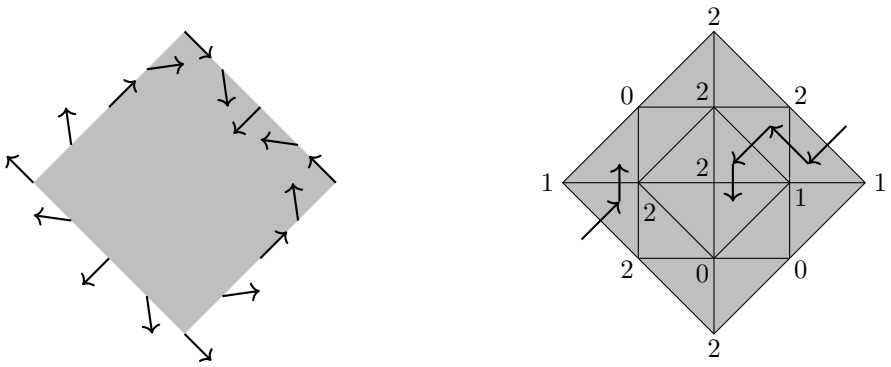
▶ **Theorem 7.** *Let $\mathcal{F}$ be a class of Hairy Ball functions that is polynomially computable and polynomially continuous. Then,* Hairy-Ball($\mathcal{F}$) *lies in* PPAD.

▶ **Corollary 8.** *For all even $k \geq 2$, k*D-Hairy-Ball *lies in* PPAD.

Proof Overview for Theorem 7. The proof can be subdivided into two parts. In the first part, we reduce kD-Hairy-Ball to a *2-source* End-of-Line problem. In the second part, we show that the 2-source version reduces to the standard version of End-of-Line, where a single source is known. Surprisingly, the reduction from 2 sources to 1 is non-trivial. The proof for this is presented separately in Section 6. In fact, we prove the more general result: as long as the number of known sources in an End-of-Line instance is polynomial, we can reduce to standard End-of-Line. Various implications of this result are also presented in Section 6.

We now give some details about the first part of the proof, in which we reduce kD-Hairy-Ball to 2-source End-of-Line through a Sperner argument. The inspiration for this comes from a proof of the 2-dimensional Hairy Ball Theorem via a version of Sperner's Lemma, given by Jarvis and Tanton [22]. Our contribution here is two-fold: we extend their proof to any higher (even) dimension and we turn it into a polynomial-time reduction.

In order to obtain a polynomial-time reduction, instead of working directly on the sphere, we use a stereographic projection to "unfold" the sphere S^k ($\subset \mathbb{R}^{k+1}$) into the space $\mathbb{R}^k$, along with the vector field. Then, we consider a sufficiently large cross-polytope C of $\mathbb{R}^k$ and prove that the "unfolded" vector field satisfies certain boundary conditions. In the case $k = 2$, this corresponds to the vector field making two full rotations when we move along the boundary of C (see Figure 1a). Next, we pick an efficient triangulation of C and a suitable colouring of its nodes. The last step then requires us to prove that this colouring yields exactly two starting points (on the boundary) for Sperner paths (see Figure 1b) that lead to *panchromatic* simplices. Using standard Sperner-arguments this yields a 2-source End-of-Line instance. The full proof for any even k can be found in Section 4.2 of the full version. Note that, as expected, the proof does not work if k is odd. Indeed, the construction then yields a starting point and an ending point on the boundary, instead of two starting points. ◀



(a) Boundary conditions after "unfolding" ... **(b)** ... yielding a Sperner instance with two sources.

Figure 1 An example for the proof of Theorem 7 in the case $k = 2$. The region C is represented in grey.

5 Computational Hardness for Hairy Ball Problems

It is possible to prove Brouwer's fixed point theorem using the Hairy Ball Theorem as follows (see [26] for the full details). Let $B_k \subset \mathbb{R}^k$ be the unit ball. If we assume that a function $f : B_k \to B_k$ does not have any fixed point, then we can construct a Hairy Ball function $g : S^k \to \mathbb{R}^k$ that does not have a zero. Brouwer's theorem follows by contradiction. The main idea for the construction of g is the following. Consider $f'(x) = f(x) - x$ and assume that it points directly inward on the boundary of B_k. Take one copy of B_k with the vector field f' and one copy with the vector field $-f'$, and glue their boundaries together. The resulting object can be deformed to yield the sphere S^k and the vector fields will perfectly match on the glued region. Thus, assuming that f' has no zero, g will have no zero either.

By making this idea fully constructive and efficient, we obtain reductions from Brouwer problems to Hairy Ball problems. Thus, existing PPAD- and FIXP-hardness results for Brouwer also hold for the corresponding Hairy Ball problems. We note that these reductions always involve using *two* copies of a Brouwer instance to obtain a single Hairy Ball instance. This further supports our claim that the fact that we obtain two sources when reducing kD-Hairy-Ball to End-of-Line (Section 4) is not an artefact of our reduction, but intrinsic to the problem.

5.1 PPAD-hardness

▶ **Theorem 9.** *For all even $k \geq 2$, k*D-Hairy-Ball *is* PPAD*-hard.*

Note that this result is particularly strong, because the type of circuit allowed in the definition of kD-Hairy-Ball (Definition 2) is particularly weak. Furthermore, the hardness is proved for inversely exponential ε/L (where L is the Lipschitz constant of the function), which is the best we can hope for in the fixed dimension case. Indeed, if ε/L is inversely polynomial, then the following is a polynomial time algorithm that solves the problem: divide the domain into a sufficiently small (but polynomial) number of regions and check an arbitrary point in each region. In the case where the dimension is not fixed, it seems likely that the problem should be hard even for constant ε/L, but we do not investigate this in this paper.

Proof Overview. One way to prove this result is to take an instance F of a 2D-Brouwer problem, which is known to be PPAD-complete [7], and embed a copy F and a copy $-F$ on the south and north hemisphere of S^2 respectively. However, since our 2D-Hairy-Ball circuit can only use gates in $\{+, \times\zeta, \max\}$, we first shrink the domain of F so that we embed it in a small region around the south pole. This ensures that even after projection onto the tangent space, no bogus solutions will appear. We do the same for $-F$ in the north pole and then define G on the rest of the sphere in such a way that no solution appears there.

In spirit, we follow this general proof idea, but take a slight detour, because it gives us the chance to define and study a discrete analog to 2D-Hairy-Ball: the 2D-Hairy-Cube problem. Intuitively, this problem is obtained from 2D-Hairy-Ball the same way that discrete 2D-Brouwer is obtained from continuous 2D-Brouwer. The domain is discretised by a grid and a circuit computes the local direction of the function in every grid-square. The natural way to discretise the sphere S^2 is to replace it by a cube with a grid on each face. The advantage of 2D-Hairy-Cube is that PPAD-hardness is easy to prove: just put a (slightly modified) discrete 2D-Brouwer instance on one face, and the inverse instance on the opposite face. Defining the instance on the remaining faces is trivial in this case. In Section 6 of the full version we define the problem and prove PPAD-hardness. An illustration of a 2D-Hairy-Cube instance is given in Figure 2.

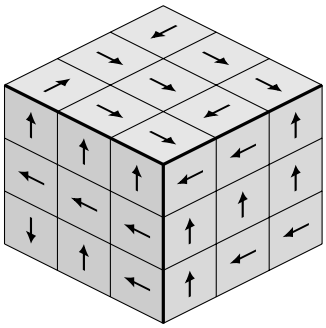


Figure 2 Partial view of a 2D-Hairy-Cube instance.

The next step is reducing 2D-Hairy-Cube to 2D-Hairy-Ball. Even though it seems natural that this should hold, the reduction is technically tedious. In particular, we have to simulate a Boolean circuit using an arithmetic circuit, but the input bits cannot always be computed exactly. Thus, we need to use an averaging trick (see [10, 8]). The details are in Appendix A of the full version.

This yields PPAD-hardness for 2D-Hairy-Ball. The final step is to extend this to kD-Hairy-Ball, by showing that kD-Hairy-Ball reduces to $(k+2)$D-Hairy-Ball. The proof can be found in Appendix B of the full version. ◀

5.2 FIXP-hardness

Up to this point we have only considered the problem of computing an *approximate* Hairy Ball solution. However, there are other computational problems one could consider, e.g. computing a point that is close to an *exact* solution, or computing the first n bits of an *exact* solution.

The corresponding problems for Brouwer fixed points have been studied by Etessami and Yannakakis [15]. In particular, they define the class FIXP that captures the complexity of computing an exact fixed point of a function given by an arithmetic circuit and mapping the unit cube into itself. They prove that computing an exact Nash equilibrium of a 3-player game is FIXP-complete. In doing so, they use a special type of reduction, called an SL-reduction, that ensures that the reduction also holds for three problems that can be studied in the standard Turing machine model: the "strong approximation problem" (i.e. find a point close to an exact solution), the "partial computation" problem (i.e. compute the first n bits of an exact solution) and various decision problems. This means that computing a strong approximation for 3-player Nash is as hard as computing a strong approximation of a Brouwer function given by an arithmetic circuit. We prove that the corresponding problems for the Hairy Ball Theorem are at least as hard as their Brouwer counterparts.

▶ **Definition 10.** *The* Exact-Hairy-Ball *problem is defined as: given an arithmetic circuit F (with gates $\{+,-,\times,/,\max,\min\}$, rational constants and that never divides by 0) that computes a tangent vector field $S^k \to \mathbb{R}^{k+1}$, k even, find $x \in S^k$ such that $F(x) = 0$.*

Note that the vector field will be continuous since we never divide by 0. The vector field can be syntactically forced to be tangent to the sphere because we can compute the projection exactly using this kind of circuit.

▶ **Theorem 11.** Exact-Hairy-Ball *is* FIXP*-hard. Furthermore, the corresponding strong approximation, partial computation and decision problems are also hard for the corresponding versions of* FIXP *(as defined in [15]).*

Proof Overview. We embed two copies of a Brouwer instance (after some preprocessing) on the sphere such that any exact Hairy Ball solution yields an exact Brouwer fixed point. The details can be found in Section 5.2 of the full version. Note that this reduction makes use of the $\times$ and / gates and cannot be used to prove PPAD-hardness of kD-Hairy-Ball. ◀

Following Etessami and Yannakakis, we could define a class HB that captures the complexity of computing an exact Hairy Ball solution (and corresponding versions of the class for the related problems) by taking the set of all problems that reduce to Exact-Hairy-Ball. Then, Theorem 11 is saying that FIXP $\subseteq$ HB. Note that the three discrete problems that can be studied in the Turing machine model lie in PSPACE, by using the same technique as in [15, Proposition 4.2].

6 End-of-Line: One Source to Rule Them All

End-of-Line is the canonical problem used to define PPAD. Investigating variants of the problem is of independent interest, in particular in order to gain a better understanding of PPAD and how it relates to other similar subclasses of TFNP. An additional motivation for studying these variants is given by this paper, since a multiple-source variant of End-of-Line is used to prove that finding an approximate Hairy Ball solution lies in PPAD (Section 4).

This section is an improved version of the corresponding content in the technical report [21]. In [21] we use these results to show that a computational problem related to the Mutilated Chessboard puzzle is PPAD-complete.

6.1 The End-of-Line problem

The End-of-Line problem is informally defined as follows: given a directed graph where each vertex has in- and out-degree at most 1 and given a known source of this graph, find a sink or another source. The problem is computationally challenging, because the graph is not given explicitly in the input. Instead, we are given an implicit concise representation of the graph through circuits that compute the predecessor and successor of a vertex in the graph. In what follows, we sometimes interpret the input and output of the circuits, which are elements in $\{0,1\}^n$, as the numbers $\{0,1,\ldots,2^n-1\}$.

▶ **Definition 12** (End-of-Line [10]). *The* End-of-Line *problem is defined as: given Boolean circuits S, P with n input bits and n output bits and such that $P(0) = 0 \neq S(0)$, find x such that $P(S(x)) \neq x$ or $S(P(x)) \neq x \neq 0$.*

The circuits define a graph as follows. There is a directed edge from vertex x to y ($x \neq y$), if and only if $S(x) = y$ and $P(y) = x$. Note that any badly defined edge, i.e. $S(x) = y$ and $P(y) \neq x$, or $P(y) = x$ and $S(x) \neq y$, qualifies as a solution of End-of-Line as defined above (because $P(S(x)) \neq x$ or $S(P(x)) \neq x$ respectively). Note that 0 is a source of the graph, unless $P(S(0)) \neq 0$, in which case 0 is a valid solution to the problem as stated above.

It is easy to check that this formal definition of the problem is computationally equivalent to the informal description given above. By definition, End-of-Line is PPAD-complete [28]. Furthermore, reduction from End-of-Line is a very common technique to show PPAD-hardness (e.g. [10, 7]).

6.2 Multiple-Source End-of-Line

What if, instead of just one, we already know *two* sources of an End-of-Line instance? We are still interested in finding any sink or any *other* source. Intuitively, the problem might seem easier, because the existence of two sources implies the existence of at least two sinks, hence more potential solutions. In fact, it is easy to see that this problem is actually at least as hard as End-of-Line: just duplicate the whole End-of-Line instance.

The other direction, however, is not trivial. Indeed, if we interpret our 2-source End-of-Line instance as a standard End-of-Line instance (and pick one of the two sources as the standard source), then the other known source is a valid solution to End-of-Line, but not a valid solution to our original problem. In other words, it is not clear how to solve this problem if we are given access to an oracle solving End-of-Line, because the oracle could just return the other known source. We consider the following more general problem, where we are given an End-of-Line graph and an explicit list of known sources.

▶ **Definition 13** (MS-EoL). *The* Multiple-Source End-of-Line *problem, abbreviated* MS-EoL*, is defined as: given circuits S, P with n inputs and n outputs and $s_1, \dots, s_k \in \{0,1\}^n$ such that $P(s_i) = s_i \neq S(s_i)$ for all i, find $x \in \{0,1\}^n$ such that $P(S(x)) \neq x$ or $x \notin \{s_1, \dots, s_k\}$ such that $S(P(x)) \neq x$.*

In passing, let us note that in the undirected case this kind of generalisation is trivial. The undirected analogue of End-of-Line is Leaf: given an undirected graph where every vertex has degree at most 2 and given a vertex of degree 1, find another vertex of degree 1, i.e. another leaf. Assume that we know k leaves instead of just one. If k is even, then the problem is not even in TFNP. If k is odd, then we can add edges between known leaves until exactly one is left. Thus, the problem is equivalent to Leaf. This kind of reduction does not work for the directed case. Nevertheless, we obtain[2]:

▶ **Theorem 14.** Multiple-Source End-of-Line *is equivalent to* End-of-Line.

Proof Overview. We inductively construct a vertex set containing various combinations of subsets of the original graph. The successor and predecessor circuits are carefully constructed so as to ensure that any solution yields a solution to the original problem. The full proof can be found in Section 8.2 of the full version. ◀

▶ Remark (Multiple Known Sources and Sinks). A natural generalisation of Multiple-Source End-of-Line is the following problem: given an End-of-Line graph and a list of k known sources and m known sinks, find another source or sink. Note that for this problem to be in TFNP, we must require $k \neq m$. Using Theorem 14, it is easy to see that this problem is equivalent to End-of-Line. If $k > m$, then we add an edge from each of the m known sinks to some corresponding known source and obtain an instance with $k - m$ known sources and no known sinks. Similarly, if $k < m$, then we first reverse all directed edges and then apply the same trick.

The next two sections present additional consequences of Theorem 14.

[2] This problem was discussed in an online thread (`https://cstheory.stackexchange.com/q/37481`). E. Jeřábek proved membership in PPADS and PPA-p for every prime p (but not membership in PPAD).

6.3 The Imbalance problem

Up to this point, we have only considered graphs where every vertex has in- and out-degree at most 1. However, the principle that guarantees the existence of a solution in an End-of-Line graph can be generalised to higher degree graphs. If we are given a directed graph and an *unbalanced* vertex, i.e. a vertex with in-degree $\neq$ out-degree, then there must exist another unbalanced vertex.

Beame et al. [3] defined the corresponding problem Imbalance, which is seemingly more general than End-of-Line. In this problem, every vertex is not constrained to have in- and out-degree at most 1. Instead, in- and out-degree are bounded by some polynomial of the input length[3]. We are given a vertex that is unbalanced and have to find another unbalanced vertex (which is guaranteed to exist). The problem can be informally defined as follows:

▶ **Definition 15** (Imbalance [3], informal)**.** *The* Imbalance *problem is defined as: given a directed graph (represented concisely by predecessor and successor functions) and a vertex z that has in-degree $\neq$ out-degree, find a vertex $x \neq z$ that also has in-degree $\neq$ out-degree.*

Beame et al. [3] claim that Imbalance reduces to End-of-Line, using the same argument as for the corresponding problems on undirected graphs. However, if the graph is directed, a complication arises (that is not an issue in the undirected case). Indeed, their proof idea is incomplete, because they overlook the fact that their reduction yields an End-of-Line instance with *multiple* known sources. Using Theorem 14 we can provide a full proof of their claim.

▶ **Theorem 16.** Imbalance *is* PPAD*-complete.*

A formal definition of the problem and a full proof can be found in Section 8.3 of the full version.

6.4 Looking for multiple solutions

If we are given an End-of-Line instance with k known sources, then we can ask for k sinks or k unknown sources. The problem is total, because at least k sinks are guaranteed to exist.

▶ **Definition 17** (k-EoL)**.** *Let $k \in \mathbb{N}$. The* k-Ends-of-Line *problem, abbreviated* k-EoL*, is defined as: given circuits S, P with n inputs and n outputs and such that $P(z) = z \neq S(z)$ for all $z < k$, find distinct $x_1, \ldots, x_k$ such that $P(S(x_i)) \neq x_i$ for all i or $S(P(x_i)) \neq x_i \geq k$ for all i.*

Intuitively, this problem seems harder than End-of-Line or MS-Eol, because we are now looking for more than one solution. However, using Theorem 14 we can show:

▶ **Theorem 18.** *For any $k \in \mathbb{N}$,* k-Ends-of-Line *is* PPAD*-complete.*

Proof Overview. The reduction to End-of-Line is obtained by constructing a Turing reduction (using Theorem 14) and then applying a result by Buss and Johnson [6] that PPAD is closed under Turing reductions. The details are in Section 8.4 of the full version. ◀

▶ Remark. The same proof also yields PPAD-completeness for the following problem. Fix some polynomial p. The problem is: given k sources, find k sinks or $p(k)$ sources. This seems quite surprising, as one might have expected this problem to be closer to PPADS.

[3] Note that this trivially holds, if the input consists of circuits that explicitly output the predecessor and successor list.

Some analogous results for the class PPADS and its canonical complete problem Sink [27, 3] are presented in Section 8.4 of the full version. Sink is identical to End-of-Line, except that we only accept a sink as a solution and are not interested in other sources. In this case the results are easier to obtain, because there is no need for an analogue of Theorem 14.

7 Conclusion and Further Work

We have obtained a satisfying answer to the question of the computational complexity of the Hairy Ball Theorem, if we are looking for an approximate solution. For other solution concepts related to exact solutions, we have provided a FIXP-hardness result. This leaves open the question of whether the problem is FIXP-complete in this case. Indeed, our reduction from Hairy Ball to Brouwer only works for approximate solutions. A first step would be to try to reduce Hairy Ball to Borsuk-Ulam, even though no such (fully constructive) mathematical proof seems to be known.

Our results on multiple-source variants of the End-of-Line problem open the way for two new research directions. First, they provide a new tool for showing membership of PPAD, which can be used to put further problems in this class. It seems very unlikely that the Hairy Ball Theorem should be the only "natural" application of these results. Furthermore, a second interesting research direction is investigating the complexity of End-of-Line with a super-polynomial number of known sources (implicitly given in the input).

Abstract

Minimum Circuit Size Problem (MCSP) asks to decide if a given truth table of an n-variate boolean function has circuit complexity less than a given parameter s. We prove that MCSP is hard for constant-depth circuits with mod p gates, for any prime $p \geq 2$ (the circuit class $\mathsf{AC}^0[p]$). Namely, we show that MCSP requires d-depth $\mathsf{AC}^0[p]$ circuits of size at least $\exp(N^{0.49/d})$, where $N = 2^n$ is the size of an input truth table of an n-variate boolean function. Our circuit lower bound proof shows that MCSP can solve the coin problem: distinguish uniformly random N-bit strings from those generated using independent samples from a biased random coin which is 1 with probability $1/2 + N^{-0.49}$, and 0 otherwise. Solving the coin problem with such parameters is known to require exponentially large $\mathsf{AC}^0[p]$ circuits. Moreover, this also implies that MAJORITY is computable by a non-uniform AC^0 circuit of polynomial size that also has MCSP-oracle gates. The latter has a few other consequences for the complexity of MCSP, e.g., we get that any boolean function in NC^1 (i.e., computable by a polynomial-size formula) can also be computed by a non-uniform polynomial-size AC^0 circuit with MCSP-oracle gates.

We thank Eric Allender and Shuichi Hirahara for their comments, and special thanks to Eric for pointing us to the paper of Dančik [9] and the discussion of various circuit and formula complexity measures for constant-depth circuit models. We are grateful to our anonymous reviewers for helpful comments on this paper.

1 Introduction

Minimum Circuit Size Problem (MCSP) asks to decide if a given boolean function $f\colon \{0,1\}^n \to \{0,1\}$ (presented by its truth table of length $N = 2^n$) can be computed by a boolean circuit of size at most s, for a given parameter $0 \leq s \leq 2^n$. There is no nontrivial algorithm currently known for MCSP other than the "brute force" enumeration of all circuits of size up to s and checking if any one of them computes f. On the other hand, while MCSP is obviously in NP, it is a major open question to decide if MCSP is NP-complete (and there is a growing list of research papers providing arguments for and against various NP-completeness reductions to MCSP [17, 2, 4, 3, 6, 13, 12, 24]).

Another natural question is to prove circuit lower bounds (for restricted circuit models) for MCSP. Here some results are known. Allender et al. [2] showed that MCSP requires super-polynomial-size AC^0 circuits (constant-depth circuits with AND, OR, and NOT gates). Hirahara and Santhanam [11] proved that MCSP requires almost quadratic-size De Morgan formulas.

It was an open question [5, 25] to prove that MCSP requires super-polynomial $\mathsf{AC}^0[p]$ circuits (constant-depth circuits with AND, OR, NOT and mod p counting gates), for a prime $p > 0$. We resolve this question in the present paper. Our main result is that MCSP requires d-depth $\mathsf{AC}^0[p]$ circuits of size at least $\exp(N^{0.49/d})$, where $N = 2^n$ is the size of an input truth table of an n-variate boolean function.

Previous proof methods of circuit lower bounds for MCSP

The lack of NP-completeness reductions to MCSP and the scarcity of circuit lower bounds for MCSP underscore the general phenomenon that there are very few known reductions to MCSP. The main (if not the only one) use of MCSP inside known reductions is to "break" pseudorandom function generators, an idea going back to the celebrated paper of Razborov and Rudich [28] on "natural proofs". The point is that known candidate constructions of pseudorandom function generators produce pseudorandom functions that do have "small" circuit complexity, whereas truly random functions are known to require "high" circuit complexity. Thus, an assumed efficient MCSP algorithm can distinguish between the truth tables of such pseudorandom functions and those of truly random functions, thereby "breaking" the pseudorandom function generator.

Both previously known circuit lower bounds for MCSP by Allender et al. [2] and by Hirahara and Santhanam [11] used MCSP's ability to break pseudorandom function generators together with the existence of known pseudorandom (function) generators that are provably secure against AC^0 and quadratic-size De Morgan formulas, respectively. The same approach cannot be applied to the case of $\mathsf{AC}^0[p]$ circuits as we currently do not have any strong enough pseudorandom generators secure against $\mathsf{AC}^0[p]$!

Our approach

Our approach instead is to reduce the Majority function to MCSP, and use the known $\mathsf{AC}^0[p]$ lower bounds against Majority [27, 31]. In fact, we give a reduction to MCSP from the coin problem where one is asked to distinguish between an N-bit uniformly random string, and an N-bit string sampled so that each bit is independently set to 1 with probability $1/2 - \epsilon$ (and to 0 otherwise), for some parameter $\epsilon > 0$. We then use the result of Shaltiel and Viola [29] showing that any algorithm solving such a coin problem yields an efficient algorithm for computing the Majority function on inputs of length $1/\epsilon$. To conclude super-polynomial-size $\mathsf{AC}^0[p]$ circuit lower bounds for MCSP from the known lower bounds for the Majority function, we need to be able to solve the coin problem for N-bit strings with the parameter $\epsilon < 1/\mathrm{poly}(\log N)$.

Here is some intuition why MCSP could be useful for solving the coin problem. For $N = 2^n$, an N-bit random string has binary entropy N. On the other hand, N-bit strings sampled using a biased coin with probability $p = 1/2 - \epsilon$ of being 1 would likely have close to $pN < N/2$ ones only, and so come from a smaller set of about $\binom{N}{pN} \approx 2^{H(p)\cdot N}$ strings of size N, where H is the binary entropy function. Information-theoretically, we can describe each string with at most pN ones using about $H(p) \cdot N$ bits. For $p \ll 1/2$, we have that $H(p) \cdot N \ll N$, and so most biased functions have a description of bit complexity much less than N. If somehow we could extend this information-theoretic argument to show that most biased functions will have *circuit complexity* noticeably smaller than that of random functions, we'd be done because MCSP would be able to distinguish between random functions (of higher circuit complexity) and random biased functions (of lower circuit complexity).

Lupanov in 1965 [21] proved that, indeed, biased random functions have circuit complexity smaller than that of random boolean functions. However, Lupanov's result applies only to the case of bias probability $p = 1/2 - \epsilon$ for large (close to constant) ϵ only, and doesn't give anything useful for our case of $\epsilon < 1/\mathrm{poly}(\log N)$. To circumvent the lack of tighter circuit upper bounds for slightly biased random functions, we employ two new ideas.

First, we show that the circuit complexity of q-random functions is very *tightly concentrated* around its expectation, for every probability q. This can be proved using a simple martingale argument (McDiarmid's Inequality [22]). The point is that the circuit complexity of a given n-variate boolean function f changes by at most $O(n)$ when we change the value of f on exactly one n-bit input (which can be simply hard-wired into the new circuit for the modified function).

Secondly, we use a *hybrid argument*. By Lupanov's result [21], one can show that for $p = 0.01$, almost all p-biased random functions will have circuit complexity noticeably smaller that $2^n/n$, and in particular, the *expected* circuit complexity of a p-biased random function is at most $0.1 \cdot 2^n/n$. On the other hand, for $p' = 1/2$, well-known counting arguments show that almost all such random functions have circuit complexity very close to $2^n/n$, and in particular, the expected circuit complexity of a random function is at least $0.9 \cdot 2^n/n$. Imagine we have t equally spaced probabilities between $p = 0.01$ and $p' = 1/2$, for some number t to be chosen. Then by the hybrid argument, there will exist two successive probabilities q and $q' \approx q + 1/t$, where the *expected circuit sizes* for q-random and q'-random functions differ by at least $\Omega(2^n/n)/t$.

By the "concentration around the expected circuit size" result mentioned above, we conclude that MCSP is able to distinguish between most q-random boolean functions and most $q' \approx q + 1/t$-random ones. By re-scaling, we conclude that MCSP is able to distinguish between $1/2 - 1/t$-random function and $1/2$-random ones, i.e., that MCSP solves the coin problem for the bias $\epsilon = 1/t$. Finally, our concentration result is strong enough to allow us to choose $t = 2^{\Omega(n)}$, which yields an exponential $\mathsf{AC}^0[p]$ circuit lower bound for MCSP. (To get the quantitatively strongest circuit lower bound for MCSP, we use the recent $\mathsf{AC}^0[p]$ lower bounds for the coin problem by [18], rather than apply the reduction from the Majority function to the coin problem from [29].)

Other results

We are able to generalize our $\mathsf{AC}^0[p]$ circuit lower bounds to several natural variants of MCSP. For a circuit class $\mathcal{C}$, let $\mathcal{C}$-MCSP denote the MCSP problem asking about the $\mathcal{C}$-type circuit complexity of a given truth table. For example, $\mathcal{C}$ can be the class AC^0, where we ask about the gate complexity of a smallest AC^0 circuit computing a given boolean function, or $\mathcal{C}$ can be the class of boolean formulas, where we ask about the formula (leaf) complexity of a smallest formula. We show that for both such cases of $\mathcal{C}$, the problem $\mathcal{C}$-MCSP requires exponential-size $\mathsf{AC}^0[p]$ circuits. This generalization requires us to re-visit Lupanov's general circuit upper bounds for biased random functions. We provide new "hashing-based" arguments for such circuit constructions that apply to the case of formulas as well as constant-depth circuits and formulas.

As a corollary of our reduction of the coin problem to MCSP and some previous results, we obtain that every function in NC^1 can be computed by a non-uniform AC^0 circuit with MCSP oracle gates. We also show that at least one of the following lower bounds must be true: either $\mathsf{NEXP} \not\subset \mathsf{P/poly}$, or $\mathsf{MCSP} \notin \mathsf{ACC}^0$.

Finally, we give a new coin-problem based proof of $\mathsf{AC}^0[p]$ circuit lower bounds for MKTP, a Kolmogorov-complexity variant of MCSP, re-proving the result of [5].

The rest of the paper

We give the necessary definitions and facts in Section 2. We prove the aforementioned circuit complexity concentration result for random biased functions in Section 3, and then prove our $\mathsf{AC}^0[p]$ circuit lower bound for MCSP in Section 4. In Section 5, we give corollaries of our main result. The lower bound for MKTP is given in Section 7. We generalize our lower bounds to the case of $\mathcal{C}$-MCSP in Section 6. Section 8 lists some open questions.

2 Preliminaries

2.1 Complexity basics

For a boolean function $f\colon \{0,1\}^n \to \{0,1\}$, let $size(f)$ denote the size of a smallest circuit (using AND, OR, and NOT gates) that computes f. Let $size(n)$ be the maximum of $size(f)$, over all n-variate boolean functions f. Finally, define $s_n = \mathbf{E}[size(f)]$ to be the average of circuit complexities over all n-variate boolean functions.

Below, all logarithms are base 2, unless stated otherwise.

Building on the work by Shannon [30], Lupanov [19] proved the following lower and upper bounds for $size(n)$.

▶ **Theorem 2.1** (Lupanov [19]). *For all sufficiently large $n \in \mathbb{N}$,*

$$size(n) \leq \frac{2^n}{n} + O\left(\frac{2^n \log n}{n^2}\right).$$

Moreover, all but $o(1)$ fraction of uniformly random n-variate boolean functions f require

$$size(f) \geq \frac{2^n}{n} + \Omega\left(\frac{2^n \log n}{n^2}\right).$$

For the case of n-variate functions with a fixed fraction of 1 inputs, Lupanov [21] proved the following generalization of his earlier bounds.

▶ **Theorem 2.2** (Lupanov [21]). *Let $f\colon \{0,1\}^n \to \{0,1\}$ be any boolean function that has the value 1 on $k \leq 2^{n-1}$ inputs, where $k \in \Omega(2^n)$. Then, for all sufficiently large $n \in \mathbb{N}$,*

$$size(f) \leq \frac{\log \binom{2^n}{k}}{\log \log \binom{2^n}{k}} + O\left(\frac{2^n \log n}{n^2}\right).$$

Moreover, all but $o(1)$ fraction of random such functions f require

$$size(f) \geq \frac{\log \binom{2^n}{k}}{\log \log \binom{2^n}{k}} + \Omega\left(\frac{2^n \log n}{n^2}\right).$$

2.2 Probability basics

▶ **Theorem 2.3** (McDiarmid's Inequality [22]). *Let $X_1, \ldots, X_N \in \{0,1\}$ be independent random variables. Let $f\colon \{0,1\}^n \to \mathbb{R}$ be any function such that, for some function $c = c(N)$, for all $1 \leq i \leq N$ and for all $b_1, \ldots, b_N, \widetilde{b}_i \in \{0,1\}$, it holds that*

$$\left| f(b_1, \ldots, b_N) - f(b_1, \ldots, b_{i-1}, \widetilde{b}_i, b_{i+1}, \ldots, b_N) \right| \leq c.$$

Then, for any $\lambda > 0$,

$$\mathbf{Pr}\left[|f(X_1, \ldots, X_N) - \mathbf{E}\left[f(X_1, \ldots, X_N)\right]| \geq \lambda\right] \leq 2 \cdot \exp\left(\frac{2\lambda^2}{Nc^2}\right).$$

Roughly speaking, the inequality states that with high probability the value of f will be of distance at most $O(\sqrt{N} \cdot c)$ around its mean.

2.3 Coin problem

A coin problem is the problem to distinguish between two coins (boolean-valued random variables), where one coin has probability p of being 1, and the other coin probability $q > p$. Usually, $p = 1/2 - \epsilon$ and $q = 1/2 + \epsilon$, for some $\epsilon > 0$; or, $p = 1/2 - \epsilon$ and $q = 1/2$. By a simple "translation argument", it is possible to show that all of these problems are essentially equivalent. For completeness, we state this argument next.

▷ Claim 2.4 (Translation Argument). Let $0 < p \leq q < 1$, $\varepsilon > 0$. Suppose C is a circuit of size S that solves the $p(1-\varepsilon)$ versus p coin problem on inputs of length N with advantage α. Then, there exists a circuit $\widetilde{C}$ of size at most S that solves the $q(1-\varepsilon)$ versus q coin problem on inputs of length N with advantage at least α.

Proof. For $p \in (0,1)$, we denote by μ_p the product distribution on $\{0,1\}^N$ where each bit is independently sampled to be 1 with probability p, and 0 otherwise. Let C be a circuit of size S that solves the $p(1-\varepsilon)$ versus p coin problem with advantage

$$\alpha := \mathop{\mathbf{Pr}}_{x\sim\mu_{p(1-\varepsilon)}}[C(x)] - \mathop{\mathbf{Pr}}_{x\sim\mu_p}[C(x)].$$

We construct a distribution over circuits C' that achieves the same advantage on the $q(1-\varepsilon)$ versus q coin problem. The randomized circuit C' is defined as follows: "For each input bit x_i, let $x'_i = x_i$ with probability p/q and $x'_i = 0$ otherwise. Apply C on $(x'_1, \ldots, x'_N)$." Note that, by design, if x is distributed according to a μ_q then x' is distributed according to μ_p, and if x is distributed according to $\mu_{q(1-\varepsilon)}$, then x' is distributed according to $\mu_{p(1-\varepsilon)}$. We get a distribution over circuits C' that solves the $q(1-\varepsilon)$ versus q coin problem with advantage at least α. By averaging, there must exist a deterministic circuit $\widetilde{C}$ that solves the $q(1-\varepsilon)$ versus q coin problem with advantage at least α. Note that $\widetilde{C}$ is obtained from C' by fixing the internal randomness that C' used to decide for each $1 \le i \le N$ whether to set $x'_i = x_i$ or $x'_i = 0$. With those choices fixed, $\widetilde{C}(x_1, \ldots, x_N)$ is just a restriction of $C(x_1, \ldots, x_N)$ where some x_i's are set to 0. Hence, the size of $\widetilde{C}$ is at most that of C, as claimed. ◁

▶ **Theorem 2.5** ([29]). *Let A be an algorithm that distinguishes, with constant distinguishing probability, between n-bit uniformly random strings, and n-bit strings sampled so that each bit is independently set to 1 with probability $1/2 - \epsilon$ (and to 0 otherwise). Then there is a non-uniform AC^0 circuit of size $\mathrm{poly}(n/\epsilon)$ that computes the majority function on binary inputs of length $1/\epsilon$, using A-oracle gates.*

Using the theorem above as well as the well-known lower bound for the majority function against $\mathsf{AC}^0[p]$ circuits, for any constant prime p, we can deduce that any algorithm solving the coin problem with bias ϵ on n-bit inputs requires $\mathsf{AC}^0[p]$ depth d circuits of size at least $\exp((1/\epsilon)^{1/O(d)})$. This lower bound has been recently sharpened.

▶ **Theorem 2.6** ([18]). *Let A be a boolean function that distinguishes, with constant distinguishing probability, between n-bit uniformly random strings, and n-bit strings sampled so that each bit is independently set to 1 with probability $1/2 - \epsilon$ (and to 0 otherwise). Then any depth d $\mathsf{AC}^0[p]$ circuit computing A must have size at least $\exp(\Omega((1/\epsilon)^{1/(d-1)}))$.*

3 Concentration of Circuit Complexity

For every $n \ge 1$, let μ be any product distribution over $\{0,1\}^N$, where $N = 2^n$. Recall that $size(f)$ is the size of a smallest circuit computing a boolean function f. For each integer $n \ge 1$, define

$$s_n^\mu = \mathbf{E}_{f\sim\mu}[size(f)],$$

the expectation of $size(f)$ over n-variate boolean functions f whose N-bit truth tables are sampled according to μ. We show that a random n-variate boolean function sampled from μ is likely to have its circuit complexity very close to the expected circuit complexity s_n^μ.

▶ **Theorem 3.1.** *For μ and s_n^μ as defined above, if a boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is chosen at random according to distribution μ, then, with probability at least $1 - 2^{-n}$,*

$$|size(f) - s_n^\mu| \le \sqrt{N} \cdot n^2.$$

Proof. Observe that for any two n-variate boolean functions f and g that differ on exactly one input $a \in \{0,1\}^n$, we have that $|size(f) - size(g)| \leq O(n)$. Indeed, suppose, without loss of generality, that $size(f) \leq size(g)$. Then we can compute g as follows: "Given $z \in \{0,1\}^n$, check if $z = a$. If so, then output the bit $b = g(a)$. Otherwise, use the circuit for f to output $f(z)$." More precisely, if C is a circuit computing f, then the circuit D for g can be described as

$$D(z) := (b \wedge (\wedge_{i=1}^{n}(z_i = a_i))) \vee (C(z) \wedge (\vee_{i=1}^{n}(z_i \neq a_i))), \tag{1}$$

where $(z_i = a_i)$ is defined to be z_i for $a_i = 1$, and the negation $\overline{z_i}$ for $a_i = 0$; and $(z_i \neq a_i)$ is the negation of $(z_i = a_i)$. Clearly, the size of D is that of C plus $O(n)$.

Let $X_1, \ldots, X_N \in \{0,1\}$ be independent random variables sampled from the product distribution μ. We apply McDiarmid's Inequality of Theorem 2.3 to the function $size\colon \{0,1\}^N \to \mathbb{N}$, which, as we just argued, differs by at most $c = O(n)$ on any two truth tables that agree in all but one coordinate. We get the desired concentration result by choosing $\lambda = \sqrt{N} \cdot n^2$. That is, all but $\exp(-n)$ fraction of μ-random n-variate boolean functions f have their circuit size $size(f)$ within $\sqrt{N} \cdot n^2$ of the expected circuit size s_n^μ. ◀

4 Main theorem

▶ **Theorem 4.1.** *Let $p \geq 2$ be any prime. For any depth $d > 0$ and large enough input size $N = 2^n$, MCSP on N-bit truth tables requires depth d $\mathsf{AC}^0[p]$ circuits of size $\exp(\Omega(N^{0.49/(d-1)}))$.*

Proof. Let $t = \lceil 2^{0.49n} \rceil$. Consider an arithmetic sequence of probabilities $(p_0, p_1, p_2, ..., p_t)$ with $p_0 = 0.01$, $p_t = 0.5$ and $p_i = p_0 + i \cdot 0.49/t$. For each $i = 0, \ldots, t$, let μ^i be the product distribution on $\{0,1\}^N$, where each bit is independently sampled to be 1 with probability p_i, and 0 with probability $1 - p_i$. Let

$$s^i = s_n^{\mu^i} = \mathbf{E}_{f \sim \mu^i}[size(f)].$$

By Lupanov's estimates of Theorem 2.1, we have

$$s^t \geq (1 - o(1)) \cdot \frac{2^n}{n} \geq 0.9 \cdot \frac{2^n}{n}.$$

By the Chernoff bound, almost all n-variate boolean functions sampled according to μ^t will assume the value 1 on at most $k = 0.011 \cdot N$ inputs. By Theorem 2.2, we have

$$s^0 \leq H(0.011) \cdot \frac{2^n}{n} + o\left(\frac{2^n}{n}\right) \leq 0.1 \cdot \frac{2^n}{n},$$

where $H()$ is the binary entropy function. It follows that

$$s^t - s^0 \geq 0.8 \cdot \frac{2^n}{n}.$$

This means that there must be an i such that $s^{i+1} \geq s^i + \Omega(2^{0.51n}/n)$. Let $s^* = (s^i + s^{i+1})/2$. By circuit complexity concentration given in Theorem 3.1, we get that, with high probability, n-variate random boolean functions sampled from μ^i have circuit size smaller than s^*, and those sampled from μ^{i+1} have circuit size larger than s^*. Hence, $\mathsf{MCSP}(x, s^*)$ can distinguish between μ^i and μ^{i+1}, with a constant distinguishing probability.

Finally, assume by contradiction that $\mathsf{MCSP} \in \mathbf{AC^0}[p]$ of size S and depth d. Let n be large enough, and let $N = 2^n$. Then, by fixing the second input of MCSP to s^*, we get an $\mathbf{AC^0}[p]$ circuit that on N-bit inputs solves the coin problem distinguishing between p_i and p_{i+1}. By Claim 2.4, there exists a circuit of size at most S and depth at most d that solves the $(1-\varepsilon)/2$ versus $1/2$ coin problem for $\varepsilon = 1 - p_i/p_{i+1} = \Theta(1/t) = \Theta(N^{-0.49})$. However, the latter implies by Theorem 2.6 that $S \geq \exp(\Omega(\varepsilon^{-1/(d-1)})) = \exp(\Omega(N^{0.49/(d-1)}))$. ◀

5 Consequences

Below, whenever we talk about circuit classes such as AC^0, ACC^0, and TC^0, we mean *non-uniform* circuit classes.

Using Theorem 2.5, we get the following corollary to Theorem 4.1 regarding the MAJORITY function, denoted MAJ.

▶ **Corollary 5.1.** $\mathrm{MAJ} \in (\mathsf{AC}^0)^{\mathsf{MCSP}}$.

Combined with the inclusion $\mathsf{NC}^1 \subseteq (\mathsf{TC}^0)^{\mathsf{MCSP}}$ of [25], Corollary 5.1 yields the following.

▶ **Corollary 5.2.** $\mathsf{NC}^1 \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}$.

In fact, using the same techniques, we can prove something more general.

▶ **Theorem 5.3.** *Let $\mathcal{C} \subseteq \mathsf{P/poly}$ be any complexity class that has a complete problem under TC^0-computable reductions that is also random-self-reducible via a TC^0-computable reduction. Then we have*

$$\mathcal{C} \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}.$$

Proof sketch. It follows from [7] that any function $f \in \mathsf{P/poly}$ has a non-uniform $(\mathsf{TC}^0)^{\mathsf{MCSP}}$ circuit C of polynomial size that agrees with f on all but an inverse polynomial fraction of inputs. If f is random-self-reducible via a TC^0 reduction, we can recover from C a new polynomial-size $(\mathsf{TC}^0)^{\mathsf{MCSP}}$ circuit computing f exactly (on all inputs). Applying Corollary 5.1 concludes the proof. ◀

As the class GapL has Determinant as a complete problem under AC^0 reductions (see [1] for a survey on logspace counting complexity classes), we get the following.

▶ **Corollary 5.4.** $\mathsf{GapL} \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}$.[1]

The following is a non-uniform version of a similar "Karp-Lipton"-style "collapse" theorem from [14], which we state just for the class EXP.

▶ **Theorem 5.5.** *If* $\mathsf{EXP} \subseteq \mathsf{P/poly}$, *then* $\mathsf{EXP} \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}$.

Proof. Using TC^0-computable locally list-decodable binary codes of [10], we get that EXP contains a complete language that is random-self-reducible via a TC^0-computable reduction. We then appeal to Theorem 5.3. ◀

[1] The potentially bigger class DET is the class of languages that are NC^1-Turing reducible to computing the determinant of an integer matrix [8]. It is not immediately clear if $\mathsf{DET} \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}$. Perhaps, one can use the techniques of [5] who showed such a result for MKTP.

We do not know if MCSP is NP-complete. There is a line of research showing that MCSP (or its variants) can't be NP-complete under very restricted kinds of reductions (e.g., "local" reductions of [24]). One corollary of Theorem 5.5 is that it will be difficult to rule out non-uniform Turing AC^0 reductions from SAT to MCSP.

▶ **Corollary 5.6.** *If* $\mathsf{SAT} \notin (\mathsf{AC}^0)^{\mathsf{MCSP}}$*, then* $\mathsf{EXP} \not\subseteq \mathsf{P/poly}$.

Finally, while we don't know how to disprove that $\mathsf{MCSP} \in \mathsf{ACC}^0$, we get that at least some lower bound must be true.

▶ **Corollary 5.7.** *Either* $\mathsf{NEXP} \not\subseteq \mathsf{P/poly}$*, or* $\mathsf{MCSP} \notin \mathsf{ACC}^0$.

Proof. Towards a contradiction, suppose that both (1) $\mathsf{NEXP} \subseteq \mathsf{P/poly}$, and (2) $\mathsf{MCSP} \in \mathsf{ACC}^0$. By the Easy Witness Lemma of [15], (1) implies that $\mathsf{NEXP} = \mathsf{EXP}$. Then by Theorem 5.5, we get that $\mathsf{NEXP} \subseteq (\mathsf{AC}^0)^{\mathsf{MCSP}}$. Combining this with (2) yields that $\mathsf{NEXP} \subseteq \mathsf{ACC}^0$. But the latter contradicts the known lower bound of [32]. ◀

6 Generalizations

Here we show that, for a number of typical circuit classes $\mathcal{C}$, our lower bound proof (and a reduction from MAJORITY) works also for $\mathcal{C}$-MCSP. In particular, we will show that both AC^0-MCSP and Formula-MCSP require exponential $\mathsf{AC}^0[p]$ circuit lower bounds.

Our lower bound for MCSP used two main ingredients: (1) circuit size concentration for random (biased) boolean functions, and (2) a noticeable difference between most likely circuit sizes for uniformly random and biased boolean functions (where each bit of the truth table is 1 with a small constant probability, say 0.01).

For property (1), we note that the concentration argument only needs the Lipschitz property of a given circuit size measure, which comes from the fact that changing a boolean function on a single n-bit input may change the circuit size of the function by at most $O(n)$ additive term. This holds for virtually every reasonable circuit model, as the proof of Theorem 3.1 shows; there is a potential increase in depth for constant-depth circuits, but this can be avoided for the case where the circuit size is defined to be the total number of gates in the constant-depth circuit (see the proof of Corollary 6.2).

For property (2), we need a Shannon-style counting argument to show that most random n-variate functions have at least certain size S in a given circuit model $\mathcal{C}$, as well as a Lupanov-style argument that (most) boolean functions with very few (a small constant fraction α of) 1s have $\mathcal{C}$-circuit complexity at most some constant fraction δ of S, for some $0 < \delta < 1$ (dependent on α).

Property (2) is known for the case of boolean circuits, as implied by Lupanov's Theorem 2.2, and is known for formulas, by the work of Pippenger [26]. Moreover, it is possible to use the celebrated constructions of Lupanov, giving tight upper bounds for circuit complexity [19] and formula complexity [20] for all boolean functions, to show that biased random functions have relatively small circuits as well as small formulas (see the full version of this paper on ECCC for more details). However, we give a different argument (based on some hashing ideas) that will allow us to reduce the problem of showing small circuit complexity of a random biased boolean function to the known worst-case upper bounds for boolean function on fewer variables. Using such known worst-case upper bounds for the classes of circuits, formulas, and constant-depth circuits (counting the number of gates), we then obtain the required upper bounds for the circuit complexity of constant-biased random functions in these circuit models.

▶ **Theorem 6.1.** *Let $0 < \alpha < 1/2$ be any constant. For all but $o(1)$ fraction of α-biased n-variate random functions f, we have*

1. *circuit-size$(f) \leq O(\alpha \cdot \log 1/\alpha) \cdot \frac{2^n}{n}$,*
2. *(AC^0)-formula-size$(f) \leq O(\alpha \cdot \log 1/\alpha) \cdot \frac{2^n}{\log n}$, and*
3. *AC^0-circuit-size$(f) \leq O(\alpha \cdot \log 1/\alpha) \cdot 2^{n/2}$ (where consider the* gate complexity *of a given constant-depth circuit); moreover, the upper bound is for some fixed depth $d_0 > 0$ (independent of f).*

We omit the proof of Theorem 6.1 due to space constraints (see the full version of this paper on ECCC for more details).

Using Theorem 6.1, we conclude the following.

▶ **Corollary 6.2.** *Let $\mathcal{C}$ be the class of general circuits, or formulas, or constant-depth AC^0 circuits. For any prime $p \geq 2$ and any depth $d > 0$ and large enough input size $N = 2^n$, $\mathcal{C}$-MCSP on N-bit truth tables requires depth d $\mathsf{AC}^0[p]$ circuits of size at least $\exp(\Omega(N^{0.49/(d-1)}))$.*

Proof. As observed earlier, our lower bound proof for MCSP requires three ingredients: the Lipschitz property of the circuit complexity measure, a Shannon-style lower bound on the complexity measure for random n-variate boolean functions, and a $O(\alpha \log(1/\alpha))$ factor smaller upper bound on the complexity measure for random α-biased boolean functions (which can be made an arbitrary constant factor ϵ smaller than the corresponding Shannon-style upper bound by choosing the constant bias $\alpha > 0$ to be sufficiently small).

The Lipschitz property is easily seen to hold for both general circuits and formulas. For constant-depth circuits, where we count the number of gates, it also holds, provided the depth of our circuits is at least 3. We sketch the argument next.

We may assume that the circuit has alternating levels of ANDs and ORs, with negations on the bottom variables level. Without loss of generality, the top gate is an OR. (The other case is symmetric.) Case 1. We want to flip the value on $a \in \{0,1\}^n$ from 0 to 1. Add an AND of $x_i^{a_i}$'s, and feed this AND into the top OR gate. (Use just one extra gate.) Case 2: We want to flip from 1 to 0 on $a \in \{0,1\}^n$. Add an OR of $x_i^{1-a_i}$'s, and feed this OR into every AND-gate just one level below the top OR-gate. (Use just one extra gate.) Note that the depth doesn't change, if the original circuit is of depth $d \geq 3$.

The Shannon-style lower bounds for random n-variate functions are known for general circuits $\Omega(2^n/n)$, formulas $\Omega(2^n/(\log n))$, and constant-depth circuits $\Omega(2^{n/2})$ (see, e.g., [16]). Finally, Theorem 6.1 gives matching upper bounds for biased functions. The proof follows. ◀

7 Circuit lower bounds for MKTP via the coin problem

Here we show how to re-prove a known $\mathsf{AC}^0[p]$ circuit lower bound for MKTP [5], using the coin problem. This was the starting point in our attempt to prove an $\mathsf{AC}^0[p]$ lower bound for MCSP. For MKTP, we managed to show that biased random strings have a noticeably smaller KT complexity than that of uniformly random strings, where the bias $1/2 - \epsilon$ can be chosen for a sufficiently small ϵ so that we immediately get an $\mathsf{AC}^0[p]$ circuit lower bound for MKTP using Theorem 2.6. We provide the details next.

We first define the KT complexity [2]. Fix a universal random-access Turing machine U. The KT complexity of a string $x \in \{0,1\}^N$ is defined as the

$$\min\{|d| + t \mid \forall\, 0 \leq i \leq N+1 \;\; U^d(i) = x_i \text{ in at most } t \text{ steps}\},$$

and $x_{N+1} = \perp$. In other words, x can be computed at every position i in time at most t by a TM U that has random access to some binary string d, and we want to minimize the total sum of the length of such an auxiliary string d and the time bound t.

MKTP is then naturally defined as follows: Given $x \in \{0,1\}^N$ and a parameter s, decide if the KT complexity of x is at most s.

To prove a super-polynomial $\mathsf{AC}^0[p]$ circuit lower bound for MKTP via the coin problem approach (using Theorem 2.6), it would suffice to show that the MKTP oracle can distinguish between uniformly random N-bit strings and those where each bit is sampled, independently, with probability $1/2 - \epsilon$, for some $\epsilon \ll 1/\mathrm{poly}\log N$. We'll show how to do this for $\epsilon = N^{-\gamma}$, for some $\gamma > 0$ (in fact, for $\gamma \approx 1/6$).

What we need is to show that a random biased N-bit string can be compressed to have its KT complexity noticeably smaller than that of a uniformly random N-bit. Let $q = 1/2 - \epsilon$ be the probability for sampling each bit to be 1 in a random biased string. By standard concentration bounds, we know that a random biased N-bit string will have, with very high probability, the number of 1s very close to $K = qN$. For the simplicity of exposition, we will assume that our random biased strings have at most $K = qN$ ones in them. We then show that every N-bit string with (at most) K ones has its KT complexity much less than N, which is the lower bound on the KT complexity of a uniformly random N-bit string.

It is natural to think of an N-bit string with K ones as a subset of size K in the universe of size N. As there are exactly $\binom{N}{K}$ such subsets, the minimal bit complexity to represent any one of such subsets is $OPT = \log_2 \binom{N}{K}$. Such an information-theoretically optimal encoding of K-size subsets of the N-size universe is known, and is achieved by using the combinatorial number system where we represent each such subset by the unique number of the form

$$\binom{c_K}{K} + \cdots + \binom{c_2}{2} + \binom{c_1}{1}.$$

In more detail, suppose we have $x \in \{0,1\}^N$ where X has exactly K ones. For the base case, when $K = 0$, we output 0. For $K > 0$, we associate with x an integer number using the following recursive procedure: if $x_N = 1$, then output $\binom{N-1}{K} + R_1$, where R_1 is the recursively computed integer associated with $N-1$-bit prefix of x and the parameter $K-1$; if $x_N = 0$, then output R_0, which is the integer associated with the $N-1$-bit prefix of x and the parameter K.

Note that the final integer associated with a given K-size subset $x \in \{0,1\}^N$ has value at most $\binom{N}{K}$ (using Pascal's identity that $\binom{N}{K} = \binom{N-1}{K-1} + \binom{N-1}{K}$), and so has the optimal bit complexity. The encoding is efficient (as outlined above). The decoding is also efficient: given an integer B encoding some unknown K-size subset $x \in \{0,1\}^N$, if $B \geq \binom{N-1}{K}$, then set $x_N = 1$, and recursively decode $B - \binom{N-1}{K}$ for a $K-1$-size subset of the $N-1$-size universe; otherwise, set $x_N = 0$, and recursively decode B for a K-size subset of the $N-1$-size universe. The running time of such a decoding algorithm is clearly $\mathrm{poly}(N)$, and can be shown to be about $O(N^2)$.

For the KT complexity of a string $x \in \{0,1\}^N$ with K ones, we could define d to be the integer encoding this K-size subset, and then define $U^d(i)$ to be an algorithm that does the decoding of d to get all the bits of x. The problem with this is that the runtime to do a complete decoding of d into x is more than N, which is too much. However, the decoding we do is *global*, recovering all bits x_i simultaneously, whereas we just need to give a *local* decoding algorithm: given i, recover x_i.

Encoding

To get a locally decodable representation for our string $x \in \{0,1\}^N$, we partition x into blocks of size b (for b to be determined). For each block j, $1 \leq j \leq N/b$, let K_i be the number of ones in that block. Note that $\sum_{j=1}^{N/b} K_j = K$. Given K_j, encode each block j information-theoretically optimally as described above, using at most $\log_2 \binom{b}{K_j}$ bits. Write the resulting encodings of all blocks one after the other; add N/b pointers (of at most $\log N$ bits each) that point to the beginnings of the encodings of the blocks; add N/b numbers K_j's to the encoding. We get that the total bit size of the overall encoding of x is at most

$$O(N/b)(\log N + \log b) + \sum_{j=1}^{N/b} \lceil \log_2 \binom{b}{K_j} \rceil.$$

The latter sum is at most

$$\sum_{j=1}^{N/b} \log_2 \binom{b}{K_j} + N/b = \log_2 \prod_{j=1}^{N/b} \binom{b}{K_j} + N/b \leq \log_2 \binom{N}{K} + N/b,$$

since the number of sets with K_j ones in block j is at most the number of all subsets of $[N]$ with K ones. Overall, the encoding size is $OPT + O(N \log N/b)$.

Decoding

Given $i \in [N]$, we first figure out which block j it is in, and then decode that entire block (after looking up its number of ones in K_j and its compressed image). As discussed earlier, the decoding runs in time about $O(b^2)$.

Upper-bounding the KT complexity

To keep the KT complexity of x low, we choose b to be $N^{1/3}$. Then the KT complexity of x is at most $OPT + O(N^{2/3})$.

Finally, we show that $\mathsf{MKTP} \notin \mathsf{AC}^0[p]$ as follows. Recall that we consider random biased strings of length N where the bias probability is $q = 1/2 - \epsilon$. Let $K = qN$ be the expected number of ones in a typical biased string, and let's assume that most biased strings have at most K ones in them (for simplicity). We get that for such a biased string, its KT complexity is at most

$$\log_2 \binom{N}{K} + O(N^{2/3}) \approx H(q) \cdot N + O(N^{2/3}),$$

where H is the binary entropy function. For $q = 1/2 - \epsilon$, we can estimate $H(q) \approx 1 - O(\epsilon^2)$. Thus, to have the KT complexity of a typical q-biased N-bit string to be strictly less than N, we need $N \cdot O(\epsilon^2) - O(N^{2/3}) > 0$, which implies that we need $\epsilon > \Omega(N^{-1/6})$. This implies by Theorem 2.6 that MKTP on inputs of size N requires $\mathsf{AC}^0[p]$ circuits of depth d of size at least $\exp(\Omega(N^{1/6(d-1)}))$.

8 Open questions

We managed to find a work-around the lack of a tighter Lupanov-style upper bound on the circuit complexity of just slightly biased random functions where the bias probability is arbitrarily close to 1/2 (as opposed to the bias probability being a small constant bounded

away from 1/2). Our proof would be much more direct and constructive if we had such refinements of Lupanov's circuit upper bounds for biased boolean functions (since then we could have proceeded similarly to our proof for the MKTP case in the previous section). Can one prove such tighter circuit upper bounds?

Our current circuit lower bound applies to MCSP, but doesn't seem to apply for its average-case version, the Razborov-Rudich natural property [28]. Can one show such an extension?

Finally, we showed (Corollary 5.7) that either $\mathsf{NEXP} \not\subseteq \mathsf{P/poly}$ or $\mathsf{MCSP} \notin \mathsf{ACC}^0$. For the proof, we used the original Easy Witness Lemma of [15], the existence of random-self-reducible problems in EXP, plus the known lower bound that $\mathsf{NEXP} \not\subseteq \mathsf{ACC}^0$ [32]. Given the new Easy Witness Lemma and the improved circuit lower bound that $\mathsf{NQP} = \mathsf{NTIME}[n^{\mathrm{poly}\log n}] \not\subseteq \mathsf{ACC}^0$ [23], it is natural to ask the following: Can we show that either $\mathsf{NQP} \not\subseteq \mathsf{P/poly}$ or $\mathsf{MCSP} \notin \mathsf{ACC}^0$? Our current proof techniques rely on the existence of a random-self-reducible problem complete for EXP, and no such problem is known for the class NQP.

Abstract

We study the minimum-cost metric perfect matching problem under online i.i.d arrivals. We are given a fixed metric with a server at each of the points, and then requests arrive online, each drawn independently from a known probability distribution over the points. Each request has to be matched to a free server, with cost equal to the distance. The goal is to minimize the expected total cost of the matching.

Such stochastic arrival models have been widely studied for the *maximization* variants of the online matching problem; however, the only known result for the *minimization* problem is a tight $O(\log n)$-competitiveness for the random-order arrival model. This is in contrast with the adversarial model, where an optimal competitive ratio of $O(\log n)$ has long been conjectured and remains a tantalizing open question.

In this paper, we show that the i.i.d model admits substantially better algorithms: our main result is an $O((\log\log\log n)^2)$-competitive algorithm in this model, implying a strict separation between the i.i.d model and the adversarial and random order models. Along the way we give a 9-competitive algorithm for the line and tree metrics – the first $O(1)$-competitive algorithm for any non-trivial arrival model for these much-studied metrics.

1 Introduction

We study the minimum-cost metric (perfect) matching problem under online i.i.d. arrivals. In this problem, we are given a fixed metric (S, d) with a server at each of the $n = |S|$ points. Then n requests arrive online, where each request is at a location that is drawn independently from a known probability distribution $\mathcal{D}$ over the points. Each such arriving request has to be matched immediately and irrevocably to a free server, whereupon it incurs a cost equal to distance of its location to this server. The goal is to minimize the total expected cost.

The minimization version of online matching was first considered in the standard adversarial setting by Khuller et al. [25] and Kalyanasundaram and Pruhs [22]; both papers showed $(2n-1)$-competitive deterministic algorithms, and proved that this was tight for, say, the star metric. After about a decade, a randomized algorithm with an $O(\log^3 n)$-competitiveness was given by Meyerson et al. [30]; this was improved to $O(\log^2 n)$ by Bansal et al. [4], which remains the best result known. (Recall that the maximization version of matching problems have been very widely studied, but they use mostly unrelated techniques.)

The competitive ratio model with adversarial online arrivals is often considered too pessimistic, since it assumes an all-powerful adversary. One model to level the playing field, and to make the model perhaps closer to practice, is to restrict the adversary's power. Two models have been popular here: the *random-order arrivals* (or *secretary*) model, and the *i.i.d.* model defined above. The random-order model is a *semi-random* model, in which the worst-case input is subjected to random perturbations. Specifically, the adversary chooses a *set* of requests, which are then presented to the algorithm in a uniformly random order. The min-cost online matching problem in this random-order model was studied by Raghvendra, who gave a tight $O(\log n)$-competitive algorithm [35]. The random-order model also captures the i.i.d. setting, so the natural goal is to get a better algorithm for the i.i.d. model. Indeed, our main result for the i.i.d. model gives exactly such a result:

▶ **Theorem 1.1** (Main Theorem). *There is an $O((\log\log\log n)^2)$-competitive algorithm for online minimum-cost metric perfect matching in the i.i.d. setting.*

Observe that the competitiveness here is better than the lower bounds of $\Omega(\log n)$ known for the worst-case and random-order models.

Matching on the Line and Trees. There has also been much interest in solving the problem for the line metric. However, getting better results for the line than for general metrics has been elusive: an $O(\log n)$-competitive *randomized* algorithm for line metrics (and for doubling metrics) was given by [18]. In the *deterministic* setting, recently Nayyar and Raghvendra [34] gave an $O(\log^2 n)$-competitive algorithm, whose competitive ratio was subsequently proven to be $O(\log n)$ by Raghvendra [36], improving on the $o(n)$-competitive algorithm of Antoniadis et al. [2]. To the best of our knowledge, nothing better is known for tree metrics than for general metrics in both the adversarial and the random-order models. Our second result for the i.i.d. model is a constant-competitive algorithm for tree metrics.

▶ **Theorem 1.2** (Algorithm for Trees). *There is a 9-competitive algorithm for online minimum-cost metric perfect matching on tree metrics in the i.i.d. setting.*

Max-Weight Perfect Matching. Recently, Chang et al. [7] presented a $1/2$-competitive algorithm for the *maximum*-weight perfect matching problem in the i.i.d. setting. We show that our algorithm is versatile, and that a small change to our algorithm gives us a maximization variant matching this factor of $1/2$. Our approach differs from that of [7], in that we match an arriving request based on the realization of free servers, while they do so based on the "expected realization". See the full version for details.

1.1 Our Techniques

Both theorems 1.1 and 1.2 are achieved by the same algorithm. The first observation guiding this algorithm is that we may assume that the distribution $\mathcal{D}$ of request locations is just the uniform distribution on the server locations. (In the full version we show how this assumption can be removed with a constant factor loss in the competitiveness.) Our algorithm is inspired by the following two complementary consequences of the uniformity of $\mathcal{D}$.

- Firstly, each of the $n-t+1$ free servers' locations at time t are equally likely to get a request in the future, and as such they should be left unmatched with equal probability. Put otherwise, we should match to them with equal probability of $1/(n-t+1)$. However, matching *any* arriving request to any free server with probability $1/(n-t+1)$ is easily shown to be a bad choice.
- So instead, we rely on the second observation: the t^{th} request is equally likely to arrive at each of the n server locations. This means we can couple the matching of free server locations with the location of the next request, to guarantee a marginal probability of $1/(n-t+1)$ for each free server to be matched at time t.

Indeed, the constraints that each location is matched at time t with probability $1/n$ (i.e., if it arrives) and each of the free servers are matched with marginal probability $1/(n-t+1)$ can be expressed as a *bipartite flow* instance, which guides the coupling used by the algorithm. Loosely speaking, our algorithm is fairly intuitive. It finds a min-cost fractional matching between the current open server locations and the expected arrivals, and uses that to match new requests. The challenge is to bound the competitive ratio – in contrast to previously used approaches (for the maximization version of the problem) it does not just try to match vertices using a fixed template of choices, but rather dynamically recomputes a template after each arrival.

A major advantage of this approach is that we understand the distribution of the open servers. We maintain the invariant that after t steps, the set of free servers form a uniform random $(n-t)$-subset of $[n]$ – the randomness being over our choices, and over the randomness of the input. This allows us to relate the cost of the algorithm in the t^{th} step to the expected cost of this optimal flow between the original n points and a uniformly random subset of $(n-t)$ of these points. The latter expected cost is just a statistic based on the metric, and does not depend on our algorithm's past choices. For paths and trees, we bound this quantity explicitly by considering the variance across edge-cuts in the tree – this gives us the proof of Theorem 1.2.

Since general metrics do not have any usable cut structure, we need a different idea for Theorem 1.1. We show that tree-embedding results can be used either explicitly in the algorithm or just implicitly in the proof, but both give an $O(\log n)$ loss. To avoid this loss, we use a different balls-and-bins argument to improve our algorithm's competitiveness to $O((\log\log n))^2)$. In particular, we provide better bounds on our algorithm's per-step cost in terms of $\mathbb{E}[OPT]$ and the expected load of the k most loaded bins in a balls and bins process, corresponding to the number of requests in the k most frequently-requested servers. Specifically, we show that $\mathbb{E}[OPT]$ is bounded in terms of the expected *imbalance* between the number of requests and servers in these top k server locations. Coupling this latter uniform k-tuple with the uniform k-tuple of free servers left by our algorithm, we obtain our improved bounds on the per-step cost of our algorithm in terms of $\mathbb{E}[OPT]$ and these bins' load, from which we obtain our improved $O((\log\log n)^2)$ competitive ratio. Interestingly, combining both balls and bins and tree embedding bounds for the per-step cost of step k (appealing to different bounds for different ranges of k) gives us a further improvement: we prove that our algorithm is $O((\log\log\log n)^2)$ competitive.

1.2 Further Related Work

I.i.d. stochastic arrivals have been studied for various online problems, e.g., for Steiner tree/forest [15], set cover [17], and k-server [9]. Closer to our work, stochastic arrivals have been widely studied in the online matching literature, though so far mostly for maximization variants. Much of this work was motivated by applications to online advertising, for which the worst-case optimal $(1 - 1/e)$-competitive ratios [24, 29, 1] seem particularly pessimistic, given the financial incentives involved and time-learned information about the distribution of requests. Consequently, many stochastic arrival models have been studied, and shown to admit better than $1 - 1/e$ competitive guarantees. The stochastic models studied for online matching and related problems, in increasing order of attainable competitive ratios, include random order (e.g., [16, 23, 27]), unknown i.i.d. – where the request distribution is unknown – (e.g., [10, 31]), and known i.i.d. (e.g., [13, 3, 6]). Additional work has focused on interpolating between adversarial and stochastic input (e.g., [11, 26]). See Mehta's survey [28] and recent work [8, 19, 21, 20, 14, 33] for more details. The long line of work on online matching, both under adversarial and stochastic arrivals, have yielded a slew of algorithmic design ideas, which unfortunately do not seem to carry over to minimization problems, nor to perfect matching problems.

As mentioned above, the only prior work for stochastic online matching with minimization objectives was the random order arrival result of Raghvendra [35]. We are hopeful that our work will spur further research in online minimum-cost perfect matching under stochastic arrivals, and close the gap between our upper bounds and the (trivial) lower bounds for the problem.

2 Our Algorithm

In this section we present our main algorithm, together with some of its basic properties. Throughout the paper we assume that the distribution over request locations is uniform over the n servers' locations. We show in the full version that this assumption is WLOG: it increases the competitive ratio by at most a constant. In particular, we show the following.

▶ **Lemma 2.1.** *Given an α-competitive algorithm $\mathrm{ALG}_{\mathcal{U}}$ for the* uniform *distribution over server locations, $\mathcal{U}$, we can construct a $(2\alpha + 1)$-competitive algorithm $\mathrm{ALG}_{\mathcal{D}}$ for any distribution $\mathcal{D}$.*

Focusing on the uniform distribution over server locations, our algorithm is loosely the following: in each round of the algorithm, we compute an optimal fractional matching between remaining free servers and remaining requests (in expectation). Now when a new request arrives, we just match the newly-arrived request according to this matching.

2.1 Notation

Our analysis will consider k-samples from the set $S = [n]$ both with and without replacement. We will set up the following notation to distinguish them:

- Let $\mathcal{I}_k$ be the distribution over k-sub-multisets of $S = [n]$ obtained by taking k i.i.d. samples from the uniform distribution over S. (E.g., $\mathcal{I}_n$ is the request set's distribution.)
- Let $\mathcal{U}_k$ be the distribution over k-subsets of S obtained by picking a uniformly random k-subset from $\binom{S}{k}$.

In other words, $\mathcal{I}_k$ is the distribution obtained by picking k elements from S uniformly *with* replacement, whereas $\mathcal{U}_k$ is *without* replacement.

For a sub-(multi)set $T \subseteq S$ of servers, let $M(T)$ denote the optimal fractional min-cost b-matching in the bipartite graph induced between T and the set of all locations S, with overall unit capacity on either side. That is, the capacity for each node in T is $1/|T|$ and the capacity for each node in S is $1/n$. So, if we denote by $d_{i,j}$ the distance between locations i and j, we let $M(T)$ correspond to the following linear program.

$$M(T) := \min \sum_{i \in T, j \in S} d_{i,j} \cdot x_{i,j} \qquad (M(\cdot))$$

$$\text{s.t.} \sum_{j \in S} x_{i,j} = \tfrac{1}{|T|} \qquad \forall i \in T$$

$$\sum_{i \in T} x_{i,j} = \tfrac{1}{n} \qquad \forall j \in S$$

$$x \geq 0$$

We emphasize that in the above LP, several servers in S (and likewise in T) may happen to be at the same point in the metric space, and hence there is a separate constraint for each such point j (and likewise i). Slightly abusing notation, we let $M(T)$ denote both the LP and its optimal value, when there is no scope for confusion.

2.2 Algorithm Description

The algorithm works as follows: at each time k, if $S_k \subseteq S$ is the current set of free servers, we compute the fractional assignment $M(S_k)$, and assign the next request randomly according to it. As argued above, since each free server location is equally likely to receive a request later (and therefore it is worth not matching it), it seems fair to leave each free server unmatched with equal probability. Put otherwise, it is only fair to match each of these servers with equal probability. Of course, matching any arriving request to a free server chosen uniformly at random can be a terrible strategy. In particular, it is easily shown to be $\Omega(\sqrt{n})$-competitive for n servers equally partitioned among a two-point metric. Therefore, to obtain good expected matching cost, we should bias servers' matching probability according to the arrived request, and in particular we should bias it according to $M(S_k)$. This intuition guides our algorithm FAIR-BIAS, and also inspires its name.

Algorithm 1 FAIR-BIAS.

$S_n \leftarrow S$. ▷ *S_k is the set of free servers, with $|S_k| = k$.*
for time step $k = n, n-1, \cdots, 1$ **do**
  compute optimal fractional matching $M(S_k)$, denoted by x^{S_k}.
  upon arrival of request $r_k = r$ **do**
    randomly choose server s from S_k, where s_i is chosen w/prob. $p_i = n \cdot x^{S_k}_{s_i,r}$.
    assign r to s.
  end event
  $S_{k-1} \leftarrow S_k \setminus \{s\}$.
end for

A crucial property of our algorithm is that the set S_k of free servers at each time k happens to be a uniformly random k-subset of S. Recall that FAIR-BIAS assigns each arriving request according to the assignment $M(S_k)$. This means that to analyze the algorithm, it suffices to relate the optimal assignment cost OPT to the optimal assignment costs for uniformly random subsets S_k, as follows.

▶ **Lemma 2.2** (Structure Lemma). *For each time k, the set S_k is a uniformly-drawn k-subset of S; i.e., $S_k \sim \mathcal{U}_k$. Consequently, the algorithm's cost is*

$$\mathbb{E}[ALG] = \sum_{k=1}^{n} \mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)].$$

Proof. The proof of the first claim is a simple induction from n down to 1. The base case of S_n is trivial. For any k-subset $T = \{s_1, \cdots, s_k\} \subseteq S$,

$$\begin{aligned}\Pr[S_k = T] &= \sum_{s \in S \setminus T} \Pr[S_{k+1} = T \cup \{s\}] \cdot \Pr[r_{k+1} \text{ assigns to } s \mid S_{k+1} = T \cup \{s\}] \\ &= (n-k) \cdot \frac{1}{\binom{n}{k+1}} \cdot \frac{1}{k+1} = \frac{1}{\binom{n}{k}},\end{aligned}$$

where the second equality follows from induction and the fact that

$$\Pr[r_{k+1} \text{ assigned to } s \mid S_{k+1} = T \cup \{s\}] = \sum_{r \in S} x_{s,r}^{S_{k+1}} = \frac{1}{k+1}.$$

To compute the algorithm's cost, we consider some set $S_k = T$ of k free servers. Since the request $r_k = r$ is chosen with probability $1/n$, following which we match it to some free server $s \in S_k$ with probability $n \cdot x_{s,r}^{S_k}$, we find that the next edge matched by the algorithm has expected cost

$$\mathbb{E}[d_{s,r_k} \mid S_k = T] = \sum_{r} \frac{1}{n} \cdot \sum_{s \in T} n \cdot x_{s,r}^{T} \cdot d_{s,r} = M(T).$$

Therefore, the expected cost of the algorithm is indeed

$$\begin{aligned}\mathbb{E}[ALG] &= \sum_{k=1}^{n} \mathbb{E}[d_{s,r_k}] = \sum_{k=1}^{n} \sum_{T \in \binom{S}{k}} \Pr_{S_k \sim \mathcal{U}_k}[S_k = T] \cdot \mathbb{E}[d_{s,r_k} \mid S_k = T] \\ &= \sum_{k=1}^{n} \sum_{T \in \binom{S}{k}} \Pr_{S_k \sim \mathcal{U}_k}[S_k = T] \cdot M(T) = \sum_{k=1}^{n} \mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)].\end{aligned}$$

◀

The structure lemma implies that we may assume from now on that the set of free servers S_k is drawn from $\mathcal{U}_k$. In what follows, unless stated otherwise, we have $S_k \sim \mathcal{U}_k$. More importantly, Lemma 2.2 implies that to bound our algorithm's competitive ratio by α, it suffices to show that $\sum_k \mathbb{E}[M(S_k)] \leq \alpha \cdot \mathbb{E}[\text{OPT}]$. This is exactly the approach we use in the following sections.

3 Bounds for General Metrics

In Section 4 we will show that algorithm FAIR-BIAS is $O(1)$-competitive for line metrics (and more generally tree metrics), by relying on variance bounds of the number of matches across tree edges in OPT and $M(S_k)$, our algorithm's guiding LP. For general metrics, if we first embed the metric in a low-stretch tree metric [12] (blowing up the expected cost of $\mathbb{E}[\text{OPT}]$ by $O(\log n)$) and run algorithm FAIR-BIAS on the obtained metric, we immediately obtain an $O(\log n)$-competitive algorithm. In fact, explicitly embedding the input metric in a tree metric is not necessary in order to obtain this result using our algorithm. By relying on an *implicit* tree embedding, we obtain the following lemma (mirroring the variance-based bound underlying our result for tree metrics). This lemma's proof is deferred to the full version.

▶ **Lemma 3.1.** $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq \frac{O(\log n)}{\sqrt{nk}} \cdot \mathbb{E}[\text{OPT}]$.

Summing over all values of $k \in [n]$, we find that FAIR-BIAS is $O(\log n)$-competitive on general metrics. While this bound is no better than that of Raghvendra's t-net algorithm for random order arrival [35] (and therefore for i.i.d arrivals), the result will prove useful in our overall bound for our algorithm. In Sections 3.1 and 3.2, we use a different balls-and-bins argument to decrease our bounds on the algorithm's competitive ratio considerably, to $O((\log\log n))^2)$, by considering the imbalance between number of requests and servers in the top k most requested locations. (The former quantity corresponds to the load of the k most loaded bins in a balls and bins process – motivating our interest in this process.) Finally, in Section 3.3, we combine this improved bound with the one from Lemma 3.1, summing different bounds for different ranges of k, to prove our main result: an $O((\log\log\log n)^2)$ bound for our algorithm's competitive ratio.

3.1 Balls and Bins: The Poisson Paradigm

For our results, we need some technical facts about the classical balls-and-bins process.

The following standard lemma from [32, Theorem 5.10] allows us to use the Poisson distribution to approximate monotone functions on the bins. For $i \in [n]$, let X_i^m be a random variable denoting the number of balls that fall into the i^{th} bin, when we throw m balls into n bins. Let Y_i^m be independent draws from the Poisson distribution with mean m/n.

▶ **Lemma 3.2.** *Let $f(x_1, \cdots, x_n)$ be a non-negative function such that $\mathbb{E}[f(X_1^m, \cdots, X_n^m)]$ is either monotonically increasing or decreasing with m, then*

$$\mathbb{E}[f(X_1^m, \cdots, X_n^m)] \leq 2 \cdot \mathbb{E}[f(Y_1^m, \cdots, Y_n^m)].$$

A classic result states that for $m = n$ balls, the maximum bin load is $\Theta(\log n / \log\log n)$ w.h.p. (see e.g., [32]). The following lemma is a partial generalization of this result. Its proof, which relies on the Poisson approximation of Lemma 3.2, is deferred to the full version.

▶ **Lemma 3.3.** *Let n balls be thrown into n bins, each ball thrown independently and uniformly at random. Let L_j be the load of the j^{th} heaviest bin, and $N_k := \sum_{j \leq k} L_j$ be the number of balls in the k most loaded bins. There exists a constant $C_0 > 0$ such that for any $k \leq C_0 n$,*

$$\mathbb{E}[N_k] \geq \Omega\left(k \cdot \frac{\log(n/k)}{\log\log(n/k)}\right).$$

In the next lemma, whose proof is likewise deferred to the full version, we rely on a simple Chernoff bound to give a weaker lower bound for $\mathbb{E}[N_k]$ that holds for all $k \leq n/2$.

▶ **Lemma 3.4.** *For sufficiently large n and any $k \leq n/2$, we have $\mathbb{E}[N_k] \geq 1.5k$.*

3.2 Relating Balls and Bins to Stochastic Metric Matching

We now bound the expected cost incurred by FAIR-BIAS at time k by appealing to the above balls-and-bins argument; this will give us our stronger bound of $O((\log\log n)^2)$. Specifically, we will derive another lower bound for $\mathbb{E}[\text{OPT}]$ in terms of $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$. In our bounds we will partition the probability space $\mathcal{I}_n$ (corresponding to n i.i.d. requests) into disjoint parts, based on $\mathbb{T}_k$, the top k most frequently requested locations (with ties broken uniformly at random). By symmetry, $\Pr[\mathbb{T}_k = T] = 1/\binom{n}{k}$ for all $T \in \binom{S}{k}$. By coupling $\mathbb{T}_k$ with $\mathcal{U}_k$, we will lower-bound $\mathbb{E}[OPT]$ by $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$ times $\mathbb{E}[N_k] - k$, the expected imbalance between number of requests and servers in $\mathbb{T}_k$. Here $\mathbb{E}[N_k]$ is the expected occupancy of the k most loaded bins in the balls and bins process discussed in Section 3.1.

To relate $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$ to $M(S_k)$, we will bound both these quantities by the cost of a min-cost perfect b-matching between S_k and $S \setminus S_k$; i.e., each vertex v has some (possibly fractional) demand b_v which is the extent to which it must be matched. To this end, we need the following simple lemma, which asserts that for any min-cost metric b-matching instance, there exists an optimal solution which matches co-located servers and requests maximally. We defer the lemma's proof, which follows from a local change argument and triangle inequality, to the full version.

▶ **Lemma 3.5.** *Let $\mathcal{I}$ be a fractional min-cost bipartite metric b-matching instance, with demand ℓ_i and r_i for the servers and requests at location i. Then, there exists an optimal solution x for $\mathcal{I}$ with $x_{ii} = \min\{\ell_i, r_i\}$ for every point i in the metric.*

We are now ready to prove our main technical lemma, lower-bounding $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$ in terms of $M(S_k)$ and the imbalance between number of requests of the k most requested locations, N_k, and the number of servers in those locations.

▶ **Lemma 3.6.** *For all $k < n$ and $S_k \in \binom{S}{k}$, we have $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k] \geq (\mathbb{E}[N_k] - k) \cdot M(S_k)$.*

Proof. Applying Lemma 3.5 to $M(S_k)$, we find that the optimal value of $M(S_k)$ is equal to that of a min-cost bipartite perfect b-matching instance with left vertices associated with S_k, each with demand $\frac{1}{k} - \frac{1}{n}$, and right vertices associated with $S \setminus S_k$, each with demand $\frac{1}{n}$.

We now turn to the meat of the proof – lower bounding $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$. In particular, we will lower bound $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$ by a min-cost bipartite perfect b-matching instance with left and right vertices as above (i.e., S_k and $S \setminus S_k$, respectively), but with uniform demands on both sides of at least $(\mathbb{E}[N_k] - k)/k$ and $(\mathbb{E}[N_k] - k)/(n - k)$, respectively. That is, the biregular min-cost bipartite b-matching whose cost C we showed lower bounds $M(S_k)$, but scaled by an $f \geq \frac{(\mathbb{E}[N_k] - k)}{k \cdot (1/k - 1/n)}$ factor. Before proving this lower bound on $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$, we note that it implies our desired bound, as

$$\mathbb{E}[\mathrm{OPT} \mid \mathbb{T}_k = S_k] \geq \frac{(\mathbb{E}[N_k] - k)}{k \cdot (1/k - 1/n)} \cdot C > (\mathbb{E}[N_k] - k) \cdot C = (\mathbb{E}[N_k] - k) \cdot M(S_k).$$

It remains to lower bound $\mathbb{E}[OPT \mid \mathbb{T}_k = S_k]$ in terms of such a biregular b-matching instance.

For the remainder of this proof, for notational simplicity we denote by Ω the probability space induced by conditioning on the event $\mathbb{T}_k = S_k$. To lower bound $\mathbb{E}_\Omega[OPT]$, we will provide a fractional perfect matching $\vec{x}$ of the expected instance (in Ω), and show that $\mathbb{E}_\Omega[OPT] \geq \sum_{ij} d_{ij} \cdot x_{ij}$, while $\sum_{j \in S \setminus S_k} x_{ij} \geq (\mathbb{E}[N_k] - k)/k$ for all $i \in S_k$ and $\sum_{i \in S} x_{ij} \geq (\mathbb{E}[N_k] - k)/(n - k)$ for all $j \in S \setminus S_k$. Consequently, focusing on edges $(i, j) \in S_k \times (S \setminus S_k)$, we find that the min-cost biregular bipartite perfect b-matching above lower bounds $\sum_{i \in S_k, j \in S \setminus S_k} d_{ij} \cdot x_{ij} \leq \sum_{ij} d_{ij} \cdot x_{ij} \leq \mathbb{E}_\Omega[OPT]$. We now turn to producing an $\vec{x}$ satisfying our desired properties.

For any two locations $i, j \in S$, we let $(i, j) \in OPT$ indicate that a request in location i is served by the server in location j. Let $p_{ij} := \Pr_\Omega[(i, j) \in OPT]$. We will show how small modifications to $\vec{p}$ will yield a fractional perfect matching $\vec{x}$ as discussed in the previous paragraph. Let Y_i be the number of requests at server i. By Lemma 3.5, we know that $(i, i) \in OPT \iff Y_i \geq 1$. So, $p_{ii} = \Pr_\Omega[Y_i \geq 1]$. Consequently, if we let $\Delta_{in}(j) := \sum_{j' \in S \setminus \{j\}} p_{j'j}$ and $\Delta_{out}(j) := \sum_{j' \in S \setminus \{j\}} p_{jj'}$, we have by Lemma 3.5 that $\Delta_{in}(j) = \Pr[Y_i \geq 1]$ and $\Delta_{out}(i) = \mathbb{E}[(Y_i - 1)^+]$ for all $i \in S$. (As usual, $x^+ = \max\{x, 0\}$.) Consequently, $\Delta_{in}(j) = \Delta_{in}(j')$ and $\Delta_{out}(j) = \Delta_{out}(j')$ for all $j, j' \in S \setminus S_k$, as $[Y_j \mid \Omega]$ and $[Y'_j \mid \Omega]$ are identically distributed. Moreover, as $\sum_{j \in S \setminus S_k} (\Delta_{in}(j) - \Delta_{out}(j)) = N_k - k \geq 0$, we find that $\Delta_{in}(j) - \Delta_{out}(j) \geq 0$ for all $j \in S \setminus S_k$. Now, suppose $Y_i \geq 1$ for all $i \in S_k$

(conditioning on the complementary event is similar), we have by Lemma 3.5 that $p_{ji} = 0$ for all $i \in S_k$ and $j \in S \setminus \{i\}$. Moreover, by symmetry we have $\Delta_{out}(i) = (\mathbb{E}[N_k] - k)/k$ for all k locations $i \in S_k$. We now show how to obtain from $\vec{p}$ a fractional matching $\vec{x}$ between S_k and $S \setminus S_k$ of no greater cost than $\vec{p}$, such that $p_{jj'} = 0$ for all $j \neq j' \in S \setminus S_k$ and such that the values $\Delta_{in}(j) - \Delta_{out}(j)$ are unchanged for all $j \in S$. Consequently, all (simple) edges in the support of $\vec{x}$ go between S_k and $S \setminus S_k$, and $\Delta_{out}(i) = (\mathbb{E}[N_k] - k)/k$ for all $i \in S_k$ and $\Delta_{in}(j) = (\mathbb{E}[N_k] - k)/(n - k)$ for all $j \in S \setminus S_k$, yielding our desired lower bound on $\mathbb{E}_\Omega[OPT]$ in terms of a biregular bipartite b-matching instance.

We start by setting $\vec{x} \leftarrow \vec{p}$. While there exists a pair $j \neq j' \in S \setminus S_k$ with $x_{j'j} > 0$, we pick such a pair. As $\Delta_{in}(j) - \Delta_{out}(j) \geq 0$, there must also be some flow coming into j. We follow a sequence of edges $j_1 \leftarrow j_2 \leftarrow j_3 \leftarrow \dots$ with each $j_r \in S \setminus S_k$ and with $x_{j_r j_{r-1}} > 0$ until we either repeat some $j_r \in S \setminus$ or reach some j_r with $x_{ij_r} 0$ for some $i \in S$. (Note that one such case must happen, as $\Delta_{in}(j) - \Delta_{out}(j) \geq 0$ for all $j \in S \setminus S_k$.) If we repeat a vertex, j_r, we only consider the sequence of nodes given by the obtained cycle, $j_1 \leftarrow j_2 \leftarrow j_3 \cdots \leftarrow j_r = j_1$. Let $\epsilon = \min_r x_{j_r j_{r-1}}$ be the smallest $x_{jj'}$ in our trail. If we repeated a vertex, we found a cycle, and we decrease $x_{jj'}$ by ϵ for all consecutive j, j' in the cycle. If we found some $i \in S$ and $x_{ij_r} > 0$, we decrease all $x_{jj'}$ values along the path (including x_{ij_r}) by ϵ and increase x_{ij_1} by ϵ. In both cases, we only decrease the cost of $\vec{x}$ (either trivially, or by triangle inequality) and we do not change $\Delta_{in}(j) - \Delta_{out}(j)$ for any $j \in S$, while decreasing $\sum_{j \neq j' \in S \setminus S_k} x_{jj'}$. As the initial x-values are all rational, repeating the above terminates, with the above sum equal to zero, which implies a biregular fractional solution $\vec{x}$ as required. The lemma follows. ◀

Coupling the distribution of $\mathbb{T}_k$ and the set of k free servers, we obtain the following.

▶ **Lemma 3.7.** $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq \mathbb{E}[\text{OPT}]/(\mathbb{E}[N_k] - k)$.

Proof. Taking expectations over $S_k \sim \mathcal{U}_k$, we obtain our claimed bound.

$$\begin{aligned}
\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] &= \sum_{S_k \in \binom{S}{k}} \frac{1}{\binom{n}{k}} \cdot M(S_k) && \text{defn. of } \mathcal{U}_k \\
&\leq \sum_{S_k \in \binom{S}{k}} \frac{1}{\binom{n}{k}} \frac{1}{(\mathbb{E}[N_k] - k)} \cdot \mathbb{E}[\text{OPT} \mid \mathbb{T}_k = S_k] && \text{Lemma 3.6} \\
&= \frac{1}{(\mathbb{E}[N_k] - k)} \cdot \mathbb{E}[\text{OPT}]. && \Pr[\mathbb{T}_k = S_k] = \frac{1}{\binom{n}{k}}. \quad ◀
\end{aligned}$$

Plugging in the lower bounds of Lemmas 3.3 and 3.4 for the top k most loaded bins' loads, $\mathbb{E}[N_k]$, we obtain the following bounds on FAIR-BIAS's per-step cost in terms of $\mathbb{E}[OPT]$.

▶ **Lemma 3.8.** *For C_0 a constant as in Lemma 3.3, there exists a constant C such that*

$$\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq \begin{cases} C \cdot \frac{\log\log(n/k)}{k \log(n/k)} \cdot \mathbb{E}[\text{OPT}] & \text{if } k < C_0 n \\ \frac{2}{k} \cdot \mathbb{E}[\text{OPT}] & \text{if } C_0 n \leq k \leq n/2. \end{cases}$$

The following lemma allows us to leverage Lemma 3.8, as it allows us to focus on $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$ for $k \leq n/2$. Its proof relies on our characterization of $M(S_k)$ in terms of a balanced b-matching instance between S_k and $S \setminus S_k$ as in the proof of Lemma 3.6, which implies that $M(S_k) \leq M(S_{n-k})$ for all $k \leq n/2$. Its proof is deferred to the full version.

▶ **Lemma 3.9.** $\sum_{k=1}^{n} \mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq 2 \cdot \sum_{k=1}^{n/2} \mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$.

Using our upper bound on $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$ of Lemma 3.8 and summing the two ranges of $k \leq n/2$ in Lemma 3.9 we find that FAIR-BIAS is $O((\log\log n)^2)$ competitive. We do not elaborate on this here, as we obtain an even better bound in the following section.

3.3 Our Main Result

We are now ready to prove our main result, by combining our per-step cost bounds given by our balls and bins argument (Lemma 3.8) and our implicit tree embedding argument (Lemma 3.1).

▶ **Theorem 3.10.** *Algorithm* FAIR-BIAS *is* $O((\log\log\log n)^2)$*-competitive for the online bipartite metric matching problem under i.i.d arrivals on general metrics.*

Proof. By the structure lemma (Lemma 2.2) and Lemma 3.9, we have that

$$\mathbb{E}[ALG] = \sum_{k=1}^{n} \mathbb{E}_{S_k\sim\mathcal{U}_k}[M(S_k)] \le 2\cdot\sum_{k=1}^{n/2} \mathbb{E}_{S_k\sim\mathcal{U}_k}[M(S_k)]. \tag{1}$$

We use the three bounds from Lemma 3.1 and Lemma 3.8 for different ranges of k to bound the above sum. Specifically, by relying on Lemma 3.1 for $k \le n/\log^2 n$, we have that

$$\begin{aligned}\sum_{k=1}^{n/\log^2 n} \mathbb{E}_{S_k\sim\mathcal{U}_k}[M(S_k)] &\le \sum_{k=1}^{n/\log^2 n} \frac{O(\log n)}{\sqrt{nk}}\cdot\mathbb{E}[OPT] \\ &\le O\left(\sqrt{\frac{n}{\log^2 n}}\cdot\frac{\log n\cdot\mathbb{E}[OPT]}{\sqrt{n}}\right) = O(1)\cdot\mathbb{E}[OPT].\end{aligned}$$

Next, by the first bound of Lemma 3.8 applied to $k \in [n/\log^2 n, C_0 n]$, we have that

$$\begin{aligned}\sum_{k=n/\log^2 n}^{C_0 n} \mathbb{E}_{S_k\sim\mathcal{U}_k}[M(S_k)] &\le \sum_{k=n/\log^2 n}^{C_0 n} \frac{O(\log\log(n/k))}{k\cdot\log(n/k)}\cdot\mathbb{E}[OPT] \\ &\le O\left(-(\log\log(n/k))^2\Big|_{n/\log^2 n}^{C_0 n}\right)\cdot\mathbb{E}[OPT] \\ &= O((\log\log\log n)^2)\cdot\mathbb{E}[OPT].\end{aligned}$$

Finally, by the second bound of Lemma 3.8 applied to $k \ge C_0 n$, we have that

$$\sum_{k=C_0 n}^{n/2} \mathbb{E}_{S_k\sim\mathcal{U}_k}[M(S_k)] \le \sum_{C_0 n}^{n/2} \frac{2}{k}\cdot\mathbb{E}[OPT] \le O\left(\log\left(\frac{n/2}{C_0 n}\right)\right)\cdot\mathbb{E}[OPT] = O(1)\cdot\mathbb{E}[OPT].$$

Combining all three bounds with Equation (1), the theorem follows. ◀

4 A Simple $O(1)$ Bound for Tree Metrics

In this section we show the power of the structure lemma, by analyzing FAIR-BIAS on tree metrics. Recall that a *tree metric* is defined by shortest-path distances in a tree $T = (V, E)$, with edge lengths d_e. By adding zero-length edges, we may assume that the tree has n leaves, and that servers are on the leaves of the tree. For any edge e in the tree, deleting this edge creates two components $T_1(e)$ and $T_2(e)$; denote by $T_1(e)$ the component with fewer servers/leaves. Let n_e denote the number of leaves on this smaller side, $T_1(e)$. Hence $n_e \le n/2$ for all edges e.

We now lower bound $\mathbb{E}[\mathrm{OPT}]$, by considering the mean average deviation of the number of requests which arrive in $T_1(e)$ for each edge e.

▶ **Lemma 4.1.** *The expected optimal matching cost in a tree metric on* $n \ge 2$ *vertices is at least* $\mathbb{E}[\mathrm{OPT}] \ge \frac{1}{2}\cdot\sum_{e\in T} d_e\cdot\sqrt{n_e}$.

Proof. Let X_e denote the number of requests that arrive in the component with fewer leaves, $T_1(e)$. Every matching will match at least $|X_e - n_e| = |X_e - \mathbb{E}[X_e]|$ requests across the edge e (with the equality due to the uniform IID arrivals). Summing over all edges and taking expectations, we find that

$$\mathbb{E}[\text{OPT}] \geq \sum_e d_e \cdot \mathbb{E}\big[|X_e - n_e|\big] = \sum_e d_e \cdot \mathbb{E}\big[|X_e - \mathbb{E}[X_e]|\big]. \tag{2}$$

It remains to lower bound $\mathbb{E}[|X_e - \mathbb{E}[X_e]|]$, the mean average deviation of X_e. Observe that $X_e \sim \text{Bin}(n, n_e/n)$, with $n_e \in [1, n-1]$. The following probabilistic bound appears in [5, Theorem 1]:

▶ **Claim 4.2.** *Let $Y \sim Bin(n,p)$, with $n \geq 2$ and $p \in [1/n, 1-1/n]$. Then, we have both*

$$\mathbb{E}|Y - \mathbb{E}Y| \geq \text{std}(Y)/\sqrt{2},$$

(Note that convexity implies that $\mathbb{E}|Y - \mathbb{E}Y| \leq \text{std}(Y)$ holds for all distributions, so this is a partial converse.) Applying Claim 4.2 to our case, where $p = n_e/n \in [1/n, 1-1/n]$,

$$\mathbb{E}[|X_e - \mathbb{E}X_e|] \geq \text{std}(X_e)/\sqrt{2} = \sqrt{n_e(1-n_e/n)/2} \geq \sqrt{n_e/4},$$

where the second inequality follows from $n_e \leq n/2$. Combined with (2), the lemma follows. ◀

To upper bound $\mathbb{E}[M(S_k)]$, we again consider the mean average deviation of the number of requests in $T_1(e)$, but this time when drawing k *i.i.d.* samples. First, we need to bound the cost of $M(S_k)$ for a set S_k resulting from k draws *without replacement* by the cost for a multiset obtained by taking k i.i.d. draws *with replacement*.

▶ **Lemma 4.3.** *(Replacement Lemma) For all S and $k \in [|S|]$, we have*

$$\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq \mathbb{E}_{S_k \sim \mathcal{I}_k}[M(S_k)].$$

We defer the proof of this lemma to the full version, where we prove a more general statement regarding stochastic convex optimization with constraints and coefficients determined by elements of a set chosen uniformly with and without replacement. Armed with this lemma, it suffices to bound $\mathbb{E}_{S_k \sim \mathcal{I}_k}[M(S_k)]$ from above, which we do in the following.

▶ **Lemma 4.4.** $\mathbb{E}_{S_k \sim \mathcal{I}_k}[M(S_k)] \leq \sum_{e \in T} d_e \cdot \sqrt{n_e/(kn)}$.

Proof. Fix some edge e and let $T_1(e)$ be its smaller subtree, containing $n_e \leq n/2$ leaves. Let $X_e \sim \text{Bin}(k, n_e/n)$ be the random variable denoting the number of servers in $T_1(e)$ chosen in k i.i.d samples from S. For any given realization of S_k (and therefore of X_e) the fractional solution to $M(S_k)$ utilizes edges between the different subtrees of e by exactly $|X_e/k - n_e/n|$. Since this is a tree metric, we have

$$M(S_k) = \sum_{e \in T} d_e \cdot \left| \frac{X_e}{k} - \frac{n_e}{n} \right| = \sum_{e \in T} d_e \cdot \frac{1}{k} \cdot \left| X_e - \frac{k}{n} \cdot n_e \right| = \sum_{e \in T} d_e \cdot \frac{1}{k} \cdot |X_e - \mathbb{E}[X_e]|.$$

Taking expectations over S_k, and using the fact that the mean average deviation is always upper bounded by the standard deviation (by Jensen's inequality), we find that indeed

$$\begin{aligned} \mathbb{E}_{S_k \sim \mathcal{I}_k}[M(S_k)] &= \sum_{e \in T} d_e \cdot \frac{1}{k} \cdot \mathbb{E}[|X_e - \mathbb{E}[X_e]|] \leq \sum_{e \in T} d_e \cdot \frac{1}{k} \cdot \text{std}(X_e) \\ &= \sum_{e \in T} d_e \cdot \frac{1}{k} \cdot \sqrt{k \cdot \frac{n_e}{n}\left(1 - \frac{n_e}{n}\right)} \leq \sum_{e \in T} d_e \cdot \sqrt{\frac{n_e}{k \cdot n}}. \end{aligned}$$

◀

Combining the replacement lemma (Lemma 4.3) with Lemmas 4.4 and 4.1, we obtain the following upper bound on $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)]$ in terms of $\mathbb{E}[OPT]$.

▶ **Lemma 4.5.** $\mathbb{E}_{S_k \sim \mathcal{U}_k}[M(S_k)] \leq 2 \cdot \frac{\mathbb{E}[OPT]}{\sqrt{nk}}$.

We can now prove our simple result for tree metrics.

▶ **Theorem 4.6.** *(Tree Bound) Algorithm* FAIR-BIAS *is* 4*-competitive on tree metrics with* $n \geq 2$ *nodes, if the requests are drawn from the uniform distribution.*

Proof. We have by the structural lemma (Lemma 2.2) and Lemma 4.5 that

$$\begin{aligned}\mathbb{E}[\text{ALG}] &= \sum_{k=1}^{n} \mathbb{E}[M(S_k)] \leq \sum_{k=1}^{n} 2 \cdot \frac{\mathbb{E}[OPT]}{\sqrt{nk}} \\ &\leq 2 \cdot \frac{\mathbb{E}[OPT]}{\sqrt{n}} \cdot \left(1 + \int_{x=1}^{n} \frac{1}{\sqrt{x}} dx\right) \leq 4 \cdot \mathbb{E}[OPT]. \end{aligned}$$ ◀

The above bound holds for all $n \geq 2$ (for $n = 1$ any algorithm is trivially 1 competitive). For n large, however, our proof yields an improved asymptotic bound of $\sqrt{2} \cdot e + o(1) \approx (3.845 + o(1))$, by relying on the asymptotic counterpart of Claim 4.2 in [5, Corollary 2], $\mathbb{E}|Y - \mathbb{E}Y| \geq \text{std}(Y)/(e/2 + o(1))$. Combining Theorem 4.6 with our transshipment argument (Lemma 2.1), we obtain a 9-competitive algorithm under any i.i.d. distribution on tree metrics on $n \geq 2$ nodes, and even better than 9-competitive algorithms for large enough n.

5 Open Questions

In this work, we presented algorithm FAIR-BIAS and proved that it is $O((\log\log\log n)^2)$-competitive for general metrics, and 9-competitive for tree metrics. Perhaps the first question is whether our algorithm (or indeed any algorithm) is $O(1)$ competitive for (known or unknown) i.i.d arrivals for general metrics. Indeed, we do not know of any instances where Algorithm FAIR-BIAS's performance is worse than $O(1)$ competitive. However, it is not clear how to extend our proofs to establish an $O(1)$ competitive ratio.

Another question is the relationship between the known and unknown i.i.d. models and the random order model. The optimal competitive ratios for the various arrival models for online problems can be sorted as follows (see e.g. [28, Theorem 2.1])

$$C.R.(Adversarial) \geq C.R.(Random\ Order) \geq C.R.(Unknown\ IID) \geq C.R.(Known\ IID).$$

For the online metric matching problem the best bounds known for the above are, respectively, $O(\log^2 n)$ [4], $\Theta(\log n), O(\log n)$ (both [35]), and $O((\log\log\log n)^2)$ (this work). Given the lower bound of [35], our work implies that one or both of the inequalities in $C.R.(Random\ Order) \geq C.R.(Unknown\ IID) \geq C.R.(Known\ IID)$ is strict (and asymptotically so). It would be interesting to see which of these inequalities is strict, by either presenting a $o(\log n)$-competitive algorithm for unknown i.i.d or a $\omega((\log\log\log n)^2)$ lower bound for this model. For the line metric, we give the first constant-competitive algorithm for this well-studied metric under any non-trivial arrivals. Extending this result, and more generally understanding the exact relationships between these arrival models for this simple metric may prove useful in understanding the relationships between the different stochastic arrival models more broadly. Moreover, it would be interesting to study these questions for other combinatorial optimization problems with online stochastic arrivals.

Abstract

Local Reconstruction Codes (LRCs) allow for recovery from a small number of erasures in a local manner based on just a few other codeword symbols. They have emerged as the codes of choice for large scale distributed storage systems due to the very efficient repair of failed storage nodes in the typical scenario of a single or few nodes failing, while also offering fault tolerance against worst-case scenarios with more erasures. A maximally recoverable (MR) LRC offers the best possible blend of such local and global fault tolerance, guaranteeing recovery from all erasure patterns which are information-theoretically correctable given the presence of local recovery groups. In an (n, r, h, a)-LRC, the n codeword symbols are partitioned into r disjoint groups each of which include a local parity checks capable of locally correcting a erasures. The codeword symbols further obey h heavy (global) parity checks. Such a code is maximally recoverable if it can correct all patterns of a erasures per local group plus up to h additional erasures anywhere in the codeword. This property amounts to linear independence of all such subsets of columns of the parity check matrix.

MR LRCs have received much attention recently, with many explicit constructions covering different regimes of parameters. Unfortunately, all known constructions require a large field size that is exponential in h or a, and it is of interest to obtain MR LRCs of minimal possible field size. In this work, we develop an approach based on function fields to construct MR LRCs. Our method recovers, and in most parameter regimes improves, the field size of previous approaches. For instance, for the case of small $r \ll \varepsilon \log n$ and large $h \geqslant \Omega(n^{1-\varepsilon})$, we improve the field size from roughly n^h to $n^{\varepsilon h}$. For the case of $a = 1$ (one local parity check), we improve the field size quadratically from $r^{h(h+1)}$ to $r^{h\lfloor (h+1)/2 \rfloor}$ for some range of r. The improvements are modest, but more importantly are obtained in a unified manner via a promising new idea.

1 Introduction

Interest in erasure codes has surged in recent years, with the demands of massive cloud storage systems raising hitherto unexplored, yet very natural and mathematically deep, questions concerning the parameters, robustness, and efficiency of the code. Distributed storage systems need to build in redundancy in the data stored in order to cope with the loss or inaccessibility of the data on one or more storage nodes. Traditional erasure codes offer a natural strategy for such robust data storage, with each storage node storing a small part of the codeword, so that the data is protected against multiple node failures. In particular, MDS codes such as Reed-Solomon codes can operate at the optimal storage vs. reliability trade-off – for a given amount of information to be stored and available storage space, these codes can tolerate the maximum number of erasures without losing these stored information.

Individual storage nodes in a large scale system often fail or become unresponsive. Reconstruction (repair) of the content stored on a failed node with the help of remaining active nodes is important to reinstate the system in the event of a permanent node failure, and to allow access to the data stored on a temporarily unavailable node. The use of erasure codes in large storage systems, therefore, brings to the fore a new requirement: the ability to *very efficiently* reconstruct *parts* of a codeword from the rest of the codeword.

Local Reconstruction Codes (LRCs), introduced in [7], offer an attractive way to meet this requirement. An LRC imposes local redundancies in the codewords, so that a single (or a small number of) erased symbol can be recovered locally from less than r other codeword symbols.[1] Here r is the locality parameter that is typically much smaller than the code length n. In the distributed storage context, an LRC allows for the low-latency repair of any failed node as one only needs to wait for the response from r nodes. LRCs have found spectacular practical applications with their use in the Windows Azure storage system [12].

The challenge in an LRC design is to balance the locality requirement, that allows fast recovery from a single or few erasures, with good global erasure-resilience (via traditional slower methods) for more worst-case scenarios. One simple metric for global fault tolerance is the minimum distance d of the code, which means that any pattern of fewer than d erasures can be corrected. The optimal trade-off between the distance, redundancy, and locality of an LRC was established in [8], and an elegant sub-code of Reed-Solomon codes meeting this bound was constructed in [17].

This work concerns a much stronger requirement on global fault-tolerance, called *Maximal Recoverability*. This requires that the code should simultaneously correct every erasure pattern that is information-theoretically possible to correct, given the locality conditions imposed on the codeword symbols. Let us describe it more formally in the setting of interest in this paper. Define an $(n, r, h, a)_\ell$-LRC to be a linear code over $\mathbb{F}_\ell$ of length n whose n codeword symbols are partitioned into r disjoint groups each of which includes a local parity checks capable of locally correcting a erasures. The codeword symbols further obey h heavy (global) parity checks. With this structure of parity checks, it is not hard to see that the erasure patterns one can hope to correct are precisely those which consist of up to a erasures per local group plus up to h additional erasures anywhere in the codeword.

[1] LRCs are also expanded as Locally Repairable Codes or Locally Recoverable Codes, eg. [16, 17, 10].

A *maximal recoverable* (MR) LRC is a *single* code that is capable of simultaneously correcting *all* such patterns. Thus, an MR code gives the most bang-for-the-buck for the price one pays for locality.

This notion was introduced in [2] motivated by applications to storage on solid-state devices, where it was called partial MDS codes. The terminology maximally recoverable codes was coined in [7], and the concept was more systematically studied in [7, 6]. By picking the coefficients of the heavy parity checks randomly, it is not hard to show the existence of MR LRCs over *very large* fields, of size exponential in h. An explicit construction over such large fields was also given in [7], which also proved that random codes *need* such large field sizes with high probability.[2]

Since encoding a linear code and decoding it from erasures involve performing numerous finite field arithmetic operations, it is highly desirable to have codes over small fields (preferably of characteristic 2). Obtaining MR LRCs over finite fields of minimal size has therefore emerged as a central problem in the area of codes for distributed storage. So far, no construction of MR LRCs that avoid the exponential dependence on h has been found. A recent lower bound shows that, unlike MDS codes, for certain parameter settings one cannot have MR LRCs over fields of linear size. This shows that the notion of maximal recoverability is quite subtle, and pinning down the optimal field size is likely a deep question. There remains a large gap between the upper and lower bounds on field size of MR LRCs, closing which is a challenge of theoretical and practical importance.

In this work, we develop a novel approach to construct MR LRCs based on function fields. Our framework recovers and in fact slightly improves most of the previous bounds in the literature in a unified way. We note that since there are at least three quantities of significance – the locality r, the local (intra group) erasure tolerance a, and number of global parity checks h – the landscape of parameters and different constructions in this area is quite complex. Also, depending on the motivation, the range of values of interest of these parameters might be different. For example, if extreme efficiency of local repair is important, r should be small. But on the other hand this increase the redundancy and thus storage requirement of the code, so from this perspective a modest r (say $\sqrt{n}$) might be relevant. If good global fault tolerance is required, we want larger h, but then the constructions have large field size. It is therefore of interest to study the problem treating these as independent parameters, without assumptions on their relative size. We next review the field size of previous constructions, and then turn to the parameters we achieve in different regimes.

1.1 Known field size bounds

For $a \in \{0, r-1\}$, optimal maximally recoverable local reconstruction codes (MR LRCs, for short) can be constructed by using either Reed-Solomon codes or their repetition. For $h \leqslant 1$, constructions of MR LRCs over fields of size $O(r)$ were given in [2]. For the remaining case: $1 \leqslant a \leqslant r-2$ and $h \geqslant 2$, there are quite a number of constructions in literature [1, 2, 3, 4, 5, 7, 6, 9, 11, 18].

For the cases of $h = 2$ and $h = 3$, the best known constructions of MR LRCs were given in [9] with field sizes of $O(n)$ and $O(n^3)$ respectively, uniformly for all r, a. (Their field sizes were worse by $n^{o(1)}$ factors compared to these bounds when the field is required to be of

[2] This is akin to what happens for random codes to have the MDS property. However, for MDS codes, the Vandermonde construction achieves a linear field size explicitly.

characteristic 2.) For most other parameter settings, the best constructions by [5] provide a family of MR LRCs over fields of sizes

$$\ell = O\left(r \cdot n^{(a+1)h-1}\right) \tag{1}$$

as well as

$$\ell = \max\left\{O(\frac{n}{r}),\ O(r)^{h+a}\right\}^h\ , \tag{2}$$

The bound (1) outperforms the bound (2) when $r = \Omega(n)$, while the bound (2) is better when $r \ll n$. In both the bounds, the field size grows exponentially with h and a.

Recently, by using maximum rank distance (MRD) codes, the paper [15] (specifically Corollary 14) gives a family of MR LRCs over fields of sizes

$$\ell = O\left(r^{\frac{n(r-a)}{r}}\right). \tag{3}$$

When $r = \Omega(n)$, and a is close to r or h is large, (3) is better than bounds (1) or (2). By using probabilistic arguments, the paper [15] shows existence of a family of MR LRCs over fields of sizes

$$\ell = O\left(\binom{n-1}{k-1}\right), \tag{4}$$

where $k = n\left(1 - \frac{a}{r}\right) - h$ is the dimension of the code.

On the other hand, a lower bound on the field size was presented in [9]. Stating the bound when $h \leqslant \frac{n}{r}$ for simplicity, they show that the field size ℓ of an $(n, r, h, a)_\ell$ MR LRC must obey

$$\ell = \Omega_{a,h}\left(n \cdot r^{\min\{a,h-2\}}\right). \tag{5}$$

The lower bound (5) is still quite far from the upper bounds (1) and (2). In particular, the exponent a or h is to the base growing with n in the known constructions, but only to the base r in the above lower bound. Thus, one can conjecture that there is still room to improve both the constructions and the lower bounds. We note that under more complex structural requirements on the local groups, notably grid-like topologies and product codes, the optimal field size has been pinned down to $\exp(\Theta(n))$ [13].

Several techniques have been employed in literature for constructions of MR LRCs. One prevalent idea is to use a "linearized" version of the Vandermonde matrix, where the heavy parity check part of the matrix consists of columns $(\alpha_i, \alpha_i^q, \ldots, \alpha_i^{q^{h-1}})^T$ where $\alpha_i \in \mathbb{F}_\ell$ for a sufficiently high degree extension field $\mathbb{F}_\ell$ of $\mathbb{F}_q$. This construction is combined with $2h$-wise independent spaces to get an $O(n^h)$ field size in [7], and is also employed in [5]. Another approach is based on rank-metric codes (see, for instance, [4, 15]). Various ad hoc methods have been employed for good constructions of MR LRCs for small h, for example for $h = 2, 3$ in [9].

1.2 Our results

In this work, we develop a new approach to construct MR LRCs based on algebraic function fields. We discuss the key elements underlying our strategy in Section 1.4, but for now state the field sizes of the MR LRCS we can construct for various regimes of parameters. Most of the existing results in literature can be recovered through our methods in a unified way.

In most regimes, the parameters of our codes beat the known ones. For easy reference, we summarize the different possible trade-offs we can achieve in one giant theorem statement below. Since this comprehensive statement may be overwhelming to parse, let us highlight just two of our significant improvements: item (i) for $a = 1$, where we improve r^{h+1} term in (2) quadratically to $r^{\lfloor \frac{h+1}{2} \rfloor}$, and item (vi) for sufficiently large h, where the exponent h in bounds (1) and (2) is improved to εh. Also the exponent h is replaced by $\min\{h, n/r\}$ in the bounds (i)-(iv) that improve (2). In the bounds (vii) and (viii) the factor n/r in the exponent is improved to $\min\{k, n/r\}$; this improvment is less significant as it only applies to the low-rate setting but included for completeness and also to reflect a construction approach based on generator matrices (as opposed to parity check matrices which is a more potent way to reason about MR LRCs that underlies the other parts of the theorem).

▶ **Theorem 1.** *One has a maximally recoverable $(n, r, h, a)_\ell$-local reconstruction code over a field of size ℓ with parameters satisfying any of the following conditions. (Below $\tilde{O}(f)$ denotes $f \log^{O(1)} f$.)*

(i) (see Theorem 10) $a = 1, r \geqslant h + 2$ *and*

$$\ell \leqslant \left(\max \left\{ \tilde{O}(\frac{n}{r}), (2r)^{\lfloor \frac{h+1}{2} \rfloor} \right\} \right)^{\min\{h, \frac{n}{r}\}} \text{ and } \ell \text{ is even;}$$

(ii) (see Theorem 11) $a = 1$ *and*

$$\ell \leqslant \left(\max \left\{ \tilde{O}(\frac{n}{r}), 2^r \right\} \right)^{\min\{h, \frac{n}{r}\}} \text{ and } \ell \text{ is even;}$$

(iii) (see Theorem 13) *for all settings of n, r, h, a and*

$$\ell \leqslant \left(\max \left\{ \tilde{O}(\frac{n}{r}), (2r)^{h+a} \right\} \right)^{\min\{h, \frac{n}{r}\}};$$

$$\ell \leqslant \left(\max \left\{ \tilde{O}(\frac{n}{r}), (2r)^{r} \right\} \right)^{\min\{h, \frac{n}{r}\}};$$

(v) (see Theorem 17) $r = O\left(\frac{\log n}{\log \log n}\right)$ *and* $hr \geqslant \Omega\left(\frac{n^{\frac{2}{3}}}{\varepsilon}\right)$ *for a positive real* $\varepsilon \in (0, 0.5)$ *and*

$$\ell \leqslant O\left(n^{\frac{2h}{3}(1+\varepsilon)}\right);$$

(vi) (see Theorem 18) $r = O\left(\frac{\varepsilon \log n}{\log \log n}\right)$ *and* $hr = \Omega\left(n^{1-\varepsilon}\right)$ *for a positive real* $\varepsilon \in (0, 0.5)$ *and*

$$\ell \leqslant n^{\varepsilon h};$$

(vii) (see Theorem 5) *for all settings of n, r, h, a*

$$\ell \leqslant \begin{cases} 2^{\min\{rk, n\}} \leqslant 2^n & \text{if } r \geqslant \log n \\ 2^{\lceil \log n \rceil \min\{k, \frac{n}{r}\}} & \text{if } r \leqslant \log n \end{cases}$$

where $k = \left(1 - \frac{a}{r}\right) - h$ is the dimension of the code;

(viii) (see Theorem 7) $r - a = \Omega(\log n)$ *and*

$$\ell \leqslant 2r^{\lfloor \frac{r-a}{2} \rfloor \min\{k, \frac{n}{r}\}} \text{ and } \ell \text{ is even.}$$

The first two bounds, and the bounds in (vii) and (viii) of Theorem 1 are derived from the rational function field $\mathbb{F}_2(x)$. In addition, bounds in (i) and (viii) of Theorem 1 are obtained via a combination with binary BCH codes. Bounds in (iii) and (iv) of Theorem 1 are derived from rational function field $\mathbb{F}_q(x)$, where ℓ is a power of q. The fifth bound is obtained via Hermitian function fields, while the sixth bound is derived from the Garcia-Stichtenoth function field tower. Our codes achieving the trade-offs stated in the above theorem can in fact be explicitly specified. But we note that for MR codes even existence questions over small fields are interesting and non-trivial.

1.3 Comparison

Each of our bounds in Theorem 1 beats the known results in some parameter regimes. Let us compare them one by one.

- The bound in Theorem 1(i) outperforms the bound (2) due to the quadratically better exponent for r.
- The bound in Theorem 1(ii) outperforms even the bound in Theorem 1(i) for $\frac{r}{\log r} < \left\lfloor \frac{h+1}{2} \right\rfloor$.
- The bound in Theorem 1(iii) outperforms the bound (2) for $h > \frac{n}{r}$.
- The bound in Theorem 1(iv) even outperforms the bound in Theorem 1(iv) for $r < h + a$, and hence it beats the bound (2) for $\frac{n}{h} < r < h + a$.
- The bound in Theorem 1(v) outperforms both the bounds (1) and (2) for all parameter settings subject to $r = \widetilde{O}(\log n)$ and $hr = \Omega\left(\frac{n^{\frac{2}{3}}}{\varepsilon}\right)$. It is clear that the bound in Theorem 1(v) is better than (1). As $r = \widetilde{O}(\log n)$, then we have $\left(\frac{n}{r}\right)^h > n^{h(1-o(1))} > n^{2h(1+\varepsilon)/3}$ and hence the bound in Theorem 1(v) beats (2) in this case.
- As the bound in Theorem 1(vi) is even better than the bound in Theorem 1(v), the bound in Theorem 1(vi) beats both the bounds (1) and (2) for all parameter settings subject to $r = \widetilde{O}(\varepsilon \log n)$ and $hr = O\left(n^{1-\varepsilon}\right)$ for a positive real $\varepsilon \in (0, 0.5)$.
- When the dimension k is much smaller than n, then the probabilistic bound (4) gives the field size $O(n^k) = O(2^{k \log n})$ which is the same size as in Theorem 1(vii) for $r \leqslant \log n$. When the dimension k is proportional to n, then the probabilistic bound (4) gives the field size $2^{O(n)}$ which is the same as the bound 2^n in Theorem 1(vii) for $r \geqslant \log n$.
- Finally, the bound in Theorem 1(viii) clearly outperforms the bound (3) when $k < n/r$.

1.4 Our techniques

Note that construction of MR LRCs is equivalent to construction of certain generator or parity-check matrices with requirement of column linear independence (see Section 2.1).

Our construction idea departs from previous approaches and is based on function fields over a finite field $\mathbb{F}_q$. The key in constructing an MR LRC is the choice of the heavy parity checks. We now briefly describe our idea to pick these. We associate with each of the $g = n/r$ local groups a distinguishing (high degree) place P_i, $1 \leqslant i \leqslant g$. The degree of the place is chosen large enough to guarantee the existence of at least g such places. For each local group, we pick functions f_{ij}, $1 \leqslant j \leqslant r$, that have *exactly one pole at* P_i. The coefficients of the h heavy parity checks corresponding to the j'th symbol of i'th local group are chosen to be

$$(f_{ij}(Q), f_{ij}^q(Q), \ldots, f_{ij}^{q^{h-1}}(Q))^T \ , \tag{6}$$

where Q is a place of sufficiently high degree, so that the evaluations $f_{ij}(Q)$ belong to an extension field $\mathbb{F}_\ell$ which will be the final alphabet size of the MR LRC. By properties of the Moore determinant (Section 2.2) and the large degree of Q, the required linear independence

of columns such as (6) over $\mathbb{F}_\ell$ reduces to a certain linear independence requirement for the f_{ij}'s over $\mathbb{F}_q$. Across different local groups such linear independence follows because a function with one pole at P_i cannot cancel a function with one pole at a different place $P_{i'}$. Within a local group, the required linear independence is ensured by choosing the f_{ij}'s within a group so that any $h+a$ of them (which is the maximum number of erasures we can have within a group) are linearly independent over $\mathbb{F}_q$.

We remark that all our various guarantees of Theorem 1 except Parts (v) and (vi) are obtained using just the rational function field, and can be described in elementary language using just polynomials, as we do in Section 3.

1.5 Organization

The paper is organized as follows. In Section 2, we introduce some preliminaries such as MR LRCs (both the generator and parity check matrix viewpoints) and Moore determinants. In Section 3, we present our constructions of MR LRCs using the rational function field together with a concatenation with classical codes of good rate vs. distance trade-off. We give two constructions, using the generator matrix viewpoint in the first part (yielding Parts (vii) and (viii) of Theorem 1), and then a parity check based construction in the second part which yields Parts (i)-(iv) of Theorem 1. This section is elementary and only uses properties of polynomials. In Section 4, we generalize the construction of MR LRCs via parity-check matrix given in Section 3 by making use of arbitrary algebraic function fields. We then apply this construction to Hermitian function fields and the Garcia-Stichtenoth tower to obtain MR LRCs promised in Parts (v) and (vi) of Theorem 1 respectively.

2 Preliminaries

2.1 Maximally recoverable local reconstruction codes

Throughout this paper, $\mathbb{F}_q$ denotes the finite field of q elements for a prime power q. We use $\mathbb{F}_q^{k\times n}$ to denote the set of all $k\times n$ matrices over $\mathbb{F}_q$.

Consider a distributed storage system where there are g disjoint locality groups and each group has size r and can locally correct any a erasure errors. In addition, the system can correct any h erasure errors together with any a erasure errors in each group. This requires a class of codes called *maximally recoverable local reconstruction codes* or *partial MDS codes* for error correction of such a system. The precise definition of MR LRCs is given below.

▶ **Definition 1.** Let ℓ be a prime power and let a, g, r, h be positive integers satisfying $ga+h<gr$. Put $n=gr$ and $k=n-ga-h$. An ℓ-ary $[n,k]$-linear code with a generator matrix of the form

$$G=(B_1|B_2|\cdots|B_g)\in\mathbb{F}_\ell^{k\times n}$$

is called a maximally recoverable $(n,r,h,a)_\ell$-local reconstruction code (or an MR $(n,r,h,a)_\ell$-LRC, for short) if

- **(i)** each B_i has size $k\times r$;
- **(ii)** the row span of each B_i is an $[r,r-a,a+1]_\ell$-MDS code for $1\leqslant i\leqslant g$ (note that B_i is not a generator matrix of this MDS code in general);
- **(iii)** after puncturing a columns from each B_i, the remaining matrix of G generates an $[n-ga,k,h+1]_\ell$-MDS code.

From the definition, an MR $(n, r, h, a)_q$-LRC can correct h erasure errors at arbitrarily positions together with any a erasure errors in each of g groups. To see the recovery procedure for an MR $(n, r, h, a)_\ell$-LRC, we first recover h erasure errors (this can be done from (iii) of Definition 1). We can then correct a errors from each block by (ii) of Definition 1.

The following lemma directly follows from Definition 1.

▶ **Lemma 2.** *A matrix $G = (B_1|B_2|\cdots|B_g) \in \mathbb{F}_\ell^{k\times n}$ is a generator matrix of an MR $(n, r, h, a)_\ell$-LRC if and only if every $k \times k$ submatrix S of G with at most $r - a$ columns per block B_i is invertible.*

One can have an equivalent definition via parity-check matrix.

▶ **Definition 2.** Let ℓ be a prime power and let a, g, r, h be positive integers satisfying $ga + h < gr$. Put $n = gr$ and $k = n - ga - h$. An ℓ-ary $[n, k]$-linear code with a parity-check matrix of the form

$$H = \left(\begin{array}{c|c|c|c} A_1 & O & \cdots & O \\ \hline O & A_2 & \cdots & O \\ \hline \vdots & \vdots & \ddots & \vdots \\ \hline O & O & \cdots & A_g \\ \hline D_1 & D_2 & \cdots & D_g \end{array}\right) \in \mathbb{F}_\ell^{(n-k)\times n} \tag{7}$$

is called an MR $(n, r, h, a)_\ell$-LRC if

- **(i)** each A_i has size $a \times r$ and each D_i has size $h \times r$;
- **(ii)** each A_i generates an $[r, a, r - a + 1]_\ell$-MDS code for $1 \leqslant i \leqslant g$ (note that the nullspace of A_i is $[r, r - a, a + 1]_\ell$ code);
- **(iii)** every $ag + h$ columns consisting of any a columns in each group and other arbitrary h columns are $\mathbb{F}_\ell$-linearly independent.

▶ Remark 1.

- **(i)** To see equivalence between Definitions 1 and 2, we note that each A_i in Definition 2 is actually a parity-check matrix of the code generated by B_i given in Definition 1.
- **(ii)** In this paper, we will use both Definitions 1 and 2 for constructions of MR LRCs. However, the major results of this paper come from the constructions based one Definition 2, i.e., via parity-check matrices of the required form in (7).

2.2 Moore determinant

Let ℓ be a power of q. For elements $\alpha_1, \ldots, \alpha_h \in \mathbb{F}_\ell$, the Moore matrix is defined by

$$M = \begin{pmatrix} \alpha_1 & \alpha_2 & \cdots & \alpha_h \\ \alpha_1^q & \alpha_2^q & \cdots & \alpha_h^q \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_1^{q^{h-1}} & \alpha_2^{q^{h-1}} & \cdots & \alpha_h^{q^{h-1}} \end{pmatrix} \in \mathbb{F}_\ell^{h\times h}.$$

The determinant $\det(M)$ is given by the following formula

$$\det(M) = \prod_{(c_1,\ldots,c_h)} (c_1\alpha_1 + \cdots + c_h\alpha_h),$$

where $(c_1, \ldots, c_h)$ runs through all non-zero direction vectors in $\mathbb{F}_q^h$. Thus, $\det(M) \neq 0$ if and only if $\alpha_1, \ldots, \alpha_h$ are $\mathbb{F}_q$-linearly independent.

3 Explicit constructions via rational function fields

In this section, we only introduce constructions of MR LRCs from rational function fields. Our description will be self-contained and elementary in terms of polynomials and we don't require any background on algebraic function fields (we have therefore deferred the background on function fields to Section 4 ahead of our more general construction in the next section).

3.1 Constructions via generator matrix

In this subsection, we present constructions of MR LRCs using Definition 1, i.e., via generator matrices of MR LRCs.

Let $N_q(d)$ denote the number of monic irreducible polynomials of degree d over $\mathbb{F}_q$. Then one has $\sum_{d|m} dN_q(d) = q^m$ for any $m \geqslant 1$ (see [14, Corollary 3.21 of Chapter 3]). This gives $\sum_{d|m} N_q(d) \geqslant \frac{q^m}{m}$. For each monic irreducible polynomial $p(x)$ of degree d with $d|m$, we get a polynomial $p(x)^{m/d}$ of degree m. Thus, for any $g \leqslant \left\lceil \frac{q^m}{m} \right\rceil$, there are g polynomials $p_1(x), p_2(x), \ldots, p_g(x)$ of degree m such that $\gcd(p_i(x), p_j(x)) = 1$ for all $1 \leqslant i \neq j \leqslant g$

Assume that (i) $m \geqslant r$; or (ii) $m < r$ and there is a q-ary $[r, r-m, \geqslant r-a+1]$-linear code, i.e. there exists a subset of $\mathbb{F}_q^m$ of size r such that any $r-a$ elements in this subset are $\mathbb{F}_q$-linearly independent.

Choose $g \leqslant \left\lceil \frac{q^m}{m} \right\rceil$ polynomials $p_1(x), p_2(x), \ldots, p_g(x)$ of degree m such that $\gcd(p_i(x), p_j(x)) = 1$ for all $1 \leqslant i \neq j \leqslant g$. Then for each $1 \leqslant i \leqslant g$, we can form an $\mathbb{F}_q$-vector space $V_i := \left\{ \frac{f(x)}{p_i(x)} : f(x) \in \mathbb{F}_q[x], \deg(f(x)) \leqslant m-1 \right\}$ of dimension m. As there is a q-ary $[r, r-m, \geqslant r-a+1]$-linear code, its parity-check matrix is an $r \times m$ matrix and any $r-a$ columns of this matrix are linearly independent. This implies that one can find r functions $g_{i1}(x), \ldots, g_{ir}(x) \in V_i$ such that any $r-a$ polynomials out of $\{g_{i1}(x), \ldots, g_{ir}(x)\}$ are $\mathbb{F}_q$-linearly independent. Choose an irreducible polynomial $Q(x) \in \mathbb{F}_q[x]$ such that $Q(x)$ is coprime with every $p_i(x)$ for $1 \leqslant i \leqslant g$. For a function $h(x) \in V_i$, we use $h(Q)$ to denote the residue class of $h(x)$ in the residue class field $\mathbb{F}_q[x]/Q(x) \simeq \mathbb{F}_{q^{\deg(Q)}}$.

▶ **Lemma 3.** *Let T be a subset $\{1, 2, \ldots, g\}$ with $|T| \leqslant \deg(Q)/m$. If $\sum_{i \in T} g_i(Q) = 0$ for some functions $g_i \in V_i$, then $g_i = 0$ for all $i \in T$.*

Proof. Write $g_i = \frac{f_i}{p_i}$ for some polynomials f_i with $\deg(f_i) \leqslant m-1$. The equality $\sum_{i \in T} g_i(Q) = 0$ implies that $\sum_{i \in T} f_i(x) \prod_{j \in T \setminus \{i\}} p_j(x)$ is divisible by $Q(x)$. As the degree of $\sum_{i \in T} f_i(x) \prod_{j \in T \setminus \{i\}} p_j(x))$ is less than $m|T|$, we must have that $\sum_{i \in T} f_i(x) \prod_{j \in T \setminus \{i\}} p_j(x)$ is the zero polynomial. Suppose that $f_t \neq 0$ for some $t \in T$, then we have

$$\sum_{i \in T \setminus \{t\}} f_i(x) \prod_{j \in T \setminus \{i\}} p_j(x) = -f_t(x) \prod_{j \in T \setminus \{t\}} p_j(x) \, .$$

The l.h.s. of the above equality is divisible by $p_t(x)$, while the r.h.s. is not divisible by $p_t(x)$. This contradiction completes the proof. ◀

Let Q be an irreducible polynomial in $\mathbb{F}_q[x]$ of degree

$$\min\{km, gm\} = \min\left\{km, \frac{nm}{r}\right\} = \min\left\{(n - \frac{an}{r} - h)m, \frac{nm}{r}\right\}.$$

Define the $k \times r$ matrix B_i as follows.

$$B_i = \begin{pmatrix} g_{i1}(Q) & g_{i2}(Q) & \cdots & g_{ir}(Q) \\ g_{i1}^{q}(Q) & g_{i2}^{q}(Q) & \cdots & g_{ir}^{q}(Q) \\ \vdots & \vdots & \vdots & \vdots \\ g_{i1}^{q^{k-1}}(Q) & g_{i2}^{q^{k-1}}(Q) & \cdots & g_{ir}^{q^{k-1}}(Q) \end{pmatrix} \in \mathbb{F}_{q^{\deg(Q)}}^{k \times r}. \tag{8}$$

The proofs of the remaining results of this Section can be found in the full version of the paper that is available at https://arxiv.org/abs/1808.04539.

▶ **Lemma 4.** *Assume that $m \geqslant r$ or there is a q-ary $[r, r-m, \geqslant r-a+1]$-linear code. Let B_i be the matrix given in (8). Put $\ell = q^{\min\left\{(n-\frac{an}{r}-h)m, \frac{nm}{r}\right\}} = q^{\min\left\{km, \frac{nm}{r}\right\}}$ and $G = (B_1|B_2|\cdots|B_g) \in \mathbb{F}_\ell^{k \times n}$. Then the ℓ-ary code C with the generator matrix G is an MR $(n, r, h, a)_\ell$-LRC.*

By taking $m = r$, we obtain the following result.

▶ **Theorem 5.** *If $r \geqslant \log n$, then there exists an MR (n, r, h, a)-LRC of dimension $k = n - \frac{na}{r} - h$ over a field of size*

$$\ell \leqslant \begin{cases} 2^{\min\{rk, n\}} \leqslant 2^n & \text{if } r \geqslant \log n \\ 2^{\min\left\{k\lceil \log n \rceil, \frac{n}{r}\lceil \log n \rceil\right\}} & \text{if } r \leqslant \log n \end{cases}$$

By considering binary BCH codes, we obtain the following binary codes.

▶ **Lemma 6.** *There exists a binary $[r, r-m, \geqslant d]$-linear code with $m = \lfloor \frac{d-1}{2} \rfloor \cdot \lceil \log_2 r \rceil + 1$.*

Combining the binary BCH codes of Lemma 6 with Lemma 4 applied with rational function field $\mathbb{F}_2(x)$ yields the following theorem.

▶ **Theorem 7.** *If $r - a = \Omega(\log n)$, then there exists an MR (n, r, h, a)-LRC of dimension $k = n - \frac{na}{r} - h$ over a field of size*

$$\ell \leqslant 2r^{\min\left\{k\lfloor \frac{r-a}{2} \rfloor, \frac{n}{r}\lfloor \frac{r-a}{2} \rfloor\right\}} \leqslant 2r^{\frac{n}{r}\lfloor \frac{r-a}{2} \rfloor}.$$

3.2 Constructions via parity-check matrix

To construct parity-check matrices of MR LRCs, we only need to construct matrices D_i given in (7). The idea of constructing matrices D_i is quite similar to that of constructing matrices B_i in the previous subsection, and leads to the following theorem.

▶ **Theorem 8.** *Let r, g, a, h, m be positive integers with $a \leqslant r$. Suppose that $q \geqslant r$ is a prime power satisfying $q^m \geqslant \frac{mn}{r}$ and there is a q-ary $[r, r-a, a+1]$-linear code. If (i) $m \geqslant r$; or (ii) $m < r$ and there exists a q-ary $[r, r-m, \geqslant h+a+1]$-linear code, then there exists an MR (n, r, h, a)-LRC with $n = rg$ over a field of size $\ell = q^{\min\{hm, \frac{nm}{r}\}}$.*

We now instantiate Theorem 8 with suitable choices of parameters to deduce the promises parts (i)–(iv) of Theorem 1.

3.2.1 The case where $a = 1$

Let $r, h \geqslant 2$ be integers. Then there is a q-ary $[r, 1, r]$-MDS code for any prime power q. Rewriting Theorem 8 for $a = 1$ gives the following lemma.

▶ **Lemma 9.** *Suppose that $q^m \geqslant \frac{mn}{r}$. If (i) $m \geqslant r$; or (ii) $m < r$ and there exists a q-ary $[r, r-m, \geqslant h+2]$-linear code, then there exists an MR $(n, r, h, 1)$-LRC over a field of size $\ell = q^{\min\{hm, \frac{nm}{r}\}}$.*

To apply Lemma 9, we need to find suitable codes and function fields as well. By taking the rational function field $\mathbb{F}_2(x)$ and applying BCH code given in Lemma 6, we obtain the following result.

▶ **Theorem 10.** *If $r \geqslant h+2$, then there exists an MR $(n, r, h, 1)$-LRC over a field of size*

$$\ell \leqslant \left(\max\left\{\tilde{O}(\frac{n}{r}), (2r)^{\lfloor \frac{h+1}{2} \rfloor}\right\}\right)^{\min\{h, \frac{n}{r}\}}.$$

Proof. Consider the rational function field $F = \mathbb{F}_2(x)$. Put

$$m = \max\left\{\left\lfloor \frac{h+1}{2} \right\rfloor \cdot \lceil \log_2 r \rceil + 1, \left\lceil \log_2\left(\frac{n}{r}\right) + 2\log_2\log_2\left(\frac{n}{r}\right)\right\rceil\right\}.$$

Then $\frac{n}{r} \leqslant \frac{1}{m}2^m$. This implies that there are $\frac{n}{r}$ places of degree m in $\mathbb{F}_2(x)$. By Lemma 6, there exists a binary $[r, r-m, \geqslant h+2]$-linear code. It follows from Lemma 9 that there exists an MR $(n, r, h, 1)$-LRC over a field of size $2^{\min\{mh, m\frac{n}{r}\}}$. By choice of our parameters, the desired result follows. ◀

▶ **Theorem 11.** *There exists an MR $(n, r, h, 1)$-LRC over a field of size*

$$\ell \leqslant \left(\max\left\{\tilde{O}(\frac{n}{r}), 2^r\right\}\right)^{\min\{h, \frac{n}{r}\}}.$$

Proof. Consider the rational function field $\mathbb{F}_2(x)$. Put $m = \max\{r, \left\lceil \log_2\left(\frac{n}{r}\right) + 2\log_2\log_2\left(\frac{n}{r}\right)\right\rceil\}$. Then $\frac{n}{r} \leqslant \frac{1}{m}2^m$. The desired result follows from Lemma 9. ◀

▶ Remark 2. Theorem 11 gives a better bound on the field size than Theorem 10 for $h > \frac{2r}{\log_2 r} - 1$, while Theorem 10 gives a better bound on the field size than Theorem 11 for $h < \frac{2r}{\log_2 r} - 1$.

3.2.2 The case where $2 \leqslant a \leqslant r-1$

▶ **Lemma 12.** *Let $a \leqslant r \leqslant q+1$ and $m \geqslant h+a$. If $q^m \geqslant \frac{mn}{r}$, then there exists an MR (n, r, h, a)-LRC code over a field of size $\ell = q^{\min\{mh, \frac{mn}{r}\}}$.*

Proof. When $a \leqslant r \leqslant q+1$ and $m \geqslant h+a$, we have an $[r, r-a, a+1]_q$-MDS code and an $[r, r-m, h+a+1]_q$-linear code. The result thus follows from Theorem 8. ◀

▶ **Theorem 13.** *There exists an MR (n, r, h, a)-LRC over a field of size*

$$\ell \leqslant \left(\max\left\{\tilde{O}(\frac{n}{r}), (2r)^{h+a}\right\}\right)^{\min\{h, \frac{n}{r}\}}.$$

Proof. Let q be the smallest prime power such that $q-1 \geqslant r$. We may take q to be a power of two, so that $q \leqslant 2r$. Consider the rational function field $F = \mathbb{F}_q(x)$ and let

$$m = \max\left\{h+a, \left\lceil \log_q\left(\frac{n}{r}\right) + 2\log_q\log_q\left(\frac{n}{r}\right)\right\rceil\right\}.$$

Then $\frac{n}{r} \leqslant \frac{1}{m}q^m$. The desired result follows from Theorem 8. ◀

▶ Remark 3. The field size $\ell \leqslant \tilde{O}\left(\max\left\{\frac{n}{r}, r^{h+a}\right\}^h\right)$ in Theorem 13 was already given in [5, Corollary 11]. Here we provide a better result for $h > \frac{n}{r}$ via a different approach.

▶ **Theorem 14.** *There exists an MR (n, r, h, a)-LRC over a field of size*

$$\ell \leqslant \left(\max\left\{\tilde{O}(\frac{n}{r}), (2r)^r\right\}\right)^{\min\{h, \frac{n}{r}\}}.$$

Proof. Put $q = 2^{\lceil \log_2 r \rceil}$. Then $2r \geqslant q \geqslant r$ and hence we have a q-ary $[r, a]$-MDS code for any $a \leqslant r$. Put $m = \max\{r, \lceil \log_q\left(\frac{n}{r}\right) + 2\log_q \log_q\left(\frac{n}{r}\right)\rceil\}$. Then $\frac{n}{r} \leqslant \frac{1}{m}q^m$. The desired result follows from Theorem 10. ◀

▶ Remark 4. Theorem 14 gives a better bound on the field size than Theorem 13 for $h+a > r$, while Theorem 13 gives a better bound on the field size than Theorem 14 for $h + a < r$.

4 Explicit construction via general function fields

The construction via rational function fields given in Section 3 can be easily generalized to arbitrary function fields. We only generalize the constructions of MR LRCs via parity-check matrices given in Section 3.2. The necessary background on algebraic function fields, and specifically Hermitian and Garcia-Stichtenoth tower of function fields, can be found in the full version of this paper. We refer the proofs in this section to the full version of this paper.

Let q be a prime power and let a, r, h, g be integers with $a \leqslant r \leqslant q + 1$. Let $F/\mathbb{F}_q$ be a function field of genus $\mathfrak{g}$. Let $P_1, P_2, \ldots, P_g$ be g positive divisors of degree r whose supports are pairwise disjoint. Let G be a divisor of degree $2\mathfrak{g} - 1$. By Riemann-Roch, $\dim \mathcal{L}(G) = \mathfrak{g}$. Assume that $\{f_1, f_2, \ldots, f_\mathfrak{g}\}$ is a basis of $\mathcal{L}(G)$. For each i, extend this basis to a basis $\{f_1, f_2, \ldots, f_\mathfrak{g}, f_{i1}, f_{i2}, \ldots, f_{ir}\}$ of $\mathcal{L}(G + P_i)$.

Let Q be a place of degree $2\mathfrak{g} + \min\{hr, n\}$ and define the matrix

$$D_i = \begin{pmatrix} f_{i1}(Q) & f_{i2}(Q) & \cdots & f_{ir}(Q) \\ f_{i1}^q(Q) & f_{i2}^q(Q) & \cdots & f_{ir}^q(Q) \\ \vdots & \vdots & \vdots & \vdots \\ f_{i1}^{q^{h-1}}(Q) & f_{i2}^{q^{h-1}}(Q) & \cdots & f_{ir}^{q^{h-1}}(Q) \end{pmatrix} \tag{9}$$

By mimicking the proof of Theorem 8, we have the following result.

▶ **Lemma 15.** *Let $A_i \in \mathbb{F}_q^{a\times r}$ be a generator matrix of an $[r, a]_q$-MDS code for $1 \leqslant i \leqslant g$. Let D_i be the matrix given in (9). Put $\ell = q^{2\mathfrak{g}+\min\{hr,n\}}$. Then the ℓ-ary code C with the matrix H defined in (7) is an MR $(n, r, h, a)_\ell$-LRC.*

Consequently, we have the following theorem.

▶ **Theorem 16.** *Let r, g, a, h be positive integers with $a \leqslant r \leqslant q + 1$. If there is a function field $F/\mathbb{F}_q$ of genus $\mathfrak{g}$ with g positive divisors of degree r whose supports are disjoint, then there exists an MR (n, r, h, a)-LRC with $n = rg$ over a field of size $\ell = q^{2\mathfrak{g}+\min\{hr,n\}}$.*

Finally, let us instantiate the above result with the Hermitian function fields and the Garcia-Stichtenoth tower, to deduce Parts (v) and (vi) promised in Theorem 1 respectively. Note that both the results below kick-in for block lengths which are asymptotically at least $r^{O(r)}$, which is why we have the condition $r \leqslant O(\frac{\log n}{\log\log n})$ in the statement of Theorem 1, Parts (v), (vi).

▶ **Theorem 17.** *Let $a \leqslant r$ be integers. Then there are infinitely many $n \geqslant r^{\Omega(r)}$ such that there is MR (n, r, h, a)-LRC over a field of size at most $n^{\frac{2h}{3}(1+\varepsilon)}$ for any desired $\varepsilon \in (0, 0.5)$ provided $hr \geqslant \Omega\left(\frac{n^{\frac{2}{3}}}{\varepsilon}\right)$.*

We finally state a similar result using the Garcia-Stichtenoth tower of function fields.

▶ **Theorem 18.** *Let $a \leqslant r$ be positive integers and let $\varepsilon \in (0, 0.5)$. Then there are infinitely many $n \geqslant r^{\Omega(r/\varepsilon)}$ such that there is MR (n, r, h, a)-LRC over a field of size at most $n^{\varepsilon h}$ provided $hr \geqslant \Omega\left(n^{1-\varepsilon}\right)$.*

Abstract

In this paper we provide new quantum algorithms with polynomial speed-up for a range of problems for which no such results were known, or we improve previous algorithms. First, we consider the approximation of the frequency moments F_k of order $k \geq 3$ in the multi-pass streaming model with updates (turnstile model). We design a P-pass quantum streaming algorithm with memory M satisfying a tradeoff of $P^2M = \widetilde{\mathcal{O}}\left(n^{1-2/k}\right)$, whereas the best classical algorithm requires $PM = \Theta(n^{1-2/k})$. Then, we study the problem of estimating the number m of edges and the number t of triangles given query access to an n-vertex graph. We describe optimal quantum algorithms that perform $\widetilde{\mathcal{O}}\left(\sqrt{n}/m^{1/4}\right)$ and $\widetilde{\mathcal{O}}\left(\sqrt{n}/t^{1/6} + m^{3/4}/\sqrt{t}\right)$ queries respectively. This is a quadratic speed-up compared to the classical complexity of these problems.

For this purpose we develop a new quantum paradigm that we call Quantum Chebyshev's inequality. Namely we demonstrate that, in a certain model of quantum sampling, one can approximate with *relative error* the mean of any random variable with a number of quantum samples that is linear in the ratio of the square root of the variance to the mean. Classically the dependence is quadratic. Our algorithm subsumes a previous result of Montanaro [47]. This new paradigm is based on a refinement of the Amplitude Estimation algorithm of Brassard et al. [11] and of previous quantum algorithms for the mean estimation problem. We show that this speed-up is optimal, and we identify another common model of quantum sampling where it cannot be obtained. Finally, we develop a new technique called "variable-time amplitude estimation" that reduces the dependence of our algorithm on the sample preparation time.

1 Introduction

Motivations and Background. Randomization and probabilistic methods are among the most widely used techniques in modern science, with applications ranging from mathematical economics to medicine or particle physics. One of the most successful probabilistic approaches is the Monte Carlo Simulation method for algorithm design, that relies on repeated random sampling and statistical analysis to estimate parameters and functions of interest. From Buffon's needle experiment, in the eighteenth century, to the simulations of galaxy formation

or nuclear processes, this method and its variations have become increasingly popular to tackle problems that are otherwise intractable. The Markov chain Monte Carlo method [35] led for instance to significant advances for approximating parameters whose exact computation is #P-hard [39, 37, 20, 36].

The analysis of Monte Carlo Simulation methods is often based on concentration inequalities that characterize the deviation of a random variable from some parameter. In particular, the Chebyshev inequality is a key element in the design of randomized methods that estimate some target numerical value. Indeed, this inequality guarantees that the arithmetic mean of Δ^2/ϵ^2 independent samples, from a random variable with variance σ^2 and mean μ satisfying $\Delta \geq \sigma/\mu$, is an approximation of μ under relative error ϵ with high probability. This basic result is at the heart of many computational problems, such as counting via Markov chains [35, 54], estimating graph parameters [16, 25, 28, 22], testing properties of classical [29, 8, 15, 13] or quantum [12, 7] distributions, approximating the frequency moments in the data stream model [2, 46, 4].

Various quantum algorithms have been developed to speed-up or generalize classical Monte Carlo methods (e.g. sampling the stationary distributions of Markov-chains [55, 51, 19, 53, 17], estimating the expected values of observables or partition functions [41, 56, 51, 47]). The mean estimation problem (as addressed by Chebyshev's inequality) has also been studied in the *quantum sampling model*. In this model, a distribution is represented by a unitary transformation (called a *quantum sampler*) preparing a superposition over the elements of the distribution, with the amplitudes encoding the probability mass function. A *quantum sample* is defined as one execution of a quantum sampler or its inverse. The number of quantum samples needed to estimate the mean of a distribution on a bounded space $[0, B]$, with *additive* error ϵ, was proved to be $\mathcal{O}(B/\epsilon)$ [32, 10], or $\widetilde{\mathcal{O}}(\bar{\sigma}/\epsilon)$ [47] given an upper-bound $\bar{\sigma}^2$ on the variance. On the other hand, the mean estimation problem with *relative* error ϵ can be solved with $\mathcal{O}\left(\sqrt{B}/(\epsilon\sqrt{\mu})\right)$ quantum samples [11, 56]. Interestingly, this is a quadratic improvement over $\sigma^2/(\epsilon\mu)^2$ if the sample space is $\{0, B\}$ (this case maximizes the variance). Montanaro [47] posed the problem of whether this speed-up can be generalized to other distributions. He assumed that one knows an upper bound[1] Δ on $1 + \sigma/\mu$, and gave an algorithm using[2] $\widetilde{\mathcal{O}}\left(\Delta^2/\epsilon\right)$ quantum samples (thus improving the dependence on ϵ, compared to the classical setting). This result was reformulated in [43] to show that, having bounds $L \leq \mu \leq H$, it is possible to use $\widetilde{\mathcal{O}}(\Delta/\epsilon \cdot H/L)$ quantum samples. However, it is usually the case that the only upper-bound known on μ is $H = B$. In this situation, the latter algorithm is less efficient than previous works [11, 56].

Quantum Chebyshev's Inequality. Our main contribution (Theorem 10 and Theorem 11) is to show that the mean μ of any distribution with variance σ^2 can be approximated with relative error ϵ using $\widetilde{\mathcal{O}}(\Delta \cdot \log(H/L) + \Delta/\epsilon)$ quantum samples, given an upper bound Δ on $1 + \sigma/\mu$ and two bounds L, H such that $L < \mu < H$. This is an exponential improvement in H/L compared to previous works [43]. Moreover, if $\log(H/L)$ is negligible, this is a quadratic improvement over the number of classical samples needed when using the Chebyshev inequality. A corresponding lower bound is deduced from [50] (Theorem 12). We also show (Theorem 14) that no such speed-up is possible if we only had access to *copies* of the quantum state representing the distribution.

---

[1] More precisely, Δ is an upper bound on ϕ/μ where ϕ^2 is the second moment, which satisfies $\sigma/\mu \leq \phi/\mu \leq 1 + \sigma/\mu$.

[2] We use the notation $\widetilde{\mathcal{O}}(x)$ to indicate $\mathcal{O}(x \cdot \operatorname{polylog} x)$.

Our algorithm is based on *sequential analysis*. Given a threshold $b \geq 0$, we will consider the "truncated" mean $\mu_{<b}$ defined by replacing the outcomes larger than b with 0. Using standard techniques, this mean can be encoded in the amplitude of some quantum state $\sqrt{1-\mu_{<b}/b}|\psi\rangle + \sqrt{\mu_{<b}/b}|\psi^{\perp}\rangle$ (Corollary 4). We then run the *Amplitude Estimation* algorithm of Brassard et al. [11] on this state for Δ steps (i.e. with Δ quantum samples), only to see whether the estimate of $\mu_{<b}/b$ it returns is nonzero (this is our *stopping rule*). A property of this algorithm (Corollary 4 and Remark 7) guarantees that it is zero with high probability if and only if the number of quantum samples is below the inverse $\sqrt{b/\mu_{<b}}$ of the estimated amplitude. The crucial observation (Lemma 9) is that $\sqrt{b/\mu_{<b}}$ is smaller than Δ for large values of b, and it becomes larger than Δ when $b \approx \mu\Delta^2$. Thus, by repeatedly running the amplitude estimation algorithm with Δ quantum samples, and doing $\mathcal{O}(\log(H/L))$ steps of a logarithmic search on decreasing values of b, the first non-zero value is obtained when b/Δ^2 is approximately equal to μ. The precision of the result is later improved, by using more precise "truncated" means.

This algorithm is extended to cover the common situation where one knows a non-increasing function f such that $f(\mu) \geq 1 + \sigma/\mu$, instead of having explicitly $\Delta \geq 1 + \sigma/\mu$. For this purpose, we exhibit another property (Corollary 4 and Remark 6) of the amplitude estimation algorithm, namely that it always outputs a number smaller than the estimated value (up to a constant factor) with high probability. This shall be seen as a quantum equivalent of the Markov inequality. Combined with the previous algorithm, it allows us to find a value $f(\widetilde{\mu}) \geq 1 + \sigma/\mu$, with a second logarithmic search on $\widetilde{\mu}$. This result is detailed in the full version of the paper [31].

Next, we study the quantum analogue of the following standard fact: s classical samples, each taking *average* time T_{av} to be prepared, can be obtained in total average time $s \cdot T_{av}$. The notion of "average preparation time" is adapted to the quantum setting using the framework of variable-time algorithms introduced by Ambainis [3]. This captures the situation where the superposition prepared by the quantum sampler has different parts taking different times to be computed. We develop a variable-time amplitude estimation algorithm that approximates the target value efficiently in this case. We use it in place of the standard amplitude estimation technique to obtain an algorithm whose complexity depends on the average, instead of worst-case, sample preparation time. This result is detailed in the full version of the paper [31].

Applications. We describe two applications that illustrate the use of the above results. We first study the problem of approximating the frequency moments F_k of order $k \geq 3$ in the multi-pass streaming model with updates. Classically, the best P-pass algorithms with memory M satisfy $PM = \Theta\left(n^{1-2/k}\right)$ [46, 57]. We give a quantum algorithm for which $P^2M = \widetilde{\mathcal{O}}\left(n^{1-2/k}\right)$ (Theorem 18). This problem was studied before in [48], where the author obtained quantum speed-ups for F_0, F_2 and F_∞, but no significant improvement for $k \geq 3$. Similar tradeoff results are known for Disjointness ($P^2M = \widetilde{\Theta}(n)$ in the quantum streaming model [42] vs. $PM = \Theta(n)$ classically), and Dyck(2) ($P^3M = \Omega(\sqrt{n})$ [49] vs. $PM = \widetilde{\Theta}(\sqrt{n})$ [45, 14, 34]).

Our construction starts with a classical one-pass *linear sketch* streaming algorithm [46, 4] with memory polylog n, that samples (approximately) from a distribution with mean F_k and variance $\mathcal{O}\left(n^{1-2/k}F_k^2\right)$. We implement it with a quantum sampler, that needs two passes for one quantum sample. The crucial observation is that the reverse computation of a linear sketch algorithm can be done efficiently in one pass (whereas usually that would require processing the same stream but in the reverse direction).

As a second application, we study the approximation of graph parameters using neighbor, vertex-pair and degree queries. We show that the numbers m of edges and t of triangles, in an n-vertex graph, can be estimated with $\widetilde{\Theta}\left(n^{1/2}/m^{1/4}\right)$ (Theorem 19) and $\widetilde{\Theta}\left(\sqrt{n}/t^{1/6} + m^{3/4}/\sqrt{t}\right)$ (Theorem 21) quantum queries respectively. This is a quadratic speed-up over the best classical algorithms [28, 22]. The lower bounds (Theorems 20 and 22) are obtained with a property testing to communication complexity reduction method.

The number of edges is approximated by translating a classical estimator [52] into a quantum sampler. The triangle counting algorithm is more involved. We need a classical estimator [22] approximating the number t_v of adjacent triangles to any vertex v. The average sample preparation time of this estimator being small, we obtain a quadratic speed-up for estimating t_v using our mean estimation algorithm for variable-time samplers. We then diverge from the classical triangle counting algorithm of [22], that requires to set up a data structure for sampling edges uniformly in the graph. This technique seems to be an obstacle for a quadratic speed-up. We circumvent this problem by adapting instead a bucketing approach from [21] that partitions the graph's vertices according to the value of t_v. The size of each bucket is estimated using a second quantum sampler.

2 Preliminaries

2.1 Computational Model

In this paper we consider probability distributions d on some finite sample spaces $\Omega \subset \mathbb{R}^+$. We denote by $d(x)$ the probability to sample $x \in \Omega$ in the distribution d. We also make the assumption, which is satisfied for most of applications, that Ω is equipped with an efficient encoding of its elements $x \in \Omega$. In particular, we can perform quantum computations on the Hilbert space $\mathcal{H}_\Omega$ defined by the basis $\{|x\rangle\}_{x\in\Omega}$. Moreover, given any two values $0 \leq a < b$, we assume the existence of a unitary $R_{a,b}$ that can perform the *Bernoulli sampling* (see below) in time polylogarithmic in b. In the rest of the paper we will neglect this complexity, including the required precision for implementing any of those unitary operators.

▶ **Definition 1.** *Given a finite space $\Omega \subset \mathbb{R}^+$ and two reals $0 \leq a < b$, an* (a,b)-Bernoulli sampler over Ω *is a unitary $R_{a,b}$ acting on $\mathcal{H}_\Omega \otimes \mathbb{C}^2$ and satisfying for all $x \in \Omega$:*

$$R_{a,b}(|x\rangle|0\rangle) = \begin{cases} |x\rangle\left(\sqrt{1-\frac{x}{b}}|0\rangle + \sqrt{\frac{x}{b}}|1\rangle\right) & \text{when } a \leq x < b, \\ |x\rangle|0\rangle & \text{otherwise.} \end{cases}$$

We say that Ω is Bernoulli samplable *if any (a,b)-Bernoulli sampler can be implemented in polylogarithmic time in b, when a, b have polylog-size encodings in b.*

The $R_{a,b}$ operation can be implemented with a controlled rotation, and is reminiscent of related works on mean estimation (e.g. [56, 10, 47]). In what follows, we always use $a = 0$ or $a = b/2$. Using these notions, we can now define what a *quantum sample* is.

▶ **Definition 2.** *Given a finite Bernoulli samplable space $\Omega \subset \mathbb{R}^+$ and a distribution d on Ω, a* (quantum) sampler $\mathcal{S}$ *for d is a unitary operator acting on $\mathcal{H}_g \otimes \mathcal{H}_\Omega$, for some Hilbert space $\mathcal{H}_g$, such that*

$$\mathcal{S}(|0\rangle|0\rangle) = \sum_{x\in\Omega} \sqrt{d(x)}|\psi_x\rangle|x\rangle$$

where $|\psi_x\rangle$ are arbitrary unit vectors. A quantum sample *is one execution of $\mathcal{S}$ or $\mathcal{S}^{-1}$ (including their controlled versions). The* output *of $\mathcal{S}$ is the random variable $v(\mathcal{S})$ obtained by measuring the x-register of $\mathcal{S}(|0\rangle|0\rangle)$. Its* mean *is denoted by $\mu_\mathcal{S}$, its* variance *by $\sigma^2_\mathcal{S}$, and its* second moment *by $\phi^2_\mathcal{S} = \mathbb{E}\left[v(\mathcal{S})^2\right]$.*

Given a non-negative random variable X and two numbers $0 \leq a \leq b$, we define the random variable $X_{a,b} = \mathrm{id}_{a,b}(X)$ where $\mathrm{id}_{a,b}(x) = x$ when $a \leq x < b$ and $\mathrm{id}_{a,b}(x) = 0$ otherwise. If $a = 0$, we let $X_{<b} = X_{0,b}$. Similarly, $X_{\geq b} = \mathrm{id}_{\geq b}(X)$ where $\mathrm{id}_{\geq b}(x) = x$ when $x \geq b$ and $\mathrm{id}_{\geq b}(x) = 0$ otherwise.

We motivate the use of a Bernoulli sampler $R_{a,b}$ by the following observation: for any sampler $\mathcal{S}$ and values $0 \leq a < b$, the modified sampler $\hat{\mathcal{S}} = (I_{\mathcal{H}_g} \otimes R_{a,b})(\mathcal{S} \otimes I_{\mathbb{C}^2})$ acting on $\mathcal{H}_{\hat{g}} \otimes \mathcal{H}_{\hat{\Omega}}$, where $\mathcal{H}_{\hat{g}} = \mathcal{H}_g \otimes \mathcal{H}_\Omega$ and $\hat{\Omega} = \{0,1\}$, generates the Bernoulli distribution $d(0) = 1 - p$, $d(1) = p$ of mean $p = \mathbb{E}\left[v(\hat{\mathcal{S}})\right] = b^{-1}\mathbb{E}\left[v(\mathcal{S})_{a,b}\right]$ (see the proof of Corollary 4). This central result will be used all along this paper.

Other Quantum Sampling Models. Instead of having access to the unitary $\mathcal{S}$, one could only have copies of the state $\sum_{x\in\Omega}\sqrt{d(x)}|\psi_x\rangle|x\rangle$ (as in [5] for instance). However, as we show in Theorem 14, the speed-up presented in this paper is impossible to achieve in this model. On another note, Aharonov and Ta-Shma [1] studied the *Qsampling* problem, which is the ability to prepare $\sum_{x\in\Omega}\sqrt{d(x)}|x\rangle$ given the decription of a classical circuit with output distribution d. This problem becomes straightforward if a garbage register ψ_x can be added (using standard reversible-computation techniques). Bravyi, Harrow and Hassidim [12] considered an oracle-based model, that is provably weaker than Qsampling, where a distribution $d = (d(1), \ldots, d(N))$ on $\Omega = [N]$ is represented by an oracle $O_d : [S] \to [N]$ (for some S), such that $d(x)$ equals the proportion of inputs $s \in [S]$ with $O_d(s) = x$. It is extended to the quantum query framework with a unitary $\mathcal{O}_d$ such that $\mathcal{O}_d|s\rangle|0\rangle = |s\rangle|O_d(s)\rangle$. It is not difficult to see that applying $\mathcal{O}_d$ on a uniform superposition gives $\sum_{x\in[N]}\sqrt{d(x)}\left(\frac{1}{\sqrt{d(x)S}}\sum_{s\in[S]:O_d(s)=x}|s\rangle\right)|x\rangle$, as required by Definition 2 (where $|\psi_x\rangle = \frac{1}{\sqrt{d(x)S}}\sum_{s\in[S]:O_d(s)=x}|s\rangle$). Finally, Montanaro [47] presented a model that is similar to ours, where he replaced the x-register of $\mathcal{S}(|0\rangle|0\rangle)$ with a k-qubit register (for some k) combined with a mapping $\phi : \{0,1\}^k \to \Omega$ where $x = \phi(s)$ is the sample associated to each $s \in \{0,1\}^k$.

2.2 Amplitude Estimation

The essential building block of this paper is the amplitude estimation algorithm [11], combined with ideas from [56, 10, 47], to estimate the modified mean $b^{-1}\mathbb{E}\left[v(\mathcal{S})_{a,b}\right]$ of a quantum sampler $\mathcal{S}$ to which a Bernoulli sampler $R_{a,b}$ has been applied. We will need the following result about amplitude estimation.

▶ **Theorem 3.** *There is a quantum algorithm* AmplEst*, called* Amplitude Estimation*, that takes as input a unitary operator U, an orthogonal projector Π, and an integer $t > 2$. The algorithm outputs an estimate $\widetilde{p} = \mathsf{AmplEst}\,(U, \Pi, t)$ of $p = \langle\psi|\Pi|\psi\rangle$, where $|\psi\rangle = U|0\rangle$, such that*

$$\begin{cases} |\widetilde{p} - p| \leq 2\pi\frac{\sqrt{p}}{t} + \frac{\pi^2}{t^2}, & \text{with probability } 8/\pi^2; \\ \widetilde{p} = 0, & \text{with probability } \frac{\sin^2(t\theta)}{t^2\sin^2(\theta)}. \end{cases}$$

and $0 \leq \theta \leq \pi/2$ satisfies $\sin(\theta) = \sqrt{p}$. It uses $\mathcal{O}\left(\log^2(t)\right)$ 2-qubit quantum gates (independent of U and Π) and makes $2t+1$ calls to (the controlled versions of) U and U^{-1}, and t calls to the reflection $I - 2\Pi$.

We now present an adaptation of the algorithms from [56, 10, 47] to estimate $b^{-1}\mathbb{E}\left[v(\mathcal{S})_{a,b}\right]$.

Input: a sampler $\mathcal{S}$ acting on $\mathcal{H}_g \otimes \mathcal{H}_\Omega$, two values (a, b), an integer t, a failure parameter $0 < \delta < 1$.
Output: an estimate $\widetilde{p} = \mathsf{BasicEst}(\mathcal{S}, (a, b), t, \delta)$ of $p = b^{-1}\mathbb{E}[v(\mathcal{S})_{a,b}]$

1. Let $U = (I_{\mathcal{H}_g} \otimes R_{a,b})(\mathcal{S} \otimes I_{\mathbb{C}^2})$ and $\Pi = I_{\mathcal{H}_g} \otimes I_{\mathcal{H}_\Omega} \otimes |1\rangle\langle 1|$.
2. For $i = 1, \ldots, \Theta(\log(1/\delta))$: compute $\widetilde{p}_i = \mathsf{AmplEst}(U, \Pi, t)$.
3. Output $\widetilde{p} = \mathrm{median}\{\widetilde{p}_1, \ldots, \widetilde{p}_{\Theta(\log(1/\delta))}\}$.

Algorithm 1 The Basic Estimation algorithm BasicEst.

▶ **Corollary 4.** *Consider a quantum sampler $\mathcal{S}$ and two values $0 \leq a < b$. Denote $p = b^{-1}\mathbb{E}[v(\mathcal{S})_{a,b}]$. Given an integer $t > 2$ and a real $0 < \delta < 1$, $\mathsf{BasicEst}(\mathcal{S}, (a, b), t, \delta)$ (see Algorithm 1) uses $\mathcal{O}(t \log(1/\delta))$ quantum samples and outputs $\widetilde{p}$ satisfying all of the following inequalities with probability $1 - \delta$:*

(1) $|\widetilde{p} - p| \leq 2\pi\frac{\sqrt{p}}{t} + \frac{\pi^2}{t^2}$, *for any t;* (2) $\widetilde{p} \leq (1 + 2\pi)^2 \cdot p$, *for any t;*

(3) $\widetilde{p} = 0$, *when $t < \frac{1}{2\sqrt{p}}$;* (4) $|\widetilde{p} - p| \leq \epsilon \cdot p$, *when $t \geq \frac{8}{\epsilon\sqrt{p}}$ and $0 < \epsilon < 1$.*

Proof. We show that each $\widetilde{p}_i$ satisfies the inequalities stated in the corollary, with probability $8/\pi^2$. Since $\widetilde{p}$ is the median of $\Theta(\log 1/\delta)$ such values, the probability is increased to $1 - \delta$ using the Chernoff bound.

For each $x \in \Omega$, denote $\nu_x = \frac{x}{b}$ if $a \leq x < b$, and $\nu_x = 0$ otherwise. Since $p = \sum_{x\in\Omega} \nu_x d(x)$, observe that

$$U(|0\rangle|0\rangle|0\rangle) = \sum_{x\in\Omega} \sqrt{d(x)}|\psi_x\rangle|x\rangle \left(\sqrt{1-\nu_x}|0\rangle + \sqrt{\nu_x}|1\rangle\right) = \sqrt{1-p}|\psi_0'\rangle|0\rangle + \sqrt{p}|\psi_1'\rangle|1\rangle$$

where $|\psi_0'\rangle = \frac{1}{\sqrt{1-p}} \sum_{x\in\Omega} \sqrt{d(x)}\sqrt{1-\nu_x}|\psi_x\rangle|x\rangle$ and $|\psi_1'\rangle = \frac{1}{\sqrt{p}} \sum_{x\in\Omega} \sqrt{d(x)}\sqrt{\nu_x}|\psi_x\rangle|x\rangle$ are unit vectors. Thus, the output $\widetilde{p}_i$ of the AmplEst algorithm applied on U and Π is an estimate of p satisfying the output conditions of Theorem 3. Therefore $|\widetilde{p}_i - p| \leq 2\pi\frac{\sqrt{p}}{t} + \frac{\pi^2}{t^2}$ with probability $8/\pi^2$, for any t. By plugging $t \geq \frac{8}{\epsilon\sqrt{p}}$ into this inequality we have $|\widetilde{p}_i - p| \leq \epsilon \cdot p$. By plugging $t \geq \frac{1}{2\sqrt{p}}$ we also have $|\widetilde{p}_i - p| \leq (4\pi + 4\pi^2)p$, and thus $\widetilde{p}_i \leq (1 + 2\pi)^2 \cdot p$. Finally, if $t < \frac{1}{2\sqrt{p}}$, denote $0 \leq \theta \leq \pi/2$ such that $\sin(\theta) = \sqrt{p}$ and observe that $\theta \leq \frac{\pi}{2}\sqrt{p} \leq \frac{\pi}{4t}$ (since $\frac{2}{\pi}x \leq \sin(x) \leq x$, for $x \in [0, \pi/2]$). The probability to obtain $\widetilde{p}_i = 0$ is $\frac{\sin^2(t\theta)}{t^2\sin^2(\theta)} \geq \frac{\sin^2(t\pi/(4t))}{t^2\sin^2(\pi/(4t))} \geq \frac{\sin^2(\pi/4)}{t^2(\pi/(4t))^2} = 8/\pi^2$, since $x \mapsto \sin^2(tx)/(t^2\sin^2(x))$ is decreasing for $0 < x \leq \pi/t$. Moreover, when $t < \frac{1}{2\sqrt{p}}$, the first two inequalities are obviously satisfied if $\widetilde{p}_i = 0$. ◀

The four results on p in Corollary 4 lie at the heart of this paper. We make a few comments on them.

▶ Remark 5. Consider a sampler $\mathcal{S}$ over $\Omega = \{0, 1\}$ for the Bernoulli distribution of parameter p. Using the Chebyshev inequality, we get that $\mathcal{O}\left((1-p)/(\epsilon^2 p)\right)$ classical samples are enough for estimating p with relative error ϵ. The inequality (4) of Corollary 4 shows that $t = \mathcal{O}\left(1/(\epsilon\sqrt{p})\right)$ quantum samples are sufficient. Our main result (Section 3) generalizes this quadratic speed-up to the non-Bernoulli case.

▶ Remark 6. The inequality (2) shall be seen as an equivalent of the Markov inequality[3], namely that $\widetilde{p}$ does not exceed p by a large factor with large probability.

[3] The Markov inequality for a non-negative random variable X states that $\mathbb{P}(X \geq k\mathbb{E}[X]) \leq 1/k$ for any $k > 0$. Here, although we do not need this result, it is possible to prove that $\mathbb{P}(\widetilde{p} \geq kp) \leq C/\sqrt{k}$, for some absolute constant C.

Input: a sampler $\mathcal{S}$, an integer $\Delta_{\mathcal{S}}$, two values $0 < L < H$, two reals $0 < \epsilon, \delta < 1/2$.
Output: an estimate $\widetilde{\mu}_{\mathcal{S}}$ of $\mu_{\mathcal{S}}$.

1. Set $M = 8H$ and $\widetilde{p} = 0$
2. While $\widetilde{p} = 0$ and $M \geq 2L$:
   a. Set $M = M/2$.
   b. Compute $\widetilde{p} = \mathsf{BasicEst}\left(\mathcal{S}, (0, M\Delta_{\mathcal{S}}^2), 25\Delta_{\mathcal{S}}, \delta'\right)$ where $\delta' = \frac{\delta}{2(3+\log(H/L))}$.
3. If $M < 2L$ then output $\widetilde{\mu}_{\mathcal{S}} = 0$.
4. Else, compute $\widetilde{q} = \mathsf{BasicEst}\left(\mathcal{S}, (0, \epsilon^{-1}M\Delta_{\mathcal{S}}^2), 35^2\epsilon^{-3/2}\Delta_{\mathcal{S}}, \delta/2\right)$ and output $\widetilde{\mu}_{\mathcal{S}} = (\epsilon^{-1}M\Delta_{\mathcal{S}}^2) \cdot \widetilde{q}$.

Algorithm 2 $\epsilon-$approximation of the mean of a quantum sampler $\mathcal{S}$.

▶ Remark 7. If $p \neq 0$, inequalities (3) and (4) imply that, with large probability, $t < 8/\sqrt{p}$ when $\widetilde{p} = 0$, and $t \geq 1/(2\sqrt{p})$ when $\widetilde{p} \neq 0$. This phenomenon, at $t = \Theta(1/\sqrt{p})$, is crucially used in the next section.

3 Quantum Chebyshev's Inequality

We describe our main algorithm for estimating the mean $\mu_{\mathcal{S}}$ of any quantum sampler $\mathcal{S}$, given an upper bound $\Delta_{\mathcal{S}} \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$ (we recall that $\phi_{\mathcal{S}}^2 = \mathbb{E}\left[v(\mathcal{S})^2\right]$ and $\sigma_{\mathcal{S}}/\mu_{\mathcal{S}} \leq \phi_{\mathcal{S}}/\mu_{\mathcal{S}} \leq 1 + \sigma_{\mathcal{S}}/\mu_{\mathcal{S}}$). The two main tools used in this section are the BasicEst algorithm of Corollary 4, and the following lemma on "truncated" means. We recall that $X_{<b}$ (resp. $X_{\geq b}$) is defined from a non-negative random variable X by substituting the outcomes greater or equal to b (resp. less than b) with 0. Note that $X = X_{<b} + X_{\geq b}$ for all $b > 0$.

▶ **Fact 8.** *For any random variable X and real numbers $0 < a \leq b$, we have $\mathbb{E}\left[X_{a,b}\right] \leq \frac{\mathbb{E}\left[X_{a,b}^2\right]}{a}$ and $\mathbb{E}\left[X_{\geq b}\right] \leq \frac{\mathbb{E}\left[X_{\geq b}^2\right]}{b}$.*

▶ **Lemma 9.** *Let X be a non-negative random variable and $\Delta \geq \sqrt{\mathbb{E}\left[X^2\right]}/\mathbb{E}\left[X\right]$. Then, for all $c_1, c_2, M > 0$ such that $c_1 \cdot \mathbb{E}\left[X\right] \leq M \leq c_2 \cdot \mathbb{E}\left[X\right]$, we have*

$$\left(1 - \frac{1}{c_1}\right)\mathbb{E}\left[X\right] \leq \mathbb{E}\left[X_{<M\Delta^2}\right] \leq \mathbb{E}\left[X\right] \quad \text{and} \quad \sqrt{c_1}\cdot\Delta \leq \sqrt{\frac{M\Delta^2}{\mathbb{E}\left[X_{<M\Delta^2}\right]}} \leq \sqrt{c_2\left(1 - \frac{1}{c_1}\right)}\cdot\Delta$$

Proof. The first inequality is a consequence of $\mathbb{E}\left[X_{<M\Delta^2}\right] = \mathbb{E}\left[X\right] - \mathbb{E}\left[X_{\geq M\Delta^2}\right]$ and $0 \leq \mathbb{E}\left[X_{\geq M\Delta^2}\right] \leq \mathbb{E}\left[X_{\geq M\Delta^2}^2\right]/(M\Delta^2) \leq \mathbb{E}\left[X^2\right]/(M\Delta^2) \leq (1/c_1)\cdot\mathbb{E}\left[X\right]$ (using Fact 8). The second inequality is a direct consequence of the left one, and of the hypothesis $c_1 \cdot \mathbb{E}\left[X\right] \leq M \leq c_2 \cdot \mathbb{E}\left[X\right]$. ◀

Our mean estimation algorithm works in two stages. We first compute a rough estimate $M \in [2\mu_{\mathcal{S}}, 2500\mu_{\mathcal{S}}]$ with $\widetilde{\mathcal{O}}\left(\Delta_{\mathcal{S}} \cdot \log(H/L)\right)$ quantum samples (where $0 < L < \mu_{\mathcal{S}} < H$ are known bounds on $\mu_{\mathcal{S}}$). Then, we improve the accuracy of the estimate to any value ϵ, at extra cost $\widetilde{\mathcal{O}}\left(\Delta_{\mathcal{S}}/\epsilon^{3/2}\right)$.

▶ **Theorem 10.** *If $\Delta_{\mathcal{S}} \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$ and $L < \mu_{\mathcal{S}} < H$ then the output $\widetilde{\mu}_{\mathcal{S}}$ of Algorithm 2 satisfies $|\widetilde{\mu}_{\mathcal{S}} - \mu_{\mathcal{S}}| \leq \epsilon\mu_{\mathcal{S}}$ with probability $1 - \delta$. Moreover, for any $\Delta_{\mathcal{S}}, L, H$ it satisfies $\widetilde{\mu}_{\mathcal{S}} \leq (1 + 2\pi)^2\mu_{\mathcal{S}}$ with probability $1 - \delta$. The number of quantum samples used by the algorithm is $\mathcal{O}\left(\Delta_{\mathcal{S}} \cdot \left(\log\left(\frac{H}{L}\right)\log\left(\frac{\log(H/L)}{\delta}\right) + \epsilon^{-3/2}\log\left(\frac{1}{\delta}\right)\right)\right)$.*

Proof. Assume that $\Delta_{\mathcal{S}} \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$ and $L < \mu_{\mathcal{S}} < H$. We denote $p = (M\Delta_{\mathcal{S}}^2)^{-1} \cdot \mathbb{E}\left[v(\mathcal{S})_{<M\Delta_{\mathcal{S}}^2}\right]$. By Lemma 9, if $M \geq 2500\mu_{\mathcal{S}}$ then $25\Delta_{\mathcal{S}} \leq \frac{1}{2\sqrt{p}}$, and if $2\mu_{\mathcal{S}} \leq M \leq 4\mu_{\mathcal{S}}$ then $25\Delta_{\mathcal{S}} > \frac{8}{\sqrt{p}}$. Therefore, by Corollary 4, with probability $1-\delta'$, the value $\widetilde{p}$ computed at Step 2.(b) is equal to 0 when $M \geq 2500\mu_{\mathcal{S}}$, and is different from 0 when $2\mu_{\mathcal{S}} \leq M \leq 4\mu_{\mathcal{S}}$. Thus, the first time Step 2.(b) of Algorithm 2 computes $\widetilde{p} \neq 0$ happens for $M \in [2\mu_{\mathcal{S}}, 2500\mu_{\mathcal{S}}]$, with probability at least $(1-\delta')^{1+\log(4H/(2\mu_{\mathcal{S}}))} > 1-\delta/2$.

Consequently, we can assume that Step 4 is executed with $M \in [2\mu_{\mathcal{S}}, 2500\mu_{\mathcal{S}}]$, and we let $M' = M/\epsilon$. According to Lemma 9 we have $(1-\epsilon/2)\mu_{\mathcal{S}} \leq \mathbb{E}\left[v(\mathcal{S})_{<M'\Delta_{\mathcal{S}}^2}\right] \leq \mu_{\mathcal{S}}$ and $35^2\epsilon^{-3/2}\Delta_{\mathcal{S}} \geq \frac{8}{(\epsilon/2)\sqrt{q}}$, where $q = (M'\Delta_{\mathcal{S}}^2)^{-1} \cdot \mathbb{E}\left[v(\mathcal{S})_{<M'\Delta_{\mathcal{S}}^2}\right]$. Thus, according to Corollary 4, the value $\widetilde{q}$ satisfies $|\widetilde{q}-q| \leq (\epsilon/2)q$ with probability $1-\delta/2$. Using the triangle inequality, it implies $|(\epsilon^{-1}M\Delta_{\mathcal{S}}^2)\cdot\widetilde{q} - \mu_{\mathcal{S}}| \leq \epsilon\mu_{\mathcal{S}}$.

If $L \geq \mu_{\mathcal{S}}$ this may only increase the probability to stop at Step 3 and output $\widetilde{\mu}_{\mathcal{S}} = 0$. If Step 4 is executed we still have $\widetilde{\mu}_{\mathcal{S}} \leq (1+2\pi)^2\mu_{\mathcal{S}}$ with probability $1-\delta$, as a consequence of Corollary 4. ◀

In the full version [31], we improve Step 4 of Algorithm 2 to obtain the following result with (nearly) optimal dependence on ϵ.

▶ **Theorem 11.** *There is an algorithm that, given a sampler $\mathcal{S}$, an integer $\Delta_{\mathcal{S}}$, two values $0 < L < H$, and two reals $0 < \epsilon, \delta < 1$, outputs an estimate $\widetilde{\mu}_{\mathcal{S}}$ of $\mu_{\mathcal{S}}$. If $\Delta_{\mathcal{S}} \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$ and $L < \mu_{\mathcal{S}} < H$, it satisfies $|\widetilde{\mu}_{\mathcal{S}} - \mu_{\mathcal{S}}| \leq \epsilon\mu_{\mathcal{S}}$ with probability $1-\delta$. Moreover, for any $\Delta_{\mathcal{S}}, L, H$ it satisfies $\widetilde{\mu}_{\mathcal{S}} \leq (1+2\pi)^2\mu_{\mathcal{S}}$ with probability $1-\delta$. The number of quantum samples used by the algorithm is $\mathcal{O}\left(\Delta_{\mathcal{S}} \cdot \left(\log\left(\frac{H}{L}\right)\log\left(\frac{\log(H/L)}{\delta}\right) + \epsilon^{-1}\log^{3/2}(\Delta_{\mathcal{S}})\log\left(\frac{\log\Delta_{\mathcal{S}}}{\delta}\right)\right)\right)$.*

In Section 4, we describe an $\Omega((\Delta_{\mathcal{S}}-1)/\epsilon)$ lower bound for this mean estimation problem. Before, we present three kinds of generalizations of the above algorithms.

- **Higher moments.** Given an upper-bound $\Delta_{\mathcal{S}}^2 \geq \left(\mathbb{E}\left[v(\mathcal{S})^k\right]/\mathbb{E}\left[v(\mathcal{S})\right]^k\right)^{1/(k-1)}$ on the relative moment of order $k \geq 2$, one can easily generalize Facts 8, Lemma 9 and Theorem 11 to show that $\mu_{\mathcal{S}}$ can be estimated using $\widetilde{\mathcal{O}}\left(\Delta_{\mathcal{S}} \cdot \epsilon^{-1/(2(k-1))}\log(H/L)\log(1/\delta)\right)$ quantum samples.
- **Implicit upper bound on $\boldsymbol{\phi_{\mathcal{S}}/\mu_{\mathcal{S}}}$.** If instead of an explicit value $\Delta_{\mathcal{S}} \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$ we are given a non-increasing function f such that $f(\mu_{\mathcal{S}}) \geq \phi_{\mathcal{S}}/\mu_{\mathcal{S}}$, we can still estimate the mean $\mu_{\mathcal{S}}$ using $\widetilde{\mathcal{O}}\left(f(\mu_{\mathcal{S}}/c)\cdot\epsilon^{-1}\log(H/L)\log(1/\delta)\right)$ quantum samples, where $c > 1$ is an absolute constant. The proof is deferred to the full version [31] (it crucially uses the Markov-like inequality "$\widetilde{\mu}_{\mathcal{S}} \leq (1+2\pi)^2\mu_{\mathcal{S}}$" of Corollary 4 and Remark 6).
- **Time complexity and variable-time samplers.** The *time complexity* (number of quantum gates) of all above algorithms is essentially equal to the number of quantum samples multiplied by the time complexity $T_{max}(\mathcal{S})$ of the considered sampler. However, $T_{max}(\mathcal{S})$ is often much larger than the more desirable *ℓ_2-average running time* $T_{\ell_2}(\mathcal{S})$ defined by Ambainis [3] in the context of variable-time algorithms, where some branches of computation may stop earlier than the others. In the full version [31], we develop a new technique called *variable-time amplitude estimation* that improves the *time* complexity of our algorithm to $\widetilde{\mathcal{O}}\left(\Delta_{\mathcal{S}}\cdot\epsilon^{-2}T_{\ell_2}(\mathcal{S})\cdot\log^4(T_{max}(\mathcal{S}))\log(H/L)\log(1/\delta)\right)$.

The last two results are combined together in the algorithm of Theorem 21 to approximate the number of triangles in any graph.

4 Optimality and Separation Results

Using a result due to Nayak and Wu [50] on approximate counting, we can show a corresponding lower bound to Theorem 11 already in the simple case of Bernoulli variables. For this purpose, we define that an algorithm $\mathcal{A}$ solves the *Mean Estimation problem for parameters* ϵ, Δ if, for any sampler $\mathcal{S}$ satisfying $\phi_{\mathcal{S}}/\mu_{\mathcal{S}} \in [\Delta, 4\Delta]$ (the constant 4 is arbitrary), it outputs a value $\widetilde{\mu}_{\mathcal{S}}$ satisfying $|\widetilde{\mu}_{\mathcal{S}} - \mu_{\mathcal{S}}| \leq \epsilon\mu_{\mathcal{S}}$ with probability 2/3.

▶ **Theorem 12.** *Any algorithm solving the Mean Estimation problem for parameters* $0 < \epsilon < 1/5$ *and* $\Delta > 1$ *on the sample space* $\Omega = \{0,1\}$ *must use* $\Omega\left((\Delta-1)/\epsilon\right)$ *quantum samples.*

Proof. Consider an algorithm $\mathcal{A}$ solving the Mean Estimation problem for parameters $0 < \epsilon < 1/5$, $\Delta > 1$ using N quantum samples. Take two integers $0 < t < n$ large enough such that $\sqrt{2}\Delta \leq \sqrt{n/t} \leq 4\Delta$ and $\epsilon t > 1$. For any oracle $\mathcal{O} : \{1, \ldots, n\} \to \{0,1\}$, define the quantum sampler $\mathcal{S}_{\mathcal{O}}(|0\rangle|0\rangle) = \frac{1}{\sqrt{n}} \sum_{i\in[n]} |i\rangle|\mathcal{O}(i)\rangle$ and let $t_{\mathcal{O}} = |\{i \in [n] : \mathcal{O}(i) = 1\}|$. Observe that $\mu_{\mathcal{S}_{\mathcal{O}}} = \phi^2_{\mathcal{S}_{\mathcal{O}}} = t_{\mathcal{O}}/n$, and one quantum sample from $\mathcal{S}_{\mathcal{O}}$ can be implemented with one quantum query to $\mathcal{O}$.

According to [50, Corollary 1.2], any algorithm that can distinguish $t_{\mathcal{O}} = t$ from $t_{\mathcal{O}} = \lceil (1+4\epsilon)t \rceil$ makes $\Omega\left(\sqrt{n/(\epsilon t)} + \sqrt{t(n-t)/(\epsilon t)}\right) = \Omega\left((\sqrt{n/t} - 1)/\epsilon\right) = \Omega\left((\Delta-1)/\epsilon\right)$ quantum queries to $\mathcal{O}$. However, given the promise that $t_{\mathcal{O}} = t$ or $t_{\mathcal{O}} = \lceil (1+4\epsilon)t \rceil$ we can use $\mathcal{A}$ with input $\mathcal{S}_{\mathcal{O}}$, ϵ, Δ to distinguish between the two cases using N samples, that is N queries to $\mathcal{O}$. Indeed, $\phi_{\mathcal{S}_{\mathcal{O}}}/\mu_{\mathcal{S}_{\mathcal{O}}} = \sqrt{n/t_{\mathcal{O}}} \in [\Delta, 4\Delta]$ for such samplers (since $\lceil (1+4\epsilon)t \rceil \leq (1+5\epsilon)t \leq 2t$). Thus, $\mathcal{A}$ must use $N = \Omega\left((\Delta-1)/\epsilon\right)$ quantum samples. ◀

One may wonder whether the quantum speed-up presented in this paper holds if we only have access to copies of a quantum state $\sum_{x\in\Omega} \sqrt{d(x)}|\psi_x\rangle|x\rangle$ (instead of access to a unitary $\mathcal{S}$ preparing it). Below we answer this question negatively. For this purpose, we define that an algorithm $\mathcal{A}$ solves the *state-based Mean Estimation problem for parameters* ϵ, Δ if, using access to some copies of an unknown state $|d\rangle = \sum_{x\in\Omega} \sqrt{d(x)}|x\rangle$ satisfying $\phi_d/\mu_d \in [\Delta, 4\Delta]$ (where $\mu_d = \sum_x d(x)x$ and $\phi_d^2 = \sum_x d(x)x^2$), it outputs a value $\widetilde{\mu}_d$ satisfying $|\widetilde{\mu}_d - \mu_d| \leq \epsilon\mu_d$ with probability 2/3.

▶ **Lemma 13.** *Consider two distributions* d, d' *represented by the states* $|d\rangle = \sum_{x\in\Omega} \sqrt{d(x)}|x\rangle$ *and* $|d'\rangle = \sum_{x\in\Omega} \sqrt{d'(x)}|x\rangle$. *The smallest integer* T *needed to be able to discriminate* $|d\rangle^{\otimes T}$ *and* $|d'\rangle^{\otimes T}$ *with success probability* 2/3 *satisfies* $T \geq \frac{\ln(9/8)}{D(d||d')}$, *where* $D(d||d')$ *is the KL-divergence from* d *to* d'.

Proof. According to Helstrom's bound [33] the best success probability to discriminate two states $|\psi\rangle$ and $|\phi\rangle$ is $\frac{1}{2}(1 + \sqrt{1 - |\langle\psi|\phi\rangle|^2})$. Consequently, T must satisfy $\frac{1}{2}(1 + \sqrt{1 - \langle d|d'\rangle^{2T}}) \geq 2/3$, which implies

$$T \geq \frac{\ln(9/8)}{-\ln(\langle d|d'\rangle^2)} = \frac{\ln(9/8)}{-2\ln\left(\sum_x d(x)\sqrt{d'(x)/d(x)}\right)} \geq \frac{\ln(9/8)}{\sum_x d(x)\ln\left(d(x)/d'(x)\right)} = \frac{\ln(9/8)}{D(d||d')}$$

where we used the concavity of the $-\ln$ function. ◀

▶ **Theorem 14.** *Any algorithm solving the state-based Mean Estimation problem for parameters* $0 < \epsilon < 1/100$ *and* $\Delta > 1$ *on the sample space* $\Omega = \{0,1\}$ *must use* $\Omega\left((\Delta^2-1)/\epsilon^2\right)$ *copies of the input state.*

Proof. Consider an algorithm $\mathcal{A}$ solving the state-based Mean Estimation problem for parameters $0 < \epsilon < 1/100$, $\Delta > 1$ using N copies of the input state. Given any $|d\rangle = \sqrt{1-p}|0\rangle + \sqrt{p}|1\rangle$ with $\phi_d/\mu_d \in [\sqrt{6}\Delta, \sqrt{8}\Delta]$ (notice that $\mu_d = \phi_d^2 = p$ and $1-p \geq 5/6 \geq 12\epsilon$), we show how to construct a state $|d'\rangle = \sqrt{1-p'}|0\rangle + \sqrt{p'}|1\rangle$ such that

$$(1)\ (1+4\epsilon)\mu_d < \mu_{d'} < (1+24\epsilon)\mu_d\ ;\ \ (2)\ \phi_{d'}/\mu_{d'} \in [\Delta, 4\Delta]\ ;\ \ (3)\ D(d||d') \leq (12\epsilon)^2/(\Delta^2-1).$$

It is clear that $\mathcal{A}$ can be used to discriminate two such states. On the other hand, according to Lemma 13, any such algorithm muse use $N = \Omega\left(1/D(d||d')\right) = \Omega\left((\Delta^2-1)/\epsilon^2\right)$ copies of the input state.

The construction of d' is adapted from [18, Section 7]. We set $p' = pe^{\alpha(1-p)}/\psi$ where $\alpha = 12\epsilon/(1-p) < 1$ and $\psi = (1-p)e^{-\alpha p} + pe^{\alpha(1-p)}$ (so that $1-p' = (1-p)e^{-\alpha p}/\psi$). We let $\dot{\psi}$ (resp. $\ddot{\psi}$) denote the first (resp. second) derivative of ψ with respect to α. A simple calculation shows that $\mu_{d'} - \mu_d = \dot{\psi}/\psi$ and $D(d||d') = \ln\psi$. Moreover, $\sigma_{d'}^2 = \mathbb{E}_{x\sim d'}\left[(x-\mu_{d'})^2\right] = \mathbb{E}_{x\sim d'}\left[(x-\mu_d)^2\right] + 2(\mu_d - \mu_{d'})\mathbb{E}_{x\sim d'}\left[x-\mu_d\right] + (\mu_d-\mu_{d'})^2 = \mathbb{E}_{x\sim d}\left[(x-p)^2 e^{\alpha(x-p)-\ln\psi}\right] - (\mu_d-\mu_{d'})^2 = \ddot{\psi}/\psi - (\dot{\psi}/\psi)^2$.

Since $\psi = \mathbb{E}_{x\sim d}\left[e^{\alpha(x-p)}\right]$, it can be deduced from the standard inequality $1+u+u^2/3 \leq e^u \leq 1+u+u^2$ (when $|u| \leq 1$) that $1 \leq 1 + \frac{p(1-p)}{3}\cdot\alpha^2 \leq \psi \leq 1 + p(1-p)\cdot\alpha^2 \leq 2$. Consequently, $\frac{2p(1-p)}{3}\cdot\alpha \leq \dot{\psi} \leq 2p(1-p)\cdot\alpha$ and $\frac{2p(1-p)}{3} \leq \ddot{\psi} \leq 2p(1-p)$. It implies that $4\epsilon p \leq \mu_{d'} - \mu_d \leq 24\epsilon p$ and $p(1-p)/3 - (24\epsilon p)^2 \leq \sigma_{d'}^2 \leq 2p(1-p)$. Thus, $(1+4\epsilon)\mu_d \leq \mu_{d'} \leq (1+24\epsilon)\mu_d \leq \sqrt{2}\mu_d$ and $\frac{1}{6}\sigma_d^2/\mu_d^2 - (24\epsilon/\sqrt{2})^2 \leq \sigma_{d'}^2/\mu_{d'}^2 \leq 2\sigma_d^2/\mu_d^2$. Since $\sigma_{d'}^2/\mu_{d'}^2 = \phi_{d'}^2/\mu_{d'}^2 - 1$ and $\phi_d/\mu_d \in [\sqrt{6}\Delta, \sqrt{8}\Delta]$, we obtain that $\Delta \leq \frac{1}{\sqrt{6}}\phi_d/\mu_d \leq \phi_{d'}/\mu_{d'} \leq \sqrt{2}\phi_d/\mu_d \leq 4\Delta$. Finally, $D(d||d') = \ln\psi \leq p(1-p)\cdot\alpha^2 = (12\epsilon)^2 p/(1-p) \leq (12\epsilon)^2/(\Delta^2-1)$. ◀

▶ Remark 15. An intermediate version of Theorem 12 can be deduced from Theorem 14, when $\mathcal{S}$ is accessed via the *reflection oracle* $\mathcal{O}_{\mathcal{S}} = I - 2\mathcal{S}(|0\rangle|0\rangle)(\langle 0|\langle 0|)\mathcal{S}^{-1}$ only (observe that this is the case for our algorithms). Indeed, according to [38, Theorem 4], for any algorithm performing q queries to a reflection oracle $\mathcal{O} = I - 2|\phi\rangle\langle\phi|$, it is possible to remove the queries to $\mathcal{O}$ by using $\sim q^2$ copies of $|\phi\rangle$ instead.

5 Applications

We describe two applications of the Quantum Chebyshev Inequality. The first one (Section 5.1) concerns the computation of the frequency moments F_k of order $k \geq 3$ in the streaming model. We design a P-pass algorithm with quantum memory M satisfying a tradeoff of $P^2M = \widetilde{\mathcal{O}}\left(n^{1-2/k}\right)$, whereas the best algorithm with classical memory requires $PM = \Theta(n^{1-2/k})$. We then study (Section 5.2) the edge and triangle counting problems in the general graph model with quantum query access. We describe nearly optimal algorithms that approximate these parameters quadratically faster than in the classical query model.

5.1 Frequency Moments in the Multi-Pass Streaming Model

In the streaming model with update (*turnstile model*), the input is a vector $x \in \mathbb{R}^n$ obtained through a stream $\vec{u} = u_1, u_2, \ldots$ of updates. Initially, $x(0) = (0, \ldots, 0)$, and each $u_j = (i, \lambda) \in [n] \times \mathbb{R}$ modifies the i-th coordinate of $x(j)$ by adding λ to it. The goal of a *streaming algorithm* $\mathcal{T}$ is to output, at the end of the stream, some function of the final vector x while minimizing the number $M \ll n$ of memory cells. In the *multi-pass* model, the same stream is repeated for a certain number P of passes, before the algorithm outputs its result.

Input: a stream $\vec{u}$, an integer $k \geq 3$, a real $\widetilde{F}_2$, an approximation parameter $0 < \epsilon < 1$.
Output: an estimate $\widetilde{F}_k$ of the frequency moment of order k of $\vec{u}$.

1. Compute $i \in [n]$ using the streaming algorithm of Theorem 16 with input $\vec{u}$, $\epsilon/4$, $\widetilde{F}_2$.
2. Compute x_i using a second pass over $\vec{u}$.
3. Output $\widetilde{F}_2 \cdot |x_i|^{k-2}$.

Estimator 3 Frequency moment F_k of a stream.

The *frequency moment of order k* is defined, for the final vector $x = (x_1, \ldots, x_n)$, as $F_k(x) = \sum_{i \in [n]} |x_i|^k$. The problem of approximating F_k when $k \geq 3$ has been addressed first with the AMS algorithm [2], that uses $\mathcal{O}\left(n^{1-1/k}\right)$ classical memory cells in the insertion-only model (where $u_j \in [n] \times \mathbb{R}^+$). A series of works in the turnstile model culminated in optimal one-pass algorithms with memory $\Theta\left(n^{1-2/k}\right)$ [44, 26], and nearly optimal P-pass algorithms with memory $\widetilde{\Theta}\left(n^{1-2/k}/P\right)$ [46, 4, 57]. In the quantum setting, Montanaro [48] obtained a small improvement in terms of the approximation parameter ϵ only.

Our algorithm relies on a classical procedure for ℓ_2 *sampling*. Given $x \in \mathbb{R}^n$, we let $D_{q,x}$ denotes the ℓ_q *distribution* that returns $i \in [n]$ with probability $\frac{|x_i|^q}{F_q(x)}$. One can observe that the (suboptimal) AMS algorithm [2] essentially samples $i \sim D_{1,x}$ and computes $F_1 \cdot |x_i|^{k-1}$. This is an unbiased estimator for $F_k(x)$ with variance $\mathcal{O}\left(n^{1-1/k} F_k(x)^2\right)$ (thus requiring to compute $\mathcal{O}\left(n^{1-1/k}\right)$ samples in one pass). Instead, we base our algorithm on the estimator $F_2(x) \cdot |x_i|^{k-2}$ where $i \sim D_{2,x}$. It reduces the variance to $\mathcal{O}\left(n^{1-2/k} F_k(x)^2\right)$ [46], but it requires a procedure for ℓ_2 sampling. To this end, we use the following algorithm from [4] to sample from an (ϵ, δ)-*approximator* to $D_{2,x}$ (meaning that each $i \in [n]$ is sampled with a probability p_i satisfying $(1-\epsilon)\frac{|x_i|^2}{F_2(x)} - \delta \leq p_i \leq (1+\epsilon)\frac{|x_i|^2}{F_2(x)} + \delta$).

▶ **Theorem 16** ([4]). *There is a randomized streaming algorithm that, given a stream $\vec{u}$ with final vector x, a real $0 < \epsilon < 1/3$ and a value $\widetilde{F}_2$ such that $|\widetilde{F}_2 - F_2(x)| \leq (1/2) \cdot F_2(x)$, outputs a value $i \in [n]$ that is distributed according to an (ϵ, n^{-2})-approximator to $D_{2,x}$. The algorithm uses $M = \mathcal{O}\left(\epsilon^{-2} \log^3 n\right)$ classical memory cells. Moreover, each element of the stream is processed in time $T_{upd} = \mathcal{O}\left(\epsilon^{-1} \log n\right)$, and the output is computed in time $T_{rec} = \mathcal{O}\left(\epsilon^{-1} n \log n\right)$ after the last element is received.*

▶ **Proposition 17** ([46, 4]). *If we let X denote the output random variable of Estimator 3, then $\mathbb{E}[X] = (1 \pm \epsilon/2) F_k$ and $\mathrm{Var}[X] \leq \mathcal{O}\left(n^{1-2/k} F_k^2\right)$, when $|\widetilde{F}_2 - F_2| \leq (\epsilon/4) \cdot F_2$.*

It is known that any deterministic computation can be made reversible, and therefore implemented by a unitary map with a limited overhead on the time and space complexities [9]. Nonetheless, implementing naively the reverse computation of a streaming algorithm would require processing the same stream but in the *reverse* direction, which may not be always possible. This motivates our specific notion of *reversible streaming algorithms*. We say that a streaming algorithm $\mathcal{T}$ with memory size M is *reversible* if there exists a streaming algorithm $\mathcal{T}^{-1}$ with memory size M such that each computational steps of $\mathcal{T}$ and $\mathcal{T}^{-1}$ are reversible, and in addition each pass of $\mathcal{T}$ can be undone by one pass of $\mathcal{T}^{-1}$ in the *same* direction. In the full version [31] we show how to make the algorithm of Theorem 16 reversible (our result is in fact more general and holds for any *linear sketch* streaming algorithm). We combine the quantum sampler that is obtained from this result with the Quantum Chebyshev Inequality (Theorem 11) to obtain the following tradeoff.

▶ **Theorem 18.** *There is a quantum streaming algorithm that, given a stream $\vec{u}$, two integers $P \geq 1$, $k \geq 3$ and an approximation parameter $0 < \epsilon < 1$, outputs an estimate $\widetilde{F}_k$ such that $|\widetilde{F}_k - F_k| \leq \epsilon F_k$ with probability $2/3$. The algorithm uses $\widetilde{\mathcal{O}}\left(n^{1-2/k}/(\epsilon P)^2\right)$ quantum memory cells, and it makes $\widetilde{\mathcal{O}}\left(P \cdot (k \log n + \epsilon^{-1})\right)$ passes over the stream $\vec{u}$.*

Proof. We first compute, in one pass, a value $\widetilde{F}_2$ such that $|\widetilde{F}_2 - F_2| \leq (\epsilon/2)F_2$ with high probability, using [2, 48] for instance. The complexity is absorbed by the final result. Then, using the *reversible* streaming algorithm associated to Estimator 3, we can design a quantum sampler $\mathcal{S}$ using memory $M = \widetilde{\mathcal{O}}\left(\epsilon^{-2} \log^3 n\right)$ such that $\mathcal{S}(|0\rangle|0\rangle) = \sum_{r \in \{0,1\}^M} |r\rangle|\psi_r\rangle|f_r\rangle$ where each $|r\rangle$ corresponds to a different random seed for the linear sketch algorithm of Theorem 16, $|f_r\rangle$ is the output of Estimator 3, and $|\psi_r\rangle$ is some garbage state obtained when making Estimator 3 reversible. According to Proposition 17, we have $\mu_{\mathcal{S}} = (1 \pm \epsilon/2)F_k$ and $\sigma_{\mathcal{S}} \leq \mathcal{O}\left(\sqrt{n^{1-2/k}}F_k\right)$. Moreover one quantum sample can be implemented with two passes over the stream.

We "concatenate" $Q = n^{1-2/k}/P^2$ such samplers and compute the mean $\bar{f} = Q^{-1} \cdot (f_{r_1} + \cdots + f_{r_Q})$ of their results to obtain

$$\bar{\mathcal{S}}(|0\rangle|0\rangle) = \sum\nolimits_{r_1,\ldots,r_Q \in \{0,1\}^M} |r_1, \ldots, r_Q\rangle|\psi_1, \ldots, \psi_Q\rangle|f_{r_1}, \ldots, f_{r_Q}\rangle|\bar{f}\rangle.$$

This sampler satisfies $\mu_{\bar{\mathcal{S}}} = \mu_{\mathcal{S}}$ and $\sigma_{\bar{\mathcal{S}}} = \sigma_{\mathcal{S}}/\sqrt{Q} \leq \mathcal{O}\left(PF_k\right)$, and it requires two passes and memory $\bar{M} = \widetilde{\mathcal{O}}\left(Q \cdot \epsilon^{-2} \log^3 n\right)$ to be implemented. Finally, we approximate F_k by applying Theorem 11 on $\bar{\mathcal{S}}$, which uses $\widetilde{\mathcal{O}}\left(P \cdot (k \log n + \epsilon^{-1})\right)$ quantum samples. ◀

5.2 Approximating Graph Parameters in the Query Model

In this section, we consider the *general graph model* [40, 27] that provides query access to a graph $G = (V, E)$ through the following operations: (1) *degree query* (given $v \in V$, returns the degree d_v of v), (2) *neighbor query* (given $v \in V$ and i, returns the i-th neighbor of v if $i \leq d_v$, and $\perp$ otherwise), and (3) *vertex-pair query* (given $u, v \in V$, indicates if $(u, v) \in E$). This is a combination of the dense graph model (pair queries) and the bounded-degree model (neighbor and degree queries). We refer the reader to [27, Chapter 10] for a more detailed discussion about it. It can be extended to the standard quantum query framework. A quantum degree query is represented as a unitary $\mathcal{O}_{deg}$ such that $\mathcal{O}_{deg}|v\rangle|b\rangle = |v\rangle|y \oplus d_v\rangle$ where $v \in V$ and $y \in \{0,1\}^{\lceil \log n \rceil}$. The quantum neighbor $\mathcal{O}_{neigh}$ and vertex-pair $\mathcal{O}_{pair}$ queries are defined similarly. The *query complexity* of an algorithm in the *quantum general graph model* is the number of times it uses $\mathcal{O}_{deg}$, $\mathcal{O}_{nei}$ or $\mathcal{O}_{pair}$.

In the following, we let n denote the number of vertices, m the number of edges and t the number of triangles in G. We consider the problems of estimating m and t, for which we provide nearly optimal quantum algorithms. The description and analysis of these algorithms is deferred to the full version [31].

Edge counting. In the classical setting, Feige [25] showed that $\Theta(n/(\epsilon\sqrt{m}))$ degree queries are sufficient to compute a factor $(2+\epsilon)$ approximation of m, but no factor $(2-\epsilon)$ approximation can be obtained in sublinear time. Using both degree and neighbor queries, it is possible to compute a factor $(1+\epsilon)$ approximation with $\Theta\left(n/(\sqrt{\epsilon m})\right)$ classical queries [28, 52, 23]. These results were generalized to k-star counting in [30, 23]. In the quantum setting, we prove the following results.

▶ **Theorem 19.** *There is an algorithm that, given query access to any n-vertex graph G with m edges, and an approximation parameter $\epsilon < 1$, outputs an estimate $\widetilde{m}$ of m such that $|\widetilde{m} - m| \leq \epsilon m$ with probability $2/3$. This algorithm performs $\widetilde{\mathcal{O}}\left(\frac{n^{1/2}}{\epsilon m^{1/4}}\right)$ quantum degree and neighbor queries in expectation. Moreover, it does not use vertex-pair queries.*

▶ **Theorem 20.** *Any algorithm that computes an ϵ-approximation of the number m of edges in any n-vertex graph, given query access to it, must use $\Omega\left(\frac{n^{1/2}}{(\epsilon m)^{1/4}} \cdot \log^{-1}(n)\right)$ quantum queries in expectation.*

Triangle counting. In the classical general graph model, the triangle counting problem requires $\widetilde{\Theta}(n/t^{1/3} + \min(m, m^{3/2}/t))$ queries in expectation [21, 22]. This result was generalized to k-clique counting in [24]. In the quantum setting, we prove the following results.

▶ **Theorem 21.** *There is an algorithm that, given query access to any n-vertex graph G with m edges and t triangles, and an approximation parameter $\epsilon < 1$, outputs an estimate $\widetilde{t}$ of t such that $|\widetilde{t} - t| \leq \epsilon t$ with probability $2/3$. This algorithm performs $\widetilde{\mathcal{O}}\left(\left(\frac{\sqrt{n}}{t^{1/6}} + \frac{m^{3/4}}{\sqrt{t}}\right) \cdot poly(1/\epsilon)\right)$ quantum queries in expectation.*

▶ **Theorem 22.** *Any algorithm that computes an ϵ-approximation to the number t of triangles in any n-vertex graph with m vertices, given query access to it, must use $\Omega\left(\left(\frac{\sqrt{n}}{t^{1/6}} + \frac{m^{3/4}}{\sqrt{t}}\right) \cdot \log^{-1}(n)\right)$ quantum queries in expectation.*

6 Open Questions

Is it possible to improve the complexity of our main result (Theorem 11) to $\mathcal{O}(\Delta_{\mathcal{S}}/\epsilon)$ exactly? Can we generalize it to sample spaces with negative values? What are other possible applications? Two promising problems are minimum spanning tree weight [16] and arbitrary subgraph counting [24, 6].

Abstract

We initiate the algorithmic study of retracting a graph into a cycle in the graph, which seeks a mapping of the graph vertices to the cycle vertices so as to minimize the maximum stretch of any edge, subject to the constraint that the restriction of the mapping to the cycle is the identity map. This problem has its roots in the rich theory of retraction of topological spaces, and has strong ties to well-studied metric embedding problems such as minimum bandwidth and 0-extension. Our first result is an $O(\min\{k, \sqrt{n}\})$-approximation for retracting any graph on n nodes to a cycle with k nodes. We also show a surprising connection to Sperner's Lemma that rules out the possibility of improving this result using certain natural convex relaxations of the problem. Nevertheless, if the problem is restricted to planar graphs, we show that we can overcome these integrality gaps by giving an optimal combinatorial algorithm, which is the technical centerpiece of the paper. Building on our planar graph algorithm, we also obtain a constant-factor approximation algorithm for retraction of points in the Euclidean plane to a uniform cycle.

1 Introduction

Originally introduced in 1930 by K. Borsuk in his PhD thesis [5], *retraction* is a fundamental concept in topology describing continuous mappings of a topological space into a subspace that leaves the position of all points in the subspace fixed. Over the years, this has developed into a rich theory with deep connections to fundamental results in topology such as Brouwer's Fixed Point Theorem [22]. Inspired by this success, graph theorists have extensively studied a discrete version of the problem in graphs, where a *retraction* is a mapping from the vertices of a graph to a given subgraph that produces the identity map when restricted to the subgraph (i.e., it leaves the subgraph fixed). For a rich history of retraction in graph theory, we refer the reader to [21]. Define the *stretch* of a retraction to be the maximum distance between the images of the endpoints of any edge, as measured in the subgraph. We use stretch-k retraction to mean a retraction whose stretch is k; in particular, a stretch-1 retraction is a mapping where every edge of the graph is mapped to either an edge of the subgraph, or both its ends are mapped to the same vertex of the subgraph[1].

In this paper, we study the algorithmic problem of finding a *minimum stretch retraction* in a graph. This problem belongs to the rich area of metric embeddings, but somewhat surprisingly, has not received much attention in spite of the deep but non-constructive results in the graph theory literature. The graph retraction problem has a close resemblance to the well-studied 0-extension problem [6, 24, 25] (and its generalizations such as metric labeling [27, 8]), which is also an embedding of a graph G to a metric over a subset of terminals H with the constraint that each vertex in H maps to itself. The two problems differ in their objective: whereas 0-extension seeks to minimize the *average* stretch of edges, graph retraction minimizes the *maximum* stretch. The different objectives lead to significant technical differences. For instance, a well-studied linear program called the earthmover LP has a nearly logarithmic integrality gap for 0-extension. In contrast, we show that a corresponding earthmover LP for graph retraction has integrality gap $\Omega(\sqrt{n})$. A well-studied problem in the metric embedding literature that considers the maximum stretch objective is the *minimum bandwidth* problem, where one seeks an isomorphic embedding of a graph into a line (or cycle) that minimizes maximum stretch. In contrast, in graph retraction, we allow homomorphic maps[2] but additionally require a subset of vertices (called the *anchors*) to be mapped to themselves.

From an applications standpoint, our original motivation for studying minimum-stretch graph retraction comes from a distributed systems scenario where the aim is to map processes comprising a distributed computation to a network of servers where some processes are constrained to be mapped onto specific servers. The objective is to minimize the maximum communication latency between two communicating processes in the embedding. Such anchored embedding problems can be shown to be equivalent to graph retraction for general subgraphs, and arise in several other domains including VLSI layout, multi-processor placement, graph drawing, and visualization [20, 19, 31].

---

[1] In the literature, a stretch-1 retraction is often simply referred to as a retraction or a retract [21]. Also, in many studies, a (stretch-1) retraction requires that the two end-points of an edge in the graph are mapped to two end-points of an edge in the subgraph. These studies differentiate between the case where the subgraph being retracted to is reflexive (has self-loops) or irreflexive (no self-loops). In this sense, our notion of graph retraction corresponds to their notion of retraction to a reflexive subgraph.

[2] A *homomorphic* map is one where an image can have multiple pre-images, while an *isomorphic* map requires that every image has at most one pre-image.

1.1 Problem definition, techniques, and results

We begin with a formal definition of the minimum stretch retraction problem.

▶ **Definition 1.** *Given an unweighted* guest *graph $G = (V, E)$ and a* host *subgraph $H = (A, E')$ of G, a mapping $f : V \to A$ is a retraction of G to H if $f(v) = v$ for all $v \in A$. For a given retraction f of G to H, define the* stretch *of an edge $e = (u, v) \in E(G)$ to be $d_H(f(u), f(v))$, where d_H is the distance metric induced by H, and define the* stretch *of f to be the maximum stretch over all edges of graph G. The goal of the* minimum-stretch graph retraction *problem is to find a retraction of G to H with minimum stretch. We refer to the vertices of A as* anchors*.*

The graph retraction problem is easy if the subgraph H is acyclic (see, e.g., [29]); therefore, the first non-trivial problem is to retract a graph into a cycle. Indeed, this problem is NP-hard even when H is just a 4-cycle [13]. Given this intractability result, a natural goal is to obtain an algorithm for retracting graphs to cycles that *approximately* minimizes the stretch of the retraction. This problem is the focus of our work. While there has been considerable interest in identifying conditions under which retracting to a cycle with stretch 1 is tractable [17, 21, 37], there has been no work (to the best of our knowledge) on deriving approximations to the minimum stretch.[3]

We consider the following lower bound for the problem: if anchors u and v are distance ℓ in H, and there exists a path of p vertices in G between u and v, then every retraction has stretch at least ℓ/p. This lower bound turns out to be tight when H is acyclic, which is the reason retraction to acyclic graphs is an easy problem. However, this lower bound is no longer tight when H is a cycle. For example, consider a grid graph where H is the border of the grid. The lower bound given above says that any retraction has stretch at least $\Omega(1)$. However, using the well-known Sperner's lemma, we show that the optimal retraction has stretch at least $\Omega(\sqrt{n})$.

Using just the simple distance based lower bound, we show that the gap on the grid is in fact the worst possible by giving a $O(\min\{k, \sqrt{n}\})$-approximation for the problem, where k is the number of vertices of H. Our algorithm works by first mapping vertices of the graph into a grid, then projecting vertices outward to the border from the largest *hole* in the grid, which is the largest region containing no vertices.

▶ **Theorem 2.** *There is a deterministic, polynomial-time algorithm that computes a retraction of a graph to a cycle with stretch at most $\min\{k/2, O(\sqrt{n})\}$ times the optimal stretch, where n and k are respectively the number of vertices in the graph and the cycle.*

Our results for retracting a general graph to a cycle appear in Section 2. We also give evidence that the gap induced by Sperner's lemma on a grid graph is fundamental, showing an $\Omega(\min\{k, \sqrt{n}\})$ integrality gap for natural linear and semi-definite programming relaxations of the problem. To overcome this gap, we focus on the special case of planar graphs, of which the grid is an example. Retraction in planar graphs has been considered in the past, most notably in a beautiful paper of Quilliot [30] that uses homotopy techniques to characterize stretch-1 retractions of a planar graph to a cycle. Quillot's proof, however, does not yield an efficient algorithm. In Section 3, we provide an exact algorithm for retraction in planar graphs by developing the gap induced by Sperner's lemma on a grid into a general lower bound on the optimal stretch for planar graphs.

[3] One direct implication of the NP-hardness proof is that approximating the maximum stretch to a multiplicative factor better than 2 is also NP-hard.

▶ **Theorem 3.** *There is a deterministic, polynomial-time algorithm that computes a retraction of a planar graph to a cycle with optimal stretch.*

Unfortunately, our techniques rely heavily on the planarity of the graph, and do not appear to generalize to arbitrary graphs. While we leave the question of obtaining a better approximation for general graphs open, we provide a more sophisticated linear programming formulation that captures the Sperner lower bound on general graphs as a possible route to attack the problem.

We also study natural special cases and generalizations of the problem, all of which are presented in the full version of our paper [18]. First, we consider a geometric setting, where a set of points in the Euclidean plane has to be retracted to a uniform cycle of anchors. By a uniform cycle of anchors we mean a set of anchors which are distributed uniformly on a circle in the plane. We obtain a constant approximation algorithm for this problem, by building on our planar graph algorithm. We next consider retraction of a graph of bounded treewidth to an *arbitrary subgraph*, and obtain a polynomial-time exact algorithm. Finally, we apply the lower bound argument of [24] for 0-extension to show that a general variant of the problem that seeks a retraction of an arbitrary weighted graph G to a metric over a subset of the vertices of G is hard to approximate to within a factor of $\Omega(\log^{1/4-\epsilon} n)$ for any $\epsilon > 0$.

1.2 Related work

List homomorphisms and constraint satisfaction. The graph retraction problem is a special case of the *list homomorphism* problem introduced by Feder and Hell [13], who established conditions under which the problem is NP-complete. Given graphs G, H, and $L(v) \subset V(H)$ for each $v \in V(G)$, a list homomorphism of G to H with respect to L is a homomorphism $f : G \to H$ with $f(v) \in L(v)$ for each $v \in V(G)$.

Several special cases of graph retraction and variants of list homomorphism have been subsequently studied (e.g., [12, 21, 36, 37]). These studies have established and exploited the rich connections between list homomorphism and Constraint Satisfaction Problems (CSPs). Though approximation algorithms for CSPs and related problems such as Label Cover have been extensively studied, the objective pursued there is that of maximizing the number of constraints that are satisfied. For our graph retraction problem, this would correspond to maximizing the number of edges that have stretch below a certain threshold. Our notion of approximation in graph retraction, however, is the least factor by which the stretch constraints need to be relaxed so that all edges are satisfied.

0-extension, minimum bandwidth, and low-distortion embeddings. From an approximation algorithms standpoint, the graph retraction problem is closely related to the 0-extension and minimum bandwidth problems [14, 4, 15, 35, 9, 32]. In the 0-extension problem, one seeks to minimize the average stretch, which can be solved to an $O(\log k / \log \log k)$ approximation using a natural LP relaxation [6, 11]. In contrast, we give polynomial integrality gaps for the graph retraction problem. In the minimum bandwidth problem, the objective is to find an embedding to a line that minimizes maximum stretch, but the constraint is that the map must be isomorphic rather than that the anchor vertices must be fixed. In a seminal result [14], Feige designed the first polylogarithmic-approximation using a novel concept of volume-respecting embeddings. A slightly improved approximation was achieved in [10] by combining Feige's approach with another bandwidth algorithm based on semidefinite-programming [4]. Interestingly, the minimum bandwidth problem is NP-hard even for (guest) trees, while graph retraction to (host) trees is solvable in polynomial time.

Conversely, the bandwidth problem is solvable in time $O(n^b)$ for bandwidth b graphs [16], while graph retraction to a cycle is NP-complete even when the host cycle has only four vertices. Nevertheless, it is conceivable that volume-respecting embeddings, in combination with random projection, could lead to effective approximation algorithms for graph retraction to a cycle in a manner similar to what was achieved for VLSI layout on the plane [35].

Also related are the well-studied variants of linear and circular arrangements, but their objective functions are average stretch, as opposed to maximum stretch. Finally, another related area is that of *low-distortion embeddings* (e.g., [23]), where recent work has considered embedding one specific n-point metric to another n-point metric [26, 28, 2] similar to the graph retraction problem. But low-distortion embeddings typically require *non-contracting* isomorphic maps, which distinguishes them significantly from the graph retraction problem.

A related recent work studies low-distortion *contractions* of graphs [3]. Specifically, the goal is to determine a maximum number of edge contractions of a given graph G such that for every pair of vertices, the distance between corresponding vertices in the contracted graph is at least a given affine function of the distance in G. Several upper bounds and hardness of approximations are presented in [3] for many special cases and problem variants. While graph retraction and contraction problems share the notion of mapping to a subgraph, the problems are considerably different; for instance, in the graph retraction problem the subgraph H is part of the input, and the objective is to minimize the maximum stretch.

2 Retracting an arbitrary graph to a cycle

In this section, we study the problem of retracting an arbitrary graph to a cycle over a subset of vertices of the graph. Let G denote the guest graph over a set V of n vertices, with shortest path distance function d_G. Let H denote the host cycle with shortest path distance function d_H over a subset $A \subseteq V$ of k anchors.

Arguably, the simplest lower bound on the optimal stretch is the *distance-based* bound $\ell(G, H) = \max_{u,v \in A} d_H(u, v)/d_G(u, v)$, since every retraction places a path of length $d_G(u, v)$ in G on a path of length at least $d_H(u, v)$ in H.

We now present our algorithm (Algorithm 1), which achieves a stretch of $\min\{k/2, \ell(G, H)\sqrt{n}\}$. Here, we give a high level overview of the algorithm. The first step of algorithm is to embed the input graph G into a grid of size $k/4 \times k/4$ subject to some constraints. The second step is to find the largest empty sub-grid D such that no point is mapped inside of D and center of D is within a desirable distance from center of grid M. And final step is to project the points in grid M to its boundary with respect to center of sub-grid D.

We now show how to implement the first step of Algorithm 1. Our goal is to embed each vertex $u \in G$ to some point $g(u)$ in a $k/4 \times k/4$ grid such that for every u, v, we have the following inequality, where $d_\infty(a, b)$ denotes the L_∞ distance between a and b. (That is, for two points (x_1, y_1) and (x_2, y_2), $d_\infty((x_1, y_1), (x_2, y_2)) = \max\{|x_1 - x_2|, |y_1 - y_2|\}$.)

$$d_\infty(g(u), g(v)) \leq \ell(G, H) d_G(u, v) \tag{1}$$

Additionally, we require that H is embedded to the boundary of the grid, such that adjacent anchors lie on adjacent grid points.

▶ **Lemma 4.** *For every G, we can find an embedding g satisfying inequality 1.*

Proof. We incrementally construct the embedding g. Initially, we place the anchors on the boundary of the grid so that the boundary is isometric to d_H. (This can be done since H is a cycle.) Since $d_\infty(g(u), g(v)) \leq d_H(u, v)$ and $d_H(u, v) \leq \ell(G, H) d_G(u, v)$, inequality 1 holds for all anchors u and v in H.

Algorithm 1 Algorithm for retracting an arbitrary graph to a cycle.

Input: Graph G, host cycle H
Output: Embedding function f

Embedding in a grid: Determine embedding g from G into a $k/4 \times k/4$ grid M such that H is embedded one-to-one to the boundary of M and for every $u, v \in V$, $d_\infty(g(u), g(v)) \leq \ell(G, H) d_G(u, v)$.

Find largest hole: Find the largest square sub-grid D of M such that (a) its center c is at L_∞ distance at most $k/16$ from the center of M and (b) there is no vertex u in G for which $g(u)$ is in the interior of D.

Projection embedding: For all v in G:

1. $R(v) \leftarrow$ ray originating from the center of D and passing through $g(v)$.
2. $f(v) \leftarrow$ the anchor on the boundary of grid M nearest in the clockwise direction to the intersection of $R(v)$ with the boundary of M.

return f

We next inductively embed the remaining vertices of G. Suppose we need to embed vertex v_i, and vertices $U = v_1, \ldots, v_{i-1}$ have already been embedded. Assume inductively that the embedding of the vertices of U satisfies inequality 1 for the vertices in U.

Let $B_\infty(g(u), r)$ denote the L_∞ ball around $g(u)$ with radius r (note that these balls are axis-aligned squares). Let x be any point in $\bigcap_{u \in U} B_\infty(g(u), \ell(G, H) d_G(u, v_i))$. If we set $g(v_i) = x$, then inequality 1 holds for all points in $U \cup \{v_i\}$. We now show that this intersection is nonempty (it is straightforward to find an element in the intersection). The set of axis aligned squares has Helly number[4] 2; therefore it is enough to show that for every $u, u' \in U$, $B_\infty(g(u), \ell(G, H) d_G(u, v_i))$ and $B_\infty(g(u'), \ell(G, H) d_G(u', v_i))$ intersect. Otherwise,

$$d_\infty(g(u), g(u')) > \ell(G, H)(d_G(u, v_i) + d_G(u', v_i)) \geq \ell(G, H) d_G(u, u').$$

This contradicts our induction hypothesis that the set of vertices in U satisfies inequality 1, and completes the proof of the lemma. ◀

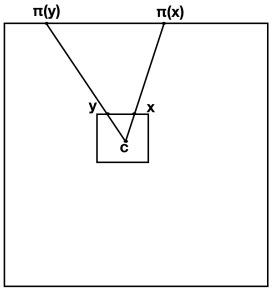
In the following lemma, we analyze the projection embedding step of the algorithm.

▶ **Lemma 5.** *Suppose r is the side length of the largest empty square D inside M. Then for any vertices u and v in G, $d_H(f(u), f(v))$ is at most $1 + (10\sqrt{2}k/r) d_\infty(g(u), g(v))$.*

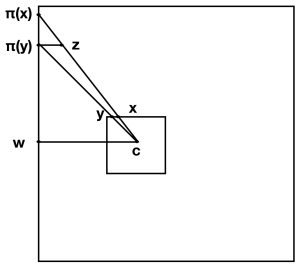
Proof. For any point x, let $\pi(x)$ denote the intersection of the boundary of M and the ray from the center c of D passing through x. Note that for any vertex v in G, $f(v)$ is the anchor in H nearest in clockwise direction to $\pi(g(v))$. We show that for any $x, y \in M$, the distance between $\pi(x)$ and $\pi(y)$ along the boundary of M is at most $(10\sqrt{2}k/r) d_\infty(x, y)$.

We first argue that it is sufficient to establish the preceding claim for points on the boundary of D, at the loss of a factor of $\sqrt{2}$. Let x and y be two arbitrary points in M but not in the interior of D. Let x' (resp., y') denote the intersection of $R(x)$ (resp., $R(y)$) and the boundary of D. From elementary geometry, it follows that $d(x', y') \leq d(x, y)$, where d is the Euclidean distance; since $d_\infty(x, y) \geq d(x, y)/\sqrt{2}$ and $d_\infty(x', y') \leq d(x', y')$, we obtain $d_\infty(x', y') \leq \sqrt{2} d_\infty(x, y)$. Since $\pi(x) = \pi(x')$ and $\pi(y) = \pi(y')$, establishing the above statement for x' and y' implies the same for x and y, up to a factor of $\sqrt{2}$.

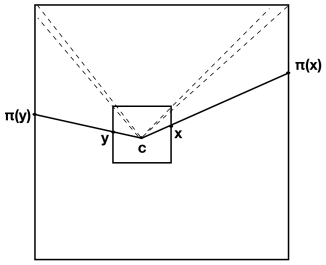
[4] A family of sets has Helly number h if any minimal subfamily with an empty intersection has h or fewer sets in it.



(a) Points x and y are on the same side of square D, and points $\pi(x)$ and $\pi(y)$ are on one side of boundary of M parallel to segment $\overline{xy}$.



(b) Points x and y are on the same side of square D, and points $\pi(x)$ and $\pi(y)$ are on one side of boundary of M orthogonal to segment $\overline{xy}$.



(c) General case where Points x and y (resp. points $\pi(x)$ and $\pi(y)$) are anywhere on the boundary of D (resp. on the boundary of M).

Figure 1 Embedding of points inside the grid M to its boundary using an empty square D. Referred to in the proof of Lemma 5.

Consider points x and y on the boundary of D. We consider three cases. In the first two cases, x and y are on the same side of D. In the first case (Figure 1a), $\pi(x)$ and $\pi(y)$ are on the same side of the boundary of M and segment $\overline{\pi(x)\pi(y)}$ is parallel to segment $\overline{xy}$; then, by similarity of triangle formed by c, x, and y and the one formed by c, $\pi(x)$ and $\pi(y)$, we obtain that the distance between $\pi(x)$ and $\pi(y)$ is at most $3kd_\infty(x,y)/(16r)$. In the second case (Figure 1b), $\pi(x)$ and $\pi(y)$ are on same side of the boundary of M, and segment $\overline{\pi(x)\pi(y)}$ is orthogonal to segment $\overline{xy}$. In this case, w.l.o.g. assume that $\pi(y)$ is closer to center c than $\pi(x)$ with respect to d_∞ distance. Let point z be a point on segment $\overline{c\pi(x)}$ such that segments $\overline{xy}$ and $\overline{\pi(y)z}$ are parallel. From center c extend a line parallel to segment $\overline{xy}$ until it hits the side of M on which $\pi(x)$ and $\pi(y)$ are. Let w be the intersection. Using elementary geometry and similarity argument, we have the following:

$$\frac{|\overline{\pi(x)\pi(y)}|}{|\overline{z\pi(y)}|} = \frac{|\overline{\pi(x)w}|}{|\overline{cw}|} \leq \frac{k/4}{k/16} = 4 \quad \text{and} \quad \frac{\overline{z\pi(y)}}{\overline{xy}} = \frac{\overline{\pi(y)w}}{r} \leq \frac{k}{4r}$$

We thus obtain $\frac{|\overline{\pi(x)\pi(y)}|}{|\overline{xy}|} \leq k/r$. For the third case (Figure 1c), we observe that $d_\infty(x,y)$ is at least half the shortest path between x and y that lies within the boundary of D. This latter shortest path consists of at most five segments, each residing completely on one side of the boundary of D. We apply the argument of the first and second case to each of these segments to obtain that the distance between $\pi(x)$ and $\pi(y)$ is at most $10kd_\infty(x,y)/r$.

To complete the proof, we note that distance between anchor nearest (clockwise) to $\pi(x)$ and anchor nearest (clockwise) to $\pi(y)$ is at most one plus the distance between $\pi(x)$ and $\pi(y)$. Therefore, the $d_H(f(u), f(v))$ is at most $1 + 10\sqrt{2}kd_\infty(g(u), g(v))/r$. ◀

▶ **Theorem 6.** *Algorithm 1 computes a retraction of G to the cycle H with stretch at most the minimum of $k/2$ and $O(\sqrt{n})$ times the optimal stretch.*

Proof. By Lemma 4, the embedding g satisfies inequality 1 for every u and v in G. By a straightforward averaging argument, there exists a square of side length $k/(8\sqrt{n})$ whose center is at L_∞ distance at most $k/16$ from the center of M and which does not contain $g(u)$ for any u in V. By Lemma 5, the projection embedding ensures that for any u and v in V, $d_H(f(u), f(v))$ is at most $1 + O(\sqrt{n})\ell(G,H)d_G(u,v)$. Since the distance in H cannot exceed $k/2$, the claim of the theorem follows. ◀

The Sperner bottleneck. Unfortunately, we cannot improve on the approximation ratio in Theorem 6 using only the distance-based lower bound. Consider the following instance: the guest graph G is the $\sqrt{n} \times \sqrt{n}$ grid, and the host H is the cycle of G formed by the $4\sqrt{n}$ vertices on the outer boundary of G. It is easy to see that the distance-based lower bound has a value of 2 on this instance. On the other hand, using Sperner's Lemma from topology, we show that a stretch of $o(\sqrt{n})$ is ruled out:

▶ **Lemma 7.** *The optimal stretch achievable for an n-vertex grid is at least $2\sqrt{n}/3$.*

Proof. Suppose we triangulate the grid by adding northwest-to-southeast diagonals in each cell of the grid. Consider the following coloring of the boundary H with 3 colors. Divide H into three segments, each consisting of a contiguous sequence of at least $\lfloor 4\sqrt{n}/3 \rfloor$ vertices; all vertices in the first, second, and third segment are colored red, green, and blue, respectively. Let f be any retraction from G to H. Let c_f denote the following coloring for $G \setminus H$: the color of u is the color of $f(u)$. By Sperner's Lemma [34], there exists a tri-chromatic triangle. This implies that there are two vertices within distance at most two in G that are at least $4\sqrt{n}/3$ apart in the retraction f, resulting in a stretch of at least $2\sqrt{n}/3$. ◀

Note that $k = \Theta(\sqrt{n})$ in this instance, so the above lemma also rules out an $o(k)$ approximation using the distance-based lower bound. A natural approach to improving the approximation factor is to use an LP or SDP relaxation for the problem. Indeed, the so-called *earthmover LP* used for the closely related 0-extension problem [24, 7] can be easily adapted to our minimum stretch retraction problem. Similarly, SDP relaxations previously used for minimum bandwidth and related problems [4, 33] can also be adapted to our problem. However, these convex relaxations also have an integrality gap of $\Omega(\sqrt{n})$ for precisely the same reason: they capture the distance-based lower bound but not the one from Sperner's lemma on the grid (see the full version of the paper [18] for a detailed discussion of these LP/SDP relaxations and integrality gaps).

In spite of these gaps, we show that the grid is not a particularly challenging instance of the problem. In fact, in the next section, we give an exact algorithm for retraction in planar graphs, of which the grid is an example. Retraction of planar graphs to cycles has been considered in the past, and non-constructive characterizations of stretch-1 embeddings were known [30]. Our constructive result, while using planarity extensively, suggests that there might be a general technique for addressing the Sperner bottleneck described above. Indeed, we give a candidate LP relaxation (in the full version of the paper [18]) that captures the Sperner bound on the grid. Rounding this LP to obtain a better approximation ratio, or showing an integrality gap for it, is an interesting open question.

3 Retracting a planar graph to a cycle

The main result of this section is the following theorem.

▶ **Theorem 8.** *Let G be a planar graph and H a cycle of G. Then there is a polynomial time algorithm that finds a retraction from G to H with optimal stretch.*

We begin by presenting some useful definitions and elementary claims in Section 3.1. We then present an overview of our algorithm in Section 3.2. Finally, we present the algorithm and its analysis in Section 3.3, leading to the proof of Theorem 8.

3.1 Preliminaries

We begin with a simple lemma that reduces the problem of finding a minimum-stretch retraction to the problem of finding a stretch-1 retraction, in polynomial time. Formally, suppose we have an algorithm $\mathcal{A}$ that, given graphs G and H either finds a stretch-1 retraction from G to H, or proves that no such retraction exists. Then, we can use this algorithm to find the minimum stretch embedding of G into H, using Lemma 9 below, whose straightforward proof is deferred to the full paper [18]. Let G_k be the graph where we replace each edge $e \in G, e \notin H$ with a path of k edges. Clearly, G_k can be computed in polynomial time.

▶ **Lemma 9.** *G can be retracted to H with stretch k if and only if G_k can be retracted in H with stretch-1.*

The following lemma, proved in [18], implies that degree-1 vertices can be eliminated.

▶ **Lemma 10.** *Without loss of generality, we can assume G is 2-vertex connected.*

Lemmas 9 and 10 apply to general graphs. In the rest of this subsection, we focus our attention on planar graphs. We note that all the transformations in Lemmas 9 and 10 preserve planarity of the graph. In 2-connected planar graph, every face of a plane embedding is bordered by a simple cycle. Finally, we can assume that there is a planar embedding of G with H bordering the outer face. If this is not the case, $G \setminus H$ contains at least two connected components, which can each be retracted independently.

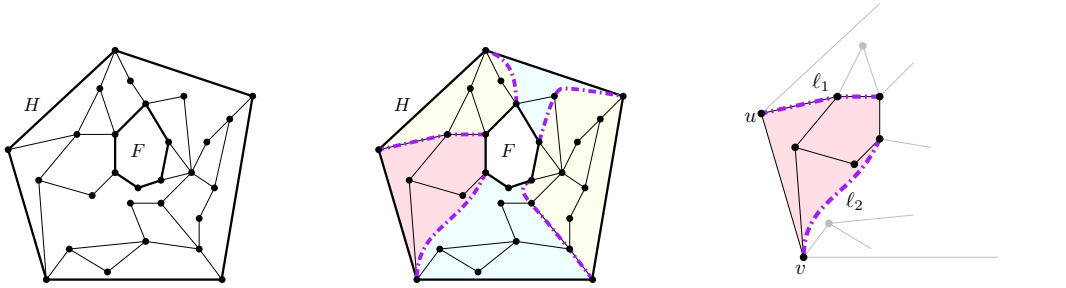
Next, we give some definitions related to planar graphs. We call G *triangulated* if it is maximally planar, i.e., adding any edge results in a graph that is not planar. Equivalently, G is triangulated if every face of a plane embedding (including the outer face) of G has 3 edges. We will make use of the Jordan curve theorem, which says that any closed loop partitions the plane into an inner and outer region (see e.g. [1]). In particular, this implies that any curve crossing from the inner to the outer region intersects the loop. For some cycle C in G and a plane embedding of G, we denote the subset of $\mathbb{R}^2$ surrounded by C as R_C (including the intersection with C itself). We say that $R \subset \mathbb{R}^2$ is *inside* cycle C of G for a plane embedding if $R \subseteq R_C$. If R is inside C, we also say that C *surrounds* R. In a slight abuse of notation, we say C surrounds subgraph G' of G for some fixed plane embedding, if C surrounds the subset of $\mathbb{R}^2$ on which G' is drawn in the plane embedding.

3.2 Overview of our algorithm

Consider some plane embedding of graph G such that H is the subgraph of G bordering G's outer face. We give a polynomial-time algorithm that finds a stretch-1 retraction from G to H or proves that none exists. Using Lemma 9, this immediately yields an algorithm that finds a minimum stretch retraction from G to H.

Fix a planar embedding of G, let H be defined as above, and let F be a bounded face of G. A key component of our algorithm is to find a suitable set of curves connecting F to H. Our aim is to find a set of $k = |V(H)|$ curves in $\mathbb{R}^2$ such that the following hold.

- Each curve begins at a distinct vertex of F and ends at a distinct vertex of H.
- The curves do not intersect each other.
- A curve that intersects an edge of G either contains the edge, or intersects the edge only at its vertices.
- Each curve lies totally in $R_H \setminus F$.



(a) A graph G. The outer cycle H and the face F are shown in bold.

(b) Non-intersecting curves partition the region contained in H but not in F.

(c) Vertices on ℓ_1 are mapped to u, and vertices on ℓ_2 are mapped to v. All other vertices in the region are mapped arbitrarily to u or v.

Figure 2 Using non-intersecting curves to find an embedding from face F to H.

We call curves with these properties *valid* with respect to F. We argue that the curves partition $R_H \setminus F$ (up to their boundaries being duplicated) into a set of regions. Each of these regions is defined by the subset of $\mathbb{R}^2$ surrounded by the closed loop made up of two of the aforementioned curves, a single edge of H, and a path on the boundary of F.

Given a face F and a set of curves valid with respect to F, we can give a stretch-1 retraction from G to H. In essence, the curves partition the graph into regions such that all vertices in a particular region map to one of two end-points of a particular edge of H. See Figure 2 for an illustration.

Of course, it is not obvious that a valid set of curves exists for a given face, and, if it does, how to compute it. We show that if the graph has a stretch-1 retraction, then there is some face F with k valid curves, and that we can efficiently compute them. Our algorithm (Algorithm 2) iterates over all faces in the graph, in each case finding the maximum number of valid curves it can with respect to that face. The number of valid curves we can find is the length of the shortest cycle surrounding F. If the shortest cycle C surrounding F has length ℓ, then it is impossible to find more than ℓ valid curves with respect to F: By the Jordan curve theorem, each curve must intersect C, and by the definition, valid curves do not intersect each other and can intersect C only at its vertices. Our construction of the valid curves shows that this is tight (i.e. we can always find ℓ curves). We show that if a stretch-1 retraction exists, then there is some face for which $\ell = k$. Algorithm 2 gives an outline of the algorithm.

Algorithm 2 Outline for finding a stretch-1 retraction, or proving that none exists.

```
for inner face F in G do
    Compute maximum number of valid curves between F and H p_1, ..., p_ℓ
    if ℓ = k then
        Compute stretch-1 retraction from G to H using p_1, ..., p_k
    end if
end for
If no retraction was computed, report no stretch-1 retraction exists
```

3.3 Algorithm and analysis

This section gives the details of various components of Algorithm 2, and provides a proof of correctness. The following is an outline of the rest of the section:

1. Lemma 12 shows how to compute a stretch-1 retraction using the k valid curves in line 4 of Algorithm 2.
2. Next, Lemma 13 shows that if a stretch-1 retraction exists, there must be some face F in the graph such that the smallest cycle surrounding F has length k.
3. Finally, Lemma 15 gives a construction of largest set of valid curves for a given face F from line 2, and shows that the number of curves computed equals the length of the smallest cycle surrounding F.

We begin by showing in Lemma 11 a somewhat obvious fact: A set of valid curves partition $R_H \setminus F$, and each region of the partition contains a single edge of H. We then show in Lemma 12 that this partition can be used to produce a stretch-1 embedding. See Figure 2 for pictorial presentation of these two lemmas.

▶ **Lemma 11.** *Let $\{p_1, \cdots, p_k\}$ be a set of curves that are valid with respect to F. Let Z denote the set of faces of $H \cup F \cup \bigcup_i p_i$ excluding the outer face and F. Then, each face $f \in Z$ is bordered by exactly 1 edge of H, and every vertex of $G \setminus \bigcup_i p_i$ is in a unique face of Z.*

Proof. Consider the faces of $H \cup F \cup \bigcup_i p_i$. H and F still define faces since the paths p_i fall in $R_H \setminus F$. Let (u, v) be an edge of H, and consider $X = p_i \cup (u, v) \cup p_j \cup p_F(i, j)$ where p_i is the path containing u, p_j is the path containing v, and $p_F(i, j)$ is the path on the boundary of F between the vertices where i and j meet F such that F is not contained in X. If p_i and p_j are both degenerate (i.e., each is empty), then $(u, v) = p_F(i, j)$. Otherwise X is a simple cycle. We claim that X defines a face. In particular, we show that the path $p_F(i, j)$ contains no other vertex of path p_z for all $z \neq i, j$. Suppose it does and let w be that vertex. Let w' be the vertex adjacent to w on p_z. Then $w' \in R_H \setminus F$, and so $w' \in X$. The other end of path p_z, call it vertex y, is in H, but $y \neq u, v$. By the Jordan curve theorem, $p_z \setminus w$ must cross X. Since the graph is planar, $p_z \setminus w$ must contain a vertex of F, H, p_i, or p_j. Any of these outcomes leads to a contradiction. ◀

▶ **Lemma 12.** *Given a non-outer face F and a set $\{p_1, p_2, \ldots, p_k\}$ of curves that are valid with respect to F, we can construct a stretch-1 retraction from G to H in polynomial time.*

Proof. Let Z be as defined in Lemma 11. For each vertex w on p_i, map w to the unique vertex $v \in H \cap p_i$. Otherwise, map w to u or v, where (u, v) is the unique edge of H contained in the same face of Z as w. Fix a face f of Z. Let (u, v) be the unique edge of H contained in f. Any edge (x, y) contained in f also has $x, y \in f$, and so x and y are each mapped to either u or v. Thus, this retraction to H has stretch 1. ◀

As mentioned earlier, we will show that our construction produces ℓ valid curves for face F, where ℓ is the minimum length cycle surrounding F. So we must show that if a stretch-1 retraction exists, there is some F such that every cycle surrounding F has length at least k.

▶ **Lemma 13.** *Fix a plane embedding of G where H defines the outer face of the embedding and suppose there is a stretch-1 retraction G to H. Then there exists a non-outer face F such that every cycle surrounding F has length at least k.*

Proof. We prove a related claim that implies the statement in the lemma. Fix some stretch-1 retraction of G to H. Then there exists a non-outer face F such that for every cycle C in the set of cycles surrounding F, and for each vertex $v \in H$, there is some vertex of C mapped to v. This implies that each of these cycles has length at least k, since the statement says that vertices of C are mapped to k vertices of H.

The claim is very similar to Sperner's lemma, and the proof is similar as well. Let $\phi : V(G) \to V(H)$ denote the retraction. We associate a score with each cycle C of the graph: Order the vertices of the cycle in clockwise order, denoted $v_1, v_2, \ldots, v_j, v_{j+1} = v_1$. Consider the sequence $\phi(v_1), \ldots, \phi(v_j), \phi(v_{j+1})$. Let the score of C be 0 to start. For each pair $\phi(v_i), \phi(v_{i+1})$, we have: either $\phi(v_i) = \phi(v_{i+1})$, or $\phi(v_i)$ and $\phi(v_{i+1})$ are adjacent in H. If $\phi(v_{i+1})$ is clockwise of $\phi(v_i)$ (i.e. if they are in the same order as on C), add 1 to the score of C. If they are in counterclockwise order, subtract 1. If they are the same vertex, the score remains the same. If $\phi(v_1), \ldots, \phi(v_j)$ does not contain every vertex on the outer cycle, the score of C must be 0, since each edge along the path $\phi(v_1), \ldots, \phi(v_{j+1})$ is traversed exactly the same number of times in each direction. On the other hand, a cycle with a non-zero score must have a score that is divisible by k.

Next, we claim that the score of cycle C is the same as the sum of the scores of the cycles defining the faces contained in C. To see this, consider the total contribution to the scores of these cycles from any fixed edge. If the edge is not in cycle C, it is a member of exactly 2 faces contained in C, and contributes either 0 to both faces, or -1 to one and 1 to the other. Edges in C are each a member of just one face surrounded by C. Therefore, the score of cycle C is the same as the sum of scores of its surrounded faces. Since the score of cycle H is k, there must be some face f that has non-zero score.

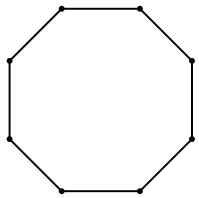
Finally, we show that there is some face with nonzero score such that every cycle surrounding the face also has nonzero score. Suppose this is not the case. Then, every face with a non-zero score is surrounded by a cycle with score 0, which implies that the sum of all scores of faces with non-zero scores is 0. This is a contradiction, since it implies that the sum of scores of all internal faces in the graph is 0. ◀

We complete the section by giving a construction of the largest set of valid curves with respect to some face F, and show that the number of curves equals the length of the shortest cycle surrounding F. Our curves will be disjoint paths in a supergraph $G_\Delta(F)$ of G. It is necessary to relate the maximum number of disjoint paths to the length of the shortest cycle surrounding F. The following lemma, proved in full paper [18], establishes this connection. We believe this lemma should be known, but cannot find it in the relevant literature.

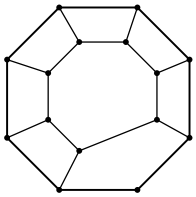
▶ **Lemma 14.** *Let G be a triangulated graph. The graph induced by any minimum s-t vertex cut is the shortest simple cycle separating s and t.*

If G was already triangulated, we could compute a set of vertex disjoint paths from F to H (note that a set of vertex disjoint paths yields a set of valid curves). By Menger's theorem and Lemma 14, we would find ℓ paths, where ℓ is the shortest cycle surrounding F. G may not be triangulated, so instead we could first triangulate G and then compute the paths. However, the number of paths we find in this case is the length of the shortest cycle surrounding F in the triangulation of G, which may be smaller than ℓ. We prevent this from happening by producing a triangulation that adds vertices as well as edges.

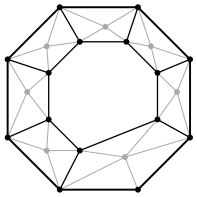
▶ **Lemma 15.** *Fix a planar embedding of G with H as the outer face, and let F be other face. Then we can compute ℓ valid curves in polynomial time, where ℓ is the length of the shortest cycle surrounding F.*



(a) Some face F' with y>3 edges.



(b) Add a new cycle C with $y-1$ edges inside F' along with connecting edges.



(c) Add stars in the newly created faces, except the one formed by C. Distances between vertices of the original face are preserved.

Figure 3 Iteratively triangulate faces.

Proof. We build a triangulated graph $G_\Delta(F)$ from the planar embedding of G. First, add vertices and edges to every face of G, excluding the outer face and F. We do this such that (1) every face except F and the outer face is a triangle, and (2) the distance between any $u, v \in G$ is preserved. From each face with more than 3 edges, we create one new face that has one fewer edge. One step of this iterative construction is shown in Figure 3.

Note that distances are preserved inductively, and we make progress by reducing the size of some face. The graph we produce has 3 edges bordering each face, except for the outer face and F. In all, the number of vertices and edges added to each face of G is polynomial in the number of edges bordering the face.

Finally, we add vertices s and t, and edges from s to each vertex of F and from t to each vertex of C. The resulting graph is triangulated, and we call this graph $G_\Delta(F)$.

At this point, we can find the maximum set of vertex disjoint paths between s and t in $G_\Delta(F)$, by setting vertex capacities to 1 and computing a max flow between s and t. Because we have preserved distances between vertices of G in our construction of $G_\Delta(F)$, the length of the minimum cycle surrounding F must be ℓ. Therefore, the number of disjoint paths we find must also be ℓ. Finally, we claim that this set of disjoint paths from F to H in $G_\Delta(F)$ is a set of valid curves for G. This is because G is a subgraph of $G_\Delta(F)$, and therefore the criteria for valid curves are still met after removing the vertices and edges of $G_\Delta(F) \setminus G$. ◀

We conclude by tying together the pieces of the section to show we proved Theorem 8.

Proof of Theorem 8. Fix a face F. By Lemma 14, we determine the set of ℓ disjoint paths from F to H where the surrounding minimum cycle is of length ℓ. By Lemma 13, there is a stretch-1 retraction only if there exists a face F whose surrounding min-cycle is of length k. So if there is no stretch-1 retraction, we find $< k$ disjoint paths for all faces, and our algorithm returns "no". Otherwise, there exists a face F for which the surrounding min-cycle is of length k, and this gives a set of k valid paths. Then, by Lemma 12, the retraction that we construct has stretch 1. ◀

4 Open problems

Our work leaves several interesting directions for further research. First, we would like to determine improved upper and/or lower bounds on the best approximation factor achievable for retracting a general graph to a cycle. Second, we would like to explore extending our approach for planar graphs (Section 3) and Euclidean metrics (details in the full paper [18]) to more general graphs and high-dimensional metrics. Another open problem is that

of finding approximation algorithms for retracting a general guest graph to an arbitrary host graph over a subset of anchor vertices, for which we present a hardness result in the full paper [18].

Abstract

In the fundamental Maximum Matching problem the task is to find a maximum cardinality set of pairwise disjoint edges in a given undirected graph. The fastest algorithm for this problem, due to Micali and Vazirani, runs in time $\mathcal{O}(\sqrt{n}m)$ and stands unbeaten since 1980. It is complemented by faster, often linear-time, algorithms for various special graph classes. Moreover, there are fast parameterized algorithms, e.g., time $\mathcal{O}(km \log n)$ relative to tree-width k, which outperform $\mathcal{O}(\sqrt{n}m)$ when the parameter is sufficiently small.

We show that the Micali-Vazirani algorithm, and in fact any algorithm following the phase framework of Hopcroft and Karp, is adaptive to beneficial input structure. We exhibit several graph classes for which such algorithms run in linear time $\mathcal{O}(n + m)$. More strongly, we show that they run in time $\mathcal{O}(\sqrt{k}m)$ for graphs that are k vertex deletions away from any of several such classes, without explicitly computing an optimal or approximate deletion set; before, most such bounds were at least $\Omega(km)$. Thus, any phase-based matching algorithm with linear-time phases obliviously interpolates between linear time for $k = \mathcal{O}(1)$ and the worst case of $\mathcal{O}(\sqrt{n}m)$ when $k = \Theta(n)$. We complement our findings by proving that the phase framework by itself still allows $\Omega(\sqrt{n})$ phases, and hence time $\Omega(\sqrt{n}m)$, even on paths, cographs, and bipartite chain graphs.

1 Introduction

The objective in the fundamental Maximum Matching problem is to find a set of disjoint edges of maximum cardinality in a given undirected graph $G = (V, E)$. Maximum Matching has been heavily studied and was the first problem for which a polynomial-time algorithm has explicitly been established [17]. Several algorithms [8, 23, 27, 39] achieve the best known running time of $\mathcal{O}(\sqrt{n}m)$ for graphs with n vertices and m edges, starting with the algorithm of Micali and Vazirani [39] in 1980. Since then, the time of $\mathcal{O}(\sqrt{n}m)$ remains unbeaten.

This state-of-the-art has motivated extensive research into faster algorithms for Maximum Matching on special inputs: Extensive effort went into beating the worst case running time of $\mathcal{O}(\sqrt{n}m)$ for Maximum Matching on special graph classes, resulting in a large number of publications [14, 21, 22, 24, 26, 29, 34, 35], often even obtaining linear-time algorithms [10, 12, 38, 43, 45]. Similarly, there is a great variety of algorithms whose running time depends on n and m but also on some structural parameter of the input graph, like its tree-width, its genus, or its vertex-deletion distance to a certain graph class (summarized in Table 2). As an example, one can solve Maximum Matching in time $\mathcal{O}(k(n + m))$ when

Table 1 The second column shows the running times of dedicated algorithms for Maximum Matching on restricted inputs, which follow as special cases of previous work (see Table 2). Columns three and four show our results for algorithms employing the phase framework with linear-time phases. Only vertex cover number and matching number had known time $\mathcal{O}(\sqrt{k}m)$, others had $\Omega(km)$ prior to our work. The parameters mw and md refer to modular-width and modular-depth.

	Dedicated algorithm	Phase framework algorithms	
Parameter / Graph class	Parameter s	Parameter s	Dist. k to parameter s
Vertex cover number	$\mathcal{O}(\sqrt{s}m)$	$\mathcal{O}(\sqrt{s}m)$	n.a.
Star forest	$\mathcal{O}(m)$	$\mathcal{O}(m)$	$\mathcal{O}(\sqrt{k}m)$
Bounded tree-depth	$\mathcal{O}(m)$	$\mathcal{O}(m)$	$\mathcal{O}(\sqrt{k}m)$
Cluster graph	$\mathcal{O}(m)$	$\mathcal{O}(m)$	$\mathcal{O}(\sqrt{k}m)$
Minimum degree $n-s$	$\mathcal{O}(sn^2 \log n)$	$\mathcal{O}(sm)$	$\mathcal{O}(\sqrt{k}sm)$
Independence number	none	$\mathcal{O}(sm)$	$\mathcal{O}(\sqrt{k}s^2m)$
Neighborhood diversity	$\mathcal{O}((s^2 \log s)n + m)$	$\mathcal{O}(sm)$	$\mathcal{O}(\sqrt{k}sm)$
Parameter mw and md	$\mathcal{O}((\mathrm{mw}^2 \log \mathrm{mw})n + m)$	$\mathcal{O}((c\,\mathrm{mw})^{\mathrm{md}}m)$	$\mathcal{O}(\sqrt{k}(c\,\mathrm{mw})^{\mathrm{md}}m)$

the input graph G is given together with a set S of k vertices such that $G - S$ belongs to a class $\mathcal{C}$ in which Maximum Matching can be solved in linear time (cf. [38]): It suffices to solve the problem on $G - S$ in linear time and to then apply at most k augmentation steps to account for vertices in S; each such step can be implemented in linear time.

A caveat of this great number of different algorithms for special cases is that we may have to first find the relevant structure, e.g., a set S so that $G - S$ belongs to a certain graph class $\mathcal{C}$, and to then decide which algorithm to apply. In some cases, finding the relevant optimal structure is NP-hard and using approximate structure may lead to increase in running time. Moreover, except for time $\mathcal{O}(\sqrt{k}m)$ relative to vertex cover number k or maximum matching size k, which can be seen to follow from the general analysis of Hopcroft and Karp [29], the previously known time bounds improve on $\mathcal{O}(\sqrt{n}m)$ only if $k = \mathcal{O}(\sqrt{n})$, at best.

Our results. We approach the Maximum Matching problem from the perspective of *adaptive analysis (of algorithms)*. Rather than developing further specialized algorithms for special classes of inputs, we prove that a single algorithm actually achieves the best time bounds relative to several graph classes and parameters; in particular, several new or improved time bounds are obtained. Moreover, that algorithm is known since 1980, namely it is the Micali-Vazirani-algorithm [39], and it is oblivious to the actual structure and parameter values. In fact, our analysis does not depend on overly specific aspects of that algorithm and, rather, applies to any algorithm for Maximum Matching that follows the "phase framework" established by Hopcroft and Karp [29] for Bipartite Matching and that implements each phase in linear time, e.g., the algorithms by Blum [8] and Goldberg and Karzanov [27]. In this framework, each phase is dedicated to finding a disjoint and maximal packing of shortest augmenting paths, and it can be shown that $\mathcal{O}(\sqrt{n})$ phases always suffice (cf. [29]).

We show that algorithms following the phase framework adapt to beneficial structure in the form of inputs from special graph classes or inputs that are few vertex deletions away from such a class, without running a recognition algorithm or computing the deletion distance (i.e., they are obliviously adaptive). Concretely, we show that any such algorithm solves Maximum Matching in linear time on several graph classes such as cluster graphs or graphs of bounded neighborhood diversity. Moreover, for many such classes we also show that any such algorithm takes time $\mathcal{O}(\sqrt{k}m)$ on graphs that are k vertex deletions away

from the class, without explicitly computing such a set of deletions (or even knowing the class in question). Furthermore, this running time interpolates between the worst-case time $\mathcal{O}(\sqrt{n}m)$ for $k \in \Theta(n)$ and linear time for $k \in \Theta(1)$, hence remaining competitive even in the absence of beneficial input structure. Except for the matching number and the vertex cover number, time bounds of the form $\mathcal{O}(\sqrt{k}m)$ are new, even for dedicated algorithms. Besides that, we improve upon the algorithm by Yuster [46] for the special case of minimum degree $n - s$ and we improve upon the algorithm by Kratsch and Nelles [33] for the special case of bounded neighborhood diversity. Our positive results are summarized in Table 1.

We complement our findings by exhibiting several graph classes on which the phase framework still allows the worst-case of $\Theta(\sqrt{n})$ phases, and hence $\Theta(\sqrt{n}m)$ time. We prove this for paths, trivially perfect graphs, which are a subclass of cographs, and bipartite chain graphs (and hence their superclasses). This, of course, does not contradict the existence of dedicated linear-time algorithms nor the possibility of tweaking a phase-based algorithm to avoid the obstructions. Nevertheless, these results do rule out the possibility of proving adaptiveness of arbitrary phase-based algorithms, and they showcase obstructions that need to be handled to obtain more general adaptive algorithms for Maximum Matching.

Related work. Our work fits into the recent program of "FPT in P"[1] or efficient parameterized algorithms, initiated independently by Abboud et al. [1] and Giannopoulou et al. [25]. This program seeks to apply the framework of parameterized complexity to tractable problems to obtain provable running times relative to certain parameters that outperform the fastest known algorithms or (conditional) lower bounds obtained in the fine-grained analysis program (see, e.g., [2, 9, 41]). In particular, Mertzios et al. [38] have suggested Maximum Matching as the "drosophila" of FPT in P, i.e., as a central subject of study, similar to the role that Vertex Cover plays in parameterized complexity. Already, there is a large number of publications on parameterized algorithms for Maximum Matching [11, 15, 16, 20, 33, 36], apart from large interest in FPT in P in general [1, 6, 19, 30, 31, 32]. There has also been interest in linear-time preprocessing, which, relative to some parameter k, reduces the problem to solving an instance of size $f(k)$ and leads to time bounds of the form $\mathcal{O}(n+m+g(k))$ [37].

Adaptive analysis of algorithms has been most successful in the context of sorting and searching [3, 4, 13, 18]. We are not aware of prior (oblivious) adaptive analysis of established algorithms for the Maximum Matching problem but two works have designed dedicated adaptive algorithms relative to tree-depth [31] and modular-width [33].

Bast et al. [5] analyzed the Micali-Vazirani algorithm for random graphs, obtaining a running time of $\mathcal{O}(m \log n)$ with high probability.

Organization. Some preliminaries on graphs and matchings are recalled in Section 2. Section 3 is dedicated to recalling the analysis of Hopcroft and Karp [29] and defining phase-based algorithms. In Section 4 we present the positive results, except for results related to neighborhood diversity and modular decomposition which can be found in the full version of the paper. The lower bounds for paths and trivially perfect graphs are given in Section 5; the lower bound for bipartite chain graphs is in the full version of the paper. We conclude in Section 6.

[1] An FPT-algorithm solves a given (usually NP-hard) problem in time $f(k)n^c$ where k is some problem-specific parameter and n is the input size.

Table 2 Known parameterized algorithms for Maximum Matching, k denotes the corresponding parameter value and ω is the matrix multiplication constant.

2 Preliminaries

We mostly consider simple graphs, unless stated otherwise, and denote an edge between v and w as the concatenation of its endpoints, vw. Let $G=(V,E)$ denote a graph. A path P in G is denoted by listing its vertices in order, i.e., $P=v_1v_2\dots v_\ell$. We use the following notation to refer to subpaths of a path P:

$$P_{[v_i,v_j]}=\begin{cases} v_iv_{i+1}\dots v_j & \text{if } i\le j,\\ v_iv_{i-1}\dots v_j & \text{if } i>j.\end{cases}$$

By *disjoint* paths we will always mean *vertex-disjoint* paths. For a set of vertices $S\subseteq V$, we define $\delta(S)=\{vw\in E : v\in S, w\notin S\}$. For two sets X,Y their *symmetric difference* is denoted by $X\triangle Y=(X\setminus Y)\cup(Y\setminus X)$.

A set $C\subseteq V$ is a *vertex cover* of G if every edge of G has at least one endpoint in C; the *vertex cover number* $\tau(G)$ of G is the minimum cardinality of any vertex cover of G. An *independent set* of G is a set $S\subseteq V$ of pairwise nonadjacent vertices; the *independence number* $\alpha(G)$ of a graph G is the maximum cardinality of any independent set of G. The *maximum degree* and *minimum degree* of G are denoted by $\Delta(G)$ and $\delta(G)$ respectively. For a class $\mathcal{C}$ of graphs we define $\mathrm{d}_{\mathcal{C}}(G)=\min_{S\subseteq V:G-S\in\mathcal{C}}|S|$ to be the *vertex deletion distance* of G to $\mathcal{C}$; a set S such that $G-S\in\mathcal{C}$ is called a *modulator*. E.g., the vertex cover number $\tau(G)$ is the vertex deletion distance of G to edgeless graphs, i.e., independent sets.

A *matching* in a graph is a set of pairwise disjoint edges. Let $G=(V,E)$ be a graph and let $M\subseteq E$ be a matching in G. The matching M is *maximal* if there is no matching M' in G such that $M\subsetneq M'$ and M is *maximum* if there is no matching M' in G such that $|M|<|M'|$; the *matching number* $\nu(G)$ of G is the cardinality of a maximum matching in G.

A vertex $v\in V$ is called *M-matched* if there is an edge in M that contains v, and v is called *M-exposed* otherwise. We do not mention M if the matching is clear from the context. We say that an edge $e\in E$ is *blue* if $e\notin M$ and e is *red* if $e\in M$. An *M-alternating path* is a path in G that alternatingly uses red and blue edges. An *M-augmenting path* is an M-alternating path that starts and ends with an M-exposed vertex; a *shortest* M-augmenting path is an M-augmenting path that uses as few edges as possible.

It is well known that matchings can be enlarged along augmenting paths and that an augmenting path always exists if the matching is not maximum. We say that the matching $M \triangle E(P)$ is obtained by *augmenting* M along P.

▶ **Lemma 2.1.** *If M is a matching in G and P is an M-augmenting path, then $M \triangle E(P)$ is also a matching in G and has size $|M \triangle E(P)| = |M| + 1$.*

▶ **Theorem 2.2** ([29])**.** *Let M and N be matchings in $G = (V, E)$ with $|N| > |M|$. The subgraph $G' = (V, M \triangle N)$ of G contains at least $|N| - |M|$ vertex-disjoint M-augmenting paths.*

▶ **Corollary 2.3** ([7])**.** *A matching M is maximum if and only if there is no M-augmenting path.*

3 Hopcroft-Karp analysis

Many of the fastest algorithms for Maximum Matching make use of a framework introduced by Hopcroft and Karp [29] for the special case of bipartite matching. We give an overview of the framework in this section, mostly following Hopcroft and Karp [29]. The main idea is to search for shortest augmenting paths instead of arbitrary augmenting paths. Exhaustively searching for shortest augmenting paths and augmenting along them leads to Algorithm 1.

Algorithm 1: Generic Matching Algorithm.

Input: Graph G
Output: Maximum matching M

```
M ← ∅;
while M is not maximum do
    Find a shortest M-augmenting path P;
    M ← M△E(P);
return M;
```

Let $P_1, P_2, \ldots, P_\ell$ be the sequence of augmenting paths in the order found during an execution of Algorithm 1. Hopcroft and Karp [29] observed the following properties of the computed shortest augmenting paths.

▶ **Lemma 3.1** ([29])**.** *Let M be a matching, let P be a shortest M-augmenting path, and let P' be a $M \triangle E(P)$-augmenting path, then $|P'| \geq |P| + 2|P \cap P'|$.*

▶ **Corollary 3.2** ([29])**.** *The sequence $|P_1|, \ldots, |P_\ell|$ is non-decreasing.*

▶ **Corollary 3.3** ([29])**.** *If $|P_i| = |P_j|$ for some $i \neq j$, then P_i and P_j are vertex-disjoint.*

Following these observations, we can partition the sequence $P_1, \ldots, P_\ell$ into maximal contiguous subsequences $P_i, P_{i+1}, \ldots, P_j$ such that $|P_i| = |P_{i+1}| = \cdots = |P_j| < |P_{j+1}|$, due to Corollary 3.3 the paths $P_i, P_{i+1}, \ldots, P_j$ must be pairwise vertex-disjoint. Every such subsequence is called a *phase* and corresponds to a maximal set of vertex-disjoint shortest augmenting paths due to Corollary 3.3. With the terminology of phases introduced, it is useful to restate Algorithm 1 as follows.

Algorithm 2: Phase Framework.

Input: Graph G
Output: Maximum matching M

```
M ← ∅;
while M is not maximum do
    Find a maximal set S of vertex-disjoint shortest M-augmenting paths;
    Augment M along all paths in S;
return M;
```

In Algorithm 2 each iteration of the **while**-loop corresponds to a single phase. If an algorithm implements Algorithm 2 we say that it *employs the phase framework*. In the following, we will abstract from the implementation details of algorithms employing the phase framework and only bound the number of phases that are required in the worst case. Hopcroft and Karp [29] presented an upper bound in terms of the matching number $\nu(G)$.

▶ **Theorem 3.4** ([29]). *Every algorithm employing the phase framework requires at most* $2\left\lceil\sqrt{\nu(G)}\right\rceil + 2$ *phases.*

The next bound is a simple corollary of Theorem 3.4 by noticing that $\nu(G) \leq \frac{n}{2}$, but we opt to give an independent proof to serve as an instructive example for the proofs to come.

▶ **Theorem 3.5** (folklore). *Every algorithm employing the phase framework requires at most* $\mathcal{O}(\sqrt{n})$ *phases.*

Proof. Let M denote the matching obtained after performing $\lceil\sqrt{n}\rceil$ phases of Algorithm 2. Every further M-augmenting path has length at least $\lceil\sqrt{n}\rceil$ by Corollary 3.2. This implies that we can pack at most $\lceil\sqrt{n}\rceil$ such augmenting paths into G and hence by Theorem 2.2, at most $\lceil\sqrt{n}\rceil$ augmentations remain. Since we perform at least one augmentation per phase, Algorithm 2 must have terminated after an additional $\lceil\sqrt{n}\rceil$ phases. Thus, Algorithm 2 terminates after at most $2\lceil\sqrt{n}\rceil$ phases. ◀

Several of the fastest Maximum Matching algorithms employ the phase framework [8, 27, 39]. Any one of these algorithms yields the following time bound for a single phase.

▶ **Theorem 3.6.** *There is an algorithm that given a matching M computes a maximal set of vertex-disjoint shortest M-augmenting paths in time $\mathcal{O}(m)$. In particular, each phase of the phase framework can be implemented to run in time $\mathcal{O}(m)$.*

With Theorem 3.5 and Theorem 3.4 we obtain the following time bounds.

▶ **Theorem 3.7.** *There is an algorithm employing the phase framework that solves* Maximum Matching *in time $\mathcal{O}(\sqrt{n}m)$ and $\mathcal{O}(\sqrt{\nu(G)}m)$.*

4 Adaptive parameterized analysis

In this section we will perform an adaptive analysis for algorithms employing the phase framework by analyzing the required number of phases in terms of various graph parameters. Theorem 3.6 yields an improved running time if the considered parameter is small enough.

Many of the considered parameters are NP-hard to compute, e.g., the vertex cover number. This is not an issue, however, as we only require the parameter value for the running time analysis and not for the execution of the algorithm. In this sense, algorithms employing the phase framework are proved to obliviously adapt to the studied parameters.

4.1 Short alternating paths

Our main lemma relies on bounding the length of shortest augmenting paths. In the interest of simplifying later arguments, we will not only bound the length of shortest augmenting paths, but also of alternating paths that are not necessarily augmenting. The strategy for obtaining such upper bounds is to take a long alternating path P and deduce that additional edges must exist in $G[V(P)]$ that enable us to find a shorter alternating path P' in $G[V(P)]$ between the endpoints of P. Hence, the replacement path P' will only visit vertices that are also visited by the original path P. The following definition formalizes this idea.

▶ **Definition 4.1.** Given a matching M in a graph G and an M-alternating path $P = v_1 \dots v_\ell$. We say that an M-alternating path $P' = w_1 \dots w_k$ *replaces* P if the following is true:

- $V(P') \subseteq V(P)$,
- $w_1 = v_1$ and $w_k = v_\ell$,
- P' has the same parity as P with respect to M, i.e.,
  $v_1v_2 \in M \iff w_1w_2 \in M$ and $v_{\ell-1}v_\ell \in M \iff w_{k-1}w_k \in M$.

In particular, if P' replaces P, then P' is at most as long as P.

A technicality that arises from considering general alternating paths, as opposed to augmenting paths, is that an alternating path that starts and ends with a blue edge, i.e. an edge not in the matching, might have endpoints that are not exposed. If we want to shortcut by taking a different edge incident to such an endpoint, then this edge might be red which causes our constructions to fail. To avoid this issue, it suffices to consider the subpath resulting from the removal of the first and last edge.

▶ **Definition 4.2.** A graph G is *ℓ-replaceable* if for every matching M each M-alternating path can be replaced by an M-alternating path of length at most ℓ. The class of ℓ-replaceable graphs is denoted $\mathcal{R}[\ell]$.

We will now show that algorithms employing the phase framework require only few phases for graphs that are close, in the sense of vertex deletion distance, to ℓ-replaceable graphs.

▶ **Lemma 4.3.** *Every algorithm employing the phase framework requires at most $\mathcal{O}(\sqrt{k\ell})$ phases on graphs G with $\mathrm{d}_{\mathcal{R}[\ell]}(G) \leq k$. In particular,* Maximum Matching *can be solved in time $\mathcal{O}(\sqrt{k\ell}m)$ for such graphs.*

Proof. Let $S \subseteq V$ with $|S| \leq k$, such that $G - S \in \mathcal{R}[\ell]$ and let M be the matching obtained after performing $\lceil\sqrt{k\ell}\rceil$ phases of Algorithm 2. We claim that every shortest M-augmenting path uses at least $\lfloor\sqrt{k}\rfloor$ vertices of S; every such path has a length of at least $\lceil\sqrt{k\ell}\rceil$ due to Corollary 3.2. Consider such a path P, since $G - S$ is ℓ-replaceable, we can assume that every time P enters $G - S$ it uses at most $\ell + 1$ vertices of $G - S$ before going back to S. Hence, P must use at least $\lfloor\sqrt{k}\rfloor - 1$ vertices of S to have a length of $\lceil\sqrt{k\ell}\rceil$ or more.

Since S is of size at most k and due to the properties of replacing paths, this implies that we can pack at most $2\lceil\sqrt{k}\rceil$ M-augmenting paths into G as

$$2\left\lceil\sqrt{k}\right\rceil\left(\left\lfloor\sqrt{k}\right\rfloor - 1\right) \geq 2\sqrt{k}\left(\sqrt{k} - 2\right) = 2k - 4\sqrt{k} \geq k \quad \text{for } k \geq 16.$$

By Theorem 2.2 at most $2\lceil\sqrt{k}\rceil$ augmentations remain, which require at most $2\lceil\sqrt{k}\rceil$ phases. In total, we need $\lceil\sqrt{k\ell}\rceil + 2\lceil\sqrt{k}\rceil \in \mathcal{O}(\sqrt{k\ell})$ phases. Theorem 3.6 implies the time bound. ◀

The following running time bound relative to the vertex cover number $\tau(G)$ follows directly from Theorem 3.7 by the use of the well-known inequality $\nu(G) \leq \tau(G)$.

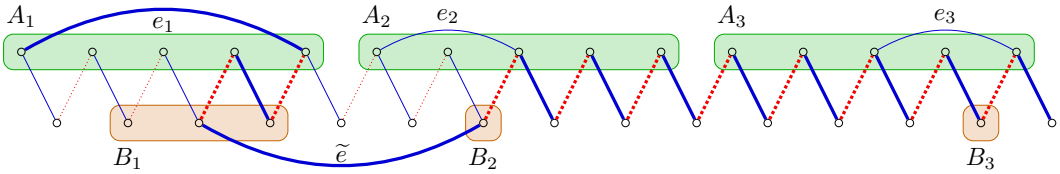

Figure 1 The construction in Theorem 4.6 for $\alpha(G) = 2$, the red dotted edges are matched and the blue edges are unmatched. The thickened edges represent the shorter alternating path P'.

▶ **Theorem 4.4.** *Every algorithm employing the phase framework requires at most* $\mathcal{O}(\sqrt{\tau(G)})$ *phases. In particular,* Maximum Matching *can be solved in time* $\mathcal{O}(\sqrt{\tau(G)}m)$.

Alternatively, observe that if $\mathcal{C}$ is the class of independent sets, then $\mathrm{d}_{\mathcal{C}}(G) = \tau(G)$ and hence Theorem 4.4 is implied by Lemma 4.3 as independent sets are trivially 1-replaceable.

More generally, every graph without paths of length $\ell + 1$ is ℓ-replaceable. It is known that a graph class has bounded path length if and only if it has bounded tree-depth (see, e.g., [40, Chapter 6]). As a further special case consider the class of *star forests*, i.e., graphs where every connected component is a star and therefore must be 2-replaceable. Hence, we obtain the following corollary of Lemma 4.3.

▶ **Corollary 4.5.** *Let* $\mathcal{C}$ *be the class of star forests. Every algorithm employing the phase framework requires at most* $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{C}}(G)})$ *phases. In particular,* Maximum Matching *can be solved in time* $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{C}}(G)}m)$.

4.2 Independence number

A graph with independence number k contains many edges in the sense that any set of $k+1$ vertices must induce an edge. We will use this property to shorten long alternating paths.

▶ **Theorem 4.6.** *Suppose that* G *is a graph such that* $\alpha(G) \leq k$*, then* G *is* $\mathcal{O}(k^2)$*-replaceable.*

Proof. First, fix a matching M. We show how to replace alternating paths that begin and end with a blue edge, i.e., an edge not in M. By replacing appropriate subpaths of long alternating paths with other parities, the general result will follow.

Suppose that $P = a_1 b_1 a_2 b_2 \dots a_\ell b_\ell$ is an alternating path that is longer than $4(k+1)^2 + 1$ and that starts and ends with a blue edge. We can assume that ℓ is odd. Distinguishing the vertices of P by their parity, we define $A = \{a_i : i \in [\ell]\}$ and $B = \{b_i : i \in [\ell]\}$. Furthermore, we define the sets A_i and A'_i for $i = 1, \dots, k+1$ by

$$A_i = \{a_{(i-1)(2k+2)+j} : j = 1, 2, 3, \dots, 2k+1\} \text{ and } A'_i = \{a_j \in A_i : j \text{ odd}\}.$$

Note that $|A'_i| = k + 1 > k$ for all i, hence the A'_i cannot be independent sets. Thus, there is at least one edge e_i in $G[A'_i]$. We denote the endpoints of e_i by

$$e_i = a_{p_i} a_{q_i}, \text{ where } p_i \leq q_i - 2, \text{ for all } i = 1, \dots, k+1. \tag{1}$$

We now consider the vertices of B that lie between the endpoints of e_i on P; we omit b_{p_i} to ensure that the constructed path is shorter than P. Concretely, let $B_i = \{b_{p_i+1}, b_{p_i+2}, \dots, b_{q_i-1}\}$ for all $i = 1, \dots, k+1$. Equation (1) implies that $B_i \neq \emptyset$. Now, we arbitrarily choose a vertex b'_i from each B_i and define $B' = \{b'_i : i = 1, \dots, k+1\}$. Observe that B' cannot be an independent set as B' contains $k+1$ vertices; thus, there must exist an edge $\tilde{e} = b'_i b'_j$ with $i < j$. We construct the path P' that replaces P by (see Figure 1)

$$P' = P_{[a_1, a_{p_i}]} P_{[a_{q_i}, b'_i]} P_{[b'_j, b_\ell]},$$

using edges $a_{p_i}a_{q_i}$ and $b'_ib'_j$; note that $P_{[a_{q_i},b'_i]}$ is a subpath of P in reverse order. Note that both edges are blue because a_{q_i} and b'_i are already incident with red edges on P. It can be easily checked that P' is an alternating path and, in particular, that it is a valid replacement for P. We will now show that P' is strictly shorter than P. It suffices to compare the length of $P_1 = P_{[a_{p_i},b'_j]}$ and $P_2 = P'_{[a_{p_i},b'_j]} = a_{p_i}P_{[a_{q_i},b'_i]}b'_j$ as P and P' agree on the remaining parts. Let s and t be the indices such that $b'_i = b_s$ and $b'_j = b_t$. The length of P_1 is $2(t-p_i)+1$. For the length of P_2 we obtain

$$\begin{aligned}|P_2| &= 1 + (2(s-q_i)+1) + 1 = 2(s-q_i)+3 < 2(s-(p_i+1))+3 = 2(s-p_i)+1\\ &< 2(t-p_i)+1 = |P_1|,\end{aligned}$$

where the first inequality follows from Equation (1). ◀

By combining this result with Lemma 4.3 we obtain the following corollary.

▶ **Corollary 4.7.** *Every algorithm employing the phase framework requires at most $\mathcal{O}(\alpha(G)^2)$ phases. In particular,* Maximum Matching *can be solved in time $\mathcal{O}(\alpha(G)^2 m)$.*

Let $\mathcal{C}_k$ denote the class of graphs with independence number at most k in each connected component. Every algorithm employing the phase framework requires at most $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{C}_k}(G)}k^2)$ phases. In particular, Maximum Matching *can be solved in time $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{C}_k}(G)}k^2 m)$.*

A better analysis in terms of the independence number can be achieved by not using replaceability, but in exchange we lose the square root dependence on the size of the modulator.

▶ **Lemma 4.8.** *Every maximal matching M covers at least $n - \alpha(G)$ vertices.*

Proof. If $\alpha(G)+1$ vertices were exposed, they would not be an independent set and hence have an edge between them. Thus, M would not be maximal. ◀

▶ **Corollary 4.9.** *Every algorithm employing the phase framework requires at most $\mathcal{O}(\alpha(G))$ phases. In particular,* Maximum Matching *can be solved in time $\mathcal{O}(\alpha(G)m)$.*

Proof. After the first phase, we know that at most $\alpha(G)$ vertices are exposed by Lemma 4.8. Hence, $\alpha(G)/2$ further augmentations suffice. ◀

4.3 s-plexes

An *s-plex*, $s \geq 1$, is an n-vertex graph G with minimum degree $\delta(G) \geq n - s$. They were introduced by Seidman and Foster [42] as a generalization of cliques, which are 1-plexes. Problems related to s-plexes have been studied in parameterized complexity before [28, 44]. Let $\mathcal{P}[s]$ denote the class of graphs that are disjoint unions of s-plexes. Given a vertex v and a set $W \subseteq V \setminus \{v\}$ of size at least s in an s-plex, we know that there is an edge vw for some $w \in W$. Thus, s-plexes allow for better control than a small independence number as we can guarantee the existence of an edge incident to some specific vertex instead of just getting some edge in a large set of vertices.

▶ **Theorem 4.10.** *If G is a k-plex, i.e., if $\delta(G) \geq n - k$, then G is $\mathcal{O}(k)$-replaceable.*

Proof. Let M be a matching in G and suppose that $P = v_1 \dots v_\ell$ is an M-alternating path in G of length $\ell - 1 \geq 2k + 5$. Let i be the smallest integer such that v_i is M-exposed or $v_{i-1}v_i$ is red, i.e., $v_{i-1}v_i \in M$. Let j be the largest integer such that v_j is M-exposed or v_jv_{j+1} is red. We have $i \in \{1, 2, 3\}$ and $j \in \{\ell - 2, \ell - 1, \ell\}$.

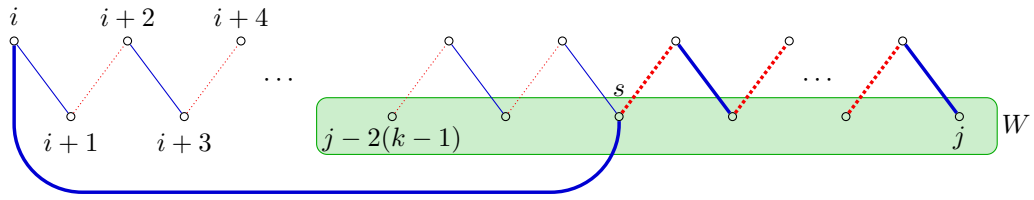

Figure 2 Replacing alternating paths in a k-plex.

Consider the vertices $W = \{v_j, v_{j-2}, v_{j-4}, \dots, v_{j-2(k-1)}\}$ and observe that $v_i \notin W$ as $3 < \ell - 2k$. The set W contains k vertices and since G is a k-plex there must be some $v_s \in W$ such that $v_i v_s \in E$. By choice of i and s the edges $v_i v_{i+1}$ and $v_{s-1} v_s$ must be blue. Similarly, by choice of i, the edge $v_i v_s$ is blue. Hence, as seen in Figure 2, we can replace P by the shorter M-alternating path $P' = P_{[v_1,v_i]} P_{[v_s,v_\ell]}$ with length $|P'| \leq 2 + 2(k-1) + 2 = 2k + 2$. ◀

By Lemma 4.3, we obtain the following corollary.

▶ **Corollary 4.11.** *Every algorithm employing the phase framework requires at most $\mathcal{O}(n - \delta(G))$ phases. In particular,* Maximum Matching *can be solved in time $\mathcal{O}((n - \delta(G))m)$.*

Every algorithm employing the phase framework requires at most $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{P}[s]}(G)}s)$ phases. Hence, Maximum Matching *can be solved in time $\mathcal{O}(\sqrt{\mathrm{d}_{\mathcal{P}[s]}(G)}sm)$. In particular,* Maximum Matching *can be solved in time $\mathcal{O}(\sqrt{k}m)$ on graphs that have distance at most k to cluster graphs.*

5 Lower bounds on the number of phases

In this section, we show that several restrictive graph classes do not admit results such as those obtained in the previous section. To this end, we show that the assumptions made about algorithms that follow the phase framework still allow a worst case of $\Omega(\sqrt{n})$ phases. In other words, further assumptions about the behavior of such an algorithm are necessary to avoid these lower bounds and to again get adaptive running times.

5.1 Paths and forests

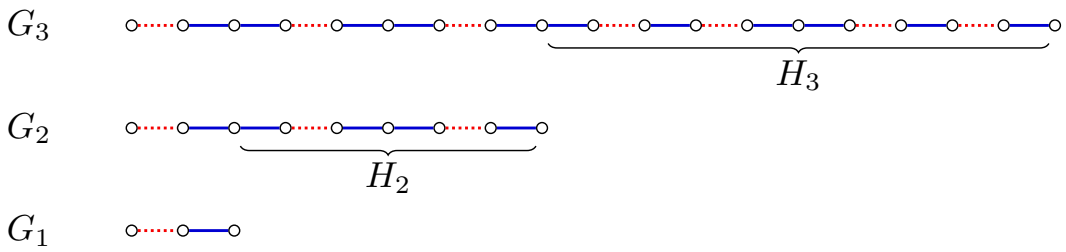

Figure 3 Lower bound construction for paths.

▶ **Lemma 5.1.** *An algorithm employing the phase framework may choose a sequence of augmentations resulting in at least $\Omega(\sqrt{n})$ phases on paths.*

Proof. We will concatenate increasingly long paths where we take every second edge into the matching in such a way that the matching on the newly added path is maximal but not maximum, so that every one of the concatenated paths requires a separate phase. More formally, on $P_{2i} = v_1 v_2 \dots v_{2i}$ we use the matching $\{v_{2k}v_{2k+1} : k \in [i-1]\}$. This matching is one edge away from the maximum and the only augmenting path has length $2i-1$.

Let H_i be obtained by concatenating two copies of P_{2i} through identification of two endpoints (obtaining a path on $4i-1$ vertices). The matching on H_i can be augmented once by an augmenting path of length $2i-1$. There are two augmenting paths on H_i, we always choose to augment along the copy of P_{2i} that is attached to the previously constructed path, i.e., the left copy in Figure 3. Using two copies of P_{2i} in H_i ensures that every H_i requires at least one augmentation. This is not the case if we simply concatenate $P_2, P_4, \dots, P_{2k}$.

We can now define our desired paths. Let $G_1 = H_1 = P_3$ and in this exceptional case we assume that the left edge of P_3 is matched. Furthermore, let G_{i+1} be obtained from G_i by concatenating H_{i+1} at the right. The number of vertices of $G_{\lceil\sqrt{n}\rceil}$ can be bounded by

$$\sum_{i=1}^{\lceil\sqrt{n}\rceil} 2|V(P_{2i})| \leq 4(\lceil\sqrt{n}\rceil)^2 \in \mathcal{O}(n).$$

Now, we argue that our choice of augmentations leads to $\Omega(\sqrt{n})$ phases for $G_{\lceil\sqrt{n}\rceil}$. In the first phase we choose to find the maximal matching that we associated with each H_i. Now, observe that $G_{\lceil\sqrt{n}\rceil}$ contains augmenting paths of lengths $3, 5, \dots, 2\lceil\sqrt{n}\rceil - 1$. In phase i, $i \geq 2$ we augment along the left copy of P_{2i} in H_i. As this does not affect the augmenting paths in the other H_i, we need $\lceil\sqrt{n}\rceil$ phases in total. ◀

Using the parameter values on paths, we obtain the following parameterized lower bounds.

▶ **Corollary 5.2.** *An algorithm employing the phase framework may choose a sequence of augmentations resulting in $\Omega(\sqrt{\alpha(G)})$, $\Omega(\sqrt{\tau(G)})$, $\Omega(\sqrt{\mathrm{d}_{\mathcal{P}[1]}(G)})$ or $\Omega(\sqrt{\mathrm{nd}(G)})$ phases, where $\mathrm{nd}(G)$ is the neighborhood diversity of G.*

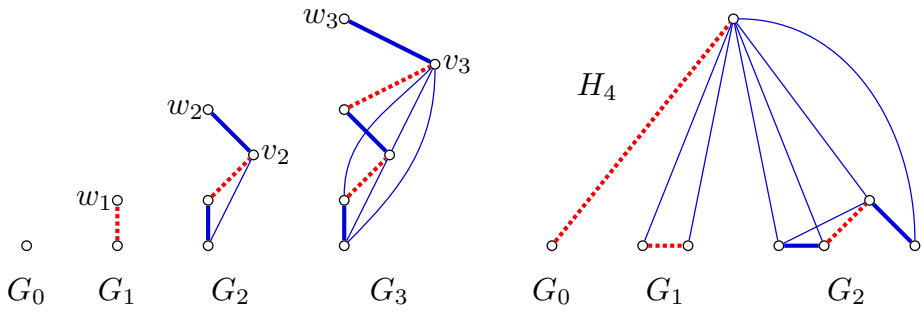
5.2 Cographs

Mertzios et al. [36] devised a Maximum Matching algorithm parameterized by vertex deletion distance to cocomparability graphs and there are several Maximum Matching algorithms parameterized by modular-width [11, 33]. In the interest of showing that these results cannot be replicated or improved by our approach, we give a lower bound result for cographs, i.e., the graphs of modular-width 2 and a subclass of cocomparability graphs.

▶ **Definition 5.3.** A graph is a *cograph* if it can be constructed from the following operations:

- K_1 is a cograph,
- the disjoint union $G \cup H$ of two cographs G and H is a cograph,
- the join $G \times H$ of two cographs G and H is a cograph, where $V(G \times H) = V(G) \cup V(H)$ and $E(G \times H) = E(G) \cup E(H) \cup \{vw : v \in V(G), w \in V(H)\}$.

▶ **Theorem 5.4.** *There is a family of cographs such that an algorithm employing the phase framework may choose a sequence of augmentations resulting in $\Omega(\sqrt{n})$ phases on this family.*



(a) Increasingly long augmenting paths. **(b)** Construction of H_4.

Figure 4 Cographs with increasingly long augmenting paths, the red dotted edges are matched and the blue edges are unmatched. The thickened edges denote the chosen augmenting paths.

Proof. We will construct appropriate cographs using the cograph operations. Let $G_0 = K_1$ and $G_1 = K_1 \times K_1 = P_2$ and for $i \geq 1$ define $G_{i+1} = (G_i \cup K_1) \times K_1$ as auxiliary graphs. Given n, we construct

$$H_n = \left(\bigcup_{i=0}^{\lceil \sqrt{n} \rceil} G_i \right) \times G_0.$$

Observe that G_i has at most $2i+1$ vertices, therefore H_n has $\mathcal{O}(n)$ vertices. We will now describe a sequence of augmentations in H_n that requires $\Omega(\sqrt{n})$ phases.

In each G_i, $i \geq 2$, there is exactly one vertex of degree one, which we call w_i. For G_1, we fix an arbitrary vertex that is called w_1. Furthermore, the vertex that is joined last in the construction of G_i, $i \geq 2$, is referred to as v_i, see Figure 4. First, we describe which maximal matchings to associate with the graphs G_i. In G_0 there is no edge to choose, in G_1 we choose the only possible edge and in G_2 we take the edge v_2w_1. Inductively, for G_{i+1}, $i \geq 2$, we use the maximal matching of G_i and add the edge $v_{i+1}w_i$. With H_n we associate the union of these matchings and add the edge between the two copies of G_0 to the matching. In this way we obtain the matching that is supposed to be found in the first phase.

We now argue that G_i, $i \geq 2$, has exactly one shortest augmenting path of length $2i-1$. This is true for $i = 2$; the other cases follow by induction. Let P_i be the shortest augmenting path in G_i starting at w_i, then $P_{i+1} = w_{i+1}v_{i+1}P_i$ is an augmenting path of length $2i+1$ in G_{i+1}. There are no further augmenting paths as there are only two exposed vertices in G_{i+1} and one of them is w_{i+1} with degree one; starting at w_{i+1}, we must first take the edge $w_{i+1}v_{i+1}$ and then the matched edge $v_{i+1}w_i$, hence we must take the path P_{i+1} by induction.

Let v denote the vertex in G_0 that is joined last in the construction of H_n. The construction of H_n does not create any additional augmenting paths as every maximal alternating path that passes through v must have one matched endpoint, namely the vertex in the other copy of G_0. In phase i we augment the shortest augmenting path of length $2i-1$ in the copy of G_i. By repeating the previous argument, these augmentations cannot introduce any new augmenting paths in the later phases. Hence, we require $\lceil \sqrt{n} \rceil$ phases for this sequence of augmentations, thereby proving the claimed lower bound. ◀

The graphs in the previous proof are also C_4-free, therefore these graphs are not only cographs but also *trivially perfect graphs*.

6 Conclusion

We have conducted an adaptive analysis that applies to all algorithms for Maximum Matching that follow the phase framework of Hopcroft and Karp [29], such as the algorithms due to Micali and Vazirani [39], Blum [8], and Goldberg and Karzanov [27]. The main take-away message of our paper is that these algorithms not only obtain the best known time $\mathcal{O}(\sqrt{n}m)$ for solving Maximum Matching but that they are also (obliviously) adaptive to beneficial structure. That is, they run in linear time on several graph classes and they run in time $\mathcal{O}(\sqrt{k}m)$ for graphs that are k vertex deletions away from any of several classes; before, most bounds were $\Omega(km)$. Arguably, such adaptive algorithms are the best possible result for dealing with unknown beneficial structure because they are never worse than the general bound, in this case taking $\Omega(\sqrt{n}m)$ when $k = \Theta(n)$, and smoothly interpolate to linear time on well-structured instances. Moreover, in the present case, they unify several special cases and remove the need to find exact or approximate beneficial structure.

We complemented our findings by proving that the phase framework alone still allows taking $\Omega(\sqrt{n})$ phases, and, hence, total time $\Omega(\sqrt{n}m)$, even on restrictive classes like paths, trivially perfect graphs, and bipartite chain graphs (and their superclasses), despite the existence of (dedicated) linear-time algorithms. Of course, all of these cases are easy to handle but it raises the question whether there are simple further properties to demand of a phase-based algorithm so that it is provably adaptive to larger classes such as cocomparability or bounded treewidth graphs? In the same vein, it would be interesting whether time $\mathcal{O}(\sqrt{k}m)$ is possible relative to feedback vertex number k, i.e., relative to deletion distance to a forest.

More generally, with the large interest in "FPT in P" (or efficient parameterized algorithms), it seems interesting what other fundamental problems admit adaptive algorithms that interpolate between, say, linear time and the best general bound. Are there other cases where a proven algorithmic paradigm, like the path packing phases of Hopcroft and Karp [29], also obliviously yields the best known running times relative to beneficial input structure?

Abstract

There are various notions of balancing set families that appear in combinatorics and computer science. For example, a family of proper non-empty subsets $S_1, \ldots, S_k \subset [n]$ is balancing if for every subset $X \subset \{1, 2, \ldots, n\}$ of size $n/2$, there is an $i \in [k]$ so that $|S_i \cap X| = |S_i|/2$. We extend and simplify the framework developed by Hegedűs for proving lower bounds on the size of balancing set families. We prove that if $n = 2p$ for a prime p, then $k \geq p$. For arbitrary values of n, we show that $k \geq n/2 - o(n)$.

We then exploit the connection between balancing families and depth-2 threshold circuits. This connection helps resolve a question raised by Kulikov and Podolskii on the fan-in of depth-2 majority circuits computing the majority function on n bits. We show that any depth-2 threshold circuit that computes the majority on n bits has at least one gate with fan-in at least $n/2 - o(n)$. We also prove a sharp lower bound on the fan-in of depth-2 threshold circuits computing a specific weighted threshold function.

1 Introduction

1.1 Balancing Families

Balancing set families are families of proper non-empty subsets of a finite universe that satisfy a *discrepancy* type property. They are well studied objects in combinatorics [12, 10, 4, 15, 5, 14], and they have found many applications in computer science [4, 20, 16, 5, 14]. In this work we prove new lower bounds on the size of such families, and then use them to prove lower bounds on depth-2 *majority* and *threshold circuits* that compute the majority and *weighted threshold* functions. We establish new sharp lower bounds on the *fan-in* of the gates in such circuits.

A central contribution of this work is the following lemma that shows a lower bound on the degree of a special class of polynomials.

▶ **Lemma 1.** *Let p be prime, and let $f(x_1, \ldots, x_{2p})$ be a polynomial over $\mathbb{F}_p$, where $\mathbb{F}_p$ is the field with p elements. Let f be such that for every input $x \in \{0,1\}^{2p}$ with exactly p ones, we have $f(x) = 0$, and $f(x)$ is non-zero when $x_1 = x_2 = \ldots = x_{2p} = 0$. Then, the degree of f is at least p.*

Hegedűs [15] used a similar lemma to prove lower bounds for balancing sets (in his lemma there are $4p$ variables, and the focus is on inputs with $3p$ ones). Hegedűs's proof uses Gröbner basis methods and linear algebra. Srinivasan found a simpler proof of Hegedűs's lemma that is based on Fermat's little theorem and linear algebra. Alon [3] gave an alternate proof of Hegedűs's lemma using the Combinatorial Nullstellensatz. The above lemma is inspired by Srinivasan's proof of Hegedűs's lemma [21, 5]. Our simple proof is presented in Section 3.

For a positive integer n, let $[n]$ denote the set $\{1, 2, \ldots, n\}$. Various notions of balancing set families have been considered in the past [12, 10, 4, 15, 5] with various terminologies. We use the following definition in this work.

▶ **Definition 2.** *Let k be a positive integer and n be a positive even integer. We say that proper non-empty subsets $S_1, \ldots, S_k \subset [n]$ are a* balancing set family *if for every $X \subset [n]$ of size $n/2$ there is an $i \in [k]$ such that $|S_i \cap X| = |S_i|/2$.*

Given any even n, let $\mathsf{B}(n)$ denote the minimum k for which a balancing set family of size k exists. Our first result gives tight bounds on $\mathsf{B}(n)$:

▶ **Theorem 3.** *If $n = 2p$ for a prime p, then $\mathsf{B}(n) = n/2 = p$.*

Moreover, if n is divisible by 4, we give an example of a balancing set family establishing that $\mathsf{B}(n) \leq n/2 - 1$. If n is divisible by 2, we show that $\mathsf{B}(n) \leq n/2$ by constructing a balancing set family of size $n/2$, in which each set is of size 2. We also show that this is tight when each set in the family is of size 2 (see the full version for a proof). Previously, for arbitrary values of n, Alon, Kumar and Volk [5] showed that $\mathsf{B}(n) \geq \Omega(n)$. We show

▶ **Theorem 4.** *If n is an even integer, then $\mathsf{B}(n) \geq n/2 - O\left(n^{0.98}\right)$.*

Our lower bounds on $\mathsf{B}(n)$ are the most interesting and they are proved using Lemma 1. See Section 4 and Section 5 for a full exposition of the proofs. We also apply our techniques to other questions about balancing sets in the literature and improve some of the previous bounds. We now briefly discuss two such notions from the literature.

(a) Galvin's question [12, 10, 15] asks for the smallest balancing family, denoted by $\mathsf{G}(n)$, where each set in the family is of size $n/2$, and n is a positive integer that is a multiple of 4.

(b) Jansen [16] and Alon, Kumar, and Volk [5] studied a variant where the size of each set in the family must satisfy $2\tau \leq |S_i| \leq n - 2\tau$ for a positive integer τ, and for every $X \subset [n]$ of size $n/2$, there is a set in the family such that $|S_i|/2 - \tau < |S_i \cap X| < |S_i|/2 + \tau$. Denote by $\mathsf{J}(n, \tau)$ to be the family of smallest size satisfying the above conditions.

We defer the discussion of previous known bounds on the quantities $\mathsf{G}(n)$ and $\mathsf{J}(n, \tau)$ to Section 2. We prove the following lower bounds on $\mathsf{G}(n)$ and $\mathsf{J}(n, \tau)$.

▶ **Theorem 5.** *If n is divisible by 4, then $\mathsf{G}(n) \geq n/2 - O\left(n^{0.53}\right)$.*

▶ **Theorem 6.**

1. *If $n = 2p$ for a prime p then $\mathsf{J}(n, \tau) \geq \frac{n}{4\tau - 2}$.*
2. $\mathsf{J}(n, \tau) \geq \frac{n - O\left(n^{0.98}\right)}{7\tau}$.

We proceed to define the notion of unbalancing set families used in this work.

▶ **Definition 7.** *Let n be a positive even integer, and $k \geq 0, 0 \leq t \leq n/2$ be integers. We say that subsets $S_1, \ldots, S_k \subset [n]$ are an* unbalancing set family *if for every $X \subset [n]$ of size $n/2 - t$, there is an $i \in [k]$ such that $|S_i \cap X| > |S_i|/2$.*

Given any even n, let $\mathsf{U}(n, t)$ denote the minimum k for which an unbalancing set family of size k exists. For unbalancing set families, we determine $\mathsf{U}(n, t)$ exactly:

▶ **Theorem 8.** $\mathsf{U}(n, t) = 2t + 2$.

Again, the lower bound here is more interesting than the upper bound. It is proved by showing a connection between $\mathsf{U}(n, t)$ and the chromatic number of an appropriately defined Kneser graph [18].

1.2 Threshold Circuits

We now discuss our results on depth-2 majority and threshold circuits. The majority function, $\mathsf{MAJ}(x)$ for $x \in \{0,1\}^n$, is defined as

$$\mathsf{MAJ}(x_1, \ldots, x_n) = \begin{cases} 1 & \sum_{i=1}^n x_i \geq n/2, \\ 0 & \text{otherwise.} \end{cases}$$

The unweighted threshold function, $T_t(x)$ for $x \in \{0,1\}^n$, is defined as

$$T_t(x_1, \ldots, x_n) = \begin{cases} 1 & \sum_{i=1}^n x_i \geq t, \\ 0 & \text{otherwise,} \end{cases}$$

for some non-negative integer t. In the rest of the paper, unless stated otherwise, we refer to threshold functions when we mean unweighted threshold functions.

A depth-2 circuit is defined by boolean functions $h, g_1, \ldots, g_k$, for some integer k, and the depth-2 circuit is said to compute a function f on input $x \in \{0,1\}^n$ if

$$f(x) = h(g_1(x), \ldots, g_k(x)).$$

Here $h, g_1, \ldots, g_k$ are called the *gates* of the circuit. h is referred to as the *top* gate, and $g_1, \ldots, g_k$ are referred to as the *bottom* gates of the circuit. Our lower bounds often hold even when h is allowed to be an arbitrary boolean function. The *fan-in* of a gate in the circuit measures the number of variables that need to be read for the gate to carry out its computation. The fan-in of the top gate in the circuit is defined to be k. The fan-in of each

of the gates g_i is r_i if g_i depends on r_i of the input variables. We sometimes refer to the top fan-in when we mean k and the bottom fan-in when we mean the maximum of $r_1, \ldots, r_k$. We say that the fan-in of the circuit is r, if r is the maximum of the top fan-in and bottom fan-in.

When functions $g_1, \ldots, g_k, h$ each compute majority, the circuit is called a majority circuit. Similarly, if all gates compute thresholds, then the circuit is called a threshold circuit. Kulikov and Podolskii [17] asked the following question: What is the minimum fan-in required to compute majority using a depth-2 majority circuit? Balancing set families are closely related to depth-2 majority circuits computing majority. One can prove that there is a depth-2 majority circuit computing majority of n bits with top fan-in at most $2 \cdot \mathsf{B}(n) + 2$, when n is even. Indeed, let $S_1, \ldots, S_k$ be the balancing set family. Define k majority gates, each on variables indexed by S_i, and another k majority gates, each on variables indexed by $[n] \setminus S_i$. The top majority gate, with fan-in $2k + 2$, reads these $2k$ gates along with two 0 inputs. It is easy to see that this circuit correctly computes the majority.

To obtain a lower bound on the fan-in of such circuits, a potential approach is to show that every depth-2 majority or threshold circuit corresponds to a balancing set family. We are able to leverage the ideas that are used to prove Theorem 3 to obtain lower bounds on the fan-in of these circuits. Moreover, our lower bounds are sharp up to a constant factor.

Let $n = 2p$ for a prime p. Note that the threshold function defined by the inequality $\sum_{i=1}^{n} x_i \geq p$ is the majority function on n bits, and yields a circuit with top fan-in 1. We prove a lower bound on the top fan-in of a depth-2 threshold circuit when the bottom gates do not have the threshold p:

▶ **Theorem 9.** *Suppose that $n = 2p$ for a prime p. Then in any depth-2 circuit computing the majority of n bits, if the bottom gates compute unweighted thresholds and read no constants, either the top fan-in is at least $n/2 = p$, or some gate at the bottom computes a threshold T_t with $t = p$.*

In fact, Theorem 9 implies a similar lower bound on the top fan-in when the bottom threshold gates read constants - see Section 6. Observe that in Theorem 9 we do not assume that the top gate h computes a threshold function. The lower bound holds with no restrictions on h.

Theorem 9 also gives tight lower bounds for the fan-in of threshold circuits computing majority. Firstly, any non-constant threshold function T_t reading at most r inputs must have $t \leq r$. Secondly, any bottom gate that computes a threshold function T_t by reading constants is equivalent to computing a threshold function $T_{t'}$ on the same input variables, for some $t' \leq t$, and $T_{t'}$ reads no constants. Here, $t' = t - \alpha$ where α is the number of ones read by T_t. Consequently, we get:

▶ **Corollary 10.** *Suppose that $n = 2p$ for a prime p. Then in any depth-2 circuit computing the majority of n bits, if the bottom gates compute unweighted thresholds, the fan-in of the circuit must be at least $n/2 = p$.*

Since majority is a special case of the threshold function, the above corollary implies the same lower bound on the fan-in of majority circuits that compute the majority. However, by directly invoking Theorem 9, we obtain a slightly stronger lower bound for majority circuits computing the majority:

▶ **Corollary 11.** *Suppose that $n = 2p$ for a prime p. Then in any depth-2 majority circuit computing the majority of n bits, either the bottom fan-in is more than $2p - 2 = n - 2$ or the top-fan in is at least $p = n/2$.*

This is because when the bottom fan-in of the majority circuit is at most $2p - 2$, the threshold of bottom gates are at most $p - 1$ and Theorem 9 applies.

Table 1 Summary of results on balancing and unbalancing families. p is a prime.

Balancing Sets	$\mathsf{B}(n) = n/2$ when $n = 2p$	Theorem 3
	$\mathsf{B}(n) \geq n/2 - o(n)$	Theorem 4
	$\mathsf{G}(n) \geq n/2 - o(n)$	Theorem 5
	$\mathsf{J}(n, \tau) \geq n/(4\tau - 2)$ when $n = 2p$	Theorem 6
	$\mathsf{J}(n, \tau) \geq n(1 - o(1))/7\tau$	Theorem 6
Unbalancing Sets	$\mathsf{U}(n, t) = 2t + 2$	Theorem 8

Theorem 9, Corollary 10 and Corollary 11 discuss the case when $n = 2p$ for a prime p. For arbitrary values of n, we can generalize Theorem 9 to show that either the top fan-in is at least $n/2 - o(n)$ or some gate at the bottom computes a threshold T_t with $t \geq p$, where p is the largest prime such that $p \leq n/2$ (see Section 6 for the proof). Naturally, this lower bound translates to Corollary 10 and Corollary 11. In particular, we get that any depth-2 majority circuit computing the majority of n bits must have that either the bottom fan-in at least $n - o(n)$ or the top fan-in at least $n/2 - o(n)$. This nearly matches Amano's [6] construction of a depth-2 majority circuit with bottom fan-in $n - 2$ and top fan-in $n/2 + 2$.

Another kind of result that we investigate is whether *weighted* threshold functions can be computed using unweighted thresholds of low fan-in. To that end, let $n = (3p - 1)/2$ for an odd prime p, and consider the weighted threshold function

$$T(x) = \begin{cases} 1 & \text{if } \sum_{i \leq p-1} x_i + 2 \sum_{i > p-1} x_i \geq p, \\ 0 & \text{otherwise.} \end{cases}$$

$T(x)$ is a weighted threshold function with weights 1 and 2.

▶ **Theorem 12.** *Any depth-2 circuit computing $T(x)$ where the bottom gates compute unweighted thresholds must have top fan-in at least $(p - 1)/2 = (n - 1)/3$.*

Observe that in Theorem 12 we do not assume an upper bound on the fan-in of the bottom gates. Our bounds are much stronger and significantly simpler than past lower bounds ([17, 9]) on such circuits. Our proofs of Theorem 3 and Theorem 9 are based on proving lower bounds on the degree of specific polynomials, using Lemma 1, that are constructed using the balancing set families and depth-2 threshold circuits, respectively.

Table 1 and Table 2 summarize all our results discussed in the introduction.

Outline

The rest of the paper is organized as follows. We discuss related work in Section 2. We prove Lemma 1 in Section 3. Theorem 3 is proved in Section 4, and the application of our techniques to generalizations of balancing set families are discussed in Section 5. In particular, Section 5 contains the proofs of Theorem 4, 5 and 6. Theorems 9 and 12 are proved in Sections 6 and 7 respectively. Theorem 8 is proved in Section 8.

Notation

$\mathbb{F}_p$ denotes the field with p elements, where p is a prime. For a positive integer n, $\mu(n)$ denotes the largest prime p so that $p \leq n$. For a natural number n, $[n]$ denotes the set $\{1, 2, \ldots, n\}$. For every $x \in \{0,1\}^n$ and $i \in [n]$, x_i denotes the i'th coordinate of x. For $x \in \{0,1\}^n$, when $x_1 = x_2 = \ldots = x_n = 0$, we refer to x as the all-zeros vector or the all-zeros input. The all-ones vector or all-ones input is defined similarly.

Table 2 Summary of results on depth-2 circuits. n is the number of input bits and p is a prime. k is the top fan-in and r is the maximum fan-in of the bottom gates. $\mu(n)$ denotes the largest prime that is no more than n.

Function	Bottom Gates	Result	
Majority	thresholds and reads no constants	$k \geq n/2$ or threshold $= p$ when $n = 2p$	Theorem 9
Majority	thresholds	$\max\{k, r\} \geq n/2$ when $n = 2p$	Corollary 10
Majority	majority	$k \geq n/2$ or $r > n - 2$ when $n = 2p$	Corollary 11
Majority	thresholds	$k \geq n/2 - o(n)$ or threshold $\geq \mu(n/2)$	Theorem 20
Majority	thresholds	$\max\{k, r\} \geq n/2 - o(n)$	Corollary 21
$T(x)$	unbounded fan-in thresholds	$k \geq (n-1)/3$	Theorem 12

Bounds on $\mu(n)$

Generalizations of Theorems 3 and 9 to the case when $n \neq 2p$ for a prime p are obtained by using a known lower bound on $\mu(n)$. Baker, Harman and Pintz [8] showed that the largest gap between consecutive primes is bounded by $O(n^{0.53})$. As a consequence, we can conclude that

▶ **Theorem 13** ([8]). $\mu(n) \geq n - O(n^{0.53})$.

2 Related Work

2.1 Balancing Families

Various notions of balancing set families have been studied. We first describe the question posed by Galvin [12, 10, 15].

▶ **Definition 14.** *Let n be a positive integer that is divisible by 4. A family of proper subsets $S_1, \ldots, S_k \subset [n]$ is* exactly balancing *if each S_i is of size $n/2$ and for every $X \subset [n]$ of size $n/2$ there is an $i \in [k]$ such that $|X \cap S_i| = |S_i|/2$.*

When n is divisible by 4, let $\mathsf{G}(n)$ denote the minimum k for which an exactly balancing set family of size k exists. Clearly, the family of all subsets of $[n]$ of size $n/2$ is exactly balancing, and any family with only one set is not exactly balancing. Therefore finding the minimum number of sets in any exactly balancing set family is interesting.

Galvin [12] observed that $\mathsf{G}(n) \leq n/2$; take $n/2$ consecutive intervals of length $n/2$. Frankl and Rödl [12] proved that $\mathsf{G}(n) \geq \Omega(n)$ if $n/4$ is odd, and later Enomote, Frankl, Ito and Nomura [10] proved that if $n/4$ is odd, then $\mathsf{G}(n) \geq n/2$. Proofs in [12, 10] are based on techniques from linear algebra and extremal set theory. Recently, Hegedűs [15] used algebraic techniques to proved that if $n/4$ is prime, then $\mathsf{G}(n) \geq n/4$. For arbitrary values of n, Alon, Kumar and Volk [5] proved that $\mathsf{G}(n) \geq \Omega(n)$. Theorem 5 improves the bound of Alon, Kumar and Volk.

Several natural variants of Galvin's problem have been studied. One such variant was studied by Jansen [16], and Alon, Kumar and Volk [5]:

▶ **Definition 15.** *Let n be an even integer, and let τ be a positive integer. Let $S_1, \ldots, S_k \subset [n]$ with $2\tau \leq |S_i| \leq n - 2\tau$. We say that $S_1, \ldots, S_k$ is a* τ-balancing set family *if for every $X \subset [n]$ of size $n/2$ there is an $i \in [k]$ such that*

$$|S_i|/2 - \tau < |X \cap S_i| < |S_i|/2 + \tau.$$

When n is even and τ is positive, let $\mathsf{J}(n, \tau)$ denote the minimum k for which such a family of size k exists. This variant allows the family to have sets with different sizes and the intersection sizes to take more than just one value. Alon, Kumar and Volk proved that $\mathsf{J}(n, \tau) \geq \frac{1}{10^5} \cdot (n/\tau)$. This lower bound is sharp up to a constant factor. Theorem 6 improves their bound to $\frac{n - o(n)}{7\tau}$.

Our techniques yield a quantitatively stronger lower bound on balancing set families. The improvement stems from the fact that the ratio of the degree of the polynomial to the number of variables of the polynomial increases from 1/4 to 1/2. Moreover, the application of Lemma 1 eliminates an additional argument using the probabilistic method employed in the work of Alon, Kumar and Volk.

There are many applications of balancing set families. Alon, Bergmann, Coppersmith and Odlyzko [4] studied a different version of balancing sets that has applications to optical data communication. Jansen [16] and Alon, Kumar, and Volk [5] showed applications to proving lower bounds for syntactic multilinear algebraic circuits (also see [20]).

2.2 Threshold Circuits

A depth-d majority circuit can be defined in analogy to depth-2 majority circuits. Let $\mathsf{M}_d(n)$ denote the minimum fan-in of a depth-d majority circuit that computes the majority of n bits. A long line of work has addressed the question of computing the majority function using majority circuits. Ajtai, Komlós and Szemerédi [1] showed that $\mathsf{M}_{c \cdot \log n}(n) = O(1)$, for some constant c. Using probabilistic arguments, Valiant [22] showed the existence of depth $O(\log n)$ majority circuit that computes the majority, where each gate has constant fan-in. Allender and Koucky [2] showed that $\mathsf{M}_c(n) = O(n^{\epsilon(c)})$, where c is a constant and $\epsilon(c)$ is a function of c. Kulikov and Podolskii proved that $\mathsf{M}_3(n) \leq \tilde{O}\left(n^{2/3}\right)$[1]. See [17, 9, 11] and references within for a detailed treatment.

We now discuss previous bounds on $\mathsf{M}_2(n)$. Kulikov and Podolskii [17] used probabilistic arguments to show that $\mathsf{M}_2(n) \geq \tilde{\Omega}\left(n^{7/10}\right)$. They also proved that $\mathsf{M}_2(n) \geq \tilde{\Omega}\left(n^{13/19}\right)$ when the gates are not required to read distinct variables. Amano and Yoshida [7] showed that for every odd $n \geq 7$, $\mathsf{M}_2(n) \leq n - 2$, where they allowed some of the gates to read variables multiple times. Later, Engles, Garg, Makino and Rao [9] used ideas from discrepancy theory to prove that $\mathsf{M}_2(n) \geq \Omega(n^{4/5})$ when the gates do not read constants. Posobin [19] showed that majority can be computed by a depth-2 majority circuit of fan-in at most $2n/3 + 4$ (this was also proved independently by Bauwens [19]). Very recently, Amano [6] gave a construction of a depth-2 majority circuit computing majority with bottom fan-in $n - 2$ and top fan-in $n/2 + 2$.

Kulikov and Podolskii [17] studied and proved lower bounds on other variants of depth-2 majority circuits. In particular, they consider circuits in which each majority gate can read a variable multiple times. Let W be the maximum over the number of times a variable is read. They prove that $\mathsf{M}_2(n) \geq \min\left\{\tilde{\Omega}\left(n^{13/19}\right), \tilde{\Omega}\left(\frac{n^{7/10}}{W^{3/10}}\right)\right\}$. In this case, our techniques yield a lower bound of $\mathsf{M}_2(n) \geq \Omega\left(\frac{n}{W}\right)$. Essentially, their lower bound is stronger when $W \geq n^{6/19}$ and our bound is stronger when $W \leq n^{6/19}$.

[1] In the rest of the paper, $\tilde{O}(a)$ and $\tilde{\Omega}(a)$ mean that $\mathsf{polylog}(a)$ factors are ignored.

The question of computing weighted thresholds using a depth-2 threshold function is connected to the study of exact threshold circuits initiated by Hansen and Podolskii [13]. It may also be useful in studying the expressibility of general functions using threshold or *ReLu* gates; see the work of Williams [23].

We would like to emphasize that the lower bounds in Theorems 9 and 12 are tight and only off by constant factors. In addition, most functions considered in past work on majority and threshold circuit lower bounds do not admit depth-2 majority or threshold circuits with linear fan-in on the gates. In fact, one can prove exponential lower bounds on the size of circuits computing these functions (see [13]).

3 Proof of Lemma 1

Let f be as in the assumption of Lemma 1. Consider the polynomial

$$g(x_1, \ldots, x_{2p}) = (1 - x_1) \cdot \prod_{i=1}^{p-1} \left(i - \sum_{i=1}^{2p} x_i \right),$$

which has degree p. For $x \in \{0,1\}^{2p}$, observe that $g(x) = 0$ if the number of ones in x is not a multiple of p or x is the all-ones input, and $g(x) \neq 0$ if x is the all-zeros input. Therefore, $f \cdot g$ is non-zero on the all-zeros input and 0 elsewhere in $\{0,1\}^{2p}$.

We will now show that the degree of $f \cdot g$ is at least $2p$. Consider the polynomial h that is obtained by multilinearizing $f \cdot g$. In other words, replace every power x_i^k with x_i in $f \cdot g$, for $k \geq 1$, Observe that the degree of h is at most the degree of f. Define $\alpha = h(0, \ldots, 0)$. Recall that there is a one-to-one correspondence between multilinear polynomials over $\mathbb{F}_p$ on $2p$ variables and the set of all functions from $\{0,1\}^{2p} \to \mathbb{F}_p$. Since h is the same as the function that is α on the all-zeros input and 0 elsewhere in $\{0,1\}^{2p}$, we can use this correspondence to conclude that

$$h(x_1, \ldots, x_{2p}) = \alpha \cdot \prod_{i=1}^{2p} (1 - x_i).$$

Therefore the degree of h is $2p$.

Hence the degree of $f \cdot g$ is at least $2p$, implying that the degree of f is at least p.

4 Upper and Lower Bounds on B(n)

In this section, we describe some explicit balancing set families.

▶ **Lemma 16.**
1. *If n is divisible by 4 and $n \neq 4$, then* $\mathsf{B}(n) \leq n/2 - 1$.
2. *If n is divisible by 2 and $n \neq 2$, then* $\mathsf{B}(n) \leq n/2$.

Proof. When 4 divides n, there is a family of $k = \frac{n}{2} - 1$ sets that are balancing: take any k sets, each of size 4, satisfying $S_i \cap S_j = \{1, 2\}$ for all $i \neq j$. This family has the property that for any subset $X \subset [n]$ of size $n/2$, there is an $i \in [k]$ such that $|X \cap S_i| = 2$.

When 2 divides n, there is a family of $k = n/2$ sets that are balancing: take any k sets, each of size 2, satisfying $S_i \cap S_j = \{1\}$ for all $i \neq j$. This family has the property that for any subset $X \subset [n]$ of size $n/2$, there is an $i \in [k]$ such that $|X \cap S_i| = 1$. ◀

As implied by Theorem 3, when $n = 2p$ for a prime p, there is no construction with $k = \frac{n}{2} - 1$ sets; the minimum possible k in this case is $\frac{n}{2}$. We now prove Theorem 3.

Proof of Theorem 3. Lemma 16 implies that $\mathsf{B}(n) \leq p = n/2$. We now proceed to show that $\mathsf{B}(n) \geq p = n/2$. Let $S_1, \ldots, S_k$ be the balancing set family. Without loss of generality each $|S_i|$ is even, and therefore $1 \leq |S_i|/2 \leq p-1$ for all $i \in [k]$. We will now construct a polynomial that is non-zero on the all-zeros input and vanishes on all $x \in \{0,1\}^{2p}$ with p ones. Define the polynomial

$$f(x_1, \ldots, x_{2p}) = \prod_{i=1}^{k} \left(|S_i|/2 - \sum_{j \in S_i} x_j \right),$$

over $\mathbb{F}_p$ that has degree k. Since $1 \leq |S_i|/2 \leq p-1$ for all $i \in [k]$, $f(0) \neq 0$. We will show that $f(x) = 0$, for $x \in \{0,1\}^{2p}$, when x exactly has p ones. This is because the input x to f with exactly p ones corresponds to a set $X \subset [2p]$ of size p. The fact that there is an $i \in [k]$ such that $|S_i \cap X| = |S_i|/2$, implies that $|S_i|/2 - \sum_{j \in S_i} x_j = 0$. By applying Lemma 1, we can conclude that $k \geq p$. ◀

Remark

In Definition 2, since $|S_i \cap X| = |S_i|/2$, it is no loss of generality to assume that each S_i is even sized. The definition can be relaxed by having $|S_i \cap X| = \lceil |S_i|/2 \rceil$. In this relaxed definition, the family $\{1\}, \{2, \ldots, 2p\}$ is balancing and the size of the family is 2. However, if we impose an extra condition that each $|S_i| \geq 2$, then we can prove that the size of any such family is at least p.

5 Balancing Families: Generalizations and Improvements

In this section we prove Theorems 4, 5 and 6. The following lemma is crucial in the proofs these theorems.

▶ **Lemma 17.** *Let n be an even integer. Let $S_1, \ldots, S_k \subset [n]$ and $T_1, \ldots, T_k \subseteq [\mu(n/2) - 1]$. Suppose that there is a set $R \subseteq [n]$ of size $n - 2\mu(n/2)$ such that for every $i \in [k]$ and $t \in T_i$, $|S_i \cap R| < t$, and for every $X \subset [n]$ of size $n/2$ there is an $i \in [k]$ such that $|X \cap S_i| \in T_i$. Then $\sum_{i=1}^{k} |T_i| \geq \mu(n/2)$.*

Proof. Define the polynomial

$$F(x_1, \ldots, x_n) = \prod_{i=1}^{k} \prod_{t \in T_i} \left(t - \sum_{j \in S_i} x_j \right).$$

Let $p = \mu(n/2)$. Define the polynomial $f(x_1, x_2, \ldots, x_{2p})$ over $\mathbb{F}_p$ by setting in F half of the variables indexed by R to 0 and the other half to 1. The degree of f is at most $\sum_{i=1}^{k} |T_i|$. We claim that f takes the value 0 on all inputs with exactly p ones and f is non-zero on the all-zeros input. This is sufficient to prove the theorem as Lemma 1 implies that $\sum_{i=1}^{k} |T_i| \geq p$.

The former part of the claim is true because the input x to f with exactly p ones along with the variables in R that are set to 1 correspond to a set $X \subset [n]$ of size $n/2$. The fact that there is an $i \in [k]$ and $t \in T_i$ with $|S_i \cap X| = t$, implies $t - \sum_{j \in S_i} x_j = 0$.

We now proceed to show that f is non-zero on the all-zeros input. On the all-zeros input for f, we know that all variables indexed by $[n] \setminus R$ are set to 0 and we do not have any control on the assignment to the variables in R. However, since for every $i \in [k]$ and $t \in T_i$, $0 < t < p$ and $|S_i \cap R| < t$, f is non-zero on the all-zeros input. ◀

Implications of Lemma 17

We now discuss the implications of Lemma 17 to the questions about balancing set families discussed in Section 1 and Section 2. The choice of R in Lemma 17 depends on the context. We obtain an asymptotically sharp lower bound for Galvin's problem and an improvement over the lower bound of Alon, Kumar and Volk.

$\mathsf{B}(n)$

We prove Theorem 4 using the following claim (the proof of the claim is presented in the full version of the paper).

▷ Claim 18. Let n be a positive integer and $S_1, \ldots, S_k \subset [n]$ be a balancing set family. If n is large enough and $k < n/2 - 2n^{0.98}$, then there exists a $R \subset [n]$ of size $n - 2\mu(n/2)$ such that for every $i \in [k]$, $|S_i \cap R| < |S_i|/2$.

Proof of Theorem 4. Assume for contradiction that $\mathsf{B}(n) < n/2 - 2n^{0.98}$. Let R be the set given by Claim 18. By invoking Lemma 17 with R and each $T_i = \{|S_i|/2\}$, we get $\mathsf{B}(n) \geq \mu(n/2) \geq n/2 - O\left(n^{0.53}\right)$, where the last inequality follows from Theorem 13. This contradicts the assumption for large values of n. ◀

$\mathsf{J}(n, \tau)$

We prove Theorem 6. We have that each

$$T_i = \{|S_i|/2 - \tau + 1, \ldots, |S_i|/2, \ldots, |S_i|/2 + \tau - 1\}.$$

When $n = 2p$ for a prime p, $R = \emptyset$. Observing that each T_i is of size $2\tau - 1$, Lemma 17 implies Part 1 of Theorem 6.

We now proceed to prove Part 2 of Theorem 6. We need the following claim, and this claim is proved in the full version of the paper.

▷ Claim 19. Let n be a positive integer, τ be a positive integer, and $S_1, \ldots, S_k \subset [n]$ be τ-balancing set family. If n is large enough and $k < n/(7\tau) - n^{0.98}/(7\tau)$, then there exists a $R \subset [n]$ of size $n - 2\mu(n/2)$ such that for every $i \in [k]$, $|S_i \cap R| \leq |S_i|/2 - \tau$.

Proof of Part 2 of Theorem 6. Assume for contradiction that

$$\mathsf{J}(n, \tau) < n/(7\tau) - n^{0.98}/(7\tau).$$

Let R be the set given by Claim 19. By invoking Lemma 17 with R and each

$$T_i = \{|S_i|/2 - \tau + 1, \ldots, |S_i|/2, \ldots, |S_i|/2 + \tau - 1\},$$

we get $\mathsf{J}(n, \tau) \geq \frac{\mu(n/2)}{2\tau - 1} \geq \frac{n - O\left(n^{0.53}\right)}{4\tau - 2}$, where the last inequality follows from Theorem 13. This contradicts the assumption for large values of n. ◀

$\mathsf{G}(n)$

We prove Theorem 5. For Galvin's problem, n is divisible by 4, each S_i is of size $n/2$ and each $T_i = \{n/4\}$. R can be chosen to be any arbitrary set of size $n - 2\mu(n/2)$. For Lemma 17 to apply, we need that for each $i \in [k]$ and $t \in T_i$, $T_i \subseteq [\mu(n/2) - 1]$ and $|S_i \cap R| < t$. This translates in to the condition that $\mu(n/2) > 3n/8$. Lemma 17 in conjunction with Theorem 13 implies Theorem 5.

Specifically Theorem 5 shows that our lower bound is sharp up to an additive $o(n)$ term as $\mathsf{G}(n) \leq n/2$. It is worth noting that $\mathsf{G}(n) < n/2$ for $n \in \{8, 16\}$, so a general $n/2$ lower bound is false (see [5]).

6 Computing Majority using Depth-2 Threshold Circuits

We first prove Theorem 9.

Proof of Theorem 9. Let k be the top fan-in of the circuit, and let $g_1, \ldots, g_k$ be the threshold functions given by the bottom gates of the circuit. We know that g_i is defined by an inequality of the form $L_i(x) \geq t_i$ for a linear function L_i. Assume towards a contradiction that $k < p$ and each $t_i \neq p$.

Define the polynomial

$$f(x) = \prod_{i \in \{j \mid 0 < t_j < 2p\}} (L_i(x) - t_i)$$

over $\mathbb{F}_p$ that has degree at most k. By definition, $f(0)$ is non-zero. We claim that $f(x) = 0$ on every $x \in \{0,1\}^{2p}$ with p ones. Indeed, for such a x we have that $\mathsf{MAJ}(x) = 1$, but for x' that is obtained from x by flipping a coordinate with value 1 to 0, we have that $\mathsf{MAJ}(x') = 0$. Observe that each L_i is a linear function with coefficients in $\{0,1\}$. Since x and x' only differ in one coordinate, we have $L_i(x) - L_i(x') \in \{0,1\}$ for every $i \in [k]$. $\mathsf{MAJ}(x) = 1$ and $\mathsf{MAJ}(x') = 0$ implies that there is an $i \in [k]$ such that $g_i(x) = 1$ and $g_i(x') = 0$. This means that $L_i(x) = t_i$, but $L_i(x') = t_i - 1$. Moreover, this implies that $0 < t_i < 2p$. Hence, for every $x \in \{0,1\}^{2p}$ with p ones, there is an $i \in [k]$ such that $L_i(x) = t_i$ and $0 < t_i < 2p$, which makes $f(x) = 0$. Therefore Lemma 1 implies that the degree of f is at least p, which is a contradiction. ◀

We obtain the following theorem for arbitrary values of n, which is proved using Theorem 9.

▶ **Theorem 20.** *In any depth-2 circuit computing the majority of n bits, if the bottom gates compute unweighted thresholds, either the top fan-in is at least $\mu(n/2)$, or some gate at the bottom computes a threshold T_t with $t \geq \mu(n/2)$.*

Proof. Let k be the top fan-in of the circuit, and let $p = \mu(n/2)$. If there exists a bottom gate with threshold at least p, then we are done. So assume that all bottom gates have threshold less than p. Set half the variables in $x_{2p+1}, \ldots, x_n$ to 0 and the other half to 1. We get a new depth-2 circuit computing the majority of $x_1, \ldots, x_{2p}$. Any bottom threshold gate computing T_t that reads constants is equivalent to a threshold gate computing $T_{t'}$ on the same input variables with $t' \leq t < p$, and $T_{t'}$ reads no constants. Here, $t' = t - \alpha$, where α is the number of ones read by T_t. Replacing each bottom gate that reads constants with its equivalent gate that reads no constants, we obtain a depth-2 circuit in which each bottom gate computes a threshold function with threshold less than p and does not read constants. By applying Theorem 9, we can conclude that $k \geq p$. ◀

Using Theorem 13 we get a corollary to Theorem 20.

▶ **Corollary 21.** *In any depth-2 circuit computing the majority of n bits, if the bottom gates compute unweighted thresholds, then the fan-in is at least $n/2 - O(n^{0.53})$.*

7 Proof of Theorem 12

Let $g_1, \ldots, g_k$ be the threshold functions given by the bottom gates of the circuit. Let

$$L(x) = \sum_{i \leq p-1} x_i + 2 \sum_{i > p-1} x_i.$$

Note that L is a polynomial on $\frac{3p-1}{2}$ variables. For $i \in [k]$, we know that g_i is defined by an inequality of the form $L_i(x) \geq t_i$ for a linear function L_i with coefficients in $\{0, 1\}$.

Consider the polynomial

$$f(x) = \prod_{i \in \{j | 0 < t_j < p\}} (L_i(x) - t_i)$$

over $\mathbb{F}_p$ that has degree at most k. By definition, f is non-zero on the all-zeros input. We will show that $f(x) = 0$ on $x \in \{0,1\}^{\frac{3p-1}{2}}$ such that $L(x) = p$.

Let $x \in \{0,1\}^{\frac{3p-1}{2}}$ be such that $L(x) = p$. Note that for every such x, the number of ones in it is at most $p-1$ and at least 1. For every $x' \in \{0,1\}^{\frac{3p-1}{2}}$ that is obtained by flipping one of the coordinates of x with value 1 to 0, we have $T(x') = 0$. For such x, x', there must be an $i \in [k]$ such that $g_i(x) = 1$ and $g_i(x') = 0$. Moreover, L_i being a linear function with coefficients in $\{0, 1\}$ implies that $L_i(x) - L_i(x') \in \{0, 1\}$. Since $g_i(x) \neq g_i(x')$, we have $L_i(x) = t_i$. In addition, since the number ones in x is at most $p-1$ and at least 1, we get that $0 < t_i < p$. Hence we can conclude that $f(x) = 0$.

We now find a polynomial g that is 0 everywhere in $\{0,1\}^{\frac{3p-1}{2}}$, except on the all-zeros input and x such that $L(x) = p$. Define

$$g(x) = (1 - x_1) \cdot \prod_{i=1}^{p-1} (i - L(x)).$$

The degree of g is p, and $f \cdot g$ is non-zero on the all-zeros input and 0 elsewhere in $\{0,1\}^{\frac{3p-1}{2}}$. We will show that the degree of $f \cdot g$ is at least $(3p-1)/2$. As in the proof of Lemma 1, let h be the multilinearization of $f \cdot g$. Then h is non-zero on the all-zeros input and 0 elsewhere in $\{0,1\}^{\frac{3p-1}{2}}$. Therefore the degree of h is at least $(3p-1)/2$. Since the degree of h is at most the degree of $f \cdot g$, the degree of f is at least $(p-1)/2$.

8 Upper and Lower Bounds on U(n, t)

Theorem 8 is proved in this section. We first recall the definition of a Kneser graph. The Kneser graph $K_{n,\alpha}$ is a graph whose vertices are identified with the subsets of $[n]$ of size α, and there is an edge between two vertices if and only if the corresponding subsets are disjoint. We need the following theorem bounding the chromatic number of Kneser graphs.

▶ **Theorem 22** ([18]). *Consider the Kneser graphs in which the vertex set is given by subsets of $[n]$ of size α. Then the chromatic number of this graph is* $\max\{1, n - 2\alpha + 2\}$.

Proof of Theorem 8. We first prove the upper bound. The following $2t + 2$ sets form an unbalancing family:

$$\{1\}, \{2\}, \ldots, \{2t+1\}, \{2t+2, 2t+3, \ldots, n\}.$$

The above family has the property that for a given $X \subseteq [n]$ of size $n/2 - t$, either $X \subseteq \{2t+2, 2t+3, \ldots, n\}$ or not. In the former case,

$$|X \cap \{2t+2, 2t+3, \ldots, n\}| = n/2 - t > \frac{n - 2t - 1}{2}.$$

In the latter case, there will be an $i \in [2t+1]$ such that $i \in X$. Therefore, $|X \cap \{i\}| = 1 > \frac{1}{2}$.

We now prove the lower bound. Consider the Kneser graph in which the vertex set is given by subsets of $[n]$ of size $n/2 - t$. We claim that the chromatic number of this graph is at most k. The coloring is as follows: For every $X \subseteq [n]$ of size $n/2 - t$, we know that there is an $i \in [k]$ such that $|S_i \cap X| > |S_i|/2$. The vertex associated with X is given the color i. This is a proper coloring because for every $X, Y \subseteq [n]$, each of size $n/2 - t$ that are disjoint, it cannot be the case that $|X \cap S_i| > |S_i|/2$ and $|Y \cap S_i| > |S_i|/2$. Therefore by Theorem 22, we can conclude that $k \geq 2t + 2$. ◀

Abstract

We introduce an (ϵ, δ)-jointly differentially private algorithm for packing problems. Our algorithm not only achieves the optimal trade-off between the privacy parameter ϵ and the minimum supply requirement (up to logarithmic factors), but is also scalable in the sense that the running time is linear in the number of agents n. Previous algorithms either run in cubic time in n, or require a minimum supply per resource that is $\sqrt{n}$ times larger than the best possible.

1 Introduction

Suppose a trusted principal has b copies of some privacy-sensitive good, and there are n agents interested in getting a copy of it. Each agent has some value for receiving a copy of the good. The principal would like to choose a subset of up to b agents to receive the good so that sum of their values is maximized.[1] However, one of the agents, Alice, gets paranoid that the others may be able to learn a lot of information about her value for the sensitive good. In particular, here is a hypothetical scenario that Alice worries about. Suppose the principal simply allocate to the k agents with the largest values, with Alice being one of them. Then, all the other $n-1$ agents may exchange information and figure out that only $b-1$ of them get a copy and, hence, Alice must also get one. Further suppose that the b-th highest value among them is, say, \$1,000; they would also learn that Alice's value for the sensitive good is at least \$1,000. *Is there an allocation algorithm that addresses Alice's concerns without losing too much in the objective?*

This problem has been studied in a series of works in the last few years [14, 15, 17]. More broadly, let us consider a general packing problem with m resources and n agents. Each agent demands a bundle consists of a certain amount of each resource, and has a certain value for getting it. The goal is to pick a subset of the agents such that granting them the corresponding bundles approximately maximizes to sum of the values, subject to the supply constraints of the resources, while protecting the privacy of any individual agent. This line of works focus on a specific notation of privacy called joint differential privacy. In a nutshell,

[1] This is also known as social welfare maximization in the literature of mechanism design.

it requires that for any individual agent, say, Alice in our example, an adversary shall not be able to learn more than a negligible amount of information about the agent's private information, i.e., her value and demands, from the allocations and prices of the other agents.

How can packing algorithms guarantee joint differential privacy? At a high level, such algorithms leave some amount of supply of each resource unallocated in some meticulous and randomized way, so that even if someone knows the allocations and prices of all other agents as in Alice's hypothetical scenario, he will not be able to learn with certainty whether Alice gets a copy of the item, or her value for it. Further, to ensure that the objective is approximately optimal even with the unallocated supplies, all jointly private algorithms require the supply of each resource to be sufficiently large. Hence, the literature measures how good a jointly private algorithm is by the trade-off between the privacy level, quantified by a parameter $\epsilon > 0$, and the minimum supply requirement, subject to getting an additive αn approximation. To this end, Huang and Zhu [17] show that a supply of $\frac{\sqrt{m}}{\epsilon\alpha}$ per resource, up to logarithmic factors, is both sufficient and necessary.

Another important consideration is the running time of the algorithms. This is particularly relevant for (jointly) differentially private algorithms, since they generally require the size of the dataset, i.e., n, to be sufficiently large to achieve good approximation in the objective. We argue that practical (jointly) differentially private algorithms must be scalable in the sense by Teng [26], i.e., the running time shall be quasi-linear in n or better. However, the aforementioned algorithm by Huang and Zhu [17], which achieves the optimal $\tilde{O}\big(\frac{\sqrt{m}}{\epsilon\alpha}\big)$ supply requirement, is not scalable, as its running time depends cubically in n. Neither are the earlier algorithms by Hsu et al. [14, 15]. Although Huang and Zhu [17] also propose an alternative algorithm that is scalable, it requires a much larger supply of $\tilde{O}\big(\frac{\sqrt{mn}}{\epsilon\alpha}\big)$ per resource. The following question is explicitly left open [17]:

> *Are there jointly differentially private algorithm that are scalable and at the same time only require a minimum supply of $\tilde{O}\big(\frac{\sqrt{m}}{\epsilon\alpha}\big)$ per resource?*

1.1 Our Contributions

We introduce a jointly differentially private packing algorithm that answers the above open question affirmatively. The main theorem of this paper is the following:

▶ **Theorem 1.** *There is an (ϵ, δ)-jointly differentially private algorithm such that:*

1. *it returns with high probability a feasible packing solution that is optimal up to an αn additive factor, provided that the supply per resource is at least $\tilde{O}\big(\frac{\sqrt{m}}{\alpha\epsilon}\big)$;*
2. *it stops in $O(n)$ time, omitting dependence in other parameters, with high probability.*

The algorithm follows the same high-level framework as the previous ones, which we summarize below. It maintains for each resource a price (per unit of the resource), which can be viewed as a dual variable that Lagrangianizes the corresponding resource constraint of the packing problem. We shall imagine that the prices are posted on a public billboard for everyone to see, including the agents and the adversary. Given the current prices, each agent gets the bundle if and only if her value is higher than the total price of the bundle. The agents' decisions induce a total demand on each resource, which can be viewed as a subgradient for the dual prices w.r.t. some dual objective. The algorithm then increases the prices of the overdemanded resources and decreases those of the underdemended ones. This process repeats for a certain number of rounds; the final allocation is obtained by averaging over all the rounds. Since the agents' allocation is coordinated only through the prices, it suffices to ensure that the sequence of prices is privacy-preserving. This is formulated as the billboard lemma by Hsu et al. [14].

What are the main differences between our algorithm and the existing ones? The previous non-scalable algorithms are essentially noisy versions of some existing optimization algorithms, including gradient descent [15] and multiplicative weight update [17], run on the dual space with a *fix step size*. They are not scalable because (1) the number of rounds needed by such algorithm generally depends on how large each coordinate of the subgradient could be (a.k.a., the width of the problem), which is roughly n in our problem, and (2) the time needed to compute the subgradient in each round is linear in n.

The scalable algorithm by Huang and Zhu [17], on the other hand, is a noisy version of the online multiplicative weight update algorithm (e.g., [2]), which use the demand of a single agent as an estimator of the overall demand in each round, iterating through all agents once in a random order. However, it does not seem plausible to avoid having an extra $\sqrt{n}$ factor in the minimum supply requirement using this approach, as it is not only jointly differentially private, but also locally private,[2] in the sense that it can be implemented in a way such that the agents add noises themselves so that even the algorithm never accesses any non-private version of the data. The extra $\sqrt{n}$ factor is ubiquitous in the literature of locally private algorithms [3, 9].

In contrast, our algorithm is a noisy version of the multiplicative weight update algorithm run on the dual space with *different step sizes*, which are optimized according on the scale of the subgradient in each round. Intuitively, it chooses a small step size when the scale of the subgradient is large, to avoid dramatic changes in prices, and a large step size when the scale of the subgradient is small, to ensure a good enough progress. The idea of using different step sizes is widely used in non-private packing algorithms to get width-independent running time (e.g., [20]). Despite being standard in non-private packing, a direct combination of it and how the existing approaches add noises to the subgradients lead to suboptimal minimum supply requirement and/or super-linear running time in n. Instead, we need to further use different noise scales in different rounds that are tailored to the scales of the subgradients and, by induction, the corresponding step sizes. In a round where the scale of the subgradient is large (respectively, small) and the step size is small (respectively, large), the algorithm adds noises at a larger (respectively, smaller) scale to the subgradient and, in some sense, uses up less (respectively, more) of the privacy budget. Setting noise scales adaptively over time introduces several technical difficulties which we will address in details in the technical sections. To get the results in Theorem 1, the noise scale is inversely proportional to the square root of the step size. Hence, our algorithm is more precisely characterized as a noisy version of the multiplicative weight update algorithm run on the dual space with *different step sizes and noise scales*, both of which are optimized according on the scale of the subgradient in each round. Table 1 provides a brief comparison of our algorithm and the existing ones.

1.2 Related Work

The notion of differential privacy is introduced by Dwork et al. [10]. It has evolved through a long line of works to become a standard notion of privacy in theoretical computer science. See Dwork and Roth [12] for a textbook introduction. A particularly related line of works study differentially private algorithms for combinatorial optimization problems and mathematical programs. McSherry and Talwar [22] introduce a generic (yet computationally inefficient) method called the exponential mechanism for privately solving optimization problems whose

[2] This is not explicitly stated in Huang and Zhu [17]. Nonetheless, it follows straightforwardly from the definition of the algorithm.

Table 1 A comparison of the algorithm in this paper and those in previous works. n and m denote the number of agents and number of resources respectively. ϵ and α quantify the privacy and approximation guarantees respectively.

feasible set of output is independent on the dataset (e.g., k-means clustering). It is not applicable to the packing problem considered in this paper, since the set of feasible allocations crucially rely on the dataset. Hsu et al. [16] study what linear programs can be solved in a differentially private manner. Unfortunately, packing linear programs are not among the solvable ones [14].

Subsequently, Kearns et al. [19] introduce a relaxed notion called joint differential privacy. It is still strong enough to provide provable privacy guarantees, but is also flexible enough to allow positive results for problems that cannot be solved under the original notion of differential privacy. This relaxed notion is widely used not only in resource allocation problems [14, 15, 17] such as the packing problem considered in this paper, but also in coordinating large games [24, 6, 23, 19, 7], privacy-presering learning [5, 25], privacy-preserving surveys [13], privacy-preserving prediction markets [8], etc.

Recently, jointly differentially private resource allocation algorithms find further applications in regularizing strategic behaviors in the problem of learning reserve prices online in strategic environments [21].

2 Model

For any positive integer ℓ, let $[\ell]$ denote the set of integers between 1 and ℓ, i.e., $\{1, 2, \ldots, \ell\}$.

Packing

Consider a packing problem with n agents and m resources. Each agent $i \in [n]$ demands a bundle of resources; let a_{ij} denote her demand for each resource $j \in [m]$. Further, agent i has value v_i for getting the bundle, and 0 for not getting it. We assume that a_{ij}'s and v_i's are bounded between 0 and 1, which is standard in the literature of differential privacy. For any agent $i \in [n]$, the demands a_{ij}'s and the value v_i are her private data. Let $U = \{(v, a_1, a_2, \ldots, a_m) \in [0, 1]^{m+1}\}$ denote the data universe. Let $\mathcal{D} \in U^n$ denote a dataset of n agents. For any resource $j \in [m]$, let b_j denote its supply. The goal is then to choose a subset of the agents who get their demanded bundles, such that the sum of the values of the chosen agents is maximized, subject to that the total demand on each resource does not exceed the corresponding supply.

We remark that we can make two simplifying assumptions because the focal point of the jointly differentially private packing problem lies in whether the minimum supply is sufficiently large. First, we may assume without loss of generality (wlog) that the supplies of all resources are equal; otherwise, we may rescale the larger ones down to be equal to the

minimum one. Second, we may focus on fractional solutions wlog; any fractional solution can be converted into an integral one using independent rounding with essentially the same objective and total demands on the resources, since we are in the large supply regime.

Therefore, the problem can be formulated as the following packing linear program:

$$\begin{aligned} \text{maximize} \quad & \textstyle\sum_{i\in[n]} v_i x_i \\ \text{subject to} \quad & \textstyle\sum_{i\in[n]} a_{ij} x_i \le b && \forall j \in [m] \\ & 0 \le x_i \le 1 && \forall i \in [n] \end{aligned}$$

Differential Privacy and Joint Differential Privacy

Next, we formally define differential privacy and joint differential privacy with respect to the packing problem. Two datasets $\mathcal{D}, \mathcal{D}' \in U^n$ are i-neighbors if they differ only in the data of the i-th agent, that is, if $\mathcal{D}_j = \mathcal{D}'_j$ for all $j \neq i$. We simply say that they are neighbors if they are i-neighbors for some $i \in [n]$. Further, let $X_i = [0, 1]$ denote the set of feasible decision to each agent $i \in [n]$. Let $X = X_1 \times X_2 \times \cdots \times X_n$ denote the set of feasible outcomes, ignoring the supply constraints. The notion of differential privacy by Dwork et al. [10] requires that the allocation of all agents is chosen from similar distributions for any neighboring datasets in the following sense:

▶ **Definition 2** (Differential Privacy). *A mechanism $\mathcal{M} : U^n \mapsto X$ is (ϵ, δ)-differentially private if for any neighbors $\mathcal{D}, \mathcal{D}' \in U^n$, and any subset of feasible allocations $S \subseteq X$:*

$$\mathbf{Pr}\big[\mathcal{M}(\mathcal{D}) \in S\big] \le \exp(\epsilon) \cdot \mathbf{Pr}\big[\mathcal{M}(\mathcal{D}') \in S\big] + \delta \ .$$

The notion of joint differential privacy by Kearns et al. [19], on the other hand, allows the allocation to each agent to depend non-privately on her own data, so long the allocation to the other agents does not. More precisely, the notion is defined as follows:

▶ **Definition 3** (Joint Differential Privacy). *A mechanism $\mathcal{M} : U^n \mapsto X$ is (ϵ, δ)-jointly differentially private if for any $i \in [n]$, any i-neighbors $\mathcal{D}, \mathcal{D}' \in U^n$, and any subset of feasible allocations to agents other than i, $S_{-i} \subseteq X_{-i}$:*

$$\mathbf{Pr}\big[\mathcal{M}(\mathcal{D})_{-i} \in S_{-i}\big] \le \exp(\epsilon) \cdot \mathbf{Pr}\big[\mathcal{M}(\mathcal{D}')_{-i} \in S_{-i}\big] + \delta \ .$$

The technical connections between the two notions are best explained by the following billboard lemma by Hsu et al. [14].

▶ **Lemma 4** (Billboard Lemma). *Suppose $\mathcal{M} : U^n \mapsto Y$ is (ϵ, δ)-differentially private. Then, for any collection of functions $f_i : U \times Y \mapsto X_i$, $i \in [n]$, the mechanism $\mathcal{M}'$ that allocates to each agent i with $f_i\big(\mathcal{D}_i, \mathcal{M}(\mathcal{D})\big)$ is (ϵ, δ)-jointly differentially private.*

3 Technical Preliminaries

3.1 Lagrangian

The Lagrangian of the packing linear program is:

$$\max_{x\in X} \min_{p\in[0,\infty)^m} \textstyle\sum_{i\in[n]} v_i x_i - \sum_{j\in[m]} p_j \big(\sum_{i\in[n]} a_{ij} x_i - b_j\big) \ .$$

Let $L(x, p)$ denote the partial Lagrangian objective, that is:

$$\begin{aligned} L(x,p) &= \textstyle\sum_{i\in[n]} v_i x_i - \sum_{j\in[m]} \big(\sum_{i\in[n]} a_{ij} x_i - b\big) p_j \\ &= \textstyle\sum_{j\in[m]} b p_j + \sum_{i\in[n]} \big(v_i - \sum_{j\in[m]} a_{ij} p_j\big) x_i \ . \end{aligned}$$

Let $D(p) = \max_{x\in[X]} L(x,p)$ denote the dual objective. We shall interpret p_j as the unit price of resource j for any $j \in [m]$. Given any prices p, an optimal solution $x^*(p)$ of the optimization problem $\max_{x\in[X]} L(x,p)$ is defined as, for any $i \in [n]$:

$$x_i^*(p) = \begin{cases} 1, & \text{if } v_i - \sum_{j\in[m]} a_{ij}p_j \geq 0; \\ 0, & \text{otherwise.} \end{cases}$$

We have the following envelope theorem (see, e.g., Afriat [1]).

▶ **Lemma 5** (Envolope Theorem)**.** *Given any prices p, the derivatives of the Lagrangian objective w.r.t. the prices, i.e., $\nabla_p L(x,p)$, is a sub-gradient of $D(p)$ when $x = x^*(p)$.*

3.2 Truncated Laplacian Distributions

The Laplacian distribution, given mean $\mu \in R$ and scale parameter $b > 0$, is a continuous distribution defined on $(-\infty, +\infty)$ such that the probability density of any $x \in \mathbf{R}$ is:

$$\frac{1}{2b}\exp\left(-\frac{|x-\mu|}{b}\right) .$$

Let $\mathrm{Lap}(\mu, b)$ denote this distribution. It has mean μ and variance $2b^2$.

Further, we will consider the truncated Laplacian distribution with support $[\mu - 1 + \alpha, \mu + 1 - \alpha]$, denoted as $\mathrm{Lap}_{1-\alpha}(\mu, b)$. The probability density of any x in the interval is proportional to that of $\mathrm{Lap}(\mu, b)$; the density is 0 if it is outside the interval. $\mathrm{Lap}_{1-\alpha}(\mu, b)$ also has mean μ, and variance $O(b^2)$. (See below for a formal statement.)

Given any mean $\mu \in [-\alpha, \alpha]$ and target standard deviation (up to a constant factor) $0 < \sigma \leq \alpha$, let $\mathcal{N}(\mu, \sigma) = \mathrm{Lap}_{1-\alpha}(\mu, \sigma)$. We use this notation to emphasize that the family of noise distributions, $\mathcal{N}(\mu, \sigma)$'s, can be replaced by distributions other than the truncated Laplacian distributions, as long as they satisfy the following properties.The proofs are deferred to the full version.

▶ **Lemma 6.** *The noise distributions $\mathcal{N}(\mu, \sigma)$'s satisfy that:*
1. *the mean of $\mathcal{N}(\mu, \sigma)$ is μ;*
2. *the variance of $\mathcal{N}(\mu, \sigma)$ is at most $2\sigma^2$.*

▶ **Lemma 7.** *Suppose $-\alpha \leq \mu_1, \mu_2 \leq \alpha$, and $0 < \sigma_1, \sigma_2 \leq \alpha$ satisfy that for some $0 < \eta \leq \alpha$, $\sigma = \max\{\sigma_1, \sigma_2\}$, and $\delta > 0$: (1) $\left|\frac{1}{\sigma_1^2} - \frac{1}{\sigma_2^2}\right| \leq \frac{\eta}{\alpha\sigma^2}$; (2) $\left|\mu_1 - \mu_2\right| \leq \eta$; and $\delta \leq \frac{\eta \ln(2/\delta)}{\sigma}$. Then, for any $S \subseteq \mathbf{R}$, we have:*

$$\mathbf{Pr}_{z\sim\mathcal{N}(\mu_1,\sigma_1)}\left[z \in S\right] \leq \exp\left(\frac{4\eta\ln(2/\delta)}{\sigma}\right) \cdot \mathbf{Pr}_{z\sim\mathcal{N}(\mu_2,\sigma_2)}\left[z \in S\right] + \delta .$$

4 Our Algorithm

The algorithm follows a primal dual approach, running best response on the primal (i.e., allocation x) and a noisy version of the multiplicative weight update (MWU) method on the dual (i.e., the prices p). Similar approaches are also used in the previous works that study jointly differentially private packing problem (e.g., [15, 17]). The new ingredients of our algorithm are the use of nonuniform step sizes as well as nonuniform noise scales, both of which are meticulously optimized to achieve both scalable running time and the optimal trade-off between privacy and the minimum supply requirement. In contrast, all previous algorithms use a fix step size and a fix noise scale across different rounds.

Algorithm 1 Private Dual MWU with Optimized Step Sizes and Noise Scales.

Input:
- Dataset $\mathcal{D} \in U^n$, represented by a_{ij}'s and v_i's;
- Supply (per resource) b.

Assumptions:
- $b \geq \tilde{O}\left(\frac{\sqrt{m}}{\alpha\epsilon}\right)$;
- We also assume $n \geq b$ as the problem is trivial otherwise.

Parameters:
- Upper bound on dual prices $p_{\max} = \frac{2n}{b}$;
- Initial dual prices p^1 such that $p_j^1 = \frac{p_{\max}}{m+1}$ for any $j \in [m+1]$;
- Upper bound on the sum of step sizes $\eta_{\text{sum}} = \frac{\ln(m+1)}{\alpha b}$.

1: **for** $t = 1, 2, \ldots,$ **until** $\sum_t \eta^t \geq \eta_{\text{sum}}$ (via a private counter) **do**
2: Let $x^t = x^*(p^t)$, i.e., the best response to p^t from the primal viewpoint.
3: Let $\nabla_j D(p^t) = b - \sum_{i \in [n]} a_{ij} x_i^t$ for all $j \in [m]$; let $\nabla_{m+1} D(p^t) = 0$.
4: Let the *step size* and the *noise scale* be:

$$\eta^t = \min\left\{\frac{\alpha}{b}, \frac{\alpha}{\nabla_1 D(p^t)}, \frac{\alpha}{\nabla_2 D(p^t)}, \ldots, \frac{\alpha}{\nabla_m D(p^t)}\right\} \quad , \quad \sigma^t = \frac{\sqrt{m\eta_{\text{sum}}\eta^t \ln(Tm/\delta)}}{\epsilon} \ .$$

5: Draw $\delta_j^t \sim \mathcal{N}\left(\mu_j^t, \sigma^t\right)$ where $\mu_j^t = \eta^t \nabla_j D(p^t)$ for all $j \in [m]$; let $\delta_{m+1}^t = 0$.
6: Let $\hat{p}_j^{t+1} = p_j^t \cdot \exp(-\delta_j^t)$ for all $j \in [m+1]$.
7: Let p^{t+1} be such that $p_j^{t+1} \propto \hat{p}_j^{t+1}$ and $\sum_{j \in [m+1]} p_j^{t+1} = p_{\max}$.
8: **end for**
9: Let T be the number of iterations in the for loop.

Output: $\bar{x} = \frac{1}{\eta_{\text{sum}}} \sum_{t=1}^{T} \eta^t x^t$, where agent i observes $\bar{x}_i$.

See Algorithm 1 for an exposition by pseudocode.

We now describe the algorithm in more details. Let us first explain the basic dynamic of the dual MWU algorithm. For technical reasons, we add a dummy resource with 0 supply, and 0 demands from all agents, and assume that the dual prices sum to a fix and sufficiently large number $p_{\max}$. Starting from some initial guess p^1 of the prices, say, with $p_{\max}$ uniformly distributed among the $m+1$ coordinates, the MWU algorithm repeatedly calculates:

$$x^t = x^*\left(p^t\right) \quad ; \quad p_j^{t+1} \propto p_j^t \cdot \exp\left(-\eta^t \nabla_j D\left(p^t\right)\right) \ , \ \forall j \in [m+1]$$

where $\eta^t > 0$ is the step size of round t. That is, the allocation x^t is the best response to p^t, which induces a subgradient of the dual objective at p^t by Lemma 5. Then, from p^t to p^{t+1}, each coordinate $j \in [m+1]$ decreases exponentially by an amount proportional to corresponding subgradient, before they are rescaled to sum to $p_{\max}$. With appropriate step sizes, standard analysis shows that the weighted average allocation across different rounds, where the weight of each round is its step size, converges to an optimal allocation.[3]

To obtain the desired privacy guarantee, our algorithm updates the prices with zero-mean noises added to the subgradients. Below we discuss the choice of step sizes and noise scales.

Step Sizes. Some standard choices of step sizes include uniform step sizes, i.e., $\eta^t = \eta$, which is used in previous works on jointly private packing algorithms [15, 17], decreasing step sizes, e.g., $\eta^t = \frac{\eta}{t}$, and step sizes inversely proportional to the magnitude of the subgradient, which

[3] The prices also converge, although this is not relevant for our analysis.

are what our algorithm uses (see, e.g., Koufogiannakis and Young [20], for an application in the non-private packing problem). Intuitively, our choice of step sizes ensure that at least one coordinate will be updated by an η amount, which in turns lower bounds the amount of progress made in each round. Our algorithm has one caveat, however, as it further caps the step size by an upper bound, which is set to $\frac{\alpha}{b}$ for technical reasons, so that the noise added in any single round does not affect the result by too much.

Noise Scales. Not surprisingly, our first attempt is to add a uniform amount of noise to every round like the previous jointly private algorithms in the literature [14, 15, 17]. This, however, either requires the minimum supply to be much larger than the best possible, or is not scalable. To see why, let us first consider an overly-simplified argument of why uniform noise scales work in the previous algorithms. Suppose the algorithm takes T rounds in total. By a standard composition theorem of differential privacy (see, e.g., Dwork and Roth [12]), adding noises at a uniform scale $\tilde{O}\big(\frac{\sqrt{T}}{\epsilon}\big)$ is sufficient for achieving (ϵ, δ)-joint differential privacy. Then, if the algorithm uses a uniform step size η, by the standard concentration bound, the cumulative noise summing over T rounds is roughly $\tilde{O}\big(\frac{\eta T}{\epsilon}\big)$. After averaging, this is essentially a fixed amount of noise $\tilde{O}\big(\frac{1}{\epsilon}\big)$ independent of T and η!

With non-uniform step sizes, however, this is no longer true. As a thought experiment, suppose there are $T' \ll T$ rounds that have large step sizes, say, all equal to η; the rest of the rounds can be omitted due to negligible step sizes. Note that the uniform noise scale, i.e., $\tilde{O}\big(\frac{\sqrt{T}}{\epsilon}\big)$, is still determined by the total number of rounds, repeating the above calculation gives that the amount of noise after averaging is $\tilde{O}\big(\frac{\sqrt{T}}{\epsilon\sqrt{T'}}\big) \gg \tilde{O}\big(\frac{1}{\epsilon}\big)$.

The lesson we learned from this though experiment is that the algorithm must choose non-uniform noise scales: smaller noise scales for more important rounds that have larger step sizes; and larger noise scales for less important rounds that have smaller step sizes. More precisely, we optimize the noise scale in each round t to be inversely proportional to the square root of the step size, i.e, $\sqrt{\eta^t}$; this is derived form a Cauchy-Schwarz inequality to balance different aspects of the analysis. (Note that δ_j^t's in Algorithm 1 denote the noises added to the subgradients *multiplied by the corresponding step size* and, hence, its scale is proportional to $\sqrt{\eta^t}$, rather than inversely proportional to it.)

Privacy-preserving Stopping Criteria. Finally, note that the stopping criteria of $\sum_t \eta^t \geq \eta_{\text{sum}}$ must be implemented approximately in a privacy-preserving manner as well. This can be done by maintaining $\sum_t \eta^t$ using a standard technique called private counter (e.g., Chan et al. [4], Dwork et al. [11]). For simplicity of exposition, we will omit this standard component and analyze the algorithm assuming the stopping criteria is implemented exactly.

5 Utility and Time Complexity

This section sketches the analysis of utility guarantees provided by Algorithm 1 and its time complexity, under the assumption that the supply is sufficiently large, i.e., $b \geq \tilde{O}\big(\frac{\sqrt{m}}{\alpha\epsilon}\big)$.

5.1 No-regret Lemma

We first introduce a technical lemma that will serve as the overarching tool in the analysis of the algorithm's approximation guarantees in terms of the objective and constraint violations, and its running time. It states that if we compare the Lagrangian objective achieved by the sequence of x^t's and p^t's computed in the algorithm, and what could have be achieved by replacing p^t's with an arbitrary but fix p, the difference can be bounded. In other words, the dual price sequence has no regret in the terminology of online learning.

▶ **Lemma 8.** *For any p such that $\|p\|_1 = p_{max}$, with high probability, we have:*

$$\sum_{t=1}^{T} \eta^t \big(L(x^t, p^t) - L(x^t, p)\big) \le D_{\mathrm{KL}}(p\|p^1) + \eta_{\mathrm{sum}} \cdot O\big(\alpha n\big) \ .$$

Proof Sketch of Lemma 8. We present a proof sketch of a weaker claim that the inequality holds in expectation, which captures the bottleneck of the analysis. Further showing the stronger claim in the lemma takes a (slightly nonstandard) concentration inequality for martingales. See the full version for a complete proof of the lemma.

Readers familiar with this kind of analysis will find it standard and may directly jump to the end to verify that the contribution from the variance term can be bounded given the noise scales chosen in the algorithm. Fix any step t, we have the followings:

$$\begin{aligned}
\mathbf{E}\big[\eta^t \big(L(x^t, p^t) - L(x^t, p)\big)\big] &= \mathbf{E}\big[\langle \eta^t \nabla D(p^t), p^t - p\rangle\big] \\
&= \mathbf{E}\big[\langle \delta^t, p^t - p\rangle\big] \\
&= \mathbf{E}\left[\left\langle \ln\left(\tfrac{\hat{p}^{t+1}}{p^t}\right), p - p^t\right\rangle\right] \\
&= \mathbf{E}\big[D_{\mathrm{KL}}\big(p\|p^t\big) - D_{\mathrm{KL}}\big(p\|\hat{p}^{t+1}\big) + D_{\mathrm{KL}}\big(p^t\|\hat{p}^{t+1}\big)\big] \\
&\le \mathbf{E}\big[D_{\mathrm{KL}}\big(p\|p^t\big) - D_{\mathrm{KL}}\big(p\|p^{t+1}\big) + D_{\mathrm{KL}}\big(p^t\|\hat{p}^{t+1}\big) - D_{\mathrm{KL}}\big(p^{t+1}\|\hat{p}^{t+1}\big)\big] \\
&\le \mathbf{E}\big[D_{\mathrm{KL}}\big(p\|p^t\big) - D_{\mathrm{KL}}\big(p\|p^{t+1}\big) + D_{\mathrm{KL}}\big(p^t\|\hat{p}^{t+1}\big)\big] \ .
\end{aligned}$$

We abuse notation and let $\ln\left(\frac{\hat{p}^{t+1}}{p^t}\right)$ denote a vector whose j-th coordinate is $\ln\left(\frac{\hat{p}_j^{t+1}}{p_j^t}\right)$ for any $j \in [m+1]$, in the 4th line of the above equation. The last two inequalities follow by the generalized Pythagorean theorem and the non-negativity of divergences, respectively.

Summing over $t \in [T]$, the first two terms form a telescopic sum; it is bounded by the first term on the right-hand-side of the inequality stated in the lemma. For the last term, we have:

$$\begin{aligned}
\mathbf{E}\big[D_{\mathrm{KL}}\big(p^t\|\hat{p}^{t+1}\big)\big] &= \mathbf{E}\big[\textstyle\sum_{j=1}^{m+1} \left(p_j^t \ln\left(\frac{p_j^t}{\hat{p}_j^{t+1}}\right) - p_j^t + \hat{p}_j^{t+1}\right)\big] \\
&= \mathbf{E}\big[\textstyle\sum_{j=1}^{m+1} p_j^t\big(\delta_j^t - 1 + \exp\big(-\delta_j^t\big)\big)\big] \\
&\le \mathbf{E}\big[\textstyle\sum_{j=1}^{m+1} p_j^t\big(\delta_j^t\big)^2\big] = \mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} p_j^t\big(\mathbf{E}\big[\delta_j^t\big]^2 + \mathbf{Var}\big[\delta_j^t\big]\big)\right] \ .
\end{aligned}$$

Note that the step sizes ensure $\mathbf{E}\big[\delta_j^t\big] \le \alpha$. The first part on the right-hand-side sums to:

$$\begin{aligned}
\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1}\sum_{t=1}^{T} p_j^t \cdot \mathbf{E}\big[\delta_j^t\big]^2\right] &\le \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} p_j^t \cdot \sum_{t=1}^{T} \big|\mathbf{E}\big[\delta_j^t\big]\big|\right] \\
&\le \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} p_j^t \cdot \Big(2b\sum_{t=1}^{T}\eta^t - \sum_{t=1}^{T}\eta^t\mathbf{E}\big[\delta_j^t\big]\Big)\right] \\
&= \eta_{\mathrm{sum}} \cdot O(\alpha n) - \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} p_j^t \sum_{t=1}^{T}\eta^t\mathbf{E}\big[\delta_j^t\big]\right] \\
&\le \eta_{\mathrm{sum}} \cdot O(\alpha n) - \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} p_j^t \sum_{t=1}^{T}\eta^t\nabla_j D(p^t)\right] \\
&= \eta_{\mathrm{sum}} \cdot O(\alpha n) - \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} \eta^t\big(L(x^t, p^t) - \sum_{i=1}^{n} v_i x_i^t\big)\right] \\
&\le \eta_{\mathrm{sum}} \cdot O(\alpha n) - \alpha\mathbf{E}\left[\textstyle\sum_{j=1}^{m+1} \eta^t L(x^t, p^t)\right] \le \eta_{\mathrm{sum}} \cdot O(\alpha n) \ .
\end{aligned}$$

Finally, the contribution from the variance part sums to:

$$\begin{aligned}
\mathbf{E}\left[\sum_{j=1}^{m+1}\sum_{t=1}^{T} p_j^t \cdot \mathbf{Var}\left[\delta_j^t\right]\right] &\le \mathbf{E}\left[\sum_{j=1}^{m+1}\sum_{t=1}^{T} p_j^t \cdot 4\left(\sigma^t\right)^2\right] && \text{(Lemma 7)}\\
&\le \tilde{O}\left(\sum_{t=1}^{T} \tfrac{p_{\max} m \eta_{\text{sum}} \eta^t}{\epsilon^2}\right) && \text{(Definition of } \sigma^t\text{'s)}\\
&\le \tilde{O}\left(\tfrac{p_{\max} m \eta_{\text{sum}}^2}{\epsilon}\right)\\
&= \eta_{\text{sum}} \cdot \tilde{O}\left(\tfrac{n}{\alpha\epsilon^2 b^2}\right) \le \eta_{\text{sum}} \cdot O(\alpha n)\ . && \text{(Assumption on } b\text{)}
\end{aligned}$$

Putting them together proves the lemma. ◀

By the choice of p^1, $p_{\max}$, η_{sum}, the fact that $L(x^t, p^t) \ge \text{OPT}$ since x^t's are best responses, and the definition of $\bar{x}$, we further have it in a simpler form as a corollary.

▶ **Lemma 9.** *For any p such that $\|p\|_1 = p_{max}$, with high probability, we have:*

$$\text{OPT} - L\left(\bar{x}, p\right) \le O\left(\alpha n\right)\ .$$

5.2 Approximate Optimality

We now argue that the algorithm gets an objective that is optimal up to an $O(\alpha n)$ additive factor, with the understanding that further improving it to an αn factor does not affect any of the asymptotic bound. To do so, simply let p be such that the first m coordinates are all equal to 0, and the last dummy coordinate equals $p_{\max}$. Then, we have that $L(\bar{x}, p) = \sum_{i=1}^{n} v_i \bar{x}_i = \text{ALG}$. The claim then follows from Lemma 9.

5.3 Feasibility

Next, we argue that the algorithm provides an allocation $\bar{x}$ that is approximately feasible in the sense that the total demand for each resource is at most $\left(1 + O(\alpha)\right)b$. To convert it into an exactly feasible solution as stated in Theorem 1, we can simply scale the allocation down by a $1 + O(\alpha)$ factor, at the cost of further reducing the objective by at most $O(\alpha n)$.

Suppose resource j^* has the largest demand. Let $s = \sum_{i=1}^{n} a_{ij^*}\bar{x}_i - b$ the gap between this demand and the supply b. Let p be such that all but the j^*-th coordinate are equal to 0, and the j^*-th coordinate is equal to $p_{\max}$. Then, we have:

$$L\left(\bar{x}, p\right) = \text{ALG} - p_{\max} s \le \left(1 + \tfrac{s}{b}\right)\text{OPT} - p_{\max} s\ .$$

By Lemma 9, we get that:

$$\left(p_{\max} - \tfrac{\text{OPT}}{b}\right) s \le O\left(\alpha n\right)\ .$$

Putting together with our choice of $p_{\max} = \frac{2n}{b}$, and that $\text{OPT} \le n$, we get $s \le O\left(\alpha b\right)$.

5.4 Time Complexity

We next show that the number of iterations of the for loop is upper bounded by a polynomial of the parameters other than n. More precisely, we show that $T \le O\left(\frac{m \ln(m+1)}{\alpha^2}\right)$.

To do so, we classify the iterations into $m+1$ types, according to how the step size is chosen. If the step size is $\eta^t = \frac{\alpha}{b}$, we call it type 0. Otherwise, if the step size is $\eta^t = \frac{\alpha}{\nabla_j D(p^t)}$ for some $j \in [m]$, we call it type j.

First, the number of type 0 iterations is at most $\frac{\ln(m+1)}{\alpha^2}$, before the sum of the step sizes exceeds $\eta_{\text{sum}} = \frac{\ln(m+1)}{\alpha b}$.

Next, consider the iterations of type j, for each resource $j \in [m]$. In each iteration t of type j, we have that $\eta^t \nabla_j D(p^t) = \alpha$. We argue that there cannot be too many such iterations, because $\sum_{t=1}^{T} \eta^t \nabla_j D(p^t)$ is upper bounded as a result of the approximate feasibility of $\bar{x}$, which follows from Lemma 9 as argued in the Section 5.3.

On the one hand, we have:

$$\textstyle\sum_{t=1}^{T} \eta^t \nabla_j D(p^t) = \sum_{t=1}^{T} \eta^t \big(\sum_{i=1}^{n} a_{ij} \bar{x}_i - b \big) \le \eta_{\text{sum}} \cdot O(\alpha b) = \tilde{O}(1) \ .$$

On the other hand, suppose there are T_j such iterations, we have:

$$\begin{aligned} \textstyle\sum_{t=1}^{T} \eta^t \nabla_j D(p^t) &= \textstyle\sum_{t \in T_j} \alpha + \sum_{t \notin T_j} \eta^t \nabla_j D(p^t) \\ &\ge \textstyle\sum_{t \in T_j} \alpha + \sum_{t \notin T_j} \eta^t (-b) \ge \alpha |T_j| - 2b\eta_{\text{sum}} = \alpha |T_j| - \frac{2\ln(m+1)}{\alpha} \ . \end{aligned}$$

Putting together gives $|T_j| \le \frac{3\ln(m+1)}{\alpha^2}$.

6 Privacy: Proof Sketch

This section sketches the proof that Algorithm 1 is (ϵ, δ)-jointly differentially private. See the full version for a complete argument.

First, consider any fix step t. Suppose $\mathcal{D}$ and $\widetilde{\mathcal{D}}$ are two neighboring datasets. Further suppose the random realizations of the first $t-1$ iterations are such that $x^1, x^2, \ldots, x^{t-1}$ and $p^1, p^2, \ldots, p^{t-1}$ are identical on $\mathcal{D}$ and $\widetilde{\mathcal{D}}$. Let us consider the privacy of step t alone.

In fact, let us focus on a resource $j \in [m]$. How does the distribution from which δ_j^t is drawn differ on the two datasets? Suppose the step sizes are η and $\tilde{\eta}$ respectively. Then, by the choice of step sizes in the algorithm and that $\nabla_j D(p^t)$ differs by at most 1, we have:

$$\big| \tfrac{1}{\eta} - \tfrac{1}{\tilde{\eta}} \big| \le \tfrac{1}{\alpha} \ .$$

Suppose the standard deviations are σ and $\tilde{\sigma}$, and the means are μ and $\tilde{\mu}$, respectively on the two datasets. They satisfy that:

$$\begin{aligned} \big| \tfrac{1}{\sigma^2} - \tfrac{1}{\tilde{\sigma}^2} \big| &= \tfrac{\epsilon^2}{m\eta_{\text{sum}} \ln(T/\delta)} \big| \tfrac{1}{\eta} - \tfrac{1}{\tilde{\eta}} \big| \le \tfrac{\epsilon^2}{\alpha m \eta_{\text{sum}} \ln(Tm/\delta)} = \tfrac{\eta}{\alpha \sigma^2} \ , \\ \big| \mu - \tilde{\mu} \big| &\le \eta \big| \tfrac{\mu}{\eta} - \tfrac{\tilde{\mu}}{\tilde{\eta}} \big| + \tilde{\mu} \eta \big| \tfrac{1}{\eta} - \tfrac{1}{\tilde{\eta}} \big| \le \eta + \alpha \eta \alpha^{-1} = 2\eta \ , \end{aligned}$$

where $\big| \frac{\mu}{\eta} - \frac{\tilde{\mu}}{\tilde{\eta}} \big| \le 1$ because it measures the difference in $\nabla_j D(p^t)$.

Also it's easy to verify that $\eta^t \le \alpha$. Therefore, by Lemma 7, we have that the update from price p_j^t to $\tilde{p}_j^{t+1}$ posted in round t for resource j is $(\epsilon^t, \frac{\delta}{Tm})$-differentially private for:

$$\epsilon^t = O\big(\tfrac{\eta^t}{\sigma^t}\big) = \tfrac{\epsilon \sqrt{\eta^t \ln(Tm/\delta)}}{\sqrt{m \eta_{\text{sum}}}} \ .$$

Then, intuitively by the composition theorem (see, e.g., Dwork and Roth [12]), the price sequence is (ϵ, δ)-differentially private because:

$$\sum_{t=1}^{T} \sum_{j=1}^{m} \big(\epsilon^t\big)^2 = O\big(\tfrac{\epsilon^2 \eta^t \ln^2(Tm/\delta)}{m \eta_{\text{sum}}}\big) = O\big(\tfrac{\epsilon^2}{\ln(2/\delta)}\big) \ .$$

However, note that the standard statement of the composition theorem does not directly apply here since the privacy budget ϵ^t in each step is chosen adaptively. Fortunately, the underlying argument still goes through. Again, see the full version for details.

Finally, the privacy guarantee of Algorithm 1 follows by the billboard lemma (Lemma 4).

Abstract

Graph Balancing is the problem of orienting the edges of a weighted multigraph so as to minimize the maximum weighted in-degree. Since the introduction of the problem the best algorithm known achieves an approximation ratio of 1.75 and it is based on rounding a linear program with this exact integrality gap. It is also known that there is no $(1.5 - \epsilon)$-approximation algorithm, unless P = NP. Can we do better than 1.75?

We prove that a different LP formulation, the configuration LP, has a strictly smaller integrality gap. Graph Balancing was the last one in a group of related problems from literature, for which it was open whether the configuration LP is stronger than previous, simple LP relaxations. We base our proof on a local search approach that has been applied successfully to the more general Restricted Assignment problem, which in turn is a prominent special case of makespan minimization on unrelated machines. With a number of technical novelties we are able to obtain a bound of 1.749 for the case of Graph Balancing. It is not clear whether the local search algorithm we present terminates in polynomial time, which means that the bound is non-constructive. However, it is a strong evidence that a better approximation algorithm is possible using the configuration LP and it allows the optimum to be estimated within a factor better than 1.75.

A particularly interesting aspect of our techniques is the way we handle small edges in the local search. We manage to exploit the configuration constraints enforced on small edges in the LP. This may be of interest to other problems such as Restricted Assignment as well.

1 Introduction

In this paper we consider weighted, undirected multigraphs that may contain loops. We write such a multigraph as $G = (V, E, r, w)$, where V is the set of vertices, E is the set of edge identities, and r is a function $E \to \{\{u, v\} : u, v \in V\}$ that defines the endpoints for every edge. Note that in the definition above we allow $u = v$, which describes a loop. E is often defined as a set of vertex pairs. We use the function r instead, since it avoids some issues due to multigraphs. The weight function $w : E \to \mathbb{R}_{>0}$ assigns positive weights to the edges. In the Graph Balancing problem we want to compute an orientation of the edges, i.e., one of the ways to turn the graph into a directed graph. The goal is to minimize the maximum weighted in-degree over all vertices, that is $\max_{v \in V} \sum_{e \in \delta^-(v)} w(e)$, where $\delta^-(v)$ are the incoming edges of vertex v in the resulting digraph. Apart from being an arguably natural problem, Graph Balancing has been of particular interest to the scheduling community.

It is one of the simplest special cases of makespan minimization on unrelated machines for which an inapproximability bound of $1.5-\epsilon$ is known, which is already the best that is known in the general problem. In the interpretation as a scheduling problem, machines correspond to vertices and jobs to edges, i.e., each job has only two potential machines to which it can be assigned. The problem was introduced by Ebenlendr, Krčál, and Sgall [9] and they gave a polynomial time 1.75-approximation for it. Indepenently and under a different name, Asahiro et al. [4] studied the problem and showed that no $(1.5-\epsilon)$-approximation is possible unless P = NP. The algorithm by Ebenlendr et al. rounds the solution of a particular linear programming formulation. This appears to be the best one can hope for using their techniques, since the ratio between integral optimum and fractional optimum of the LP, the integrality gap, can be arbitrarily close to 1.75 [9]. Using a completely different approach to [9], Huang and Ott developed a purely combinatorial algorithm for the problem [10]. With $5/3+4/21 \approx 1.857$, however, their approximation ratio is inferior to the original algorithm. Another algorithm for Graph Balancing, developed by Wang and Sitters [21], achieves an approximation ratio of $11/6 \approx 1.833$, i.e., also worse than the original, but notable for being simpler. For the special case of only two different edge weights, three independent groups found a tight 1.5-approximation [7, 10, 17].

A good candidate for a stronger linear program to that from [9] is the configuration LP. It was introduced by Bansal and Sviridenko for the more general problem Scheduling on Unrelated Machines and the closely related Santa Claus problem [5]. It is easy to show that this LP is at least as strong as the LP from [9] (see the same paper), i.e., the integrality gap must be at most 1.75 as well. The best lower bound known is 1.5 (see for instance [11], this holds even for the case of Graph Balancing). In recent literature, the configuration LP has enabled breakthroughs in the restricted variants for both of the problems above [3, 19]. The restricted variant of Scheduling on Unrelated Machines (also known as Restricted Assignment) can be seen as Graph Balancing with hyperedges. In particular, it contains the Graph Balancing problem as a special case. In this setting, the configuration LP was shown first to have an integrality gap of at most $33/17 \approx 1.941$ [19], which was improved to $11/6 \approx 1.833$ by us [13]. This non-constructive proof is by a local search algorithm that is not known to terminate in polynomial time. In this paper, we present a sophisticated local search algorithm for Graph Balancing and obtain the following result.

▶ **Theorem 1.** *The integrality gap of the configuration LP is at most* 1.749 *for* Graph Balancing.

In other words, it is stronger than the LP from [9]. Although this does not give a polynomial time approximation algorithm, it is strong evidence that such an algorithm can be developed using the configuration LP. Furthermore, the optimal solution can be estimated in polynomial time within a factor of $1.749+\epsilon$ for any $\epsilon > 0$ by approximating the configuration LP. We emphasize that the purpose of this paper is to show a separation between the configuration LP and the previously used LP relaxation. The constants in the proof are not optimized. We chose to keep the case analysis (which is already difficult) and constants as simple as possible instead of improving the third decimal place. A summary of results regarding the configuration LP is given in Table 1. In fact, for all of the problems except for Graph Balancing it was known whether the configuration LP improves over the previous state-of-the-art. Our work in [15] indicates that earlier bounds on the integrality gap of the configuration LP in related problems disregard many constraints enforced on small edges/jobs, but that without them the LP might be much weaker. More precisely, these proofs used only properties that are already enforced by a weaker configuration LP that allows small edges/jobs to appear fractionally in a configuration. This weaker LP, however, has an integrality gap strictly

Table 1 Integrality gap of the configuration LP for various problems.

	Lower bound	Upper bound
Scheduling on Unrelated Machines	2	2 [16]
⊃ Restricted Assignment	1.5	1.833.. [13]
⊃ Graph Balancing	1.5	**1.749**
⊃ Unrelated Graph Balancing	2 [20]	2
Santa Claus	∞ [5]	∞ [5]
⊃ Restricted Santa Claus	2	3.833.. [14, 8]
⊃ Max-Min Unrelated Graph Balancing	2	2 [20]

higher than 1.5, whereas for the configuration LP it is still open whether 1.5 is the correct answer. The backbone of our new proof is the utilization of these small edge constraints (see end of Section 3.1). This may be relevant to other related local search based proofs as well.

Other related work. The problem of minimizing the maximum out-degree is equivalent to the maximum in-degree. The very similar problem of maximizing the minimum in- or out-degree has been settled by Wiese and Verschae [20]. They gave a 2-approximation and this is the best possible assuming P $\neq$ NP. Surprisingly, this holds even in the unrelated case when the value of an edge may be different on each end. They do not use the configuration LP, but it is easy to also get a bound of 2 on its integrality gap using their ideas. For the restricted case (a special case of the unrelated one) this bound of 2 was already proven by [6]. We are not aware of any evidence that Graph Balancing is easier on simple weighted graphs (without multiedges and loops). The same reduction for the state-of-the-art lower bound holds even in that case. A number of recent publications deal with the important question on how related local search algorithms can be turned into efficient algorithms [1, 2, 12, 18].

2 Preliminaries

Notation. For some $v \in V$ we will denote by $\delta(v)$ the incident edges, i.e. those $e \in E$ with $v \in r(e)$. When a particular orientation is clear from the context, we will write $\delta^-(v)$ for the incoming edges and $\delta^+(v)$ for the outgoing edges of a vertex. For some $F \subseteq E$ we will denote by $\delta_F(v)$ the incident edges of v restricted to F and $\delta_F^-(v)$, $\delta_F^+(v)$ accordingly. For some $e \in E$ we will describe by $t(e) \in r(e)$ the vertex it is oriented towards and by $s(e) \in r(e)$ the vertex it is leaving. For a loop e, i.e., $r(e) = \{v\}$ for some $v \in V$, it always holds that $t(e) = s(e)$. For a subset of edges $S \subseteq E$ we will write $w(S)$ for $\sum_{e \in S} w(e)$ and similar for other functions over the edges.

LP relaxations. The following linear programs have no objective functions. Instead they parameterized by τ, the makespan. The optimum is the lowest τ for which it is feasible. This will be denoted by OPT^* (referring to the configuration LP in the rest of the paper). First we look at the assignment LP by Lenstra, Shmoys, and Tardos [16]. It has a variable $x_{e,v}$ for every vertex v and incident edge $e \in \delta(v)$, which indicates whether e is oriented towards v.

The assignment LP.

$$\sum_{e \in \delta(v)} w(e) \cdot x_{e,v} \leq \tau \quad \forall v \in V, \qquad \sum_{v \in r(e)} x_{e,v} = 1 \quad \forall e \in E, \qquad x_{e,v} \in [0,1]$$

The first constraint ensures that no vertex has more than weight τ of edges oriented towards it. The second one describes that each edge is oriented towards one vertex. The assignment LP has an integrality gap of 2. Let B denote the big edges e, which have $w(e) > 0.5 \cdot \tau$. It is clear that an integral orientation can assign at most one such edge to each vertex. Ebenlendr et al. [9] show that adding the constraint $\sum_{e \in \delta_B(v)} x_{e,v} \leq 1 \quad \forall v \in V$ improves the integrality gap to 1.75. They also give other LP relaxations, but show that none of them have an integrality gap strictly better than 1.75.

Now we will introduce the configuration LP. A configuration is a subset of edges that can be oriented towards a particular vertex without exceeding a particular makespan τ. Formally, we define the configurations of a vertex v and a makespan τ as $\mathcal{C}(v, \tau) := \{C \subseteq \delta(v) : w(C) \leq \tau\}$. The configuration LP now assigns fractions of configurations to each machine.

Primal of the configuration LP.	Dual of the configuration LP.
$\sum_{v \in V} \sum_{C \in \mathcal{C}(v,\tau)} x_{v,C} \leq 1 \quad \forall v \in V$	$\min \sum_{v \in V} y_v - \sum_{e \in E} z_e$
$\sum_{v \in r(e)} \sum_{C \in \mathcal{C}(v,\tau): e \in C} x_{v,C} \geq 1 \quad \forall e \in E$	s.t. $\sum_{e \in C} z_e \leq y_v \quad \forall v \in V, C \in \mathcal{C}(v,\tau)$
$x_{v,C} \geq 0$	$y, z \geq 0$

Although the configuration LP has exponential size, a $(1+\epsilon)$-approximation can be computed in polynomial time for every $\epsilon > 0$ [5]. We are particularly interested in the dual of the configuration LP (which is constructed after adding the objective function $\min (0, \ldots, 0)^T x$). Note that τ is considered a constant in both the primal and the dual. A common idea for proving τ is lower than the optimum is to show that the dual is unbounded for τ (instead of directly showing that the primal is infeasible for τ).

▶ **Lemma 2.** *If there exists $y : V \to \mathbb{R}_{\geq 0}$, and $z : E \to \mathbb{R}_{\geq 0}$, such that $\sum_{e \in C} z(e) \leq y(v)$ for all $v \in V, C \in \mathcal{C}(v, \tau)$ and $\sum_{v \in V} y(v) < \sum_{e \in E} z(e)$, then $\tau < \mathrm{OPT}^*$.*

This holds because y, z is a feasible solution with negative objective value for the dual and so are the same values scaled by any $\alpha > 0$. This way an arbitrarily low objective value can be obtained. Lemma 2 can be seen as a generalization of a space argument: Consider $y(v) = \tau$ and $z(e) = w(e)$. Then for all $v \in V, C \in \mathcal{C}(v, \tau)$, $\sum_{e \in C} z(e) = \sum_{e \in C} w(e) \leq \tau = y(v)$. Thus, by the Lemma we have that $|V| \cdot \tau = \sum_{v \in V} y(v) < \sum_{e \in E} z(e) = w(E)$ implies $\tau < \mathrm{OPT}^*$.

3 Graph Balancing in a special case

To introduce our techniques, we first consider a simplified case where $w(e) \in (0, 0.5] \cup \{1\}$ for each $e \in E$ and the configuration LP is feasible for 1. We will show that there exists an orientation with maximum weighted in-degree $1 + R$ where $R = 0.74$. The proof for the general case (with a slightly worse rate) can be found in the full version of the paper.

▶ **Definition 3** (Tiny, small, big edges). *We call an edge e* tiny, *if $w(e) \leq 1 - R$;* small, *if $1 - R < w(e) \leq 1/2$; and* big, *if $w(e) = 1$. We will write for the tiny, small, and big edges $T \subseteq E, S \subseteq E$, and $B \subseteq E$, respectively.*

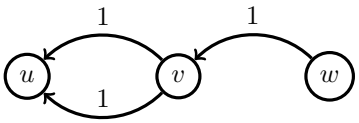
▶ **Definition 4** (Good and bad vertices). *For a given orientation, we call a vertex v* good, *if $w(\delta^-(v)) \leq 1 + R$. A vertex is* bad, *if it is not good.*

The local search algorithm starts with an arbitrary orientation and flips edges until all vertices are good. During this process, a vertex that is already good will never be made bad. It is then proved that (1) the algorithm terminates and (2) when it cannot find a useful edge to flip, the configuration LP also cannot distribute the edges well, i.e., $\mathrm{OPT}^* > 1$, a contradiction.

3.1 Informal overview

Before we give a formal definition of the local search algorithm, we devote this section to giving intuition. We start with very easy algorithms and give challenging instances that motivate the more advanced ideas.

As a toy algorithm consider the following: Start with an arbitrary orientation and repeat until all vertices are good. Whenever there is an edge oriented towards a bad vertex such that its other vertex is good and would remain good even if the edge was flipped (this is called a valid flip), flip this edge. In the following example, both LP and integral optimum are 1. Suppose the algorithm tries to obtain a solution of makespan $2-\epsilon$ with $\epsilon > 0$.



u is bad, v and w are good. However, the algorithm cannot flip one of the edges between u and v, because this would make v bad. It will not flip the edge between v and w, because v is already good. Hence, the algorithm fails. Obviously, in this example we should flip the edge between v and w and then fix u. Let us try to integrate this in the algorithm. We introduce the concept of *pending flips*. When the algorithm wants to flip an edge, but it cannot, because this would make a vertex bad, we add this edge to a list of pending flips. These will be executed once the flip is valid. In the example above, the algorithm could add the edges between u and v to the pending flips, but would not change their orientation, yet. For a pending flip e let us call $s(e)$ the *prospect vertex* and $t(e)$ the *current vertex*. As seen in the example above a sensible local search algorithm should try to move edges away from pending flips' prospect vertices as well (in addition to the bad vertices).

We now state the second toy algorithm. Initialize the pending flips as an empty list. Repeat the following until all vertices are good. Let U be the set of vertices that are either bad or prospect vertices of pending flips. Find an edge from V/U to U and add it to the pending flips. As long as there is a valid pending flip, (1) execute it and (2) delete all pending flips added after it. (2) is to ensure obsolete pending flips are removed. Without it there can be situations where a pending flip has its current vertex in $V \setminus U$, because the pending flip that initially led us to adding it has been executed. This algorithm always succeeds for makespan 1.75 in the special case where weights are in $(0, 0.5] \cup \{1\}$ and $\mathrm{OPT}^* = 1$. We will quickly go over the arguments, since it gives a good idea on how to use the dual of the configuration LP. At this point we will only argue that the algorithm does not get stuck. Normally, we would also have to prove that it terminates (we omit this for sake of brevity). Suppose toward contradiction that the algorithm gets stuck, i.e., there is no valid pending flip and there are no edges from V/U to U. Let F be the big edges e with $t(e) \in U$. We set

$$z(e) = \begin{cases} w(e) & \text{if } t(e) \in U, \\ 0 & \text{otherwise.} \end{cases}$$

$$y(v) = \begin{cases} w(\delta^-(v)) + \frac{1}{4}|\delta_F^+(v)| - \frac{1}{4}|\delta_F^-(v)| & \text{if } v \in U \text{ and } v \text{ is good,} \\ w(\delta^-(v)) + \frac{1}{4}|\delta_F^+(v)| - \frac{1}{4}|\delta_F^-(v)| - 0.1 & \text{if } v \in U \text{ and } v \text{ is bad,} \\ \frac{1}{4}|\delta_F^+(v)| - \frac{1}{4}|\delta_F^-(v)| & \text{if } v \in V \setminus U. \end{cases}$$

What is left to do is to check that for these values the premise of Lemma 2 is fulfilled. Let $v \in V$ and $C \in \mathcal{C}(v, 1)$. Recall that by definition, $C \subseteq \delta(v)$ and $w(C) \leq 1$. We have to verify that $z(C) \leq y(v)$.

Case 1: $v \in V \setminus U$. Since the algorithm is stuck, there is no edge $e \in \delta^+(v)$ with $t(e) \in U$. Hence, $z(e) = 0$ for all $e \in \delta(v)$ and $z(C) = 0$. By definition of F we have that $\delta_F^-(v) = \emptyset$. Thus, $y(v) \geq 0 = z(C)$.

Case 2: $v \in U$. If v is bad, then $w(\delta^-(v)) > 1.75$ and

$$y(v) \geq \begin{cases} w(\delta_F^-(v)) - \frac{1}{4}|\delta_F^-(v)| - 0.1 \geq \frac{3}{4}|\delta_F^-(v)| - 0.1 \geq 1.4 > z(C) & \text{if } |\delta_F^-(v)| \geq 2, \\ w(\delta^-(v)) - \frac{1}{4}|\delta_F^-(v)| - 0.1 > 1.75 - \frac{1}{4} - 0.1 \geq 1.4 > z(C) & \text{if } |\delta_F^-(v)| \leq 1. \end{cases}$$

If $v \in U$ is good, then it is the prospect vertex of some pending flip e. An invariant of the algorithm is that all pending flips have their current vertex in U. In particular, $z(e) = w(e)$. Furthermore, e is not a valid flip. Thus, $w(\delta^-(v)) + w(e) > 1.75$. Also note that $|\delta_F^-(v)| \leq 1$, since v is good. If $w(e) \leq 0.5$, then

$$y(v) \geq w(\delta^-(v)) - \frac{1}{4}|\delta_F^-(v)| > 1.75 - w(e) - \frac{1}{4} \geq 1 \geq z(C).$$

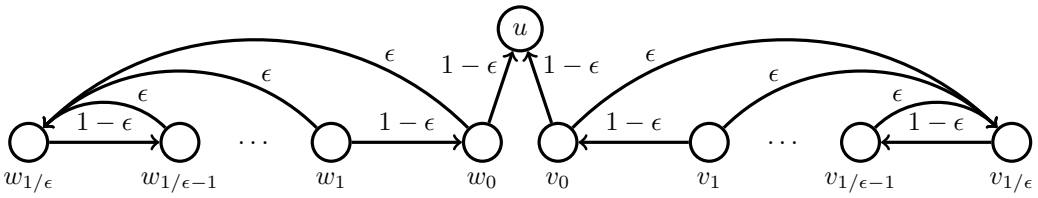
If $w(e) = 1$, then $e \in \delta_F^+(v)$. Hence,

$$y(v) \geq \begin{cases} w(\delta^-(v)) + \frac{1}{4}|\delta_F^+(v)| - \frac{1}{4}|\delta_F^-(v)| \geq 1.75 - w(e) + \frac{1}{4} \geq 1 \geq z(C) & \text{if } |\delta_F^-(v)| = 0, \\ w(\delta_F^-(v)) + \frac{1}{4}|\delta_F^+(v)| - \frac{1}{4}|\delta_F^-(v)| \geq 1 + \frac{1}{4} - \frac{1}{4} \geq 1 \geq z(C) & \text{if } |\delta_F^-(v)| = 1. \end{cases}$$

The second condition of Lemma 2 is that $z(E) > y(V)$. This holds because

$$z(E) = \sum_{v \in U} w(\delta^-(v)) = \sum_{v \in U} w(\delta^-(v)) + \frac{1}{4} \sum_{v \in V} [|\delta_F^+(v)| - |\delta_F^-(v)|] > y(V).$$

The strict inequality follows from the fact that there is at least one bad vertex. In the general case this algorithm does not get better than 2 as can be seen in the example below. In a similar, but more complicated way one can also show that in the special case with weights in $(0, 0.5] \cup \{1\}$, the algorithm does not succeed for $1.75 - \epsilon$, where $\epsilon > 0$ is arbitrary. In other words, the analysis for 1.75 is tight.



The LP and integral optima are again 1. Suppose the algorithm tries to find a solution with makespan $2 - 3\epsilon$. The only bad vertex is u. Hence, the algorithm will add the $(1 - \epsilon)$-edges to the pending flips one after another. However, at the time it reaches $v_{1/\epsilon}$ or $w_{1/\epsilon}$ it will get stuck, since there is a load of $1/\epsilon \times \epsilon$ on them. The way to fix this is to allow edges (in this case those of weight ϵ) to also be flipped towards vertices in U, i.e., vertices where we wanted to reduce the load. We cannot simply allow arbitrary flips back and forth between U,

because we have to take care that the algorithm eventually terminates. This is where the concept of vertices *repelling* edges comes in: Depending on the current orientation of the edges and the list of pending flips we will define a binary relation between vertices and edges. The exact definition has to be chosen carefully. For a pair (v, e) of this relation we write vertex v repels edge e. When a vertex repels an edge, it means it is undesirable that the edge is oriented towards this vertex. When it does not repel the edge, we do not care. This will be used in the algorithm when adding pending flips: An edge e may only be added to the pending flips, when it is repelled by its current vertex and not repelled by its prospect vertex.

In the earlier toy algorithms a vertex either repels all edges (when it is in U) or none (when it is not in U). By adding a fine-grained strategy of repelled edges, we gain much more flexibility. A strategy that appears particularly simple and powerful is the following. (1) We let bad vertices repel all edges. Moreover, (2) for every pending flip e with prospect vertex v we find maximum threshold W such that all edges in $\delta^-(v)$ with weight at least W are already enough to prevent the flip from being executed, i.e., their total weight is greater than $1 + R - w(e)$. We let v repel all edges of weight at least $\min\{w(e), W\}$.

Now the third toy algorithm is to repeat the following until all vertices are good. Find an edge e that is repelled by $t(e)$, but not by $s(e)$ and add it to the list of pending flips. As long as there is a valid pending flip, execute it and delete all pending flips added after it. This algorithm succeeds in the previous example. It will add the $(1-\epsilon)$-edges to the pending flips, but the vertices $u, v_1, \ldots, v_{1/\epsilon-1}, w_1, \ldots, w_{1/\epsilon-1}$ repel only the $(1-\epsilon)$-edges and not the ϵ-edges. Once the pending flips reach $w_{1/\epsilon}$ or $v_{1/\epsilon}$, these vertices will repel the ϵ-edges and start flipping them. Finally, there will be enough space on $w_{1/\epsilon}$ or $v_{1/\epsilon}$ and the $1-\epsilon$ edges can be flipped one after another.

For the simple case at least this is very close to the algorithm that gives us the bound of 1.74. However, to make the analysis work, we add a couple of tweaks. One of them is the idea of critical vertices. When the threshold of repelled edges, i.e., $\min\{w(e), W\}$, reaches a low value, e.g., 0.26, we make the vertex repel all edges. We call such a vertex a *critical* vertex. This tweak (together with some technicalities) allows us to argue that at least half of the critical vertices are prospect vertices of pending flips for tiny edges. This is helpful, since (unless the pending flip is valid) such prospect vertices have a lot of weight oriented towards them and this makes it easier to argue that the configuration LP also cannot distribute this weight very well; thereby reaching a contradiction.

An important novelty in this paper compared to earlier local search algorithms is that we are able to repel only a subset of edges small/tiny edges. In the Restricted Assignment proofs [19, 13] it is always the case that a machine (vertex) repels all small/tiny jobs (edges) or none. To utilize the flexibility in the small/tiny edges we scale the z values of tiny edges up by a factor $\beta > 1$. It is not obvious at all that this works out and the proof is quite tricky.

In a sense, we push the threshold for repelling all edges down to some value less than 0.5 (see description of critical vertices above). A logical conclusion to draw would be that pushing it down even more (or removing it completely) should give an even better algorithm. This would bring us back to toy algorithm 3. In fact, we are not aware of bad instances. It is an intriguing question whether this can also be proved that this simple algorithm is good.

3.2 Algorithm

The central data structure we use is an ordered list of pending flips $P = (e_1^P, e_2^P, \ldots, e_\ell^P)$. Here, every component e_k^P, stands for an edge the algorithm wants to flip. If P is clear from the context, we simply write *flip* when we speak of a pending flip e_k^P. A *tiny flip* is a flip where e_k^P is tiny. In the same way we define *small* and *big flips*. The prospect vertex of a

flip e_k^P is the vertex $s(e_k^P)$ to which we want to orient it. The algorithm will not perform the flip, if this would create a bad vertex, i.e., $w(\delta^-(s(e_k^P))) + w(e_k^P) > 1 + R$. If it does not create a bad vertex, we say that the flip e_k^P is a *valid flip*. For every $0 \leq k \leq \ell$ define $P_{\leq k} := (e_1^P, \ldots, e_k^P)$, i.e., the first k elements of P (with $P_{\leq 0}$ being the empty list).

At each point during the execution of the algorithm, the vertices repel certain edges. This can be thought of as a binary relation between vertices and their incident edges, i.e., a subset of $\{(v, e) : v \in r(e)\}$, and this relation changes dynamically as the current orientation or P change. The definition of which vertices repel which edges is given in Section 3.3. The algorithm will only add a new pending flip e to P, if e is repelled by the vertex it is oriented towards and not repelled by the other.

Algorithm 1: Local search algorithm for simplified Graph Balancing.

Input : Weighted multigraph $G = (V, E, r, w)$ with $\mathrm{OPT}^* = 1$ and $w(e) \in (0, 0.5] \cup \{1\}$ for all $e \in E$
Result: Orientation $s, t : E \to V$ with maximum weighted in-degree $1 + R$
let $s, t : E \to V$ map arbitrary source and target vertices to each edge ;
// i.e., $\{s(e), t(e)\} = r(e)$ for all $e \in E$
$\ell \leftarrow 0$; // number of pending edges P to flip
while *there is a bad vertex* **do**
  if *there exists a valid flip* $e \in P$ **then**
    let $0 \leq k \leq \ell$ be minimal such that e is repelled by $t(e)$ w.r.t. $P_{\leq k}$;
    exchange $s(e)$ and $t(e)$;
    $P \leftarrow P_{\leq k}$; $\ell \leftarrow k$; // Forget pending flips $e_{k+1}^P, \ldots, e_\ell^P$
  else
    choose an edge $e \in E \setminus P$ with $w(e)$ minimal and e is repelled by $t(e)$ and not repelled by $s(e)$ w.r.t. P ;
    $P_{\ell+1} \leftarrow e$; $\ell = \ell + 1$; // Append e to P
  end
end

3.3 Repelled edges

Consider the current list of ℓ pending flips $P_{\leq \ell}$. The repelled edges are defined inductively. For some $k \leq \ell$ we will now define the repelled edges w.r.t. $P_{\leq k}$.

(initialization) If $k = 0$, let every bad vertex v repel every edge in $\delta(v)$. Furthermore, let every vertex v repel every loop e where $\{v\} = r(e)$.

(monotonicity) If $k > 0$ and v repels e w.r.t. $P_{\leq k-1}$, then let v repel e w.r.t. $P_{\leq k}$.

The rule on loops is only for a technical reasons. Loops will never appear in the list of pending flips. The remaining rules regard $k > 0$ and the last pending flip in $P_{\leq k}$, e_k^P. The algorithm should reduce the load on $s(e_k^P)$ to make it valid.

Which edges exactly does the prospect vertex of e_k^P, i.e., $s(e_k^P)$, repel? First, we define $\tilde{E}(P_{\leq k-1}) \subseteq E$ where $e \in \tilde{E}(P_{\leq k-1})$ if and only if e is repelled by $s(e)$ w.r.t. $P_{\leq k-1}$. We will omit $P_{\leq k-1}$ when it is clear from the context. $\tilde{E}$ are edges that we do not expect to be able to flip: Recall that when an edge e is repelled by $s(e)$, it cannot be added to P. Moreover, for every W define $E_{\geq W} = \{e \in E : w(e) \geq W\}$. We are interested in values W such that

$$w(\delta^-_{\tilde{E} \cup E_{\geq W}}(s(e_k^P))) + w(e_k^P) > 1 + R. \tag{1}$$

Let $W_0 \in (0, w(e_k^P)]$ be maximal such that (1) holds. To be well-defined, we set $W_0 = 0$, if no such W exists. In that case, however, it holds that $w(\delta^-(s(e_k^P))) + w(e_k^P) \leq 1 + R$. This means that e_k^P is valid and the algorithm will remove it from the list immediately. Hence, the case is not particularly interesting. We define the following edges to be repelled by $s(e_k^P)$:
(uncritical) If $W_0 > 1 - R$, let $s(e_k^P)$ repel every edge in $\delta_{\tilde{E} \cup E_{\geq W_0}}(s(e_k^P))$.
(critical) If $W_0 \leq 1 - R$, let $s(e_k^P)$ repel every edge in $\delta(s(e_k^P))$.
Note that in the cases above there is not a restriction to incoming edges like in (1).

▶ **Fact 1.** *$s(e_k^P)$ repels e_k^P w.r.t. $P_{\leq k}$.*

This is because of $W_0 \leq w(e_k^P)$ in the rules for $P_{\leq k}$. An important observation is that repelled edges are stable under the following operation.

▶ **Fact 2.** *Let $e \notin P_{\leq k}$ be an edge that is not repelled by any vertex w.r.t. $P_{\leq k-1}$, and possibly by $t(e)$ (but not $s(e)$) w.r.t. $P_{\leq k}$. If the orientation of e changes and this does not affect the sets of good and bad vertices, the edges repelled by some vertex w.r.t. $P_{\leq k}$ will still be repelled after the change.*

Proof. We first argue that the repelled edges w.r.t. $P_{\leq k'}$, $k' = 0, \ldots, k-1$ have not changed. This argument is by induction. Since the good and bad vertices do not change, the edges repelled w.r.t. $P_{\leq 0}$ do not change. Let $k' \in \{1, \ldots, k-1\}$ and assume that the edges repelled w.r.t. $k'-1$ have not changed. Moreover, let W_0 be as in the definition of repelled edges w.r.t. $P_{\leq k'}$ before the change. We have to understand that e is not and was not in $\delta^-_{\tilde{E} \cup E_{\geq W_0}}(s(e_{k'}^P))$ (with $\tilde{E} = \tilde{E}(P_{\leq k'-1})$). This means that flipping it does not affect the choice of W_0 and, in particular, not the repelled edges. Let v and v' denote the vertex e is oriented towards before the flip and after the flip, respectively. Since e was not repelled by v and v' w.r.t. $P_{\leq k'}$, it holds that $v, v' \neq s(e_k^P)$ or $w(e) < W_0$: $s(e_k^P)$ repelled all edges greater or equal W_0 in both the case (uncritial) and (critical), but e was not repelled by v or v'.

Therefore $e \notin \delta^-_{E_{\geq W_0}}(s(e_{k'}^P))$ before and after the change. Moreover, since e was not repelled by any vertex w.r.t. $P_{\leq k'-1}$ (and by induction hypothesis, it still is not), it follows that $e \notin \tilde{E}(P_{\leq k'-1})$. By this induction we have that edges repelled w.r.t. $P_{\leq k-1}$ have not changed and by the same argument as before, e is not in $\delta^-_{\tilde{E} \cup E_{\geq W_0}}(s(e_k^P))$ after the change. This means W_0 has not increased and edges repelled w.r.t. $P_{\leq k}$ are still repelled. It could be that W_0 decreases, if e was in $\delta^-_{\tilde{E} \cup E_{\geq W_0}}(s(e_k^P))$ before the flip. This would mean that the number of edges repelled by $s(e_k^P)$ increases. ◀

We note that W_0 (in the definition of $P_{\leq k}$) is either equal to $w(e_k^P)$ or it is the maximal value for which (1) holds. Furthermore,

▶ **Fact 3.** *Let W_0 be as in the definition of repelled edges w.r.t. $P_{\leq k}$. If $W_0 < w(e_k^P)$, then there is an edge of weight exactly W_0 in $\delta^-(s(e_k^P))$. Furthermore, it is not a loop and it is not repelled by its other vertex, i.e., not $s(e_k^P)$, w.r.t. $P_{\leq k}$.*

Proof. We prove this for $P_{\leq k-1}$. Since the change from $P_{\leq k-1}$ to $P_{\leq k}$ only affects $s(e_k^P)$, this suffices. All edges that are repelled by their other vertex w.r.t. $P_{\leq k-1}$ (in particular, loops) are in $\tilde{E}$. Recall that $w(\delta^-_{\tilde{E} \cup E_{\geq W_0}}(s(e_k^P))) + w(e_k^P) > 1 + R$. Assume toward contradiction there is no edge of weight W_0 in $\delta^-(s(e_k^P))$, which is not in $\tilde{E}$. This means there is some $\epsilon > 0$ such that $\delta^-_{\tilde{E} \cup E_{\geq W_0 + \epsilon}}(s(e_k^P)) = \delta^-_{\tilde{E} \cup E_{\geq W_0}}(s(e_k^P))$. Hence, W_0 is not maximal. ◀

3.4 Analysis

The following analysis holds for the values $R = 0.74$ and $\beta = 1.1$. β is a central parameter in the proof. These can be slightly improved, but we refrain from this for the sake of simplicity. The proof consists of two parts. We need to show that the algorithm terminates and that there is always either a valid flip in P or some edge can be added to P.

▶ **Lemma 5.** *The algorithm terminates after finitely many iterations of the main loop.*

Proof. We consider the potential function $s(P) = (g, |\tilde{E}(P_{\leq 0})|, \ldots, |\tilde{E}(P_{\leq \ell})|, -1)$, where g is the number of good vertices. We will argue that this vector increases lexicographically after every iteration of the main loop. Intuitively $|\tilde{E}(P_{\leq k})|$, $k \leq \ell$, is an measure for progress. When an edge e is repelled by a vertex v, then we want that $s(e) = v$. $|\tilde{E}(P_{\leq k})|$ counts exactly these situations. Since ℓ is bounded by $|E|$, there can be at most $|V| \cdot |E|^{O(|E|)}$ possible values for the vector. Thus, the algorithm must terminate after at most this many iterations. In an iteration either a new flip is added to P or a flip is executed.

If a flip e is added as the $(\ell+1)$-th element of P, then clearly $\tilde{E}(P_{\leq i})$ does not change for $i \leq \ell$. Furthermore, the last component of the vector is replaced by some non-negative value.

Now consider a flip $e \in P$ that is executed. If this flip turns a bad vertex good, we are done. Hence, assume otherwise and let v and v' be the vertex it was previously and the one it is now oriented towards. Furthermore, let ℓ' be the length of P after the flip. Recall that ℓ' was chosen such that before the flip is executed v repels e w.r.t. $P_{\leq \ell'}$, but not w.r.t. $P_{\leq k}$ for any $k \leq \ell' - 1$. Also, e is not repelled by v' w.r.t. $P_{\leq k}$ for any $k \leq \ell'$ or else the flip would not have been added to P in the first place. By Fact 2 this means that repelled edges w.r.t. $P_{\leq k}$, $k \leq \ell'$, are still repelled after the flip. Because of this and because the only edge that changed direction, e, is not in $\tilde{E}(P_{\leq k})$ for any $k \leq \ell'$, $|\tilde{E}(P_{\leq k})|$ has not decreased. Finally, e has not been in $\tilde{E}(P_{\leq \ell'})$ before the flip, but now is. Thus, the first $\ell' - 1$ components of the vector have not decreased and the ℓ'-th one has increased. ◀

▶ **Lemma 6.** *If there at least one bad vertex remaining, then there is either a valid flip in P or a flip that can be added to P.*

Proof. We assume toward contradiction that there exists a bad vertex, no valid pending flip and no edge that can be added to P. We will show that this implies $\mathrm{OPT}^* > 1$.

Like above we denote by $\tilde{E} = \tilde{E}(P)$ those edges e that are repelled by $s(e)$. In particular, if an edge e is in P or repelled by $t(e)$ it must also be in $\tilde{E}$: If such an edge is in P, this follows from Fact 1. Otherwise, such an edge must be repelled also by $s(e)$ or else it could be added to P. For every $e \in E \setminus \tilde{E}$, set $z(e) = 0$. For every $e \in \tilde{E}$, set

$$z(e) = \begin{cases} 1 & \text{if } w(e) = 1, \\ w(e) & \text{if } 1 - R < w(e) \leq 1/2, \text{ and} \\ \beta w(e) & \text{if } w(e) \leq 1 - R. \end{cases}$$

In general, we would like to set each $y(v)$ to $z(\delta^-(v))$ (or equivalently, $z(\delta^-_{\tilde{E}}(v))$). However, there are two kinds of amortization between vertices that we include in the values of y.

As can be seen in the definition of repelled edges, a vertex v repels either edges with weight at least a certain threshold $W > 1 - R$ and edges in $\delta^-(v)$ that are repelled by their other vertex; or they repel all edges. We will call vertices of the latter kind *critical*. In other words, a vertex v is critical, if in the inductive definition of repelled edges at some point $v = s(e_k^P)$ and the rule (critical) applies. There might be a coincidence where only rule (uncritical) applies for v, but this already covers all edges in $\delta^-(v)$. This is not a critical vertex. We note that every vertex that is prospect vertex of a tiny flip e_k^P must be critical: In the inductive definition when considering e_k^P we have that $W_0 \leq w(e_k^P) \leq 1 - R$ by definition.

Critical vertex amortization. If v is a good vertex and critical, but is not a prospect vertex of a tiny flip, set $a_v := \beta - 1$. If v is a good vertex and prospect vertex of tiny flip (in particular, v is critical), set $a_v := -(\beta - 1)$. Otherwise, set $a_v = 0$.

Big edge amortization. Let $F \subseteq P$ denote the set of big flips. Then in particular $F \subseteq \tilde{E}$ (Fact 1). We define for all $v \in V$, $b_v := (|\delta_F^+(v)| - |\delta_F^-(v)|) \cdot (1 - R)$.

We conclude the definition of y by setting $y(v) = z(\delta^-(v)) + a_v + b_v$ for all good vertices v and $y(v) = z(\delta^-(v)) + a_v + b_v - \mu$ for all bad vertices v, where $\mu = 0.01$.

▷ Claim 7. It holds that $\sum_{v \in V} y(v) < \sum_{e \in E} z(e)$.

▷ Claim 8. $y(v), z(e) \geq 0$ f.a. $v \in V, e \in E$ and f.a. $v \in V$, $C \in \mathcal{C}(v, 1)$, $\sum_{e \in C} z(e) \leq y(v)$.

By Lemma 2 this implies that $\mathrm{OPT}^* > 1$. ◀

Proof of Claim 7. First we note that

$$\sum_{v \in V} b_v = (1 - R) \underbrace{\left(\sum_{v \in V} |\delta_F^+(v)| - \sum_{v \in V} |\delta_F^-(v)|\right)}_{=0} = 0.$$

Moreover, we have that $\sum_{v \in V} a_v \leq 0$: This is because at least half of all good vertices that are critical are prospect vertices of tiny flips. The proof for this is omitted due to space constraints. We conclude,

$$\sum_{e \in E} z(e) \geq \sum_{v \in V} \sum_{e \in \delta^-(v)} z(e) + \sum_{v \in V} [b_v + a_v] > \sum_{v \in V} y(v),$$

where the strict inequality holds because there exists at least one bad vertex. ◁

Proof of Claim 8. Let $v \in V$ and $C \in \mathcal{C}(v, 1)$. We need to show that $z(C) \leq y(v)$. Obviously the z values are non-negative. By showing the inequality above, we also get that the y values are non-negative. First, we will state some auxiliary facts.

▶ **Fact 4.** *For every edge flip $e \in P$, we have $w(\delta_{\tilde{E}}^-(s(e))) + w(e) > 1 + R$.*

This is due to the fact that e is not a valid flip and by definition of repelled edges.

▶ **Fact 5.** *If v is a good vertex and not prospect vertex of a tiny pending flip, then $y(v) \geq z(C) + w(\delta_{\tilde{E}}^-(v)) - 1 + b_v$. In other words, it is sufficient to show that $w(\delta_{\tilde{E}}^-(v)) + b_v \geq 1$.*

If v is critical, then $y(v) = z(\delta^-(v)) + \beta - 1 + b_v \geq w(\delta_{\tilde{E}}^-(v)) + z(C) - 1 + b_v$. If v is uncritical, all edges $e \in C$ with $z(e) > w(e)$ must be in $\delta^-(v)$. Otherwise, the flip e could be added to P. Therefore,

$$\begin{aligned} y(v) = z(\delta^-(v)) + a_v + b_v &\geq z(\delta_{\tilde{E}}^-(v)) - w(\delta_{\tilde{E}}^-(v)) + w(\delta_{\tilde{E}}^-(v)) + b_v \\ &\geq z(\tilde{C}) - w(\tilde{C}) + w(\delta_{\tilde{E}}^-(v)) + b_v \geq z(C) + w(\delta_{\tilde{E}}^-(v)) - 1 + b_v. \end{aligned}$$

▶ **Fact 6.** *For every vertex v it holds that (1) v repels no edges, (2) v repels all edges (critical), or (3) there exists a threshold $W > 1 - R$ such that v repels edges $e \in \delta^-(v)$ if $w(e) \geq W$ or they are also repelled by $s(e)$.*

Furthermore, in (3) we have that $W = \min_{e \in \delta_P^+(v)} w(e)$ or $W < \min_{e \in \delta_P^+(v)} w(e)$ and $W \in \{w(e) : e \in \delta_{\tilde{E}}^-(v)\}$ (see Fact 3).

Case 1: v is a bad vertex. If $|\delta_F^-(v)| \geq 2$,

$$y(v) \geq z(\delta^-(v)) - |\delta_F^-(v)| \cdot (1-R) - \mu \geq |\delta_F^-(v)| \cdot (1-(1-R)) - \mu \geq 2R - \mu \geq \beta \geq z(C).$$

Otherwise, $|\delta_F^-(v)| \leq 1$ and therefore

$$y(v) \geq z(\delta^-(v)) - 1 + R - \mu \geq w(\delta^-(v)) - 1 + R - \mu > 1 + R - 1 + R - \mu = 2R - \mu \geq \beta \geq z(C).$$

Here we use that $w(\delta^-(v)) > 1 + R$ by the definition of a bad vertex. Assume for the remainder that v is a good vertex, in particular that $|\delta_F^-(v)| \leq 1$.

Case 2: v is good and prospect vertex of a tiny flip. Using Fact 4 we get $w(\delta_{\tilde{E}}^-(v)) > 1 + R - (1-R) = 2R$. Since $z(e) \geq w(e)$ for all $e \in \tilde{E}$, we also have $z(\delta^-(v)) \geq 2R$. Moreover, since the vertex is good, $|\delta_F^-(v)| \leq 1$ and consequently $b_v \geq -(1-R)$. We conclude

$$y(v) \geq z(\delta^-(v)) - (\beta - 1) - (1-R) \geq 2R - (\beta - 1) - (1-R) = \beta + \underbrace{3R - 2\beta}_{\geq 0} \geq z(C).$$

Case 3: v is good, not prospect vertex of a tiny flip, but prospect vertex of a small flip. If $|\delta_F^-(v)| = 0$, again with Fact 4 we get $w(\delta_{\tilde{E}}^-(v)) + b_v \geq 1 + R - 0.5 + 0 > 1$. This suffices because of Fact 5. Moreover, if $|\delta_F^-(v)| = 1$ and $\delta_{\tilde{E}}^-(v)$ contains a small edge, it holds that

$$w(\delta_{\tilde{E}}^-(v)) + b_v \geq w(\delta_F^-(v)) + (1-R) + b_v \geq 1 + (1-R) - (1-R) = 1.$$

Here we use that the small edge must have a size of at least $1 - R$. The case that remains is where $\delta_{\tilde{E}}^-(v)$ contains one edge from F and tiny edges. Since the overal weight of $\delta_{\tilde{E}}^-(v)$ is at least $1 + R - 0.5$, the weight of tiny edges is at least $R - 0.5$. Thus, the z-value of the tiny edges is at least $\beta(R - 0.5)$. If v is critical,

$$y(v) \geq z(\delta^-(v)) - (1-R) + (\beta - 1) \geq 1 + \underbrace{\beta(R - 0.5) - (1-R)}_{\geq 0} + (\beta - 1) \geq z(C).$$

Notice that $\beta(R - 0.5) \geq 1 - R$ by choice of R and β. Assume for the remainder of this case that v is uncritical. If C contains a big edge, this must be the only element in C. Therefore,

$$y(v) \geq z(\delta^-(v)) - (1-R) \geq 1 + \beta(R - 0.5) - (1-R) \geq 1 = z(C).$$

Consider the case where $C \cap \tilde{E}$ contains at most one small edge and no big edge. Since v is uncritical, all tiny edges in C with positive z value must also be in $\delta^-(v)$. Therefore, $z(C) \leq 0.5 + z(\delta_T^-(v))$. Thus,

$$y(v) \geq z(\delta^-(v)) - (1-R) \geq 1 + z(\delta_T^-(v)) - (1-R) > 0.5 + z(\delta_T^-(v)) \geq z(C).$$

In the final case $C \cap \tilde{E}$ contains $k \in \{2, 3\}$ small edges. We let s denote the weight of the smallest edge with a pending flip whose prospect vertex is v. Since v is not critical and there is no small edge in $\delta^-(v)$, v repels exactly those edges with weight at least s. This means the small edges in $C \cap \tilde{E}$ must be of weight at least s: Otherwise, they could be added as pending flips. Therefore,

$$\begin{aligned} y(v) &\geq z(\delta^-(v)) - (1-R) \geq z(\delta_F^-(v)) + z(\delta_T^-(v)) - (1-R) \\ &\geq 1 + \beta(w(\delta_{\tilde{E}}^-(v)) - w(\delta_F^-(v))) - (1-R) = R + \beta(w(\delta_{\tilde{E}}^-(v)) - 1) \geq R + \beta(R - s). \end{aligned}$$

Note that $s \leq 1/k$ and, by choice of β, $k - \beta(k-1) \geq 0$. It follows that

$$\begin{aligned} z(C) &\leq k \cdot s + \beta(1 - k \cdot s) \\ &\leq y(v) + k \cdot s - R + \beta(1 - R - (k-1)s) \leq y(v) + k \cdot \frac{1}{k} - R + \beta\left(1 - R - \frac{k-1}{k}\right) \\ &= y(v) + 1 - R + \beta\left(\frac{1}{k} - R\right) \leq y(v) + 1 - R + \beta(0.5 - R) \leq y(v). \end{aligned}$$

Case 4: v is good and not prospect vertex of a small/tiny flip. If $|\delta_F^+(v)| = 0$, then v does not repel any edges. In particular, $\delta_F^-(v) = \emptyset$ and every $e \in \delta(v)$ with $z(e) > 0$ must be in $\delta^-(v)$. Therefore, $z(C) \leq z(\delta^-(v)) \leq y(v)$. We assume in the remainder that $|\delta_F^+(v)| = 1$.
If $|\delta_F^-(v)| = 1$, we get $w(\delta_{\tilde{E}}^-(v)) + b_v \geq 1 + 0$. Otherwise, it must hold that $|\delta_F^-(v)| = 0$ and $w(\delta_{\tilde{E}}^-(v)) + b_v \geq R + (1 - R) = 1$. ◁

Abstract

We study an important case of ILPs $\max\{c^T x \mid \mathcal{A}x = b, l \leq x \leq u,\ x \in \mathbb{Z}^{nt}\}$ with $n \cdot t$ variables and lower and upper bounds $\ell, u \in \mathbb{Z}^{nt}$. In n-fold ILPs non-zero entries only appear in the first r rows of the matrix $\mathcal{A}$ and in small blocks of size $s \times t$ along the diagonal underneath. Despite this restriction many optimization problems can be expressed in this form. It is known that n-fold ILPs can be solved in FPT time regarding the parameters s, r, and Δ, where Δ is the greatest absolute value of an entry in $\mathcal{A}$. The state-of-the-art technique is a local search algorithm that subsequently moves in an improving direction. Both, the number of iterations and the search for such an improving direction take time $\Omega(n)$, leading to a quadratic running time in n. We introduce a technique based on Color Coding, which allows us to compute these improving directions in logarithmic time after a single initialization step. This leads to the first algorithm for n-fold ILPs with a running time that is near-linear in the number nt of variables, namely $(rs\Delta)^{\mathcal{O}(r^2 s + s^2)} L^2 \cdot nt \log^{\mathcal{O}(1)}(nt)$, where L is the encoding length of the largest integer in the input. In contrast to the algorithms in recent literature, we do not need to solve the LP relaxation in order to handle unbounded variables. Instead, we give a structural lemma to introduce appropriate bounds. If, on the other hand, we are given such an LP solution, the running time can be decreased by a factor of L.

1 Introduction

Solving integer linear programs of the form $\max\{c^T x \mid \mathcal{A}x = b, x \in \mathbb{Z}_{\geq 0}\}$ is one of the most fundamental tasks in optimization. This problem is very general and broadly applicable, but unfortunately also very hard. In this paper we consider n-fold ILPs, a class of integer linear programs with a specific block structure. This is, when non-zero entries appear only in the first r rows of $\mathcal{A}$ and in blocks of size $s \times t$ along the diagonal underneath. More precisely,

the contraint matrix in an n-fold ILP has the form

$$\mathcal{A} = \begin{pmatrix} A_1 & A_2 & \dots & A_n \\ B_1 & 0 & \dots & 0 \\ 0 & B_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & B_n \end{pmatrix},$$

where $A_1, \dots, A_n$ are $r \times t$ matrices and $B_1, \dots, B_n$ are $s \times t$ matrices. In n-fold ILPs we also allow upper and lower bounds on the variables. Throughout the paper we subdivide a solution x into bricks of length t and denote by $x^{(i)}$ the i-th one. The corresponding columns in $\mathcal{A}$ will be called blocks.

Lately, n-fold ILPs received great attention [2, 7, 12, 14, 16] and were studied intensively due to two reasons. Firstly, many optimization problems are expressible as n-fold ILPs [5, 10, 12, 14]. Secondly, n-fold ILPs indeed can be solved much more efficiently than arbitrary ILPs [7, 10, 16]. The previously best algorithm has a running time of $(rs\Delta)^{\mathcal{O}(r^2s+rs^2)}L \cdot (nt)^2 \log^2(n \cdot t) + \text{LP}$ and is due to Eisenbrand et al. [7]. Here LP is the running time required for solving the corresponding LP relaxation. This augmentation algorithm is the last one in a line of research, where local improvement/augmenting steps are used to converge to an optimal solution. Clever insights about the structure of the improving directions allow them to be computed fast. Nevertheless, the dependence on n in the algorithm above is still high. Indeed, in practice a quadratic running time is simply not suitable for large data sets [3, 6, 13]. For example when analyzing big data, large real world graphs as in telecommunication networks or DNA strings in biology, the duration of the computation would go far beyond the scope of an acceptable running time [3, 6, 13]. For this reason even problems which have an algorithm of quadratic running time are still studied from the viewpoint of approximation algorithms with the objective to obtain results in subquadratic time, even at the cost of a worse quality [3, 6, 13]. Hence, it is an intriguing question, whether the quadratic dependency on the number nt of variables can be eliminated. In this paper, we answer this question affirmatively. The technical novelty comes from a surprising area: We use a combinatorial structure called splitter, which has been used to derandomize Color Coding algorithms. It allows us to build a powerful data structure that is maintained during the local search and from which we can derive an improving direction in logarithmic time. Handling unbounded variables in an n-fold ILP is a non-trivial issue in the previous algorithms from literature. They had to solve the corresponding LP relaxation and use proximity results. Unfortunately, it is not known whether linear programming can be solved in near-linear time in the number of variables. Hence, it is an obstacle for obtaining a near-linear running time. We manage to circumvent the necessity of solving the LP by introducing artificial bounds as a function of the finite upper bounds and the right-hand side of the n-fold ILP.

Summary of Results

- We present an algorithm, which solves n-fold ILPs in time $(rs\Delta)^{\mathcal{O}(r^2s+s^2)}L \cdot nt \log^5(nt) + \text{LP}$, where LP is the time to solve the LP relaxation of the n-fold ILP. This is the first algorithm with a near-linear dependence on the number of variables. The crucial step is to speed up the computation of the improving directions.
- We circumvent the need for solving the LP relaxation. This leads to a purely combinatorial algorithm with running time $(rs\Delta)^{\mathcal{O}(r^2s+s^2)}L^2 \cdot nt \log^7(nt)$.
- In the running times above the dependence on the parameters, i.e., $(rs\Delta)^{\mathcal{O}(r^2s+s^2)}$, improves on the function $(rs\Delta)^{\mathcal{O}(r^2s+rs^2)}$ in the previous best algorithms.

Outline of New Techniques

We will briefly elaborate the main technical novelty in this paper. Let x be some feasible, non-optimal solution for the n-fold ILP. It is clear that when y^* is an optimal solution for $\max\{c^T y \mid \mathcal{A}y = 0, \ell - x \leq y \leq u - x, y \in \mathbb{Z}^{nt}\}$, then $x + y^*$ is optimal for the initial n-fold ILP. In other words, y^* is a particularly good improving step. A sensible approximation of y^* is to consider directions y of small size and multiplying them by some step length, i.e., find some $\lambda \cdot y$ with $\|y\|_1 \leq k$ for a value k depending only on Δ, r, and s. This implies that at most k of the n blocks are used for y. If we randomly color the blocks with k^2 colors, then with high probability at most one block of every color is used. This reduces the problem to choosing a solution of a single brick for every color and to aggregate them. We add data structures for every color to implement this efficiently. There is of course a chance that the colors do not split y perfectly. We handle this by using a deterministic structure of multiple colorings (instead of one) such that it is guaranteed that at least one of them has the desired property.

Related Work

The first XP-time algorithm for solving n-fold integer programs is due to De Loera et al. [5] with a running time of $n^{g(\mathcal{A})}L$. Here $g(\mathcal{A})$ denotes a so-called Graver complexity of the constraint matrix $\mathcal{A}$ and L is the encoding length of the largest number in the input. This algorithm already uses the idea of iterative converging to the optimal solution by finding improving directions. Nevertheless, the Graver complexity appears to be huge even for small n-fold integer linear programs and thus this algorithm was of no practical use [10]. The exponent of this algorithm was then greatly improved by Hemmecke et al. [10] to a constant factor yielding the first cubic time algorithm for solving n-fold ILPs. More precisely, the running time of their algorithm is $\Delta^{\mathcal{O}(t(rs+st))}L \cdot (nt)^3$, i.e., FPT-time parameterized over Δ, r, s, and t. Lately, two more breakthroughs were obtained. One of the results is due to Koutecký et al. [16], who gave a strongly polynomial algorithm with running time $\Delta^{\mathcal{O}(r^2s+rs^2)}(nt)^6 \cdot \log(nt) + LP$. Here LP is the running time for solving the corresponding LP relaxation, which is possible in strongly polynomial time, since the entries of the matrix are bounded. Simultaneously, Eisenbrand et al. reduced in [7] the running time from a cubic factor to a quadratic one by introducing new proximity and sensitivity results. This leads to an algorithm with running time $(\Delta rs)^{\mathcal{O}(r^2s+rs^2)}L \cdot (nt)^2 \log^2(nt) + LP$. Note that both results require only polynomial dependency on t.

As for applications, n-fold ILPs are broadly used to model various problems such as string, flow or scheduling problems. We refer to the works [5, 10, 11, 12, 15, 19] and the references therein for an overview.

Structure of the Document

In Section 2 we introduce the necessary preliminaries. Section 3 gives the algorithm for efficiently computing the augmenting steps. This is then integrated into an algorithm for n-fold ILPs in Section 4. At first we require finite variable bounds and then discuss how to eliminate this requirement using the solution of the LP relaxation. Finally, in Section 5 we discuss how to handle infinite variable bounds without the LP relaxation and give new structural results.

2 Preliminaries

In the following we introduce n-fold ILPs formally and state the main results regarding them. Further we familiarize splitters, a technique known from Color Coding.

▶ **Definition 1.** *Let $n, r, s, t \in \mathbb{N}$. Furthermore let $A_1, \ldots, A_n$ be $r \times t$ integer matrices and $B_1, \ldots, B_n$ be $s \times t$ integer matrices. Then the n-fold matrix $\mathcal{A}$ is of following form:*

$$\mathcal{A} = \begin{pmatrix} A_1 & A_2 & \ldots & A_n \\ B_1 & 0 & \ldots & 0 \\ 0 & B_2 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & B_n \end{pmatrix}.$$

The matrix $\mathcal{A}$ is of dimension $(r+n\cdot s)\times n\cdot t$. We will divide $\mathcal{A}$ into blocks of size $(r+n\cdot s)\times t$. Similarly, the variables of a solution x are partitioned into bricks of length t. This means each brick $x^{(i)}$ corresponds to the columns of one submatrix A_i and therefore also B_i. Given $c, \ell, u \in \mathbb{Z}^{n\cdot t}$ and $b \in \mathbb{Z}^{r+n\cdot s}$, the corresponding n-fold Integer Linear Programming problem is defined by:

$$\max\{c^T x \mid \mathcal{A}x = b, \ell \leq x \leq u, x \in \mathbb{Z}^{n\cdot t}\}.$$

The main idea for the state-of-the-art algorithms relies on some insight about the Graver basis of n-fold ILPs, which are special elements of the kern of $\mathcal{A}$. More formally, we introduce the following definitions:

▶ **Definition 2.** *The kern of a matrix A is defined as the set of integral vectors $x \in \mathbb{Z}^{\aleph\cdot\approx}$ with $Ax = 0$. We write* $\ker(A)$ *for them.*

▶ **Definition 3.** *A Graver basis element g is a minimal element of* $\ker(A)$*. An element is minimal, if it is not the sum of two sign-compatible elements $u, v \in \ker(A)$.*

Here, sign-compatible means that $u_i \cdot v_i \geq 0$ for every i.

▶ **Theorem 4** ([4])**.** *Let $A \in \mathbb{Z}^{n\times m}$ and let $x \in \ker(A)$. Then there exist $2n-1$ Graver basis elements $g_1, \ldots, g_{2n-1}$, which are sign-compatible with x such that*

$$x = \sum_{i=1}^{2n-1} \lambda_i g_i$$

for some $\lambda_1, \ldots, \lambda_{2n-1} \in \mathbb{Z}_{\geq 0}$.

Many results for n-fold ILPs rely on the fact that the ℓ_1-norm of Graver basis elements for n-fold matrices are small. The best bound known for the ℓ_1-norm is due to Eisenbrand et al. [7].

▶ **Theorem 5** ([7])**.** *The ℓ_1-norm of the Graver basis elements of an n-fold matrix $\mathcal{A}$ is bounded by $\mathcal{O}(rs\Delta)^{rs}$.*

Next, we will introduce a technique called splitters (see e.g. [17]), which has its origins in the FPT community and was used to derandomize the Color Coding technique [1]. So far it has not been used with n-fold ILPs. We refer the reader to the outline of techniques in the introduction for the idea on how we apply the splitters.

▶ **Definition 6.** *An (n, k, ℓ) splitter is a family of hash functions F from $\{1, \ldots, n\}$ to $\{1, \ldots, \ell\}$ such that for every $S \subseteq \{1, \ldots, n\}$ with $|S| = k$, there exists a function $f \in F$ that splits S evenly, that is, for every $j, j' \leq \ell$ we have $|f^{-1}(j) \cap S|$ and $|f^{-1}(j') \cap S|$ differ by at most 1.*

If $\ell \geq k$, the above means that there is some hash function that has no collisions when restricted to S. Interestingly, there exist splitters of very small size.

▶ **Theorem 7** ([1, 18])**.** *There exists an (n, k, k^2) splitter of size $k^6 \log(k) \log(n)$ which is computable in time $k^6 \log(k) \cdot n \log(n)$.*

We note that an alternative approach to the result above is to use FKS hashing. Although it has an extra factor of $\log(n)$, it is particularly easy to implement.

▶ **Theorem 8** (Corollary 2 and Lemma 2, [9])**.** *Define for every prime $q < k^2 \log(n)$ and prime $p < q$ the hash function $x \mapsto 1 + (p \cdot (x \mod q) \mod k^2)$. This is an (n, k, k^2) splitter of size $\mathcal{O}(k^4 \log^2(n))$.*

We remark that a hash function from $\{1, \ldots, n\}$ to $\{1, \ldots, \ell\}$ naturally corresponds to a partition of the set $\{1, \ldots, n\}$ into exactly ℓ subsets.

3 Efficient Computation of Improving Directions

The backbone of our algorithm is the efficient computation of augmenting steps. The important aspect is the fact that we can update the augmenting steps very efficiently if the input changes only slightly. In other words, whenever we change the current solution by applying an augmenting step, we do not have to recompute the next augmenting step from scratch. The augmenting steps depend on a partition of the bricks. In the following we define the notion of a best step based on a fixed partition. Later, we will independently find steps for a number of partitions and take the best among them.

▶ **Definition 9.** *Let P be a partition of the n bricks into k^2 disjoint sets $P_1, P_2, \ldots, P_{k^2}$. Let $\overline{u} \in \mathbb{Z}^{nt}_{\geq 0}$ and $\overline{\ell} \in \mathbb{Z}^{nt}_{\leq 0}$ be some upper and lower bounds on the variables (not necessarily the same as in the n-fold ILP). A (P, k)-best step is an optimal solution of the system below. We slightly abuse notation by using P_j or bricks $S_j \in P_j$ for the indices of variables contained in them.*

$$
\begin{aligned}
\max\ & c^T x && \\
\mathcal{A}x &= 0 && \\
\sum_{i \in S_j} |x_i| &\leq k && \forall j \in \{1, \ldots, k^2\} \\
x_i &= 0 && \forall j \in \{1, \ldots, k^2\}, i \in P_j \setminus \{S_j\} \\
\overline{\ell} \leq x &\leq \overline{u} && \\
x &\in \mathbb{Z}^{nt} && \\
S_j &\in P_j && \forall j \in \{1, \ldots, k^2\}.
\end{aligned}
$$

This means a (P, k)-best step is an element of $\ker(\mathcal{A})$, which uses only one brick of every $P_j \in P$. Within that brick the norm of the solution must be at most k. Later, we will choose k as the upper bound for the ℓ_1-norm of a Graver basis element, i.e., $k = \mathcal{O}(rs\Delta)^{rs}$.

▶ **Theorem 10.** *Consider the problem of finding a (P,k)-best step in an n-fold matrix where the lower and upper bounds $\overline{u}, \overline{\ell}$ can change. This problem can be solved initially in time $k^{\mathcal{O}(r)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot nt$ and then in $k^{\mathcal{O}(r)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot \log(nt)$ update time whenever the bounds of a single variable change.*

Proof. Let P be a partition of the bricks from matrix $\mathcal{A}$ into k^2 disjoint sets $P_1, P_2, \ldots, P_{k^2}$. Solving the (P,k)-best step problem requires that from each set $P_j \in P$ we choose at most one brick and set this brick's variables. All variables in other bricks of P_j must be 0.

Let x be a (P,k)-best step and let $x^{(j)}$ have the values of x in variables of P_j and 0 in all other variables. Then by definition, $\|x^{(j)}\|_1 \leq k$. This implies that the right-hand side regarding $x^{(j)}$, that is to say, $\mathcal{A}x^{(j)}$, is also small. Since the absolute value of an entry in $\mathcal{A}$ is at most Δ, we have that $\|\mathcal{A}x^{(j)}\|_\infty \leq k\Delta$. Let a_i be the i-th row of $\mathcal{A}$. If $i > r$, then $a_i x^{(j)} = 0$. This is because $\mathcal{A}x = 0$ and a_i has all its support either completely inside P_j or completely outside P_j. Meaning, the value of $\mathcal{A}x^{(j)}$ is one of the $(2k\Delta+1)^r$ many values we get by enumerating all possibilities for the first r rows. Furthermore, since P has only k^2 sets, the partial sum $\mathcal{A}(x^{(1)} + \cdots + x^{(j)})$ is always one of $(2k^3\Delta+1)^r = (k\Delta)^{\mathcal{O}(r)}$ many candidates.

Hence to find a (P,k)-best step we can restrict our search to solutions whose partial sums stay in this range. To do so, we set up a graph containing k^2+2 layers $L_0, L_1, \ldots L_{k^2}, L_{k^2+1}$. An example is given in figure 1. The first layer L_0 will consist of just one node marking the starting point with partial sum zero. Similarly, the last layer L_{k^2+1} will just contain the target point also having partial sum zero, since a (P,k)-best step is an element of $\ker(\mathcal{A})$. Each layer L_j with $1 \leq j \leq k^2$ will contain $(2k^3\Delta+1)^r$ many nodes, each representing one possible value of $\mathcal{A}(x^{(1)} + \cdots x^{(j)})$. Two points v, w from adjacent layers L_{j-1}, L_j will be connected if the difference of the corresponding partial sums, namely $w - v$, can be obtained by a solution y of variables from only one brick of P_j (with $\|y\|_1 \leq k$). The weight of the edge will be the largest gain for the objective function $c^T y$ over all possible bricks. Hence, it could be necessary to compute and compare up to n values for each P_j and each difference in the partial sums to insert one edge into the graph. Finally, we just have to find the longest path in this graph as it corresponds to a (P,k)-best step. The out-degree of each node is bounded by $(2k^3\Delta+1)^r$ since at most this many nodes are reachable in the next layer. Therefore the overall number of edges is bounded by

$$(k^2+2) \cdot (2k^3\Delta+1)^r \cdot (2k^3\Delta+1)^r = (k\Delta)^{\mathcal{O}(r)}.$$

Using the Bellman-Ford algorithm we can solve the Longest Path problem for a graph with N vertices and M edges in time $\mathcal{O}(N \cdot M)$ as the graph is directed and acyclic. This gives a running time of $(k\Delta)^{\mathcal{O}(r)} \cdot (k\Delta)^{\mathcal{O}(r)} = (k\Delta)^{\mathcal{O}(r)}$ for solving the problem. Constructing the graph, however, requires solving a number of IPs of the form

$$\begin{aligned} \max\ & c'^T x \\ \begin{pmatrix} A_j \\ B_j \end{pmatrix} x &= \begin{pmatrix} b' \\ 0 \end{pmatrix} \\ \|x\|_1 &\leq k \\ \ell' \leq x &\leq u' \\ x &\in \mathbb{Z}^t, \end{aligned}$$

where $b' \in \mathbb{Z}^r$ is the corresponding right-hand side of the top rows and ℓ', u', c' are the upper and lower bounds, and the objective of the block. This is an IP with $r+s+1$ constraints, t variables, lower and upper bounds, and entries of the matrix bounded by Δ in absolute value.

Using the algorithm by Eisenbrand and Weismantel [8], solving one of them requires time

$$t \cdot \mathcal{O}(r+s+1)^{r+s+4} \cdot \mathcal{O}(\Delta)^{(r+s+1)(r+s+4)} \cdot \log^2((r+s+1)\Delta) + \mathrm{LP} = t \cdot \Delta^{\mathcal{O}(r^2+s^2)} + \mathrm{LP},$$

where LP is the time for solving the LP relaxation. Note that strictly speaking the constraint $\|x\|_1 \leq k$ is not linear, but by standard construction the ILP can easily be transformed into an equivalent one replacing every variable x_i with a composition $x_i^+ - x_i^-$ of two positive variables. Then the ℓ_1-norm is simply the sum over all variables. This does not affect the asymptotic running time.

Furthermore, a little thought allows us to reduce the dependency on t to a logarithmic one: Since the number of constraints in the ILP above is very small, there are only $\Delta^{\mathcal{O}(r+s)}$ many different columns. Because of the cardinality constraint $\|x\|_1 \leq k$, we only have to consider $2k$ many variables of each type of column, namely: The k many with $u'_i > 0$ and maximal c'_i and the k many with $\ell'_i < 0$ and minimal c'_i.

If some solution uses a variable not in this set, then by pigeonhole principle there is a variable with the same column values and a superior objective value and which can be increased/decreased. We can reduce the variable outside this set and increase the corresponding variable inside this set until all variables outside the set are 0. We can use an appropriate data structure (e.g. AVL trees) to maintain a set of all variables with $u'_i > 0$ ($\ell'_i < 0$) such that we can find the k best among them in time $\mathcal{O}(k \log(t))$. Whenever the bounds of some variable change, we might have to add or remove entries, which also takes only logarithmic time. After initialization in time $\mathcal{O}(nt)$ (in total for all bricks) solving such an IP can therefore be implemented in time

$$k\log(t) + 2k\Delta^{\mathcal{O}(r+s)}\Delta^{\mathcal{O}(r^2+s^2)} + \mathrm{LP} \leq k\log(t)\Delta^{\mathcal{O}(r^2+s^2)} + \mathrm{LP} \leq k\log(t)\Delta^{\mathcal{O}(r^2+s^2)}.$$

The last inequality holds, because using Tardos' algorithm [20] LPs can be solved in time polynomial in the encoding size of the matrix, which can be bounded by $2k\Delta^{\mathcal{O}(r+s)} \cdot (r+s) \cdot \log(\Delta)$. This is dominated by the other term. The number of IPs to solve is at most n times the number of edges, since we have to compare the values of up to n bricks. This gives a running time of

$$\mathcal{O}(nt) + n \cdot (k\Delta)^{\mathcal{O}(r)} \cdot \log(t) \cdot \Delta^{\mathcal{O}(r^2+s^2)} \leq nt \cdot k^{\mathcal{O}(r)} \cdot \Delta^{\mathcal{O}(r^2+s^2)}$$

for constructing the graph. To obtain the update time from the premise of the theorem, it is perfectly fine to solve the Longest Path problem again, but we cannot construct the graph from scratch. However, in order to construct the graph we still have to find the best value over all bricks for each edge. Fortunately, if only a few bricks are updated (in their lower and upper bounds) it is not necessary to recompute all values. Each edge corresponds to a particular $P_j \in P$ and a fixed right-hand side (a possible value of $\mathcal{A}x^{(j)}$). We require an appropriate data structure $\mathcal{D}_e$ for every edge e, which supports fast computation of the operations FindMax, Insert, and Delete. Again, an AVL tree computes each of these operations in time $\mathcal{O}(\log(N))$, where N is the number of elements. In $\mathcal{D}_e$ we store pairs (v, i) where i is a brick in P_j and v is the maximum gain of brick i for the right-hand side of e. The pairs are stored in lexicographical order. Since there are at most n bricks in P_j, the data structure will have at most n elements. Initially, we can build $\mathcal{D}_e$ in time $nt \cdot \Delta^{\mathcal{O}(r^2+s^2)}$ (this is replicated for each edge). Now consider a change to the instance. Recall that we are looking at changes that affect only a single brick, namely the upper and lower bounds within that brick change. We are going to update the data structure $\mathcal{D}_e$ (for each edge) to reflect the changes and we are going to recompute the edge value of each edge e using $\mathcal{D}_e$. Then we

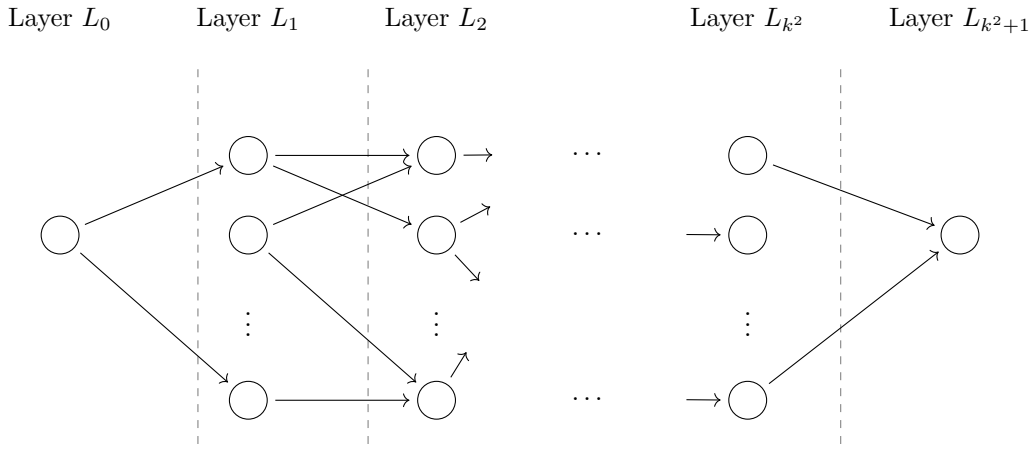

Figure 1 This figure shows an example for a layered graph obtained while solving the (P, k)-best step problem. There are $k^2 + 2$ layers, visually separated by gray dashed lines. This includes one source layer L_0, one target layer L_{k^2+1} both with just a single node representing the zero sum. Further there are k^2 layers with $(2k^3\Delta + 1)^r$ nodes each, where in one layer the nodes stand for all reachable partial sums. Two points v, w from adjacent layers L_{j-1}, L_j will be connected if the difference of the corresponding partial sums, namely $w - v$, can be obtained by a solution y of variables from only one brick of P_j (with $\|y\|_1 \leq k$). The weight of the edge will be the largest gain for the objective function $c^T y$ over all possible bricks. For the sake of clarity both the values of the nodes and the edges are not illustrated.

simply solve the Longest Path problem again. Let $P_j \in P$ be the set that contains the brick i that has changed in some variable. We only have to consider edges from L_{j-1} to L_j, since none of the other edges are affected by the change. For a relevant edge e we compute the previous value v and current value v' that the brick i would produce (before and after the bounds have changed). In $\mathcal{D}_e$ we have to remove (v, i) and insert (v', i). Both operations need only $O(\log(n))$ time. Then the running time to update $\mathcal{D}_e$ for one edge is

$$k \log(t) \cdot \Delta^{\mathcal{O}(r^2+s^2)} + \mathcal{O}(\log(n)) \leq k \log(nt) \cdot \Delta^{\mathcal{O}(r^2+s^2)}.$$

In order to update the edge value of e using $\mathcal{D}_e$, we simply have to find the maximum element in $\mathcal{D}_e$, which again takes time $\mathcal{O}(\log(n))$. To summarize, the total time to update the (P, k)-best step after a change to a single brick consists of (1) updating each $\mathcal{D}_e$, (2) finding the maximum in each $\mathcal{D}_e$, and (3) solving the Longest Path problem. We conclude that the update time is

$$k \log(nt) \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot (k\Delta)^{\mathcal{O}(r)} + \log(n) \cdot (k\Delta)^{\mathcal{O}(r)} + (k\Delta)^{\mathcal{O}(r)} \leq k^{\mathcal{O}(r)} \Delta^{\mathcal{O}(r^2+s^2)} \cdot \log(nt).$$ ◀

4 The Augmenting Step Algorithm

In this section we will assume that all lower and upper bounds are finite and give a complete algorithm for this case. Later, we will explain how to cope with infinite bounds. We start by showing how to converge to an optimal solution when an initial feasible solution is given. To

compute the initial solution, we also apply this algorithm on a slightly modified instance. The approach resembles the procedure in previous literature, although we apply the results from the previous section to speed up the computation of augmenting steps.

Let x be a feasible solution for the n-fold ILP, in particular $\mathcal{A}x = b$. Let x^* be an optimal one. Theorem 4 states that we can decompose the difference vector $x' = x^* - x$ into at most $2nt - 1$ weighted Graver basis elements, that is

$$x' = x^* - x = \sum_{j=1}^{2nt-1} \lambda_j g_j.$$

For intuition, consider the following simple approach (this is similar to the algorithm by Hemmecke et al. [10]). Suppose we are able to guess the best vector $\lambda_i g_i = \operatorname{argmax}_j\{c^T(\lambda_j g_j)\}$ regarding the gain for the objective function. This pair of step length λ_i and Graver element g_i is called the Graver best step. Then we can augment the current solution x by adding $\lambda_i g_i$ to it, i.e., we set $x \leftarrow x + \lambda_i g_i$. Feasibility follows because all g_j are sign-compatible. This procedure is repeated until no improving step is possible and therefore x must be optimal. In each iteration this decreases the gap to the optimal solution by a factor of at least $1 - 1/(2nt)$ by the pigeonhole principle. It may be costly to guess the precise Graver best step, but for our purposes it will suffice to find an augmenting step that is approximately as good.

We will now describe how to guess λ_i. Since $x + \lambda_i g_i$ is feasible, we have that $\lambda_i g_i \leq u - x \leq u - \ell$ and $\lambda_i g_i \geq \ell - x \geq \ell - u$. Let $(g_i)_j \in \operatorname{supp}(g_i)$ be some non-zero variable. If $(g_i)_j > 0$, then $\lambda_i \leq (\lambda_i g_i)_j \leq u_j - \ell_j$. Otherwise, $(g_i)_j < 0$ and $\lambda_i \leq -(\lambda_i g_i)_j \leq -(\ell_j - u_j) = u_j - \ell_j$. Hence, it suffices to check all values in the range $\{1, \ldots, \Gamma\}$, where $\Gamma = \max_j\{u_j - \ell_j\}$. Proceeding like in [7], we lower the time a bit further by not taking every value into consideration. Instead, we look at guesses of the form $\lambda' = 2^k$ for $k \in \{0, \ldots, \lfloor \log(\Gamma) \rfloor\}$. Doing so we lose a factor of at most 2 regarding the improvement of the objective function, since $c^T(\lambda' g_i) > 0.5 \cdot c^T(\lambda_i g_i)$ when taking $\lambda' = 2^{\lfloor \log(\lambda_i) \rfloor} > \lambda_i/2$. Fix λ' to the value above. Next we describe how to compute an augmenting step that is at least as good as $\lambda' g_i$. Note that g_i is a solution of

$$\begin{aligned} \mathcal{A}y &= 0 \\ \|y\|_1 &\leq k \\ \lceil \frac{\ell - x}{\lambda'} \rceil \leq y &\leq \lfloor \frac{u - x}{\lambda'} \rfloor, \end{aligned}$$

where $k = \mathcal{O}(rs\Delta)^{rs}$ is the bound on the norm of Graver elements from Theorem 5. Suppose we have guessed some partition $P = \{P_1, \ldots, P_{k^2}\}$ of the bricks such that of each P_j only a single brick has non-zero variables in g_i. Clearly, the augmenting step $\lambda' y^*$, where y^* is a (P, k)-best step with bounds $\overline{\ell} = \lceil \frac{\ell - x}{\lambda'} \rceil$ and $\overline{u} = \lfloor \frac{u - x}{\lambda'} \rfloor$ would be at least as good as $\lambda' g_i$. Indeed Theorem 10 explains how to compute such a (P, k)-best step dynamically and when we add $\lambda' g_i$ to x we only change the bounds of at most k^3 many variables. Hence, it is very efficient to recompute (P, k)-best steps until we have converged to the optimal solution. However, valid choices of λ' and P might be different in every iteration. Regarding λ', we simply compute (P, k)-best steps for each of the $\mathcal{O}(\log(\Gamma))$ many guesses and take the best among them. We proceed similarly for P. We guess a small number of partitions and guarantee that always at least one of them is valid. For this purpose we employ splitters. More precisely, we compute a (n, k, k^2) splitter of the n bricks. Since g_i has a norm bounded by k, it can also only use at most k bricks. Therefore the splitter always contains a partition $P = \{P_1, \ldots, P_{k^2}\}$ where g_i only uses a single brick in every P_j.

To recap, in every iteration we solve a (P, k)-best step problem for every guess λ' and every partition P in the splitter and take the overall best solution as an improving direction $\lambda' y^*$. Then we update our solution x by adding $\lambda' y^*$ onto it. At most k^2 many bricks change

(and within each brick only k variables can change) and therefore we can efficiently recompute the (P, k)-best steps for every guess for the next iteration. This way we guarantee that we improve the solution by a factor of at least $1 - 1/(4nt)$ in every iteration. The explicit running time of these steps will be analyzed in the next theorem.

Recall that we still have to find an initial solution. This solution can indeed be computed by using the augmenting step algorithm described above. Roughly speaking, we modify our n-fold matrix by introducing new variables, such that it admits a trivial initial solution. Introducing a new objective function which penalizes using these new variables, an optimal solution clearly corresponds to an initial solution of the original n-fold ILP. The detailed procedure is given in the full version of this paper.

▶ **Theorem 11.** *The dynamic augmenting step algorithm described above computes an optimal solution for the n-fold Integer Linear Program problem in time* $(rs\Delta)^{\mathcal{O}(r^2s+s^2)} \cdot \mathcal{O}(L^2 \cdot nt \log^5(nt))$ *when finite variable bounds are given for each variable. Here L is the encoding length of the largest occurring number in the input.*

Proof. Due to Theorem 4 we know that the difference vector of an optimal solution x^* to our current solution x, i.e. $x' = x^* - x$, can be decomposed into $2nt - 1$ weighted Graver basis elements. Hence, if we adjust our solution x with the Graver best step, we reduce the gap between the value of an optimal solution and our current solution by a factor of at least $1 - 1/(2nt)$ due to the pigeonhole principle. Our algorithm finds an augmenting step that is at least half as good as the Graver best step. Therefore, the gap to the optimal solution is still reduced by at least a factor of $1 - 1/(4nt)$.

Regarding the running time we first have to compute the splitter. Theorem 7 says, that this can be done in time $k^{\mathcal{O}(1)} \cdot n \log(n) = (rs\Delta)^{\mathcal{O}(rs)} \cdot n \log(n)$. Next we have to try all values for the weight λ. Due to our step-length we get $\mathcal{O}(\log(\Gamma))$ guesses. Recall that Γ denotes the largest difference between an upper bound and the corresponding lower bound, i.e., $\Gamma = \max_j\{u_j - \ell_j\}$. Fixing one, we have to find the best improving direction regarding each of the $((rs\Delta)^{\mathcal{O}(rs)})^{\mathcal{O}(1)} \log(n) = (rs\Delta)^{\mathcal{O}(rs)} \log(n)$ partitions. In the first iteration we have to set up the tables in time $k^{\mathcal{O}(r)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot nt = (rs\Delta)^{\mathcal{O}(r^2s)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot nt$ by computing the gain for each possible summand for each set and setting up the data structure. In each following iteration we update each table and search for the optimum in time $k^{\mathcal{O}(r)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot \log(nt) = (rs\Delta)^{\mathcal{O}(r^2s)} \cdot \Delta^{\mathcal{O}(r^2+s^2)} \cdot \log(nt)$. Now it remains to bound the number I of iterations needed to converge to an optimal solution. To obtain such a bound we calculate:

$$1 > (1 - 1/(4nt))^I |c^T(x^* - x)|.$$

By reordering the term, we get

$$I < \frac{-\log(|c^T(x^* - x)|)}{\log(1 - 1/(4nt))}.$$

As $\log(1 + x) = \Theta(x)$, we can bound $\log(1 - 1/(4nt))$ by $\Theta(-1/(4nt))$ and thus

$$I < \mathcal{O}(\frac{-\log(|c^T(x^* - x)|)}{-1/(4nt)}) \leq \mathcal{O}(4nt \log(|c^T(x^* - x)|)).$$

As the maximal difference between the current solution x and an optimal one x^* can be at most the maximal value of c times the largest number in between the bounds for each variable, we get $|c^T(x^* - x)| \leq nt \max_i |c_i| \cdot \Gamma$ and thus

$$I < \mathcal{O}(4nt \log(|c^T(x^* - x)|)) \leq \mathcal{O}(nt \log(nt \max_i |c_i| \cdot \Gamma)) \leq \mathcal{O}(nt \log(nt\Gamma \max_i |c_i|)).$$

Let L denote the encoding length of largest integer in the input. Clearly 2^L bounds the largest absolute value in c and thus we get

$$I < \mathcal{O}(nt\log(nt\Gamma \max_i |c_i|)) = \mathcal{O}(nt\log(nt\Gamma 2^L)) = \mathcal{O}(nt\log(nt\Gamma 2^L)).$$

Hence after this amount of steps by always improving the gain by a factor of at least $1-1/(4nt)$ we close the gap between the initial solution and an optimal one. Given this, we can now bound the overall running time with:

$$\underbrace{(rs\Delta)^{\mathcal{O}(rs)}\cdot n\log(n)}_{\text{Splitter}} + \underbrace{(rs\Delta)^{\mathcal{O}(rs)}\log(n)}_{\text{Partitions}}\cdot\underbrace{(rs\Delta)^{\mathcal{O}(r^2s)}\cdot(rs\Delta)^{\mathcal{O}(r^2+s^2)}\cdot nt}_{\text{First Iteration}} +$$
$$\underbrace{\mathcal{O}(nt\log(nt\Gamma 2^L))}_{I}\cdot\underbrace{\mathcal{O}(\log(\Gamma))}_{\lambda\text{ Guesses}}\cdot\underbrace{(rs\Delta)^{\mathcal{O}(rs)}\log(n)}_{\text{Partitions}}\cdot\underbrace{(rs\Delta)^{\mathcal{O}(r^2s)}\cdot(rs\Delta)^{\mathcal{O}(r^2+s^2)}\cdot\log(nt))}_{\text{Update Time}}$$
$$= \mathcal{O}((nt\log(nt\Gamma 2^L))\cdot\mathcal{O}(\log(\Gamma))\cdot(rs\Delta)^{\mathcal{O}(r^2s+s^2)}\cdot\log^2(nt)$$
$$= (rs\Delta)^{\mathcal{O}(r^2s+s^2)}\cdot\mathcal{O}(\log^2(\Gamma+2^L)\cdot nt\log^3(nt)).$$

Here *Splitter* denotes the time to compute the initial set $\mathcal{P}$ of partitions and *Partitions* denotes the cardinality of $\mathcal{P}$. *First Iteration* is the time to solve the first iteration of the (P,k)-best step problem. Further λ *Guesses* is the number of guesses we have to do to get the right weight and lastly *Update Time* is the time needed to solve each following (P,k)-best step including updating the bounds and data structures.

Note, that we still have to argue about finding the initial solution, since in the construction of the modified n-fold ILP the parameters slightly change. The length of a brick expand to $t' = t+r+s$, as shown in the full version of this paper. This, however, can be hidden in the $\mathcal{O}$-Notation of $(rs\Delta)^{\mathcal{O}(r^2s+s^2)}$. Further, Γ', the biggest difference in upper and lower bounds can change as we introduced new variables admitting new bounds. The difference between the bounds of old variables does not change. For the new variables, however, the difference can be as large as $\|b'\|_\infty$. Thus we bound this value by

$$\|b'\|_\infty = \|b-\mathcal{A}\ell\|_\infty \le \|b\|_\infty + \|\mathcal{A}\ell\|_\infty \le \|b\|_\infty + \Delta\cdot\|\ell\|_1 \le \mathcal{O}(\Delta\cdot nt\cdot 2^L).$$

We conclude that the running time for finding an initial solution (and also the overall running time) is

$$(rs\Delta)^{\mathcal{O}(r^2s+s^2)}\mathcal{O}(\log^2(\Gamma'+2^L)nt\log^3(nt)) = (rs\Delta)^{\mathcal{O}(r^2s+s^2)}\mathcal{O}(\log^2(\Delta 2^L nt)nt\log^3(nt))$$
$$= (rs\Delta)^{\mathcal{O}(r^2s+s^2)}\cdot L^2 nt\log^5(nt).$$ ◀

Handling Infinite Bounds

Remark, that if no finite bounds are given for all variables, we have to introduce some artificial bounds first. Here we can proceed as in [7], where first the LP relaxation is solved to obtain an optimal fractional solution z^*. Using the proximity results from [7], we know that an optimal integral solution x^* exists such that $\|x^*-z^*\|_1 \le nt(rs\Delta)^{\mathcal{O}(rs)}$. This allows us to introduce artificial upper bounds for the unbounded variables. Remark that this comes at the price of solving the corresponding relaxation of the n-fold Integer Linear Program problem. However we also lessen the dependency from L^2 to L as the finite upper and lower bounds can also be bounded more strictly due to the same proximity result. This yields an overall running time of $(rs\Delta)^{\mathcal{O}(r^2s+s^2)}\cdot L\cdot nt\log^5(nt)+\text{LP}$. Nevertheless, solving this LP can be very costly, indeed it is not clear if a potential algorithm even runs in time linear in n.

Thus, it may even dominate the running time of solving the n-fold ILP with finite upper bounds. Fortunately we can circumvent the necessity of solving the LP as we will describe in the following section using new structural results.

▶ **Theorem 12.** *The dynamic augmenting step algorithm described above computes an optimal solution for the n-fold Integer Linear Program problem in time $(rs\Delta)^{\mathcal{O}(r^2s+s^2)} \cdot L \cdot nt \log^5(nt) + LP$ when some variables have infinite upper bounds. Here LP is the running time to solve the corresponding relaxation of the n-fold ILP problem.*

5 Bounds on ℓ_1-norm

In the following, we state that even with infinite variable bounds in an n-fold ILP there always exists a solution of small norm (if the n-fold ILP has a finite optimum). Therefore, we can apply the algorithm for finite variable bounds by replacing every infinite one with this value. However, due to space restrictions, the proofs are omitted. They can be found in the full version of this paper.

▶ **Lemma 13.** *If the n-fold ILP is feasible and $\overline{y}$ is some vector satisfying the variable bounds, then there exists a feasible solution x with $\|x\|_1 \leq \mathcal{O}(rs\Delta)^{rs+1} \cdot (\|\overline{y}\|_1 + \|b\|_1)$*

▶ **Lemma 14.** *If the n-fold ILP is bounded and feasible, then there exists an optimal solution x with $\|x\|_1 \leq (rs\Delta)^{\mathcal{O}(rs)} \cdot (\|b\|_1 + nt\zeta)$, where ζ denotes the largest absolute value among all finite variable bounds.*

This yields an alternative approach to solving the LP relaxation, because now we can simply replace all infinite bounds with $\pm(rs\Delta)^{\mathcal{O}(rs)} \cdot nt \cdot 2^L$. Then we can apply the algorithm that works only on finite variable bounds. The new encoding length L' of the largest integer in the input can be bounded by

$$L' \leq \log((rs\Delta)^{\mathcal{O}(rs)} \cdot 2^L \cdot nt) \leq \mathcal{O}(rs \cdot \log(rs\Delta) \cdot L \cdot \log(nt)).$$

This way we obtain the following.

▶ **Corollary 15.** *We can compute an optimal solution for an n-fold ILP in time $(rs\Delta)^{\mathcal{O}(r^2s+s^2)} \cdot L^2 \cdot nt \log^7(nt)$.*

In a similar way, we can derive the following bound on the sensitivity of an n-fold ILP. This bound is not needed in our algorithm, but may be of independent interest, since it implies small sensitivity for problems that can be expressed as n-fold ILPs.

▶ **Theorem 16.** *Let x be an optimal solution of an n-fold ILP with right-hand side b, in particular, $\mathcal{A}x = b$. If the right hand side changes to b' and the n-fold ILP still has a finite optimum, then there exists an optimal solution x' for b' ($\mathcal{A}x' = b'$) with $\|x - x'\|_1 \leq \mathcal{O}(rs\Delta)^{rs} \cdot \|b - b'\|_1$.*

It is notable that this bound does not depend on n. This is in contrast to the known bounds for the distance between LP and ILP solutions of an n-fold ILP [7].

An Improved FPTAS for 0-1 Knapsack

Ce Jin
Institute for Interdisciplinary Information Sciences, Tsinghua University, Beijing, China
jinc16@mails.tsinghua.edu.cn

Abstract

The 0-1 knapsack problem is an important NP-hard problem that admits fully polynomial-time approximation schemes (FPTASs). Previously the fastest FPTAS by Chan (2018) with approximation factor $1+\varepsilon$ runs in $\tilde{O}(n+(1/\varepsilon)^{12/5})$ time, where $\tilde{O}$ hides polylogarithmic factors. In this paper we present an improved algorithm in $\tilde{O}(n+(1/\varepsilon)^{9/4})$ time, with only a $(1/\varepsilon)^{1/4}$ gap from the quadratic conditional lower bound based on $(\min,+)$-convolution. Our improvement comes from a multi-level extension of Chan's number-theoretic construction, and a greedy lemma that reduces unnecessary computation spent on cheap items.

1 Introduction

1.1 Background

In the *0-1 knapsack* problem, we are given a set I of n items where each item $i \in I$ has weight w_i and profit p_i, and we want to select a subset $J \subseteq I$ such that $\sum_{j\in J} w_j \le W$ and $\sum_{j\in J} p_j$ is maximized.

The 0-1 knapsack problem is a fundamental optimization problem in computer science and is one of Karp's 21 NP-complete problems [8]. An important field of study on NP-hard problems is to find efficient approximation algorithms. A $(1+\varepsilon)$-approximation algorithm (for a maximization problem) outputs a value SOL such that $\mathrm{SOL} \le \mathrm{OPT} \le (1+\varepsilon)\cdot \mathrm{SOL}$, where OPT denotes the optimal answer. The 0-1 knapsack problem is one of the first problems that were shown to have fully polynomial-time approximation schemes (FPTASs), i.e., algorithms with approximation factor $1+\varepsilon$ for any given $0<\varepsilon<1$ and running time polynomial in both n and $1/\varepsilon$.

There has been a long line of research on finding faster FPTASs for the 0-1 knapsack problem, as summarized in Table 1. The first algorithm with only subcubic dependence on $1/\varepsilon$ was due to Rhee [15]. Very recently, Chan [3] gave an elegant algorithm for the 0-1 knapsack problem in deterministic $O(n\log\frac{1}{\varepsilon}+(\frac{1}{\varepsilon})^{5/2}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ via simple combination of the SMAWK algorithm [1] and a standard divide-and-conquer technique. The speedup of superpolylogarithmic factor $2^{\Omega(\sqrt{\log(1/\varepsilon)})}$ is due to recent progress on $(\min,+)$-convolution [2, 16, 4]. Using an elementary number-theoretic lemma, Chan further improved the algorithm to $O(n\log\frac{1}{\varepsilon}+(\frac{1}{\varepsilon})^{12/5}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time, and obtained two new algorithms running in $\tilde{O}(\frac{1}{\varepsilon}n^{3/2})$ and $O((\frac{1}{\varepsilon})^{4/3}n+(\frac{1}{\varepsilon})^2)/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time respectively, which are faster for small n.

FPTASs on several special cases of 0-1 knapsack are also of interest. For the *unbounded knapsack* problem, where every item has infinitely many copies, Jansen and Kraft [7] obtained an $O(n+(\frac{1}{\varepsilon})^2\log^3\frac{1}{\varepsilon})$-time algorithm; the unbounded version can be reduced

to 0-1 knapsack with only a logarithmic blowup in the problem size [5]. For the *subset sum* problem, where every item has $p_i = w_i$, Kellerer et al. [9] obtained an algorithm with $O(\min\{n/\varepsilon, n + (\frac{1}{\varepsilon})^2 \log \frac{1}{\varepsilon}\})$ running time, which will be used in our algorithm as a subroutine. For the *partition* problem, which is a special case of the subset sum problem where $W = \frac{1}{2}\sum_{i\in I} w_i$, Mucha et al. [14] obtained an algorithm with a subquadratic $\tilde{O}(n + (\frac{1}{\varepsilon})^{5/3})$ running time.

On the lower bound side, recent reductions showed by Cygan et al. [5] and Künnemann et al. [12] imply that 0-1 knapsack and unbounded knapsack have no FPTAS in $O((n+\frac{1}{\varepsilon})^{2-\delta})$ time, unless $(\min,+)$-convolution has truly subquadratic algorithm [14]. It remains open whether 0-1 knapsack has a matching upper bound.

1.2 Our results

In this paper we present improved FPTASs for the 0-1 knapsack problem. Our results are summarized in the following two theorems.

▶ **Theorem 1.** *There is a deterministic $(1+\varepsilon)$-approximation algorithm for 0-1 knapsack with running time $O(n\log \frac{1}{\varepsilon} + (\frac{1}{\varepsilon})^{9/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$.*

▶ **Theorem 2.** *For $n = O(\frac{1}{\varepsilon})$, there is a deterministic $(1+\varepsilon)$-approximation algorithm for 0-1 knapsack with running time $O\Big(\big(n^{3/4}(\frac{1}{\varepsilon})^{3/2} + (\frac{1}{\varepsilon})^2\big)/2^{\Omega(\sqrt{\log(1/\varepsilon)})}\Big)$.*

Theorem 2 gives the current best time bound for $(\frac{1}{\varepsilon})^{2/3} \ll n \ll \frac{1}{\varepsilon}$, improving upon the previous $O((\frac{1}{\varepsilon})^{4/3}n + (\frac{1}{\varepsilon})^2)/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ algorithm by Chan [3]. For $n \ll (\frac{1}{\varepsilon})^{2/3}$, Chan's $\tilde{O}(\frac{1}{\varepsilon}n^{3/2})$ time randomized algorithm [3] remains the fastest.

For $n \gg \frac{1}{\varepsilon}$, Theorem 1 gives a better time bound, improving upon the previous $O(n\log \frac{1}{\varepsilon} + (\frac{1}{\varepsilon})^{12/5}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ algorithm by Chan [3].

1.3 Outline of our algorithm

We give an informal overview of our improved algorithm for 0-1 knapsack.

Using a known reduction [3], it suffices to solve an easier instance of 0-1 knapsack where profits of all items satisfy $p_i \in [1,2]$. Here "solving an instance" means approximating the function $f(x) :=$ [maximum total profit of items with at most x total weight] for all $x \geq 0$, rather than for just a single point $x = W$. In this restricted case, simple greedy (sorting

according to *unit profits* p_i/w_i) gives an additive error of at most $\max_j p_j = O(1)$, so it suffices to approximate the capped function $\min\{\varepsilon^{-1}, f(x)\}$ with approximation factor $1 + O(\varepsilon)$. Chan gave an algorithm that $(1+\varepsilon)$-approximates $\min\{B, f(x)\}$ in $\tilde{O}(n + \varepsilon^{-2}B^{1/2})$ time (implied by [3, Lemma 7]), which immediately implies an $\tilde{O}(n + \varepsilon^{-5/2})$ time FPTAS by setting $B = \varepsilon^{-1}$.

Greedy. Now we explain how to use a greedy argument (described in detail in Section 5) to improve this algorithm to $\tilde{O}(n + \varepsilon^{-7/3})$ time. We sort all items (with $p_i \in [1, 2]$) in non-increasing order of unit profits p_i/w_i, and divide them into three subsets H, M, L (items with high, medium, low unit profits), where H contains the top $\Theta(\varepsilon^{-1})$ items, and L contains all items i for which $p_i/w_i \le (1 - \varepsilon^{2/3}) \cdot \min_{h \in H}\{p_h/w_h\}$, so there is a gap between the unit profits of H-items and L-items. Intuitively, there are sufficiently many H-items available, so it's not optimal to include too many cheap L-items when the knapsack capacity is not very big. To be more precise, we prove that in any optimal solution we care about (i.e., having optimal total profit smaller than ε^{-1}), the total profit contributed by L-items cannot exceed $O(\varepsilon^{-2/3})$. Hence, for subset L we only need to approximate up to $B = \Theta(\varepsilon^{-2/3})$ in $\tilde{O}(n + \varepsilon^{-2}B^{1/2}) = \tilde{O}(n + \varepsilon^{-7/3})$ time. Subset H has only $O(\varepsilon^{-1})$ items and can be solved using Chan's $\tilde{O}(\varepsilon^{-4/3}n + \varepsilon^{-2})$ algorithm in $\tilde{O}(\varepsilon^{-7/3})$ time. To solve subset M, we round down the profit value p_i for every item $i \in M$, so that the unit profit p_i/w_i becomes a power of $(1+\varepsilon)$. Then there are $O(\varepsilon^{-1/3})$ distinct unit profit values in M. Items with the same unit profit can be solved together using the efficient FPTAS for *subset sum* by Kellerer et al. [9] in $\tilde{O}(n + \varepsilon^{-2})$ time. Finally we merge the results for H, M, L. The total time complexity is $\tilde{O}(n + \varepsilon^{-7/3})$.

Multi-level number-theoretic construction. The above approach invokes two of Chan's algorithms: an $\tilde{O}(n + \varepsilon^{-2}B^{1/2})$ algorithm (useful for small B) and an $\tilde{O}(\varepsilon^{-4/3}n + \varepsilon^{-2})$ algorithm (useful for small n). The key ingredient in these algorithms is a number-theoretic lemma: we can $(1+\varepsilon)$-approximate all profit values $p_i \in [1, 2]$ by multiples of elements from a small set $\Delta \subset [\delta, 2\delta]$ of size $|\Delta| = \tilde{O}(\frac{\delta}{\varepsilon})$ (small $|\Delta|$ can reduce the additive error incurred from rounding).

Chan obtained an $\tilde{O}(n + \varepsilon^{-2}B^{2/5})$ time algorithm using some additional tricks. First, evenly partition Δ into r subsets $\Delta^{(1)}, \ldots, \Delta^{(r)}$, and divide the items into $P = P^{(1)} \cup \cdots \cup P^{(r)}$ accordingly, so that profit values from $P^{(j)}$ are approximated by $\Delta^{(j)}$-multiples. To $(1+\varepsilon)$-approximate the profit function f_j for each $P^{(j)}$, pick a threshold $B_0 \ll B$, and return the combination of a $(1+\varepsilon)$-approximation of $\min\{f_j, B_0\}$ and an εB_0-additive-approximation of $\min\{f_j, B\}$. Since the size of $\Delta^{(j)}$ is only $|\Delta|/r$, the latter function can be approximated faster when $r \gg 1$. Finally, merge f_j over all $1 \le j \le r$. By fine-tuning the parameters r, δ, B_1, the time complexity is improved to $\tilde{O}(n + \varepsilon^{-2}B^{2/5})$.

Our new algorithm extends this technique to *multiple levels*. To $(1+\varepsilon)$-approximate the profit function f_j for each $P^{(j)}$, we will pick $B_0 \ll B_1 \ll \cdots \ll B_{d-1} \ll B_d \approx B$, and compute the εB_{i-1}-additive-approximation of $\min\{f_j, B_i\}$, for all $i \in [d]$. An issue of this multi-level approach is that, different levels have different optimal parameters δ_i and different $\Delta_i^{(1)}, \ldots, \Delta_i^{(r)}$, but we have to stick to the same partition of items $P = P^{(1)} \cup \cdots \cup P^{(r)}$ over all levels. We overcome this issue by enforcing that $\Delta_i^{(j)}$ at level i must be generated by multiples of elements from $\Delta_{i-1}^{(j)}$ at level $i-1$, so that $P^{(j)}$ can be approximated by $\Delta_i^{(j)}$-multiples for all levels. To achieve this, we need a multi-level version of the number-theoretic lemma. We will discuss this part in detail in Section 4.

Using this multi-level construction, we obtain algorithms in $\tilde{O}(n + \varepsilon^{-2}B^{1/3})$ time and $\tilde{O}(\varepsilon^{-3/2}n^{3/4} + \varepsilon^{-2})$ time. Combining these improved algorithms with the greedy argument previously described (the threshold which splits M and L needs to be adjusted accordingly), we obtain an algorithm in $\tilde{O}(n + \varepsilon^{-9/4})$ time as claimed in Theorem 1.

2 Preliminaries

Throughout this paper, $\log x$ stands for $\log_2 x$, and $\tilde{O}(f)$ stands for $O(f \cdot \operatorname{poly}\log(f))$.

We will describe our algorithm with approximation factor $1 + O(\varepsilon)$, which can be lowered to $1 + \varepsilon$ if we scale down ε by a constant factor at the beginning.

We are only interested in the case where $n = O(\varepsilon^{-4})$. For greater n, Lawler's $O(n \log \frac{1}{\varepsilon} + (\frac{1}{\varepsilon})^4)$ algorithm [13] is already near-optimal. Hence we assume $\log n = O(\log \varepsilon^{-1})$.

Assume $0 < w_i \le W$ and $p_i > 0$ for every item i. Then a trivial lower bound of the maximum total profit is $\max_j p_j$. At the beginning, we discard all items i with $p_i \le \frac{\varepsilon}{n} \max_j p_j$. Since the total profit of discarded items is at most $\varepsilon \max_j p_j$, the optimal total profit is only reduced by a factor of $1 + O(\varepsilon)$. So we can assume that $\frac{\max_j p_j}{\min_j p_j} \le \frac{n}{\varepsilon}$.

We adopt Chan's terminology in presenting our algorithm. For a set I of items, define the profit function

$$f_I(x) = \max\left\{ \sum_{i \in J} p_i : \sum_{i \in J} w_i \le x, \;\; J \subseteq I \right\}$$

over non-negative real numbers $x \ge 0$. Note that f_I is a monotone (nondecreasing) step function. The *complexity* of a monotone step function refers to the number of its steps.

We say that a function $\tilde{f}$ approximates a function f with factor $1 + \varepsilon$ if $\tilde{f}(x) \le f(x) \le (1 + \varepsilon)\tilde{f}(x)$ for all $x \ge 0$. We say that $\tilde{f}$ approximates f with additive error δ if $\tilde{f}(x) \le f(x) \le \tilde{f}(x) + \delta$ for all $x \ge 0$. Our goal is to approximate f_I with factor $1 + O(\varepsilon)$ on the input item set I.

Let I_1, I_2 be two disjoint subsets of items, and $I = I_1 \cup I_2$. We have $f_I = f_{I_1} \oplus f_{I_2}$, where $\oplus$ denotes the $(\max, +)$-convolution, defined by $(f \oplus g)(x) = \max_{0 \le x' \le x}(f(x') + g(x - x'))$. If two non-negative monotone step functions f, g are approximated with factor $1 + \varepsilon$ by functions $\tilde{f}, \tilde{g}$ respectively, then $f \oplus g$ is also approximated by $\tilde{f} \oplus \tilde{g}$ with factor $1 + \varepsilon$.

For a monotone step function f with range[1] contained in $\{0\} \cup [A, B]$, we can obtain a function $\tilde{f}$ with complexity only $O(\varepsilon^{-1} \log(B/A))$ which approximates f with factor $1 + \varepsilon$, by simply rounding f down to powers of $(1 + \varepsilon)$. For our purposes, B/A will be bounded by polynomial of n and $1/\varepsilon$, hence we may always assume that the approximation results are monotone step functions with complexity $\tilde{O}(\varepsilon^{-1})$.

For an item set I with the same profit $p_i = p$ for every item $i \in I$, the step function f_I can be exactly computed in $O(n \log n)$ time by simple greedy: the function values are $0, p, 2p, \ldots, np$ and the x-breakpoints are $w_1, w_1 + w_2, \ldots, w_1 + \cdots + w_n$, after sorting all w_i's in nondecreasing order. We say that a monotone step function is *p-uniform* if its function values are of the form $0, p, 2p, \ldots, lp$ for some l. We say that a p-uniform function is *pseudo-concave* if the differences of consecutive x-breakpoints are nondecreasing from left to right. In the previous case where all p_i's are equal to p, f_I is indeed p-uniform and pseudo-concave.

[1] Here *range* refers to the set of possible output values of the function.

3 Chan's techniques

In this section we review several useful lemmas by Chan [3].

3.1 Merging profit functions

▶ **Lemma 3** ([3, Lemma 2(i)]). *Let $f_1, \dots, f_m$ be monotone step functions with total complexity $O(n)$ and ranges contained in $\{0\} \cup [A, B]$. Then we can compute a monotone step function that approximates $f_1 \oplus \cdots \oplus f_m$ with factor $1 + O(\varepsilon)$ and complexity $\tilde{O}(\frac{1}{\varepsilon} \log B/A)$ in $O(n) + \tilde{O}((\frac{1}{\varepsilon})^2 m / 2^{\Omega(\sqrt{\log(1/\varepsilon)})} \log B/A)$ time.*

▶ Remark 4. Lemma 3 is proved using a divide-and-conquer method, which was also used previously in [10]. The speedup of superpolylogarithmic factor $2^{\Omega(\sqrt{\log(1/\varepsilon)})}$ is due to recent progress on $(\min, +)$-convolution [2, 16, 4].

Lemma 3 enables us to focus on a simpler case where all $p_i \in [1, 2]$. For the general case, we divide the items into $O(\log \frac{\max_j p_j}{\min_j p_j}) = O(\log \varepsilon^{-1})$ groups, each containing items with $p_i \in [2^j, 2^{j+1}]$ for some j (which can be rescaled to $[1, 2]$), and finally merge the profit functions of all groups by using Lemma 3 in $\tilde{O}(n + \varepsilon^{-2})$ time.

Assuming ε^{-1} is an integer and every $p_i \in [1, 2]$, we can round every p_i down to a multiple of ε, introducing only a $1 + \varepsilon$ error factor. Then there are only $m = O(\varepsilon^{-1})$ distinct values of p_i. For every value of p_i, the corresponding profit function f_i is p_i-uniform and pseudo-concave, and can be obtained by simple greedy (as discussed in Section 2).

3.2 Approximating big profit values using greedy

When all p_i's are small, simple greedy gives good approximation guarantee when the answer is big enough.

▶ **Lemma 5.** *Suppose $p_i \in [1, 2]$ for all $i \in I$. For $B = \Omega(\varepsilon^{-1})$, the function f_I can be approximated with additive error $O(\varepsilon B)$ in $O(n \log n)$ time.*

Proof. Sort the items in nonincreasing order of unit profit p_i/w_i. Let $\tilde{f}$ be the monotone step function resulting from greedy, with function values $0, p_1, p_1 + p_2, \dots, p_1 + \cdots + p_n$ and x-breakpoints $0, w_1, w_1 + w_2, \dots, w_1 + \cdots + w_n$. It approximates f_I with an additive error of $\max_i p_i \le 2 \le O(\varepsilon B)$ for $B = \Omega(\varepsilon^{-1})$. ◀

When every $p_i \in [1, 2]$, we set $B = \varepsilon^{-1}$ and let f_H denote the result from greedy (Lemma 5). Then we only need to obtain a function f_L which $1 + O(\varepsilon)$ approximates $\min\{f_I, B\}$, and finally return $\max\{f_L, f_H\}$ as a $1 + O(\varepsilon)$ approximation of f_I (because when $f_I(x)$ exceeds B, an additive error $O(\varepsilon B)$ implies $1 + O(\varepsilon)$ approximation factor).

3.3 Approximation using Δ-multiples of small set Δ

For a set Δ of numbers, we say that p is a Δ-multiple if it is a multiple of δ for some $\delta \in \Delta$.

▶ **Lemma 6** ([3, Lemma 5]). *Let $f_1, \dots, f_m$ be monotone step functions with ranges contained in $[0, B]$. Let $\Delta \subset [\delta, 8\delta]$. If every f_i is p_i-uniform and pseudo-concave for some $p_i \in [1, 2]$ which is a Δ-multiple, then we can compute a monotone step function that approximates $\min\{f_1 \oplus \cdots \oplus f_m, B\}$ with additive error $O(|\Delta|\delta)$ in $\tilde{O}(Bm/\delta)$ time.*

▶ Remark 7. An intuition of Lemma 6 is as follows. When p_i's are exact multiples of δ, standard dynamic programming algorithm maintains a result array of length B/δ, and adding a new f_i to the result can be done in linear time (by exploiting the pseudo-concavity of f_i using the SMAWK algorithm[2]). Now if the next p_i to be considered is a multiple of $\delta' \neq \delta$, we first have to round down the current results to multiples of δ', introducing an additive error of δ'. We round our results for $|\Delta| - 1$ times, so smaller $|\Delta|$ implies smaller overall additive error.

▶ **Corollary 8.** *Let $f_1, \ldots, f_m$ be monotone step functions with ranges contained in $[0, B]$. If every f_i is p_i-uniform and pseudo-concave for some $p_i \in [1, 2]$, then we can compute a monotone step function that approximates $\min\{f_1 \oplus \cdots \oplus f_m, B\}$ with factor $1 + O(\varepsilon)$ in $\tilde{O}(\varepsilon^{-1}Bm)$ time.*

Proof. Assuming ε^{-1} is an integer, adjust every p_i down to the nearest multiple of ε, and adjust f_i accordingly. This introduces a $1 + \varepsilon$ overall error factor. Then use Lemma 6 with $\delta = \varepsilon, \Delta = \{\varepsilon\}$ to compute the desired function in $\tilde{O}(Bm\varepsilon^{-1})$ time. ◀

4 Extending Chan's number-theoretic construction

As mentioned in Section 1.3, the main results of this section are two approximation algorithms in $\tilde{O}(n + \varepsilon^{-2}B^{1/3})$ and $\tilde{O}(\varepsilon^{-3/2}n^{3/4} + \varepsilon^{-2})$ time respectively (the latter time bound assumes $n = O(1/\varepsilon)$). These results rely on Lemma 6.

4.1 Number-theoretic construction

To avoid checking boundary conditions, from now on we assume $\varepsilon > 0$ is sufficiently small.

Our algorithm extends Chan's technique by using a multi-level structure defined as follows.

▶ **Definition 9.** *For fixed parameters $\delta_1, \delta_2, \ldots, \delta_d$ satisfying condition*

$$\varepsilon \leq \delta_1,\ \delta_i \leq \delta_{i+1}/2,\ \delta_d \leq 1/8 \tag{1}$$

and a finite real number set $\Delta_1 \subset [\delta_1, 8\delta_1]$, a set tower *$(\Delta_1, \Delta_2, \ldots, \Delta_d)$ generated by Δ_1 is defined by recurrence*[3]

$$\Delta_{i+1} := [\delta_{i+1}, 8\delta_{i+1}] \cap \bigcup_{k \in \mathbb{Z}} k\Delta_i, \quad i = 1, 2, \ldots, d-1. \tag{2}$$

We refer to Δ_1 as the base set *and Δ_d as the* top set *of this set tower. We also say that the base set Δ_1 generates the top set Δ_d.*

If Δ_d^* is the top set generated by a singleton base set $\Delta_1^* = \{x\}$, then for every $y \in \Delta_d^*$ we say x generates *y.*

We have the following simple facts about set towers.

▶ **Proposition 10.** *If x generates y then $x \in \Delta_1$ implies $y \in \Delta_d$. Conversely, for every $y \in \Delta_d$, there exists $x \in \Delta_1$ which generates y, and for every $1 \leq i \leq d$ there exists $z \in \Delta_i$ such that both y/z and z/x are integers.*

---

[2] The SMAWK algorithm [1] finds all row-minima in an $n \times n$ matrix A satisfying the *Monge property* $A[i, j] + A[i + 1, j + 1] \leq A[i, j + 1] + A[i + 1, j]$ using only $O(n)$ queries.

[3] For a number k and a set A of numbers, $kA := \{ka : a \in A\}$.

▶ **Proposition 11.** *For any $1 \le i \le d$, $|\Delta_i| \le 8^{i-1}(\delta_i/\delta_1)|\Delta_1|$, and we can compute Δ_i in $\tilde{O}(8^{i-1}(\delta_i/\delta_1)|\Delta_1|)$ time given Δ_1 as input.*

Proof. For $2 \le i \le d$, we have

$$|\Delta_i| = \Big|[\delta_i, 8\delta_i] \cap \bigcup_{k\in\mathbb{Z}} k\Delta_{i-1}\Big| \le \sum_{x\in\Delta_{i-1}} 8\delta_i/x \le |\Delta_{i-1}|8\delta_i/\delta_{i-1}.$$

The proof of size upper bounds follows by induction. Elements of Δ_i can be generated straightforwardly within the time bound. ◀

▶ **Lemma 12.** *Let $T_1, T_2, \ldots, T_d$ be positive real numbers satisfying $T_1 \ge 2$ and $T_{i+1} \ge 2T_i$. There exist at least $T_d/(\log T_d)^{O(d)}$ integers t satisfying the following condition: t can be written as a product of integers $t = n_1 n_2 \cdots n_d$, such that $n_1 n_2 \cdots n_i \in (T_i/2, T_i]$ for every $1 \le i \le d$.*

The proof of Lemma 12 is deferred to Appendix A. Lemma 12 helps us prove the following fact, which is a multi-level extension of [3, Lemma 6].

▶ **Lemma 13.** *For any parameters $\delta_1, \ldots, \delta_d$ satisfying condition (1), there exists a base set Δ_1 of size $\frac{\delta_1}{\varepsilon} \cdot (\log \varepsilon^{-1})^{O(d)}$, such that every $p \in [1, 2]$ can be approximated by a Δ_d-multiple with additive error $O(\varepsilon)$, where Δ_d is the top set generated by Δ_1.*

This base set Δ_1 can be constructed in $\tilde{O}(\varepsilon^{-1}\delta_1^{-1})$ time deterministically.

Proof. Let $P = \{1, 1+\varepsilon, 1+2\varepsilon, \ldots, 1+\lfloor\frac{1}{\varepsilon}\rfloor\varepsilon\}$. It suffices to approximate every value $p \in P$ with additive error ε using Δ_d-multiples. For any $p \in P$ and $y \in \Delta_d \subset [\delta_d, 8\delta_d]$, p is approximated with additive error ε by a multiple of y if and only if $y \in \bigcup_{j\in\mathbb{Z}} \left[\frac{p-\varepsilon}{j}, \frac{p}{j}\right]$.

Our constructed base set Δ_1 will satisfy $\Delta_1 \subset [\delta_1, 4\delta_1]$. Suppose integers $k_1, k_2, \ldots, k_{d-1}$ satisfy

$$k_1 k_2 \cdots k_{i-1} \in [\delta_i/\delta_1, 2\delta_i/\delta_1], \quad \text{for every } 2 \le i \le d. \tag{3}$$

Then by Definition 9, for any $x \in \Delta_1 \subset [\delta_1, 4\delta_1]$, we have $xk_1k_2\cdots k_{i-1} \in \Delta_i$ for every $2 \le i \le d$.

For any integer j satisfying

$$k_1 k_2 \cdots k_{d-1} j \in [p/(4\delta_1), p/(2\delta_1)], \tag{4}$$

the interval $[\frac{p-\varepsilon}{k_1k_2\cdots k_{d-1}j}, \frac{p}{k_1k_2\cdots k_{d-1}j}]$ is contained in $[\delta_1, 4\delta_1]$.

We say an integer K is *good* for p, if K can be expressed as a product of integers $k_1k_2\cdots k_{d-1}j$ satisfying conditions (3) and (4). For such K, any $x \in [\frac{p-\varepsilon}{K}, \frac{p}{K}] \cap \Delta_1$ generates an element $y = xk_1k_2\cdots k_{d-1} \in \Delta_d \cap [\frac{p-\varepsilon}{j}, \frac{p}{j}]$ such that p can be approximated by a multiple of y with additive error ε.

By Lemma 12, the number of good integers K for p is at least

$$\frac{p/(4\delta_1)}{\big(\log(p/(4\delta_1))\big)^{O(d)}} = \Omega\Big(\frac{\delta_1^{-1}}{(\log\varepsilon^{-1})^{O(d)}}\Big),$$

and at most $p/(2\delta_1) = O(\delta_1^{-1})$, by (4). Using conditions (3) and (4) we can compute all these K's by simple dynamic programming. We denote the union of their associated intervals by

$$I_p := \bigcup_{K \text{ good for } p} \left[\frac{p-\varepsilon}{K}, \frac{p}{K}\right] \subset [\delta_1, 4\delta_1]. \tag{5}$$

Note that these intervals are disjoint since $p/(K+1) \le (p-\varepsilon)/K$, so the total length of I_p can be lower-bounded as

$$\lambda(I_p) \ge \frac{\delta_1^{-1}}{(\log \varepsilon^{-1})^{O(d)}} \cdot \frac{p-(p-\varepsilon)}{\max K} \ge \frac{\varepsilon}{(\log \varepsilon^{-1})^{O(d)}}. \tag{6}$$

We have seen that p is approximated by a Δ_d-multiple with additive error ε as long as $\Delta_1 \cap I_p \neq \emptyset$. We compute I_p for every $p \in P$, and use the standard greedy algorithm (for Hitting Set problem) to construct a base set $\Delta_1 \subset [\delta_1, 4\delta_1]$ which intersects with every I_p: in each round we find a point $x \in [\delta_1, 4\delta_1]$ that hits the most I_p's, include x into Δ_1, and remove the I_p's that are hit by x. In each round the number of remaining I_p's decreases by

$$s := \frac{\min_p \lambda(I_p)}{4\delta_1 - \delta_1} \ge \frac{\varepsilon/\delta_1}{(\log \varepsilon^{-1})^{O(d)}},$$

so the solution size $|\Delta_1|$ is upper-bounded by

$$1 + \log_{1/(1-s)} |P| = O\left(\frac{\log |P|}{s}\right) = \frac{\delta_1}{\varepsilon} (\log \varepsilon^{-1})^{O(d)}.$$

To implement this greedy algorithm, we use standard data structures (for example, segment trees) that support finding x which hits the most intervals, reporting an interval hit by x, removing an interval, all in logarithmic time per operation. The number of operations is bounded by the total number of small intervals, so the running time is at most $\tilde{O}(|P| \cdot \frac{p}{2\delta_1}) = \tilde{O}(\delta_1^{-1}\varepsilon^{-1})$. ◀

The following lemma evenly partitions the base set Δ_1 into r subsets $\Delta_1^{(1)}, \ldots, \Delta_1^{(r)}$, and partitions the profit values $P = \{p_1, \ldots, p_m\}$ into $P^{(1)} \cup \cdots \cup P^{(r)}$, so that $P^{(j)}$ can be approximated by $\Delta_d^{(j)}$-multiples. An additional requirement is that $P^{(1)}, \ldots, P^{(r)}$ should have size $O(|P|/r)$ each.

▶ **Lemma 14.** *Let $\delta_1, \ldots, \delta_d$ be parameters satisfying condition (1). Let $P = \{p_1, \ldots, p_m\} \subset [1,2]$ with $m = O(\varepsilon^{-1})$. Given a positive integer parameter $r = O(\min\{\frac{\delta_1}{\varepsilon}, m\})$, there exist r base sets $\Delta_1^{(1)}, \Delta_1^{(2)}, \ldots, \Delta_1^{(r)}$ each of size $\frac{\delta_1}{\varepsilon r} \cdot (\log \varepsilon^{-1})^{O(d)}$, and a partition of $P = P^{(1)} \cup P^{(2)} \cup \cdots \cup P^{(r)}$ each of size $O(m/r)$, such that for every $1 \le j \le r$, every $p \in P^{(j)}$ can be approximated by a $\Delta_d^{(j)}$-multiple with additive error $O(\varepsilon)$, where $\Delta_d^{(j)}$ is the top set generated by $\Delta_1^{(j)}$.*

These r base sets and the partition of P can be computed by a deterministic algorithm in $\tilde{O}(\varepsilon^{-2}/r)$ time .

Proof. First construct the base set Δ_1 of size $\frac{\delta_1}{\varepsilon}(\log \varepsilon^{-1})^{O(d)}$ from Lemma 13 in $\tilde{O}(\delta_1^{-1}\varepsilon^{-1}) = \tilde{O}(\varepsilon^{-2}/r)$ time, and compute the top set Δ_d that it generates. By Proposition 11, $|\Delta_d| \le 8^{d-1}\frac{\delta_d}{\delta_1}|\Delta_1| \le \frac{\delta_d}{\varepsilon}(\log \varepsilon^{-1})^{O(d)}$. Generate and sort all Δ_d-multiples in interval $[1,2]$. For every $p \in P$, use binary search to find the Δ_d-multiple $ky \le p\,(y \in \Delta_d)$ closest to p, and then add p to the set Q_x, where $x \in \Delta_1$ is an element that generates y. (Q_x is initialized as empty for every $x \in \Delta_1$.) Then remove every x with $Q_x = \emptyset$ from Δ_1, so that $|\Delta_1| \le m$, while every $p \in P$ can still be approximated with $O(\varepsilon)$ additive error by a Δ_d-multiple.

Let $D := \max\{r, |\Delta_1|\}$ and let $s := \lceil m/D \rceil$. For every $x \in \Delta_1$ we divide Q_x evenly into small subsets each having size at most s. The total number of these small subsets is

$$\sum_{x \in \Delta_1} \lceil |Q_x|/s \rceil \le |\Delta_1| + \sum_{x \in \Delta_1} |Q_x|/s = |\Delta_1| + m/s \le 2D.$$

We merge these small subsets into r groups, each having at most $\lceil 2D/r \rceil$ small subsets. Then, define set $P^{(j)}$ as the union of small subsets from the j-th group, and let base set $\Delta_1^{(j)}$ contain $x \in \Delta_1$ if any of these small subsets comes from Q_x. So $|\Delta_1^{(j)}| \le \lceil 2D/r \rceil = \frac{\delta_1}{\varepsilon r}(\log \varepsilon^{-1})^{O(d)}$, and $|P^{(j)}| \le s \cdot \lceil 2D/r \rceil = O(m/D) \cdot O(D/r) = O(m/r)$. ◀

4.2 Approximation using set towers

We first prove a slightly improved version of Corollary 8. The only purpose of this lemma is to get rid of the $(\log \varepsilon^{-1})^{O(\log\log \varepsilon^{-1})}$ factor in the final running time.

▶ **Lemma 15.** *Let $f_1, \ldots, f_m$ be monotone step functions with ranges contained in $[0, B]$ for some $1 \le B \le O(\varepsilon^{-1})$. If every f_i is p_i-uniform and pseudo-concave for some $p_i \in [1, 2]$, then we can compute a monotone step function that approximates $\min\{f_1 \oplus \cdots \oplus f_m, B\}$ with factor $1 + O(\varepsilon)$ in $\tilde{O}(\varepsilon^{-1}(Bm + \varepsilon^{-1})/B^{0.01})$ time.*

Proof. Using Lemma 13 with parameters $d = 1, \delta_1 = \varepsilon B^{0.01}$, we get $\Delta \subset [\delta_1, 8\delta_1]$ with size $|\Delta| \le \tilde{O}(\delta_1/\varepsilon) = \tilde{O}(B^{0.01})$, in $\tilde{O}(\varepsilon^{-2}/B^{0.01})$ time. Adjust every p_i down to the nearest Δ-multiple, and adjust f_i accordingly. This introduces at most $1+O(\varepsilon)$ error factor. Then use Lemma 6 to compute a monotone step function f_H that approximates $\min\{f_1 \oplus \cdots \oplus f_m, B\}$ with additive error $e = O(|\Delta|\delta_1) = \tilde{O}(\varepsilon B^{0.02})$, in $\tilde{O}(B^{0.99} m\varepsilon^{-1})$ time.

Let $B_L := e/\varepsilon$, and use Corollary 8 to compute a monotone step function f_L that approximates $\min\{f_1 \oplus \cdots \oplus f_m, B_L\}$ with factor $1+O(\varepsilon)$ in only $\tilde{O}(B_L m\varepsilon^{-1}) = \tilde{O}(B^{0.02} m\varepsilon^{-1})$ time.

Since f_H approximates $\min\{f_1 \oplus \cdots \oplus f_m, B\}$ with additive error εB_L, $\max\{f_L, f_H\}$ is a $1 + O(\varepsilon)$ approximation of $\min\{f_1 \oplus \cdots \oplus f_m, B\}$. ◀

Now we can approximate the profit function $\min\{B, \bigoplus_{p_k \in P^{(j)}} f_k\}$ for each group $P^{(j)}$, using the multi-level approach described in Section 1.3.

▶ **Lemma 16.** *Let $f_1, \ldots, f_m$ be given monotone step functions with ranges contained in $[0, B]$, and every f_k is p_k-uniform and pseudo-concave for some $p_k \in [1, 2]$. Assume $m = O(\varepsilon^{-1})$, $\Omega(\varepsilon^{-0.01}) \le B \le O(\varepsilon^{-1})$. Let r be a given positive integer parameter with $r = O(m), r = o(B)$.*

We can set $d = O(\log\log \varepsilon^{-1})$ and choose d parameters $\delta_1, \ldots, \delta_d$ satisfying condition (1), such that the following statement holds:

Let $P^{(1)} \cup \cdots \cup P^{(r)}$ be the partition of set $P = \{p_1, \ldots, p_m\}$ returned by the algorithm in Lemma 14 with the above parameters. Then for any $1 \le j \le r$, using the base set $\Delta_1^{(j)}$ from Lemma 14, we can compute a monotone step function that approximates $\min\{B, \bigoplus_{p_k \in P^{(j)}} f_k\}$ with factor $1 + O(\varepsilon)$, in $(\varepsilon^{-2}/r^{0.01} + m\varepsilon^{-1}B^{1/2}/r^{3/2})(\log \varepsilon^{-1})^{O(d)}$ time.

Proof. We can assume $B \ge 4r$, and define d to be the unique positive integer such that

$$2^{2^{d-1}} \le \frac{\sqrt{B}}{\sqrt{r}} < 2^{2^d} = 4^{2^{d-1}}.$$

Then $d = O(\log\log \frac{\sqrt{B}}{\sqrt{r}}) = O(\log\log \varepsilon^{-1})$. Pick $\alpha \in [2, 4)$ such that

$$\alpha^{2^{d-1}} = \frac{\sqrt{B}}{\sqrt{r}}. \tag{7}$$

Define

$$\delta_i := \varepsilon\sqrt{Br} \Big/ \alpha^{2^{d-i}},\ 0 \le i \le d. \tag{8}$$

Then

$$\delta_d = \frac{\varepsilon\sqrt{Br}}{\alpha},\ \delta_1 = \varepsilon r \tag{9}$$

Note that $\delta_d = \varepsilon\sqrt{B}\cdot O(\sqrt{r}) = \varepsilon\sqrt{B}\cdot o(\sqrt{B}) = \varepsilon\cdot o(B) = o(1)$. Hence the parameters $\delta_1,\ldots,\delta_d$ satisfy condition (1) for sufficiently small ε.

The base set $\Delta_1^{(j)}$ from Lemma 14 has size $\frac{\delta_1}{\varepsilon r}(\log\varepsilon^{-1})^{O(d)}$. We compute the generated set tower $\Delta_1^{(j)},\Delta_2^{(j)},\ldots,\Delta_d^{(j)}$. By Proposition 11, $|\Delta_i^{(j)}| \le \frac{\delta_i}{\varepsilon r}(\log\varepsilon^{-1})^{O(d)}$. Let

$$t := \max\left\{\alpha,\ \max_j |\Delta_i^{(j)}| \Big/ \frac{\delta_i}{\varepsilon r}\right\} = (\log\varepsilon^{-1})^{O(d)} \tag{10}$$

and define

$$B_i := Bt\Big/\alpha^{2^{d-i}},\ 0\le i\le d. \tag{11}$$

Then $B \le B_d \le B\cdot(\log\varepsilon^{-1})^{O(d)}$, and it's easy to verify that

$$|\Delta_i^{(j)}|\cdot\delta_i \le B_{i-1}\varepsilon,\ \ (1\le i\le d). \tag{12}$$

For every $1\le i\le d$, adjust every $p_k\in P^{(j)}$ down to the nearest $\Delta_i^{(j)}$-multiple and adjust f_k accordingly, which introduces a $1+O(\varepsilon)$ error factor. Then use Lemma 6 to obtain a monotone step function g_i which approximates $\min\{\bigoplus_{p_k\in P^{(j)}} f_k, B_i\}$ with additive error $O(|\Delta_i^{(j)}|\delta_i) = O(\varepsilon B_{i-1})$ in $\tilde{O}(|P^{(j)}|B_i/\delta_i)$ time.

Then we use Lemma 15 to obtain a monotone step function g_0 which approximates $\min\{\bigoplus_{p_k\in P^{(j)}} f_k, B_0\}$ with $1+O(\varepsilon)$ factor, in $\tilde{O}(\varepsilon^{-1}(|P^{(j)}|B_0+\varepsilon^{-1})B_0^{-0.01})$ time. Notice that $B_0 = rt$.

Finally, $\max\{g_0,g_1,g_2,\ldots,g_d\}$ is a $1+O(\varepsilon)$ approximation of $\min\{\bigoplus_{p_k\in P^{(j)}} f_k, B_d\}$, where $B_d\ge B$. Overall running time is

$$\begin{aligned}
&\tilde{O}(\varepsilon^{-1}(|P^{(j)}|B_0+\varepsilon^{-1})B_0^{-0.01}) + \sum_{1\le j\le d}\tilde{O}(|P^{(j)}|B_j/\delta_j)\\
&= \tilde{O}\big(\varepsilon^{-1}(\frac{m}{r}\cdot(rt)+\varepsilon^{-1})(rt)^{-0.01}\big) + d\cdot\tilde{O}\big(\frac{m}{r}B_d/\delta_d\big)\\
&= (\varepsilon^{-2}/r^{0.01} + m\varepsilon^{-1}B^{1/2}/r^{3/2})(\log\varepsilon^{-1})^{O(d)}.
\end{aligned}$$

◀

Now we merge the results from all r groups, and obtain an approximation of the final result $\min\{f_1\oplus\cdots\oplus f_m, B\}$.

▶ **Lemma 17.** *Let $f_1,\ldots,f_m$ be given monotone step functions with ranges contained in $[0,B]$, and every f_k is p_k-uniform and pseudo-concave for some $p_k\in[1,2]$. Assume $m = O(1/\varepsilon), \Omega(\varepsilon^{-0.01}) \le B \le O(\varepsilon^{-1})$. We can approximate $\min\{f_1\oplus\cdots\oplus f_m, B\}$ with factor $1+O(\varepsilon)$ in $O(\varepsilon^{-2}B^{1/3}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time.*

Proof. Assume $m\ge\varepsilon^{-1}$, by adding zero functions which do not change the answer.

Let $r = o(B)$ be a positive integer parameter to be determined later.

Using Lemma 14 and Lemma 16, we can get a partition of $\{p_1,\ldots,p_m\} = P^{(1)}\cup\cdots\cup P^{(r)}$ and then get an $1+O(\varepsilon)$ approximation of $\min\{\bigoplus_{p_k\in P^{(j)}} f_k, B\}$ for every $1\le j\le r$, in $r\cdot(\varepsilon^{-2}/r^{0.01} + m\varepsilon^{-1}B^{1/2}/r^{3/2})(\log\varepsilon^{-1})^{O(d)} = (r^{0.99}+\sqrt{B/r})\varepsilon^{-2}(\log\varepsilon^{-1})^{O(\log\log\varepsilon^{-1})}$ overall time.

Then we use Lemma 3 to merge all these r functions in $\tilde{O}((\frac{1}{\varepsilon})^2 r/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time.

Setting $r = B^{1/3}2^{c\sqrt{\log(1/\varepsilon)}}$, where $c > 0$ is some small enough constant, the total complexity is

$$O(\varepsilon^{-2}B^{1/3}/2^{\Omega(\sqrt{\log(1/\varepsilon)})}).$$ ◀

▶ **Lemma 18.** *Let I be a set of m items with $p_i \in [1,2]$ for every $i \in I$, where $\Omega(\varepsilon^{-2/3}) \le m \le O(\varepsilon^{-1})$. One can approximate f_I with factor $1+O(\varepsilon)$ in $O(\varepsilon^{-3/2}m^{3/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time.*

Proof. Let $f_1, \ldots, f_m$ denote the profit functions of the m items.

Let $r = o(m^{1/2})$ be a positive integer parameter to be determined later. Obtain a partition of $\{p_1, \ldots, p_m\} = P^{(1)} \cup \cdots \cup P^{(r)}$ using Lemma 14. Let $B := \max_i \sum_{p \in P^{(i)}} p \le 2\max_i |P^{(i)}| = \Theta(m/r)$. Then $r = o(B)$. Use Lemma 16 to get an $1+O(\varepsilon)$ approximation of $\bigoplus_{p_k \in P^{(j)}} f_k = \min\{\bigoplus_{p_k \in P^{(j)}} f_k, B\}$ for every $1 \le j \le r$, in $r \cdot (\varepsilon^{-2}/r^{0.01} + m\varepsilon^{-1}B^{1/2}/r^{3/2})(\log \varepsilon^{-1})^{O(d)} = (\varepsilon^{-2}r^{0.99} + m^{3/2}\varepsilon^{-1}/r)(\log \varepsilon^{-1})^{O(\log\log \varepsilon^{-1})}$ overall time.

Then we use Lemma 3 to merge all these r functions in $\tilde{O}((\frac{1}{\varepsilon})^2 r/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time.

Setting $r = m^{3/4}\varepsilon^{1/2}2^{c\sqrt{\log(1/\varepsilon)}}$, where $c > 0$ is some small enough constant, the total complexity is

$$O(\varepsilon^{-3/2}m^{3/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})}).$$ ◀

▶ **Corollary 19** (restated Theorem 2). *For $n = O(\frac{1}{\varepsilon})$, there is a deterministic $(1+\varepsilon)$-approximation algorithm for 0-1 knapsack in $O\Big((n^{3/4}(\frac{1}{\varepsilon})^{3/2} + (\frac{1}{\varepsilon})^2)/2^{\Omega(\sqrt{\log(1/\varepsilon)})}\Big)$ time.*

Proof. Divide the items into $O(\log \frac{n}{\varepsilon})$ groups, each containing items with $p_i \in [2^j, 2^{j+1}]$ for some j. Use Lemma 18 to solve each group, and merge them using Lemma 3. ◀

5 Main algorithm

5.1 A greedy lemma

Our improved algorithm uses the following lemma, which gives an upper bound on the total profit of cheap items (with low p_i/w_i) in an optimal knapsack solution.

▶ **Lemma 20.** *Let H, L be two subsets of items with $p_i \in [1,2]$. Let $W = \sum_{h\in H} w_h$ and $q = \min_{h\in H} \frac{p_h}{w_h}$. Suppose $\max_{l\in L} \frac{p_l}{w_l} \le q(1-\alpha)$ for some $0 < \alpha < 1$. Let $f = f_H \oplus f_L, \tilde{f} = f_H \oplus \min\{\frac{2}{\alpha}, f_L\}$. Then for every $x \le W$, $f(x) = \tilde{f}(x)$.*

Proof. By greedy, $f(W) = \sum_{h\in H} p_h = \tilde{f}(W)$ clearly holds. Now consider $0 \le x < W$. Suppose $f_L(x') + f_H(x-x')$ achieves its maximum value at $x' = w_L$, i.e., $f(x) = f_L(w_L) + f_H(x-w_L)$. It suffices to prove $f_L(w_L) \le \frac{2}{\alpha}$.

Let $J \subseteq H$ be a subset of items with total weight $w_J \le x - w_L$ and total profit achieving optimal value $f_H(x-w_L)$. Let $K \subseteq H\backslash J$ be a subset of items with total weight w_K, such that $w_K \le w_L$, and $w_K + w_i > w_L$ for every remaining item $i \in H\backslash(J \cup K)$. Such K can be constructed by a simple greedy algorithm.

Since $w_J + w_K \le (x - w_L) + w_L < W = \sum_{h\in H} w_h$, the remaining set $H\backslash(J\cup K)$ contains at least one item h_0. Hence, $w_L - w_K < w_{h_0} = p_{h_0}/\frac{p_{h_0}}{w_{h_0}} \le 2/q$, and equivalently $qw_K > qw_L - 2$.

Since $J \cup K$ is a subset of H with total weight bounded by x, we have $f_H(x) \geq \sum_{k\in K} p_k + \sum_{j\in J} p_j$, and thus $f_H(x) - f_H(x-w_L) = f_H(x) - \sum_{j\in J} p_j \geq \sum_{k\in K} p_k \geq qw_K > qw_L - 2$.

Hence $qw_L - 2 < f_H(x) - f_H(x-w_L) \leq f(x) - f_H(x-w_L) = f_L(w_L) \leq q(1-\alpha)w_L$, which shows that $q\alpha w_L \leq 2$. So $f_L(w_L) \leq q(1-\alpha)w_L \leq qw_L \leq 2/\alpha$, which concludes the proof. ◀

5.2 FPTAS for Subset Sum

We will use the efficient FPTAS for the subset sum problem by Kellerer et al. [9] as a subroutine in our algorithm.

▶ **Lemma 21** ([9], implicit). *Let I be a set of n items and W be a number. We can obtain a list S of $O(\frac{1}{\varepsilon})$ numbers in $O(n + (\frac{1}{\varepsilon})^2 \log \frac{1}{\varepsilon})$ time, such that for every $s \leq W$ that is the subset sum $s = \sum_{j\in J} w_j$ of some subset $J \subseteq I$, there exists $s' \in S$ with $s - \varepsilon W \leq s' \leq s$.*

▶ Remark 22. This result wasn't explicitly stated in [9], but can be easily seen from their analysis of the correctness of the FPTAS.

▶ **Corollary 23.** *Let I be a set of n items with $p_i \in [1,2]$ and $p_i = w_i$ for every item $i \in I$. We can approximate f_I with factor $1 + O(\varepsilon)$ in $O(n \log n + \varepsilon^{-2} \log \frac{1}{\varepsilon} \log n)$ time.*

Proof. Notice that approximating s with additive error εW implies approximation factor $1 + O(\varepsilon)$ for $W/2 \leq s \leq W$. So we simply apply Lemma 21 with $W = 2^j$ for $0 \leq j \leq 1 + \log n$, and merge all obtained lists. ◀

5.3 Improved algorithm

▶ **Lemma 24.** *Let I be a set of n items with $p_i \in [1,2]$ for every $i \in I$. We can approximate f_I with factor $1 + O(\varepsilon)$ in $O(n \log \frac{1}{\varepsilon} + (\frac{1}{\varepsilon})^{9/4} / 2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time.*

Proof. Let $B = \lceil \varepsilon^{-1} \rceil$ and assume $n \geq B$ (if $n < B$, we can simply apply Lemma 18). By Lemma 5, we can approximate f_I with additive error $O(\varepsilon B)$ in $O(n \log \frac{1}{\varepsilon})$ time, so we only need to approximate $\min\{f_I, B\}$ with factor $1 + O(\varepsilon)$.

We sort the items by their unit profits p_i/w_i. Let set H contain the top B items with the highest unit profits. Define $q = \min_{h\in H} \frac{p_h}{w_h}$, and let M be the set of remaining items i with $q(1-\alpha) \leq \frac{p_i}{w_i} \leq q$, where parameter $0 < \alpha < 1$ is to be determined later. Let set L contain the remaining items not included in H or M.

Using Lemma 18, we can compute $\tilde{f}_H$ which approximates f_H with factor $1 + O(\varepsilon)$ in time $O(B^{3/4}\varepsilon^{-3/2}/2^{\Omega(\sqrt{\log(1/\varepsilon)})}) = O(\varepsilon^{-9/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$.

Since $\max_{l\in L} \frac{p_l}{w_l} < q(1-\alpha)$, Lemma 20 states that $f_H \oplus f_L$ and $f_H \oplus \min\{2/\alpha, f_L\}$ agree when $x \leq W_H = \sum_{h\in H} w_h$. Since $(f_H \oplus f_L)(W_H) = \sum_{h\in H} p_h \geq B$, this implies $\min\{B, f_H \oplus f_L\} = \min\{B, f_H \oplus \min\{2/\alpha, f_L\}\}$. For every item $l \in L$, we round down p_l to a power of $1+\varepsilon$, so that there are only $\log_{1+\varepsilon} 2 = O(\varepsilon^{-1})$ distinct values. This only multiplies the approximation factor by $1 + \varepsilon$. Then we use Lemma 17 to compute an approximation of $\min\{2/\alpha, f_L\}$ with factor $1 + O(\varepsilon)$ in $\tilde{O}(\varepsilon^{-2}(2/\alpha)^{1/3}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ time. We merge it with $\tilde{f}_H$ and obtain an approximation of $\min\{f_H \oplus f_L, B\}$ with factor $1 + O(\varepsilon)$.

For every $m \in M$, we round down p_m so that the unit profit p_m/w_m becomes a power of $1 + \varepsilon$. After rounding, the approximation factor is only multiplied by $1 + \varepsilon$, and there are at most $\log_{1+\varepsilon} \frac{q}{q(1-\alpha)} = O(\alpha/\varepsilon)$ distinct unit profits in M. Let M_q denote the set of items in M with unit profit q. For each q, we use Lemma 23 to obtain a $1 + \varepsilon$ approximation of the function f_{M_q} in $O(|M_q| + \varepsilon^{-2})$ time. Then we use Lemma 3 to merge these functions and obtain a $1 + \varepsilon$ approximation of f_M. The total time is $O(|M| \log n) + \tilde{O}(\alpha\varepsilon^{-3})$.

Finally we merge the functions and get an approximation of $\min\{B, f_L \oplus f_H \oplus f_M\}$ with factor $1 + O(\varepsilon)$. The total time is $O(n \log \frac{1}{\varepsilon}) + \tilde{O}(\alpha\varepsilon^{-3} + \varepsilon^{-2}(2/\alpha)^{1/3}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$, which is $O(n \log \frac{1}{\varepsilon} + \varepsilon^{-9/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$ if we choose $\alpha = \varepsilon^{3/4}/2^{c\sqrt{\log(1/\varepsilon)}}$ for a sufficiently small constant c. ◀

▶ **Corollary 25** (restated Theorem 1). *There is a deterministic $(1+\varepsilon)$-approximation algorithm for 0-1 knapsack with running time $O(n \log \frac{1}{\varepsilon} + (\frac{1}{\varepsilon})^{9/4}/2^{\Omega(\sqrt{\log(1/\varepsilon)})})$.*

Proof. Divide the items into $O(\log \frac{n}{\varepsilon})$ groups, each containing items with $p_i \in [2^j, 2^{j+1}]$ for some j. Use Lemma 24 to solve each group, and merge them using Lemma 3. ◀

A Proof of Lemma 12

▶ **Theorem 26** (Reminder of Lemma 12). *Let $T_1, T_2, \ldots, T_d$ be positive real numbers satisfying $T_1 \geq 2$ and $T_{i+1} \geq 2T_i$. There exist at least $T_d/(\log T_d)^{O(d)}$ integers t satisfying the following condition: t can be written as a product of integers $t = n_1 n_2 \cdots n_d$, such that $n_1 n_2 \cdots n_i \in (T_i/2, T_i]$ for every $1 \leq i \leq d$.*

Proof. For every $1 \leq k \leq d$, we say an ordered k-tuple $(p_1, p_2, \ldots, p_k)$ is *valid* if every p_i is prime, and $p_1 p_2 \cdots p_i \in (T_i/2, T_i]$ for every $1 \leq i \leq k$. Then the product $t = p_1 p_2 \cdots p_d$ of any valid d-tuple $(p_1, \ldots, p_d)$ satisfies our condition. For any integer t, there are at most $d!$ different valid d-tuples with product t (which could be obtained by permuting t's prime factors). Let N_k denote the number of valid k-tuples. Then it suffices to show $N_d/(d!) \geq T_d/(\log T_d)^{O(d)}$.

By the prime number theorem and Bertrand-Chebyshev theorem, there exists a positive constant C such that

$$\pi(x) - \pi(x/2) \geq x/(C \log x), \text{ for all } x \geq 2,$$

where $\pi(x)$ denotes the number of primes less than or equal to x. We will prove $N_k \geq T_k/(C \log T_k)^k$ for all $1 \leq k \leq d$ by induction.

First note that this statement is trivial for $k = 1$. For $k \geq 2$, a valid k-tuple $(p_1, \ldots, p_k)$ can be obtained by appending any prime $p_k \in \big(T_k/(2P), T_k/P\big]$ to any valid $(k-1)$-tuple $(p_1, \ldots, p_{k-1})$ with product $P = p_1 \cdots p_{k-1} \leq T_{k-1}$. The number of such primes p_k is

$$\pi(T_k/P) - \pi\big(T_k/(2P)\big) \geq \frac{T_k/P}{C \log(T_k/P)} \geq \frac{T_k/T_{k-1}}{C \log T_k}.$$

Summing over all valid $(k-1)$-tuples, we have

$$N_k \geq N_{k-1} \cdot \frac{T_k/T_{k-1}}{C \log T_k} \geq \frac{T_{k-1}}{(C \log T_{k-1})^{k-1}} \cdot \frac{T_k/T_{k-1}}{C \log T_k} \geq \frac{T_k}{(C \log T_k)^k}.$$

Hence, $N_d \geq T_d/(C \log T_d)^d$ by induction. Observe that $T_d \geq 2^d$ and we have

$$\frac{N_d}{d!} \geq \frac{T_d}{(Cd \log T_d)^d} \geq \frac{T_d}{(C \log^2 T_d)^d} \geq \frac{T_d}{(\log T_d)^{O(d)}},$$

which finishes the proof. ◀

Testing the Complexity of a Valued CSP Language

Vladimir Kolmogorov
Institute of Science and Technology Austria, Klosterneuburg, Austria
vnk@ist.ac.at

Abstract

A *Valued Constraint Satisfaction Problem* (VCSP) provides a common framework that can express a wide range of discrete optimization problems. A VCSP instance is given by a finite set of variables, a finite domain of labels, and an objective function to be minimized. This function is represented as a sum of terms where each term depends on a subset of the variables. To obtain different classes of optimization problems, one can restrict all terms to come from a fixed set Γ of cost functions, called a *language*.

Recent breakthrough results have established a complete complexity classification of such classes with respect to language Γ: if all cost functions in Γ satisfy a certain algebraic condition then all Γ-instances can be solved in polynomial time, otherwise the problem is NP-hard. Unfortunately, testing this condition for a given language Γ is known to be NP-hard. We thus study exponential algorithms for this *meta-problem*. We show that the tractability condition of a finite-valued language Γ can be tested in $O(\sqrt[3]{3}^{|D|} \cdot poly(\texttt{size}(\Gamma)))$ time, where D is the domain of Γ and $poly(\cdot)$ is some fixed polynomial. We also obtain a matching lower bound under the *Strong Exponential Time Hypothesis* (SETH). More precisely, we prove that for any constant $\delta < 1$ there is no $O(\sqrt[3]{3}^{\delta|D|})$ algorithm, assuming that SETH holds.

1 Introduction

Minimizing functions of discrete variables represented as a sum of low-order terms is a ubiquitous problem occurring in many real-world applications. Understanding complexity of different classes of such optimization problems is thus an important task. In a prominent *VCSP framework* (which stands for *Valued Constraint Satisfaction Problem*) a class is parameterized by a set Γ of cost functions of the form $f : D^n \to \mathbb{Q} \cup \{\infty\}$ that are allowed to appear as terms in the objective. Set Γ is usually called a *language*.

Different types of languages give rise to many interesting classes. A widely studied type is *crisp* languages Γ, in which all functions f are $\{0, \infty\}$-valued. They correspond to *Constraint Satisfaction Problems (CSPs)*, whose goal is to decide whether a given instance has a feasible solution. Feder and Vardi conjectured in [11] that there exists a dichotomy for CSPs, i.e. every crisp language Γ is either tractable or NP-hard. This conjecture was refined by Bulatov, Krokhin and Jeavons [7], who proposed a specific algebraic condition

46th International Colloquium on Automata, Languages, and Programming (ICALP 2019).

that should separate tractable languages from NP-hard ones. The conjecture was verified for many special cases [27, 5, 3, 2, 8], and was finally proved in full generality by Bulatov [6] and Zhuk [31].

At the opposite end of the VCSP spectrum are the finite-valued CSPs, in which functions do not take infinite values. In such VCSPs, the feasibility aspect is trivial, and one has to deal only with the optimization issue. One polynomial-time algorithm that solves tractable finite-valued CSPs is based on the so-called basic linear programming (BLP) relaxation, and its applicability (also for the general-valued case) was fully characterized by Kolmogorov, Thapper and Živný [22]. The complexity of finite-valued CSPs was completely classified by Thapper and Živný [29], where it is shown that all finite-valued CSPs not solvable by BLP are NP-hard.

A dichotomy is also known to hold for general-valued CSPs, i.e. when cost functions in Γ are allowed to take arbitrary values in $\mathbb{Q} \cup \{\infty\}$. First, Kozik and Ochremiak showed [23] that languages that do not satisfy a certain algebraic condition are NP-hard. Kolmogorov, Krokhin and Rolínek then proved [21] that all other languages are tractable, assuming the (now established) dichotomy for crisp languages conjectured in [7].

In this paper languages Γ that satisfy the condition in [23] are called *solvable*. Since optimization problems encountered in practice often come without any guarantees, it is natural to ask what is the complexity of checking solvability of a given language Γ. We envisage that an efficient algorithm for this problem could help in theoretical investigations, and could also facilitate designing optimization approaches for tackling specific tasks.

Checking solvability of a given language is known as a *meta-problem* or a *meta-question* in the literature. Note that it can be solved in polynomial time for languages on a fixed domain D (since the solvability condition can be expressed by a linear program with $O(|D|^{|D|^m})$ variables and polynomial number of constraints, where $m = 2$ if the language is finite-valued and $m = 4$ otherwise). This naive solution, however, becomes very inefficient if D is a part of the input (which is what we assume in this paper).

The meta-problem above was studied by Thapper and Živný for finite-valued languages [29], and by Chen and Larose for crisp languages [10]. In both cases it was shown to be NP-complete. We therefore focus on exponential-time algorithms. We obtain the following results for the problem of checking solvability of a given finite-valued language Γ:

- An algorithm with complexity $O(\sqrt[3]{3}^{|D|} \cdot \mathit{poly}(\mathtt{size}(\Gamma)))$, where D is the domain of Γ and $\mathit{poly}(\cdot)$ is some fixed polynomial.
- Assuming the *Strong Exponential Time Hypothesis* (SETH), we prove that for any constant $\delta < 1$ the problem cannot be solved in $O(\sqrt[3]{3}^{\delta|D|} \cdot \mathit{poly}(\mathtt{size}(\Gamma)))$ time.

We also present a few weaker results for general-valued languages (see Section 3).

Other related work. There is a vast literature devoted to exponential-time algorithms for various problems, both on the algorithmic side and on the hardness side. Hardness results usually assume one of the following two hypotheses [15, 16, 9].

▶ **Conjecture 1** (Exponential Time Hypothesis (ETH)). *Deciding satisfiability of a* 3*-CNF-SAT formula on* n *variables cannot be solved in* $O(2^{o(n)})$ *time.*

▶ **Conjecture 2** (Strong Exponential Time Hypothesis (SETH)). *For any* $\delta < 1$ *there exists integer* k *such that deciding satisfiability of a* k*-CNF-SAT formula on* n *variables cannot be solved in* $O(2^{\delta n})$ *time.*

Below we discuss some results specific to CSPs. Let (k, d)-CSP be the class of CSP problems on a d-element domain where each constraint involves at most k variables. The number of variables in an instance will be denoted as n. A trivial exhaustive search for

a (k,d)-CSP instance runs in $O^*(d^n)$ time, where notation $O^*(\cdot)$ hides factors polynomial in the size of the input. For $(2,d)$-CSP instances the complexity can be improved to $O^*((d-1)^n)$ [26]. Some important subclasses of $(2,d)$-CSP can even be solved in $O^*(2^{O(n)})$ time. For example, [25] and [4] developed respectively $O(2.45^n)$ and $O^*(2^n)$ algorithms for solving the d-coloring problem. On the negative side, ETH is known to have the following implications:

- The $(2,d)$-CSP problem cannot be solved in $d^{o(n)} = 2^{o(n \log d)}$ time [30].
- The Graph Homomorphism problem cannot be solved in $2^{o\left(\frac{n \log d}{\log \log d}\right)}$ time [12]. (This problem can be viewed as a special case of $(2,d)$-CSP, in which a single binary relation is applied to different pairs of variables).

Recently, exponential-time algorithms for crisp NP-hard languages have been studied using algebraic techniques [17, 18, 24]. For example, [18] showed that the following conditions are equivalent, assuming the (now proved) algebraic CSP dichotomy conjecture: (a) ETH fails; (b) there exists a finite crisp NP-hard language Γ that can be solved in subexponential time (i.e. all Γ-instances on n variables can be solved in $O(2^{o(n)})$ time); (c) all finite crisp NP-hard languages Γ can be solved in subexponential time.

The rest of the paper is organized as follows: Section 2 gives a background on the VCSP framework, and Section 3 presents our results. All proofs are given in the full version of this paper [20].

2 Background

We denote $\overline{\mathbb{Q}} = \mathbb{Q} \cup \{\infty\}$, where ∞ is the positive infinity. A function of the form $f : D^n \to \overline{\mathbb{Q}}$ will be called a *cost function over D of arity n*. We will always assume that the set D is finite. The *effective domain* of f is the set $\mathtt{dom}\, f = \{x \mid f(x) < \infty\}$. Note that $\mathtt{dom}\, f$ can be viewed both as an n-ary relation over D and as a function $D^n \to \{0, \infty\}$. We assume that f is represented as a list of pairs $\{(x, f(x)) \ : \ x \in \mathtt{dom}\, f\}$. Accordingly, we define $\mathtt{size}(f) = \sum_{x \in \mathtt{dom}\, f} [n \log |D| + \mathtt{size}(f(x))]$, where the size of a rational number p/q (for integers p, q) is $\log(|p|+1) + \log|q|$.

▶ **Definition 1.** *A valued constraint satisfaction language Γ over domain D is a set of cost functions $f : D^n \to \overline{\mathbb{Q}}$, where the arity n depends on f and may be different for different functions in Γ. The domain of Γ will be denoted as D_Γ. For a finite Γ we define $\mathtt{size}(\Gamma) = |D| + \sum_{f \in \Gamma} \mathtt{size}(f)$.*

A language Γ is called *finite-valued* if all functions $f \in \Gamma$ take finite (rational) values. It is called *crisp* if all functions $f \in \Gamma$ take only values in $\{0, \infty\}$. We denote $\mathrm{Feas}(\Gamma) = \{\mathtt{dom}\, f \mid f \in \Gamma\}$ to be the crisp language obtained from Γ in a natural way. Throughout the paper, for a subset $A \subseteq D$ we use u_A to denote the unary function $D \to \{0, \infty\}$ with $\arg\min u_A = A$. (Domain D should always be clear from the context). For a label $a \in D$ we also write $u_a = u_{\{a\}}$ for brevity.

▶ **Definition 2.** *An instance $\mathcal{I}$ of the valued constraint satisfaction problem (VCSP) is a function $D^V \to \overline{\mathbb{Q}}$ given by*

$$f_{\mathcal{I}}(x) \ = \ \sum_{t \in T} f_t(x_{v(t,1)}, \dots, x_{v(t,n_t)}) \tag{1}$$

It is specified by a finite set of variables V, finite set of terms T, cost functions $f_t : D^{n_t} \to \overline{\mathbb{Q}}$ of arity n_t and indices $v(t,k) \in V$ for $t \in T, k = 1, \dots, n_t$. A solution to $\mathcal{I}$ is a labeling $x \in D^V$ with the minimum total value. The size of $\mathcal{I}$ is defined as $\mathtt{size}(\mathcal{I}) = |V| + |D| + \sum_{t \in T} \mathtt{size}(f_t)$.

The instance $\mathcal{I}$ is called a Γ-instance if all terms f_t belong to Γ.

The set of all Γ-instances will be denoted as $\mathrm{VCSP}(\Gamma)$. A finite language Γ is called *tractable* if all instances $\mathcal{I} \in \mathrm{VCSP}(\Gamma)$ can be solved in polynomial time, and it is *NP-hard* if the corresponding optimization problem is NP-hard. A long sequence of works culminating with recent breakthrough papers [6, 31] has established that every finite language Γ is either tractable or NP-hard.

2.1 Polymorphisms and cores

Let $\mathcal{O}_D^{(m)}$ denote the set of all operations $g : D^m \to D$ and let $\mathcal{O}_D = \bigcup_{m \geq 1} \mathcal{O}_D^{(m)}$. When D is clear from the context, we will sometimes write simply $\mathcal{O}^{(m)}$ and $\mathcal{O}$.

Any language Γ defined on D can be associated with a set of operations on D, known as the polymorphisms of Γ, which allow one to combine (often in a useful way) several feasible assignments into a new one.

▶ **Definition 3.** *An operation $g \in \mathcal{O}_D^{(m)}$ is a* polymorphism *of a cost function $f : D^n \to \overline{\mathbb{Q}}$ if, for any $x^1, x^2, \ldots, x^m \in \mathtt{dom}\, f$, we have that $g(x^1, x^2, \ldots, x^m) \in \mathtt{dom}\, f$ where g is applied component-wise.*

For any valued constraint language Γ over a set D, we denote by $\mathrm{Pol}^{(m)}(\Gamma)$ the set of all operations on $\mathcal{O}_D^{(m)}$ which are polymorphisms of every $f \in \Gamma$. We also let $\mathrm{Pol}(\Gamma) = \bigcup_{m \geq 1} \mathrm{Pol}^{(m)}(\Gamma)$.

Clearly, if g is a polymorphism of a cost function f, then g is also a polymorphism of $\mathtt{dom}\, f$. For $\{0, \infty\}$-valued functions, which naturally correspond to relations, the notion of a polymorphism defined above coincides with the standard notion of a polymorphism for relations. Note that the projections (aka dictators), i.e. operations of the form $e_n^i(x_1, \ldots, x_n) = x_i$, are polymorphisms of all valued constraint languages. Polymorphisms play the key role in the algebraic approach to the CSP, but, for VCSPs, more general constructs are necessary, which we now define.

▶ **Definition 4.** *An m-ary* fractional operation *ω on D is a probability distribution on $\mathcal{O}_D^{(m)}$. The support of ω is defined as $\mathrm{supp}(\omega) = \{g \in \mathcal{O}_D^{(m)} \mid \omega(g) > 0\}$.*

For an operation $g \in \mathcal{O}^{(m)}$ we will denote χ_g to be characteristic vector of g, i.e. the fractional operation with $\chi_g(g) = 1$ and $\chi_g(h) = 0$ for $h \neq g$.

▶ **Definition 5.** *A m-ary fractional operation ω on D is said to be a* fractional polymorphism *of a cost function $f : D^n \to \overline{\mathbb{Q}}$ if, for any $x^1, x^2, \ldots, x^m \in \mathtt{dom}\, f$, we have*

$$\sum_{g \in \mathrm{supp}(\omega)} \omega(g) f(g(x^1, \ldots, x^m)) \leq \frac{1}{m}(f(x^1) + \ldots + f(x^m)). \tag{2}$$

For a constraint language Γ, $\mathrm{fPol}^{(m)}(\Gamma)$ will denote the set of all m-ary fractional operations that are fractional polymorphisms of each function in Γ. Also, let $\mathrm{fPol}(\Gamma) = \bigcup_{m \geq 1} \mathrm{fPol}^{(m)}(\Gamma)$, $\mathrm{supp}^{(m)}(\Gamma) = \bigcup_{\omega \in \mathrm{fPol}^{(m)}(\Gamma)} \mathrm{supp}(\omega)$ and $\mathrm{supp}(\Gamma) = \bigcup_{m \geq 1} \mathrm{supp}^{(m)}(\Gamma)$.

(It is easy to check that $\mathrm{supp}(\Gamma) \subseteq \mathrm{Pol}(\Gamma)$, and $\mathrm{supp}(\Gamma) = \mathrm{Pol}(\Gamma)$ if Γ is crisp).

Next, we will need the notion of *cores*.

▶ **Definition 6.** *Language Γ on domain D is called a* core *if all operations $g \in \mathrm{supp}^{(1)}(\Gamma)$ are bijections. Subset $B \subseteq D$ is called a* core of Γ *if $B = g(D)$ for some operation $g \in \mathrm{supp}^{(1)}(\Gamma)$ and the language $\Gamma[B]$ is a core, where $\Gamma[B]$ is the language on domain B obtained by restricting each function $f : D^n \to \overline{\mathbb{Q}}$ in Γ to B^n.*

The following facts are folklore knowledge. We do not know an explicit reference (at least in the case of general-valued languages), so we prove them in [20] for completeness.

▶ **Lemma 7.** *Let B be a subset of $D = D_\Gamma$ such that $B = g(D)$ for some $g \in \mathrm{supp}^{(1)}(\Gamma)$.*
(a) *Set B is a core of Γ if and only if $|B| = \texttt{core-size}(\Gamma) \stackrel{\text{def}}{=} \min\{|g(D)| : g \in \mathrm{supp}^{(1)}(\Gamma)\}$.*
(b) *There exists vector $\omega \in \mathrm{fPol}^{(1)}(\Gamma)$ such that $g(D) \subseteq B$ for all $g \in \mathrm{supp}(\omega)$. Furthermore, if B is a core of Γ then such ω can be chosen so that $g(a) = a$ for all $g \in \mathrm{supp}(\omega)$ and $a \in B$.*
(c) *Let $\mathcal{I}$ be a Γ-instance on variables V. Then $\min_{x \in B^V} f_{\mathcal{I}}(x) = \min_{x \in D^V} f_{\mathcal{I}}(x)$.*
For a language Γ we denote $\mathcal{B}_\Gamma^{\texttt{core}}$ to be the set of subsets $B \subseteq D$ which are cores of Γ, and $\mathcal{O}_\Gamma^{\texttt{core}}$ to be set of operations $g \in \mathrm{supp}^{(1)}(\Gamma)$ such that $g(D) \in \mathcal{B}_\Gamma^{\texttt{core}}$ (or equivalently such that $|g(D)| = \texttt{core-size}(\Gamma)$).

2.2 Dichotomy theorem

Several types of operations play a special role in the algebraic approach to (V)CSP.

▶ **Definition 8.** *An operation $g \in \mathcal{O}_D^{(m)}$ is called*
- idempotent *if $g(x, \dots, x) = x$ for all $x \in D$;*
- cyclic *if $m \geq 2$ and $g(x_1, x_2, \dots, x_m) = g(x_2, \dots, x_m, x_1)$ for all $x_1, \dots, x_m \in D$;*
- symmetric *if $m \geq 2$ and $g(x_1, x_2, \dots, x_m) = g(x_{\pi(1)}, x_{\pi(2)}, \dots, x_{\pi(m)})$ for all $x_1, \dots, x_m \in D$, and any permutation π on $[m]$;*
- Siggers *if $m = 4$ and $g(r, a, r, e) = g(a, r, e, a)$ for all $a, e, r \in D$.*

A fractional operation ω is said to be idempotent/cyclic/symmetric if all operations in $\mathrm{supp}(\omega)$ have the corresponding property.

Note, the Siggers operation is traditionally defined in the literature as an **idempotent** operation g satisfying $g(r, a, r, e) = g(a, r, e, a)$. Here we follow the terminology in [1] that does not require idempotency. (In [10] such an operation was called *quasi-Siggers*).

We can now formulate the dichotomy theorem.

▶ **Theorem 9.** *Let Γ be a language. If the core of Γ admits a cyclic fractional polymorphism then Γ is tractable [21, 6, 31]. Otherwise Γ is NP-hard [23].*

We will call languages Γ satisfying the condition of Theorem 9 *solvable*. The following equivalent characterizations of solvability are either known or can be easily be derived from previous work [28, 19, 22, 23] (see [20]):

▶ **Lemma 10.** *Let Γ be a language and $g \in \mathrm{supp}^{(1)}(\Gamma)$. The following conditions are equivalent:*
(a) *Γ is solvable.*
(b) *Γ admits a cyclic fractional polymorphism of some arity $m \geq 2$.*
(c) *$\mathrm{supp}(\Gamma)$ contains a Siggers operation.*
(d) *$\Gamma \cup \{u_a \mid a \in B\}$ is solvable for any core B of Γ.*
(e) *$\Gamma[g(D_\Gamma)]$ is solvable.*
Furthermore, a finite-valued language Γ is solvable if and only if it admits a symmetric fractional polymorphism of arity 2.

Note that checking solvability of a given language Γ is a decidable problem. Indeed, condition (c) can be tested by solving a linear program with $|\mathcal{O}_D^{(4)}| = |D|^{|D|^4}$ variables and $O(poly(\texttt{size}(\Gamma)))$ constraints, where we maximize the total weight of Siggers operations subject to linear constraints expressing that $\omega \in \mathbb{R}^{\mathcal{O}_D^{(4)}}$ is a fractional polymorphism of Γ of arity 4.

2.3 Basic LP relaxation

Symmetric operations are known to be closely related to LP-based algorithms for CSP-related problems. One algorithm in particular has been known to solve many VCSPs to optimality. This algorithm is based on the so-called *basic LP relaxation*, or BLP, defined as follows.

Let $\mathbb{M}_n = \{\mu \geq 0 \mid \sum_{x \in D^n} \mu(x) = 1\}$ be the set of probability distributions over labelings in D^n. We also denote $\Delta = \mathbb{M}_1$; thus, Δ is the standard $(|D|-1)$-dimensional simplex. The corners of Δ can be identified with elements in D. For a distribution $\mu \in \mathbb{M}_n$ and a variable $v \in \{1, \dots, n\}$, let $\mu_{[v]} \in \Delta$ be the marginal probability of distribution μ for v:

$$\mu_{[v]}(a) \;=\; \sum_{x \in D^n : x_v = a} \mu(x) \qquad \forall a \in D.$$

Given a VCSP instance $\mathcal{I}$ in the form (1), we define the value $\mathrm{BLP}(\mathcal{I})$ as follows:

$$\begin{aligned} \mathrm{BLP}(\mathcal{I}) \;=\; & \min_{\mu,\alpha} \sum_{t \in T} \sum_{x \in \mathtt{dom}\, f_t} \mu_t(x) f_t(x) && (3)\\ \text{s.t.}\;\; (\mu_t)_{[k]} &= \alpha_{v(t,k)} && \forall t \in T, k \in \{1, \dots, n_t\}\\ \mu_t &\in \mathbb{M}_{n_t} && \forall t \in T\\ \mu_t(x) &= 0 && \forall t \in T, x \notin \mathtt{dom}\, f_t\\ \alpha_v &\in \Delta && \forall v \in V \end{aligned}$$

If there are no feasible solutions then $\mathrm{BLP}(\mathcal{I}) = \infty$. The objective function and all constraints in this system are linear, therefore this is a linear program. Its size is polynomial in $\mathtt{size}(\mathcal{I})$, so $\mathrm{BLP}(\mathcal{I})$ can be found in time polynomial in $\mathtt{size}(\mathcal{I})$.

We say that BLP *solves* $\mathcal{I}$ if $\mathrm{BLP}(\mathcal{I}) = \min_{x \in D^n} f_{\mathcal{I}}(x)$, and BLP solves $\mathrm{VCSP}(\Gamma)$ if it solves all instances $\mathcal{I}$ of $\mathrm{VCSP}(\Gamma)$. The following results are known.

▶ **Theorem 11** ([22]). *(a) BLP solves* $\mathrm{VCSP}(\Gamma)$ *if and only if* Γ *admits a symmetric fractional polymorphism of every arity* $m \geq 2$*. (b) If* Γ *is finite-valued then BLP solves* $\mathrm{VCSP}(\Gamma)$ *if and only if* Γ *admits a symmetric fractional polymorphism of arity* 2 *(i.e. if it is solvable).*

BLP relaxation also plays a key role for general-valued languages, as the following result shows. Recall that u_A for a subset $A \subseteq D$ is the unary function $D \to \{0, \infty\}$ with $\mathtt{dom}\, u_A = A$.

▶ **Definition 12.** *Consider instance* $\mathcal{I}$ *with the set of variables* V *and domain* D*. For node* $v \in V$ *denote* $D_v = \{a \in D \mid \exists x \in D^V \text{ s.t. } f_{\mathcal{I}}(x) < \infty, x_v = a\}$*. We define* $\mathrm{Feas}(\mathcal{I})$ *and* $\mathcal{I} + \mathrm{Feas}(\mathcal{I})$ *to be the instances with variables* V *and the following objective functions:*

$$f_{\mathrm{Feas}(\mathcal{I})}(x) = \sum_{v \in V} u_{D_v}(x_v) \qquad\qquad f_{\mathcal{I}+\mathrm{Feas}(\mathcal{I})}(x) = f_{\mathcal{I}}(x) + f_{\mathrm{Feas}(\mathcal{I})}(x)$$

It is easy to see that $f_{\mathcal{I}}(x) = f_{\mathcal{I}+\mathrm{Feas}(\mathcal{I})}(x)$ for any $x \in D^V$. However, the BLP relaxations of these two instances may differ.

▶ **Theorem 13** ([21]). *If* Γ *is solvable and* $\mathcal{I}$ *is a* Γ*-instance then BLP solves* $\mathcal{I} + \mathrm{Feas}(\mathcal{I})$*.*

If Γ is solvable and we know a core B of Γ, then an optimal solution for every Γ-instance can be found by using the standard self-reducibility method, in which we repeatedly add unary terms of the form $u_a(x_v)$ to the instance for different $v \in V$ and $a \in B$ and check whether this changes the optimal value of the BLP relaxation. A formal description of the method is given below. (Notations $\mathcal{I}[B]$ and $\mathcal{I} + u_a(x_v)$ should be self-explanatory; in particular, the former is the instance obtained from $\mathcal{I}$ by restricting each term to domain B).

Algorithm 1: `LP-Probe`$(\mathcal{I}, B)$. Input: instance $\mathcal{I}$ with variables V and domain D, set $B \subseteq D$. Output: either a labeling $x^* \in \arg\min_{x \in D^V} f_{\mathcal{I}}(x)$ with $x^* \in B^V$ or a flag in $\{\varnothing, \texttt{FAIL}\}$.

1 compute value $LP^* = BLP(\mathcal{I}+\text{Feas}(\mathcal{I}))$, then update $\mathcal{I} \leftarrow \mathcal{I}[B]$ (or return $\varnothing$ if $LP^* = \infty$)
2 **for** *each variable* $v \in V$ *in some order* **do**
3 **for** *each label* $a \in B$ *in some order* **do**
4 let $\mathcal{I}' = \mathcal{I} + u_a(x_v)$, and compute $LP' = BLP(\mathcal{I}' + \text{Feas}(\mathcal{I}'))$
5 if $LP' = LP^*$ then update $\mathcal{I} \leftarrow \mathcal{I}'$ and go to line 2 (i.e. proceed with the next variable v)
6 return `FAIL`
7 return labeling $x^* \in B^V$ where x^*_v equals the label a for which term $u_a(x_v)$ has been added

▶ **Lemma 14.**

(a) *If* `LP-Probe`$(\mathcal{I}, B)$ *returns a labeling* x^* *then* $x^* \in \arg\min_{x \in D^V} f_{\mathcal{I}}(x)$.

(b) *If* `LP-Probe`$(\mathcal{I}, B)$ *returns* $\varnothing$ *then instance* $\mathcal{I}$ *is infeasible.*

(c) *Suppose that* $\mathcal{I}$ *is a* Γ*-instance where* Γ *is solvable and* $B \in \mathcal{B}_\Gamma^{core}$. *Then* `LP-Probe`$(\mathcal{I}, B) \neq$ `FAIL`.

Proof. Part (a) holds by construction, and part (b) can be derived from the following two facts (which hold under the preconditions of part (b)):

- $\min_{x \in B^V} f_{\mathcal{I}}(x) = \min_{x \in D^V} f_{\mathcal{I}}(x)$ by Lemma 7(c).
- BLP solves all instances to which it is applied during the algorithm. Indeed, by Lemma 10 the language $\Gamma' = \Gamma[B] \cup \{u_a \mid a \in B\}$ is solvable. The initial instance is a Γ-instance, and all instances in line 4 are Γ'-instances. The claim now follows from Theorem 13. ◀

2.4 Meta-questions and uniform algorithms

In the light of the previous discussion, it is natural to ask the following questions about a given language Γ: (i) Is Γ solvable? (ii) Is Γ a core? (iii) What is a core of Γ? Such questions are usually called *meta-questions* or *meta-problems* in the literature. For finite-valued languages their computational complexity has been studied in [29].

▶ **Theorem 15** ([29]). *Problems (i) and (ii) for* $\{0,1\}$*-valued languages are NP-complete and co-NP-complete, respectively.*

▶ **Theorem 16** ([29]). *There is a polynomial-time algorithm that, given a core finite-valued language* Γ*, either finds a binary idempotent symmetric fractional polymorphism* ω *of* Γ *with* $|\text{supp}(\omega)| = O(poly(\texttt{size}(\Gamma)))$*, or asserts that none exists.*

For crisp languages the following hardness results are known.

▶ **Theorem 17** ([14]). *Deciding whether a given crisp language* Γ *with a single binary relation is a core is a co-NP-complete problem. (Equivalently, testing whether a given directed graph has a non-bijective homomorphism onto itself is an NP-complete problem).*

▶ **Theorem 18** ([10]). *Deciding whether a given crisp language* Γ *with binary relations is solvable is an NP-complete problem.*

It is still an open question whether an analogue of Theorem 16 holds for crisp languages, i.e. whether solvability of a given core crisp language Γ can be tested in polynomial time. However, it is known [10] that the answer would be positive assuming the existence of a certain *uniform* polynomial-time algorithm for CSPs.

▶ **Definition 19.** *Let $\mathcal{F}$ be a class of languages. A uniform polynomial-time algorithm for $\mathcal{F}$ is a polynomial-time algorithm that, for each input $(\Gamma, \mathcal{I})$ with $\Gamma \in \mathcal{F}$ and $\mathcal{I} \in \mathrm{VCSP}(\Gamma)$, computes $\min_x f_{\mathcal{I}}(x)$.*

▶ **Theorem 20** ([10])**.** *Suppose that there exists a uniform polynomial-time algorithm for the class of solvable core crisp languages. Then there exists a polynomial-time algorithm that decides whether a given core crisp language is solvable (or equivalently admits a Siggers polymorphism).*

Currently it is not known whether a uniform polynomial-time algorithm for core crisp languages exists. (Algorithms in [6, 31] assume that needed polymorphisms of the language are part of the input; furthermore, the worst-case bound on the runtime is exponential in $|D|$).

We remark that [10] considered a wider range of meta-questions for crisp languages. In particular, they studied the complexity of deciding whether a given Γ admits polymorphism $g \in O_D^{(m)}$ satisfying a given *strong linear Maltsev condition* specified by a set of linear identities. Examples of such identities are $g(x, \dots, x) \approx x$ (meaning that g is idempotent), $g(x_1, x_2, \dots, x_m) \approx g(x_2, \dots, x_m, x_1)$ (meaning that g is cyclic), and $g(r, a, r, e) \approx g(a, r, e, a)$ (meaning that g is Siggers). We refer to [10] for further details.

3 Our results

In this section the domain of language Γ is always denoted as D, and its size as $d = |D|$.

Our algorithms will construct Γ-instances $\mathcal{I}$ on $n = d^m$ variables (where $m \le 4$) with $\mathtt{size}(\mathcal{I}) = O(poly(\mathtt{size}(\Gamma)))$ for some fixed polynomial. We denote $T_{n,\Gamma}$ to be the running time of a procedure that computes $\mathrm{Feas}(\mathcal{I})$ for such $\mathcal{I}$'s. Also, let $T^*_{n,\Gamma}$ be the combined running times of computing $\mathrm{Feas}(\mathcal{J})$ for instances $\mathcal{J}$ during a call to $\mathtt{LP\text{-}Probe}(\mathcal{I}, B)$ for such $\mathcal{I}$ and some subset B. Note, if Γ is finite-valued then computing $\mathrm{Feas}(\mathcal{I})$ is a trivial problem, so $T_{n,\Gamma}$ and $T^*_{n,\Gamma}$ would be polynomial in $n + \mathtt{size}(\Gamma)$.

Conditional cores. First, we consider the problem of computing a core $B \in \mathcal{B}_\Gamma^{\mathtt{core}}$ of a given language Γ. A naive solution is to solve a linear program with $|\mathcal{O}^{(1)}| = d^d$ variables. We will present an alternative technique that runs more efficiently (in the case of finite-valued languages) but is allowed to output an incorrect result if Γ is not solvable. It will be convenient to introduce the following terminology: language Γ is a *conditional core* if either Γ is a core or Γ is not solvable. Similarly, set B is a *conditional core of* Γ if either $B \in \mathcal{B}_\Gamma^{\mathtt{core}}$ or Γ is not solvable. Note, $B = \varnothing$ is a conditional core of Γ if and only if Γ is not solvable.

To compute a conditional core of Γ, we will use the following approach. Consider a pair (Γ, σ) where σ is a string of size $O(poly(\Gamma))$ that specifies set $\mathcal{B}_\sigma$ of candidate cores of Γ. Formally, $\mathcal{B}_\sigma = \{B_1, \dots, B_N\}$ where $\varnothing \ne B_i \subseteq D$ for each $i \in [N]$. We assume that elements of $\mathcal{B}_\sigma$ can be efficiently enumerated, i.e. there exists a polynomial-time procedure for computing B_1 from σ and B_{i+1} from (σ, B_i). If $\mathcal{B}$ is a set of subsets $B \subseteq D$, we will denote

$$\begin{aligned} \mathcal{O}[\mathcal{B}] &= \{g \in \mathcal{O}^{(1)} \mid g(D) = B \text{ for some } B \in \mathcal{B}\} \\ \widehat{\mathcal{O}}[\mathcal{B}] &= \{g \in \mathcal{O}^{(1)} \mid g(D) \subseteq B \text{ for some } B \in \mathcal{B}\} \end{aligned}$$

▶ **Theorem 21.** *There exists an algorithm that for a given input* (Γ, σ) *does one of the following:*

(a) *Produces a fractional polymorphism* $\omega \in \mathrm{fPol}^{(1)}(\Gamma)$ *with* $\mathrm{supp}(\omega) \subseteq \widehat{\mathcal{O}}[\mathcal{B}_\sigma]$ *and* $|\mathrm{supp}(\omega)| \le 1 + \sum_{f\in\Gamma} |\mathtt{dom}\, f|$.

(b) *Asserts that there exists no vector* $\omega \in \mathrm{fPol}^{(1)}(\Gamma)$ *with* $\mathrm{supp}(\omega) \subseteq \widehat{\mathcal{O}}[\mathcal{B}_\sigma]$.

(c) *Asserts that one of the following holds: (i)* Γ *is not solvable; (ii)* $\mathcal{B}_\sigma \cap \mathcal{B}_\Gamma^{core} = \varnothing$.

It runs in $(|\mathcal{B}_\sigma| + O(poly(\mathtt{size}(\Gamma)))) \cdot (T^*_{d,\Gamma} + O(poly(\mathtt{size}(\Gamma))))$ *time and uses* $O(poly(\mathtt{size}(\Gamma)))$ *space.*

The algorithm in the theorem above is based on the ellipsoid method [13], which tests feasibility of a polytope using a polynomial number of calls to the separation oracle. In our case this oracle is implemented via one or more calls to $\mathtt{LP\text{-}Probe}(\mathcal{I}, B)$ for appropriate $\mathcal{I}$ and B.

One possibility would be to use Theorem 21 with the set $\mathcal{B}_\sigma = \{B \subseteq D \mid B \neq \varnothing, B \neq D\}$. If the algorithm returns result (a) then we can take operation $g \in \mathrm{supp}(\omega)$ and call the algorithm recursively for the language $\Gamma[g(D)]$ on a smaller domain. If we get result (b) or (c) then one can show that Γ is a conditional core, so we can stop. For finite-valued languages this approach would run in $O(2^d \cdot poly(\mathtt{size}(\Gamma)))$ time. We will pursue an alternative approach with an improved complexity $O(\sqrt[3]{3}^{\,d} \cdot poly(\mathtt{size}(\Gamma)))$.

This approach will use partitions $\Pi = \{D_1, \dots, D_k\}$ of domain D. For such Π we denote

$$\begin{aligned} \mathcal{O}_\Pi &= \{g \in \mathcal{O}_D^{(1)} \,:\, g(a) = g(b) \qquad \forall a, b \in A \in \Pi\} \\ \Pi^\perp &= \{B \subseteq D \,:\, |B \cap A| = 1 \qquad \forall A \in \Pi\} \end{aligned}$$

We say that Π is a *partition of* Γ if the set $\mathcal{O}_\Pi \cap \mathrm{supp}(\Gamma)$ is non-empty. In particular, the partition $\Pi = \{\{a\} \mid a \in D\}$ of D into singletons is a partition of Γ, since $\mathrm{supp}(\Gamma)$ contains the identity mapping $D \to D$. We say that Π is a *maximal partition of* Γ if Π is a partition of Γ and no coarser partition $\Pi' \succ \Pi$ (i.e. Π' with $\mathcal{O}_{\Pi'} \subset \mathcal{O}_\Pi$) has this property. Clearly, for any Γ there exists at least one Π which is a maximal partition of Γ. By analogy with cores, we say that Π is a *conditional (maximal) partition of* Γ if either Π is a (maximal) partition of Γ or Γ is not solvable.

In the results below Π is always assumed to be a partition of D.

▶ **Lemma 22.**

(a) *If* Π *is a maximal partition of* Γ *then* $\mathcal{B}_\Gamma^{core} \subseteq \Pi^\perp$ *and* $\mathcal{O}_\Gamma^{core} = \mathcal{O}[\Pi^\perp] \cap \mathrm{supp}(\Gamma)$.

(b) *If* Π *is a partition of* D *then* $|\Pi^\perp| \le \sqrt[3]{3}^{\,d}$.

▶ **Theorem 23.** *There exists an algorithm with runtime* $T_{d,\Gamma} + T_{|\Pi|,\Gamma} + O(poly(\mathtt{size}(\Gamma)))$ *that for a given input* (Γ, Π) *does one of the following:*

(a) *Asserts that* Π *is a conditional partition of* Γ.

(b) *Asserts that* Π *is not a partition of* Γ.

As before, the algorithm in Theorem 23 is based on the ellipsoid method. However, now we cannot use procedure $\mathtt{LP\text{-}Probe}(\mathcal{I}, B)$ to implement the separation oracle, since a candidate core B is not available. Instead, we solve the BLP relaxation of instance $\mathcal{I}$ and derive a separating hyperplane from a (fractional) optimal solution of the relaxation.

▶ **Corollary 24.** (1) *A conditional maximal partition* Π *of* Γ *can be computed in* $O(d^2) \cdot T_{d,\Gamma} + O(poly(\mathtt{size}(\Gamma)))$ *time.* (2) *Once such* Π *is found, a conditional core* B *of* Γ *can be computed using* $(|\Pi^\perp| + O(poly(\mathtt{size}(\Gamma)))) \cdot (T^*_{d,\Gamma} + O(poly(\mathtt{size}(\Gamma))))$ *time and* $O(poly(\mathtt{size}(\Gamma)))$ *space. If* $B \neq \varnothing$ *then the algorithm also produces a fractional polymorphism* $\omega \in \mathrm{fPol}(\Gamma)$ *such that* $\mathrm{supp}(\omega) \subseteq \mathcal{O}[\Pi^\perp]$, $|\mathrm{supp}(\omega)| \le 1 + \sum_{f\in\Gamma} |\mathtt{dom}\, f|$ *and* $\mathrm{supp}(\omega)$ *contains an operation* g *with* $g(D) = B$.

In part (1) we use a greedy search that starts with $\Pi = \{\{a\} \mid a \in D\}$ and then repeatedly calls the algorithm in Theorem 23 for coarser partitions Π. In part (2) we call the algorithm from Theorem 21 with $\sigma = \Pi$ and $\mathcal{B}_\sigma = \Pi^\perp$. For further details we refer to [20].

Testing solvability of a conditional core. Once we have found a conditional core B of Γ, we need to test whether language $\Gamma[B]$ is solvable. This problem is known to be solvable in polynomial-time for finite-valued languages [29], see Theorem 16. Their result can be extended as follows.

▶ **Theorem 25.** *There exists an algorithm that for a given language Γ does one of the following:*

(a) *Produces an idempotent fractional polymorphism $\omega \in \mathrm{fPol}(\Gamma)$ certifying solvability of Γ:*
- *ω has arity $m = 2$ and is symmetric, if Γ is finite-valued;*
- *ω has arity $m = 4$ and contains a Siggers operation in the support, if Γ is not finite-valued. Furthermore, in each case vector ω satisfies $|\operatorname{supp}(\omega)| \le 1 + \sum_{f\in\Gamma} \binom{|\mathtt{dom}\, f|}{m}$.*

(b) *Asserts that one of the following holds: (i) Γ is not solvable; (ii) Γ is not a core.*

Its runtime is $O(poly(\mathtt{size}(\Gamma)))$ if Γ is finite-valued, and $O(T^*_{d^4,\Gamma} \cdot poly(\mathtt{size}(\Gamma)))$ otherwise.

Combining procedures in Corollary 24 and the algorithm in Theorem 25 yields our main algorithmic result.

▶ **Corollary 26.** *Solvability of a given finite-valued language Γ can be tested in $O(\sqrt[3]{3}^{\,d} \cdot poly(\mathtt{size}(\Gamma)))$ time. If the answer is positive, the algorithm also returns a fractional polymorphism $\omega_1 \in \mathrm{fPol}^{(1)}(\Gamma)$ with $\operatorname{supp}(\omega_1) \subseteq \mathcal{O}_\Gamma^{\mathtt{core}}$ and a symmetric idempotent fractional polymorphism $\omega_2 \in \mathrm{fPol}^{(2)}(\Gamma[B])$ where $B = g(D)$ for some $g \in \operatorname{supp}(\omega_1)$; furthermore, $|\operatorname{supp}(\omega_m)| \le 1 + \sum_{f\in\Gamma} \binom{|\mathtt{dom}\, f|}{m}$ for $m \in \{1, 2\}$.*

Hardness results. Let us fix a constant $L \in \{1, \infty\}$. As Theorems 15, 17 and 18 state, testing whether Γ is (i) solvable and (ii) is a core are both NP-hard problems for $\{0, L\}$-valued languages. We now present additional hardness results under the Exponential Time Hypothesis (ETH) and the Strong Exponential Time Hypothesis (SETH) (see Conjectures 1 and 2). Note that for Theorem 27 we simply reuse the reductions from [10]. We say that a family of languages $\mathcal{F}$ is *k-bounded* if each $\Gamma \in \mathcal{F}$ satisfies $\mathtt{size}(\Gamma) = O(poly(d))$ for some fixed polynomial, and $\mathtt{arity}(f) \le k$ for all $f \in \Gamma$.

▶ **Theorem 27.** *Suppose that ETH holds. Then there exists a 2-bounded family $\mathcal{F}$ of $\{0, L\}$-valued languages such that the following problems cannot be solved in $O(2^{o(d)})$ time:*

(a) *Deciding whether language $\Gamma \in \mathcal{F}$ is solvable.*

(b) *Deciding whether language $\Gamma \in \mathcal{F}$ is a core.*

▶ **Theorem 28.** *Suppose that SETH holds. Then for any $\delta < 1$ there exists an $O(1)$-bounded family $\mathcal{F}$ of $\{0, L\}$-valued languages such that the following problems cannot be solved in $O(\sqrt[3]{3}^{\,\delta d})$ time:*

(a) *Deciding whether language $\Gamma \in \mathcal{F}$ is solvable (assuming the existence of a uniform polynomial-time algorithm for core crisp languages, in the case when $L = \infty$).*

(b) *Deciding whether language $\Gamma \in \mathcal{F}$ satisfies $\mathtt{core\text{-}size}(\Gamma) \le d/3$.*

Abstract

We show that any n-variate polynomial computable by a syntactically multilinear circuit of size $\text{poly}(n)$ can be computed by a depth-4 syntactically multilinear ($\Sigma\Pi\Sigma\Pi$) circuit of size at most $\exp\left(O\left(\sqrt{n \log n}\right)\right)$. For degree $d = \omega(n/\log n)$, this improves upon the upper bound of $\exp\left(O(\sqrt{d} \log n)\right)$ obtained by Tavenas [14] for general circuits, and is known to be asymptotically optimal in the exponent when $d < n^{\varepsilon}$ for a small enough constant ε. Our upper bound matches the lower bound of $\exp\left(\Omega\left(\sqrt{n \log n}\right)\right)$ proved by Raz and Yehudayoff [12], and thus cannot be improved further in the exponent. Our results hold over all fields and also generalize to circuits of small individual degree.

More generally, we show that an n-variate polynomial computable by a syntactically multilinear circuit of size $\text{poly}(n)$ can be computed by a syntactically multilinear circuit of product-depth Δ of size at most $\exp\left(O\left(\Delta \cdot (n/\log n)^{1/\Delta} \cdot \log n\right)\right)$. It follows from the lower bounds of Raz and Yehudayoff [12] that in general, for constant Δ, the exponent in this upper bound is tight and cannot be improved to $o\left((n/\log n)^{1/\Delta} \cdot \log n\right)$.

1 Introduction

An algebraic circuit over a field $\mathbb{F}$ and variables $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ is a directed acyclic graph whose internal vertices (called gates) are labeled as either $+$ (sum) or $\times$ (product), and leaves (vertices of indegree zero) are labeled by the variables in $\mathbf{x}$ or constants from $\mathbb{F}$. The gates of outdegree zero in a circuit are called its output gates. Algebraic circuits give a natural and succinct representation for multivariate polynomials; analogous to the way Boolean circuits give a succinct representation of Boolean functions. We refer the reader to the excellent survey of Shpilka and Yehudayoff [13] for an introduction to the area of algebraic circuit complexity. One of the main protagonists in the results in this paper will be the class of syntactically multilinear circuits which we now define.

▶ **Definition 1** (Syntactically Multilinear Circuits)**.** *An algebraic circuit C is said to be syntactically multilinear if at every product gate v in C with inputs $u_1, u_2, \ldots, u_t$, the set of variables in the sub-circuits rooted at u_i are pairwise disjoint from each other.*

The size of an algebraic circuit is the number of edges in it, and its depth is the length of the longest path from an output gate to a leaf. Intuitively, the size of a circuit is an indicator of the time complexity of computing the polynomial, and its depth indicates how fast the polynomial can be computed in parallel.

We now introduce a sequence of fundamental structural results for algebraic circuits, that are collectively called depth reductions; this is the main focus of this paper.

Depth Reductions

In a beautiful, surprising and influential work, Valiant et al. [15] showed that every polynomial family which is efficiently computable by an algebraic circuit is also efficiently computable in parallel. Formally, they showed the following theorem.

▶ **Theorem 2** ([15])**.** *There is an absolute constant $c \in \mathbb{N}$ such that the following is true. If P be an n-variate homogeneous polynomial of degree d over any field $\mathbb{F}$ which can be computed by an algebraic circuit C of size s, then P can be computed by an algebraic circuit C' (of unbounded fan-in) of depth $c \log d$ and size $(snd)^c$.*

In particular, the theorem says that every polynomial family of polynomially bounded (in n) degree that is computable by a circuit of size $\mathrm{poly}(n)$ and arbitrary depth, is also efficiently computable by a circuit of size $\mathrm{poly}(\log n)$ and depth $O(\log n)$.

In a remarkable extension of Theorem 2, Agrawal and Vinay [1] showed that one can parallelize algebraic circuits even more (reducing the depth to a constant), at the cost of a larger (a non-trivial subexponential factor) blow up in the circuit size. The version of their theorem stated below is due to Tavenas [14], who optimized the parameters further.

▶ **Theorem 3** ([1, 8, 14])**.** *There is an absolute constant $c \in \mathbb{N}$ such that the following is true. If P is an n-variate homogeneous polynomial of degree d over any field $\mathbb{F}$ which can be computed by an algebraic circuit C of size s, then P can be computed by a homogeneous $\Sigma\Pi\Sigma\Pi$ algebraic circuit C' of size $(snd)^{c\sqrt{d}}$.*

Here, a $\Sigma\Pi\Sigma\Pi$ circuit is an algebraic circuit with four layers of alternating sum and product gates with the top layer being a sum layer. Throughout this paper, when we say a depth-4 circuit, we mean a $\Sigma\Pi\Sigma\Pi$ circuit.

We note that while Theorem 3 as stated above reduces a homogeneous circuit of arbitrary depth to a homogeneous circuit of depth-4, but it easily follows from the proof that the depth reduction preserves syntactic restrictions. That is, if we start with a syntactically multilinear

and homogeneous circuit, the resulting depth-4 circuit is also syntactically multilinear and homogeneous. This statement will be of particular interest as we study depth reductions for syntactically multilinear circuits in this paper.

On the optimality of reductions to depth-4

An immediate consequence of Theorem 2 and Theorem 3 is that strong enough lower bounds for algebraic circuits of bounded depth imply superpolynomial lower bounds for general algebraic circuits. Thus, the questions of proving lower bounds for bounded depth circuits, and that of understanding if the parameters in Theorem 3 can be improved further seem to be of fundamental interest. In the last few years, we have had significant progress on both these fronts. Following a long line of work starting with a work of Kayal [7] and Gupta et al. [5], we now know extremely good lower bounds for homogeneous depth-4 circuits.

▶ **Theorem 4** (Kumar and Saraf [9]). *There exists a polynomial family $\{f_n\}$, where f_n is a homogeneous n-variate polynomial of degree $d = n^{\varepsilon}$, for an absolute constant $\varepsilon > 0$, such that f_n is computable by an algebraic circuit of size* $\mathrm{poly}(n)$*, but any homogeneous depth-4 circuit computing f_n has size $n^{\Omega(\sqrt{d})}$.*

Moreover, the family $\{f_n\}$ is computable by a syntactically multilinear circuit of polynomial size.

If we allow the hard polynomial to be explicit but not necessarily have small circuits, then upper bound on the degree d in the above theorem can be increased to as large as $n^{1-\varepsilon}$ for any constant $\varepsilon > 0$.[1] Thus, in general, the exponent in the upper bound on the size of the depth-4 circuit obtained in Theorem 3 cannot be improved asymptotically. In fact, the theorem shows that we cannot even expect such an improvement for syntactically multilinear circuits in the setting when the degree d is sufficiently smaller than the number of variables n. A natural question here is to understand if Theorem 3 is also asymptotically tight in the exponent when the degree is larger. The following result of Raz and Yehudayoff goes a long way towards answering this question.

▶ **Theorem 5** ([12]). *There is a family of multilinear polynomials $\{f_n\}$ such that, for every n, the polynomial f_n is an n-variate degree $d = \Theta(n)$ polynomial that can be computed by a syntactically multilinear circuit of size* $\mathrm{poly}(n)$*, but any multilinear circuit of depth-4 computing f_n has size $n^{\Omega\left(\sqrt{n/\log n}\right)}$.*

More generally, for any constant Δ, any syntactically multilinear circuit of product-depth[2] *Δ computing f_n must have size $n^{\Omega\left((n/\log n)^{1/\Delta}\right)}$.*

For depth-4 circuits (or $\Delta = 2$), asimilar result was proved by Hegde and Saha [6] for the more general[3] class of circuits called multi-k-ic circuits, where the *formal degree* of any variable in the circuit is bounded by a parameter k (formally defined in Definition 17).

▶ **Theorem 6** ([6]). *There is an explicit family $\{f_n\}$ of n-variate multilinear polynomials of degree $d = \Theta(n)$ such that, for every $k \leq (n \log n)^{0.9}$, any multi-k-ic circuit of depth-4 computing f_n has size at least $n^{\Omega\left(\sqrt{n/(k \log n)}\right)}$.*

[1] Though this is not explicitly mentioned in these results, the proofs can be extended to this regime of parameters.
[2] Also referred to as a syntactically multilinear $(\Sigma\Pi)^{\Delta}$ circuit.
[3] A multilinear circuit is a multi-k-ic circuit for $k = 1$.

Thus, Theorem 5 and Theorem 6 shows that the exponent $\sqrt{d}$ in the exponent in Theorem 3 cannot be replaced by $o\left(\sqrt{n/\log n}\right)$. Thus, in the regime when $d = \Theta(n)$, there is a gap of $\sqrt{\log n}$ between the known lower bounds and what is potentially achievable via depth reduction. Raz and Yehudayoff [12] also observe that using their techniques, the lower bound cannot be improved to $n^{\omega(\sqrt{n/\log n})}$. Our main motivation for this work was to bridge this gap. In the light of Theorem 4, we believed the upper bound of $n^{O(\sqrt{d})}$ in Theorem 3 to be right bound for multilinear circuits for all d, and had hoped to improve the lower bound in Theorem 5 to $n^{\Omega(\sqrt{n})}$.

However, as we discuss next, the correct exponent for depth reduction to depth-4 in the high degree regime turns out to be $\sqrt{n/\log n}$. In addition to being surprising, this also offers a potentially viable approach to the question of proving superpolynomial lower bounds for syntactically multilinear circuits by extending Theorem 4 to the high degree regime. We now state our results and discuss the connections to multilinear circuit lower bounds.

1.1 Results

We start by stating our main theorems.

▶ **Theorem 7.** *Let C be a multi-k-ic circuit of size s computing a polynomial in n variables. Then, there is a multi-k-ic $\Sigma\Pi\Sigma\Pi$ circuit C' of size $s^{O\left(\sqrt{\frac{kn}{\log s}}\right)}$ computing the same polynomial.*

The ideas in the proof of Theorem 7 generalize to give the following statement about reduction to depth Δ circuits for any constant Δ.

▶ **Theorem 8.** *Let C be a multi-k-ic circuit of size s computing a polynomial in n variables. Then, there is a multi-k-ic $(\Sigma\Pi)^{\Delta}$ circuit C' computing the same polynomial whose size is at most*

$$s^{O\left(\Delta\cdot(nk/\log s)^{1/\Delta}\right)}.$$

Thus, for $s = \text{poly}(n)$, $k = o(\log s)$ and $n \geq d \geq \omega\left(\frac{kn}{\log s}\right)$, the exponents in the upper bounds in Theorem 7 are asymptotically better than that in Theorem 3. An immediate consequence of Theorem 7 is the following corollary.

▶ **Corollary 9.** *Let $\{f_n\}$ be an explicit family of multilinear polynomials, such that f_n is an n variate polynomial of degree $d = \omega(n/\log n)$, and any multilinear $\Sigma\Pi\Sigma\Pi$ circuit computing f_n has size at least $n^{\Omega(\sqrt{d})}$. Then, $\{f_n\}$ requires superpolynomial size syntactically multilinear circuits.*

The corollary is of interest since by Theorem 4, we know $n^{\Omega(\sqrt{d})}$ lower bounds for homogeneous multilinear $\Sigma\Pi\Sigma\Pi$ circuits, when $d = n^{\varepsilon}$. Thus extending these bounds so that they hold for higher degree polynomials will imply superpolynomial lower bounds for multilinear circuits. The current best lower bound known for multilinear circuits is a nearly quadratic lower bound in a recent work of Alon et al. [3]. The standard technique for proving lower bounds for multilinear models is via the rank of the *partial derivative matrix* under a random partition of variables (due to Raz [10]). This has been useful in almost all of the known lower bounds for multilinear models, such as super polynomial lower bounds for multilinear formulas [10], exponential lower bounds for constant depth multilinear circuits [12] as well as the currently known superlinear and nearly quadratic lower bounds for multilinear circuits [11, 3]. However, this technique is too weak to yield even super-cubic lower bounds for syntactically multilinear circuits. Thus, currently we do not even have potential approaches to proving superpolynomial

lower bounds for multilinear circuits. In the light of this, it certainly seems worth exploring if the partial derivative based methods used in the proof of Theorem 4 can be extended to work for multilinear polynomials whose degree $d = \omega(n/\log n)$ is high. As far as we understand, there does not seem to be strong evidence one way or the other about this.

For multi-k-ic circuits, we do not even know superpolynomial lower bounds for formulas or even constant depth formulas. Based on the discussion above, Theorem 7 does seem to offer a potentially viable approach to prove these lower bounds.

Finally, we note again that the upper bound on the size of the depth-4 circuit obtained in Theorem 7 cannot be further improved asymptotically in the exponent as Theorem 5 shows.

1.2 Proof Overview

We focus on giving an outline of the proof of Theorem 7 for the multilinear case (or $k = 1$). The proof follows the strategy of the proof of Theorem 3 with some key differences, which we point out as we go along. There are two main steps and we now give a sketch of both of them.

Balancing a syntactically multilinear circuit

For this step, the key notion is that of a *balanced* circuit. We say that a circuit C is balanced with respect to a potential function $\Phi : C \to \mathbb{N}$ (e.g. degree, number of variables), if the fan-in of every product g in C is a constant, and $\Phi(g) \geq 2\Phi(h)$ for every child h of g. In the proof of Theorem 3, the authors essentially use the results of Valiant et al. [15] to balance a homogeneous circuit with the potential function Φ being the formal degree of a gate. For our proof, we show that a syntactically multilinear circuit can in fact be balanced with the potential function being the number of variables in the sub-circuit rooted at a gate. Our proof of this part involves the machinery of *gate quotients* and *frontier decompositions* developed by Valiant et al. in their original proof, although there are some crucial differences which require some non-trivial (albeit simple) insights.

One such challenge stems from the fact that in a homogeneous circuit, the formal degree of any two children of a product gate is the same and equal to the formal degree of the parent, whereas the children might depend on very different (even completely disjoint) sets of variables. To get around this, our notion of *frontier* is different from that of Valiant et al [15]. In [15], frontier is defined with respect to vertices, whereas we define frontier with respect to edges. As a consequence, our frontier decomposition statements are slightly different from those in [15], although they continue to have a natural semantic meaning. This is detailed in Section 5.

Reduction to depth-4 from a balanced circuit

In the second part of our proof, we show that any balanced syntactically multilinear circuit of size s computing a polynomial in n variables can be depth reduced to a syntactically multilinear depth-4 circuit of size $s^{O(\sqrt{n/\log n})}$. The proof is along the lines of the proof of the analogous statement in the homogeneous (non-multilinear) setting by Chillara et al. [4]. The high level idea of the proof is the following : in a balanced circuit C, the polynomial computed at any gate g can be written as a sum of product of *terms*, where the product fan-in is a constant, the sum fan-in is upper bounded by the size of the circuit, and the number of variables in any of the terms is at most half of the number of variables in g. Moreover, each of the terms is a polynomial computed by a gate in C, so this decomposition can be recursively applied. We apply this decomposition repeatedly till every term in the sum of products expression of the output depends on at most t variables. We argue that the

sum fan-in of this sum of products expression is at most $s^{O(n/t)}$. Now, we expand each of the terms (which is a multilinear polynomial) as a sum of multilinear monomials in t variables. Thus, the total size of the $\Sigma\Pi\Sigma\Pi$ circuit obtained is $2^t \cdot s^{O(n/t)}$ which is $s^{O(\sqrt{n/\log s})}$ for $t = \sqrt{n \log s}$.

In the proof of the analogous statement for homogeneous non-multilinear circuits, at the end of the repeated applications of the decomposition, each of the terms is of degree at most t. Thus, a sum of product expansion of each such term has size $\binom{n}{t}$, and so the total size of the $\Sigma\Pi\Sigma\Pi$ circuit obtained is $n^t \cdot s^{O(n/t)}$, which for $s = \text{poly}(n)$ is minimized for $t = \sqrt{n}$ and equals $s^{O(\sqrt{n})}$. This explains the gain in the size obtained by Theorem 7.

2 Preliminaries

In this section, we describe the notion of parse-trees and gate quotients which are crucial to our proof and set up some of the machinery we need for the proof.

2.1 Parse-trees and quotients

▶ **Definition 10** (Parse-trees). *Let C be an algebraic circuit. For any $u_0 \in C$, a* parse-tree T rooted at u_0 *is a subcircuit of C that satifies the following properties:*

- *the node $u_0 \in T$,*
- *if $u \in T$ is a multiplication gate of C with $u = v_1 \times v_2$, then v_1, v_2 are also in T,*
- *if $u \in T$ is an addition gate of C with $u = v_1 + v_2$, then* exactly one *of v_1 or v_2 is in T.*

Any such sub-circuit computes just a monomial, and this shall be called the value the parse-tree. Although the parse-tree defined above need not be a tree, it shall unfolded to a tree.

If T is a parse-tree rooted at u, and v is a node that appears on its right-most path, then the tree T' obtained by replacing v only on the right-most path by a leaf labelled 1 is said to be a v-snipped parse-tree rooted at u.

▶ **Definition 11** (Var operator). *For any nodes $u \in C$, we denote by* $\text{Var}(u)$ *the vector $(d_1, \ldots, d_n) \in \mathbb{N}^n_{\geq 0}$ where d_i is the maximum x_i-degree over all parse-trees rooted at u.*

Similarly, for any pair of nodes $u, v \in C$, we denote by $\text{Var}(u : v)$ *the vector $(d_1, \ldots, d_n)$ where d_i is the maximum x_i-degree over all v-snipped parse-tree rooted at u.*

We shall also define $|(d_1, \ldots, d_n)| = \sum d_i$.

For a syntactically multilinear circuit C, note that $|\text{Var}(g)|$ for any gate $g \in C$ is precisely the number of distinct variables in the sub-circuit rooted at g.

▶ Remark 12. Throughout this discussion, we will assume that the circuit is *right heavy*. This means that for every multiplication gate, $w = w_L \times w_R$, $\text{Var}(w_R) \geq \text{Var}(w_L)$. Note that this is without loss of generality, since *left* and *right* are merely labels that we can assign arbitrarily to the children of every gate in the circuit.

▶ **Definition 13** (Gate Quotient). *For every two gates u, v in C, the* gate quotient *of u with respect to v, denoted by $[u : v]$ is defined inductively as follows.*

- *If $u = v$, then $[u : v] = 1$.*
- *If $u = u_1 + u_2$, then $[u : v] = [u_1 : v] + [u_2 : v]$.*
- *If $u = u_L \times u_R$, then $[u : v] = [u_L][u_R : v]$.*
- *If v does not appear in the subcircuit rooted at u, then $[u : v] = 0$.*

▶ **Lemma 14.** *Let $u, v \in C$. Then, the polynomial $[u]$ is the sum of values of all parse-trees rooted at u. Furthermore, the polynomial $[u : v]$ is the sum of the values of all the v-snipped parse-trees T that are rooted at u.*

The above lemma is almost folklore and a proof of it can be seen in the work of Allender et al. [2].

2.2 Syntactic restrictions on parse-trees

We remark that throughout this paper, by degree, we mean the syntactic or formal degree, which could be much larger than the actual or semantic degree. The following observation records some basic properties of the Var operator.

▶ **Observation 15.** *Let C be any algebraic circuit. Then,*

- $\mathrm{Var}(u)$ *is monotonically non-increasing as u moves towards the leaves. That is, if u is an ancestor of v, then ever coordinate of* $\mathrm{Var}(u)$ *is at least as large as the corresponding coordinate in* $\mathrm{Var}(v)$.
  Similarly, for any fixed v, the vector $\mathrm{Var}(u : v)$ *is monotonically non-increasing as u moves towards the leaves.*
- *For any multiplication gate $u = u_1 \times u_2$, we have* $\mathrm{Var}(u) = \mathrm{Var}(u_1) + \mathrm{Var}(u_2)$. *Similarly for any v, we have* $\mathrm{Var}(u : v) = \mathrm{Var}(u_1) + \mathrm{Var}(u_2 : v)$.
- *For any addition gate $u = u_1 + u_2$, we have* $\mathrm{Var}(u) = \max(\mathrm{Var}(u_1), \mathrm{Var}(u_2))$, *the coordinate-wise max of the two vectors. Similarly for any v,* $\mathrm{Var}(u : v) = \max(\mathrm{Var}(u_1 : v), \mathrm{Var}(u_2 : v))$.

Proof. The proofs immediately follow from the definitions. ◀

For two vectors $\mathbf{v}_1, \mathbf{v}_2 \in \mathbb{N}^n_{\geq 0}$, we shall say $\mathbf{v}_1 \preceq \mathbf{v}_2$ if each coordinate of $\mathbf{v}_1$ is at most the corresponding coordinate in $\mathbf{v}_2$.

▶ **Observation 16.** *Suppose $u \in C$ and w is a node in C such that there is some parse-tree rooted at u with w appearing on its rightmost path. Then,*

$$\mathrm{Var}(u : w) + \mathrm{Var}(w) \preceq \mathrm{Var}(u).$$

Similarly, suppose w is a node in C such that there is some v-parse-tree rooted at u with w appearing on its rightmost path. Then,

$$\mathrm{Var}(u : w) + \mathrm{Var}(w : v) \preceq \mathrm{Var}(u : v).$$

Proof. The proof is straightforward; we just give the proof of the second equation. Fix a coordinate i. If $d_i = (\mathrm{Var}(u : w))_i$ then there is some w-snipped parse-tree T_i rooted at u whose x_i-degree equals d_i. Similarly if $e_i = (\mathrm{Var}(w : v))_i$, then there is some v-snipped parse-tree T'_i rooted at w whose x_i-degree is e_i. Clearly the *gluing* of T_i and T'_i obtained by replacing the snipped vertex w in T_i with the tree T'_i is a v-snipped parse-tree rooted at u with x_i-degree $d_i + e_i$. Therefore $d_i + e_i \leq (\mathrm{Var}(u : v))_i$ and the claim follows. ◀

▶ **Definition 17** (Syntactically multilinear and multi-k-ic circuits). *A circuit C is said to be* syntactically multilinear *if* $\mathrm{Var}(u) \in \{0, 1\}^n$ *for all $u \in C$.*

A circuit C is said to be syntactically multi-k-ic *if* $\mathrm{Var}(u) \in \{0, 1, \ldots, k\}^n$ *for all $u \in C$.*

3 Frontier edges and quotient

▶ **Definition 18** (Frontier edges). *For a circuit C, an edge between two gates g_1, g_2 (where g_1 is the parent) is said to be an* m-frontier edge *(for a parameter m) if*

$$|\mathrm{Var}(g_1)| \geq m \text{ and } |\mathrm{Var}(g_2)| < m.$$

We use $\mathcal{F}_m^{\times}$ to denote the set of all m-frontier edges (g_1, g_2) where g_1 is a multiplication gate and g_2 is its right child. *We use $\mathcal{F}_m^{+}$ to denote those where g_1 is an addition gate.*

Furthermore, if $v \in C$ is a fixed gate, we shall say that (g_1, g_2) is an m-frontier edge with respect to v *if*

$$|\mathrm{Var}(g_1 : v)| \geq m \text{ and } |\mathrm{Var}(g_2 : v)| < m.$$

We will use $\mathcal{F}_{m,v}^{\times}$ to denote the set of all edges (g_1, g_2) that are m-frontier edges with respect to v where g_1 is a multiplication gate (and g_2 is its right child), and $\mathcal{F}_{m,v}^{+}$ to denote those where g_1 is an addition gate (and g_2 is any child).

4 Decomposition via gate quotients

In this section, we prove the following lemma, which is the key technical observation needed for our proofs.

▶ **Lemma 19.** *Let u, v be gates in an algebraic circuit C with $|\mathrm{Var}(u)| \geq m$ and $|\mathrm{Var}(v)| < m$. Then,*

$$[u] = \sum_{(w,z)\in\mathcal{F}_m^{\times}} [u : w] \cdot [w_L] \cdot [z] \; + \sum_{(w,z)\in\mathcal{F}_m^{+}} [u : w] \cdot [z] \tag{1}$$

$$[u : v] = \sum_{(w,z)\in\mathcal{F}_{m,v}^{\times}} [u : w] \cdot [w_L] \cdot [z : v] \; + \sum_{(w,z)\in\mathcal{F}_{m,v}^{+}} [u : w] \cdot [z : v] \tag{2}$$

We shall give an informal sketch using the concept of parse-trees. A complete formal proof of the lemma can be found in Appendix A. For any u, v, we have that $[u : v]$ is the sum of all v-snipped parse-trees rooted at u. For any parse-tree, since $|\mathrm{Var}(u)| \geq m$ and $|\mathrm{Var}(v)| < m$ and $\mathrm{Var}(\cdot)$ is a monotonically non-increasing function as we move towards the leaves, there must be a unique edge $(w, z) \in \mathcal{F}_{m,v}^{\times} \cup \mathcal{F}_{m,v}^{+}$ on its right-most path such that $|\mathrm{Var}(w)| \geq m$ and $|\mathrm{Var}(z)| < m$.

If $(w, z) \in \mathcal{F}_{m,v}^{\times}$, then $w = w_L \times z$ is a multiplication gate. Therefore, the sum of the values of all v-snipped parse-trees with w (and hence the edge (w, z)) on its rightmost path is exactly $[u : w][w : v] = [u : w][w_L][z : v]$.

If $(w, z) \in \mathcal{F}_{m,v}^{+}$, then $w = w_1 + z$ is an addition gate. Then, $[u : w] \cdot [w : v]$ is the sum of all v-snipped parse-trees with w on its rightmost path and $[u : w][w : v] = [u : w][w_1 : v] + [u : w][z : v]$. Each v-snipped parse-tree with w on its rightmost path either has (w, w_1) on the rightmost path or (w, z). The term $[u : w][w_1 : v]$ is precisely the sum of the values of such[4] parse-trees with (w, w_1) on its rightmost path, and $[u : w][z : v]$ is precisely the sum of the values of those parse-trees with (w, z) on its rightmost path.

[4] v-snipped parse-trees rooted at u that have w on its rightmost path

Since the rightmost path of any v-snipped parse-tree rooted at u has a *unique* edge $(w,z) \in \mathcal{F}^{\times}_{m,v} \cup \mathcal{F}^{+}_{m,v}$, summing over all such potential edges gives

$$[u:v] = \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot[w_L]\cdot[z:v] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v].$$

5 Balancing syntactically multilinear circuits

In this section, we prove the following theorem.

▶ **Theorem 20.** *Suppose C is an algebraic circuit of size s. Then, there is a circuit C' of size* poly(s) *computing the same polynomial with the following structural properties.*

- *all addition gates in C' have fan-in $O(s^4)$,*
- *all multiplication gates in C' have fan-in at most 5,*
- *for any multiplication gate $g \in C'$, any child h of g satisfies $|\mathrm{Var}(h)| \le |\mathrm{Var}(g)|/2$.*

Furthermore, if C is syntactically multi-k-ic, then so is C'.

Proof. Without loss of generality, we may assume that the circuit is *right-heavy* in the sense that for every multiplication gate $u = u_1 \times u_2$ we have $|\mathrm{Var}(u_2)| \ge |\mathrm{Var}(u_1)|$. We shall build a new circuit C' that computes all $[u:v]$'s and $[u]$'s for gates $u, v \in C$ using the equations in Lemma 19.

We shall assume inductively that we have already computed all $[w]$'s with $|\mathrm{Var}(w)| < t$ and also all $[w,v]$ with $|\mathrm{Var}(w,v)| < t$. Suppose $u \in C$ such that $|\mathrm{Var}(u)| = t$. Using (1) from Lemma 19 with $m = t/2$ we have

$$[u] = \sum_{(w,z)\in\mathcal{F}^{\times}_{m}} [u:w]\cdot[w_L]\cdot[z] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m}} [u:w]\cdot[z].$$

By Observation 16, $|\mathrm{Var}(w)| \ge t/2$ implies that $|\mathrm{Var}(u:w)| \le t/2$. Furthermore, $|\mathrm{Var}(z)| \le t/2$ by the choice of the frontier edge and $|\mathrm{Var}(w_L)| \le t/2$ since C is right-heavy. This allows us to compute all nodes of the form $[u]$ with $|\mathrm{Var}(u)| \le t$.

If $u, v \in C$ such that $|\mathrm{Var}(u:v)| = t$. Using (2) from Lemma 19 with $m = t/2$, we have

$$[u:v] = \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot[w_L]\cdot[z:v] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v].$$

We can restrict the edges in the RHS to only those edges (w,z) that is present in at least one v-snipped parse-tree rooted at u (if not, this edge's contribution to the RHS is zero). Therefore by Observation 16, $\mathrm{Var}(w:v) + \mathrm{Var}(u:w) \preceq \mathrm{Var}(u:v)$ and therefore we have $|\mathrm{Var}(u:w)| \le t/2$. Furthermore, by the choice of the frontier, we also have $|\mathrm{Var}(z:v)| \le t/2$. The non-trivial case is $\mathrm{Var}(w_L)$ which could in principle be large but again $\mathrm{Var}(w_L) \preceq \mathrm{Var}(w:v) \preceq \mathrm{Var}(u:v)$ as any parse-tree rooted w_L is a sub-tree of a v-snipped tree rooted at u. Since we have already computed all gates $[w]$ with $\mathrm{Var}(w) \le t$, we can write

$$\begin{aligned}
[u:v] &= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot[w_L]\cdot[z:v] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v] \\
&= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot\left(\sum_{(p,q)\in\mathcal{F}^{\times}_{m_w}} [w_L:p]\cdot[p_L]\cdot[q] \;+\; \sum_{(p,q)\in\mathcal{F}^{+}_{m_w}} [w_L:p]\cdot[q]\right)\cdot[z:v]
\end{aligned}$$

$$+ \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v],$$

where $m_w = \mathrm{Var}(w_L)/2$.

The required structural properties of C' are readily seen from the above construction. ◀

6 Reduction to depth four from balanced circuits

We now show how to reduce a balanced circuit to a depth-4 circuit. This would complete the proof of our main theorem. We shall use the notation $\Sigma\Pi\left(\Sigma\Pi\right)_t$ to refer to $\Sigma\Pi\Sigma\Pi$ circuits computing polynmomials of the form

$$F = \sum_i \prod_j Q_{ij},$$

with $|\mathrm{Var}(Q_{ij})| \le t$.

The proof of this part follows the outline of a similar argument in Chillara et al. [4] of reducing to depth-4 from a balanced circuit. However, there are some differences: our potential is $|\mathrm{Var}(\,\cdot\,)|$ and not the degree (as is usually the case). Since this potential function also falls as we go from a sum (+) gate to its children, we need one more simple observation in our argument to bound the number of steps in the recursion in the proof. We now provide the details.

▶ **Lemma 21.** *Let C be a multi-k-ic circuit of size s such that every multiplication gate g in C has fan-in at most 5 and for every child h of g in C, $\mathrm{Var}(h) \le \mathrm{Var}(g)/2$.*

Then, for any positive integer $0 \le t \le kn$, there is an equivalent multi-k-ic $\Sigma\Pi\left(\Sigma\Pi\right)_t$ circuit C' that computes the same polynomial, with the following properties:

- *the top fan-in of C' is at most $s^{O(kn/t)}$,*
- *the size of C' is at most $2^t \cdot s^{O(kn/t)}$,*
- *each of the (+)-gates closer to the leaves compute polynomials that are computed by gates in C.*

Proof. Since C is balanced, with product fan-in at most 5, every gate g in C can be written as

$$g = \sum_{i=1}^{s} \prod_{j=1}^{5} g_{i,j}\,, \tag{3}$$

where each $g_{i,j}$ is also computed by a gate in the circuit C, $|\,\mathrm{Var}(g_{i,j})| \le |\,\mathrm{Var}(g)|/2$. With this notation, (3) applied on the root of C says that C, which is a syntactically multi-k-ic circuit, can be trivially written as a $\Sigma\Pi\left(\Sigma\Pi\right)_{kn/2}$. A natural idea would be to apply (3) on the $g_{i,j}$'s until we get a $\Sigma\Pi\left(\Sigma\Pi\right)_t$ circuit. All that is needed is to bound the number of summands (or the top fan-in of the resulting $\Sigma\Pi\left(\Sigma\Pi\right)_t$ circuit) at the end of this process. Observe that for every $i \in \{1,2,\ldots,s\}$, we could have that $\left|\mathrm{Var}(\prod_{j=1}^{5} g_{i,j})\right|$ is *much* smaller than $|\mathrm{Var}(g)|$ itself. To handle this, we shall pretend that

We will view the process as a tree in the natural way. The root of the tree corresponds to the root of the circuit, and all other nodes in the tree correspond to products of addition gates in C. The children of a node in the tree correspond to the summands in the sum of product representation of that node obtained by expanding one of its factors according to (3). The leaves of this tree are products of addition gates $\prod g'_i$ such that $|\mathrm{Var}(g'_i)| \le t$ for

each factor g_i'. The tree has a branching factor of at most s, hence it suffices to get a bound on the depth of the tree to get a bound on the number of leaves which would be the top fan-in of the $\Sigma\Pi(\Sigma\Pi)_t$ representation.

Let $g\prod_\ell w_\ell$ be an internal node in the tree with $|\mathrm{Var}(g)| > t$. After applying (3) on g, we get

$$g\left(\prod_\ell w_\ell\right) = \sum_{i=1}^{s}\left(\prod_{j=1}^{5} g_{i,j}\cdot\prod_\ell w_\ell\right).$$

We now consider two cases.

- $\left|\mathbf{Var}\left(\prod_{j=1}^{5} g_{i,j}\right)\right| < 3t/4$: In this case, $\left|\mathrm{Var}\left(\prod_{j=1}^{5} g_{i,j}\cdot\prod_\ell w_\ell\right)\right| \le |\mathrm{Var}\left(g\cdot\prod_\ell w_\ell\right)| - t/4$.
- $\left|\mathbf{Var}\left(\prod_{j=1}^{5} g_{i,j}\right)\right| \ge 3t/4$: Since $\mathrm{Var}(g) \succeq \mathrm{Var}(g_{i,1}\cdots g_{i,5}) = \mathrm{Var}(g_{i,1}) + \cdots + \mathrm{Var}(g_{i,5})$ and $|\mathrm{Var}(g_{i,j})| \le t/2$, it follows that the number of factors h in $\prod_{j=1}^{5} g_{i,j}\cdot\prod_\ell w_\ell$ with $|\mathrm{Var}(h)| \ge t/16$ is at least one more than the number of such factors in $g\cdot\prod_\ell w_\ell$. This is because besides the factor $g_{i,j}$ with largest $|\mathrm{Var}(g_{i,j})|$, the other four factors together must contribute at least $(3t/4) - (t/2) = (t/4)$ to $|\mathrm{Var}(g_{i,1}\cdots g_{i,5})|$ and hence at least one of them must have $|\mathrm{Var}(g_{i,k})| \ge t/16$.

Thus, in any edge of the tree, either $|\mathrm{Var}(\,\cdot\,)|$ decreases by $t/4$ or the number of factors with $|\mathrm{Var}(\,\cdot\,)| \ge t/16$ increases by one. The root node g_0 has $|\mathrm{Var}(g_0)| \le kn$. Hence, the depth of the tree is bounded by $(16+4)(kn/t) = O(nk/t)$. Therefore, C can be computed by a syntactically multi-k-ic $\Sigma\Pi(\Sigma\Pi)_t$ circuit of top fan-in at most $s^{O(nk/t)}$.

To get the bound on the overall size of the $\Sigma\Pi(\Sigma\Pi)_t$ circuit, we need to bound the sparsity of the polynomials computed by bottom two layers. Note that if $\mathrm{Var}(f) = (d_1,\ldots,d_n)$, then f can have at most $\prod(1+d_i)$ monomials. Since $2^x \ge 1+x$ for all positive integers x, it follows that $|\mathrm{Var}(f)| \le t$ implies that f has at most 2^t monomials. Therefore, the total size of the $\Sigma\Pi(\Sigma\Pi)_t$ circuit is $2^t\cdot s^{O(kn/t)} = 2^{O\left(t+\frac{kn\log s}{t}\right)}$. ◀

From Theorem 20 and setting $t = \sqrt{kn\log s}$ in Lemma 21, we get Theorem 7 restated below.

▶ **Theorem 7.** *Let C be a multi-k-ic circuit of size s computing a polynomial in n variables. Then, there is a multi-k-ic $\Sigma\Pi\Sigma\Pi$ circuit C' of size $s^{O\left(\sqrt{\frac{kn}{\log s}}\right)}$ computing the same polynomial.*

6.1 Reduction to higher depths

We now prove Theorem 8 which shows that similar savings can be obtained in depth reductions to larger depth.

▶ **Theorem 8.** *Let C be a multi-k-ic circuit of size s computing a polynomial in n variables. Then, there is a multi-k-ic $(\Sigma\Pi)^\Delta$ circuit C' computing the same polynomial whose size is at most*

$$s^{O\left(\Delta\cdot(nk/\log s)^{1/\Delta}\right)}.$$

Proof of Theorem 8. We shall assume, without loss of generality, that the circuit C is balanced (by applying Theorem 20 if necessary). The proof follows via repeated applications of Lemma 21.

Applying Lemma 21 with $t = nk/(nk/\log s)^{1/\Delta}$, we obtain a $\Sigma\Pi\,(\Sigma\Pi)_t$ circuit C' of the form

$$C' = \sum_{i=1}^{s'} \prod_j g_{ij},$$

with $s' = s^{O\left((kn/\log s)^{1/\Delta}\right)}$ and $|\mathrm{Var}(g_{ij})| \leq t$ for all i, j. Furthermore, since each g_{ij} being a polynomial computed by a gate in C, they are computable by multi-k-ic circuits of size at most s. By induction, each g_{ij} has a multi-k-ic $(\Sigma\Pi)^{\Delta-1}$ circuit of size at most

$$s^{O\left((\Delta-1)\cdot(t/\log s)^{1/(\Delta-1)}\right)} = s^{O\left((\Delta-1)\cdot(nk/\log s)^{1/\Delta}\right)}.$$

Replacing each g_{ij} by this circuit, we obtain a $(\Sigma\Pi)^{\Delta}$ circuit of size at most

$$s' \cdot s^{O\left((\Delta-1)\cdot(nk/\log s)^{1/\Delta}\right)} = s^{O\left(\Delta\cdot(kn/\log s)^{1/\Delta}\right)}.$$ ◀

7 Open problems

The most interesting question that comes out of this work is to prove a lower bound of $n^{\omega(\sqrt{n/\log n})}$ for syntactically multilinear circuits of depth-4 for an explicit polynomial. A natural and first approach to this could be to understand if the shifted partials based methods can prove a lower bound of $n^{\Omega(\sqrt{d})}$ for homogeneous depth-4 circuits for a polynomial family with degree $d = \omega(n/\log n)$.

Another question of interest would be to understand the *correct* exponent for the depth reduction results to depth-4 (and also to higher depth) for various regimes of the degree d. From [9], we know that for $d = O(n^{\varepsilon})$ for a small enough constant ε, $\sqrt{d}$ is the correct exponent, whereas for d being nearly n, the results in this paper and those of Raz and Yehudayoff [12] show that the correct exponent is $\sqrt{n/\log n}$. But we do not understand this phenomenon for other values of d.

A Proof of Lemma 19

Proof of Lemma 19. The proof shall proceed by induction on the height of u (leaves are at height 0). We shall present the proof of (2); the proof of (1) is analogous.

Case 1: $u = u_L \times u_R$. For any w, we have that $[u : w] = 1$ if $u = w$, and $[u : w] = [u_1] \cdot [u_2 : w]$ whenever $u \neq w$. In particular, since $|\mathrm{Var}(v)| < m \leq |\mathrm{Var}(u)|$ the LHS is $[u : v] = [u_L] \cdot [u_R : v]$.

If $|\mathrm{Var}(u_R)| \geq m$, then for any $(w, z) \in \mathbb{F}^+_{m,v}$ or $\mathcal{F}^\times_{m,v}$ we have $w \neq u$. Inducting on u_R,

$$\begin{aligned}
\mathrm{LHS} &= [u_L] \cdot [u_R : v] \\
&= [u_L] \cdot \left(\sum_{(w,z) \in \mathcal{F}^\times_{m,v}} [u_R : w] \cdot [w_L] \cdot [z : v] \; + \sum_{(w,z) \in \mathcal{F}^+_{m,v}} [u_R : w] \cdot [z : v] \right) \\
&= \sum_{(w,z) \in \mathcal{F}^\times_{m,v}} [u_L] \cdot [u_R : w] \cdot [w_L] \cdot [z : v] \; + \sum_{(w,z) \in \mathcal{F}^+_{m,v}} [u_L] \cdot [u_R : w] \cdot [z : v] \\
&= \sum_{(w,z) \in \mathcal{F}^\times_{m,v}} [u : w] \cdot [w_L] \cdot [z : v] \; + \sum_{(w,z) \in \mathcal{F}^+_{m,v}} [u : w] \cdot [z : v] \; = \; \mathrm{RHS}.
\end{aligned}$$

On the other hand, if $|\mathrm{Var}(u_R)| < m$ then $[u : w] = 0$ for any $w \neq u$ with $|\mathrm{Var}(w)| \geq m$. Hence,

$$\begin{aligned}\text{RHS} &= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot[w_L]\cdot[z:v] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v] \\ &= [u:u]\cdot[u_L]\cdot[u_R:v] = [u:v] = \text{LHS}.\end{aligned}$$

Case 2: $u = u_1 + u_2$. For any w, we have that $[u : w] = 1$ if $u = w$, and $[u : w] = [u_1 : w] + [u_2 : w]$ whenever $u \neq w$. In particular, since $|\mathrm{Var}(v)| < m \leq |\mathrm{Var}(u)|$ the LHS is $[u : v] = [u_1 : v] + [u_2 : v]$.
Since u is a + gate, $(u, u_j) \notin \mathcal{F}^{\times}_{m,v}$ for any j. If $|\mathrm{Var}(u_j)| < m$ for some j, then the edge $(u, u_j) \in \mathcal{F}^{+}_{m,v}$. Hence,

$$\begin{aligned}\text{RHS} &= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u:w]\cdot[w_L]\cdot[z:v] \;+\; \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v] \\ &=: \qquad\qquad T_1 \qquad\qquad + \qquad\qquad T_2\end{aligned}$$

In T_1, since every $(w, z) \in \mathcal{F}^{\times}_{m,v}$ has $w \neq u$ we have

$$\begin{aligned}T_1 &:= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} \left(\sum_i [u_i:w]\right)\cdot[w_L]\cdot[z:v] \\ &= \sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} \left(\sum_{i:|\mathrm{Var}(u_i)|\geq m} [u_i:w]\right)\cdot[w_L]\cdot[z:v] \qquad (\text{since } [u_j:w]=0 \text{ if } |\mathrm{Var}(u_j)|<m) \\ &= \sum_{i:|\mathrm{Var}(u_i)|\geq m} \;\sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u_i:w]\cdot[w_L]\cdot[z:v].\end{aligned}$$

As for the other term, it can be written as

$$\begin{aligned}T_2 &:= \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u:w]\cdot[z:v] \\ &= \sum_{\substack{(w,z)\in\mathcal{F}^{+}_{m,v}\\ w\neq u}} [u:w]\cdot[z:v] \;+\; \sum_{j:|\mathrm{Var}(u_j)|<m} [u:u]\cdot[u_j:v] \\ &= \sum_{\substack{(w,z)\in\mathcal{F}^{+}_{m,v}\\ w\neq u}} \left(\sum_i [u_i:w]\right)\cdot[z:v] \;+\; \sum_{j:|\mathrm{Var}(u_j)|<m} [u_j:v] \\ &= \sum_{\substack{(w,z)\in\mathcal{F}^{+}_{m,v}\\ w\neq u}} \left(\sum_{i:|\mathrm{Var}(u_i)|\geq m} [u_i:w]\right)\cdot[z:v] \;+\; \sum_{j:|\mathrm{Var}(u_j)|<m} [u_j:v] \\ &= \sum_{i:|\mathrm{Var}(u_i)|\geq m} \;\sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u_i:w]\cdot[z:v] \;+\; \sum_{j:|\mathrm{Var}(u_j)|<m} [u_j:v].\end{aligned}$$

The last equality holds because $[u_i : u] = 0$. Putting it together,

$$\begin{aligned}\text{RHS} &= T_1 + T_2 \\ &= \sum_{i:|\mathrm{Var}(u_i)|\geq m} \left(\sum_{(w,z)\in\mathcal{F}^{\times}_{m,v}} [u_i:w]\cdot[w_L]\cdot[z:v] + \sum_{(w,z)\in\mathcal{F}^{+}_{m,v}} [u_i:w]\cdot[z:v]\right)\end{aligned}$$

$$+ \sum_{j:|\mathrm{Var}(u_j)|<m} [u_j : v]$$

$$= \sum_{i:|\mathrm{Var}(u_i)|\geq m} [u_i : v] + \sum_{j:|\mathrm{Var}(u_j)|<m} [u_j : v] \qquad \text{(induction)}$$

$$= [u : v] = \mathrm{LHS}. \qquad \blacktriangleleft$$

Sum-Of-Squares Bounds via Boolean Function Analysis

Abstract

We introduce a method for proving bounds on the SoS rank based on Boolean Function Analysis and Approximation Theory. We apply our technique to improve upon existing results, thus making progress towards answering several open questions.

We consider two questions by Laurent. First, finding what is the SoS rank of the linear representation of the set with no integral points. We prove that the SoS rank is between $\lceil \frac{n}{2} \rceil$ and $\lceil \frac{n}{2} + \sqrt{n \log 2n} \rceil$. Second, proving the bounds on the SoS rank for the instance of the Min Knapsack problem. We show that the SoS rank is at least $\Omega(\sqrt{n})$ and at most $\lceil \frac{n+4\lceil \sqrt{n} \rceil}{2} \rceil$. Finally, we consider the question by Bienstock regarding the instance of the Set Cover problem. For this problem we prove the SoS rank lower bound of $\Omega(\sqrt{n})$.

1 Introduction

A *boolean hypercube optimization problem* is a (constrained) polynomial optimization problem in n-variables, where the set of feasible points is restricted to a subset of an n-dimensional hypercube. This family of problems lies at the heart of theoretical computer science. However, solving general optimization problem over boolean hypercube is NP-hard, since the class contains, e.g., the Independent Set problem.

One of the most successful approaches for constructing theoretically efficient algorithms for this family of problems is the *Sum of Squares (SoS)* algorithm [23, 41, 43, 51]. For a wide variety of combinatorial optimization problems it provides the best available algorithms [1, 20, 5, 24, 36]. Recently, SoS has also been applied to problems in ROBUST ESTIMATION [26], DICTIONARY LEARNING [3, 49] and TENSOR COMPLETION AND DECOMPOSITION [4, 25, 45]. Other applications can be found in [5, 7, 12, 13, 17, 18, 24, 38, 39, 46]; see also the surveys [14, 33, 35].

On the other hand it is known that the SoS algorithm admits certain weaknesses. For example, a $\Omega(n)$ degree SoS certificate is needed to detect a simple integrality argument for some instance of the KNAPSACK problem as shoved by Grigoriev in [21], see also [22, 28, 34]. Further weaknesses of SoS for KNAPSACK problems were proved in [11, 31]. Some lower bounds on the effectiveness of the SoS have been shown for CSP problems [27, 52] and for

the planted clique problem [2, 40]. Finally, degree $\Omega(\sqrt{n})$ SoS was proved to have problems scheduling unit size jobs on a single machine to minimize the number of late jobs, see [30]. The problem is solvable in polynomial time using the Moore-Hodgson algorithm.

Proving SoS lower bounds is not an easy task. In most of the results, the lower bound is proved on the *Lasserre relaxation* side, by explicitly giving a *pseudoexpectation* operator that maps polynomials of certain degree to real numbers, such that the corresponding *moment matrix* for variables and *localizing matrices* for constraints are Positive Semi-definite (PSD). Both finding a suitable pseudoexpectation and proving PSDness might be very difficult.

In this paper we follow the less common approach of working on a *dual* side, the *SoS certificate of nonnegativity*. This approach does not require finding a pseudoexpectation operator and proving PSDness of the matrices, which we find very convenient. We prove lower bounds by exploiting the properties of boolean functions and by using the results from approximation theory, especially the theory of approximating boolean functions, see e.g. [44, 50, 53]. This, in our case, directly implies the existence/non-existence of the SoS certificate. To the best of our knowledge there are not that many SoS lower bounds using this approach, see e.g. [37].

On an intuitive level our approach might be explained in the following way. Imagine one wants to write a degree d SoS certificate for some function f that is nonnegative over a subset of the boolean hypercube. Consider a vertex x of the hypercube, where $f(x) < 0$. Note that in order to successfully write a certificate one has to use the constraint g, that made the point x infeasible, and multiply it by some SoS polynomial s of degree at most $2d$. Moreover, the values $f(x)$ and $g(x)$ give some lower bound on the value of $s(x)$. Ideally, we would like s to take value zero on other vertices of the hypercube, this is the case for degree n certificates. However, the lower the degree d, the more other vertices of the hypercube are "affected" by the value of $s(x)$.

This simple observation is strong enough to provide the best known SoS ranks for the following problems:

For $B \geq 2$. The Empty Integral Hull (EIH) problem is a feasibility problem of the form

$$EIH = \{0,1\}^n \cap \{x \in [0,1]^n \mid \sum_{i \in [n] \setminus I} x_i + \sum_{i \in I} (1 - x_i) \geq \frac{1}{B} \text{ for all } I \subseteq [n]\} \tag{1.1}$$

For $B = 2$, a long list of results for the performance of the lift and project methods for EIH problem is known. In [33], Laurent shows that the Sherali-Adams *rank* is n. They then conjecture the SoS rank of EIH is $n - 1$. Moreover, the rank is also equal to n for the Lovász-Schrijver N_+ operator (with positive semidefiniteness) [19], the Lovász-Schrijver N_+ operator strengthen with Chvátal cuts [15], and the N_+ operator combined with Gomory mixed integer cuts (equivalent to disjunctive cuts) [16]. Recently, in [29], the conjecture was disproved, and it was shown that the SoS rank of EIH is between $\Omega(\sqrt{n})$ and $n - \Omega(n^{1/3})$. In this paper we prove the following result:

▶ **Theorem 1.** *For $B = 2$, the SoS rank of EIH problem is between $\lceil \frac{n}{2} \rceil$ and $\lceil \frac{n}{2} + \sqrt{n \log 2n} \rceil$.*

In this paper we also prove lower and upper bounds on the SoS rank for any $B \geq 2$, see Theorem 12 and Lemma 13.

The second considered problem is the instance of the Min Knapsack (MK) problem. For $P \geq 2$, the problem is defined as:

$$\text{MK:} \quad \min \sum_{i \in [n]} x_i \qquad \text{s.t.} \quad \sum_{i \in [n]} x_i \geq \frac{1}{P} \qquad x \in \{0,1\}^n \tag{1.2}$$

For $P = 2$ the problem was previously considered by Cook and Dash [15]. They proved that the Lovasz-Schrijver hierarchy rank is n. For the Sherali-Adams hierarchy Laurent in [33] proved that the rank is also equal to n and raised the open question to find the rank for the SoS hierarchy. For $n = 2$ they also proved that the SoS rank is 2, but whether or not this happens for general n was left open. In [30] the possibility that the Lasserre/SoS rank is n for $n \geq 3$ is ruled out. Finally, in [28], a SoS rank lower bound of $t = \Omega(\log^{1-\varepsilon} n)$, for $\epsilon > 0$, was presented. In this paper we prove the following result:

▶ **Theorem 2.** *For $P = 2$, the SoS rank of the MK problem is between $\Omega(\sqrt{n})$ and $\lceil \frac{n+4\lceil\sqrt{n}\rceil}{2} \rceil$.*

Moreover, we prove a SoS rank lower bound for any $P \geq 2$ of the value $\Omega(\sqrt{n} + \sqrt{n \log P})$, see Lemma 14.

The third problem we consider is the instance of the Set Cover (SC) problem:

$$\text{SC:} \qquad \min \sum_{i\in[n]} x_i \qquad \text{s.t.} \quad \sum_{i\in[n]\setminus\{j\}} x_i \geq 1 \qquad \forall j \in [n] \qquad (1.3)$$
$$x \in \{0,1\}^n$$

This instance was considered in [8], where an open question was raised asking what is the rank of this polytope, conjecturing that the SoS rank is at least $n/4$, based on numerical experiments. In [29], the conjecture was supported by proving that the rank is at least $\log^{1-\delta}(n)$ for any $\delta > 0$. Finally, the instance can be seen as the Min Knapsack instance with Knapsack Cover inequalities, see [29]. In this paper we prove the following result:

▶ **Theorem 3.** *The SoS rank of the SC problem is at least $\Omega(\sqrt{n})$.*

2 Preliminaries

For any $n \in \mathbb{N}$ we denote $[n] = \{1, \ldots, n\}$. Let $\mathbb{R}[x] = \mathbb{R}[x_1, \ldots, x_n]$ be the ring of *n-variate real polynomials*. Furthermore, let $\mathcal{G}$ be the set of polynomials

$$\mathcal{G} \;:=\; \{g_0 := 1, g_1, \ldots, g_m : \; g_i \in \mathbb{R}[x] \text{ for all } \; i \in [m]\}.$$

For a given set $\mathcal{G}$, the corresponding *semialgebraic set* is defined as

$$\mathcal{G}_+ \;:=\; \{x \in \mathbb{R}^n \mid g(x) \geq 0 \text{ for all } g \in \mathcal{G}\} \subseteq \mathbb{R}^n.$$

Moreover, for any given semialgebraic set $\mathcal{G}_+ \subseteq \mathbb{R}^n$, let $\mathcal{K}(\mathcal{G}_+)$ be the set of *nonnegative polynomials* over the set $\mathcal{G}_+$

$$\mathcal{K}(\mathcal{G}_+) \;:=\; \{f \in \mathbb{R}[x] \mid f(x) \geq 0 \text{ for all } x \in \mathcal{G}_+\}.$$

For a given $f \in \mathbb{R}[x]$ and a set $\mathcal{G}$ we define the corresponding *constrained polynomial optimization problem* (CPOP)

$$f^* \;:=\; \min\{f(x) \mid x \in \mathcal{G}_+\} \;=\; \max\{\lambda \in \mathbb{R} \mid f - \lambda \in \mathcal{K}(\mathcal{G}_+)\}. \qquad (2.1)$$

and the *constrained polynomial feasibility problem* (CPFP), which consists in testing whether the corresponding set $\mathcal{G}_+$ is empty or not, see e.g., [9].

Since the problems CPOP and CPFP are NP-hard in general it is desirable to find a proper subset that is a good inner approximation of $\mathcal{K}(\mathcal{G}_+)$ such that the corresponding program is computationally *tractable*.

SoS method

The *SoS method* approximates the cone $\mathcal{K}(\mathcal{G}_+)$ by using the set of *sum of square polynomials*. Let $\mathbb{SOS} := \{s \mid s = \sum_{i=1}^{k} f_i^2,\ f \in \mathbb{R}[x],\ k \in \mathbb{N}^*\}$ be the set of *(finite) sum of square polynomials (SoS)*. Let

$$\Sigma_{n,d}^{\mathcal{G}} := \left\{\sum_{i=1}^{m} s_i g_i \mid s_i \in \mathbb{SOS},\ g_i \in \mathcal{G},\ deg(s_i) \leq 2d, \text{ for all } i \in [m] \text{ and } deg(s_0) \leq 2\left\lceil \tfrac{2d+deg(\mathcal{G})}{2} \right\rceil\right\},$$

where $deg(\mathcal{G}) = \max\{deg(g) \mid g \in \mathcal{G}\}$. The *degree d SoS certificate* for f being nonnegative over $\mathcal{G}_+$ is $f \in \Sigma_{n,d}^{\mathcal{G}}$. The *degree d SoS program* for CPOP takes the form:

$$f_{\mathbb{SOS}}^d := \max\{\lambda \in \mathbb{R} \mid f - \lambda \in \Sigma_{n,d}^{\mathcal{G}}\}; \tag{2.2}$$

and for CPFP it consists in testing whether or not $-1 \in \Sigma_{n,d}^{\mathcal{G}}$ and, if so, implying that the set $\mathcal{G}_+$ is empty.

SoS method over the boolean hypercube

In this paper we consider optimization over the boolean hypercube $\mathcal{H} := \{0,1\}^n$. We assume that $\mathcal{G}$ is such that $\mathcal{G}_+ \subseteq \mathcal{H}$. We fix the following notation. Let $\mathcal{H}^+$ and $\mathcal{H}^-$ be $\mathcal{G}_+$ and $\mathcal{H} \setminus \mathcal{G}_+$, respectively. For $I \in [n]$, let $x_I \in \mathbb{R}^n$ be the characteristic vector of set I such that $(x_I)_i = 1$ if $i \in I$ and 0 otherwise. Moreover, for any $f \in \mathbb{R}[x]$, let $\mathcal{H}^-(f) := \{x \in \mathcal{H} \mid f(x) < 0\}$ and $\mathcal{H}^+(f) := \{x \in \mathcal{H} \mid f(x) \geq 0\}$.

Throughout the paper we assume that $\mathcal{G}$ is always of the form

$$\mathcal{G} := \{g_0 := 1, g_1, \ldots, g_m, \pm(x_1^2 - x_1), \ldots, \pm(x_n^2 - x_n) :\ g_i \in \mathbb{R}[x] \text{ for all } \ i \in [m]\}.$$

In this case solving a degree d SoS program can be done via Semi-definite Program (SDP) of size $O(\sum_{k=0}^{d} \binom{n}{k})$. Moreover, it is known that degree n SoS program is *exact* meaning that for CPOP we have $f_{\mathbb{SOS}}^n = f^*$ and for CPFP we have $-1 \in \Sigma_{n,n}$ if and only if the set $\mathcal{G}_+$ is empty, see e.g. [6, 32, 33]. A very useful result was recently proved in [48] giving an upper bound on the degree of the SoS certificate for every degree r unconstrained boolean hypercube optimization problem:

▶ **Theorem 4** ([48]). *Every n-variate polynomial of degree r, nonnegative over the unconstrained boolean hypercube has a degree $\lceil \frac{n+r-1}{2} \rceil$ SoS certificate.*

Now we give the following definition.

▶ **Definition 5.** *The SoS* rank *for a CPOP (CPFP) is the smallest degree d such that the degree d SoS program is exact.*

That is why the SoS rank for EIH problem is the smallest degree d such that there exist SoS polynomials s_I, for all $I \subseteq [n]$ of degree at most $2d$ and s_0 of degree at most $2d+2$ such that: $-1 = s_0 + \sum_{I \subseteq [n]} s_I(x) \left(\sum_{i \in [n] \setminus I} x_i + \sum_{j \in I}(1 - x_j) - 1/B\right)$.

Analogously, the SoS rank for the MK problem is the smallest d such that there exist SoS polynomials s_1 of degree at most $2d$ and s_0 of degree at most $2d+2$ such that: $\sum_{i \in [n]} x_i - 1 = s_0 + s_1 \left(\sum_{i \in [n]} x_i - 1/P\right)$.

Finally, the SoS rank for the SC problem is the smallest degree d such that there exist SoS polynomials $s_1, \ldots, s_n$ of degree at most $2d$ and s_0 of degree at most $2d+2$ such that: $\sum_{i \in [n]} x_i - 2 = s_0 + \sum_{j \in [n]} s_j(x) \left(\sum_{j \neq i \in [n]} x_i - 1\right)$.

3 Analysis of boolean functions

In this section we show some properties of boolean functions.

The first one is a very intuitive statement saying that the lower degree SoS boolean function we consider, the less of the total mass of the values is in one particular point.

The second one is the special case of results in [44, 50, 53] giving a lower bound on the degree of a real polynomial that approximates the NOR boolean function in ℓ_∞-norm.

▶ **Lemma 6.** *For every function $f : \{0,1\}^n \to \mathbb{R}$ of degree at most d and every subset $J \subseteq [n]$ the following holds:*

$$\sum_{S\subseteq[n]} f^2(x_S) \geq \frac{2^n}{\sum_{i=0}^{d}\binom{n}{i}} f^2(x_J).$$

Moreover, for every $J \subseteq [n]$ there exists a degree d polynomial such that the above inequality is satisfied with equality.

Proof. We will use some elementary Fourier analysis of boolean functions (see e.g. [42, Ch. 1]). For the sake of following an established notation we analyze the function $h : \{\pm 1\}^n \to \mathbb{R}$ instead of $f : \{0,1\}^n \to \mathbb{R}$ using the bijective transformation $f(x) = h(w)$, for $w = 1 - 2x$. Clearly this transformation preserves the degree of the function.

Let $w_I \in \mathbb{R}^n$ be the characteristic vector of set $I \subseteq [n]$ such that $(w_I)_i = -1$ if $i \in I$ and 1 otherwise. The *Fourier expansion* of the function h takes the following form:

$$h(w) = \sum_{\substack{I\subseteq[n]\\|I|\leq d}} \widehat{h}(I) \prod_{i\in I} w_i,$$

where $\widehat{h}(I)$ it the *Fourier coefficient* of the monomial $\prod_{i\in I} w_i$. Let $g : \{\pm 1\}^n \to \mathbb{R}$ be such that $g := h^2$. Thus $g(w) = \left(\sum_{\substack{I\subseteq[n]\\|I|\leq d}} \widehat{h}(I) \prod_{i\in I} w_i\right)^2$ and its Fourier expansion is of the form:

$$g(w) = \sum_{\substack{I\subseteq[n]\\|I|\leq d}} \left(\widehat{h}(I)\right)^2 + \sum_{\substack{I\neq K\subseteq[n]\\|I|,|K|\leq d}} \widehat{h}(I)\widehat{h}(K) \prod_{i\in I\triangle K} w_i, \tag{3.1}$$

since all monomials squared evaluate to 1 over the $\{\pm 1\}^n$ boolean hypercube.

By [42, Fact 1.12] and Equation 3.1 we know that

$$\widehat{g}(\varnothing) = \mathop{\mathbb{E}}_{w\sim\{\pm1\}^n} g(w) = 2^{-n} \sum_{I\subseteq[n]} g(w_I) = \sum_{\substack{I\subseteq[n]\\|I|\leq d}} \left(\widehat{h}(I)\right)^2 \tag{3.2}$$

Without loss of generality, we assume that the set J in the statement of the Theorem is the empty set. Thus:

$$g(w_\varnothing) = \sum_{\substack{I\subseteq[n]\\|I|\leq d}} \left(\widehat{h}(I)\right)^2 + \sum_{\substack{I\neq K\subseteq[n]\\|I|,|K|\leq d}} \widehat{h}(I)\widehat{h}(K). \tag{3.3}$$

Now, we show that among all boolean functions normalized to have expected value over $\{\pm 1\}^n$ boolean hypercube equal to $\sum_{\substack{I\subseteq[n]\\|I|\leq d}} \left(\widehat{h}(I)\right)^2$ the function $g := h^2$, such that all Fourier

coefficients of h are the same, takes the largest value on the point $w_\varnothing$. Indeed, consider a function g evaluated at point $w_\varnothing$. The RHS of Equation 3.3 satisfies:

$$\sum_{\substack{I,K\subseteq[n]\\|I|,|K|\leq d}} \widehat{h}(I)\widehat{h}(K) \leq \frac{1}{2}\sum_{\substack{I,K\subseteq[n]\\|I|,|K|\leq d}} \left(\widehat{h}^2(I)+\widehat{h}^2(K)\right) = \sum_{i=0}^{d}\binom{n}{i}\sum_{\substack{I\subseteq[n]\\|I|\leq d}}\widehat{h}^2(I)$$

and the equality holds when all Fourier coefficients of h are the same.

Finally, we show that for the function $g = h^2$, such that all Fourier coefficients of h are the same, the Theorem holds. Assume w.l.o.g. that for every $I \subseteq [n]$, $\widehat{h}(I) = 1$. Then we get

$$h^2(w_\varnothing) = g(w_\varnothing) = \left(\sum_{i=0}^{d}\binom{n}{i}\right)^2 \quad \text{and} \quad \sum_{I\subseteq[n]} h^2(w_I) = 2^n \sum_{\substack{I\subseteq[n]\\|I|\leq d}}\left(\widehat{h}(I)\right)^2 = 2^n\sum_{i=0}^{d}\binom{n}{i}.$$

thus the first part of the statement follows.

Note, that, for $J = \varnothing$, the above proof gives an explicit construction of a degree d polynomial that satisfies the inequality in the statement of Lemma 6 with equality. In an analogous way one can construct a function for other sets $J \subseteq [n]$, thus the second part of the claim follows. ◀

Clearly a similar statement holds for functions being a sum of squares of boolean functions.

▶ **Corollary 3.1.** *For every function $s = \sum_i h_i^2$ such that for every i, $h_i : \{0,1\}^n \to \mathbb{R}$ is of degree at most d and every subset $J \subseteq [n]$ the following holds:*

$$\sum_{S\subseteq[n]} s(x_S) \geq \frac{2^n}{\sum_{i=0}^{d}\binom{n}{i}} s(x_J).$$

Now we present the second result in [44, 50, 53]. We start with the following definitions.

A boolean function $f : \{0,1\}^n \to \mathbb{R}$ is *symmetric* if $f(x) = f_i \in \mathbb{R}$ for every $x \in \{0,1\}^n$ such that $|x| = i$. A polynomial $p : \mathbb{R}^n \to \mathbb{R}$ *approximates* a symmetric boolean function f in ℓ_∞-norm within an error c, if $|f(x) - p(x)| \leq c$ for every $x \in \{0,1\}^n$. A symmetric boolean function $f := \{0,1\}^n \to \{0,1\}$ is a *NOR* function if it satisfies $f(0,\ldots,0) = 1$ and $f(x) = 0$ for every other $x \in \{0,1\}^n$.

Now we present the result proved in [44, 50, 53].

▶ **Theorem 7** ([44, 50, 53]). *For every constant $2^{-n} \leq c < 1/2$ the minimum degree of a real polynomial that approximates a NOR boolean function in ℓ_∞-norm within en error c is $\Theta(\sqrt{n} + \sqrt{n\log 1/c})$.*

3.1 Application to the SoS certificates

In this section, we apply Theorem 4, Corollary 3.1 and Theorem 7 to provide lower and upper bounds on the SoS rank for some family of problems. We start with the following definition.

▶ **Definition 8.** *A polynomial f is called a* Single Vertex Cutting *(SVC) constraint if there exists only one $x \in \{0,1\}^n$ such that $f(x) < 0$. A set $\mathcal{G}$ is SVC if all functions $g_1,\ldots,g_m \in \mathcal{G}$ are SVC and every $x \in \{0,1\}^n$ is cut by at most one $g \in \mathcal{G}$. A problem is SVC if its corresponding set $\mathcal{G}$ is SVC.*

Note that all three problems considered in this paper are SVC Problems.

▶ **Theorem 9.** *Consider an SVC system $\mathcal{G}$. For some $f \in \mathbb{R}[x]$, assume that $\mathcal{H}^-(f) = \mathcal{H}^-$, thus $|\mathcal{H}^-(f)| = m$. For every $x_J \in \mathcal{H}^-(f)$ let $g_J \in \mathcal{G}$ be such that $g_J(x_J) < 0$, g_J is unique.*

There is no degree d certificate for f over system $\mathcal{G}$, if for every $c_J \geq 1$, for every J such that $x_J \in \mathcal{H}^-(f)$, the following holds

$$\sum_{x_J \in \mathcal{H}^+(f)} f(x_J) + \sum_{x_J \in \mathcal{H}^-(f)} f(x_J)(1-c_J) < \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) \sum_{x_I \in \mathcal{H}^-(f)} c_I \frac{f(x_I)}{g_I(x_I)} \cdot \min_{\substack{x_J \in \mathcal{H} \\ J \neq I}} g_I(x_J)$$

Proof. Assume, there exists a SoS certificate for f of degree d over $\mathcal{G}$, then

$$f(x) = s_0 + \sum_{x_J \in \mathcal{H}^-} s_J(x) g_J(x), \qquad \text{for every } x \in \{0,1\}^n,$$

for s_J, being SoS of degree at most $2d$, and s_0 being SoS of degree at most $2\left\lceil \frac{2d+deg(\mathcal{G})}{2} \right\rceil$. Consider $x_J \in \mathcal{H}^-(f)$. Since g_J is the only constraint from $\mathcal{G}$ that is negative on this point we get that

$$s_J(x_J) \geq \frac{f(x_J)}{g_J(x_J)}$$

Let $c_J \geq 1$ be such that $s_J(x_J) = c_J \cdot \frac{f(x_J)}{g_J(x_J)}$, we obtain:

$$f(x_J) = \underbrace{s_0(x_J)}_{\geq 0} + \underbrace{s_J(x_J) g_J(x_J)}_{= c_J f(x_J)} + \sum_{\substack{x_I \in \mathcal{H}^- \\ I \neq J}} \underbrace{s_I(x_J) g_I(x_J)}_{\geq 0}.$$

By summing up over all points in $\mathcal{H}^-(f)$ we get:

$$\sum_{x_J \in \mathcal{H}^-(f)} f(x_J) = \underbrace{\sum_{x_J \in \mathcal{H}^-(f)} s_0(x_J)}_{\geq 0} + \underbrace{\sum_{x_J \in \mathcal{H}^-(f)} s_J(x_J) g_J(x_J)}_{= \sum_{x_J \in \mathcal{H}^-(f)} c_J f(x_J)} + \sum_{x_J \in \mathcal{H}^-(f)} \sum_{\substack{x_I \in \mathcal{H}^- \\ I \neq J}} s_I(x_J) g_I(x_J)$$

thus

$$\sum_{x_J \in \mathcal{H}^-(f)} f(x_J)(1 - c_J) = \sum_{x_J \in \mathcal{H}^-(f)} s_0(x_J) + \sum_{x_J \in \mathcal{H}^-(f)} \left(\sum_{\substack{x_I \in \mathcal{H}^- \\ I \neq J}} s_I(x_J) g_I(x_J) \right).$$

Finally, we have

$$\sum_{x_J \in \mathcal{H}^+(f)} f(x_J) + \sum_{x_J \in \mathcal{H}^-(f)} f(x_J)(1 - c_J) = \sum_{x_J \in \mathcal{H}} s_0(x_J) + \sum_{x_J \in \mathcal{H}} \left(\sum_{\substack{x_I \in \mathcal{H}^- \\ I \neq J}} s_I(x_J) g_I(x_J) \right),$$

where

$$\sum_{x_J \in \mathcal{H}} \left(\sum_{\substack{x_I \in \mathcal{H}^- \\ I \neq J}} s_I(x_J) g_I(x_J) \right) \geq \sum_{x_I \in \mathcal{H}^-} \left(\left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) s_I(x_I) \left(\min_{\substack{x_J \in \mathcal{H} \\ J \neq I}} g_I(x_J) \right) \right)$$

and the last inequality follows by Corollary 3.1. Since, $\sum_{x_J \in \mathcal{H}} s_0(x_J) \geq 0$ and $s_I(x_I) = c_I \cdot \frac{f(x_I)}{g_I(x_I)}$, the claim follows. ◀

▶ **Theorem 10.** *If every SoS certificate of f over system $\mathcal{G}$ of the form $f = s_0 + \sum_{i=1}^{m} s_i g_i$, is such that the polynomial $s(x) := \sum_{i=1}^{m} s_i(x)$ necessarily has to take at least value $1-c$ for $x = (0,0,\ldots,0)$ and at most value c, for every other $x \in \{0,1\}^n$, for some constant $2^{-n} \leq c < 1/2$, then the degree of the certificate is at least $\Omega\left(\sqrt{n} + \sqrt{n \log 1/c}\right)$.*

Proof. Assume by contradiction that there exists a SoS certificate of degree smaller than $\Omega\left(\sqrt{n} + \sqrt{n \log 1/c}\right)$. Note that s is a real polynomial that approximates the NOR function in ℓ_∞-norm within the constant error c. Since s is of degree smaller than $\Omega\left(\sqrt{n} + \sqrt{n \log 1/c}\right)$ it contradicts Theorem 7. ◀

Finally, we show an argument for an upper bounds on the SoS rank.

▶ **Lemma 11.** *Let f be of degree at most $d+1$ and let g_i for $i \in [m]$ be linear. If there exist SoS polynomials $s_i, \ldots, s_m$ of degree at most d such that*

$$f(x) \geq \sum_{i=1}^{m} s_i(x) g_i(x), \qquad \text{for every } x \in \{0,1\}^n,$$

then there exists a SoS certificate for f of degree $\lceil \frac{n+d}{2} \rceil$.

Proof. Note that $f(x) - \sum_{i=1}^{m} s_i(x) g_i(x) \geq 0$, for every $x \in \{0,1\}^n$. By Theorem 4 and the fact that we consider g_i linear, for $i \in [m]$, we get that there exists a SoS polynomial s_0 of degree at most $\lceil \frac{n+(d+1)-1}{2} \rceil$ such that: $f(x) - \sum_{i=1}^{m} s_i(x) g_i(x) = s_0$. ◀

4 Application to the EIH problem

In this section we show how to use the results presented in Section 3.1 to derive lower and upper bounds on the SoS rank for the Empty Integral Hull problem.

4.1 SoS rank lower bounds

In this section we prove a lower bounds on the SoS rank for the Empty Integral Hull problem.

▶ **Theorem 12.** *The SoS rank for the Empty Integral Hull problem parametrized by constant B, is greater or equal the minimum d, which satisfies:*

$$\frac{B}{B-1} \geq \frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}}.$$

Proof. We directly apply Theorem 9. We want to prove that for $f(x) = -1$ there is no SoS certificate of degree d, for d such that $\frac{B}{B-1} < \frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}}$. Following the notation from Theorem 9 note that for every $g_I \in \mathcal{G}$, the smallest nonnegative value over the hypercube $\{0,1\}^n$ of g_I is $1 - 1/B$. By Theorem 9 there is no degree d SoS certificate for $f = -1$, if for every $c_I \geq 1$, $I \subseteq [n]$, the following is satisfied:

$$(-1) \sum_{I \subseteq [n]} (1 - c_I) < \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) \sum_{I \subseteq [n]} c_I \frac{-1}{-\frac{1}{B}} \cdot \left(1 - \frac{1}{B}\right).$$

Let $c = 1/2^n \sum_{I \subseteq [n]} c_I$. The above is satisfied if

$$\frac{c-1}{c} < \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) (B-1).$$

Since $c \geq 1$, we have $\frac{c-1}{c} < 1$ and the above inequality holds if $\frac{1}{B-1} < \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right)$. ◀

We get the following corollary.

▶ **Corollary 4.1.** *The SoS rank for the EIH problem with $B = 2$, is at least $\lceil n/2 \rceil$.*

Proof. By Theorem 12 the SoS rank of the EIH for $B = 2$ is greater or equal to the minimum d that satisfies: $2 \geq \frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}}$. which holds for $d \geq \lceil n/2 \rceil$. ◀

One can apply Theorem 12 to easily reprove the result from [31], saying that for $B = 2^{n+1}$ the SoS rank is at least n.

▶ **Corollary 4.2.** *For $B = 2^{n+1}$ the EIH problem has the SoS rank n.*

4.2 SoS rank upper bounds

In this section we prove an upper bound on the SoS rank for the Empty Integral Hull problem.

▶ **Lemma 13.** *The SoS rank for the Empty Integral Hull problem parametrized by the constant B, is less or equal the minimum d, that satisfies*

$$\frac{Bn}{Bn-1} > \frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}}.$$

Proof. We follow the notation and reasoning from Theorem 9. Let $c_I \geq 1$, for $I \subseteq [n]$ be large enough constants, whose value is specified later.

Our goal is to construct a SoS certificate for $f = -1$ using the SoS polynomials of degree at most $2d$, for d given in the statement of this lemma. In our construction we take $s_0 = 0$ and consider s_J, for $J \subseteq [n]$, to be 2^n polynomials squared, each of which constructed as in Lemma 6, such that for every $I, J \subseteq [n]$ we have $\sum_{K \subseteq [n]} s_I(x_K) g_I(x_K) = \sum_{K \subseteq [n]} s_J(x_K) g_J(x_K)$.

We want to prove that there exists a certificate of the form

$$-1 = f(x_J) = \underbrace{s_J(x_J) g_J(x_J)}_{= c_J f(x_J) = -c_J} + \sum_{\substack{x_I \in \mathcal{H} \\ I \neq J}} \underbrace{s_I(x_J) g_I(x_J)}_{\geq 0}, \qquad \text{for every } J \subseteq [n], \tag{4.1}$$

where, for every $J \subseteq [n]$, by the construction of the polynomial s_J, we know that:

$$\left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) s_J(x_J) \left(\underbrace{\min_{\substack{x_I \in \mathcal{H} \\ I \neq J}} g_J(x_I)}_{= 1 - 1/B} \right) \leq \sum_{\substack{x_I \in \mathcal{H} \\ I \neq J}} \underbrace{s_I(x_J) g_I(x_J)}_{\geq 0} \leq \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) s_J(x_J) \left(\underbrace{\max_{\substack{x_I \in \mathcal{H} \\ I \neq J}} g_J(x_I)}_{= n - 1/B} \right).$$

Let

$$\sum_{\substack{x_I \in \mathcal{H} \\ I \neq J}} \underbrace{s_I(x_J) g_I(x_J)}_{\geq 0} = \alpha \left(1 - \frac{1}{B} \right) \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) s_J(x_J), \qquad \text{for every } J \subseteq [n],$$

for some $1 \leq \alpha \leq \frac{n - 1/B}{1 - 1/B}$. Since $s_J(x_J) = c_J \cdot f(x_J)/g_J(x_J) = c_J \cdot \frac{-1}{-1/B} = c_J \cdot B$, thus satisfying Equation 4.1 requires:

$$\frac{c_J - 1}{c_J} = \alpha \left(\frac{2^n}{\sum_{k=0}^{d} \binom{n}{k}} - 1 \right) (B - 1), \qquad \text{for every } J \subseteq [n].$$

Now, put all c_J equal and note that c_J can be chosen arbitrarily, so there exists SoS certificate of degree d if we can satisfy,

$$\alpha\left(\frac{2^n}{\sum_{k=0}^{d}\binom{n}{k}}-1\right)(B-1)<1.$$

which holds if

$$\frac{n-1/B}{1-1/B}(B-1)\left(\frac{2^n}{\sum_{k=0}^{d}\binom{n}{k}}-1\right)=(Bn-1)\left(\frac{2^n}{\sum_{k=0}^{d}\binom{n}{k}}-1\right)<1.$$

Finally, the above is satisfied if $\frac{2^n}{\sum_{k=0}^{d}\binom{n}{k}}<\frac{Bn}{Bn-1}$. ◀

For $B=2$ we get the following corollary.

▶ **Corollary 4.3.** *The SoS rank for the EIH problem for $B=2$ is at most $\lceil \frac{n}{2}+\sqrt{n\log 2n}\ \rceil$.*

Proof. By Lemma 13 we know that the SoS rank is smaller or equal to the smallest d that satisfies

$$\frac{2^n}{\sum_{k=0}^{d}\binom{n}{k}}<\frac{2n}{2n-1}.$$

Since $2^n=\sum_{k=0}^{d}\binom{n}{k}+\sum_{k=d+1}^{n}\binom{n}{k}$ we get the requirement

$$\frac{\sum_{k=d+1}^{n}\binom{n}{k}}{2^n-\sum_{k=d+1}^{n}\binom{n}{k}}<\frac{2n}{2n-1}-1$$

and finally

$$\sum_{k=d+1}^{n}\binom{n}{k}<\frac{2^n}{2n}.$$

By the standard Chernoff bound, see e.g. [10], for $d>n/2$ we know that $\sum_{k=d+1}^{n}\binom{n}{k}=\sum_{k=0}^{n-d-1}\binom{n}{k}\le 2^n\exp\frac{-(2d+2-n)^2}{4n}$. Thus for $d>\frac{1}{2}\left(n-2+2\sqrt{n\log 2n}\right)$ there exists a SoS certificate for EIH problem for $B=2$. ◀

5 Application to the MK problem

In this section we prove SoS rank lower and upper bounds for the MK problem.

5.1 SoS rank lower bound

We start with presenting the lower bound for the MK Problem.

▶ **Lemma 14.** *The SoS rank lower bound for the MK problem for is at least $\Omega(\sqrt{n}+\sqrt{n\log P})$.*

Proof. By contradiction, assume there exists a SoS certificate of degree smaller than $\Omega(\sqrt{n}+\sqrt{n\log P})$ for the function $\sum_{i=1}^{n}x_i-1$, namely

$$\sum_{i=1}^{n}x_i-1=s_0(x)+s_1(x)\left(\sum_{i=1}^{x}x_i-\frac{1}{P}\right),\qquad\text{for every } x\in\{0,1\}^n.$$

for s_0 and s_1 SoS of degree smaller than $\Omega(\sqrt{n}+\sqrt{n\log P})$. Since $s_0(x)\geq 0$, for every $x\in\{0,1\}^n$, we know that

$$s_1(0,\ldots,0)\geq \frac{-1}{-\frac{1}{P}}=P \qquad \text{and} \qquad s_1(x)\leq \frac{\sum_{i=1}^n x_i-1}{\sum_{i=1}^x x_i-\frac{1}{P}}\leq 1 \text{ for every other } x\in\{0,1\}^n.$$

This implies the existence of the function $\overline{s}(x)=s(x)/P$ of degree smaller than $\Omega(\sqrt{n}+\sqrt{n\log P})$ that approximates the NOR function within ℓ_∞-norm within the error $1/P$ which contradicts Theorem 10. ◀

A direct application of Lemma 14 gives the following corollary:

▶ **Corollary 5.1.** *The SoS rank lower bound for MK problem for $P=2$ is at least $\Omega(\sqrt{n})$.*

5.2 SoS rank upper bounds

In this section we prove an upper bound on the SoS rank for the MK problem for $P=2$. We start with proving the following Lemma.

▶ **Lemma 15.** *For every $n\in\mathbb{N}$ there exists a function $f:\{0,1\}^n\to\mathbb{R}$ of degree $2\lceil\sqrt{n}\,\rceil$ such that $f(0,\ldots,0)\geq 2$, $f(x)=0$ for every $x\in\{0,1\}^n$ such that $|x|=1$ and for every other $x\in\{0,1\}^n$ the function takes the value $|f(x)|\leq 1$.*

Proof. Our construction provides a symmetric polynomial thus in the following we construct a univariate polynomial $g:\mathbb{R}\to\mathbb{R}$ such that $f(x_1,\ldots,x_n):=g(\sum_{i=1}^n x_i)$ satisfies the claimed properties. We start with presenting steps for constructing polynomial g.

Step 1: Consider a Chebyshev polynomial $T_d(x):[-1,1]\to[-1,1]$ of degree $d=2\lceil\sqrt{n}\,\rceil$. Prove that the smallest root (left-most one) appears before point $x=-1+1/n$.

Step 2: Shift and spread the polynomial $T_d(x)$ such that the domain is $[0,n]$, namely consider $T_d^{'}(x)=T_d(2x/n-1)$. Note that the smallest zero of $T_d^{'}$ appears before point $x=1/2$.

Step 3: Extend the domain of $T_d^{'}(x)$ to be $[-1/2,n]$ and then prove that $T_d^{'}(-1/2)=T_d(-1-1/n)$ takes the absolute value at least 2.

Step 4: Consider a polynomial $T_d^{''}$ obtained from shifting the polynomial $T_d^{'}$ to the right such that the smallest zero is exactly at point $x=1$. Note that $g:=T_d^{''}$ satisfies all the required properties.

It remains to prove the claims from Step 1 and 3. Let us start with the claim from Step 1. It is known that Chebyshev polynomial of degree d, $T_d(x)$, has zeros at points $\cos\left(\frac{2j-1}{d}\frac{\pi}{2}\right)$ for $j=1,\ldots,d$ see e.g. [47][Equation 1.17], thus smallest zero is at the point $\cos\left(\pi-\frac{\pi}{2d}\right)$. We consider $d=2\lceil\sqrt{n}\,\rceil$, thus it is sufficient to prove that $\cos\left(\pi-\frac{\pi}{4\sqrt{n}}\right)+1-\frac{1}{n}\leq 0$ for every $n\in\mathbb{R}_+$. To do so, consider the function

$$h(z)=\cos\left(\pi-\frac{\pi}{4z}\right)+1-\frac{1}{z^2}$$

and note that $h(z)$ is increasing in z for $z\in\mathbb{R}_+$. Indeed the derivative of $h(z)$ is equal to

$$h^{'}(z)=\frac{2}{z^3}-\frac{\pi}{4z^2}\sin\left(\pi-\frac{\pi}{4z}\right)=\frac{8-\pi z\sin\left(\frac{\pi}{4z}\right)}{4z^3}.$$

Since, for all $z\in\mathbb{R}_+$, $\sin z\leq z$, it is enough to show that $8-\pi z\frac{\pi}{4z}\geq 0$, which is clearly the case. Next we show that $\lim_{z\to\infty}h(z)=0$. Indeed, by the algebraic limit theorem

$$\lim_{z\to\infty}\left(\cos\left(\pi-\frac{\pi}{4z}\right)+1-\frac{1}{z^2}\right)=\lim_{z\to\infty}\cos\left(\pi-\frac{\pi}{4z}\right)-\lim_{z\to\infty}\frac{1}{z^2}+1=0.$$

It remains to prove the claim from Step 3. To do so, we use the characterization of Chebyshev polynomial given in [47, Equation 1.12]:

$$T_d(x) = \frac{1}{2}\left(\left(x - \sqrt{x^2-1}\right)^d + \left(\sqrt{x^2-1} + x\right)^d\right).$$

For $d = 2\lceil\sqrt{n}\rceil$ and $x = -1 - 1/n$ we get:

$$T_{2\lceil\sqrt{n}\rceil}\left(-1-\frac{1}{n}\right) \geq \frac{1}{2}\left(\left(-1-\frac{1}{n}-\sqrt{\left(-1-\frac{1}{n}\right)^2-1}\right)^{2\lceil\sqrt{n}\rceil}\right)$$
$$\geq \frac{1}{2}\left(\left(-1-\frac{\sqrt{2}}{\sqrt{n}}\right)^{2\sqrt{n}}\right)$$

where $\frac{1}{2}\left(\left(-1-\frac{\sqrt{2}}{\sqrt{n}}\right)^{2\sqrt{n}}\right)$ is increasing in n and for $n = 1$ takes value bigger than 2. ◀

Finally, we prove the SoS rank upper bound for the MK problem for $P = 2$.

▶ **Lemma 16.** *The SoS rank for the MK for $P = 2$ is at most $d = \lceil\frac{n+4\lceil\sqrt{n}\rceil}{2}\rceil$.*

Proof. We show that there exist a SoS certificate of degree $d = \lceil\frac{n+4\lceil\sqrt{n}\rceil}{2}\rceil$ for the function $\sum_{i=1}^m x_i - 1$. Consider the polynomial f of degree $2\lceil\sqrt{n}\rceil$ constructed in Lemma 15. Take $s_1 = f^2$ and note that $\sum_{i=1}^n x_i - 1 - 0.8f^2(x)\left(\sum_{i=1}^m x_i - 1/2\right) \geq 0$ for every $x \in \{0,1\}^n$, since $(0.8 \cdot 2)^2 > 2$ and $0.8^2 < 2/3$. Applying Theorem 4 we get that there exists a SoS certificate for $\sum_{i=1}^n -1$ of degree $d = \lceil\frac{n+4\lceil\sqrt{n}\rceil}{2}\rceil$. ◀

6 Application to the SC problem

In the last section we prove the SoS rank lower bound for the SC problem.

▶ **Lemma 17.** *The SoS rank for the SC problem is at least $\Omega(\sqrt{n})$.*

Proof. By contradiction, assume there exists a SoS certificate of degree smaller than $\Omega(\sqrt{n})$ for the function $\sum_{i=1}^n x_i - 2$, namely: $\sum_{i=1}^n x_i - 2 = s_0(x) + \sum_{j=1}^n s_j(x)\left(\sum_{\substack{i=1\\i\neq j}}^n x_i - 1\right)$. We follow the idea in the proof of Lemma 14. Let $s(x) = \sum_{i=1}^n s_i(x)$ and take $k = \lfloor n/3\rfloor$. For every $j \in [n]$ and $x \in \{0,1\}^n$ such that $|x| \geq 3$ we know that $\sum_{\substack{i=1\\i\neq j}}^n x_i - 1 \geq \sum_{i=1}^n x_i - 2$. Thus, note that for every $\ell \in [k]$ and for every $x \in \{0,1\}^n$ such that $|x| = 3\ell$ we have:

$$s(0,\ldots,0) \geq 2 \qquad \text{and} \qquad s(x) \leq 1, \qquad \text{for every } x \in \{0,1\}^n, \text{ s.t. } |x| = 3\ell, \text{ for } \ell \in [k].$$

Now consider a symmetric function $\overline{s}$ over k-dimensional boolean hypercube $\{0,1\}^k$, $\overline{s} := \{0,1\}^k \to \mathbb{R}$ that takes the values:

$$\overline{s}(z) := \binom{n}{3\ell}^{-1} \sum_{\substack{x\in\{0,1\}^n\\|x|=3\ell}} s(x), \qquad \text{for every } z \in \{0,1\}^k,\ |z| = \ell.$$

Clearly, $deg(\overline{s})$ is at most $deg(s)$ and note that it holds:

$$\overline{s}(0,\ldots,0) \geq 2 \qquad \text{and} \qquad \overline{s}(z) \leq 1 \qquad \text{for every other } z \in \{0,1\}^k$$

and the function $\overline{s}(z)/3$ is of degrees smaller than $\Omega(\sqrt{n})$ and approximates the NOR function in ℓ_∞-norm within the error $1/3$, which contradicts Theorem 10. ◀

Dynamic Time Warping in Strongly Subquadratic Time: Algorithms for the Low-Distance Regime and Approximate Evaluation

William Kuszmaul
Massachusetts Institute of Technology, Cambridge, USA
kuszmaul@mit.edu

Abstract

Dynamic time warping distance (DTW) is a widely used distance measure between time series, with applications in areas such as speech recognition and bioinformatics. The best known algorithms for computing DTW run in near quadratic time, and conditional lower bounds prohibit the existence of significantly faster algorithms.

The lower bounds do not prevent a faster algorithm for the important special case in which the DTW is small, however. For an arbitrary metric space Σ with distances normalized so that the smallest non-zero distance is one, we present an algorithm which computes $\text{dtw}(x, y)$ for two strings x and y over Σ in time $O(n \cdot \text{dtw}(x, y))$. When $\text{dtw}(x, y)$ is small, this represents a significant speedup over the standard quadratic-time algorithm.

Using our low-distance regime algorithm as a building block, we also present an approximation algorithm which computes $\text{dtw}(x, y)$ within a factor of $O(n^\epsilon)$ in time $\tilde{O}(n^{2-\epsilon})$ for $0 < \epsilon < 1$. The algorithm allows for the strings x and y to be taken over an arbitrary well-separated tree metric with logarithmic depth and at most exponential aspect ratio. Notably, any polynomial-size metric space can be efficiently embedded into such a tree metric with logarithmic expected distortion. Extending our techniques further, we also obtain the first approximation algorithm for edit distance to work with characters taken from an *arbitrary metric space*, providing an n^ϵ-approximation in time $\tilde{O}(n^{2-\epsilon})$, with high probability.

Finally, we turn our attention to the relationship between edit distance and dynamic time warping distance. We prove a reduction from computing edit distance over an arbitrary metric space to computing DTW over the same metric space, except with an added null character (whose distance to a letter l is defined to be the edit-distance insertion cost of l). Applying our reduction to a conditional lower bound of Bringmann and Künnemann pertaining to edit distance over $\{0, 1\}$, we obtain a conditional lower bound for computing DTW over a three letter alphabet (with distances of zero and one). This improves on a previous result of Abboud, Backurs, and Williams, who gave a conditional lower bound for DTW over an alphabet of size five.

With a similar approach, we also prove a reduction from computing edit distance (over generalized Hamming Space) to computing longest-common-subsequence length (LCS) over an alphabet with an added null character. Surprisingly, this means that one can recover conditional lower bounds for LCS directly from those for edit distance, which was not previously thought to be the case.

1 Introduction

Dynamic Time Warping distance (DTW) is a widely used distance measure between time series. DTW is particularly flexible in dealing with temporal sequences that vary in speed. To measure the distance between two sequences, portions of each sequence are allowed to be warped (meaning that a character may be replaced with multiple consecutive copies of itself), and then the warped sequences are compared by summing the distances between corresponding pairs of characters. DTW's many applications include phone authentication [19], signature verification [35], speech recognition [34], bioinformatics [1], cardiac medicine [15], and song identification [44].

The textbook dynamic-programming algorithm for DTW runs in time $O(n^2)$, which can be prohibitively slow for large inputs. Moreover, conditional lower bounds [13, 3] prohibit the existence of a strongly subquadratic-time algorithm[1], unless the Strong Exponential Time Hypothesis is false.

The difficulty of computing DTW directly has motivated the development of fast heuristics [39, 28, 29, 27, 11, 38] which typically lack provable guarantees.

On the theoretical side, researchers have considered DTW in the contexts of locality sensitive hashing [20] and nearest neighbor search [21], but very little additional progress has been made on the general problem in which one is given two strings x and y with characters from a metric space Σ, and one wishes to compute (or approximate) $\mathrm{dtw}(x, y)$.

To see the spectrum of results one might aim for, it is helpful to consider edit distance, another string-similarity measure, defined to be the minimum number of insertions, deletions, and substitutions needed to get between two strings. Like DTW, edit distance can be computed in time $O(n^2)$ using dynamic programming [42, 37, 41], and conditional lower bounds suggest that no algorithm can do significantly better [7, 13]. This has led to researchers focusing on specialized versions of the problem, especially in two important directions:

- **Low-Distance Regime Algorithms:** In the special case where the edit distance between two strings is small (less than $\sqrt{n}$), the algorithm of Landau, Myers and Schmidt [33] can be used to compute the exact distance in time $O(n)$. In general, the algorithm runs in time $O(n + \mathrm{ed}(x, y)^2)$. Significant effort has also been made to design variants of the algorithm which exhibit small constant overhead in practice [17].
- **Approximation Algorithms:** Andoni, Krauthgamer and Onak introduced an algorithm estimating edit distance within a factor of $(\log n)^{O(1/\varepsilon)}$ in time $O(n^{1+\varepsilon})$ [5], culminating a long line of research on approximation algorithms that run in close to linear time [6, 10, 9, 18]. Recently, Chakraborty et al. gave the first strongly subquadratic algorithm to achieve a *constant* approximation, running time $O(n^{12/7})$ [16].

This paper presents the first theoretical results in these directions for DTW.

[1] An algorithm is said to run in strongly subquadratic time if it runs in time $O(n^{2-\epsilon})$ for some constant $\epsilon > 0$. Although strongly subquadratic time algorithms are prohibited by conditional lower bounds, runtime improvements by subpolynomial factors are not. Such improvements have been achieved [25].

A Low-Distance Regime Algorithm for DTW (Section 3)

We present the first algorithm for computing DTW in the low-distance regime. Our algorithm computes $\mathrm{dtw}(x, y)$ in time $O(n \cdot \mathrm{dtw}(x, y))$ for strings x and y with characters taken from an arbitrary metric space in which the minimum non-zero distance is one. The key step in our algorithm is the design of a new dynamic-programming algorithm for DTW, which lends itself especially well to the low-distance setting.

Our dynamic program relies on a recursive structure in which the two strings x and y are treated asymmetrically within each subproblem: One of the strings is considered as a sequence of letters, while the other string is considered as a sequence of runs (of equal letters). The subproblems build on one-another in a way so that at appropriate points in the recursion, we toggle the role that the two strings play. The asymmetric treatment of the strings limits the number of subproblems that can have return-values less than any given threshold K to $O(nK)$, allowing for a fast algorithm in the low-distance setting.

We remark that the requirement of having the smallest distance between distinct characters be 1 is necessary for the low-distance regime algorithm to be feasible, since otherwise distances can simply be scaled down to make every DTW instance be low-distance.

Approximating DTW Over Well Separated Tree Metrics (Section 4)

We design the first approximation algorithm for DTW to run in strongly subquadratic time. Our algorithm computes $\mathrm{dtw}(x, y)$ within an n^ϵ-approximation in time $\tilde{O}(n^{2-\epsilon})$. The algorithm allows for the strings x and y have characters taken from an arbitrary well-separated tree metric of logarithmic depth and at most exponential aspect ratio.[2] These metric spaces are universal in the sense that any finite metric space M of polynomial size can be efficiently embedded into a well-separated tree metric with expected distortion $O(\log |M|)$ and logarithmic depth [22, 8].

An important consequence of our approximation algorithm is for the special case of DTW over the reals. Exploiting a folklore embedding from $\mathbb{R}$ to a well-separated tree metric metric, we are able to obtain with high probability an $O(n^\epsilon)$-approximation for $\mathrm{dtw}(x, y)$ in time $\tilde{O}(n^{2-\epsilon})$, for any strings x and y of length at most n over a subset of the reals with a polynomial aspect ratio.

In the special case of DTW over the reals, previous work has been done to find approximation algorithms under certain geometric assumptions about the inputs x and y [4, 43]. To the best of our knowledge, our approximation algorithm is the first to not rely on any such assumptions.

It is interesting to note that our results on low-distance regime and approximation algorithms for DTW have bounds very similar to the earliest results for edit distance in the same directions. Indeed, the first algorithm to compute edit distance in the low-distance regime [23] exploited properties of a (now standard) dynamic-programming algorithm in order to compute $\mathrm{ed}(x, y)$ in time $O(n \cdot \mathrm{ed}(x, y))$. This implicitly resulted in the first approximation algorithm for edit distance, allowing one to compute an $O(n^\epsilon)$-approximation in time $O(n^{2-\epsilon})$. Until the work of [6] and [5], which culminated in an algorithm with a polylogarithmic approximation ratio, the best known approximation ratio for edit distance remained polynomial for roughly twenty years [33, 9, 10].

[2] The *aspect* ratio of a metric space is the ratio between the largest and smallest non-zero distances in the space.

The $\tilde{O}(n^{2-\epsilon})$-time $O(n^{\epsilon})$-approximation tradeoff is also the current state-of-the-art for another related distance measurement known as Fréchet distance [14], and is achieved using an algorithm that differs significantly from its edit-distance and DTW counterparts.

Reduction from Edit Distance to DTW (Section 5)

We show that the similarity between our results for DTW and the earliest such results for edit distance is not coincidental. In particular, we prove a simple reduction from computing edit distance over an arbitrary metric space to computing DTW over the same metric space (with an added null character). Consequently, any algorithmic result for computing DTW in the low-distance regime or approximating DTW immediately implies the analogous result for edit distance. The opposite direction is true for lower bounds. For example, the conditional lower bound of Bringmann and Künnemann [13], which applies to edit distance over the alphabet $\{0, 1\}$, now immediately implies a conditional lower bound for DTW over an alphabet of size three (in which characters are compared with distances zero and one). This resolves a direction of work posed by Abboud, Backurs, and Williams [3], who gave a conditional lower bound for DTW over an alphabet of size five, and noted that if one could prove the same lower bound for an alphabet of size three, then the runtime complexity of DTW over generalized Hamming space would be settled (modulo the Strong Exponential Time Hypothesis). Indeed, it is known that over an alphabet of size two, DTW can be computed in strongly subquadratic time [3].

Using a similar approach we also prove a simple reduction from computing edit distance (over generalized Hamming space) to computing the longest-common-subsequence length (LCS) between two strings. Thus conditional lower bounds for computing edit distance directly imply conditional lower bounds for computing LCS (over an alphabet with one additional character). This was not previously though to be the case. Indeed, the first known conditional lower bounds for LCS came after those for edit distance [2, 7], and it was noted by Abboud et al. [2] that *"A simple observation is that the computation of the LCS is equivalent to the computation of the Edit-Distance when only deletions and insertions are allowed, but no substitutions. Thus, intuitively, LCS seems like an easier version of Edit Distance, since a solution has fewer degrees of freedom, and the lower bound for Edit-Distance does not immediately imply any hardness for LCS."* Our reduction violates this intuition by showing that edit distance without substitutions can be used to efficiently simulate edit distance without substitutions.

Approximating Edit Distance Over an Arbitrary Metric (Section 6)

The aforementioned results for approximating edit distance [23, 9, 10, 33, 6, 5, 16, 32] consider only the case in which insertion, deletion, and substitution costs are all constant. To the best of our knowledge, no approximation algorithm is known for the more general case in which characters are taken from an arbitrary metric space and edit costs are assigned based on metric distances between characters. This variant of edit distance is sometimes referred to as *general edit distance* [36]. The study of general edit distance dates back to the first papers on edit distance [42, 40], and allowing for nonuniform costs is important in many applications, including in computational biology [26].

We present an approximation algorithm for edit distance over an an arbitrary metric. Our algorithm runs in time $\tilde{O}(n^{2-\epsilon})$ and computes an $O(n^{\epsilon})$-approximation for $\mathrm{ed}(x, y)$ with high probability. Note that for the case where characters are taken from a well-separated tree metric with logarithmic depth and at most exponential aspect ratio, the result already

follows from our approximation algorithm for DTW, and our reduction from edit distance to DTW. The approach taken in Section 6 is particularly interesting in that it places no restrictions on the underlying metric space.

Both our approximation algorithm for DTW and our approximation algorithm for edit distance exhibit relatively weak runtime/approximation tradeoffs. To the best of our knowledge, however, they are the first such algorithms to run in strongly subquadratic time.

2 Preliminaries

In this section, we present preliminary definitions and background on dynamic time warping distance (DTW) and edit distance.

Dynamic Time Warping Distance

For a metric space Σ, the dynamic time warping distance (DTW) between two strings $x, y \in \Sigma^n$ is a natural measure of similarity between the strings.

Before fully defining DTW, we first introduce the notion of an *expansion* of a string.

▶ **Definition 2.1.** *The* runs *of a string $x \in \Sigma^n$ are the maximal subsequences of consecutive letters with the same value. One can* extend *a run by replacing it with a longer run of the same letter. An* expansion *of the string x is any string which can be obtained from x by extending runs.*

As an example, consider $x = aaaccbbd$. Then the runs of x are aaa, cc, bb, and d. The string $\overline{x} = aaacccccbbdd$ is an expansion of x and extends the runs containing c and d.

Using the terminology of expansions, we now define DTW.

▶ **Definition 2.2.** *Consider strings x and y of length n over a metric (Σ, d). A* correspondence *$(\overline{x}, \overline{y})$ between x and y is a pair of equal-length expansions $\overline{x}$ of x and $\overline{y}$ of y. The* cost *of a correspondence is given by $\sum_i d(\overline{x}_i, \overline{y}_i)$.*

The dynamic time warping distance $\mathrm{dtw}(x, y)$ *is defined to be the minimum cost of a correspondence between x and y.*

When referring to a run r in one of x or y, and when talking about a correspondence $(\overline{x}, \overline{y})$, we will often use r to implicitly refer to the extended run corresponding with r in the correspondence. Whether we are referring to the original run or the extended version of the run should be clear from context.

Note that any minimum-length optimal correspondence between strings $x, y \in \Sigma^n$ will be of length at most $2n$. This is because if a run r_1 in x overlaps a run r_2 in y in the correspondence, then we may assume without loss of generality that at most one of the two runs is extended by the correspondence. (Otherwise, we could un-extend each run by one and arrive at a shorter correspondence with no added cost.)

Edit Distance Over an Arbitrary Metric

The *simple edit distance* between two strings x and y is the minimum number of insertions, deletions, and substitutions needed to transform x into y. In this paper we will mostly focus on a more general variant of edit distance, in which characters are taken from an arbitrary metric:

▶ **Definition 2.3.** *Let x and y be strings over an alphabet Σ, where $(\Sigma \cup \{\emptyset\}, d)$ is a metric space. We say that the* magnitude *$|l|$ of a letter $l \in \Sigma$ is $d(\emptyset, l)$. We define the* edit distance *between x and y to be the minimum cost of a sequence of edits from x to y, where the insertion or deletion of a letter l costs $d(\emptyset, l)$, and the substitution of a letter l to a letter l' costs $d(l, l')$.*

3 Computing DTW in the Low-Distance Regime

In this section, we present a low-distance regime algorithm for DTW (with characters from an arbitrary metric in which all non-zero distances are at least one). Given that $\mathrm{dtw}(x, y)$ is bounded above by a parameter K, our algorithm can compute $\mathrm{dtw}(x, y)$ in time $O(nK)$. Moreover, if $\mathrm{dtw}(x, y) > K$, then the algorithm will conclude as much. Consequently, by doubling our guess for K repeatedly, one can compute $\mathrm{dtw}(x, y)$ in time $O(n \cdot \mathrm{dtw}(x, y))$.

Consider x and y of length n with characters taken from a metric space Σ in which all non-zero distances are at least one. In the textbook dynamic program for DTW [30], each pair of indices $i, j \in [n]$ represents a subproblem $T(i, j)$ whose value is $\mathrm{dtw}(x[1 : i], y[1 : j])$. Since $T(i, j)$ can be determined using $T(i - 1, j), T(i, j - 1), T(i - 1, j - 1)$, and knowledge of x_i and y_j, this leads to an $O(n^2)$ algorithm for DTW. A common heuristic in practice is to construct only a small band around the main diagonal of the dynamic programming grid; by computing only entries $T(i, j)$ with $|i - j| \leq 2K$, and treating other subproblems as having infinite return values, one can obtain a correct computation for DTW as long as there is an optimal correspondence which matches only letters which are within K of each other in position. This heuristic is known as the Sakoe-Chiba Band [39] and is employed, for example, in the commonly used library of Giorgino [24].

The Sakoe-Chiba Band heuristic can perform badly even when $\mathrm{dtw}(x, y)$ is very small, however. Consider $x = abbb \cdots b$ and $y = aaa \cdots ab$. Although $\mathrm{dtw}(x, y) = 0$, if we restrict ourselves to matching letters within K positions of each other for some small K, then the resulting correspondence will cost $\Omega(n)$.

In order to obtain an algorithm which performs well in the low-distance regime, we introduce a new dynamic program for DTW. The new dynamic program treats x and y asymmetrically within each subproblem. Loosely speaking, for indices i and j, there are two subproblems $\mathrm{SP}(x, y, i, j)$ and $\mathrm{SP}(y, x, i, j)$. The first of these subproblems evaluates to the DTW between the first i runs of x and the first j letters of y, with the added condition that the final run of $y[1 : j]$ is not extended. The second of the subproblems is analogously defined as the DTW between the first i runs of y and the first j letters of x with the added condition that the final run of $x[1 : j]$ is not extended.

The recursion connecting the new subproblems is somewhat more intricate than for the textbook dynamic program. By matching the i-th run with the j-th letter, however, we limit the number of subproblems which can evaluate to less than K. In particular, if the j-th letter of y is in y's t-th run, then any correspondence which matches the i-th run of x to the j-th letter of y must cost at least $\Omega(|i - t|)$. (This is formally shown in the extended paper [31].) Thus for a given j, there are only $O(K)$ options for i such that $\mathrm{SP}(x, y, i, j)$ can possibly be at most K, and similarly for $\mathrm{SP}(y, x, i, j)$. Since we are interested in the case of $\mathrm{dtw}(x, y) \leq K$, we can restrict ourselves to the $O(nK)$ subproblems which have the potential to evaluate to at most $O(K)$. Notice that, in fact, our algorithm will work even when $\mathrm{dtw}(x, y) > K$ as long as there is an optimal correspondence between x and y which only matches letters from x from the r_x-th run with letters from y from the r_y-th run if $|r_x - r_y| \leq O(K)$.

Formally we define our recursive problems in a manner slightly different from that described above. Let x and y be strings of length at most n and let K be a parameter which we assume is greater than $\text{dtw}(x, y)$. Our subproblems will be the form $\text{SP}(x, y, r_x, r_y, o_y)$, which is defined as follows. Let x' consist of the first r_x runs of x and y' consist of the first r_y runs of y until the o_y-th letter in the r_y-th run. Then $\text{SP}(x, y, r_x, r_y, o_y)$ is the value of the optimal correspondence between x' and y' such that the r_y-th run in y' is not extended.[3] If no such correspondence exists (which can only happen if $r_y \leq 1$ or $r_x = 0$), then the value of the subproblem is ∞. Note that we allow r_x, r_y, o_y to be zero, and if r_y is zero, then o_y must be zero as well. We also consider the symmetrically defined subproblems of the form $\text{SP}(y, x, r_y, r_x, o_x)$. We will focus on the subproblems of the first types, implicitly treating subproblems of the second type symmetrically.

▶ Example 3.1. Suppose characters are taken from generalized Hamming space, with distances of 0 and 1. The subproblem $\text{SP}(efabbccccd, ffaabcccddd, 5, 4, 2)$ takes the value of the optimal correspondence between $efabbcccc$ and $ffaabcc$ such that the final cc run in the latter is not extended. The subproblem's value turns out to be 3, due to the correspondence:

e f a a b b c c c c
f f a a b b b b c c .

The next lemma presents the key recursive relationship between subproblems. The lemma focuses on the case where $r_x, r_y, o_y \geq 1$.

▶ **Lemma 3.2.** *Suppose that r_x and r_y are both between 1 and the number of runs in x and y respectively; and that o_y is between 1 and the length of the r_y-th run in y. Let l_x be the length of the r_x-th run in x and l_y be the length of the r_y-th run in y. Let d be the distance between the letter populating the r_x-th run in x and the letter populating the r_y-th run in y. Then $\text{SP}(x, y, r_x, r_y, o_y)$ is given by*

$$\begin{cases} \min\left(\text{SP}(x, y, r_x, r_y, o_y - 1) + d, \text{SP}(x, y, r_x - 1, r_y, o_y - l_x) + d \cdot l_x\right) & \text{if } l_x \leq o_y \\ \min\left(\text{SP}(x, y, r_x, r_y, o_y - 1) + d, \text{SP}(y, x, r_y - 1, r_x, l_x - o_y) + d \cdot o_y\right) & \text{if } l_x > o_y. \end{cases}$$

Proof. Consider a minimum-cost correspondence A between the first r_x runs of x and the portion of y up until the o_y-th letter in the r_y-th run, such that the r_y-th run in y is not extended.

If the r_x-th run in A is extended, then the cost of A will be $\text{SP}(x, y, r_x, r_y, o_y - 1) + d$. If the r_x-th run in A is not extended, then we consider two cases.

In the first case, $l_x \leq o_y$. In this case, the entirety of the r_x-th run of x is engulfed by the r_y-th run of y in the correspondence A. Since the r_x-th run is not extended, the cost of the overlap is $l_x \cdot d$. Thus the cost of A must be $\text{SP}(x, y, r_x - 1, r_y, o_y - l_x) + d \cdot l_x$.

Moreover, since A is minimum-cost, as long as $l_x \leq o_y$, the cost of A is at most the above expression, regardless of whether the r_x-th run in x is extended in A.

In the second case, $l_x > o_y$. In this case, the first o_y letters in the r_y-th run of y all overlap the r_x-th run of x in A. Since the r_y-th run is not extended, the cost of the overlap is $d \cdot o_y$. Thus, since the r_x-th run in x is also not extended in A, the cost of A must be $\text{SP}(y, x, r_y - 1, r_x, l_x - o_y) + d \cdot o_y$. Moreover, since A is minimal, as long as $l_x > o_y$, the cost of A is at most the above expression, regardless of whether the r_x-th run in x is extended. ◀

[3] If $o_y = 0$, then the r_y-th run in y' is empty and thus trivially cannot be extended.

The above lemma handles cases where $r_x, r_y, o_y > 0$. In the case where $r_x > 0$, $r_y > 0$, and $o_y = 0$, $\mathrm{SP}(x, y, r_x, r_y, o_y)$ is just the dynamic time warping distance between the first r_x runs of x and the first $r_y - 1$ runs of y, given by $\min\left(\mathrm{SP}(x, y, r_x, r_y - 1, t_1), \mathrm{SP}(y, x, r_y - 1, r_x, t_2)\right)$, where t_1 is the length of the $(r_y - 1)$-th run in y and t_2 is the length of the r_x-th run in x. The remaining cases are edge-cases with $\mathrm{SP}(x, y, r_x, r_y, o_y) \in \{0, \infty\}$. (See the extended paper [31].)

One can show that any correspondence A in which a letter from the r_x-th run of x is matched with a letter from the r_y-th run of y must contain must contain at least $\frac{|r_x - r_y| - 1}{2}$ instances of unequal letters being matched. It follows that if $\mathrm{dtw}(x, y) \leq K$, then we can limit ourselves to subproblems in which $|r_x - r_y| \leq O(K)$. For each of the n options of (r_y, o_y), there are only $O(K)$ options of r_x that must be considered. This limits the total number of subproblems to $O(nK)$. The resulting dynamic program yields the following theorem, the full proof of which appears in the extended paper [31].

▶ **Theorem 3.3.** *Let x and y be strings of length n taken from a metric space Σ with minimum non-zero distance at least one, and let K be parameter such that $\mathrm{dtw}(x, y) \leq K$. Then there exists a dynamic program for computing $\mathrm{dtw}(x, y)$ in time $O(nK)$. Moreover, if $\mathrm{dtw}(x, y) > K$, then the dynamic program will return a value greater than K.*

By repeatedly doubling one's guess for K until the computed value of $\mathrm{dtw}(x, y)$ evaluates to less than K, one can therefore compute $\mathrm{dtw}(x, y)$ in time $O(n \cdot \mathrm{dtw}(x, y))$.

4 Approximating DTW Over Well-Separated Tree Metrics

In this section, we present an $\tilde{O}(n^{2-\epsilon})$-time $O(n^{\epsilon})$-approximation algorithm for DTW over a well-separated tree metric with logarithmic depth. We begin by presenting a brief background on well-separated tree metrics.

▶ **Definition 4.1.** *Consider a tree T whose vertices form an alphabet Σ, and whose edges have positive weights. T is said to be a* well-separated tree metric *if every root-to-leaf path consists of edges ordered by nonincreasing weight. The* distance *between two nodes $u, v \in \Sigma$ is defined as the maximum weight of any edge in the shortest path from u to v.*

Well-separated tree metrics are universal in the sense that any metric Σ can be efficiently embedded (in time $O(|\Sigma|^2)$) into a well-separated tree metric T with expected distortion $O(\log |\Sigma|)$ [22]. Moreover, the tree metric may be made to have logarithmic depth using Theorem 8 of [8]. For strings $x, y \in \Sigma^n$, let $\mathrm{dtw}_T(x, y)$ denote the dynamic time warping distance after embedding Σ into T. Then the tree-metric embedding guarantees that $\mathrm{dtw}(x, y) \leq \mathrm{dtw}_T(x, y)$ and that $\mathbb{E}[\mathrm{dtw}_T(x, y)] \leq O(\log n) \cdot \mathrm{dtw}(x, y)$. (The latter fact may be slightly nonobvious and is further explained in the extended paper [31].)

It follows that any approximation algorithm for DTW over well-separated tree metrics will immediately yield an approximation algorithm over an arbitrary polynomial-size metric Σ, with two caveats: the new algorithm will have its multiplicative error increased by $O(\log n)$; and $O(\log n)$ instances of Σ embedded into a well-separated tree metric must be precomputed for use by the algorithm (requiring, in general, $O(|\Sigma|^2 \log n)$ preprocessing time). In particular, given $O(\log n)$ tree embeddings of Σ, $T_1, \ldots, T_{O(\log n)}$, with high probability $\min_i \left(\mathrm{dtw}_{T_i}(x, y)\right)$ will be within a logarithmic factor of $\mathrm{dtw}(x, y)$.

The remainder of the section will be devoted to designing an approximation algorithm for DTW over a well-separated tree metric. We will prove the following theorem:

▶ **Theorem 4.2.** *Consider $0 < \epsilon < 1$. Suppose that Σ is a well-separated tree metric of polynomial size and at most logarithmic depth. Moreover, suppose that the aspect ratio of Σ is at most exponential in n (i.e., the ratio between the largest distance and the smallest non-zero distance). Then in time $\tilde{O}(n^{2-\epsilon})$ we can obtain an $O(n^\epsilon)$-approximation for $\mathrm{dtw}(x, y)$ for any $x, y \in \Sigma^n$.*

An important consequence of the theorem occurs for DTW over the reals. When Σ is an $O(n)$-point subset of the reals with a polynomial aspect ratio, there exists an $O(n \log n)$-time embedding with $O(\log n)$ expected distortion from Σ to a well-separated tree metric of size $O(n)$ with logarithmic depth. (This is further discussed in the extended paper [31].). This gives the following corollary:

▶ **Corollary 4.3.** *Consider $0 < \epsilon < 1$. Suppose that $\Sigma = [0, n^c] \cap \mathbb{Z}$ for some constant c. Then in time $\tilde{O}(n^{2-\epsilon})$ we can obtain an $O(n^\epsilon)$-approximation for $\mathrm{dtw}(x, y)$ with high probability for any $x, y \in \Sigma^n$.*

In proving Theorem 4.2, our approximation algorithm will take advantage of what we refer to as the *r-simplification* of a string over a well-separated tree metric.

▶ **Definition 4.4.** *Let T be a well-separated tree metric whose nodes form an alphabet Σ. For a string $x \in \Sigma^n$, and for any $r \geq 1$, the* r-simplification *$s_r(x)$ is constructed by replacing each letter $l \in x$ with its highest ancestor l' in T that can be reached from l using only edges of weight at most $r/4$.*

Our approximation algorithm will apply the low-distance regime algorithm from the previous section to $s_r(x)$ and $s_r(y)$ for various r in order to extract information about $\mathrm{dtw}(x, y)$. Notice that using our low-distance regime algorithm for DTW, we get the following useful lemma for free:

▶ **Lemma 4.5.** *Consider $0 < \epsilon < 1$. Suppose that for all pairs l_1, l_2 of distinct letters in Σ, $d(l_1, l_2) \geq \gamma$. Then for $x, y \in \Sigma^n$ there is an $O(n^{2-\epsilon})$ time algorithm which either computes $\mathrm{dtw}(x, y)$ exactly, or concludes that $\mathrm{dtw}(x, y) > \gamma n^{1-\epsilon}$.*

The next lemma states three important properties of r-simplifications. We remark that the same lemma appears in our concurrent work on the communication complexity of DTW, in which we use the lemma in designing an efficient one-way communication protocol [12].

▶ **Lemma 4.6.** *Let T be a well-separated tree metric with distance function d and whose nodes form the alphabet Σ. Consider strings x and y in Σ^n.*

Then the following three properties of $s_r(x)$ and $s_r(y)$ hold:

- *For every letter $l_1 \in s_r(x)$ and every letter $l_2 \in s_r(y)$, if $l_1 \neq l_2$, then $d(l_1, l_2) > r/4$.*
- *For all α, if $\mathrm{dtw}(x, y) \leq nr/\alpha$ then $\mathrm{dtw}(s_r(x), s_r(y)) \leq nr/\alpha$.*
- *If $\mathrm{dtw}(x, y) > nr$, then $\mathrm{dtw}(s_r(x), s_r(y)) > nr/2$.*

The first and second parts of Lemma 4.6 are straightforward from the definitions of $s_r(x)$ and $s_r(y)$. The third part follows from the observation that a correspondence C between x and y can cost at most $|C| \cdot \frac{r}{4}$ more than the corresponding correspondence between $s_r(x)$ and $s_r(y)$, where $|C|$ denotes the length of the correspondence. Since there exists an optimal correspondence between $s_r(x)$ and $s_r(y)$ of length no more than $2n$, it follows that $\mathrm{dtw}(x, y) \leq \mathrm{dtw}(s_r(x), s_r(y)) + nr/2$, which implies the third part of the lemma.

A full proof of Lemma 4.6 appears in the extended paper [31]. Next we prove Theorem 4.2.

Proof of Theorem 4.2. Without loss of generality, the minimum non-zero distance in Σ is 1 and the largest distance is some value m, which is at most exponential in n.

We begin by defining the (r, n^ϵ)-*DTW gap* problem for $r \geq 1$, in which for two strings x and y a return value of 0 indicates that $\mathrm{dtw}(x, y) < nr$ and a return value of 1 indicates that $\mathrm{dtw}(x, y) \geq n^{1-\epsilon}r$. By Lemma 4.6, in order to solve the (r, n^ϵ)-DTW gap problem for x and y, it suffices to determine whether $\mathrm{dtw}(s_r(x), s_r(y)) \leq n^{1-\epsilon}r$. Moreover, because the minimum distance between distinct letters in $s_r(x)$ and $s_r(y)$ is at least $r/4$, this can be done in time $O(n^{2-\epsilon} \log n)$ using Lemma 4.5.[4]

In order to obtain an n^ϵ-approximation for $\mathrm{dtw}(x, y)$, we begin by using Lemma 4.5 to either determine $\mathrm{dtw}(x, y)$ or to determine that $\mathrm{dtw}(x, y) \geq n^{1-\epsilon}$. For the rest of the proof, suppose we are in the latter case, meaning that we know $\mathrm{dtw}(x, y) \geq n^{1-\epsilon}$.

We will now consider the $(2^i, n^\epsilon/2)$-DTW gap problem for $i \in \{0, 1, 2, \ldots, \lceil \log m \rceil\}$. (Recall that m is the largest distance in Σ.) If the $(2^0, n^\epsilon/2)$-DTW gap problem returned 0, then we would know that $\mathrm{dtw}(x, y) \leq n$, and thus we could return $n^{1-\epsilon}$ as an n^ϵ-approximation for $\mathrm{dtw}(x, y)$. Therefore, we need only consider the case where the $(2^0, n^\epsilon/2)$-DTW gap returns 1. Moreover we may assume without computing it that $(2^{\lceil \log m \rceil}, n^\epsilon/2)$-DTW gap returns 0 since trivially $\mathrm{dtw}(x, y)$ cannot exceed nm. Because $(2^i, n^\epsilon/2)$-DTW gap returns 1 for $i = 0$ and returns 0 for $i = \lceil \log m \rceil$, there must be some i such that $(2^{i-1}, n^\epsilon/2)$-DTW gap returns 1 and $(2^i, n^\epsilon/2)$-DTW gap returns 0. Moreover, we can find such an i by performing a binary search on i in the range $R = \{0, \ldots, \lceil \log m \rceil\}$. We begin by computing $(2^i, n^\epsilon/2)$-DTW gap for i in the middle of the range R. If the result is a one, then we can recurse on the second half of the range; otherwise we recurse on the first half of the range. Continuing like this, we can find in time $\tilde{O}(n^{2-\epsilon} \log \log m) = \tilde{O}(n^{2-\epsilon})$ some value i for which $(2^{i-1}, n^\epsilon/2)$-DTW gap returns 1 and $(2^i, n^\epsilon/2)$-DTW gap returns 0. Given such an i, we know that $\mathrm{dtw}(x, y) \geq \frac{2^{i-1}n}{n^\epsilon/2} = 2^i n^{1-\epsilon}$ and that $\mathrm{dtw}(x, y) \leq 2^i n$. Thus we can return $2^i n^{1-\epsilon}$ as an n^ϵ approximation of $\mathrm{dtw}(x, y)$. ◀

5 Reducing Edit Distance to DTW and LCS

In this section we present a simple reduction from edit distance over an arbitrary metric to DTW over the same metric.At the end of the section, we prove as a corollary a conditional lower bound for DTW over three-letter Hamming space, prohibiting any algorithm from running in strongly subquadratic time.

Surprisingly, the *exact same reduction*, although with a different analysis, can be used to reduce the computation of edit distance (over generalized Hamming space) to the computation of longest-common-subsequence length (LCS). Since computing LCS is equivalent to computing edit distance without substitutions, this reduction can be interpreted as proving that edit distance without substitutions can be used to efficiently simulate edit distance with substitutions, also known as *simple edit distance*.

Recall that for a metric $\Sigma \cup \{\emptyset\}$, we define the edit distance between two strings $x, y \in \Sigma^n$ such that the cost of a substitution from a letter l_1 to l_2 is $d(l_1, l_2)$, and the cost of a deletion or insertion of a letter l is $d(l, \emptyset)$. Additionally, define the *simple edit distance* $\mathrm{ed}_S(x, y)$ to be the edit distance using only insertions and deletions.

For a string $x \in \Sigma^n$, define the *padded string* $p(x)$ of length $2n + 1$ to be the string $\emptyset x_1 \emptyset x_2 \emptyset x_3 \cdots x_n \emptyset$. In particular, for $i \leq 2n + 1$, $p(x)_i = \emptyset$ when i is odd, and $p(x)_i = x_{i/2}$ when i is even. The following theorem proves that $\mathrm{dtw}(p(x), p(y)) = \mathrm{ed}(x, y)$.

[4] The logarithmic factor comes from the fact that evaluating distances between points may take logarithmic time in our well-separated tree metric.

▶ **Theorem 5.1.** *Let $\Sigma \cup \{\emptyset\}$ be a metric. Then for any $x, y \in \Sigma^n$, $\mathrm{dtw}(p(x), p(y)) = \mathrm{ed}(x, y)$.*

Proof sketch. A key observation is that when constructing an optimal correspondence between $p(x)$ and $p(y)$, one may w.l.o.g. extend only runs consisting of $\emptyset$ characters. In particular, suppose that one extends a non-$\emptyset$ character a in $p(x)$ to match a non-$\emptyset$ character b in $p(y)$. Then the extended run of a's must not only overlap b, but also the $\emptyset$-character preceding b. The total cost of extending a to overlap b is therefore $d(a, \emptyset) + d(a, b)$, which by the triangle inequality is at least $d(\emptyset, b)$. Thus instead of extending the run containing a, one could have instead extend a run of $\emptyset$-characters to overlap b at the same cost.

The fact that optimal correspondences arise by simply extending runs of $\emptyset$-characters can then be used to prove Theorem 5.1; in particular, given such a correspondence, one can obtain a sequence of edits from x to y by performing a substitution every time the correspondence matches two non-$\emptyset$ characters and a insertion or deletion every time the correspondence matches a non-$\emptyset$ character and a $\emptyset$-character. ◀

Theorem 5.2 proves an analogous reduction from edit distance to LCS.

▶ **Theorem 5.2.** *Let Σ be a generalized Hamming metric. Then for any $x, y \in \Sigma^n$, $\mathrm{ed}_S(p(x), p(y)) = 2\,\mathrm{ed}(x, y)$.*

Proof sketch. Each edit in x can be simulated in $s(x)$ using exactly two insertions/deletions. In particular, the substitution of a character in x corresponds with the deletion and insertion of the same character in $s(x)$; and the insertion/deletion of a character in x corresponds with the insertion/deletion of that character and an additional $\emptyset$-character in $s(x)$.

This establishes that $\mathrm{ed}_S(p(x), p(y)) \leq 2\,\mathrm{ed}(x, y)$. The other direction of inequality is somewhat more subtle, and is differed to the extended paper [31]. ◀

Whereas Theorem 5.2 embeds edit distance into simple edit distance with no distortion, Theorem 5.3 shows that no nontrivial embedding in the other direction exists.

▶ **Theorem 5.3.** *Consider edit distance over generalized Hamming space. Any embedding from edit distance to simple edit distance must have distortion at least 2.*

Combining Theorem 5.1 with known conditional lower bounds for computing edit distance [13] yields a new conditional lower bound for computing DTW over a three-letter alphabet (in which character distances are zero or one). This concludes a direction of work initiated by Abboud, Backurs, and Williams [3], who proved the same result over five-letter alphabet.

▶ **Corollary 5.4.** *Let $\Sigma = \{a, b, c\}$ with distance function $d(a, b) = d(a, c) = d(b, c) = 1$. If we assume the Strong Exponential Time Hypothesis, then for all $\epsilon > 1$, no algorithm can compute $\mathrm{dtw}(x, y)$ for $x, y \in \Sigma^n$ in time less than $O(n^{2-\epsilon})$.*

The full proofs of Theorems 5.1, 5.2, and 5.3, as well as Corollary 5.4 are differed to the extended paper [31].

6 Approximating Edit Distance Over an Arbitrary Metric

In this section we present an approximation algorithm for edit distance over an arbitrary metric space. Our algorithm achieves approximation ratio at most n^ϵ (with high probability) and runtime $\tilde{O}(n^{2-\epsilon})$. Note that when the metric is a well-separated tree metric, such an algorithm can be obtained by combining the approximation algorithm for DTW from Section

4 with the reduction in Section 5. Indeed the algorithm in this section is structurally quite similar to the one in Section 4, but uses a probability argument exploiting properties of edit distance in order to hold over an arbitrary metric.

▶ **Theorem 6.1.** *Let $(\Sigma \cup \{\emptyset\}, d)$ be an arbitrary metric space such that $|l| \geq 1$ for all $l \in \Sigma$. For all $0 < \epsilon < 1$, and for strings $x, y \in \Sigma^n$, there is an algorithm which computes an $O(n^\epsilon)$-approximation for $\mathrm{ed}(x, y)$ (with high probability) in time $\tilde{O}(n^{2-\epsilon})$.*

Using the standard dynamic-programming algorithm for computing $\mathrm{ed}(x, y)$ [42, 37, 41], one can easily obtain the following observation, analogous to Lemma 4.5 in Section 4:

▶ Observation 6.2. Consider $x, y \in \Sigma^n$, and let R be the smallest magnitude of the letters in x and y. There is an $O(n^{2-\epsilon})$-time algorithm which returns a value at least as large as $\mathrm{ed}(x, y)$; and which returns exactly $\mathrm{ed}(x, y)$ when $\mathrm{ed}(x, y) \leq R \cdot n^{1-\epsilon}$.

In order to prove Theorem 6.1, we present a new definition of the r-simplification of a string. The difference between this definition and the one in the preceding section allows the new definition to be useful when studying edit distance rather than dynamic time warping.

▶ **Definition 6.3.** *For a string $x \in \Sigma^n$ and for $r \geq 1$, we construct the* r-simplification $s_r(x)$ *by removing any letter l satisfying $|l| \leq r$.*

In the proof of Theorem 6.1 we use randomization in the selection of r in order to ensure that $s_r(x)$ satisfies desirable properties in expectation. The key proposition follows:

▶ **Proposition 6.4.** *Consider strings x and y in Σ^n. Consider $0 < \epsilon < 1$ and $R \geq 1$. Select r to be a random real between R and $2R$. Then the following three properties hold:*

- *Every letter l in $s_r(x)$ or $s_r(y)$ satisfies $|l| \geq R$.*
- *If $\mathrm{ed}(x, y) \leq \frac{nR}{15n^\epsilon}$ then $\mathbb{E}[\mathrm{ed}(s_r(x), s_r(y))] \leq \frac{nR}{3n^\epsilon}$.*
- *If $\mathrm{ed}(x, y) > 5nR$, then $\mathrm{ed}(s_r(x), s_r(y)) > nR$.*

The full proofs of Proposition 6.4 and of Theorem 6.1 appear in the extended paper [31]. Structurally, both proofs are similar to the analogous results in Section 4. The key difference appears in the proof of the second part of Proposition 6.4, which uses the random selection of r in order to probabilistically upper-bound $\mathrm{ed}(s_r(x), s_r(y)$. This is presented below.

▶ **Lemma 6.5.** *Consider strings x and y in Σ^n. Consider $R \geq 1$ and select r to be a random real between R and $2R$. Then $\mathbb{E}[\mathrm{ed}(s_r(x), s_r(y))] \leq 5\,\mathrm{ed}(x, y)$.*

Proof. Consider an optimal sequence S of edits from x to y. We will consider the cost of simulating this sequence of edits to transform $s_r(x)$ to $s_r(y)$. Insertions and deletions are easily simulated by either performing the same operation to $s_r(x)$ or performing no operation at all (if the operation involves a letter of magnitude less than or equal to r). Substitutions are slightly more complicated as they may originally be between letters $l_1 \in x$ and $l_2 \in y$ of different magnitudes. By symmetry, we may assume without loss of generality that $|l_1| < |l_2|$. We will show that the expected cost of simulating the substitution of l_1 to l_2 in $s_r(x)$ is at most $5d(l_1, l_2)$. Because insertions and deletions can be simulated with no overhead, it follows that $\mathbb{E}[\mathrm{ed}(s_r(x), s_r(y))] \leq 5\,\mathrm{ed}(x, y)$.

If $|l_1| \leq r < |l_2|$ then l_1 does not appear in $s_r(x)$ but l_2 remains in $s_r(y)$. Thus what was previously a substitution of l_1 with l_2 becomes an insertion of l_2 at cost $|l_2|$. On the other hand, if we do not have $|l_1| \leq r < |l_2|$, then either both l_1 and l_2 are removed from $s_r(x)$ and $s_r(y)$ respectively, in which the substitution operation no longer needs to be performed, or both l_1 and l_2 are still present, in which case the substitution operation can still be performed at cost $d(l_1, l_2)$. Therefore, the expected cost of simulating the substitution of l_1 to l_2 in $s_r(x)$ is at most

$$\Pr[|l_1| \leq r < |l_2|] \cdot |l_2| + d(l_1, l_2). \tag{1}$$

Because r is selected at random from the range $[R, 2R]$, the probability that $|l_1| \leq r < |l_2|$ is at most $\frac{|l_2|-|l_1|}{R}$. By the triangle inequality, this is at most $\frac{d(l_1,l_2)}{R}$. If we suppose that $|l_2| \leq 4R$, then it follows by (1) that the expected cost of simulating the substitution of l_1 to l_2 in $s_r(x)$ is at most $\frac{d(l_1,l_2)}{R} \cdot 4R + d(l_1, l_2) \leq 5d(l_1, l_2)$.

If, on the other hand, $|l_2| > 4R$, then in order for $|l_1| \leq r$ to be true, we must have $|l_1| \leq 2R$, meaning by the triangle inequality that $d(l_1, l_2) \geq |l_2|/2$. Thus in this case $|l_2| \leq 2d(l_1, l_2)$, meaning by (1) that the expected cost of simulating the substitution of l_1 to l_2 in $s_r(x)$ is at most three times as expensive as the original substitution. ◀

A Simple Gap-Producing Reduction for the Parameterized Set Cover Problem

Bingkai Lin

lin@nii.ac.jp

Abstract

Given an n-vertex bipartite graph $I = (S, U, E)$, the goal of set cover problem is to find a minimum sized subset of S such that every vertex in U is adjacent to some vertex of this subset. It is NP-hard to approximate set cover to within a $(1 - o(1)) \ln n$ factor [14]. If we use the size of the optimum solution k as the parameter, then it can be solved in $n^{k+o(1)}$ time [16]. A natural question is: can we approximate set cover to within an $o(\ln n)$ factor in $n^{k-\epsilon}$ time?

In a recent breakthrough result[24], Karthik, Laekhanukit and Manurangsi showed that assuming the Strong Exponential Time Hypothesis (SETH), for any computable function f, no $f(k) \cdot n^{k-\epsilon}$-time algorithm can approximate set cover to a factor below $(\log n)^{\frac{1}{poly(k, e(\epsilon))}}$ for some function e.

This paper presents a simple gap-producing reduction which, given a set cover instance $I = (S, U, E)$ and two integers $k < h \leq (1 - o(1)) \sqrt[k]{\log |S| / \log \log |S|}$, outputs a new set cover instance $I' = (S, U', E')$ with $|U'| = |U|^{h^k} |S|^{O(1)}$ in $|U|^{h^k} \cdot |S|^{O(1)}$ time such that

- if I has a k-sized solution, then so does I';
- if I has no k-sized solution, then every solution of I' must contain at least h vertices.

Setting $h = (1 - o(1)) \sqrt[k]{\log |S| / \log \log |S|}$, we show that assuming SETH, for any computable function f, no $f(k) \cdot n^{k-\epsilon}$-time algorithm can distinguish between a set cover instance with k-sized solution and one whose minimum solution size is at least $(1 - o(1)) \cdot \sqrt[k]{\frac{\log n}{\log \log n}}$. This improves the result in [24].

1 Introduction

We consider the *set cover* problem (SetCover): given an n-vertex bipartite graph $I = (S, U, E)$, where U is the underlying universe set and S represents the set family, find a minimum sized subset C of S such that every vertex of U is adjacent to some vertex of C. We use $S(I)$, $U(I)$ and $opt(I)$ to denote the sets S, U and the minimum size of the solution of I respectively. A vertex $u \in U$ is *covered* by a subset $C \subseteq S$ if u is adjacent to some vertex of C. The set cover problem is NP-hard [23]. Unless $P = NP$, we do not expect to solve it in polynomial time. One way to handle NP-hard problems is to use approximation algorithms. An algorithm of SetCover achieves an r-approximation if for every input instance I, it returns a subset C of $S(I)$ such that C covers $U(I)$ and $|C| \leq r \cdot opt(I)$. The polynomial time approximability of SetCover is well-understood: the greedy algorithm can output a solution of size at most $opt(I) \cdot (1 + \ln n)$ [10, 21, 28, 34, 35] and it was shown that

no polynomial time algorithm can achieve an approximation factor within $(1 - o(1)) \ln n$ unless $P = NP$ [4, 14, 17, 29, 32]. On the other hand, if we take the optimum solution size $k = opt(I)$ as a parameter, then the simple brute-force searching algorithm can solve this problem in n^{k+1} time. Assuming the exponential time hypothesis (ETH) [19, 20], i.e., 3-SAT on n variables cannot be solved in $2^{o(n)}$ time, there is no $n^{o(k)}$ time algorithm for SetCover. Under the strong exponential time hypothesis (SETH) [19, 20], which claims that for any $\epsilon \in (0, 1)$ there exists a $d \geq 3$ such that d-SAT on n variables cannot be solved in $2^{(1-\epsilon)n}$ time, we can further rule out $n^{k-\epsilon}$-time algorithm for set cover for any $\epsilon > 0$ [31]. It is quite natural to ask [11]:

Is there any $o(\ln n)$-approximation algorithm for the parameterized set cover problem (or dominating set problem) with running time $n^{k-\epsilon}$?

Exponential time approximation algorithms for the unparameterised version of set cover problem were studied in [7, 13]. It was shown that for any ratio r, there is a $(1 + \ln r)$-approximation algorithm for SetCover with running time $2^{n/r} n^{O(1)}$. No $n^{k-\epsilon}$ time algorithm for SetCover achieving an approximation ratio in $o(\ln n)$ is known in literature. On the other hand, proving inapproximability for a parameterized problem is not an easy task. In fact, even the constant FPT-approximability, i.e., the existence of $f(k) \cdot n^{O(1)}$-time algorithm for any computable function f (henceforth referred to as FPT-algorithm) with constant approximation, has been open for many years [30]. Lacking techniques like PCP-theorem [5], many results on the parameterized inapproximability of set cover problem had to use strong conjectures [6, 8] to create a gap in the first place. It is of great interest to develop techniques to prove hardness of approximation for parameterized problems only using hypothesis such as $SETH$, ETH or even weaker assumptions like W[1] $\neq FPT$ or W[2] $\neq FPT$ [15, 18] from the parameterized complexity theory. The success of this quest might extend the arsenal of methods for proving hardness of approximation and lead to PCP-like theorems for Fine-Grained Complexity [3].

The first constant FPT-inapproximability result for parameterized SetCover based on W[1] $\neq FPT$ was given by [9] using the one-sided gap of Biclique from [26]. In fact, [9] deals with dominating set problem, which is essentially the same as SetCover. Recently, Karthik, Laekhanukit and Manurangsi [24] significantly improved the FPT-inapproximation factor to $(\log n)^{1/k^{O(1)}}$ under the hypothesis W[1] $\neq FPT$. They also rule out the existence of $(\log n)^{1/k^{O(1)}}$-approximation algorithm with running time $f(k) \cdot n^{o(k)}$ for any computable function f, assuming ETH, and the existence of $(\log n)^{\frac{1}{(k+e(\epsilon))^{O(1)}}}$-approximation algorithms with running time $f(k) \cdot n^{k-\epsilon}$, assuming SETH. Their approach is to first establish a $(\log n)^{\frac{1}{\Omega(k)}}$ gap for MaxCover, then reduce MaxCover to SetCover and obtain a $(\log n)^{\frac{1}{\Omega(k^2)}}$-gap. This paper presents a new technique which allows us to design simple reductions improving the inapproximation factor to $(1 - \epsilon) \cdot \sqrt[k]{\frac{\log n}{\log \log n}}$. The reduction in [8] can get the ratio $(\log n)^{\Omega(1/k)}$ but it has to assume Gap-ETH.

▶ **Theorem 1.** *Assuming SETH, for every $\epsilon, \delta \in (0, 1)$, sufficiently large k[1] and computable function $f : \mathbb{N} \to \mathbb{N}$, there is no $f(k) \cdot N^{k-\epsilon}$ time algorithm that can, given an N-vertex set cover instance I, distinguish between*

- $opt(I) \leq k$,
- $opt(I) > \frac{1}{1+\delta} \left(\frac{\log N}{\log \log N} \right)^{\frac{1}{k}}$.

[1] We need large k to get the $\frac{1}{1+\delta} \left(\frac{\log N}{\log \log N} \right)^{\frac{1}{k}}$ gap for small δ. If we want to obtain an $\Theta\left(\sqrt[k]{\frac{\log N}{\log \log N}} \right)$ gap, then our reduction works for all $k \geq 2$.

▶ **Theorem 2.** *Assuming ETH, there is a constant $\epsilon \in (0,1)$ such that for every $\delta \in (0,1)$ and computable function $f : \mathbb{N} \to \mathbb{N}$, no $f(k) \cdot N^{\epsilon k}$ time algorithm that can, given an N-vertex set cover instance I , distinguish between*

- $opt(I) \leq k$,
- $opt(I) > \frac{1}{1+\delta} \cdot \left(\frac{\log N}{\log \log N}\right)^{\frac{1}{k}}$.

Behind these results is a reduction which, given an integer k, an n-vertex set cover instance I and an integer $h \leq O(\log n / \log \log n)$, produces an $n^{O(1)} \cdot (|U(I)|)^{O(h^k)}$-vertex instance I' in $n^{O(1)} \cdot |U(I)|^{O(h^k)}$ time such that if $opt(I) \leq k$ then $opt(I') \leq k$, otherwise $opt(I') > h$. Therefore, to prove the h-factor parameterized inapproximability of SetCover, it suffices to show the hardness of SetCover when the input instances have $n^{O(1/h^k)}$-size universe set. Note that the standard reduction for the SETH-hardness of set cover parameterized by the solution size k produces instances I with $|U(I)| = O(k \log |S(I)|)$. With our reduction, this immediately yields the above theorems. Let us not fail to mention that the results of [24] also imply the hardness of SetCover with logarithmic sized universe set assuming the k-SUM hypothesis and W[1] $\neq FPT$ hypothesis respectively. Similarly, we can obtain the corresponding inapproximability for set cover based on each of these hypotheses as well. In particular, using a simple trick, we can even rule out $(\log N)^{1/\epsilon(k)}$-approximation FPT-algorithm of set cover for any unbounded computable function ϵ under W[1] $\neq FPT$.

▶ **Theorem 3.** *Assuming k-SUM hypothesis for any $\delta, \epsilon \in (0,1)$, sufficiently large k and computable function $f : \mathbb{N} \to \mathbb{N}$, there is no $f(k) \cdot N^{\lceil k/2 \rceil - \epsilon}$ time algorithm that can, given an N-vertex set cover instance I, distinguish between*

- $opt(I) \leq k$,
- $opt(I) > \frac{1}{1+\delta} \left(\frac{\log N}{\log \log N}\right)^{\frac{1}{k}}$.

▶ **Theorem 4.** *Assuming W[1] $\neq FPT$, for and computable function $f : \mathbb{N} \to \mathbb{N}$ and unbounded computable function $\epsilon : \mathbb{N} \to \mathbb{N}$, there is no $f(k) \cdot N^{O(1)}$-time algorithm that can, given an N-vertex set cover instance I, distinguish between*

- $opt(I) \leq k$,
- $opt(I) > \log N^{1/\epsilon(k)}$.

Technique contribution. The main technique contribution of this paper is to introduce a gadget that can be used to design gap-producing reductions from the set cover problem to its approximation version and provide a construction of this gadget using (n,k)-*universal sets*. Compared to the reductions in [24], the gap amplification step in this paper is independent of the starting assumptions. This simplifies the proof for showing the inapproximability of the set cover problem. In particular, the inapproximability result in [24] assuming SETH needs some heavy machinery like AG codes to create the gap, while our reduction is completely elementary.

In addition to it simplicity, an important feature of our reduction is that it can be computed by constant depth circuits. Combining this observation with Rossman's $\Omega(n^{k/4})$ size lower bound for constant depth circuits detecting k-clique [33], Wenxin Lai [25] showed that there is no constant-depth circuits of size $f(k)n^{o(\sqrt{k})}$ that can distinguish between a set cover instance with solution size at most k and one whose minimum solution size is at least $(\log n / \log \log n)^{1/\binom{k}{2}}$.

Another advantage of our reduction is that it can give hardness approximation result from assumptions that the distributed PCP technique cannot. If we assume that k-set-cover with large universe set, say $|U| = n^{1/h(k)^k}$, has no $n^{k-\epsilon}$-time algorithm, then our reduction gives

$h(k)$ factor hardness of approximation k-set-cover in $n^{k-\epsilon}$ time. This cannot be achieved by the distributed PCP technique used in [24] due to known lower bounds in communication complexity of set disjointness.

The gap-gadget we introduce in this paper is similar to the bipartite graphs with threshold property in [26, 27]. Such kind of gadgets may have further applications in proving hardness of approximation for other parameterized problems.

2 Preliminaries

For $n, k \in \mathbb{N}$, an (n, k)-universal set is a set of binary strings with length n, such that the restriction to any k indices contains all the 2^k possible binary configurations.

▶ **Lemma 5.** *[See Sections 10.5 and 10.6 of [22]] For $k2^k \leq \sqrt{n}$, (n, k)-universal sets of size n can be computed in $O(n^3)$ time.*

Hypotheses. Below is a list of hardness hypotheses we will use in this paper.

- W[1] $\neq$ *FPT*: for any computable function $f : \mathbb{N} \to \mathbb{N}$, no algorithm can, given an n-vertex graph G and an integer k, decide if G contains a k-clique in $f(k) \cdot n^{O(1)}$ time.
- W[2] $\neq$ *FPT*: for any computable function $f : \mathbb{N} \to \mathbb{N}$, there is no algorithm which, given an n-vertex set cover instance I and an integer k, decides if $opt(I) \leq k$ in $f(k) \cdot n^{O(1)}$ time.
- Exponential Time Hypothesis (ETH)[19, 20]: there exists a $\delta \in (0, 1)$ such that 3-SAT on n variables cannot be solved in $O(2^{\delta n})$ time.
- Strong Exponential Time Hypothesis (SETH)[19, 20] for any $\epsilon \in (0, 1)$ there exists $d \geq 3$ such that d-SAT on n variables cannot be solved in $O(2^{(1-\epsilon)n})$ time.
- k-SUM hypothesis (k-SUM) [1]: for every $k \geq 2$ and $\epsilon > 0$, no $O(n^{\lceil k/2 \rceil - \epsilon})$ time algorithm can, given k sets $S_1, \ldots, S_k$ each with n integers in $[-n^{2k}, n^{2k}]$, decide if there are k integers $x_1 \in S_1, \ldots, x_k \in S_k$ such that $\sum_{i \in [k]} x_i = 0$.

We refer the reader to [18, 15] for more information about the parameterized complexity hypotheses. Using the Sparsification lemma [20], we can assume that the instances of 3-SAT in ETH have Cn clauses for some constant C and the instances of d-SAT in SETH have $C_{d,\epsilon}n$ clauses where $C_{d,\epsilon}$ depends on d and ϵ.

3 Reductions

We start with the definition of (k, n, m, ℓ, h)-gap-gadgets. In Lemma 7, we show how to use theses gadgets to create an (h/k)-gap for the set cover problem. Lemma 10 gives a polynomial time construction of gap-gadgets with $h \leq O(\log n / \log \log n)$ and $\ell = h^k$. Since for every input instance $I = (U, S, E)$ of set cover, our reduction runs in time $|S|^{O(1)}|U|^{\ell}$. If $|U| = \Omega(n)$, we can not afford such running time. Our next step is to prove the hardness of set cover with $U = f(k) \cdot (\log n)^{O(1)}$ based on each of the aforementioned hypotheses.

▶ **Definition 6** ((k, n, m, ℓ, h)-Gap-Gadget)**.** *A (k, n, m, ℓ, h)-Gap-Gadget is a bipartite graph $T = (A, B, E)$ satisfying the following conditions.*

(G1) *A is partitioned into $(A_1, A_2, \ldots, A_m)$. For every $i \in [m]$, $|A_i| = \ell$.*

(G2) *B is partitioned into $(B_1, B_2, \ldots, B_k)$. For every $j \in [k]$, $|B_j| = n$.*

(G3) *For all $b_1 \in B_1, b_2 \in B_2, \ldots b_k \in B_k$, there exist $a_1 \in A_1, \ldots, a_m \in A_m$ such that for all $i \in [m]$ and $j \in [k]$, a_i is adjacent to b_j.*

(G4) *For all $X \subseteq B$ and $a_1 \in A_1, \ldots, a_m \in A_m$, if every a_i has at least $k + 1$ neighbors in X, then $|X| > h$.*

To use this gadget, given a set cover instance $I = (S, U, E)$, we will identify the set B with the set S. Then we construct a new set cover instance $I' = (S', U', E')$ with $S' = S$ such that

(⋆) for any subset X of S' that can cover U', there must exist a vertex $a_i \in A_i$ for every $i \in m$ *witnessing* that X contains a solution of I, i.e., there exists $C \subseteq X$ that can cover U in the instance I and all the vertices of C are adjacent to a_i in the gap-gadget.

It is easy to check the correctness of this reduction:

If there is a k-vertex set X that can cover U, then by (G3) we can pick $a_i \in A_i$ for all $i \in [m]$ such that a_i is adjacent to all vertices in X. This means that X is also a solution of I'.

If $opt(I) > k$, then no matter how we pick $a_i \in A_i$, each a_i must have $k+1$ neighbors in X. This implies that $X > h$ by (G4).

To achieve $(\star)$, we will use the idea of *hypercube set system* from Feige's work [17] (which is also used in [24, 8]). For each $i \in [m]$, we construct a set U^{A_i}. Each element in U^{A_i} can be regarded as a function $f : A_i \to U$. In the new set cover instance, f is covered by $s \in S$ if there exists $a_i \in A_i$ such that a_i is adjacent to s in the gap-gadget and $f(a_i)$ is covered by s in I. More details can be found in the proof of the following lemma.

▶ **Lemma 7.** *There is an algorithm which, given an integer k, an instance $I = (S, U, E)$ of* SetCover*, where $S = S_1 \cup S_2 \ldots \cup S_k$ and $|S_i| = n$ for all $i \in [k]$, and a (k, n, m, ℓ, h)-Gap-Gadget, outputs a set cover instance $I' = (S', U', E')$ with $S' = S$ and $U' = m|U|^\ell$ in $|U|^\ell \cdot n^{O(1)}$ time such that*

- *if there exist $s_1 \in S_1, \ldots, s_k \in S_k$ that can cover U, then $opt(I') \le k$;*
- *if $opt(I) > k$, then $opt(I') > h$.*

Proof. Let $T = (A, B, E_T)$ be the (k, n, m, ℓ, h)-Gap-Gadget. Without loss of generality, assume that for all $i \in [k]$ $B_i = S_i$. The new instance $I' = (S', U', E')$ is defined as follows.

- $S' = S$.
- $U' = (\bigcup_{i \in [m]} U^{A_i})$.
- For all $s \in S'$ and $f \in U^{A_i}$ where $i \in [m]$, E' contains $\{s, f\}$ if there exists an $a \in A_i$ such that
  - **(E'1)** $\{s, f(a)\} \in E$,
  - **(E'2)** $\{a, s\} \in E_T$.

Completeness. If $opt(I) \le k$, then there exist $s_1 \in S_1, \ldots, s_k \in S$ that can cover the whole set U. We will show that for every $f \in U'$, f is covered by some vertex in $\{s_1, s_2, \cdots, s_k\}$. Firstly, by (G3), there exist $a_1 \in A_1, \ldots, a_m \in A_m$ such that $a_i s_j \in E_T$ for all $i \in [m]$ and $j \in [k]$. Assume that $f \in U^{A_i}$ for some $i \in [m]$. Observe that $f(a_i) \in U$ must be covered by some s_j with $j \in [k]$, i.e., $\{s_j, f(a_i)\} \in E$. Since $\{a_i, s_j\} \in E_T$ and $\{s_j, f(a_i)\} \in E$, according to the definition of E', we must have $\{s_j, f\} \in E'$.

Soundness. Suppose $opt(I) > k$. Let $X \subseteq S'$ be a set covering U'. For every $a \in A$, let $N^T(a)$ be the set of neighbors of a in T. We have the following claim.

▷ Claim 8. For every $i \in [m]$ there exists $a_i \in A_i$ such that $|N^T(a_i) \cap X| \ge k + 1$.

Proof. Suppose there exists an $i \in [m]$ such that for all $a \in A_i$, $|N^T(a) \cap X| \le k$. Since $opt(I) > k$, every solution of I has size at least $k + 1$. It follows that for every $a \in A_i$, there exists some $u_a \in U$ such that u_a is not covered by $N^T(a) \cap X$ in the set cover instance I. Define a function $f \in U^{A_i}$ such that $f(a) = u_a$ for every $a \in A_i$. We claim that f is not covered by X. Otherwise, suppose there exists an $s \in X$ that can cover f. According to the definition of E', there must exists an $a \in A_i$ such that (E'1) and (E'2) hold. However, if

$s \in N^T(a) \cap X$, then $\{s, f(a)\} = \{s, u_a\} \notin E$. On the other hand, if $s \notin N^T(a) \cap X$, then $\{a, s\} \notin E_T$. In both cases, we obtain contradictions. ◁

By Claim 8, we can pick $a_i \in A_i$ for each $i \in [m]$ such that every a_i has at least $k+1$ neighbors in X. By the property of Gap-Gadget, $|X| > h$. ◀

▶ Remark 9. Recall that the greedy algorithm can approximate the set cover problem within a $(1+\ln|U|)$-approximation ratio. If one could construct a gap-gadget for parameters satisfying

$$k(1+\ln|U'|) = k(1+\ell\ln|U|+\ln m) < h,$$

then applying the greedy algorithm on input I' could decide whether $opt(I) = k$ in $|U|^\ell \cdot n^{O(1)}$ time.

It is well known that given a CNF formula ϕ on n variables, one can construct a set cover instance $I = (S, U, E)$ with $|U| = O(n)$ and $|S| = \Theta(k2^{n/k})$ in $2^{O(n/k)}$ time such that ϕ is satisfiable if and only if $opt(I) = k$. This implies that, assuming ETH there is no algorithm that can construct $(k, |S|, m, \ell, h)$-gap-gadgets with $k(1+\ell ln|U|+\ln m) < h$ and $|U|^\ell \le 2^{o(n)}$ in $2^{o(n)}$ time.

3.1 Construction of Gap-Gadgets

In [27], a similar gadget is used to prove the parameterized complexity of k-Biclique. One would wonder if the randomized construction from [27] can be used to construct the gap-gadget in this paper. Informally, the gadget in [27] is a bipartite random graph $T = (A, B, E)$ satisfying the following properties with high probability:

(T1) a k-vertex set in B has $m = n^{\Theta(1/k)}$ common neighbors;

(T2) any $(k+1)$-vertex set in B has at most $O(k^2)$ common neighbors.

It is not hard to show that if $Y \subseteq A$ is an m-vertex set and every vertex in Y has at least $k+1$ neighbors in $X \subseteq B$, then $|X| \ge \sqrt[k+1]{\frac{|Y|}{O(k^2)}}$ by (T2) and the pigeonhole principle. We may partition the vertex set A into m parts. Each part contains $n^{1-\Theta(1/k)}$ vertices. This gives us a gap-gadget with large gap $h = \sqrt[k+1]{\frac{m}{O(k^2)}}$ and $\ell = n^{1-\Theta(1/k)}$. Unfortunately, such gadget does not suit our purpose. We need a gap-gadget with $\ell \le \log n/\log\log n$. In this section, we provide a construction using universal sets.

▶ **Lemma 10.** *There is an algorithm that can, for every $k, h, n \in \mathbb{N}$ with $k\log\log n \le \log n$ and $h \le \frac{\log n}{(2+\epsilon)\log\log n}$, compute a $(k, n, n\log h, h^k, h)$-Gap-Gadget in $O(n^4)$ time.*

Proof. Let $m = n\log h$ and $K = h\log h$. Note that $(\log m)/2 = (\log n + \log\log h)/2 \ge (2+\epsilon)h\log h/2 \ge \log h + \log\log h + h\log h = \log K + K$, i.e., $K2^K \le \sqrt{m}$. By Lemma 5, an (m, K)-universal set $S = \{s_1, s_2, \ldots, s_m\}$ can be constructed in $O(m^3) \le O(n^4)$ time. Partition every $s \in S$ into $n = \frac{m}{\log h}$ blocks so that each block has length $\log h$. Interpret the values of blocks as integers in $[h]$. We obtain an $m \times n$ matrix M by setting the value $M_{r,c}$ equal to the value of the c-th block of s_r. The matrix M satisfies the following conditions.

(M1) For all $r \in [m]$ and $c \in [n]$, $M_{r,c} \in [h]$.

(M2) For any set $C \subseteq [n]$ with $|C| \le h$, there exists a row $r \in [m]$ such that $|\{M_{r,c} : c \in C\}| = |C|$.

Condition (M1) is obvious. To see why (M2) holds, for each $C \subseteq [n]$ with $|C| \le h$, let C' be the set of indices corresponding to the blocks in C. Note that $|C'| = |C|\log h \le h\log h = K$. By the property of (m, K)-universal set, there exists an $s_r \in S$ such that each block in C takes distinct value. It follows that $|\{M_{r,c} : c \in C\}| = |C|$.

For each $i \in [m]$, let

$$A_i = \{(a_1, a_2, \ldots, a_k) : \text{for all } j \in [k],\ a_j \in [h]\}.$$

Note that $|A_i| = h^k$. For each $j \in [k]$, let $B_j = [n]$. Let $T = (A, B, E)$ be a bipartite graph with

- $A = \bigcup_{i\in[m]} A_i$.
- $B = \bigcup_{j\in[k]} B_j$.
- $E = \{\{\vec{a}, b\} : \vec{a} \in A_i, b \in B_j \text{ and } M_{i,b} = \vec{a}[j] \text{ for all } j \in [k]\}$.

We will show that T is an (k, n, m, h^k, h)-gap-gadget. Obviously, T satisfies (G1) and (G2).

T satisfies (G3). For any $b_1 \in B_1, b_2 \in B_2, \ldots, b_k \in B_k$. We define $\vec{a}_i \in A_i$ by setting

$$\vec{a}_i = (M_{i,b_1}, M_{i,b_2}, \ldots, M_{i,b_k}).$$

It is routine to check that $\{\vec{a}_i, b_j\} \in E$ for all $i \in [m]$ and $j \in [k]$.

T satisfies (G4). Let $X \subseteq B$ and $\vec{a}_1 \in A_1, \vec{a}_2 \in A_2, \ldots, \vec{a}_m \in A_m$. Suppose for every $i \in [m]$, $\vec{a}_i$ has at least $k+1$ neighbors in X and $|X| \leq h$. By (M2), there exists an $r \in [m]$ such that $|\{M_{r,c} : c \in X\}| = |X|$. Since $\vec{a}_r$ has at least $k+1$ neighbors in X, there exists an $j \in [k]$ such that $\vec{a}_r$ has two neighbors b, b' in $X \cap B_j$. According to the definition of E, we must have

$$M_{r,b} = M_{r,b'} = \vec{a}_r[j].$$

This contradicts the fact that $|\{M_{r,c} : c \in X\}| = |X|$. ◀

The construction above produces gap-gadgets with $\ell = h^k$. Note that the parameter h is related to the inapproximation factor we will get for the set cover problem and the running time of our reduction is $n^{O(1)}|U|^\ell$. We want to set h as large as possible while keeping the running time of reduction in $f(k) \cdot n^{O(1)}$. Assuming $|U| = g(k) \cdot (\log n)^{O(1)}$, the best we can achieve is $h = (\log n / \log\log n)^{1/k}$.

On the probabilistic construction. A natural question is, can we construct gap-gadgets with better parameters h and ℓ, say $\ell = h = o(\log n)$, using the probabilistic method?

Consider the probability space of bipartite random graphs on the vertex sets $A = A_1 \cup A_2 \cup \cdots \cup A_m$ and $B = B_1 \cup B_2 \cup \cdots B_k$, where $|A_i| = \ell$ and $|B_j| = n$. Let p be the edge probability. Each bipartite graph T on $A \cup B$ has probability $Pr[T] = p^{|E(T)|}(1-p)^{|A|\cdot|B|-|E(T)|}$. Fix k vertices $b_1, b_2, \ldots, b_k$ in B. Let X_{good} be the random variable that for every bipartite graph T, $X_{good}(T)$ is the number of complete bipartite subgraphs of T which contains exactly one vertex in each A_i and the k vertices $b_1, b_2, \ldots, b_k$ in B. Let X_{bad} be the random variable that for every bipartite graph T, $X_{bad}(T)$ is the number of subgraphs of T with h vertices in B and one vertex in each A_i such that each vertex in A_i has at least $k+1$ neighbors in B. We want to set the edge probability p so that $\Pr[X_{bad}(T) \geq 1] + \Pr[X_{good}(T) = 0] \leq 1 - n^{-c}$ for some constant $c > 0$. One way to bound $\Pr[X_{bad}(T) \geq 1]$ above is to use Markov's inequality, which gives us $\Pr[X_{bad}(T) \geq 1] \leq E[X_{bad}]$. So we might assume that $E[X_{bad}] < 1$. On the other hand, we have $E[X_{good}] \geq \Pr[X_{good}(T) \geq 1] \geq n^{-c}$. Note that expectations of these two random variables are $E[X_{good}] = \ell^m p^{km}$ and $E[X_{bad}] = \ell^m \binom{n}{h} p^{(k+1)m} \binom{h}{k+1}^m$. We deduce that

$$m \log \ell + mk \log p > -c \log n$$

and

$$m \log \ell + h \log n + m(k+1) \log p + m(k+1) \log h < 0.$$

Thus

$$\frac{c \log n}{mk} + \frac{\log \ell}{k} > \frac{\log \ell}{(k+1)} + \frac{h \log n}{m(k+1)} + \log h. \tag{1}$$

We might choose m large enough so that the terms $\frac{c \log n}{mk}$ and $\frac{h \log n}{m(k+1)}$ in (1) become relatively small. In order to make (1) hold, we have to set $\ell \geq h^{O(k^2)}$. This does not give us better (k, n, m, ℓ, h)-gap-gadgets.

3.2 Proofs of Theorem 1 and Theorem 2

▶ **Lemma 11.** *There is an algorithm, which given $k \in \mathbb{N}$, $\delta > 0$ with $(1 + 1/k^3)^{1/k} \leq (1+\delta)/(1+\delta/2)$ and $(1+\delta/2)^k \geq 2k^4$ and a SAT instance ϕ with n variables and Cn clauses, where n is much larger than k and C, outputs an integer $N \leq 2^{n/k+n/k^3}$ and a set cover instance I satisfying the following conditions in $2^{5n/k}$ time.*

- $|S(I)| + |U(I)| \leq N$.
- *If ϕ is satisfiable, then $opt(I) \leq k$.*
- *If ϕ is not satisfiable, then $opt(I) > \frac{1}{1+\delta} \cdot \sqrt[k]{\frac{\log N}{\log \log N}}$.*

Proof. Let k be a positive integer and ϕ be a CNF with n variables and Cn clauses. We first construct a set cover instance $I' = (S', U', E')$ as follows. Partition the variable set into k parts, each having at most $\lceil n/k \rceil$ variables. For each $i \in [k]$, let S_i be the set of assignments to the i-th part. Let $S' = S_1 \cup \cdots \cup S_k$. Let U' be the set consisting of all the clauses of ϕ and k additional nodes $u_1, u_2, \ldots, u_k$. For every $i \in [k]$ and assignment $s \in S_i$, we add an edge between s and u_i. If the assignment $s \in S'$ satisfies a clause $u \in U'$, we also add an edge between u and s. The set cover instance I' has the following properties.

- If ϕ is satisfiable, then $opt(I') = k$. Moreover, there exist k vertices $s_1 \in S_1, \cdots, s_k \in S_k$ that can cover the whole set U'.
- If ϕ is not satisfiable, then $opt(I') > k$.
- $|U'| = k + Cn$.
- $|S'| \leq k2^{n/k}$.

Let $M = k2^{n/k} \geq |S|$ and $N = M^{1+1/k^3} \leq 2^{n/k+n/k^3}$. Note that $\log M / \log \log M \geq n/(k \log n) \geq k$. Applying Lemma 10 with $k \leftarrow k$, $n \leftarrow M$, $\ell \leftarrow \frac{\log M}{(1+\delta/2)^k \log \log M}$, $h \leftarrow \frac{1}{1+\delta/2} \cdot \sqrt[k]{\frac{\log M}{\log \log M}}$ and $m \leftarrow M \log h \leq M \log \log M$, we obtain a gap-gadget T in $O(M^4 \leq 2^{5n/k})$ time. Using Lemma 7 on I' and T, we obtain our target set cover instance $I = (S, U, E)$ satisfying the following properties.

- If ϕ is a yes-instance, then $opt(I) \leq k$.
- If ϕ is a no-instance, then $opt(I) > \frac{1}{1+\delta/2} \cdot \sqrt[k]{\log M / \log \log M}$. Using $(1 + 1/k^3)^{1/k} \leq (1 + \delta)/(1 + \delta/2)$, we get $opt(I) > \frac{1}{1+\delta} \cdot \sqrt[k]{\log N / \log \log N}$.
- $|S| = |S| \leq k2^{n/k}$.
- $|U| \leq M \log \log M \cdot |U|^{\frac{\log M}{(1+\delta/2)^k \log \log M}} = M \log \log M \cdot (k + Cn)^{\frac{\log M}{(1+\delta/2)^k \log \log M}}$.

The number of vertices in I is

$$\begin{aligned}
|S(I)| + |U(I)| &\leq M + M \log\log M \cdot (k + Cn)^{\frac{\log M}{(1+\delta/2)^k \log\log M}} \\
&\leq M + M \log\log M \cdot (2Ck \log M)^{\frac{\log M}{(1+\delta/2)^k \log\log M}} \\
&\leq M + M \log\log M \cdot (\log M)^{\frac{2\log\log M}{(1+\delta/2)^k \log\log M}} \quad \text{(using } \log M \geq 2Ck \text{ for large } n\text{)} \\
&\leq M + M \log\log M \cdot M^{\frac{2}{(1+\delta/2)^k}} \\
&\leq M + M \log\log M \cdot M^{1/k^4} \quad \text{(using } (1+\delta/2)^k \geq 2k^4\text{)} \\
&\leq M^{1+1/k^3} \quad \text{(using } M^{1/k^3} \geq 1 + M^{1/k^4} \log\log M \text{ for large } n\text{)} \\
&= N.
\end{aligned}$$

◀

Now we are ready to prove Theorem 1. Suppose for some computable function f, there is an $f(k) \cdot N^{k-\epsilon}$-time algorithm that can, for every N-vertex set cover instance I and every integer k, distinguish between $opt(I) \leq k$ and $opt(I) \geq \frac{1}{1+\delta} \cdot \sqrt[k]{\frac{\log N}{\log\log N}}$. For every $\delta \in (0,1)$, choose $k \in \mathbb{N}$ large enough so that $(1+1/k^3)^{1/k} \leq (1+\delta)/(1+\delta/2)$ and $(1+\delta/2)^k \geq 2k^4$ hold. Let $\epsilon' = 1 - \epsilon/k + 1/k^2$, by SETH, there exists an integer d such that d-SAT with n variables cannot be solved in $2^{n(1-\epsilon')}$-time. Given an instance ϕ of d-SAT with n variables and m clauses. By the sparsification lemma [20], we can assume that $m = C_{d,\epsilon'} \cdot n$ for some constant $C_{d,\epsilon'}$ depending on d and ϵ'. Without loss of generality, assume that n is much larger than k. Applying Lemma 11 on ϕ and k, we obtain a set cover instance I with $N \leq 2^{n/k+n/k^3}$ vertices in time $2^{5n/k} \leq 2^{\epsilon n}$ for $k \geq 5/\epsilon$. Then we use the approximation algorithm to decide if $opt(I) \leq k$ or $opt(I) \geq \frac{1}{1+\delta} \cdot \sqrt[k]{\frac{\log N}{\log\log N}}$. Thus we can solve d-SAT in time $2^{\epsilon n} + f(k) \cdot N^{k-\epsilon} \leq 2^{\epsilon n} + f(k) \cdot 2^{(n/k+n/k^3)(k-\epsilon)} \leq 2^{n(1-\epsilon/k+1/k^2)} = 2^{n(1-\epsilon')}$, which contradicts SETH.

Theorem 2 can be proved similarly. By ETH, there exists $\epsilon > 0$ such that 3-SAT on n variables cannot be solved in $2^{\epsilon n}$ time. Let $\epsilon' = \epsilon/2$. For every 3-SAT instance ϕ with n variable and Cn clause, where n is much larger than k, apply Lemma 11 to obtain a set cover instance I with $N = 2^{n/k+n/k^3}$ vertices in $2^{5n/k} \leq 2^{\epsilon' n}$ time. If there is an $f(k) \cdot N^{\epsilon' k}$-time algorithm that can distinguish between $opt(I) \leq k$ and $opt(I) > \frac{1}{1+\delta} \cdot \sqrt[k]{\frac{\log N}{\log\log N}}$, then we can decide whether ϕ is satisfiable in time $2^{\epsilon' n} + f(k) \cdot 2^{(n/k+n/k^3)\cdot\epsilon' k} \leq 2^{\epsilon n}$.

3.3 Proof of Theorem 3

We use a lemma in [2] to reduce k-SUM to k-VECTOR-SUM over small numbers. Then we present a reduction from k-VECTOR-SUM to set cover.

▶ **Lemma 12** (Lemma 3.1 of [2]). *Let $k, p, d, s, M \in \mathbb{N}$ satisfy $k < p$, $p^d \geq kM + 1$, and $s = (k+1)^{d-1}$. There is a collection of mappings $f_1, \ldots, f_s : [0, M] \times [0, kM] \to [-kp, kp]^d$, each computable in time $O(poly \log M + k^d)$, such that for all numbers $x_1, \ldots, x_k \in [0, M]$ and targets $t \in [0, kM]$,*

$$\sum_{j=1}^{k} x_j = t \Leftrightarrow \exists i \in [s] \text{ such that } \sum_{j=1}^{k} f_i(x_j, t) = \vec{0}.$$

▶ **Lemma 13.** *There is an algorithm which, given k sets $S_1, S_2, \ldots, S_k$ where S_i is a set of n vectors in $[-f(k), f(k)]^{g(k)\log n}$ for some computable functions f and g, outputs a set cover instance $I = (S, U, E)$ with $|U| \leq k^{(2f(k))^{k-1}} g(k) \log n$ and $S = S_1 \cup S_2 \cup \ldots \cup S_k$ in $k^{(2f(k))^{k-1}} g(k) n^{O(1)}$-time such that*

(i) *if there exist* $\vec{x}_1 \in S_1, \ldots, \vec{x}_k \in S_k$ *such that* $\sum_{i\in[k]} \vec{x}_i = \vec{0}$*, then* $\{\vec{x}_1, \ldots, \vec{x}_k\}$ *covers* U*;*
(ii) *if the sum of any* k *vectors* $\vec{x}_1 \in S_1, \ldots \vec{x}_k \in S_k$ *is not zero, then* $opt(I) > k$*.*

Proof. Let $D = \{(d_1, \ldots, d_k) \in [-f(k), f(k)]^k : \sum_{i\in[k]} d_i = 0\}$. Note that $|D| \leq (2f(k))^{k-1}$. Suppose $D = \{\vec{a}_1, \ldots, \vec{a}_{|D|}\}$. For every $j \in [g(k)\log n]$, let $U_j = [k]^{|D|}$. We define the target set cover instance $I = (S, U, E)$ as follows.

- $S = S_1 \cup \cdots \cup S_k$.
- $U = \bigcup_{i\in[g(k)\log n]} U_i$.
- For every $\vec{x} \in S_i$ and every $\vec{u} \in U_j$, we add an edge $\{\vec{x}, \vec{u}\}$ into E if there exists $\ell \in [|D|]$ such that $\vec{u}[\ell] = i$ and $\vec{x}[j] = \vec{a}_\ell[i]$.

Completeness. Suppose there exist $\vec{x}_1 \in S_1, \ldots, \vec{x}_k \in S_k$ such that $\sum_{i\in[k]} \vec{x}_i = \vec{0}$. Then for all $j \in [g(k)\log n]$ we have $\vec{x}_1[j] + \vec{x}_2[j] + \ldots + \vec{x}_k[j] = 0$, i.e.,

$$(\vec{x}_1[j], \vec{x}_2[j], \ldots, \vec{x}_k[j]) = \vec{a}_\ell \in D \text{ for some } \ell \in [|D|]. \tag{2}$$

For all $\vec{u} \in U_j$, let $i = \vec{u}[\ell] \in [k]$. Then by (2), $\vec{x}_i[j] = \vec{a}_\ell[i]$. It follows that $\{\vec{x}_i, \vec{u}\} \in E$.

Soundness. Suppose the sum of any k vectors in $S_1 \cup \cdots \cup S_k$ is not zero. Let X be a subset of S with $|X| \leq k$, we need to show that X does not cover U. Firstly, we note that if $X \cap S_i = \emptyset$ for some $i \in [k]$, then the vector $\vec{u} = (i, i, \ldots, i) \in [k]^{|D|}$ is not covered by any vector in X. Now assume that $X = \{\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_k\}$ and $\vec{x}_i \in S_i$ for all $i \in [k]$. Since $\sum_{i\in[k]} \vec{x}_i \neq \vec{0}$, there exists a $j \in [g(k)\log n]$ such that

$$\sum_{i\in[k]} \vec{x}_i[j] \neq 0.$$

We deduce that

$$(\vec{x}_1[j], \vec{x}_2[j], \ldots, \vec{x}_k[j]) \notin D.$$

In other word, for all $\ell \in [|D|]$, there exists an $i_\ell \in [k]$ such that

$$\vec{x}_{i_\ell}[j] \neq \vec{a}_\ell[i_\ell]. \tag{3}$$

Define a vector $\vec{u} \in U_j$ such that for all $\ell \in [|D|]$,

$$\vec{u}[\ell] = i_\ell. \tag{4}$$

Suppose $\vec{u}$ is covered by $x_i \in X$, then by the definition, there exists $\ell \in [|D|]$ such that $i = \vec{u}[\ell] = i_\ell$ and $\vec{x}_{i_\ell}[j] = \vec{a}_\ell[i_\ell]$, which contradicts (3) and (4). ◀

Proof of Theorem 3. Given k sets $S_1, \ldots, S_k$ of integers in $[-n^{2k}, n^{2k}]$. Let $p = k^{4k^{c+1}}$, $M = 2n^{2k}$ and $d = \log n/k^c$. Without loss of generality, assume that k is large and n is much larger than k, we have $p^d = k^{4k\log n} \geq n^{4k} \geq 2kn^{2k} + 1$. On the other hand, for any $\epsilon > 0$, we can pick c such that $s = (k+1)^d = n^{\log(k+1)/k^c} \leq n^{\epsilon/4}$. Applying Lemma 12, we obtain a collection of mappings $f_1, \ldots, f_s : [0, M] \times [0, kM] \to [-kp, kp]^d$ in $O(poly\log M + k^d)$ time such that

- there exist $x_1 \in S_1, \ldots, x_k \in S_k$ with $\sum_{j\in[k]} x_j = 0$ if and only if there exist $i \in [s]$ such that $\sum_{j\in[k]} f_i(x_j + n^{2k}, kn^{2k}) = \vec{0}$.

Using Lemma 10, we construct a $(k, n, O(n\log\log n), \frac{\log n}{(1+\delta/2)^k \log\log n}, \frac{1}{(1+\delta/2)} \cdot (\frac{\log n}{\log\log n})^{1/k})$-gap-gadget T for some small $\delta > 0$. For every $i \in [s]$, and $j \in [k]$, let $S_j^i = \{f_i(x + n^{2k}, kn^{2k}) : x \in S_j\}$. Applying Lemma 7 to $S_1^i, S_2^i, \ldots, S_k^i$ and T, we obtain a set cover instance I_i with $S(I_i) = S_1^i \cup S_2^i \ldots S_k^i$ and $|U(I_i)| \leq n\log\log n \cdot (g(k)\log n)^{\frac{\log n}{(1+\delta/2)^k \log\log n}} \leq n^{1+1/k^3}$. The set cover instances $I_1, \ldots, I_s$ satisfy the following properties.

- If there exist $x_1 \in S_1, \ldots, x_k \in S_k$ with $\sum_{j\in[k]} x_j = 0$, then there exist $i \in [s]$ and $y_1 = f_i(x_1 + n^{2k}, n^{2k}) \in S_1^i \ldots y_k = f_i(x_k + n^{2k}, n^{2k}) \in S_k^i$ such that $y_1, \ldots, y_k$ cover $U(I_i)$.
- If there are no $x_1 \in S_1, \ldots, x_k \in S_k$ with $\sum_{j\in[k]} x_j = 0$, then for all $i \in [s]$, $opt(I_i) > \frac{1}{1+\delta/2} \cdot \left(\frac{\log n}{\log\log n}\right)^{1/k}$.

Let $N = n^{1+1/k^2}$. We have

$$|S(I_i)| + |U(I_i)| \leq kn + n^{1+1/k^3} \leq N,$$

$$f(k) \cdot N^{\lceil k/2\rceil - \epsilon} \leq n^{\lceil k/2\rceil - \epsilon + 1/k},$$

and

$$\frac{1}{(1+\delta)} \left(\frac{\log N}{\log\log N}\right)^{1/k} \leq \frac{1}{(1+\delta/2)} \left(\frac{\log n}{\log\log n}\right)^{1/k}.$$

For every $i \in [s]$, we apply the $f(k) \cdot N^{\lceil k/2\rceil-\epsilon}$-time algorithm to decide if $opt(I_i) \leq k$ or $opt(I_i) > \frac{1}{1+\delta} \cdot (\log N/\log\log N)^{1/k}$. If for some $i \in [s]$, it found that $opt(I_i) \leq k$, then we know that the input instance of k-SUM is a yes-instance. The running time is $O(poly\log M + k^d) + f(k) \cdot N^{\lceil k/2\rceil-\epsilon} \leq O(poly\log M + k^d) + s \cdot n^{\lceil k/2\rceil-\epsilon+1/k} \leq n^{\lceil k/2\rceil-\epsilon/2}$ for large k. ◀

3.4 Proof of Theorem 4

Firstly, we give a reduction from Clique to SetCover which produces instances with logarithmic sized universe set. The main idea of this reduction is due to Karthik et al. [24].

▶ **Lemma 14.** *There is an $n^{O(1)}$-time algorithm which, given an integer k, an n-vertex graph G with $V(G) = V_1 \cup V_2 \cup \cdots \cup V_k$ such that $G[V_i]$ is an independent set for all $i \in [k]$, outputs a set cover instance $I = (S, U, E)$ with $|U| = k^{O(1)}\log n$ and $S = E(G) = \bigcup_{\{i,j\}\in\binom{[k]}{2}} S_{\{i,j\}}$, where each $S_{\{i,j\}}$ is the set of edges between V_i and V_j, such that*

- **(i)** *if G contains a k-clique, then $opt(I) \leq \binom{k}{2}$. Moreover, there exists a $\binom{k}{2}$-sized subset of S, which contains exactly one vertex from each $S_{\{i,j\}}$ ($\{i,j\} \in \binom{[k]}{2}$), that can cover U;*
- **(ii)** *if G contains no k-clique, then $opt(I) > \binom{k}{2}$.*

Proof. We will construct a set cover instance I such that if G has a k-clique, then we can select its $\binom{k}{2}$ edges to cover the whole universe set. For every $v \in V(G)$, denote by $encode(v) \in \{0,1\}^{\log n}$ the binary string representation of v. For every $\ell \in [\log n]$, the ℓth bit of $encode(v)$ is $encode(v)[\ell]$. For every $i \in [k]$, let $\sigma_i : [k] \setminus \{i\} \to [k-1]$ be an arbitrary bijection. Our target set cover instance $I = (S, U, E)$ is defined as follows.

- $S = E(G) = \bigcup_{\{i,j\}\in\binom{[k]}{2}} S_{\{i,j\}}$, where $S_{\{i,j\}} = \{\{v_i, v_j\} : v_i \in V_i, v_j \in V_j, \{v_i, v_j\} \in E(G)\}$.
- $U = [k] \times [k-1]^{\{0,1\}} \times [\log n]$.
- For $s = \{v_i, v_j\} \in S$ and $u = (i, f, \ell) \in U$ we add $\{s, u\}$ into E if

$$v_i \in V_i,\ v_j \in V_j \text{ and } f(encode(v_i)[\ell]) = \sigma_i(j).$$

The set cover instance I satisfies the following conditions.

- If G contains a k-clique, then there exists a $\binom{k}{2}$-sized subset of S which contains exactly one vertex from each $S_{\{i,j\}}$ ($\{i,j\} \in \binom{[k]}{2}$) that can cover U. Suppose that $v_1 \in V_1, \ldots, v_k \in V_k$ induce a k-clique. Let $X = \{\{v_i, v_j\} : \{i,j\} \in \binom{[k]}{2}\}$. We will show that X covers the whole set U. For any $(i,f,\ell) \in U$, let $b = \mathit{encode}(v_i)[\ell]$. Since $f(b) \in [k-1]$, there must exist a $j \in [k] \setminus \{i\}$ such that $\sigma_i(j) = f(b)$. By the definition of E, $\{v_i, v_j\}$ is adjacent to (i,f,ℓ) .
- If G does not contain a k-clique, then $\mathit{opt}(I) > \binom{k}{2}$. Let $X \subseteq S$ be a set such that $|X| \leq \binom{k}{2}$ and X covers U.
  For each $\{i,j\} \in \binom{[k]}{2}$, define

  $$X_{\{i,j\}} = \{\{v_i, v_j\} : v_i \in V_i, v_j \in V_j, \{v_i, v_j\} \in X\}.$$

  We claim that for every $\{i,j\} \in \binom{[k]}{2}$, $|X_{\{i,j\}}| > 0$. Otherwise let $f(0) = f(1) = \sigma_i(j)$ and consider the vertex $(i,f,1) \in U$. According to the definition of E, if a vertex $\{v,u\} \in S$ covers $(i,f,1)$, then either v or u must be in V_i. Let us assume $v \in V_i$ and $u \in V_{j'}$ for some $j' \in [k] \setminus \{i\}$. We must have $f(\mathit{encode}(v_i)[1]) = \sigma_i(j')$. However, if $j \neq j'$, then $f(0) = f(1) = \sigma_i(j) \neq \sigma_i(j')$.
  Since $\binom{k}{2} \geq |X| = \sum_{\{i,j\} \in \binom{[k]}{2}} |X_{\{i,j\}}|$ and $|X_{\{i,j\}}| > 0$, we conclude that $|X_{\{i,j\}}| = 1$ for all $\{i,j\} \in \binom{[k]}{2}$.
  For every $i \in [k]$ and distinct $j, j' \in [k] \setminus \{i\}$, let $\{\{v, v_j\}\} = X_{\{i,j\}}$ and $\{\{v', v_{j'}\}\} = X_{i,j'}$, where $v, v' \in V_i$, we claim that $v = v'$. Otherwise, since $v \neq v'$ there exists $\ell \in [\log n]$ such that $\mathit{encode}(v)[\ell] \neq \mathit{encode}(v')[\ell]$. Now consider a function f with $f(\mathit{encode}(v')[\ell]) = \sigma_i(j)$ and $f(\mathit{encode}(v)[\ell]) = \sigma_i(j')$. The vertex (i,f,ℓ) must be covered by some $\{x,y\}$ with $x \in V_i$ and $y \in V_h$ such that $\sigma_i(h) = f(\mathit{encode}(v)[\ell]) \in \{\sigma_i(j), \sigma_i(j')\}$. We must have $y \in V_j$ or $y \in V_{j'}$. Since $|X_{\{i,j\}}| = |X_{\{i,j'\}}| = 1$, we deduce that either $\{x,y\} = \{v, v_j\}$ or $\{x,y\} = \{v', v_{j'}\}$. However, if $\{x,y\} = \{v, v_j\}$, we must have $\sigma_i(j) = f(\mathit{encode}(v)[\ell]) = \sigma_i(j') \neq \sigma_i(j)$, a contradiction. Similarly, if $\{x,y\} = \{v', v_{j'}\}$, then $\sigma_i(j') = f(\mathit{encode}(v')[\ell]) = \sigma_i(j) \neq \sigma_i(j')$. We conclude that the vertex (i,f,ℓ) can not be covered by X.
  Now we have for every $i \in [k]$, there exists a $v_i \in V_i$ such that

  $$\{v_i\} = \bigcap_{j \in [k] \setminus \{i\}, e \in X_{\{i,j\}}} e.$$

  Obviously, for every $\{i,j\} \in \binom{[k]}{2}$, $\{\{v_i, v_j\}\} = X_{\{i,j\}}$. This implies that $\{v_1, v_2, \ldots, v_k\}$ is a k-clique in G. ◀

Proof of Theorem 4. Given an n-vertex graph G and a positive integer k, we invoke Lemma 14 to obtain a set cover instance $I = (S, U, E)$ with $|S| = |E(G)|$ and $|U| \leq k^3 \log n$ satisfying (i) and (ii). Let $m = |S|$. Then we use Lemma 10 to construct a $(\binom{k}{2}, m, n^{O(1)}, \frac{\log m}{\log\log m}, \frac{\log m}{\log\log m}^{1/\binom{k}{2}})$-gap-gadget T in $m^{O(1)} = n^{O(1)}$ time. Applying Lemma 7 on I and T, we finally obtain our target set cover instance $I' = (S', U', E')$ with the following properties:

- if G has a k-clique, then $\mathit{opt}(I') = \binom{k}{2}$,
- if G has no k-clique, then $\mathit{opt}(I') > \left(\frac{\log m}{\log\log m}\right)^{1/\binom{k}{2}}$,
- $|S'| = |E(G)| = m$,
- $|U'| = (k^3 \log n)^{\log m / \log\log m} = m^{1+o(1)}$.

Let $N = |U'| + |S'|$. We have $N = n^{O(1)}$. Since ϵ is an unbounded computable function, there is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that $k' = g(k) > \binom{k}{2}$ and $\epsilon(k') > \binom{k}{2}$. When n is large enough,

$$\frac{\log m}{\log\log m}^{1/\binom{k}{2}} \geq \frac{\log N}{O(\log\log N)}^{1/\binom{k}{2}} \geq (\log N)^{1/\epsilon(k')}.$$

Any $f(k') \cdot N^{O(1)}$ time algorithm that can distinguish between $opt(I') \leq k'$ and $opt(I') > (\log N)^{\frac{1}{\epsilon(k')}}$ can be used to decide if an input graph G has k-clique in $f(g(k))n^{O(1)}$ time. ◀

4 Conclusion

We have improved the hardness approximation factor for the parameterized set cover problem using a simple reduction. Our result shows that in order to prove inapproximability of parameterized set cover, it suffices to prove the hardness of set cover problem with small universe set. A natural question is:

Is there any algorithm that can, given an n-vertex set cover instance I and an integer k, outputs a new instance I' and an integer k' in $f(k) \cdot n^{O(1)}$ time for some computable function $f : \mathbb{N} \to \mathbb{N}$ such that

- $k' = g(k)$ for some computable function $g : \mathbb{N} \to \mathbb{N}$,
- $opt(I) \leq k$ if and only if $opt(I') \leq k'$,
- $|U(I')| \leq h(k) \cdot (\log |S(I')|)^{O(1)}$ for some computable function $h : \mathbb{N} \to \mathbb{N}$.

A positive answer to the above question would imply that SetCover parameterized by the optimum solution size has no $(\log n)^{1/\epsilon(k)}$-approximation FPT algorithm assuming W[2] $\neq FPT$. Of course, if we just want a ρ-factor hardness of approximation, then it suffices to have $|U(I')| \leq h(k)|S(I')|^{O(1/\rho^k)}$. Note that using Dynamic Programming, SetCover can be solved in $2^{|U(I)|}(|U(I)| + |S(I)|)^{O(1)}$ time [12]. We do not expect to reduce the size of universe set below $o(k \log n)$ under ETH.

Our hardness result is far from matching the $(1+\ln n)$ approximation ratio of the greedy algorithm in polynomial time. Could it be the case that there exists a $(\ln n)^{1/\rho(k)}$-approximation algorithm for SetCover with running time $n^{k-\epsilon}$? What is the best approximation ratio we can achieve for parameterized set cover in $n^{k-\epsilon}$ time?

Abstract

The min-cost matching problem suffers from being very sensitive to small changes of the input. Even in a simple setting, e.g., when the costs come from the metric on the line, adding two nodes to the input might change the optimal solution completely. On the other hand, one expects that small changes in the input should incur only small changes on the constructed solutions, measured as the number of modified edges. We introduce a two-stage model where we study the trade-off between quality and robustness of solutions. In the first stage we are given a set of nodes in a metric space and we must compute a perfect matching. In the second stage $2k$ new nodes appear and we must adapt the solution to a perfect matching for the new instance.

We say that an algorithm is (α, β)-robust if the solutions constructed in both stages are α-approximate with respect to min-cost perfect matchings, and if the number of edges deleted from the first stage matching is at most βk. Hence, α measures the quality of the algorithm and β its robustness. In this setting we aim to balance both measures by deriving algorithms for constant α and β. We show that there exists an algorithm that is $(3, 1)$-robust for any metric if one knows the number $2k$ of arriving nodes in advance. For the case that k is unknown the situation is significantly more involved. We study this setting under the metric on the line and devise a $(10, 2)$-robust algorithm that constructs a solution with a recursive structure that carefully balances cost and redundancy.

1 Introduction

Weighted matching is one of the founding problems in combinatorial optimization, playing an important role in the settling of the area. The work by Edmonds [8] on this problem greatly influenced the role of polyhedral theory on algorithm design [23]. On the other hand, the problem found applications in several domains [1, 2, 6, 22, 26]. In particular

Figure 1 Example instance on the line. Vertices in Stage 1 are depicted by light grey dots and second stage arrivals are indicated as dark grey crosses. First and second state optimum are depicted by solid and dotted edges, respectively. The arrival of two new vertices leads to a significant drop in the cost of the optimum.

routing problems are an important area of application, and its procedures often appeared as subroutines of other important algorithms, the most notable being Christofides' algorithm [5] for the *traveling salesperson problem (TSP)*.

An important aspect of devising solution methods for optimization problems is studying the sensitivity of the solution towards small changes in the input. This sensitivity analysis has a long history and plays an important role in practice [10]. Min-cost matching is a problem that has particularly sensitive optimal solutions. Assume for example that nodes lie on the real line at points ℓ and $\ell + 1 - \varepsilon$ for some $0 < \varepsilon < 1$ and all $\ell \in \{1, \ldots, n\}$, see Figure 1. The min-cost matching, for costs equal the distance on the line, is simply the edges $\{\ell, \ell + 1 - \varepsilon\}$. However, even under a minor modification of the input, e.g., if two new nodes appear at points $1 - \varepsilon$ and $n + 1$, the optimal solution changes all of its edges, and furthermore the cost decreases by a $\Theta(1/\varepsilon)$ factor. Rearranging many edges in an existing solution is often undesirable and may incur large costs, for example in an application context where the matching edges imply physical connections or binding commitments between nodes. A natural question in this context is whether we can avoid such a large number of rearrangements by constructing a *robust* solution that is only slightly more expensive. In other words, we are interested in studying the trade-off between robustness and the cost of solutions.

We consider a two-stage robust model with recourse. Assume we are given an underlying metric space $(\mathcal{X}, c)$. The input for the *first stage* is a complete graph G_1 whose node set $V(G_1)$ is a finite, even subset of $\mathcal{X}$. The cost of an edge $\{v, w\}$ is given by the corresponding cost $c(v, w)$ in the metric space[1]. In a second stage we get an extended complete graph G_2 containing all nodes in $V(G_1)$ plus $2k$ additional nodes. As before, costs of edges in G_2 are given by the underlying metric. In the first stage we must create a perfect matching M_1 for G_1. In the second stage, after G_2 is revealed, we must adapt our solution by constructing a new perfect matching M_2 for G_2, called the *second stage reply*. We say that a solution M_1 is two-stage (α, β)-robust if for any instantiation of the second stage there exists a solution M_2 such that two conditions hold. First, the total cost of edges in M_i must satisfy $c(M_i) \leq \alpha \cdot c(O_i)$ for $i \in \{1, 2\}$, where O_i denotes a min-cost perfect matching in G_i. Second, it must hold that $|M_1 \setminus M_2| \leq \beta k$. An algorithm is two-stage (α, β)-robust if, given G_1 and c, it returns a two-stage (α, β)-robust matching and, given the set of new arrivals, a corresponding second stage reply. We refer to α as the *competitive factor* and β as the *recourse factor* of the algorithm. Our main goal is to balance cost and recourse, and thus we aim to obtain algorithms where α and β are constants.

Our model is closely related to an online model with recourse. Consider a graph whose nodes are revealed online two by two. Our objective is to maintain a perfect matching at all times. As above, irrevocable decisions do not allow for constant competitive factors. This suggests a model where in each iteration we are allowed to modify a constant number of edges.

[1] Graphs with arbitrary cost functions do not allow for $(O(1), O(1))$-robust matchings in general, e.g., consider a variant of the example in Figure 1 in which all omitted edges have infinite cost.

An online algorithm that maintains an α-approximation at all time while deleting at most β edges per iteration can be easily transformed into a two-stage (α, β)-robust algorithm. Given an instance of the two-stage model, we choose an arbitrary order for the nodes available in the first stage and create M_1 by following the updates proposed by an online algorithm. Then, we repeat the procedure for the arrivals in Stage 2. Thus, our two-stage model is also the first necessary step for understanding this more involved online model. Megow et al. [20] study a similar online model for minimum spanning trees and the TSP in metric graphs. After giving a $(1+\varepsilon)$-competitive algorithm with recourse factor $\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon})$ for the former problem, they are able to derive a $(2+\varepsilon)$-competitive algorithm with constant recourse factor for the latter problem by combining their results with a modified version of the well-known double-tree algorithm. An algorithm for the online variant of our proposed model together with the aforementioned results, would give rise to an online variant of Christofide's algorithm which can yield an improved competitiveness factor for the considered online TSP.

Our Results and Techniques. We distinguish two variants of the model. In the *k-known* case we assume that in Stage 1 we already know the number of new nodes $2k$ that will arrive in Stage 2. For this case we present a simple two-stage $(3,1)$-robust algorithm.

▶ **Theorem 1.** *Let $(\mathcal{X}, c)$ be a metric space, $V_1 \subseteq \mathcal{X}$ with $|V_1|$ even, and G_1 be the complete graph on V_1. For $k \in \mathbb{N}$ known in advance, there is a perfect matching M_1 in G_1 that is two-stage $(3,1)$-robust for $2k$ arrivals. Such a matching and corresponding second stage reply can be computed in time poly$(|V_1|, k)$.*

The example in Figure 1 illustrates a worst case scenario for the strategy of choosing O_1 as the first stage matching for $k = 1$. The reason for this is that the nodes arriving in Stage 2 induce a path in $O_1 \Delta O_2$ that incurs a significant drop in the optimal cost. Our algorithm is designed towards preparing for such bad scenarios. To this end, we define the notion of *gain* for a path P with respect to a matching X as follows:

$$\text{gain}_X(P) := c(P \cap X) - c(P \setminus X).$$

In Stage 1, our algorithm chooses k edge-disjoint O_1-alternating paths of maximum total gain with respect to O_1. For each such path P we modify O_1 by removing $P \cap O_1$ and adding $(P \setminus O_1) \cup \{e(P)\}$, where $e(P)$ is the edge that connects the endpoints of P. Our choice of paths of maximum gain implies that $P \cap O_1$ is larger than $P \setminus O_1$. Therefore we can bound the cost of the solution in the first stage against that of O_1 and also infer that most of its costs is concentrated on the edges $e(P)$. For the second stage we construct a solution for the new instance by removing the k edges of the form $e(P)$ and adding new edges on top of the remaining solution. The algorithm is described in detail in Section 2.

For the case where k is unknown the situation is considerably more involved as a first stage solution must work for any number of arriving nodes simultaneously. In this setting we restrict our study to the real line and give an algorithm that is two-stage $(10,2)$-robust.

▶ **Theorem 2.** *Let $\mathcal{X} = \mathbb{R}$ and $c = |\cdot|$, $V_1 \subseteq \mathcal{X}$ with $|V_1|$ even, and let G_1 be the complete graph on V_1. Then there is a perfect matching M_1 in G_1 that is two-stage $(10,2)$-robust. Such a matching, as well as the second stage reply, can be computed in time poly$(|V_1|, k)$.*

The first stage solution M is constructed iteratively, starting from the optimal solution. We will choose a path P greedily such that it maximizes $\text{gain}_M(P)$ among all alternating paths that are *heavy*, i.e., the cost of $P \cap M$ is a factor 2 more expensive than the cost of $P \setminus M$. Then M is modified by augmenting along P and adding edge $e(P)$, which we fix to

be in the final solution. We iterate until M only consists of fixed edges. As we are on the line, each path P corresponds to an interval and we can show that the constructed solution form a laminar family. Furthermore, our choice of heavy paths implies that their lengths satisfy an exponential decay property. This allows us to bound cost of the first stage solution. For the second stage, we observe that the symmetric difference $O_1 \Delta O_2$ induces a set of intervals on the line. For each such an interval, we remove on average at most two edges from the first stage matching and repair the solution with an optimal matching for the exposed vertices. A careful choice of the removed edges, together with the greedy construction of the first stage solution, enables us to bound the cost of the resulting second stage solution within a constant factor of the optimum. See Sections 3 and 4 for a detailed description of this case.

Related Work. Intense research has been done on several variants of the *online bipartite matching* problem [17, 16, 18, 4, 21]. In this setting we are given a known set of *servers* while a set of *clients* arrive online. In the *online bipartite metric matching problem* servers and clients correspond to points from a metric space. Upon arrival, each client must be matched to a server irrevocably, at cost equal to their distance. For general metric spaces, there is a tight bound of $(2n-1)$ on the competitiveness factor of deterministic online algorithms, where n is the number of servers [18, 16]. Recently, Raghvendra presented a deterministic algorithm [24] with the same competitiveness factor, that in addition is $O(\log(n))$-competitive in the random arrival model. Also, its analysis can be parameterized for any metric space depending on the length of a TSP tour and its diameter [21]. For the special case of the metric on the line, Raghvendra [25] recently refined the analysis of the competitive ratio to $O(\log(n))$. This gives a deterministic algorithm that matches the previously best known bound by Gupta and Lewi [15], which was attained by a randomized algorithm. As the lower bound of 9.001 [9] could not be improved for 20 years, the question whether there exists a constant competitive algorithm for the line remains open.

The *online matching with recourse problem* considers an unweighted bipartite graph. Upon arrival, a client has to be matched to a server and can be reallocated later. The task is to minimize the number of reallocations under the condition that a maximum matching is always maintained. The problem was introduced by Grove, Kao and Krishnan [11]. Chaudhuri et al. [4] showed that for the random arrival model a simple greedy algorithm uses $O(n \log(n))$ reallocations with high probability and proved that this analysis is tight. Recently, Bernstein, Holm and Rotenberg [3] showed that the greedy algorithm needs $O(n \log^2 n)$ allocations in the adversarial model, leaving a small gap to the lower bound of $O(n \log n)$. Gupta, Kumar and Stein [14] consider a related problem where servers can be matched to more than one client, aiming to minimize the maximum number of clients that are assigned to a server. They achieve a constant competitive factor server while doing in total $O(n)$ reassignments.

Online min-cost problems with reassignments have been studied in other contexts. For example in the *online Steiner tree problem with recourse* a set of points on a metric space arrive online. We must maintain Steiner trees of low cost by performing at most a constant (amortized) number of edge changes per iteration. While the pure online setting with no reassignment only allows for $\Omega(\log(n))$ competitive factors, just one edge deletion per iteration is enough to obtain a constant competitive algorithm [12]; see also [13, 20].

The concept of *recoverable robustness* is also related to our setting [19]. In this context the perfect matching problem on unweighted graphs was considered by Dourado et. al. [7]. They seek to find perfect matchings which, after the failure of some edges, can be recovered to a perfect matching by making only a small number of modifications. They establish computational hardness results for the question whether a given graph admits a robust recoverable perfect matching.

2 Known Number of Arrivals

In this section, we consider the setting where k (number of arrival pairs in Stage 2) is already known in Stage 1. Let G_1 be the complete graph given in Stage 1 (with edge costs c induced by an arbitrary metric) and let O_1 be a min-cost perfect matching in G_1. Without loss of generality assume that $|O_1| > 2k$, as otherwise, we can remove all edges of M_1 in Stage 2.

Algorithm 1.1 works as follows:

(i) Let $P_1, \dots, P_k$ be edge-disjoint, O_1-alternating paths maximizing $\sum_{i=1}^{k} \text{gain}_{O_1}(P_i)$.
(ii) Set $\overline{M} := O_1 \Delta P_1 \Delta \dots \Delta P_k$.
(iii) Return $M_1 := \overline{M} \cup \{e(P_i) : i \in [k]\}$.

It is easy to see that each path P_i starts and ends with an edge from O_1 and $\text{gain}_{O_1}(P_i) \geq 0$. As a consequence, M_1 is a perfect matching and

$$c(\overline{M}) = c(O_1) - \sum_{i=1}^{k} \text{gain}_{O_1}(P_i) \leq c(O_1).$$

Using $c(e(P_i)) \leq c(P_i)$ and $\bigcup_{i=1}^{k} P_i = O_1 \Delta \overline{M} \subseteq O_1 \cup \overline{M}$ we obtain

$$c(M_1) \leq c(\overline{M}) + \sum_{i=1}^{k} c(P_i) \leq c(\overline{M}) + c(\overline{M}) + c(O_1) \leq 3 \cdot c(O_1).$$

Now consider the arrival of $2k$ new vertices, resulting in the graph G_2 with min-cost matching O_2. Note that $O_2 \Delta \overline{M}$ is a U-join, where U is the union of the endpoints of the paths $P_1, \dots, P_k$ and the $2k$ newly arrived vertices.

Algorithm 1.2 works as follows:

(i) Let $P'_1, \dots, P'_{2k}$ be the $2k$ maximal paths from $O_2 \Delta \overline{M}$.
(ii) Return $M_2 := \overline{M} \cup \{e(P'_i) : i \in [2k]\}$.

Note that $O_1 \Delta O_2$ consists of k alternating paths $R_1, \dots, R_k$, from which we remove the starting and ending O_2-edge. Then these paths would have been a feasible choice for $P_1, \dots, P_k$, implying that the total gain of the R_i's is at most that of the P_i's. We conclude that

$$c(\overline{M}) = c(O_1) - \sum_{i=1}^{k} \text{gain}_{O_1}(P_i) \leq c(O_1) - \sum_{i=1}^{k} \text{gain}_{O_1}(R_i) \leq c(O_2).$$

Applying $\bigcup_{i=1}^{2k} P'_i \subseteq O_2 \Delta \overline{M} \subseteq O_2 \cup \overline{M}$, we obtain

$$c(M_2) \leq c(\overline{M}) + \sum_{i=1}^{2k} c(P'_i) \leq c(\overline{M}) + c(\overline{M}) + c(O_2) \leq 3 \cdot c(O_2).$$

As $|M_1 \setminus M_2| \leq |M_1 \setminus \overline{M}| = k$, we conclude that M_1 is indeed two-stage $(3, 1)$-robust.

We remark that $\overline{M}$ is always a min-cost matching of cardinality $|V(G_1)| - 2k$ in G_1. Thus, alternatively to Algorithm 1.1, we can compute a min-cost matching of cardinality $|V(G_1)| - 2k$ and match uncovered nodes at minimum cost. Finding $\overline{M}$ directly as well as finding gain-maximizing paths as described in Algorithm 1.1 can be done efficiently by solving a min-cost T-join problem in an extension of G_1. This concludes our proof of Theorem 1.

3 Unknown Number of Arrivals – Stage 1

In this section, we consider the case that the underlying metric corresponds to the real line. This implies that there is a Hamiltonian path L in G_1 such that $c(v, w) = c(L[v, w])$ for all $v, w \in V(G_1)$, where $L[v, w]$ is the subpath of L between nodes v and w. We will refer to L as *the line* and call the subpaths of L *intervals*. The restriction to the metric on the line results in a uniquely defined min-cost perfect matching O_1 with a special structure. All proofs omitted due to space constraints can be found in the appendix of the full version.

Figure 2 For fixed $\alpha, \beta \in O(1)$, we construct an instance for which Algorithm 1.1 is not (α, β)-robust for any $k \in O(1)$. G_1 is constructed such that O_1 contains $\beta + 1$ edges of size c_1 and $\beta^3 + \beta^2$ of size c_3 that are equally distributed between c_1-edges. The distance between any two consecutive edges in O_1 is c_2. Values c_1, c_2, c_3 are chosen depending on α, guaranteeing $c_1 \gg \beta^3 c_2 \gg \beta^6 c_3$. Algorithm 1.1 with $k \geq \beta + 1$ chooses $M_1 = O_1$. Now, assume there are two arrivals at the extremes of the line: while the optimal costs in the second stage decrease heavily to $c(O_2) \in \Theta(\beta^3 c_2)$, only β deletions are allowed within M_1. As a result, there does not exist a feasible second stage reply. Now, consider Algorithm 1.1 with $k \leq \beta$. Then, M_1 contains more than $\beta^2 + \beta$ edges of size c_2. If in the second stage $2(\beta + 1)$ nodes arrive right next to the endpoints of c_1-edges, the optimal costs drop to $\Theta(\beta^3 c_3)$ while only $\beta^2 + \beta$ deletions are allowed. Again, no feasible second stage reply exists.

▶ **Lemma 3.** *O_1 is the unique perfect matching contained in L.*

When the number of arrivals is not known in the first stage, the approach for constructing the first stage matching introduced in Section 2 does not suffice anymore. Figure 2 illustrates a class of instances for which Algorithm 1.1 cannot achieve $(O(1), O(1))$-robustness, no matter how we choose k. For a matching M, define $g(M) := \max_{e \in L} |\{\{v, w\} \in M : e \in L[v, w]\}|$. Informally speaking, $g(M)$ captures the maximal number of times a part of the line is traversed by edges in M. The example in Figure 2 can be generalized to show that we cannot restrict ourselves to constructing matchings M_1 such that $g(M_1)$ is bounded by a constant.

In view of the example in Figure 2, we adapt the approach from Section 2 as follows. Instead of creating a fixed number of paths, our algorithm now iteratively and greedily selects a path P of maximum gain with respect to a dynamically changing matching X (initially $X = O_1$). In order to bound the total cost incurred by adding edges of the form $e(P)$, we only consider paths P for which $X \cap P$ contributes a significant part to the total cost of P.

▶ **Definition 4.** *Let $X, P \subseteq E(G_1)$.*

1. *We say that P is X-heavy if $c(P \cap X) \geq 2 \cdot c(P \setminus X)$.*
2. *We say that P is X-light if $c(P \cap X) \leq \frac{1}{2} \cdot c(P \setminus X)$.*

Algorithm 2.1 works as follows:

(i) Set $M_1 := \emptyset$ and $X := O_1$.

(ii) While $X \neq \emptyset$: Let P be an X-heavy X-alternating path maximizing $\text{gain}_X(P)$ and update $M_1 \leftarrow M_1 \cup \{e(P)\}$ and $X \leftarrow X \Delta P$.

(iii) Return M_1.

Note that in each iteration, the path P starts and ends with an edge from X as it is gain-maximizing (if P ended with an edge that is not in X, we could simply remove that edge and obtain a path of higher gain). Therefore it is easy to see that $X \cup M_1$ is always a perfect matching, and in each iteration the cardinality of X decreases by 1.

Now number the iterations of the while loop in Algorithm 2.1 from 1 to n. Let $X^{(i)}$ be the state of X at the beginning of iteration i. Let $P^{(i)}$ be the path chosen in iteration i and let $e^{(i)} = e(P^{(i)})$ be the corresponding edge added to M. The central result in this section is Lemma 7, in which we show that the paths $P^{(i)}$ form a laminar family of intervals on the line.

Within the proof we will make use of observations stated in Lemmas 5 and 6. For convenience, we define the projection $\psi(e) := L[v, w]$ that maps an edge $e = \{v, w\} \in E(G_1)$ to the corresponding subpath $L[v, w]$.

Figure 3 A minimal example of a situation in which Lemma 7 would be violated. There are two iterations $i < j$ with paths $P^{(i)}$ (depicted in blue) and $P^{(j)}$ (depicted in red) such that $X \cap P^{(j)}$ was not modified between iteration i and iteration j. Then, extending the blue path $P^{(i)}$ with the rightmost edge yields an $X^{(i)}$-heavy path with higher gain than $P^{(i)}$, a contradiction.

▶ **Lemma 5.** *Let $X \subseteq E(G_1)$.*
1. *Let $A, B \subseteq E(G_1)$ be two X-heavy (X-light, respectively) sets with $A \cap B = \emptyset$. Then $A \cup B$ is X-heavy (X-light, respectively).*
2. *Let $A, B \subseteq E(G_1)$ with $B \subseteq A$. If A is X-heavy and $\operatorname{gain}_X(B) < 0$, then $A \setminus B$ is X-heavy. If A is X-light and $\operatorname{gain}_X(B) > 0$, then $A \setminus B$ is X-light.*

▶ **Lemma 6.** *Let $X \subseteq L$ be a matching.*
1. *Let P be an X-heavy X-alternating path maximizing $\operatorname{gain}_X(P)$. If X covers all vertices in $V(\psi(P))$, then $P = \psi(P)$.*
2. *Let $I \subseteq L$ be an interval. Then there is an X-alternating path P such that $c(P \cap X) = c(X \cap I)$ and $c(P \setminus X) = c(I \setminus X)$.*

▶ **Lemma 7.**
1. *$X^{(i)}, P^{(i)} \subseteq L$ for all $i \in [n]$.*
2. *For all $i, j \in [n]$ with $i < j$, either $P^{(i)} \cap P^{(j)} = \emptyset$ or $P^{(j)} \subset P^{(i)}$.*

Proof. We say a pair (i, j) with $i < j$ is *violating* if $\psi(P^{(i)}) \cap \psi(P^{(j)}) \neq \emptyset$ and $\psi(P^{(j)}) \setminus \psi(P^{(i)}) \neq \emptyset$. We will show that no violating pair exists. This proves the lemma as the following claim asserts.

▷ Claim. If $P^{(j)} \neq \psi(P^{(j)})$, then there is a violating pair (i', j') with $i' < j' \leq j$.

Proof. Let j' be minimal with $P^{(j')} \neq \psi(P^{(j')})$. Note that minimality of j' implies that $X^{(j')} = O_1 \Delta P^{(1)} \Delta \ldots \Delta P^{(j'-1)} \subseteq L$. Then Lemma 6 implies that there must be a vertex $v \in V(\psi(P^{(j')}))$ not covered by $X^{(j')}$. Because $X^{(j')}$ covers exactly those vertices not covered by $\{e^{(i')} : i' < j'\}$, there must be an $i' < j'$ such that v is an endpoint of $P^{(i')}$. The vertex v cannot be an endpoint of $P^{(j')}$, because v is exposed in $X^{(j')}$ and $P^{(j')}$ starts and ends with edges from $X^{(j')}$. This implies that (i', j') is a violating pair. ◁

Now let us assume there are no violating pairs. Then $P^{(i)} = \psi(P^{(i)}) \subseteq L$ for all $i \in [n]$ by the claim, which also implies $X^{(i)} \subseteq L$. This implies the lemma as, in this situation, the condition for violating pairs coincides with the condition in point 2 of the lemma.

By contradiction assume there is a violating pair. Choose j such that j is minimal among all possible choices of violating pairs. Then choose i such that it is maximal for that j among all violating pairs.

Note that the claim implies that $P^{(i)}, X^{(i)}, X^{(j)} \subseteq L$. Furthermore, our choice of i and j implies that $\psi(P^{(j')}) \cap \psi(P^{(j)}) = \emptyset$ for all j' with $i < j' < j$, as otherwise (i, j') or (j', j) would be a violating pair. In particular, $P^{(j')} \cap P^{(j)} = \emptyset$ for all j' with $i < j' < j$ and thus

$$X^{(j)} \cap P^{(j)} = X^{(i+1)} \cap P^{(j)} = (X^{(i)} \Delta P^{(i)}) \cap P^{(j)}. \tag{1}$$

Now consider $I_1 := \psi(P^{(j)}) \cap P^{(i)}$ and $I_2 := \psi(P^{(j)}) \setminus P^{(i)}$, both of which are non-empty since (i, j) is a violating pair. Then (1) implies $X^{(j)} \cap I_1 = I_1 \setminus X^{(i)}$ and $I_1 \setminus X^{(j)} = X^{(i)} \cap I_1$. We conclude that $\operatorname{gain}_{X^{(j)}}(I_1) = -\operatorname{gain}_{X^{(i)}}(I_1) \leq 0$, as I_1 is a prefix of the gain-maximizing path $P^{(i)}$ (see the appendix of the full version for a formal proof).

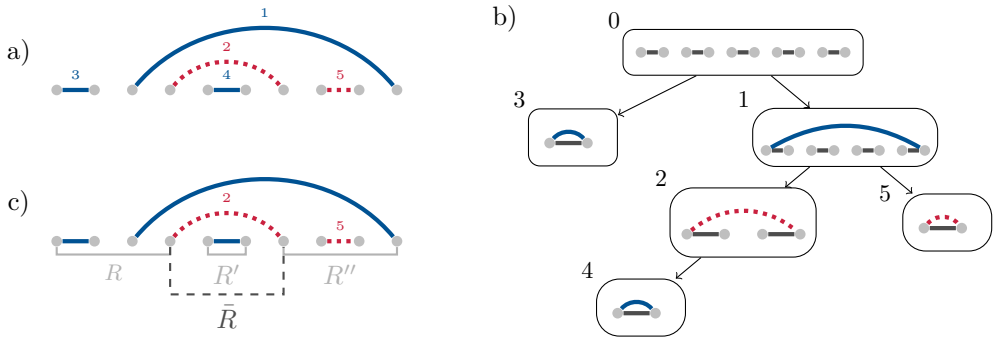

Figure 4 a) Illustration of the matching created by an example execution of Algorithm 2.1. Edges added to M_1 in an iteration from W_{H} are depicted by blue solid lines and edges created in an iteration from W_{L} are illustrated by red dotted lines. b) Illustration of the corresponding tree. For every tree-node $i \in W$, grey edges indicate $X^{(i)}$ and an arc illustrates the edge connecting the end nodes of $P^{(i)}$. c) Illustration of example assignment of requests to iterations (defined in Section 4). Requests $R, R', R'' \in \mathcal{R}$ are assigned such that $R, R'' \in \mathcal{R}(0)$ and $R' \in \mathcal{R}(2)$. $\bar{R} \in \bar{\mathcal{R}}(0)$ is a gap between two requests associated with tree-node 0.

Therefore $I_2 = \psi(P^{(j)}) \setminus I_1$ is $X^{(j)}$-heavy by Lemma 5. But then I_2 is also $X^{(i)}$-heavy because (1) implies $X^{(j)} \cap I_2 = X^{(i)} \cap I_2$. Hence $I' := P^{(i)} \cup I_2$ is $X^{(i)}$-heavy by Lemma 5 and further

$$\mathrm{gain}_{X^{(i)}}(I') = \mathrm{gain}_{X^{(i)}}(P^{(i)}) + \mathrm{gain}_{X^{(j)}}(I_2) > \mathrm{gain}_{X^{(i)}}(P^{(i)}),$$

because $\mathrm{gain}_{X^{(j)}}(I_2) \geq \frac{1}{3}c(I_2)$. By Lemma 6 there is an $X^{(i)}$-heavy, $X^{(i)}$-alternating path with higher gain than $P^{(i)}$, a contradiction. ◀

Tree structure. Lemma 7 induces a tree structure on the paths selected by Algorithm 2.1. We define the directed tree $T = (W, A)$ as follows. We let $W := \{0, \dots n\}$ and define $P^{(0)} := L$. For $i, j \in W$ we add the arc (i, j) to A if $P^{(j)} \subset P^{(i)}$ and there is no $i' \in W$ with $P^{(j)} \subset P^{(i')} \subset P^{(i)}$. It is easy to see that T is an out-tree with root 0. We let $T[i]$ be the unique 0-i-path in T. We define the set of children of $i \in W$ by $\mathrm{ch}(i) := \{j \in W : (i, j) \in A\}$. Furthermore, let $W_{\mathrm{H}} := \{i \in W : |T[i]| \text{ is odd}\}$ and $W_{\mathrm{L}} := \{i \in W : |T[i]| \text{ is even}\}$ be the set of *heavy* and *light* nodes in the tree, respectively. These names are justified by the following lemma. See Figure 4 a)-b) for an illustration.

▶ **Lemma 8.** *If $i \in W_H$, then $P^{(i)} \cap X^{(i)} = P^{(i)} \cap O_1$ and, in particular, $P^{(i)}$ is O_1-heavy. If $i \in W_L \setminus \{0\}$, then $P^{(i)} \cap X^{(i)} = P^{(i)} \setminus O_1$ and, in particular, $P^{(i)}$ is O_1-light.*

Proof. Let $i \in W \setminus \{0\}$. From Lemma 7 we know that for every iteration $i' \in W \setminus \{0\}$ with $i' < i$ it holds that either $P^{(i)} \cap P^{(i')} = \emptyset$ or $P^{(i)} \subset P^{(i')}$. In the first case it holds that $P^{(i)} \cap X^{(i'+1)} = P^{(i)} \cap X^{(i')}$, in the latter case it holds that $P^{(i)} \cap X^{(i'+1)} = P^{(i)} \cap (P^{(i)} \Delta X^{(i')})$. Moreover, it is easy to see that $i' < i$ and $P^{(i)} \subset P^{(i')}$ holds if and only if $i' \in V(T[i]) \setminus \{0, i\}$. If $i \in W_{\mathrm{H}}$, this implies that there exist an even number of iterations $i' < i$ for which $P^{(i)} \subset P^{(i')}$ holds. Hence, we obtain

$$P^{(i)} \cap X^{(i)} = P^{(i)} \cap (\underbrace{P^{(i)} \Delta \dots \Delta P^{(i)}}_{\text{evenly often}} \Delta\, O_1) = P^{(i)} \cap O_1.$$

If $i \in W_{\mathrm{L}}$, this implies that there exist an odd number of iterations $i' < i$ for which $P^{(i)} \subset P^{(i')}$ holds. Hence, we can deduce that

$$P^{(i)} \cap X^{(i)} = P^{(i)} \cap (\underbrace{P^{(i)} \Delta \dots \Delta P^{(i)}}_{\text{oddly often}} \Delta\, O_1) = P^{(i)} \setminus O_1.$$ ◀

The fact that nested paths are alternatingly O_1-heavy and O_1-light implies an exponential decay property. As a consequence we can bound the cost of M_1.

▶ **Lemma 9.** *Let $i \in W \setminus \{0\}$. Then $\sum_{j \in \mathrm{ch}(i)} c(P^{(j)}) \leq \frac{1}{2} \cdot c(P^{(i)})$.*

Proof. Let $i \in W \setminus \{0\}$. Then

$$\sum_{j \in \mathrm{ch}(i)} c(P^{(j)}) \leq \tfrac{3}{2} \sum_{j \in \mathrm{ch}(i)} c(P^{(j)} \cap X^{(j)}) \leq \tfrac{3}{2} c(P^{(i)} \setminus X^{(i)}) \leq \tfrac{1}{2} c(P^{(i)}),$$

where the first inequality follows from the fact that $P^{(j)}$ is $X^{(j)}$-heavy; the second inequality follows from the fact that $P^{(j)} \cap X^{(j)} \subseteq P^{(i)} \setminus X^{(i)}$ for $j \in \mathrm{ch}(i)$ and the fact that the intervals $P^{(j)}$ for all children are disjoint; the last inequality follows from the fact that $P^{(i)}$ is $X^{(i)}$-heavy. ◀

▶ **Lemma 10.** *$c(M_1) \leq 3c(O_1)$.*

Proof. Note that $c(M_1) = \sum_{i=1}^{n} c(e^{(i)}) = \sum_{i \in W \setminus \{0\}} c(P^{(i)})$. For $\ell \in \mathbb{N}$, let

$$W_\ell := \{i \in W : |T[i]| = \ell\}.$$

Observe that Lemma 9 implies that $\sum_{i \in W_\ell} c(P^{(i)}) \leq \left(\frac{1}{2}\right)^{\ell-1} \sum_{i \in W_1} c(P^{(i)})$ for all $\ell \in \mathbb{N}$. Furthermore $\sum_{i \in W_1} c(P^{(i)}) \leq \frac{3}{2} c(O_1)$, because $W_1 \subseteq W_{\mathrm{H}}$. Hence

$$c(M_1) = \sum_{\ell=1}^{\infty} \sum_{i \in W_\ell} c(P^{(i)}) \leq \sum_{\ell=1}^{\infty} \left(\frac{1}{2}\right)^{\ell-1} \sum_{i \in W_1} c(P^{(i)}) = 2 \cdot \frac{3}{2} c(O_1).$$ ◀

4 Unknown Number of Arrivals – Stage 2

We now discuss how to react to the arrival of $2k$ additional vertices. We let O_2 be the min-cost perfect matching in the resulting graph G_2 and define

$$\mathcal{R} := \{P : P \text{ is a maximal path in } (O_1 \Delta O_2) \cap L\}.$$

We call the elements of $\mathcal{R}$ *requests*. An important consequence of our restriction to the metric space on the line is that $|\mathcal{R}| \leq k$ (in fact, each of the k maximal paths of $O_1 \Delta O_2$ is contained in L after removing its first and last edge).

▶ **Lemma 11.** *$|\mathcal{R}| \leq k$ and each $R \in \mathcal{R}$ starts and ends with an edge of O_1.*

For simplification of the analysis we make the following assumptions on the structure of the request set.

▶ **Assumption A.** *For all $i \in W_L$ and all $R \in \mathcal{R}$, either $P^{(i)} \cap R = \emptyset$ or $P^{(i)} \subseteq R$, or $R \subseteq P^{(i)}$.*

▶ **Assumption B.** *For all $j \in W_H$, if $\bigcup_{R \in \mathcal{R}} R \cap P^{(j)} \neq \emptyset$, then the first and last edge of $P^{(j)}$ are in $\bigcup_{R \in \mathcal{R}} R$.*

In the appendix of the full version we prove formally that these are without loss of generality. For intuition, we give a short sketch of the proof. Assume we are confronted with a set of requests $\mathcal{R}$ that violates at least one of the assumptions. Based on $\mathcal{R}$, we can construct a modified set of requests $\mathcal{R}'$ complying with the assumptions and fulfilling two properties: First, $\mathrm{gain}_{O_1}(\bigcup_{R \in \mathcal{R}'} R) > \mathrm{gain}_{O_1}(\bigcup_{R \in \mathcal{R}} R)$, i.e., R' induces smaller second

stage optimal costs than $\mathcal{R}$ and secondly, $|\mathcal{R}'| \leq |\mathcal{R}|$, i.e., $\mathcal{R}'$ allows for at most as many modifications as $\mathcal{R}$ does. As a consequence, if we run our proposed second stage algorithm for $\mathcal{R}'$ and construct M_2 accordingly, the analysis of the approximation and recourse factor carry over from the analysis of $\mathcal{R}'$ to the actual set of requests $\mathcal{R}$. Hence, we can assume w.l.o.g. that $\mathcal{R}$ fulfills the assumptions.

From the set of requests $\mathcal{R}$, we will determine a subset of at most $2k$ edges that we delete from M_1. To this end, we assign each request to a light node in W_{L} as follows. For $R \in \mathcal{R}$ we define $i_R := \max\{i \in W_{\mathrm{L}} : R \subseteq P^{(i)}\}$, i.e., $P^{(i_R)}$ is the inclusionwise minimal interval of a light node containing R. For $i \in W_{\mathrm{L}}$, let

$$\mathcal{R}(i) := \big\{R \in \mathcal{R} : i_R = i\big\}.$$

Furthermore, we also keep track of the gaps between the requests in $\mathcal{R}(i)$ as follows. For $i \in W_{\mathrm{L}}$, let

$$\bar{\mathcal{R}}(i) := \big\{\bar{R} \subseteq P^{(i)} : \bar{R} \text{ is a maximal path in } P^{(i)} \setminus \textstyle\bigcup_{R\in\mathcal{R}(i)} R \text{ and } \bar{R} \subseteq P^{(j)} \text{ for some } j \in \mathrm{ch}(i)\big\}.$$

Note that $R' \cap R'' = \emptyset$ for all $R', R'' \in \mathcal{R}(i) \cup \bar{\mathcal{R}}(i), i \in W_{\mathrm{L}}$. However, $\bar{R} \in \bar{\mathcal{R}}(i)$ may contain a request $R \in \mathcal{R}(j)$ from descendants j of i. See Figure 4 c) for an illustration of the assignment.

For $i \in W_{\mathrm{L}}$, let $W_{\mathrm{H}}(i) := \mathrm{ch}(i)$ and $W_{\mathrm{L}}(i) := \{i' \in W : i' \in \mathrm{ch}(j) \text{ for some } j \in W_{\mathrm{H}}(i)\}$. Note that $W_{\mathrm{H}}(i) \subseteq W_{\mathrm{H}}$ and $W_{\mathrm{L}}(i) \subseteq W_{\mathrm{L}}$. Before we can state the algorithm for computing the second stage reply, we need one final lemma.

▶ **Lemma 12.** *Let $i \in W_L$. For every $R \in \mathcal{R}(i)$, there is a $j \in W_H(i)$ with $P^{(j)} \cap R \neq \emptyset$. For every $\bar{R} \in \bar{\mathcal{R}}(i)$, there is an $i' \in W_L(i)$ with $P^{(i')} \cap R \neq \emptyset$.*

We are now ready to state the algorithm. We first describe and discuss a simplified version, which yields an approximation guarantee of 19. At the end of the paper, we discuss how to slightly adapt the algorithm so as to obtain the factor of 10 given in Theorem 2.

Algorithm 2.2 works as follows:

(i) Create the matching M' by removing the following edges from M_1 for each $i \in W_{\mathrm{L}}$:
  1. The edge $e^{(i)}$ if $i \neq 0$ and $\mathcal{R}(i) \neq \emptyset$.
  2. For each $R \in \mathcal{R}(i)$ the edge $e^{(j^*_R)}$ where $j^*_R := \min\{j \in W_{\mathrm{H}}(i) : P^{(j)} \cap R \neq \emptyset\}$.
  3. For each $\bar{R} \in \bar{\mathcal{R}}(i)$ the edge $e^{(i^*_{\bar{R}})}$ where $i^*_{\bar{R}} := \min\{i' \in W_{\mathrm{L}}(i) : P^{(i')} \cap R \neq \emptyset\}$.

(ii) Let M'' be a min-cost matching on all vertices not covered by M' in G_2.

(iii) Return $M_2 := M' \cup M''$.

Let Z be indices of the edges removed in step (i). It is not hard to see that $|\bar{\mathcal{R}}(i)| \leq |\mathcal{R}(i)| - 1$ for each $i \in W_{\mathrm{L}}$ and therefore $|Z| \leq 2k$, bounding the recourse of Algorithm 2.2 as intended.

▶ **Lemma 13.** $|Z| \leq 2k$.

Now let $Y := W \setminus (Z \cup \{0\})$ be the nodes corresponding to edges that have not been removed and

$$\bar{Y} := \{i \in Y : T[i] \setminus \{0, i\} \subseteq Z\}$$

the nodes that correspond to maximal intervals that have not been removed.

The following lemma is a consequence of the exponential decay property. It shows that in order to establish a bound on the cost of M_2, it is enough to bound the cost of all paths $P^{(i)}$ for $i \in \bar{Y}$.

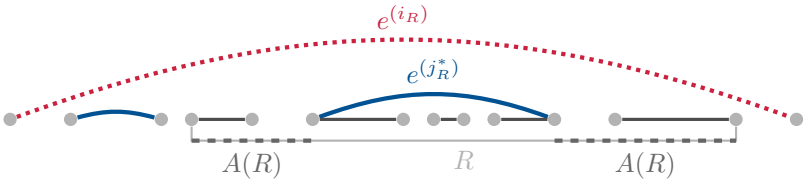

Figure 5 Illustration of the proof of Lemma 15. The solid dark grey lines depict edges in $O_1 \cap R$. At the time when Algorithm 2.1 constructed $P^{(j_R^*)}$, no other child interval of i_R intersecting with R was present. Thus $X^{(j_R^*)} \cap R = X^{(i_R+1)} \cap R = O_1 \cap R$. If $A(R)$ was O_1-heavy, then $P^{(j_R^*)} \cup A(R)$ would be an O_1-heavy path of higher O_1-gain than $P^{(j_R^*)}$, contradicting the greedy construction.

▶ **Lemma 14.** $c(M_2) \leq c(O_2) + 3\sum_{i \in \bar{Y}} c(P^{(i)})$.

It remains to bound the cost of the paths associated with the tree nodes in $\bar{Y}$. We establish a charging scheme by partitioning the line into three areas A, B, C:

1. For $R \in \mathcal{R}$, let $A(R) := R \setminus P^{(j_R^*)}$. We define $A := \bigcup_{R \in \mathcal{R}} A(R)$.
2. For $i \in W_{\mathrm{L}}$ and $\bar{R} \in \bar{\mathcal{R}}(i)$, let $B(\bar{R}) := \bar{R} \setminus \bigcup_{i' \in W_{\mathrm{L}}(i) \cap Z} P^{(i')}$.
   We define $B := \bigcup_{\bar{R} \in \bar{\mathcal{R}}} B(\bar{R})$.
3. We define $C := L \setminus (A \cup B)$.

Consider a set $A(R)$ for some $R \in \mathcal{R}$. Recall that i_R is the index of the smallest light interval constructed by Algorithm 2.1 containing R and that j_R^* is the first child interval of i_R created by Algorithm 2.1 that intersects R. From the choice of j_R^* and the greedy construction of $P^{(j_R^*)}$ as a path of maximum $X^{(j_R^*)}$-gain we can conclude that $A(R)$ is not O_1-heavy; see Figure 5 for an illustration. Therefore $c(A(R) \setminus O_1) > \frac{1}{3}c(A(R))$. Note that $O_2 \cap A(R) = A(R) \setminus O_1$, because $A(R) \subseteq R$. Hence we obtain the following lemma.

▶ **Lemma 15.** *Let $R \in \mathcal{R}$. Then $\frac{1}{3}c(A(R)) \leq c(O_2 \cap A(R))$.*

A similar argument implies the same bound for all sets of the type $B(\bar{R})$ for some $\bar{R} \in \bar{\mathcal{R}}(i)$ and $i \in W_{\mathrm{L}}$.

▶ **Lemma 16.** *Let $\bar{R} \in \bar{\mathcal{R}}$. Then $\frac{1}{3}c(B(\bar{R})) \leq c(O_2 \cap B(\bar{R}))$.*

Furthermore, one can show that the sets of the form $A(R)$ and $B(\bar{R})$ and the set C form a partition of L (see the appendix of the full version). We define $x : L \to \mathbb{R}_+$ by

$$x(e) := \begin{cases} \frac{1}{3} & \text{if } e \in A \cup B \\ 1 & \text{if } e \in C \cap O_2 \\ 0 & \text{if } e \in C \setminus O_2 \end{cases}$$

and obtain the following lemma as a consequence of Lemmas 15 and 16.

▶ **Lemma 17.** $\sum_{e \in L} c(e)x(e) \leq c(O_2 \cap L)$.

We are now able to bound the cost of each path $P^{(i)}$ for $i \in \bar{Y}$ against its local budget $\sum_{e \in P^{(i)}} c(e)x(e)$. We consider the cases where $i \in \bar{Y}$ corresponds to a heavy and light edge in Lemma 18 and Lemma 19, respectively.

▶ **Lemma 18.** *Let $j \in \bar{Y} \cap W_H$. Then $c(P^{(j)}) \leq 6\sum_{e \in P^{(j)}} c(e)x(e)$.*

Proof. We first show that each request intersecting with $P^{(j)}$ is either contained in a child interval of j or the edges in $P^{(j)}$ intersecting with the request are covered by A.

▷ Claim. Let $R \in \mathcal{R}$ with $R \cap P^{(j)} \neq \emptyset$. Then $R \cap P^{(j)} \subseteq A(R)$ or $R \subseteq P^{(i')}$ for some $i' \in \mathrm{ch}(j)$.

Proof. Assume $R \not\subseteq P^{(i')}$ for any $i' \in \mathrm{ch}(j)$. In particular, this implies that $i_R \notin \mathrm{desc}(j)$. Let i be the parent node of j in T. We first exclude the possibility that i_R is an ancestor of i. Indeed, if this was the case then $R \not\subseteq P^{(i)}$ and thus by Assumption A, $P^{(i)} \subseteq R$. But then $P^{(i)}$ can neither contain other request intervals, nor can it intersect any non-request intervals. Therefore $\mathcal{R}(i) = \emptyset$ and $i \neq i^*_{\bar{R}}$ for all $\bar{R} \in \bigcup_{i' \in W_{\mathrm{L}}} \bar{\mathcal{R}}(i')$. Therefore, $i \notin Z$, a contradiction to $j \in \bar{Y}$. This implies that $i_R = i$. Further note that $j \in \bar{Y}$ implies $j \neq j^*_R$ for all $R \in \mathcal{R}$, as otherwise, j would have been tagged for removal. We conclude that $j^*_R \in \mathrm{ch}(i) \setminus \{j\}$ and thus $R \cap P^{(j)} \subseteq R \setminus P^{(j^*_R)} = A(R)$, as $P^{(j)}$ and $P^{(j^*_R)}$ are disjoint. ◁

Let $Q := \bigcup_{i' \in \mathrm{ch}(j)} P^{(i')}$. Consider $e \in P^{(j)} \cap O_1$. Note that the claim implies that if $e \notin A \cup Q$, then $e \in O_2$. We conclude that $(P^{(j)} \cap O_1) \setminus Q \subseteq A \cup B \cup (C \cap O_2)$. Further, a variant of Lemma 9 implies that $c(P^{(j)} \cap O_1) \leq \frac{4}{3} c((P^{(j)} \cap O_1) \setminus Q)$ (see appendix of the full version for details). We obtain

$$c(P^{(j)}) \leq \tfrac{3}{2} c(P^{(j)} \cap O_1) \leq 2c((P^{(j)} \cap O_1) \setminus Q) \leq 6 \textstyle\sum_{e \in P^{(j)}} c(e)x(e),$$

where the first inequality follow from the fact that $P^{(j)}$ is O_1-heavy and the last inequality follows from the fact that $x(e) \geq 1/3$ for every $e \in A \cup B \cup (C \cap O_2)$. This proves the lemma. ◀

▶ **Lemma 19.** *Let $i \in \bar{Y} \cap W_L$. Then $c(P^{(i)}) \leq 3 \sum_{e \in P^{(i)}} c(e)x(e)$.*

The proof of Lemma 19 is given in the appendix of the full version. We state a short proof sketch for intuition. Let $i \in \bar{Y} \cap W_{\mathrm{L}}$. Due to the removal of light edges with associated requests and Assumption A, we know that $P^{(i)}$ either does not intersect with any request or $P^{(i)}$ is completely covered by a request. In the former case one can show that $P^{(i)}$ is included in B and hence the lemma holds. In the latter case, $P^{(i)}$ is either included in A and hence the lemma holds or it is included in C in which case the lemma holds since $P^{(i)}$ is O_1-light.

As a consequence, we can now show a first constant factor bound. Because the paths $P^{(i)}$ for $i \in \bar{Y}$ are pairwise disjoint, Lemmas 17 to 19 imply $\sum_{i \in \bar{Y}} c(P^{(i)}) \leq 6c(O_2)$. Plugging this into Lemma 14 we obtain

$$c(M_2) \leq c(O_2) + 3 \textstyle\sum_{i \in \bar{Y}} c(P^{(i)}) \leq 19c(O_2).$$

Improvement of approximation factor. We can improve the approximation factor from 19 to 10 by a slight modification of the set of edges removed in Stage 2. To this end, note that the factor for the bound given in Lemma 18 is greater than the one given in Lemma 19. Indeed, the only reason for the weaker bound is that edges in $\bar{Y} \cap W_{\mathrm{H}}$ can have descendants with associated requests. Excluding this case improves the factor within the bound of the lemma from 6 to 3. We formalize this in the following lemma.

▶ **Lemma 20.** *Let $j \in \bar{Y} \cap W_H$ such that $\mathrm{ch}(j) \cap Z = \emptyset$. Then $c(P^{(j)}) \leq 3 \sum_{e \in P^{(j)}} c(e)x(e)$.*

We now modify Algorithm 2.2 as follows: Compute the set Z of edges tagged for removal by Algorithm 2.2. Now construct the set Z' by defining

$$\bar{H} := \{j \in W_{\mathrm{H}} \setminus Z \,:\, \mathrm{ch}(j) \cap Z \neq \emptyset\} \qquad \text{and} \qquad Z' := (Z \cup \bar{H}) \setminus \textstyle\bigcup_{j \in \bar{H}} \mathrm{ch}(j).$$

Now execute step 2 of Algorithm 2.2 with Z' instead of Z, i.e., remove the edges with indices in Z' and connect the unmatched vertices by a min-cost matching. It is easy to see that $|Z'| \leq |Z|$ and therefore the recourse factor is still bounded by 2. For analyzing the approximation factor, we define $Y' := W \setminus (Z' \cup \{0\})$ the nodes corresponding to edges that have not been removed and $\bar{Y}' := \{i \in Y : T[i] \setminus \{0, i\} \subseteq Z'\}$ in analogy to the original analysis. It is easy to see that $\mathrm{ch}(j) \cap Z = \emptyset$ for every $j \in \bar{Y}' \cap W_{\mathrm{H}} = \bar{Y} \setminus \bar{H}$ and hence $c(P^{(j)}) \leq 3 \sum_{e \in P^{(j)}} c(e)x(e)$ by Lemma 20. Furthermore, if $i \in \bar{Y}' \cap W_{\mathrm{L}}$ then either $i \in \bar{Y}$ and $c(P^{(i)}) \leq 3 \sum_{e \in P^{(i)}} c(e)x(e)$ by Lemma 19, or $i \in \mathrm{ch}(j)$ for some $j \in \bar{Y} \setminus \bar{Y}' = \bar{H}$. Note that Lemmas 9 and 18 imply

$$\sum_{j \in \bar{H}} \sum_{i \in \mathrm{ch}(j)} c(P^{(i)}) \leq \tfrac{1}{2} \sum_{j \in \bar{H}} c(P^{(j)}) \leq 3 \sum_{j \in \bar{H}} \sum_{e \in P^{(j)}} c(e)x(e).$$

We thus obtain $\sum_{i \in \bar{Y}'} c(P^{(i)}) \leq 3c(O_2)$ and hence for the modified algorithm it holds that

$$c(M_2) \leq c(O_2) + 3 \sum_{i \in \bar{Y}'} c(P^{(i)}) \leq 10c(O_2).$$

Abstract

We study the minimum weight basis problem on matroid when elements' weights are uncertain. For each element we only know a set of possible values (an uncertainty area) that contains its real weight. In some cases there exist bases that are uniformly optimal, that is, they are minimum weight bases for every possible weight function obeying the uncertainty areas. In other cases, computing such a basis is not possible unless we perform some queries for the exact value of some elements.
